Orthopox viruses are oval, brick-shaped particles with geometrically corrugated outer surface. The particles' sizes range from 220 to 450 nm in length and 140 to 260 nm in width. The outer envelope consists of a lipoprotein layer embedding surface tubules and enclosing a biconcave core. The core contains the viral DNA and core fibrils, and is surrounded by the core envelope and a tightly arranged layer of rod-shaped structures known as the palisade layer. Between the palisade layer and the outer envelope exist two oval masses known as the lateral bodies.

Genus *Orthopoxvirus* is one of the 11 known genera in the viral family Poxviridae, which comprises two subfamilies: Chordopoxvirina and Entomopoxvirinae. Subfamily Chordopoxvirinae contains eight genera: *Avipoxvirus*, *Capripoxvirus*, *Leporipoxvirus*, *Molluscipoxvirus*, *Orthopoxvirus*, *Parapoxvirus*, *Suipoxvirus*, and *Yatapoxvirus*, and at least 36 species that are associated with vertebrates. Subfamily Entomopoxvirinae contains three genera: *Entomopoxvirus* A, B, and C, and 25 species that are associated with insects.

Genus *Orthopoxvirus* contains 11 known species: buffalopox, camelpox, cowpox, ectromelia, monkeypox, rabbitpox, raccoonpox, taterapox, *Vaccinia*, *Variola*, and volepox viruses and two tentative species: skunkpox and Uasin Gishu viruses.

Orthopox viruses contain double-stranded DNA genomes whose 5′ and 3′ ends are closed, forming terminal loops. The genomes of camelpox, cowpox, ectromelia, monkeypox, *Vaccinia*, and *Variola* viruses have been sequenced and are published in GenBank. The genome size of these viruses varies from 177,923 bp (*Vaccinia* Ankara) to 224,499 bp (cowpox Brighton). The genome size of camelpox Kazakhstan, ectromelia Moscow, monkeypox Zaire-1996, and *Variola* Bangladesh-1975 viruses are 205,719, 209,771, 196,858, and 186,103 bp, respectively. The 5′ and 3′ termini contain inverted terminal repeats (ITR) whose sizes vary considerably in different species. The size of ITR in camelpox, cowpox, ectromelia, monkeypox, *Vaccinia*, and *Variola* viruses are 7736, 9710, 9413, 6378, 12,068, and 725 bp, respectively. The number of genes also varies in different species. The number of genes of camelpox, cowpox, ectromelia, monkeypox, *Vaccinia*, and *Variola* genomes are 212, 234, 176, 193, 266, and 191, respectively.

REPLICATION AND INFECTIVITY

Orthopoxvirus genomes encode about 176 to 266 proteins, including a number of enzymes and factors that are necessary for self-replication and maturation. The central region of the genome contains highly conserved genes that are essential for viral replication, and the terminal

DOI: 10.1081/E-EDGP 120021390

regions contain less conserved genes that are important for virus–host interactions. Although it is well known that replication occurs in the cytoplasm, it is not clear how or if host cell nuclear factors are involved in viral replication or maturation.

Viral replication begins with attachment of viral particles to host cell surface, most likely through cell receptors, e.g., epidermal growth factor in the case of *Vaccinia*, and involves expression of early, intermediate, and late genes. Initial uncoating occurs during entry, followed by synthesis of early mRNAs which are translated to facilitate further uncoating and transcription of intermediate mRNAs. Intermediate mRNAs, in turn, are translated to allow transcription of the late mRNAs. The late mRNAs are translated into structural and enzymatic components of the virions. These components, along with DNA concatemers that are formed during the early phase of replication, are assembled into genomic DNA and packaged into immature virions, then infectious intracellular mature virions (IMV). The last step of viral replication is the acquisition by IMV of virus-altered Golgi membranes and plasma membranes, and formation of infectious extracellular mature virus (EMV).

The newly replicated progeny exits the lysed cells and invades other cells, repeating the cycle. The entire replication cycle is completed within about 12 hr. Within a few hours after infection, the virus takes over the cell machinery, inhibiting cellular DNA, RNA, and protein synthesis, and causing cell death.

Although orthopox viruses have highly similar morphological and genomic characteristics, they have distinct host preferences and vary considerably in their infectivity and pathogenicity.

Variola virus is specific for humans, but it has also been shown experimentally to cause lethal infections in nonhuman primates.[1] The severity of human infections depends on the host immune response and the viral strain. Infections with *Variola* major induce severe, generalized, or systemic disease with fatality rates up to 40%, whereas infections with *Variola* minor cause a milder form of the disease with case fatality rates of 1% or less.

Vaccinia virus has no definitive host, but it has been isolated from camels, buffalos, cows, pigs, and rabbits.[2] *Vaccinia* has been used in humans as a vaccine against smallpox infections because it produces mild, localized infections; however, it can also induce life-threatening complications in immune-compromised individuals.[3]

Cowpox virus is probably maintained in rodent reservoirs in nature, but can occasionally infect humans, elephants, cattle, cheetahs, cats, and other animals.[2] Human infections with cowpox were known for centuries, but have been brought to public attention since the early vaccination attempts by Edward Jenner. Although most infections with cowpox produce localized lesions, severe infections were reported.[4]

Monkeypox virus was first identified in laboratory-maintained cynomolgus monkeys.[5] The virus is believed to have been circulating for a long time in numerous animal hosts, particularly squirrels, in central and western Africa. Human infections with monkeypox virus were first recognized in Zaire and later in Liberia and Sierra Leone.[6] The disease caused by monkeypox virus closely resembles smallpox, but the pustular rash is mostly localized in the neck and groin areas. Most infections occur by direct contact with infected animals. Person-to-person transmission rarely occurs.

Mousepox (ectromelia) virus was first recognized as a mouse pathogen in 1930. Its pathogenesis differs from other orthopox viruses in that the virulent strains induce severe hepatitis in mice. It is highly infectious and can easily decimate mouse colonies in laboratories and breeding facilities. Vaccinating mice with the *Vaccinia* confers protection and has been used to control infections in mouse colonies.[7] No human infections have been reported due to ectromelia. However, the virus was useful as model to study the molecular basis of *Orthopoxvirus* virulence despite the fact that the mouse disease differs significantly from smallpox.

MOLECULAR TESTING

Many phenotypic and genotypic methods involving virological, immunological, and molecular approaches have been used to identify *Orthopoxvirus*. The molecular approaches, including DNA sequencing, polymerase chain reaction (PCR), restriction fragment-length polymorphism (RFLP), real-time PCR, and microarrays, are more sensitive and specific than the virological and immunological approaches. Of these approaches, sequencing provides the highest level of specificity for species or strain identification but current sequencing techniques are not yet practical as rapid diagnostic tools in most laboratories. Restriction fragment-length polymorphism analysis[8] and microarray genotyping[9] also provide high levels of specificity, and when combined with PCR, these approaches can offer high levels of sensitivity as well. Real-time PCR methods provide exquisite levels of sensitivity and specificity.[10,11] The basic concept behind real-time PCR is the measurement, by fluorescence detection, of the amount of nucleic acids produced during every cycle of the PCR. Several detection chemistries, e.g., intercalating dyes (SYBR Green), hydrolysis probes [5′ nuclease or Taqman, minor groove-binding proteins (MGB)], hybridization probes [fluorescence resonance energy transfer (FRET)], and molecular

beacons, are used. Several instruments for real-time PCR, e.g., the ABI 7700, Smart Cycler, LightCycler, RAPID, Opticon, MX 4000, Rotor-Gene, and others, are commercially available. When combined with portable analytical platforms such as the Smart Cycler or LightCycler, real-time PCR systems can be readily deployed to field sites for rapid testing.

In the following section, we describe an approach for genome typing of orthopox viruses by using long polymerase chain reaction (LPCR) amplification, followed by RFLP analysis.

GUIDELINES ON PERFORMING LPCR–RFLP ANALYSIS

Processing *Orthopoxvirus* Samples

Successful performance of LPCR–RFLP analysis requires pure and undegraded DNA roughly 40–150 kb in length. There are numerous commercial nucleic acid purification technologies for a variety of sample types, e.g., QIAamp Genomic DNA (Qiagen) and AquaPure DNA (Bio-Rad). These methods involve cell lysis and protein denaturation followed by DNA precipitation or fractionation by reversible binding to an affinity matrix. They have been used to purify high-quality DNA from *Orthopoxvirus* cultures and clinical specimens.

Primer Design

Ideally, LPCR primers length should be 20 to 29 bases with no hairpins or 3′ complementarity, and with T_m between 60°C and 68°C in 85 mM salt. Several software programs for primer design are available commercially, such as Primer Express (ABI Biosystems) and Oligo (National Biosciences), among many others. To amplify as many orthopox viruses as possible, consensus or degenerate primers should be designed. Table 1 shows examples of consensus primers designed to amplify eight overlapping segments spanning about 98% of *Orthopoxvirus* genomes.

LPCR–RFLP Performance and Analysis

Amplifying large DNA fragments requires high-fidelity DNA polymerase enzymes, e.g., TAKARA LA (Takara). The conditions for LPCR amplification require optimizing primer, magnesium ion, and enzyme concentrations as well as thermal cycling number and timing. In a typical LPCR reaction protocol, 1–100 ng of template DNA is amplified in the presence of 1 μM of each primer, 300 μM of dNTPs, 2.5 mM $MgCl_2$, and 1.5 U of TAKARA LA polymerase. The amplified LPCR products are purified on agarose gels, then are digested with a restriction enzyme, e.g., *Cla*I. The digested DNA fragments are then electrophoresed on 6% polyacrylamide gel for a constant period of time at constant voltage. A reference DNA marker is run along with the digested DNAs in the first, middle, and last lanes to help identify the size of the restricted DNA fragments. After staining with ethidium bromide, the restriction pattern is visualized and photographed with a digital camera.

Standardization of electrophoretic conditions, i.e., using the same lot of precast polyacrylamide gel, and applying the same voltage, e.g., 50 V for the same period of time, e.g., 6.5 hr for each run, is very important to obtain reproducible banding patterns. The positions for all DNA fragments in each restriction pattern are determined and digitized by fingerprinting software, e.g., Dendron (Solltech). The program assigns a molecular weight value for each DNA fragment in each restriction pattern using the reference DNA marker. A similarity coefficient (S_{AB})

Table 1 LPCR primers and their 5′ and 3′ coordinates in relation to *Variola* genome (GenBank LL22579)

Segment	Forward primer	Reverse primer
1	1,297/5′–GCTCCGTTGCATCAGTTCTG–3′/1,316	17,296/5′–GGATGTGGTCCGTTGTTGG–3′/17,278
2	16,778/5′–GAYGCATCTTATGGATCCCA–3′/16,797	35,810/5′–TAACGCMGACACATCGTGTG–3′/35,791

4	55,915/5′–RCCGATCGCAGTTAGAACGG–3′/55,934	79,733/5′–CGGAACACCAATGYGGYGAC–3′/79,714
5	79,541/5′–CTRCCGCAAGCTATTAGGCG–3′/79,560	103,460/5′–GGAAGAGTRGTGTTCGCTCC–3′/103,441
6	103,272/5′–GCCGGTGTAACATTCTCCAC–3′/103,291	126,608/5′–CGRAGGTAACCCATGCGAAC–3′/126,589
7	126,028/5′–TCGAACGAAGRCCTCCTTCG–3′/126,047	151,555/5′–GGTYCCGGAKTCGCGATTTC–3′/151,536
8	150,516/5′–CRTGTACCGACRCACTWGAG–3′/150,535	184,518/5′–RCACCTTCAGATRCCGATCC–3′/184,499

is calculated for every pair of restriction patterns using the absolute difference/total area formula:

$$S_{AB} = 1.0 - \frac{\sum_{i=1}^{k} |a_i - b_i|}{\sum_{i=1}^{k} (a_i + b_i)}$$

where a_i and b_i are the intensities of fragment position i in the restriction patterns A and B, and k is the total number of possible positions. If only fragment position is used in calculations (without regard to the fragment intensity), a and b are set to either 1 or 0 for presence or absence of a fragment at a given position. If two restriction patterns are completely different, then $S_{AB}=0$; if they are identical then $S_{AB}=1$; and if half of the total fragments have an identical fragment in both patterns, then $S_{AB}=0.5$. A dendrogram, graphically representing the relationships between multiple patterns, is constructed from a matrix of similarity coefficients by using the unweighted pair group method.[12] The pairs with the highest similarity values are grouped together with the similarity coefficient corresponding to the branch point on the dendrogram. The remaining branch points are calculated in order of descending similarity coefficients. When more than two restriction patterns are considered for a branch point, the branch point is calculated as the average of all the similarity values involved.

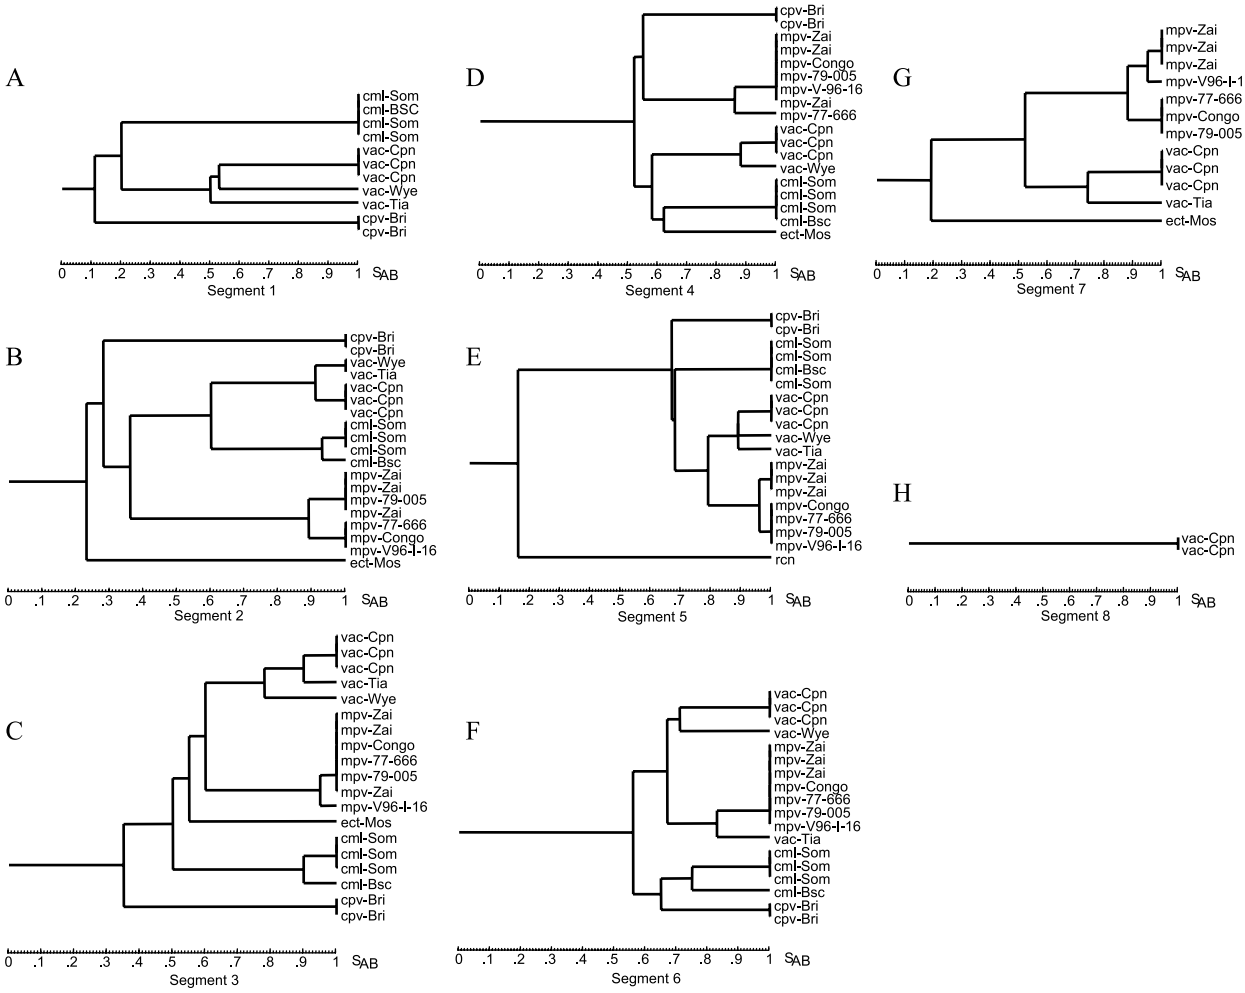

Fig. 1 A–H. Dendrograms of the restriction fragment-length polymorphism (RFLP) profiles of camelpox Somalia (cml-Som), camelpox BSC-40 (cml-BSC), cowpox Brighton (cpv-Bri), ectromelia Moscow (ect-Mos), monkeypox 77-666 (mpv-77-666), monkeypox 79-005 (mpv-79-005), monkeypox Congo-8 (mpv-Congo), monkeypox V96-I-16 (mpv-V96-I-16), monkeypox Zaire (mpv-Zai), raccoonpox (rcn), *Vaccinia* Copenhagen (vac-Cpn), *Vaccinia* Tian-Tan (vac-Tia), and *Vaccinia* Wyeth (vac-Wye) viruses of segments 1 to 8. The similarity coefficient S_{AB} values are indicated on the horizontal axes.

Figure 1 illustrates one LPCR–RRFLP approach using the LPCR primers listed in Table 1 and following the guidelines described above. The experiments were carried out with genomic DNAs from different strains of camelpox, cowpox, ectromelia, cotia, monkeypox, raccoonpox, and *Vaccinia* viruses. As shown, it was possible to classify every sample within each species. The S_{AB} ranges of the different strains within a species were 0.53–1, 0.89–1, 0.78–1, 0.86–1, 0.89–1, 0.71–1, and 0.74–1 in segments 1, 2, 3, 4, 5, 6, and 7, respectively. The lowest S_{AB} value within the same species (0.53) was observed with *Vaccinia* Copenhagen and *Vaccinia* Tian Tan in segment 1. The S_{AB} ranges of different species were 0–0.31, 0.15–0.67, 0.21–0.7, 0.43–0.63, 0.13–0.86, 0.31–0.83, and 0.31–0.61 in segments 1, 2, 3, 4, 5, 6, and 7, respectively. Because only one species, *Vaccinia* Copenhagen, was amplified in segment 8, it was not possible to estimate the S_{AB} values with other species or strains, but the S_{AB} value for the different replicates of the same strain was 1.0. These results suggest that closely related species and strains can be grouped and identified using any of the eight segments. However, because lower S_{AB} values were obtained with the flanking segments 1, 2, 7, and 8 than with the central segments 3, 4, 5, and 6, we concluded that genotyping with the terminal segments can be useful for strain differentiation whereas genotyping with the central segments can be useful for species differentiation.

CONCLUSION

All members of genus *Orthopoxvirus* share common morphological and biological characteristics notwithstanding the broad spectrum of their mammalian host repertoire that includes rodents, domesticated and feral mammals, humans and nonhuman primates. They differ from other double-stranded DNA viruses in that they are self-reliant in their replication strategy, as they replicate exclusively in the cell cytoplasm using a set of specialized enzymes, transcription, and replication factors. There are 11 recognized *Orthopoxvirus* species, five of which (buffalopox, cowpox, monkeypox, *Vaccinia*, and *Variola* viruses) are known to cause human disease with varied severity depending on the viral strain and host's immune response. Changes in certain protein genes or insertion of foreign genes into the genome may influence virulence.[13,14] Furthermore, *Vaccinia* virus, which has been used for years as a vaccine against smallpox, is still widely used as an expression vector for a variety of genes from numerous infectious agents. For these, and other reasons, there have been concerns that members of the *Orthopoxvirus* genus may emerge as natural, incidental, or deliberate health threats. Therefore, the development of rapid, sensitive, and specific methods for identification and classification of these viruses is critically important to prepare and deter against their potential resurgence. Among the modern methods for rapid, sensitive, and specific identification of orthopox viruses are real-time PCR, RFLP analysis, and microarray analysis. A method using LPCR–RFLP analysis is described to illustrate the utility of this approach in whole-genome typing of *Orthopoxvirus*. Using this approach, and other new approaches, could discriminate *Orthopoxvirus* species and strains, and possibly identify genetically mutated or altered viruses.

ACKNOWLEDGMENTS

We thank Ms. Kathy Kenyon (USAMRIID, Ft. Detrick, MD) for reviewing the manuscript and Dr. Joseph Esposito (CDC, Atlanta, GA) for providing *Ortjopoxvirus* DNA. Osteogenesis Imperfecta

Anna Gajko-Galicka
Medical University of Bialystok, Bialystok, Poland

INTRODUCTION

Osteogenesis imperfecta (OI) is an autosomal dominant genetic disorder of connective tissues, which is also known as ''brittle bone disease'' because of the susceptibility of the affected individuals to fracture from the mildest trauma. It exhibits a broad range of clinical severity, ranging from multiple fracturing and perinatal death to a mild form that may elude clinical detection. Biochemical and molecular genetic studies have shown that the vast majority of affected individuals have mutations in the either the *COL1A1* or *COL1A2* gene that encodes the chains of type I procollagen—the major structural protein of bone. The relationship of specific mutations to severity is an exceedingly difficult task. Most patients with mild type I OI produce structurally normal collagen in reduced amounts because of null *COL1A1* allele. The structural mutations in patients with types II, III, and IV affect connective tissues through a dominant negative mechanism, in which the presence of the mutant chain results in defective extracellular matrix. Prenatal diagnostic techniques have allowed the early detection of this disorder, particularly in families in which the molecular defect is already known. Because OI is an incurable genetic disease, two alternative approaches for gene therapy are being investigated: one is replacement of mutant cells with normal cells through bone marrow transplantation, and the second involves the suppression of mutant genes by introducing ribozymes into the cells to change a structural defect in collagen to a quantitative defect in normal collagen with mild phenotype. Types V, VI, and VII are not associated with type I collagen gene defects. However, for now, treatment of patients by bisphosphonate therapy can improve bone mass and improve quality of life in all types of OI.

PREVALENCE AND CLINICAL DIVERSITY

OI is an autosomal genetic disorder characterized by brittleness of bones and susceptibility to bone fractures from very mild trauma. Fractures may be rare or frequent (more than 200 prior to puberty), and bone fragility may be accompanied by reduced life span and various connective tissue abnormalities: short stature, blue sclerae, joint laxity, dentinogenesis imperfecta, easy bruising, and hearing loss. OI represents extreme variation in severity from lethal perinatal to barely detectable. These clinical features, along with radiological and genetic criteria, were used to separate four major clinical types of OI.[1] The patients affected with the mildest (type I) OI have blue sclerae, osteopenia, slight growth retardation or normal height, and premature deafness; dentinogenesis imperfecta is less common. Fractures are not commonly observed at birth, but begin with ambulation and decrease following puberty. Type II is the lethal perinatal form; infants exhibit multiple intrauterine fractures of the ribs and long bones. They have a relatively large and soft cranium, short limbs, and a narrow thoracic cavity; death usually results from pulmonary insufficiency. Type III is the progressively deforming form with multiple fractures, short stature, and severe dentinogenesis imperfecta. Children with type III may die of respiratory problems in infancy; surviving patients require multiple orthopedic rodding procedures and wheelchairs for mobility. Type IV OI is characterized by phenotypical variability, from severe to mild bone deformity, normal sclerae, variable short stature, and possible brittle teeth. The Sillence classification of OI[1] is being expanded to include a greater range of subgroups of patients. Patients with type V, VI, and VII OI exhibit moderate to severe bone fragility. Type V is characterized by three distinctive features: the presence of hypertrophic callus formation at fracture sites, calcification of interosseous membranes between the bones of the forearm, and the presence of a radio-opaque metaphyseal band immediately adjacent to the growth plates upon X-ray.[2] The distinctive features of type VI OI are the fishscale-like appearance of the bone lamellae and the presence of excessive osteoids.[3] The characteristic feature of type VII is a rhizomelic shortening of the humerus and femur.[4]

In its various forms, OI probably affects about 1 in 5000 to 1 in 10,000 individuals of all ethnic origins.

MOLECULAR GENETICS

Types I–IV OI are associated with mutations in the *COL1A1* and *COL1A2* genes that encode the two $\alpha 1$(I)

DOI: 10.1081/E-EDGP 120020636

and one α2(I) chains, respectively, of the type I collagen trimer (Database of Human Type I and Type III Collagen Mutations: http://www.le.ac.uk/genetics/collagen). Type I collagen is the major structural protein of bones, skin, ligaments, tendons, and most other connective tissues. It is synthesized as a soluble procollagen, containing globular propeptides at the ends of each chain. Cleavage of propeptides generates the collagen that self-assembles into fibrils, which are the major source of mechanical strength of connective tissues and the template for matrix deposition and mineralization in the bones. The chains comprising the triple-helical domain of type I collagen are constructed from repeating Gly–X–Y triplets, in which X and Y can be any amino or imino acid (except for tryptophan or cysteine). Glycine, with its small side chain, is essential at every third position for triple-helix formation. The most common mutations (about 85%) are single-base substitutions in the triple-helical domain that change a codon for a glycine to a codon for another amino acid with a charged, polar, or bulky side chain. Replacement of glycine by serine, cysteine, alanine, valine, aspartic acid, glutamic acid, arginine, and tryptophan has been identified, with serine being the most common and tryptophan being exceedingly rare. Another substantial group of mutations (about 12%) consists of single-exon splicing defects, and the remaining mutations include nonsense substitutions, frameshift or in-frame deletions, and insertions. The nonsense substitutions and frameshift mutations have not been detected in the *COL1A2* gene. The genetic defect underlying types V and VI OI remains to be elucidated, as it does not appear to be associated with collagen type I mutations. In the case of type VII OI, the existence of extended affected families has enabled the chromosome location of the gene defect to be mapped to chromosome 3p22–24.1.[5]

GENOTYPE–PHENOTYPE CORRELATION

Although more than 250 different mutations have been characterized in OI, a mechanism by which individual mutations cause various degrees of skeletal abnormalities is not well understood. Many investigators have attempted to correlate the type of mutation, the gene in which the mutation occurred, and the location of the mutation with phenotypical consequences. Mutations in the *COL1A1* gene resulting in one null allele and in the synthesis of half the normal amount of functional proα1(I) chains have mild clinical consequences in individuals with type I OI. The phenotypical effects of mutations that result in the generation of abnormal type I procollagen molecules are more deleterious than those of null mutations. The structural mutations affect connective tissues through a dominant negative mechanism, in which the presence of the mutant chain in the extracellular matrix directly disorganizes and weakens the matrix. Therefore the extent of mutant chain incorporation into extracellular fibrils can play a role in the clinical outcome. In general, bulky residues are more deleterious than small residues, but the existence of lethal substitutions by serine and alanine indicates that the region in which the substitution occurred is also important. Mutations in *COL1A2* can alter up to 50% of the procollagen molecules, whereas similar mutations in *COL1A1* can alter up to 75% of the newly synthesized molecules. It has also been proposed that the position of a mutation along the α1(I) chains may be a crucial factor, with mutations closer to the carboxyl end resulting in a more severe phenotype than mutations near the amino terminal end of the chain.[6] However, there are many exceptions to these rules. Because the collagen triple helix is not a uniform structure and exhibits regional differences in its stability and ability to accommodate mutations, a regional model has been postulated for the relationship of genotype to phenotype.[7] Examination of the lethal clusters regularly occurring along the α2 chain revealed a striking alignment with the binding regions of proteoglycans. The genetic background and modifier genes as well as environmental or epigenetic factors may affect the expression of phenotype.

DIAGNOSIS

The diagnosis of OI is usually made based on clinical findings alone. The presence of fractures, together with short stature, bone deformity, blue sclerae, dentinogenesis imperfecta, or a family history of OI, is usually sufficient for diagnosis. However, it is important to rule out diseases and other reasons that can cause fractures of bones in children. Most patients with types I–IV OI have private mutation; therefore extensive analysis of the *COL1A1* (18,000 bp) and *COL1A2* (38,000 bp) genes must be undertaken to define the mutations. Most investigators have developed a two-step experimental strategy to detect mutations. In the first step, an attempt is made to localize a region in collagen gene that may contain a mutation by procedures such as analysis of the type I collagen synthesized by cultured skin fibroblasts and cyanogen bromide peptide mapping. After the region containing the mutation is identified, the mutation is defined by sequencing cDNA or genomic DNA from the region. However, only some mutations cause overmodification of collagen chains, resulting in delayed electrophoretic mobility that can be detected by analysis of the protein, and no current procedure for scanning mRNA or DNA for mutations has been shown to detect all single

base substitutions. An automated procedure of cDNA sequencing for the procollagen chains with sequencing primer information was described.[8] In the diagnosis of type I OI with no detectable biochemical abnormality of type I collagen, a 4-bp insertion polymorphism in the 3′ untranslated region of the *COL1A1* gene is highly informative for null allele testing and can be used in prenatal diagnosis.[9]

GENETIC COUNSELING

In general, OI is an autosomal dominant condition, resulting either from inheritance of a mutant gene from an affected parent, or from a new dominant mutation; autosomal recessive cases of OI are very rare (type VII). Some children suffer from OI as a result of mosaicism in a parent who shows little or no clinical abnormality but carries the mutation in a small number of gonadal and somatic cells. The risk of recurrence of OI in families with genetic mosaicism is approximately 7% with each pregnancy.

PRENATAL DIAGNOSIS

Prenatal diagnosis is of concern in families at risk for recurrence of OI where there is a risk for the birth of an affected child because of parental germline mosaicism, or in a family affected with an autosomal dominant form of OI. Four techniques are used at present for prenatal diagnosis. High-resolution ultrasound scan of fetal limb length and morphology can reliably identify fetuses with type II OI by 14–16 weeks' gestation, and some fetuses with the progressive deforming variety of OI (type III) by 18–20 weeks' gestation. In the absence of fracture or significant bowing, ultrasound cannot be used to identify fetuses with the milder forms of OI, even in families with a positive history of OI. If mutant type I collagen has been identified in cultured fibroblasts from an affected parent or child, then mesenchymal cells cultured from chorionic vilus biopsies taken at about 10–11 weeks' gestation, which synthesize collagen comparable to dermal fibroblasts, can be used for diagnostic studies.[10] Because OI represents a private mutation in most families, mutational analysis of DNA from chorionic vilus or amniotic fluid cells can be used only in pregnancies where the molecular defect has been previously identified. In large families, linkage studies may identify the gene and the allele, which contain the mutant sequence, thus permitting prenatal diagnosis by haplotype analysis of fetal DNA and can be used in pregnancies at risk for all types of OI.

CLINICAL MANAGEMENT

The management of OI focuses on minimizing fractures and maximizing function in all aspects of the child's life. Until recently, the correction of deformities, intramedullary rodding of long bones, orthotic support, muscle strengthening, and mobility devices, such a wheelchairs, were the mainstays of treatment.[11] The recombinant human growth hormone has been used to augment growth and bone mass. The greatest potential currently resides in bisphosphonate therapy. Bisphosphonates as potent inhibitors of bone resorption have been shown to be highly effective in improving bone mass in children with severe forms of OI.[12] As a consequence, the fracture rate was reduced significantly and quality of life increased in all patients. However, in long-term therapy, bone turnover is suppressed to levels lower than those in healthy children, and the consequences of chronically low bone turnover in children with OI are unknown.

THERAPEUTIC APPROACHES

The finding that marrow stromal cells (MSCs) infused into irradiated transgenic mice with OI were engrafted in bones and contributed to the formation of osteoblasts led to a trial of bone marrow transplantation in children with type III OI.[13] The trabecular bone histological examination showed changes indicative of new dense bone formation; increase in bone mineral content and reduction in the frequency of fractures were also reported. The goal of gene therapy of dominant negative disorders such as OI must be to shut off the expression of the mutant allele, creating a functionally null allele. Selective suppression of the expression of the mutant allele in connective tissues could modulate the clinically severe forms of OI into the biochemical equivalent of mild type I OI. The specificity of mutant allele suppression observed in the experiments with the use of antisense oligonucleotides appears to be insufficient for therapeutic trials. The use of ribozymes is an alternative and particularly attractive approach of antisense therapy.[14] The specificity of their action is greatly improved because they can cut only RNA molecules containing the specific cleavage site. For OI, about 25% of the causative type I collagen point mutations generates a novel ribozyme cleavage site. Information on the required level of suppression can be obtained from studies of mutant type I collagen expression levels in bones of clinically mild mosaics. The use of MSCs as vehicles to deliver therapeutic genes to bones is being evaluated in laboratory and animal studies. In this approach, bone marrow is harvested and, ex vivo, mesenchymal stromal cells are isolated, expanded in numbers,

genetically modified, and then reinfused into the donor.[15] The next step in the development of somatic gene therapy is the use of recently created mice with a point mutation in the *COL1A1* gene, which truly mimics the most common forms of OI.[16]

CONCLUSION

The underlying defects of clinical heterogeneity in individuals with OI as well as the relationship between genotype and phenotype are still not completely understood. Current medical treatment with bisphosphonates aims to improve bone mass and is independent of both phenotype and genotype. However, bisphosphonates have a prolonged half-life in bones, and their safety and efficacy have not been established in controlled trials in children. The heterogeneity of mutations in type I collagen genes poses many problems in planning new strategies for OI treatment. Specific treatment will need to be directed to each affected individual's unique mutation. The continued creation of true animal models of OI and the evaluation of each intervention are essential in the identification of an effective and safe therapy.

INTRODUCTION

Over the past several years, knowledge of molecular mechanisms regulating normal and aberrant cell growth leading to tumor formation has been enhanced. Although human cancers are biologically and pathologically quite distinct, it is surprising that perturbation of the p53 pathway occurs in most, if not all, types of human cancers, highlighting the central role of p53 in tumor development. p53 inactivation determines a condition of genetic instability, justifying the subsequent susceptibility to acquire mutations of different other genes. Alterations to *p53* gene appear to have little or no prognostic value for patients treated by surgery alone, but are associated with worse survival for patients treated with chemotherapy. Studies have begun to identify markers predicting whether a tumor will respond to a particular chemotherapy. The ultimate goal is to prospectively identify patients who should receive chemotherapy and to tailor the treatment to the molecular profile of the tumor and the patient. Such an approach has the potential to dramatically improve response rates. The role of new biomarkers, such as p53, seems to be very promising in predicting prognosis and sensitivity to chemotherapy, thus representing the first step toward a better definition of therapeutic strategies according to the molecular characterization of individual patients. Treatments that depend on the p53 pathway require the scanning of the entire *p53* gene and the identification of any type of mutation. Several diagnostic strategies have been developed to identify mutations in the *p53* gene; among these, automated direct sequence analysis remains the most precise method for high-throughput screening of a wide range of mutations. The improvement of the emerging chip technology will represent the most advanced alternative. Novel strategies are emerging for the treatment of tumors that have *p53* mutations. There are several approaches leading to the restoration of the normal p53 function: the most direct one involves gene therapy used to transfer the wild-type *p53* gene to cancer cells that express mutant *p53*; other ambitious strategies aim to convert mutant p53 protein into its wild-type form by using small peptides, or by introducing drugs that disrupt the interaction between viral and cellular proteins and p53; and another angle of attack is provided by the stimulation of the host's immune response to mutant *p53*.

We report an overview of the *p53* status in tumors, major methods for screening *p53* mutations, and therapeutic approaches suggested for restoring p53 function.

P53 ONCOSUPPRESSOR GENE

The first role of p53 to be discovered was in tumor generation. *p53* gene has the features of a recessive oncosuppressor in its wild-type form, and it can be a dominant oncogene in its mutated form. Mutations in the *p53* oncosuppressor gene occur in most of human cancers, and regulation of the protein is defective in a variety of others (for review see Ref. [1]).

Recently, two proteins, p73 and p63, have been identified as members of the *p53* gene family. Unlike *p53*, both *p73* and *p63* are rarely mutated in human cancers, and their involvement in tumor generation is still to be clarified.[2]

The *p53* gene (20 kbp) is located in a single copy on the short arm of chromosome 17 and contains 11 exons interrupted by 10 introns. It codes for a protein of 393 amino acids consisting of at least four functional and regulatory domains: the N-terminus contains the transactivation domain; the central domain is responsible for sequence-specific DNA binding; the oligomerization domain ensures assembly of p53 into conformationally active tetramers; and the C-terminus contains a negative regulatory domain whose posttranslational modification may play an important role in modulating the specific activity of p53.

DOI: 10.1081/E-EDGP 120030843

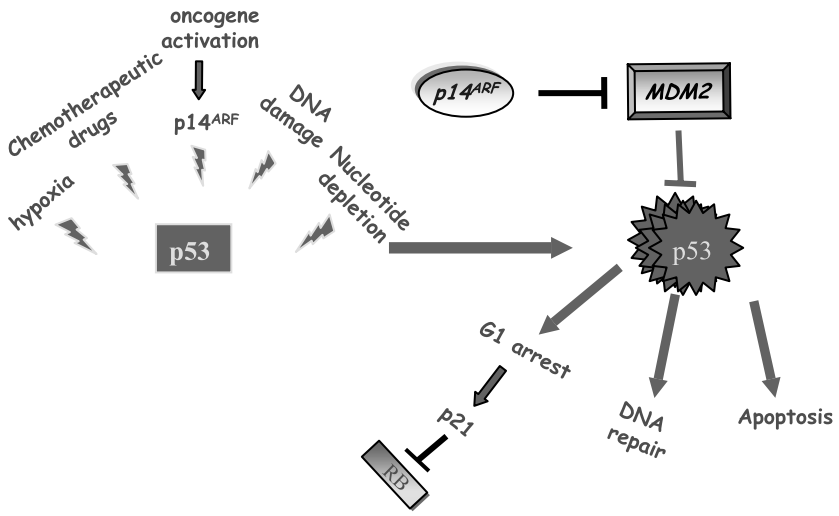

Fig. 1 The p53 pathway. p53 is activated by different stresses and induces the expression of several genes involved in cell growth inhibition, DNA repair, and apoptosis. p14ARF inactivates MDM2 and stabilizes p53. (*View this art in color at www.dekker.com.*)

The biochemical activity involves its ability to bind DNA in a sequence-specific manner and to act as a transcription factor. The p53 protein is extensively posttranslationally modified by phosphorylation and acetylation, which affect its sequence-specific DNA binding and transcriptional activities. In normally growing cells, p53 protein levels are very low. In response to different cellular stresses, such as DNA damage, oxidative stress, radiations, hypoxia, and so on, p53 is stabilized by covalent and noncovalent modifications, succeeding specific protein–protein interactions that, in turn, rapidly increase p53 protein levels and induce the expression of genes involved in cell cycle arrest to allow repair processes, or, failing that, to induce the expression of genes promoting apoptosis (Fig. 1).[3] Genotoxic damage, also caused by chemotherapy or radiotherapy, induces p53 overexpression to control the rate of proliferating damaged cells, thus triggering the mismatch repair or apoptotic pathway.

The activity of p53 is regulated primarily through control of protein stability. One of the principal regulators of p53 stability is MDM2, which not only binds the transactivation domain of p53, inhibiting its ability to function as a transcription factor, but also targets p53 for degradation. The factor, which can inactivate MDM2 and stabilize p53, is the $p14^{ARF}$ tumor-suppressor gene product that binds directly to MDM2, thereby inhibiting p53 proteolysis (Fig. 1).

p53 PATHWAY IN SPORADIC TUMORS

The occurrence of *p53* mutations ranges from 20% to 60% in sporadic solid tumors (Table 1). *p53* mutations may also be inherited in families with a predisposition to multiple tumors as in the Li–Fraumeni syndrome. Different tumors show different mutation patterns according to mutation type and location. Furthermore, some mutations are typical of certain geographical areas (Asian countries) and depend on exposure to environmental mutagens (e.g., aflatoxin B1). Moreover, single nucleotide polymorphisms (SNPs) have been proposed to play a role in tumor genesis (e.g., Arg72Pro).

The International Association of Cancer Registries (IARC database) report 18,585 somatic and 225 germline

Table 1 *p53* mutations in sporadic tumors

Tumor	*p53* mutation (%)
Esophagus	49
Ovary	48
Colorectum	44
Head and neck	41
Pancreas	39
Lung	39
Skin	36
Bladder	33
Stomach	31
Brain	27
Liver	27
Breast	25
Uterus	23
Soft tissues	16
Bones	15
Hematological	15
Prostate	14
Kidney	14
Testis	12
Thyroid	12

mutations in the *p53* gene with over 1700 different mutations (http://www.iarc.fr/p53/Index.html).[4] The most frequent are missense mutations, which are scattered throughout the 11 exons as well as at splice junctions. Although most mutations are in exons 5–8, which are involved directly in DNA binding, over 13% of mutations occurs outside. Moreover, inactivation of p53 may occur without a change in its sequence. Mutations in the genes involved in the p53 pathway may affect p53 function without affecting p53 structure or protein expression. Both viral and cellular proteins bind p53 and modulate its activity.

MDM2 and $p14^{ARF}$ are the principal cellular proteins that interact with p53, determining its stability. It was found that MDM2 is overexpressed in different tumor types such as sarcomas, breast, brain, bladder, lung cancers, and leukemia. In these tumors, MDM2 overexpression and *p53* mutations are mutually exclusive, suggesting that either mechanism may inactivate p53.

$p14^{ARF}$ is frequently deleted in cancers with a wild-type *p53* gene, providing strong evidence for a role played by this protein as an upstream regulator of p53 function in some tumor types. In addition, mutations in different enzymes, such as kinases and acetylases, which activate p53, could also disrupt p53 function. Mutations in downstream p53 effectors involved in cell cycle arrest and apoptosis could lead to a p53 ''null'' phenotype even if the *p53* sequence is wild type.

It has been found that the toxicity and efficacy of many of the current treatments are also profoundly affected by the activity of the p53 pathway. Most striking was the observation, using the same colorectal cancer cell type, that 5-fluorouracil-induced apoptosis requires wild-type p53, but not its principal target gene $p21^{WAF1}$, whereas adriamycin-dependent apoptosis could be inhibited by the $p53–p21^{WAF1}$ axis.[5] In ovarian tumor, *p53* status is a strong predictor of response to platinum-based chemotherapy. Patients whose tumors have p53 mutations show fewer chances to achieve a complete response following platinum-based regimens compared with patients without *p53* mutations. Conversely, experimental and clinical data seem to show that paclitaxel enhances apoptosis through a p53-independent pathway. Such observations highlight the usefulness of *p53* gene profiling as a form of cancer diagnosis and genotyping in defining the best therapeutic treatment for each patient.[6]

Treatments depending on the p53 pathway require the scanning of the entire *p53* gene and the identification of any type of mutation, not only in the *p53* gene.

p53 MOLECULAR DIAGNOSIS

Most studies of p53 have defined mutations by using immunohistochemistry (IHC), even if the use of IHC as an indirect measure of *p53* status gives ambiguous results.

Later, several molecular methods are developed for rapid prescreening of *p53* mutations, which do not give any information on the nature of the mutation. They can be grouped as either conformation-based techniques or base mismatch recognition techniques (for review, see Ref. [1]).

The conformation-based procedures for mutation detection are single-strand conformation polymorphism (SSCP), heteroduplex analysis (HA), denaturing gradient gel electrophoresis (DGGE), and modifications of DGGE: temperature gradient gel electrophoresis (TGGE) and constant gradient gel electrophoresis (CDGE). These techniques utilize the property that DNA fragments containing a sequence alteration have altered mobility under certain conditions of gel electrophoresis compared with a control.

Base mismatch recognition methods exploit the ability of chemicals or proteins (e.g., endonuclease V, RNase, or MutS and MutY mismatch repair proteins) to recognize mismatched bases in DNA heteroduplexes. The single-strand specificity of RNase has similarly been utilized to digest RNA:DNA or RNA:RNA (nonisotopic RNase cleavage assay or NIRCA) heteroduplex.

In recent years, the previously described technologies have been significantly simplified and automated to make them less time-consuming, and they have been coupled together, producing a variety of methodological approaches for *p53* mutation detection. The possibility of binding heteroduplex and oligonucleotides arrays to solid and semisolid supports has led to automation. Moreover, the possibility to detect DNA fragments of different sizes by capillary electrophoresis (CE) instead of labor-intensive gel electrophoresis, miniaturization (chip technology), as well as the use of fluorophores instead of dangerous reagents have all drastically reduced the drawbacks of the above methods and have improved their sensitivity (100%) and throughput.

Moreover, the increased efficiency of DNA sequencing analysis is an important goal in modern biology. Direct sequence analysis is the most precise method for determining *p53* mutation status (100% specificity). Automated sequencing has streamlined sequence data production and acquisition.

Another recent approach, pyrosequencing, has shown accurate results for *p53* mutation detection. Pyrosequencing is a nonelectrophoretic real-time DNA sequencing method that uses luciferase–luciferin light release as the detection signal for nucleotide incorporation into a target DNA.

Advances in genomics, proteomics, bioinformatics, and nanotechnology have recently increased exponentially. The integration of these scientific fields with multiplexed assays allows the development of devices that undoubtedly enable higher throughput both in screening of mutations and sequencing determination: the chip technology.

The high-density oligonucleotide arrays (DNA chip), attached to a solid glass or nylon matrix, allow the rapid scanning of any gene to determine the zygosity (i.e., discrimination between homozygotes and heterozygotes) for all possible allelic variations in patient samples (mutations and polymorphisms) and expression studies. Dedicated instrumentation and software allow fluorescence detection, data acquisition, and analysis of hybridization patterns.

THERAPEUTIC APPROACHES RELATED TO p53 STATUS

As testified by the extensive bibliography, *p53* is used as a tool for better diagnosis and prognosis, and also for development of new cancer therapies (Ref. [1]; for review, see Ref. [7]). There are several approaches for restoring normal p53 function, depending on the status of the gene. If the *p53* gene is mutated, the most direct approach is gene therapy, in which normal *p53* gene is introduced back into tumor cells using mostly replication-defective adenoviruses that deliver a human p53 cDNA sequence driven by strong viral promoters. One significant limitation of this gene transfer approach is the inability to properly regulate gene expression after gene transfer. A second potential complication is that most *p53* mutations found in human cancers are not null mutations, but rather encode mutant versions of the p53 protein that may have unwanted activities such as a gain of function. However, several studies are exploring new vectors that have modified tissue and cellular tropism.

Another example of targeting cancer cells containing a high level of mutant p53 protein or without p53 uses an adenovirus hybrid, called ONYX-015, engineered to kill cells with mutant p53, but not wild-type p53. Briefly, the human adenoviruses infect quiescent cells and induce them into the S-phase of the cell cycle so that viral DNA replication can proceed. The E1A protein of human adenoviruses, which binds pRB (retinoblastoma oncosuppressor gene) and other related proteins, is largely responsible for this entry into the S-phase. The E1B adenovirus gene encodes a 55-kDa protein that binds and inactivates the cellular p53 protein. In the ONYX-015 mutant adenovirus, the E1B gene product has been inactivated by mutation so that the virus cannot replicate in normal cells with a functional p53 protein. It has been reported that injection of this mutated virus into human p53-deficient solid tumors caused a significant regression of the tumor.

An alternative tumor targeting strategy exploits the loss of wild-type p53 function with regard to its dual role in the transcriptional regulation of gene expression. In fact, p53 can positively regulate the expression of target genes involved in cell growth inhibition or induction of apoptosis, but it is also able to suppress the transcription of other genes having a canonical promoter. Compelling evidence has indicated that such repressing activity is an important component of the tumor-suppressor function of p53. This gene therapy maximizes the expression of a potential therapeutic gene in tumors while simultaneously downregulates the same gene in normal cells. This system should be able to incorporate a number of different therapeutic genes, including prodrug-activating genes and immunomodulators. This approach makes use of two constructs. In the first construct, the potential therapeutic gene is placed under the control of the human heat shock protein 70 (Hsp70) gene promoter, which is upregulated in tumor cells in a more advanced stage and with poor prognosis. In addition, this promoter is activated by several p53 mutants and is repressed by wild-type p53. In this way, the therapeutic gene is selectively expressed only in tumoral cells with a mutated *p53*. In normal cells, residual expression of the therapeutic gene is repressed by using the second construct that drives a transcriptional repressor, or an antisense of the therapeutic gene under the control of a promoter activated by wild-type p53.

Other ambitious strategies aim to convert mutant p53 protein into its wild-type form by using small peptides, or by introducing drugs disrupting the interaction between MDM2 protein and p53.

The study of the allosteric and structural classes of mutant p53 protein has permitted researches to obtain the design of small peptides, which promote the stability not only of the wild-type p53, but also of mutant p53 to maintain an active conformation. Different classes of mutants require different rescue strategies, and before using activating drugs, it is crucial to define the type of *p53* mutation.

Another attractive area of therapeutic development is the discovery of molecules that mimic the function of gene products whose synthesis is induced by p53. In particular, attention of researchers is focused on two principal genes: the cyclin-dependent kinase (CDK) inhibitor $p21^{WAF1}$ and the proapototic gene *bax*.

If *p53* is wild type in a tumor and p53 pathway is ablated, therapeutic strategies are addressed to the activation of endogenous *p53* gene. Many therapeutic strategies have focused on MDM2, the principal negative regulator of the p53 pathway. By making use of MDM2 antisense, it is possible to inhibit MDM2 expression and to activate the p53 apoptotic response in tumor. Moreover, natural peptides have been found to bind MDM2 20 times more efficiently than p53, thus preventing the interaction between MDM2 and p53. In addition, several general inhibitors of transcription and the CDK inhibitor, roscovitine, are potent activators of p53-dependent transcription when delivered at moderate doses by selectively decreasing the expression of MDM2. Recently, it has been found that another small molecule, leptomycin

B, which inhibits the CMR1 nuclear exportin, is a potent activator of the p53 response. It can kill neuroblastoma cells in a p53-dependent manner while inducing only a reversible growth arrest in nontransformed cells.

CONCLUSION

Because p53 alterations are so frequent in human tumors, the detection of *p53* mutations and the analysis of the p53 pathway should be a useful diagnostic tool for rational drug or therapy development. Indeed, cancers presenting mutations of *p53* tend to be more aggressive in resisting chemotherapy and are less respondent to most protocols than cancers of similar tissues expressing wild-type *p53*. The repair of p53 pathways in cancer cells holds tremendous promise for the development of new, safer, more selective and effective cancer treatments.

The ultimate goal of identifying prognostic indicators is that they might eventually guide oncologists in the design of appropriate treatment regimens. The principal therapeutic strategies described here will have merit in the clinic and some of them have already been found to have successful therapeutic effects. Future progress will require a precise diagnosis of the p53 pathway status of individual tumors.

Padlock Probes

David Y. Zhang
Josephine Wu
Mount Sinai School of Medicine, New York, New York, U.S.A.

INTRODUCTION

The padlock probe or circularizable oligonucleotide probe (C-probe) is a unique molecule that offers significant advantages over conventional oligonucleotide probes. A closed circular structure forms through ligation of its ends after hybridization onto a target, and locks onto its target due to helical turns formed between complementary sequences of the target and the padlock probe. The nature of padlock and stringent requirement for ligation make this probe especially useful for in situ hybridization and detection of single-nucleotide polymorphisms (SNPs).

TECHNICAL DESCRIPTION

Oligonucleotide probes provide a useful method for the detection of target nucleic acids by the formation of a double-helical structure between complementary sequences based on stringent requirements of Watson–Crick base pairing, making hybridization extremely specific. First described by Kool in 1991,[1] the padlock probe or C-probe is a uniquely designed oligonucleotide probe containing three regions: two target complementary sequences located at the 5′ and 3′ termini and an interposed generic linker region.[2,3] Once the padlock probe hybridizes to a target, its 5′ and 3′ ends are juxtaposed (Fig. 1A) and a closed circular molecule is then generated by incubating the padlock probe–target complex with a DNA ligase. The resulting closed circular molecule is locked on its target due to the helical turns formed between the complementary sequences of the target and the padlock probe.[2] The permanently bound padlock probe allows for stringent washing to remove unbound components, thereby enhancing assay signal-to-noise ratios. Therefore, the advantage of the padlock probe is that it offers greater specificity and less background when compared to current conventional probes. Furthermore, once the padlock probe hybridizes to a specific target sequence, it can then serve as a template for linear (rolling circle amplification, RCA) or exponential (ramification amplification method, RAM) amplification and significantly increases the specificity and sensitivity of signal detection.

Recently, two interesting methods were presented for catenation of padlock probes to double-stranded DNA (dsDNA) sequences. Escudé et al.[4] demonstrated the formation of a triplex complex between a dsDNA and a circularizable probe through the interaction between polypurine–polypyrimidine sequences in the dsDNA target and padlock probe. The advantage of the triplex padlock probe is that it allows for binding of the padlock probe to dsDNA without predenaturation. Kuhn and colleagues designed two peptide nucleic acid (PNA) probes that are complementary to the opposite strand of padlock probe binding site.[5] These PNA ''openers'' can invade the dsDNA and may facilitate binding of the padlock probe to target DNA. Furthermore, they prevent the padlock probe from shifting laterally, resulting in more specific localization of the signal intracellularly.

The padlock probe ranges from 70 to 125 nucleotides long with two target complementary regions, each ranging from 15 to 30 nucleotides, and a linker region ranging from 30 to 75 nucleotides.[2,3,6,7] The padlock probe can be readily synthesized with most DNA synthesizers. The 5′ end of the probe must be phosphorylated and the 3′ end must contain a hydroxyl group; both are required by DNA ligase. Addition of a phosphate group to the 5′ end is usually achieved by incubation with a polynucleotide kinase in the presence of ATP or during chemical synthesis.[8]

Successful ligation of the two ends depends on two factors: both ends must bind adjacent to each other and no mismatch should exist at the ends, especially the first 1–3 nucleotides at its 5′ and 3′ ends (Fig. 1B).[2,8] A variety of ligases can be used for this reaction, such as T4 DNA ligase, Taq ligase, Ampligase, and T4 RNA ligase.[9] However, ligation efficiency can reach as high as 90% with T4 DNA ligase.[5,8] Furthermore, Nilsson et al.[2] demonstrated the ligation specificity of T4 DNA ligase depended on increasing the NaCl concentration. Whereas NaCl concentrations between 50 and 150 mM result in optimal ligation activity, at 250 mM NaCl T4 DNA ligase was shown to correctly distinguish a C/G match from notoriously difficult T/G mismatches, resulting in a greater than 1000-fold difference in ligation rates. Although T4 DNA ligase is efficient for ligation of DNA probe onto a DNA target, ligation of a DNA probe

DOI: 10.1081/E-EDGP 120020719

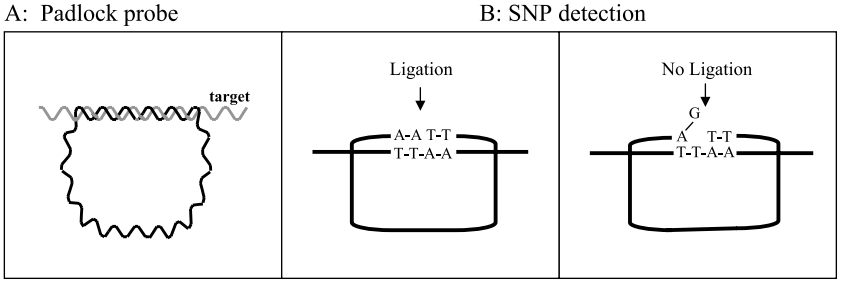

Fig. 1 Schematic representation of the padlock probe. (A) A padlock probe hybridizes to its target through its complementary regions and helical turns to form a closed circular probe. This results in the interlocking of the padlock probe onto the target. (B) Only when the ends of the padlock probe perfectly match with its target can ligation occur, thus allowing detection of a single-nucleotide polymorphism.

onto an RNA target is very poor.[8] However, the ligation efficiency can reach 80% by addition of $MnCl_2$, low NaCl concentration, low ATP concentration, and high concentration of T4 DNA ligase.[8,10] The stringent requirement of ligation allows detection of single nucleotide differences between target DNA and probe (Fig. 1B).

Application

As a result of its high specificity, the padlock probe has found clinical and research applications in several genetic assays, including in situ hybridization and SNP detection. The padlock probe was initially designed to analyze chromosomes in a cell undergoing interphase or metaphase.[2] Because of its ability to lock onto target DNA, a glass slide can be washed under stringent conditions (above the melting temperature), therefore lowering background signal and improving detection sensitivity. With the aid of fluorescent reporter molecules, such as biotin or digoxigenin, the bound padlock probes attached to interphase or metaphase chromosomes can be visualized under a microscope.[2] Two fluorescent-labeled padlock probes have been used to detect human centromeric alpha satellite DNA of chromosome 13 and 21, which contains multiple repeats.[11] Two chromosomes were individually visualized under a microscope. Furthermore, the padlock probe can detect a single nucleotide difference in two satellite sequences.[11] Although the padlock probe alone is adequate to detect a repeat motif, it is insufficient to detect a single-copy gene sequence in situ because of low signal intensity.

Single-nucleotide polymorphisms of genomic DNA are considered to be the most common form of genetic variations, occurring in approximately every 250–2000 bases. With the availability of large SNP databases, detection of specific sets of SNPs will allow for identification of disease-associated polymorphisms to correlate therapies with clinical outcomes and drug effect as well as parentage and forensic testing. The padlock probe offers a significant advantage to detect SNPs. For ligation to occur, both ends must perfectly hybridize to the target at juxtaposition (Fig. 1B). The discrimination of SNPs by ligation was approximately 1:100 to 1:1000 in a mixture of mutant alleles in an excess of wild-type alleles.[12] For RNA targets, the discrimination by ligation ranged from 20- to 200-fold.[10]

CONCLUSION

The padlock probe represents the next generation of probe-based hybridization with the ability of direct target detection. The padlock probe improves the binding affinity and hybridization stringency and allows more efficient SNP discrimination. With the use of different fluorescent-labeled padlock probes, multiplex padlock assays could greatly increase throughput in genotyping and permit highly sensitive and specific measurement of gene expression. The padlock probe and its amplifications (i.e., rolling circle amplification and ramification amplification) allow for broad applications in clinical testing, research laboratories, and drug discovery. Clinically, it can be used for detection and identification of infectious agents, cancer screening and diagnosis, neonatal genetic diagnosis and parentage, and forensic testing.

Paraoxonase (PON1) Gene Polymorphisms

Lucio G. Costa
Clement E. Furlong
University of Washington, Seattle, Washington, U.S.A.

INTRODUCTION

Paraoxonase-1 (PON1) (EC 3.1.8.1 or EC 3.1.1.2) is a high-density lipoprotein (HDL)-associated serum enzyme whose primary physiological role is to protect low-density lipoproteins (LDLs) from oxidative modifications. PON1 can also hydrolyze organophosphorus (OP) compounds, including commonly used insecticides, and its name derives from one of its most commonly used in vitro substrates—paraoxon. More recently, in addition to its role in lipid metabolism and, hence, in cardiovascular disease and arteriosclerosis, PON1 has also been shown to be involved in the metabolism of lactones and cyclic carbonates. Early studies of enzymatic activity in serum indicated a bimodal or trimodal distribution in Caucasian populations. Two main polymorphisms in the coding region, as well as five in the 5′ regulating region, have been characterized. The Q192R polymorphism determines the catalytic efficiency of hydrolysis of some substrates, and certain promoter polymorphisms, in particular C-108T, contribute to the level of expression of PON1. Recently, additional polymorphisms in the coding region, 5′ regulatory region, and PON1 introns have been reported.

STRUCTURE AND POLYMORPHISMS OF PON1

The PON1 cDNA encodes a protein of 355 amino acids from which only the amino-terminal methionine residue is removed during secretion and maturation.[1] The retained leader sequence is required for the association of PON1 with HDL particles, and, indeed, PON1 is entirely associated with HDL in human serum. PON1 protein is synthesized mostly in the liver, from which it is released by a docking process whereby HDL particles transiently associate with the cell membrane and remove PON1 from the membrane. Physical mapping placed the human *PON1* gene on chromosome 7 q21–22. Two polymorphisms are present in the PON1 coding sequence: a Glu (Q)/Arg (R) substitution at position 192, and a Leu (L)/Met (M) substitution at position 55.[2] These coding region polymorphisms have been studied for effects on catalytic efficiencies of hydrolysis of specific substrates. The L/M polymorphism at position 55 has not been found to affect catalytic efficiency, but has been associated with plasma PON1 levels, with PON1 M55 individuals having, on average, lower PON1 levels.[3,4] This association appears to result primarily from linkage disequilibrium of the M55 allele with the inefficient −108T promoter polymorphism.[4] However, the Q/R polymorphism at position 192 significantly affects the catalytic efficiency of PON1 in a substrate-dependent manner.[5] Five additional 5′ regulatory region polymorphisms of the *PON1* gene have been characterized: −108TC, −126GC, −162GA, −832GA, and −109CG.[4,6] The −108TC polymorphism has the largest effect of these 5′ regulatory region polymorphisms on PON1 expression, with the −108C allele generating, on average, approximately twice the level of plasma PON1 as the −108T allele.[4] Recently, 2 additional coding region polymorphisms (I102V in Finns and R160G in Chinese), 8 new 5′ regulatory region polymorphisms, and more than 140 polymorphisms in PON1 introns have been identified. New functional coding region polymorphisms have been described and characterized.[7] An illustration of the *PON1* gene with its polymorphisms known to date is given in Fig. 1.

The gene frequencies of some of these polymorphisms have been determined. The $PON1_{Q192}$ gene frequency ranges from 0.75 for Caucasians of Northern European origin to 0.31 for some Asian populations.[8] Gene frequency for $PON1_{L55}$ ranges from 0.57 in Caucasian populations to 0.99 in an Oji–Cree population. Several studies have shown that the L_{55} and R_{192} alleles are in strong disequilibrium, with >90% of the R_{192} allele having L at position 55.[8]

THE IMPORTANCE OF DETERMINING PON1 STATUS

In recent years, the importance of determining an individuals' PON1 status has been repeatedly highlighted.[7,9–13] The term *PON1 status* includes both the $PON1_{192}$ genotype as well as PON1 activity. The concept was prompted by examination of a number of epidemiological studies, which examined only the $PON1_{192}$ and $PON1_{55}$ genotypes, without considering the large

DOI: 10.1081/E-EDGP 120030804

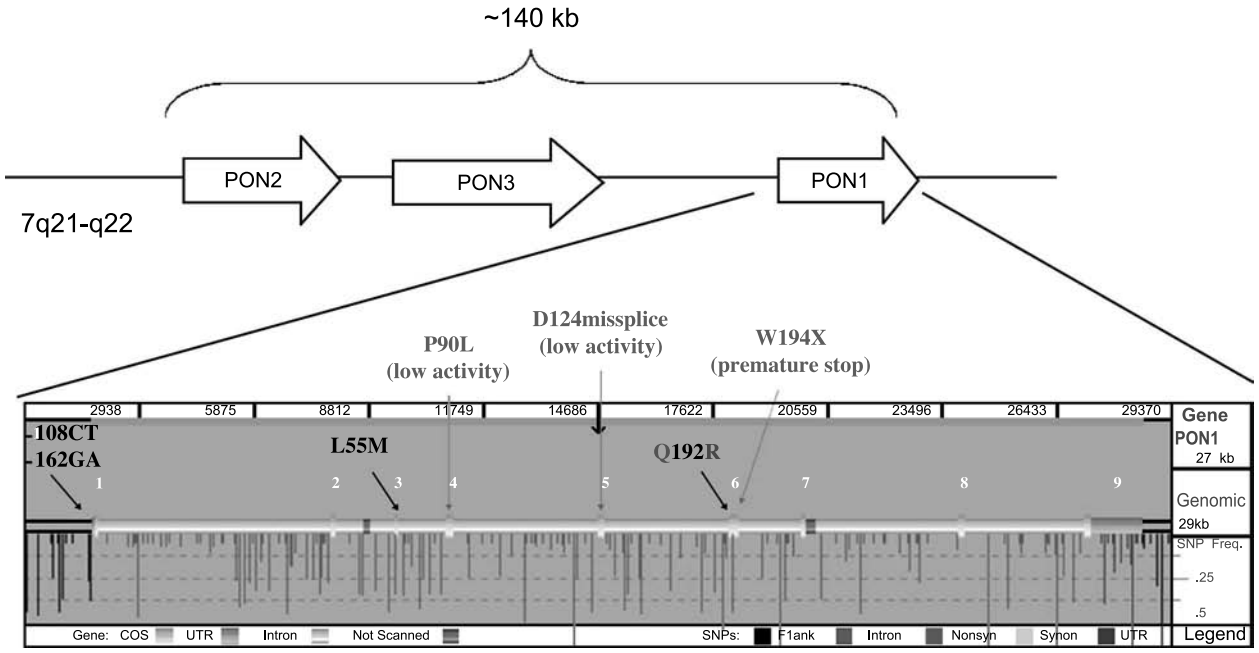

Fig. 1 The *PON1* gene is located on human chromosome 7, near the genes encoding PON2 and PON3. The expanded *PON1* gene diagram shown illustrates the locations and frequencies of single nucleotide polymorphisms (SNPs) that have been identified in the *PON1* gene, with SNP locations indicated by vertical lines below the gene structure diagram. The numbered boxes correspond to the nine exons found in *PON1*. The length of each line indicates the frequency of that SNP in the population. In addition to the previously identified SNPs that result in amino acid substitutions at L55M and Q192R, 166 new SNPs were identified by the UW/FHCRC Variation Discovery Resource (Seattle SNPs). The PON1 SNP diagram at the bottom was created at the SeattleSNPs web site (http://pga.gs.washington.edu/), using the GeneSNPs public web resource (http://www.genome.utah.edu/genesnps) available from the Utah Genome Center. (*View this art in color at www.dekker.com.*)

variability of PON1 protein levels within each genotype (Fig. 2). Indeed, PON1 levels are at least as important as genotype in determining rates of clearance of oxidized lipids, as well as determining resistance to organophosphate toxicity.[10] By plotting the rates of diazoxon hydrolysis against paraoxon hydrolysis at high salt concentration (2 M NaCl) for individuals in a population, the subjects are clearly divided into three groups: individuals homozygous for $PON1_{Q192}$, heterozygotes ($PON1_{Q/R192}$), and individuals homozygous for $PON1_{R192}$; in addition, information of PON1 activity levels is also obtained (Fig. 2; Ref. [9]). The procedure can be easily carried out in 96-well microtiter plate readers capable of following continuous enzyme kinetics at the appropriate wavelength (for details, see Ref. [14]). For this assay, plasma from blood collected in heparin or citrate can be used, but not ethylenediaminetetraacetic acid (EDTA) plasma, because EDTA irreversibly inhibits PON1. The accuracy of this PON1 status approach to determine the $PON1_{192}$ functional genotype has been verified by direct genotyping using a polymerase chain reaction (PCR) method,[2,14] and has been found to be close to 100%. Individuals with discrepant assignments have been found to have one dysfunctional PON1 allele.[15] For example, several individuals were genotyped as 192 Q/R heterozygotes by PCR, but the functional enzyme analytic assay followed by the sequencing of their *PON1* genes demonstrated that one or the other PON1 alleles were defective.[15] Methods for genotyping other polymorphisms in the 5′ promoter region (e.g., −108TC), as well as newly discovered polymorphisms in the coding region (e.g., W194X), have also been described.[14]

ROLE OF PON1 IN ORGANOPHOSPHATE TOXICITY

Several in vitro experiments have shown that PON1 hydrolyzes a number of organophosphates—among these, paraoxon, chlorpyrifos oxon, and diazoxon; active metabolites of the insecticides parathion, chlorpyrifos, and diazinon; as well as nerve agents sarin, soman, and VX. The effects of the $PON1_{192}$ polymorphism may be substrate-dependent, as the $PON1_{Q192}$ isoform hydrolyzes diazoxon, sarin, and soman more rapidly than $PON1_{R192}$

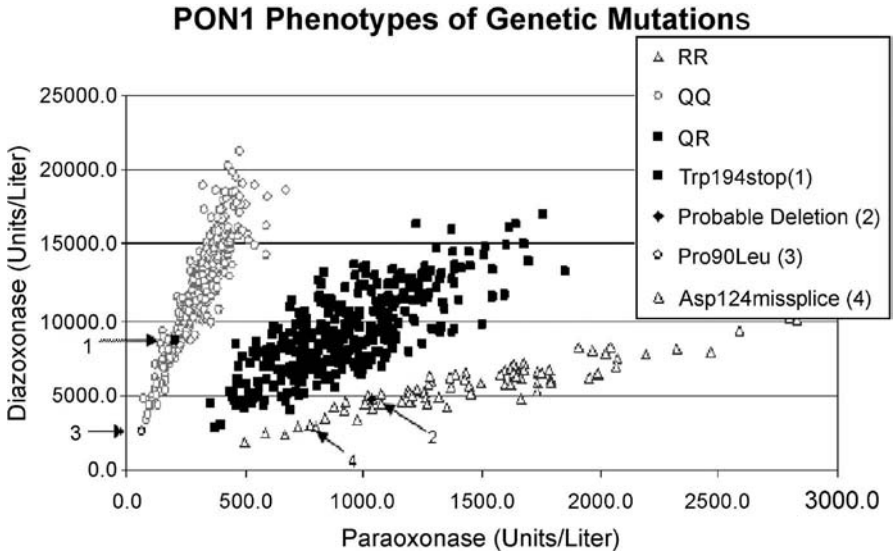

Fig. 2 Determination of PON1 Status. Plot of diazoxonase vs. paraoxonase activities in the plasma of carotid artery disease cases and controls, coded for PON1 Q192R genotype (determined by PCR). Note that the two-substrate assay provides an accurate inference of $PON1_{192}$ genotype as well as the level of plasma PON1 activities (PON1 status). Because it is a functional analysis, it provides a 100% accurate determination of the functional genomics of PON1 status. Newly discovered SNPs explain why some individuals have lower PON1 activity than would be predicted by Q192R genotype alone. Individuals 1–4 were genotyped as heterozygotes (Q/R192); however, their enzyme analysis indicated homozygosity for Q or R. Complete sequencing of their *PON1* genes revealed mutations in one allele, resulting in only one alloform of PON1 in their serum. The mutations revealed are noted in the figure. (Note the large variability in PON1 levels, even among individuals of the same Q192R genotype). (From Refs. [7], [9], and [15].)

in in vitro assays.[5] However, $PON1_{R192}$ is more efficient at hydrolyzing paraoxon and chlorpyrifos oxon than the Q isoform. The existence of polymorphisms in PON1 that confer different hydrolyzing abilities toward OPs, as well as different levels of expression, has long suggested that certain individuals may be more sensitive to OP toxicity.

Animal studies have provided evidence for the role of PON1 in modulating OP toxicity, and have clarified the role of $PON1_{192}$ polymorphism. Initial studies showed that administration of exogenous PON1 to rats or mice would confer protection against the acute toxicity of various OPs (reviewed in Refs. [11] and [16]). Further evidence was provided by studies carried out in PON knockout ($PON1^{-/-}$) mice and PON1 transgenic (TG) mice expressing either the human $PON1_{R192}$ or the $PON1_{Q192}$ allele. As predicted, $PON1^{-/-}$ mice have drastically increased sensitivity to the toxicity of chlorpyrifos oxon and diazoxon, but not to paraoxon.[17,18] Administration of purified human $PON1_{R192}$ or $PON1_{Q192}$ to $PON1^{-/-}$ mice indicated that both isoforms were equally protective toward diazoxon toxicity and equally ineffective in protecting against paraoxon toxicity, whereas $PON1_{R192}$ offered better protection than the $PON1_{Q192}$ isozyme toward chlorpyrifos oxon.[18] These in vivo findings were explained by results from kinetic analyses of substrate hydrolysis by purified human PON1 isoforms under physiological conditions. The catalytic efficiencies of both isoforms for diazoxon were similar, whereas that of $PON1_{R192}$ was higher than $PON1_{Q192}$ for chlorpyrifos oxon. In case of paraoxon, even though the $PON1_{R192}$ was more efficient than $PON1_{Q192}$, its overall catalytic efficiency was very low, indicating that PON1 does not play a significant role in detoxifying paraoxon in vivo.[18] Studies in TG mice have supported these findings by indicating that the toxicity of chlorpyrifos oxon is greatly reduced in $hPON1_{R192}$ TG mice, but not in $hPON1_{Q192}$ TG mice compared with $PON1^{-/-}$ mice.[19] Current work is exploring the role of PON1 in modulating the effects of OPs on gene expression in the brain by microarray analysis. Although these studies clearly indicate that the $PON1_{192}$ genotype and the level of PON1 expression modulate OP toxicity in animal models, direct confirmation in humans of the relevance of PON1 status in determining relative sensitivity to OP toxicity needs to be further investigated. The limited number of studies aimed at testing this hypothesis in humans has been recently summarized,[16] but more studies are needed, where better indications of the level and nature of exposure and the consequences of exposure are documented. Nevertheless, results of animal studies have also pointed out the potential therapeutic use of PON1 in treating individuals for exposure to OP insecticides or nerve agents. Engineering recombinant PON1 variants with high catalytic efficiencies toward specific compounds

may indeed prove to be a useful addition to the treatment of OP intoxication.[10]

PON1 AND CARDIOVASCULAR DISEASE

In recent years, PON1 has taken center stage in research endeavors aimed at identifying possible risk factors for cardiovascular disease.[10–12,20] The influence of PON1 and its polymorphisms on cardiovascular disease appears to be related to its ability to inhibit LDL and HDL oxidation.[21,22] Overall, in vitro studies have shown that PON1 has esterase-like, peroxidase-like, and phospholipase-like activities that inhibit the formation of proinflammatory oxidized phospholipids, or, perhaps more correctly, degrade them once they are formed.[11] Studies in TG animals have added strong evidence for a role of PON1 in the development of arteriosclerotic lesions. $PON1^{-/-}$ mice fed a high-fat diet exhibited larger aortic atherosclerotic lesions than wild-type mice.[17] On the contrary, TG mice expressing human PON1 (L55, Q192) had significantly decreased arteriosclerotic lesions.[23] In agreement with these in vivo findings, HDL isolated from $PON1^{-/-}$ and hPON1 TG mice had no ability or had an increased ability, respectively, to prevent LDL oxidation in vitro. Additional studies have shown that $PON1_{Q192}$ is twice as efficient as $PON1_{R192}$ in reducing the total lipid peroxide content of human arteriosclerotic lesion homogenates.[22]

A large number of population studies have tested the association of $PON1_{Q192R}$ and $PON1_{L55M}$ polymorphisms with coronary heart disease (CHD). Among these studies (for more details, see Refs. [10] and [11]), about half yielded significant results, where the 192R allele was consistently associated with CHD. The $PON1_{R192}$ and $PON1_{55L}$ alleles are in strong linkage disequilibrium, and the $PON1_{55L}$ genotype predicted CHD in several studies, including one in which $PON1_{192}$ genotype did not predict disease. However, the $PON1_{55L}$ polymorphism is in linkage disequilibrium with the T-108C promoter polymorphism, which is correlated with higher plasma PON1 concentrations, hence the importance, as pointed out earlier, of determining each individual's PON1 status, which encompasses both plasma PON1 levels as well as $PON1_{192}$ genotypes.[9] Indeed, PON1 phenotype has been shown to be a better predictor of vascular disease than the $PON1_{192}$ or $PON1_{55}$ genotype,[13] a finding that has been confirmed in other studies (e.g., Refs. [15] and [24]).

PON1 AND DRUG METABOLISM

Evidence exists that PON1 may be involved in the metabolism of pharmaceutical drugs, in which case the PON1 status of an individual would be relevant to a drug's effectiveness and/or side effects. The diuretic spironolactone is hydrolyzed by PON1, with similar efficiency by the Q and R isoforms.[25] However, the hypocholesterolemic drugs mevastatin, lovastatin, and simvastatin, previously reported to be hydrolyzed by PON1, are instead metabolized by PON3.[12] The antibacterial prodrug prolifloxacin is activated by PON1, with $PON1_{R192}$ displaying higher activity. However, glucocorticoid γ-lactones are inactivated by PON1. Although evidence is still limited, novel classes of so-called prodrugs may be developed by incorporating a lactone or cyclic carbonate moiety into their molecules, which can be inactivated or bioactivated in vivo by PON1.[11,12,26]

CONCLUSION

The *PON1* gene, located on chromosome 7, displays several polymorphisms in the coding and promoter regions that affect the catalytic ability of the protein as well as its level of expression. Both aspects need to be considered when investigating the role of PON1 in organophosphate toxicity, cardiovascular heart disease, and other diseases as well as drug metabolism. Additional areas of current and future research should elucidate the contribution of environmental, dietary and lifestyle factors to the modulation of PON1 expression, as well as the relationship between PON1 and *PON2* and *PON3*, two related genes located on chromosome 7.[10,12] Furthermore, nothing is yet known about the contributions of the recently described >150 polymorphisms in modulating PON1 message splicing efficiency and thereby PON1 levels.

Parkinsonism, Autosomal Dominant

Dominic Thyagarajan
Flinders University of South Australia, Bedford Park, Australia

INTRODUCTION

In this article, I review recent findings in genetic parkinsonian syndromes, focusing on those showing autosomal dominant inheritance. The finding of genes for recessive and dominant syndromes is providing insights into the pathophysiology of common, sporadic Parkinson's disease. These findings have again stimulated renewed interest in the Lewy body, thought to be the pathological ''hallmark'' of the sporadic disease. I conclude by reviewing what the genes in autosomal dominant parkinsonian syndromes mean for a diagnostic and conceptual approach to Parkinson's disease.

GENES AND PARKINSONISM

Parkinsonism is a syndrome of rest tremor, rigidity, bradykinesia, loss of postural reflexes, and the freezing phenomenon.[1] Most often, it is a manifestation of Parkinson's disease (PD), which is characterized neuropathologically by brainstem Lewy bodies. Recent epidemiological and molecular data suggest that this is not one disorder, but is comprised of at least several disorders with genetic, environmental, or mixed etiologies. Genes play a complex role in PD. Most twin studies, which are powerful tools in dissecting genetic from environmental contributions to the disease, have discounted a genetic influence in PD. However, it is difficult to draw solid conclusions from them because of methodological shortcomings.[2] The largest of them, an unselected population-based cross-sectional twin study, has shown similar concordance for PD in monozygotic (MZ) and dizygotic (DZ) twin pairs with onset >50 years, but a striking concordance in MZ pairs with onset <50 years.[3] This is consistent with a strong genetic component in young-onset disease. This does not support a strong genetic component in late-onset disease, but a large population-based and geneological study in Iceland[4] showed that 560 patients with late-onset PD were significantly more related to each other than were subjects in matched groups of controls. The risk ratio (RR) for PD was 6.7 [95% confidence interval (CI), 4.3–9.6] for siblings, 3.2 (95% CI, 1.2–7.8) for offspring, and 2.7 (95% CI, 1.6–3.9) for nephews and nieces of patients with late-onset PD. The study claimed that shared environmental influences in late-onset PD are not the explanation because the relatedness extended beyond the nuclear family and spouses was not at increased risk. However, the different RR values for siblings and offspring are consistent with shared environmental factors in early life. [^{18}F] dopa positron emission tomography (PET) studies in MZ and DZ twin pairs discordant for PD[5] showed reduced striatal uptake not only in the affected twin but also in the clinically unaffected twin, indicating that concordance for nigral pathology in twins with PD is higher than that suggested by clinical twin studies.

Most familial aggregation studies indicate a familial component in PD, but have not adequately compared early-onset vs. late-onset disease.[6] A recent community-based study, in which 221 probands had onset <50 years and 266 had onset >50 years, found significantly greater risk in siblings (RR of 7.9; 95% CI, 2.5–25.5), but not parents (RR of 1.7; 95% CI, 0.9–3.3), of early-onset cases; however, the RR in parents and siblings of late-onset cases was similar (roughly 2–3), confirming a familial component in both early-onset and late-onset PD and further suggesting a recessive genetic influence in early-onset disease.[6]

Dominantly Inherited PD

Golbe et al.[7] described the first large kindred of autosomal dominant PD with autopsy verification in 1990 and later reported a clinical genetic analysis of 60 individuals in five generations. The kindred originated from Contursi, a hill town in the Salerno province of the southcentral region of Italy. There was severe neuronal loss and Lewy bodies in the substantia nigra, typical of PD. Mean age at onset was 46.5 years—15 years younger than that of PD in the community—and the disease had a rapid course, averaging 9.7 years from onset to death. Contrary to observations in the initial report of the pedigree, rest tremor was frequent, present in 58.1%. Most of the affected individuals responded well to levodopa and exhibited its usual motor complications. Most also developed cognitive impairment toward the end of the illness. At the time, a number of other pedigrees of dominantly inherited parkinsonism had been described, some with clinical and neuropathological features similar to sporadic Lewy body PD and some with none.[8]

α-Synuclein Mutations (PARK1 and PARK4)

PARK1: missense mutations in the α-synuclein gene

In 1996, genetic markers on chromosome 4q21–q23 were found to be linked to the PD phenotype in the Contursi pedigree and, a year later, a mutation causing the disease in the kindred and three other unrelated Greek families was found—A53T in exon 4 of the gene encoding the presynaptic protein α-synuclein.[9] The mutation, denoted PARK1, was almost fully penetrant, but there was phenotypic variability (e.g., isolated postural tremor and dementia with Lewy bodies in the Contursi kindred). The same mutation has been subsequently identified in a handful of other families of Mediterranean origin,[10] and, in some instances, additional clinical features were described,[10] such as the presence of myoclonus, central hypoventilation, and orthostatic hypotension. A second mutation in α-synuclein, A30P, has since been found in autosomal dominant PD in a German family,[11] but large surveys in Caucasian[12] and other ethnic groups[13] have indicated that alterations in the α-synuclein gene are rare in sporadic and familial PD, confined to only few families and are possibly the result of founder mutations. However, a case–control study in PD has shown that noncoding variability in the synuclein gene is a risk factor for the development of PD.[14]

PARK4: triplication of the α-synuclein gene

Genetic and clinical heterogeneity in autosomal dominant parkinsonism was evident soon after α-synuclein gene mutations were reported. In a four-generation Iowan kindred of suspected Prussian or Irish descent, originally described in 1962 and in detail by Muenter et al.,[15] linkage to 4q21–q23 was excluded and segregation with a 4p15 haploptype was found, denoted PARK4.[16] This family is probably related to one described by Waters and Miller[8] and Muenter et al.[15] This disease has an asymmetrical, early-onset (mean 33.5±8.5 years), and rapidly progressive course with death within 4–11 years. Levodopa-responsive parkinsonism with bradykinesia, rigidity, resting tremor, stooped posture, loss of postural reflexes, and marked early weight loss are the initial manifestations. Motor complications of levodopa develop early. In the terminal stages, there is often global dementia with rigidity, stupor, and myoclonus. Autonomic features occur. Except for a somewhat later onset of dementia, most of these clinical features (i.e., early onset, rapid progression, rest tremor, levodopa responsiveness, levodopa motor complications, and dementia) are similar to those in the Contursi kindred. Within the Iowan pedigree, there is a separate phenotype consisting of mild late-onset parkinsonism and also several cases of essential tremor in whom there was segregation with the 4p haplotype.[16] Pathologically, limbic areas and pigmented nuclei are severely involved with nerve cell loss, gliosis, and widespread Lewy bodies, many of them in the cerebral cortex.[15] The changes are more extensive than in sporadic PD, and the pattern of neurochemical abnormalities is different—pronounced decrease of choline acetyl transferase in the frontal and temporal cortices and hippocampus, and a severe depletion of striatal dopamine affecting the caudate and putamen equally, rather than interregional and subregional loss maximal in the caudal putamen. In contrast, members of the Contursi kindred have a distribution of Lewy bodies and neuronal loss restricted more to the substantia nigra and nucleus basalis of Meynert. An interesting twist emerged when an unaffected member of the Iowan pedigree who did not share the 4p15 haplotype later developed the disease, prompting a second genomewide search at higher resolution, which refocused attention on the synuclein locus.[17] Reevaluation of the 4p linkage data revealed a sample swap. Resequencing of the α-synuclein gene revealed no mutations, but use of intragenic markers suggested multiple α-synuclein alleles. Quantitative real-time polymerase chain reaction (PCR) yielded gene-dosage data consistent with triplication of α-synuclein in affected individuals, confirmed by fluorescence in situ hybridization (FISH). The triplicated region is between 1.6 and 2.04 Mb in size, and carriers of the triplicated region have four functional copies of the α-synuclein gene and a doubling of the gene dosage in an estimated 17 genes. It seems likely that parkinsonism in the Iowan kindred is related to the gene dose effect of α-synuclein. Interestingly, the α-synuclein triplication segregates only with parkinsonism, not postural tremor.[17] The PARK4 classification has become confusing, and, no doubt, nomenclature will evolve as more genes are characterized.

Other evidence for genetic and clinical heterogeneity in dominant parkinsonism: PARK3, PARK5, and PARK10

Linkage to 2p13 in several families of Northern European descent[18,19] (PARK3), an I93M mutation in exon 4 of the ubiquitin carboxy-terminal hydrolase (UCH-L1) in a German family[20] (PARK5), confirmation of linkage to a locus 12p11.2-q13 (PARK10),[21,22] and a susceptibility locus on 1p32 (PARK10)[23] have indicated further genetic and clinical heterogeneity in dominant parkinsonism. The features are summarized in Table 1.

Diagnostic Considerations

Commercial testing for autosomal dominant parkinsonism is not well developed, partly because the known mutations

Table 1 Autosomal dominant parkinsonism

Condition	Gene	Mutation type	Chromosome	Penetrance	Onset and course	Population	Pathology	Clinical	Detection
PARK1	α-Synuclein	Missense A53T, A30P	4q21.3	~100%	Late 40s, rapid	Isolated Mediterranean and German families; not in sporadic or familial PD	Lewy bodies more apparent in substantia nigra and nucleus basalis of Meynert; cortical Lewy bodies in some	Postural and rest tremor, myoclonus, central hypoventilation, orthostatic hypotension, L-dopa responsiveness, L-dopa motor complications, eventual dementia in most	Sequencing RFLP analysis
PARK4	α-Synuclein	Triplication	4q	~100%	30s, rapid	Iowan kindred of suspected Irish or Prussian descent	Widespread Lewy bodies, including cortex	Similar to PARK1 Subgroups with later onset and essential tremor	Quantitative RT-PCR FISH
PARK5	UCH-L1	Missense I93M	4p14		Similar to sporadic PD	Single German pedigree; not in 500 controls; not in other AD families or sporadic PD,[24,25]	NA	Similar to sporadic PD; rest tremor with asymmetrical onset	RFLP analysis
PARK3	Unknown	NA	2p13	40%	Similar to sporadic PD	Several Northern European families	Similar to PD	Similar to sporadic PD	Linkage only
PARK8	Unknown	NA	12p11.2–q13.1	Low	Similar to sporadic PD	21 Caucasian-dominant PD pedigrees; large dominant Japanese family; two Caucasian families from Western Nebraska and Canada (German origin)	Nigral degeneration *without* Lewy bodies in Japanese family[21]	Similar to sporadic PD	Linkage only
PARK10	Unknown	NA	1p32	Low	Similar to sporadic PD	51 Icelandic families with more than one patient with PD	NA	Late-onset PD	Linkage only

RFLP, restriction fragment-length polymorphism; RT, reverse transcription.

are rare, the search for novel mutations in known genes involves more sequencing or a mutation detection assays, or the gene itself is not known. The two known point mutations in the α-synuclein gene may be conveniently detected by restriction endonuclease digestion of PCR products: the A53T mutation creates a novel *Tsp*45 I restriction site in exon 4[9] and the A30P mutation creates a new *Mva*I site in exon 3.[11] In the *UCH-L1* gene, the I53M change, found only in a single family so far, introduces a new *Bsm*F1 site.[20]

A diagnostic assay for the triplication of the α-synuclein gene is more complex and would involve FISH or quantitative real-time PCR.[17] Although large studies in various populations have shown the lack of utility of screening, even in most families with apparent dominant inheritance of PD,[12] if an α-synuclein mutation is found, the significance is great because the penetrance is practically 100%.

WHAT DO GENES IN AUTOSOMAL DOMINANT PD TELL US ABOUT PATHOGENESIS?

The cause and pathogenesis of PD are incompletely understood, but rare mutations in familial cases (Table 1) are beginning to unravel the variety of cellular processes involved in the accumulation of Lewy bodies and dopaminergic cell death. It is not possible to discuss this fully without reference to the genetic discoveries in autosomal recessive parkinsonism, which have occurred in parallel with the finding of dominant genes and are outside the scope of this article. The subject has been recently reviewed.[26,27] Derangements in protein handling seem to be central in the pathogenesis of PD (Fig. 1). α-Synuclein is a small protein characterized by imperfect repeats (KTKEGV) distributed through most its amino-terminal half of the polypeptide that also includes a hydrophobic middle region and an acidic carboxy-terminal region. Its function is not established but it is believed to modulate synaptic vesicle turnover and synaptic plasticity. In vitro, it polymerizes into ~10-nm fibrils, which are a major component of nigral Lewy bodies and Lewy neurites in PD and other forms of parkinsonism. It is unfolded in its native state but becomes structured on binding to lipid membranes. In the unfolded form, it is degraded by proteosomes in a ubiquitin-independent manner. In diseases where it aggregates, it forms a β-sheet structure. α-Synuclein promotes mitochondrial dysfunction and oxidative stress—another central aspect in the pathogenesis of PD.[28] Oxidative stress may further promote aggregation and lead to Lewy body formation. α-Synuclein knockout mice are phenotypically normal and show no abnormalities of dopaminergic function, and α-synuclein mutations are likely to be gain-of-function mutations rather than loss-of-function mutations. Although none of the transgenic animal models replicates all features of the human disease, they do show neurodegeneration associated with abnormal accumulation of detergent-insoluble α-synuclein and abnormal proteolytic processing of α-synuclein, particularly in the

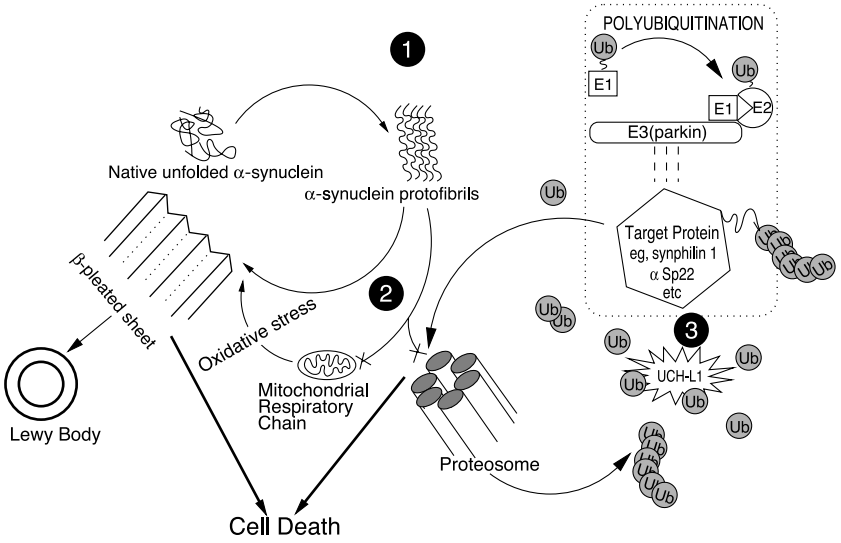

Fig. 1 A simplified hypothetical model for the pathogenesis of Parkinson's disease. (From Refs. [26] and [27].) In PARK1, mutated α-synuclein appears to aggregate more readily in transgenic models. The protofibrils appear to inhibit the proteasomal degradation of proteins (site 2). PARK4 may induce neurodegeneration by a simple gene dosage effect (site 1). Mutations in UCH-L1 may interfere with polyubiquitination of protein in the cell, or may cause aggregation of the UCH-L1 itself. The proteosomal system and its relevance for autosomal recessive forms of parkinsonism (e.g., due to parkin mutations) are outside the scope of this article.

A53T mutant. In the case of the α-synuclein triplication, simple overexpression of the protein may be responsible for accumulation and neurodegeneration. Overexpression of human wild-type α-synuclein in mice produces selective decrements in DA nerve terminals in the striatum. Oxidative ligation of dopamine to α-synuclein leads to the accumulation of the α-synuclein protofibril, which may explain the relative selectivity of neurodegeneration in the dopaminergic system even though α-synuclein is widely expressed through the brain. In PARK5, the reduced catalytic activity of UCH-L1 may affect the cleavage and turnover of the protein substrate, leading to aggregation of substrate and, as a seed, of other aggregation-prone abundant proteins. Alternatively, the I93M substitution may render UCH-L1 itself prone to aggregation.[20]

CONCLUSION

Mutations in and triplication of α-synuclein, a ubiquitous synaptic protein and major component of Lewy bodies, have been found in autosomal dominant parkinsonism closely resembling sporadic PD clinically and neuropathologically. Abnormal processing and aggregation of this protein are now center stage in the pathogenesis of PD. Other loci indicate that PD, like historical concepts of fever, is not a single disorder, but several (Table 1). The study of rare mutations in individual families has shifted attention to the causal influence of genes. Ultimately, genetic studies will provide insights into the treatment and prevention of this common neurodegeneration.

Parvovirus B19

Timm C. Harder
Landeslabor Schleswig-Holstein, Neumuenster, Germany

Peter Rautenberg
University Clinics Schleswig-Holstein, Campus Kiel, Kiel, Germany

INTRODUCTION

Clinical manifestations of parvovirus B19 infections vary with the immunological and hematological status of the patient. In healthy children and adults, parvovirus B19 causes a self-limiting anemia, whereas in individuals with chronic hemolytic anemia and in immunocompromised patients, it can exacerbate an already existing anemia. Infection of the fetus may result in fetal loss or nonimmune *hydrops fetalis*. Recently, B19 has been implicated in other nonhematological disorders.

TYPE OF PATHOGEN

The *Erythrovirus* genus of the Parvoviridae family embraces the human parvovirus B19 as its type species as well as several simian parvovirus species, all of which reveal a narrow host range and replicate in erythroid progenitor cells. Parvoviruses are nonenveloped icosahedric particles that are 18–26 nm in diameter.

MOLECULAR CHARACTERIZATION

Genome Structure

The 5594-nucleotide, single-stranded DNA genome of parvovirus B19 is flanked by identical palindromic inverted terminal repeats of 382 nucleotides at each end of the genome, which are required in cis for replication. Transcription of two main open reading frames (ORFs), which encode one nonstructural protein (NS1) and two virion polypeptides (VP1 and VP2), is initiated at the *p6* promoter on the extreme left end of the plus-strand genome (Table 1). At least nine differentially spliced transcripts are generated.

Replication Cycle

Parvovirus B19 binds to cells expressing the glycosphingolipid blood group antigen P and requires the presence of $\alpha_5\beta_1$ integrin as a coreceptor for cell entry.[1] Replication is confined to cells that cycle through the S-phase. This restricts the spectrum of fully permissive host cells mainly to erythroid precursors in the bone marrow and liver of the fetus, and to erythroid progenitors postnatally. The viral transactivating NS1 protein regulates both transcription and replication. It also mediates a multistep cell cycle arrest, which is mainly confined to the G_1 phase.[2]

NS1 induces apoptosis, possibly because of its nucleoside–triphosphate binding motif, which triggers pathways also used by tumor necrosis factor-α (TNF-α).[3] Apoptosis contributes to loss of erythroid progenitors. Heterologous NS1 transactivation also involves IL-6 expression, which may have triggering effects on various inflammatory and autoimmune disorders associated with B19 infection.

The minor (VP1) and major (VP2) virion polypeptides are generated from alternatively spliced, partially overlapping mRNA, and autoassemble into virions of 60 capsomeres into which either a negative-stranded or a positive-stranded viral genome in approximately equal ratios is packaged. Replication is unusually efficient, producing virus loads of 10^8–10^{13} particles per milliliter of blood during an acute primary infection. The function of the phospholipase A2-like activity in the N-terminal region of VP1 (VP1u) remains unclear, although it may play a role in host cell entry, nuclear transport, and release of mature virions through phospholipase A2-specific secretory pathways. Interestingly, release of cellular phospholipase A2 is stimulated by IL-6, which in turn is upregulated by NS1 in infected cells.[4]

PREVALENCE

Transmission and Epidemiology

Parvovirus B19 is transmitted mainly by droplets via the respiratory route, but contaminated blood products and vertical transmission from mother to fetus represent further important pathways. The incubation period, as defined by the appearance of rashes, is 13–18 days and

signals the decline of infectivity. The infectious period starts 7 days before onset of rash. Clusters of acute primary infection occur in spring and early summer, with regional epidemics recurring every 4–5 years.[5]

The prevalence of B19-specific IgG antibodies increases with age to about 80% in the elderly. The annual seroconversion rate among susceptible women of childbearing age is estimated to be 1.5%, increasing about 10-fold during epidemics.[6] The prevalence of B19 DNA in blood donors varies between 1:200 and 1:35,000.[5] Current virucidal procedures applied to blood products fail to prevent the transmission of B19 virus. However, B19 loads of $<10^{4.0}$ genomes per milliliter of blood are regarded as unlikely to be contagious.[7]

Molecular Epidemiology

B19 viruses exhibit a remarkably high degree of sequence conservation, with a <2% variation between temporally and geographically widely separated isolates. However, the VP1u fragment has been reported to vary by up to 8% in chronically infected patients.[8] This might reflect evasion of neutralization as one mechanism of persistence because VP1u is predominantly involved in the formation of neutralization-relevant epitopes.

Recently, several genetically distinct B19-like parvovirus isolates were obtained from patients in France. Servant et al.[9] have proposed distinguishing between three genotypes [a classical B19-like (genotype 1), a Lali-like genotype (genotype 2), and a V9-like genotype (genotype 3)], which are equidistantly related to each other (differences of up to 14.2% across the whole genome) and were shown to cocirculate. Although the clinical spectrum of the newly discovered genotypes appears to resemble that of the B19 lineage, explicit differences in the *p6* promoter region (up to 25.2%) point toward distinct cell tropisms. The high ratio of synonymous vs. nonsynonymous mutations characterizing these genotypes indicates ancient separation and long-term evolution of these viruses.[9]

CLINICAL ASPECTS

Immunocompetent Hosts

Infection in immunocompetent hosts is asymptomatic in about 25% of cases. During childhood, the clinical hallmark of acute B19 infection is an exanthematous malar rash (''slapped cheeks''), also referred to as *erythema infectiosum* or fifth disease (to be distinguished from measles, rubella, scarlet fever, and varicella). In persons with normal hematopoiesis, parvovirus B19 induces a clinically unapparent self-limited transient anemia and reticulocytopenia.[10] Apoptotic death of nonpermissive megakaryocytes due to overexpression of NS1 protein[11] occasionally leads to thrombocytopenia, especially in children.

Symmetrical peripheral arthropathies affect about 60% and 30% of acutely infected adult females and males, respectively. In the majority of cases, clinical symptoms usually resolve within 4 weeks because of a classical Th1 response, which aids in clearing B19 virus through VP2-specific IgM and high-affinity neutralizing VP1-specific

IgG antibodies.[5] However, in some cases, B19 DNA can be detected in plasma—albeit only by the most sensitive amplification techniques—for months and even years after symptoms have receded.

Immunity following uncomplicated recovery is believed to ensure life-long protection. Whether B19 infection plays a causal, putatively HLA-restricted role in chronic joint diseases and various other vasculitic and neurological disorders is still being debated.[12] In individuals with elevated red blood cell turnover rates (e.g., sickle cell anemia, congenital erythrocyte membrane defects, and enzymopathies), parvovirus B19 infection may lead to a transient aplastic crisis (TAC) that can prove fatal if not treated promptly.[5,10]

Infection During Pregnancy

About 30–50% of women of child-bearing age are susceptible to B19 infection. The annual seroconversion rate in susceptible women of child-bearing age is estimated to be 1.5%. The risk of infection is highest in women with infected children in the household.[6,13]

The risk of fetal loss appears to be highest (9–15%) in mothers infected during the first 20 weeks of gestation. The highest risk of fetal loss coincides with the period of highest fetal hepatic hematopoietic activity in the second trimester.[13–15]

The risk of *hydrops fetalis* developing 2–6 weeks after primary maternal infection varies between 0% and 3%. About two thirds of all cases shows remission either spontaneously or after intrauterine transfusion of blood containing B19-neutralizing antibodies.[13,16] The presence of virions in the nuclei of cardiac myocytes suggests that, in addition to B19 fetal anemia, direct cardiac involvement plays a role in the pathogenesis of B19-induced *hydrops fetalis*.[12]

Cardiac Manifestations

Cardiac myocytes are fully B19-permissive only in the fetus. However, B19 DNA has also been detected in P-antigen-bearing endothelial cells and myocytes of the heart in patients with myocarditis or dilated cardiomyopathy who otherwise have no signs of viremic B19 infection.[17–19]

Infection in Immunodeficient Patients

Life-threatening pure red cell aplasia (PRCA) is observed in patients who are unable to mount appropriate titers of neutralizing antibodies against B19 because of severe congenital or acquired immunodeficiencies. In most cases, a chronic persisting course, which demands therapeutic intervention, develops.[10] Recent findings indicate an increased risk of kidney and heart allograft rejection in transplant patients with nonacute, low-level parvovirus B19 DNA (<1000 genomes per milliliter of blood), which is potentiated by simultaneous infection with the human cytomegalovirus.

DIAGNOSIS

Diagnostic measures depend on the immune status of the patient and the clinical picture. As a rule, detection and staging of B19 infection are best achieved by combined

Table 2 Methods for detection of parvovirus B19 DNA in clinical material

Method	Indication	Sensitivity/detection limit[a]	Reference
DNA hybridization	Large-scale quantitative screening	ca. 10^6 (1 pg)	[23]
In situ hybridization	Noncanonical symptoms (e.g., myocarditis)	Single cells	[12]
Single-round PCR (agarose gel, ethidium bromide)	Initial individual diagnosis, screening	10^5	[24]
Single-round PCR-EIA (DIG-labeled or DNP-labeled probes)	Large-scale screening (plasma pools, factor concentrates)	1.6×10^3 (colorimetric); 6×10^2 (chemoluminometric)	[7,25]
Nested multiplex PCR (agarose gel, ethidium bromide)	Differential diagnosis of exanthematic viral infections	ca. 10^2	[26]
Quantitative real-time PCR (TaqMan and LightCycler, internal standard)	Initial individual diagnosis of chronic/relapsing infections; follow-up studies, therapeutic guidance; contagiosity estimates	10^2–10^9(linear quantification range)	[21,27]

[a]All values represent genome equivalents per milliliter (gEq/mL); 0.65 gEq equals approximately 1 IU (WHO standard).

testing for B19-specific IgM (and IgG) and DNA in serum.[20] Various commercially available formats for antibody detection are available, all based on recombinant VP1/VP2 proteins. Elaborate qualitative and quantitative DNA amplification techniques for detection of B19 DNA abound (Table 2). However, being tailored to detection of B19 genotype 1, they might require adaptation to the newly discovered genotypes 2 and 3. Quantification of B19 DNA, now based on a World Health Organization (WHO) standard, is appropriate to guide therapeutic planning and to assess the contagiosity of pooled plasma and other blood products. In situ detection of B19 DNA is indicated if noncanonical forms of B19-associated disorders, such as myocarditis and chronic joint disorders, are suspected.[12]

MANAGEMENT

Treatment Options

Virus-neutralizing antibodies contribute to clearance of B19 virus in both acute and persistent infections, and are currently the only safe treatment option for TAC and PRCA. In iatrogenically immunosuppressed patients with B19 infection, transient relaxation of the immunosuppressive regimen often enables virus clearance by the patient's invigorated immune system.[5,21]

Prevention and Control

No licensed vaccine for humans is available. Phase I clinical studies of recombinant baculovirus-expressed parvovirus B19 virus-like particle vaccines with an enriched content of VP1 have been promising.[22] Screening of blood products is advisable before use in high-risk patients.

RECOMBINANT B19 VECTORS

Recombinant B19 virus is highly efficient at transducing cells of the erythroid lineage. It is also capable of low-level transduction of nonerythroid P-antigen-bearing cells.

CONCLUSION

Parvovirus B19, which generally provokes an acute but mild, self-limiting disease in children, can cause life-threatening disorders and chronic infection in immunocompromised patients or patients with congenital hemolytic disorders. There is mounting evidence that B19 virus is an emerging pathogen for viral myocarditis and dilated cardiomyopathy. Currently available elaborate molecular B19 diagnostic techniques need to be modified to factor the sequence variation of the two recently discovered new human *Erythrovirus* genotypes. Quantification of the B19 virus load can help to guide therapeutic planning for immunocompromised patients and to facilitate the assessment of the contagiosity of B19-contaminated blood products.

Patent Aspects in Proteomics and Genomics

P

Hans Wilhelm Meyers
Patent Attorneys von Kreisler Selting Werner, Köln, Germany

INTRODUCTION

Without patent protection, no successful commercialization of a new technical entity can take place. In particular, this proves true in the highly competitive field of biotechnology. This contribution describes the current state of the patentability of issues in Genomics and Proteomics.

NATURE OF PATENTS

The basic principle underlying patent protection is simple: Only the patentee is allowed to use and practice the invention for commercial exploitation. The duration of a patent is generally 20 years from the date of application. A patent is limited to the territory of the state in which it was granted.

Contrary to widespread conventional wisdom, a patent does not grant the patentee a right to practice the invention, but only to exclude others from doing so. Statutory regulations may interfere with the patentee's freedom to practice his invention.

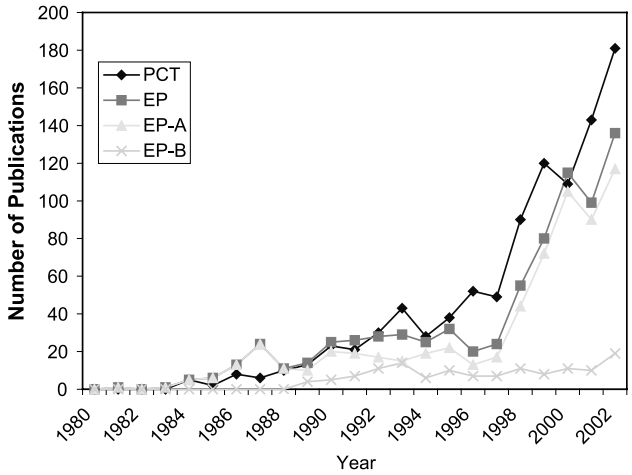
The patentee's so-called ''freedom-to-operate'' may be further restricted by the existence of other patents. It often happens that a first patentee holds a patent for a basic invention, e.g., the polymerase chain reaction (PCR) method, which is the subject of further research and development activities resulting in patents for improvements of the basic invention, e.g., diagnostic kits using PCR. If the patent for such an improvement is held by someone other than the first patentee, then the second patentee cannot practice the improvement without permission of the first patentee. Likewise, the first patentee cannot carry out the improvement without an arrangement with the second patentee.

SIGNIFICANCE OF PATENTING

Research results in the field of genomics and proteomics frequently have considerable relevance in medical or pharmaceutical applications. For example, a new drug has to cope with many obstacles before it is granted permission for use in the human setting. According to reliable estimates, the downstream process of developing a drug until it achieves regulatory approval costs about $500–800 million. Imitation of scientific and technical results in any field is legal, so long as no issues of unfair competition come up. The only possibility to protect, e.g., a new drug or an application of a known substance in the pharmaceutical field, is to obtain patent protection. In the absence of patent protection, competitors can adopt the results and commercialize the drug without incurring the expense of drug development costs.

A further issue is commercial exploitation of results of basic research, e.g., finding of a target such as a receptor or an enzyme having relevance in patho-physiology or potential application in diagnostics. Such entities are often discovered and validated by universities or nonprofit scientific institutes. Also, these institutions try to obtain return on investment and have to cooperate with large companies having the financial resources for screening ligands interacting with the target for drug development. It goes without saying that these institutions, in particular, need patent protection for their research results.

The relevance of patenting in the field of proteomics and genomics is illustrated by the following figure[a]:



The figure depicts the number of patent applications containing the keyword ''genomi'' starting 1980 until May 2003. PCT means patent application published as International Patent Application; EP-A means Patent applications published by the European Patent Office (EPO); EP-B refers to the number of published granted European Patents

[a]*View this art in color at www.dekker.com.*

DOI: 10.1081/E-EDGP 120020939

and EP is the sum of the foregoing. Patent applications are published 18 months after first filing (priority).

PATENTABILITY REQUIREMENTS: NOVELTY, INVENTIVE STEP, INDUSTRIAL APPLICABILITY

Novelty

Novelty is a patentability essential which is well-defined in the patent laws of most of the member states of the World Trade Organization. Nothing can be patented that is not new. Although novelty is basic to patentability, different concepts of novelty exist throughout the different patent systems worldwide. The most straightforward is that of ''absolute novelty,'' which is, e.g., applied by the European Patent Convention (EPC) in Art. 54 EPC.

The definition of the state of the art given by the EPC is very broad. It is held to comprise everything made available to the public via written or oral description, by use, or in any other way, before the date of filing of the European patent application (or the priority application). The state of the art, according to EPC, is not locally restricted. When examining the claims of the patent application with regard to their novelty, the European Patent Office will consider a prior publication of the invention irrespective of whether the publication took place in one of the member states of the EPC or elsewhere.

In contrast to the EPC, the statutory standard for novelty in the United States, according to 35 U.S.C. section 102, gives a negative definition of novelty and grants a grace period of one year, in which a publication of the invention by the inventors will not be considered relevant to novelty.

The different definitions of novelty throughout these important patent systems have very significant consequences. An invention may be novel in the United States, even if it lacks novelty in the terms defined by the EPC.

How Is Novelty Assessed by the Patent Authorities?

An invention is novel when its subject matter, as defined in the claims, was not disclosed prior to the first filing date of the invention. The claims are a listing of features defining the invention in certain categories and normally in generalized terms, which have to be supported by the description or specification. Patent categories include devices, substances, processes, methods of use, to name the most important ones. For example, if a publicly available reference discloses each and every feature of an invention, i.e., a claim, then the invention is not novel. The reference can be a publication in oral, written, and electronic (or any other) form.

However, if more than one reference is necessary to identify each and every feature of a claim, then the subject matter of the claim is novel.

Inventive Step

While novelty is a well-defined issue, the question of the presence of an inventive step (EPC terminology) is often more striking. When novelty has been acknowledged by an examiner, a patent will only be granted if the subject matter is also not obvious over prior art. Article 56 EPC reads as follows:

> An invention shall be considered as involving an inventive step if, having regard to the state of the art, it is not obvious to a person skilled in the art.

The respective U.S. regulation section 103 (a) reads as follows:

> (a) A patent may not be obtained though the invention is not identically disclosed or described as set forth in section 102 of this title, if the differences between the subject matter sought to be patented and the prior art are such that the subject matter as a whole would have been obvious at the time the invention was made to a person having ordinary skill in the art to which said subject matter pertains.

How Is Inventive Step Assessed by the Patent Authorities?

The references cited by an examining authority have to be assessed in view of the so-called ''person skilled in the art.'' The skilled person represents an individual who knows all references that have ever been published in any language, but who lacks the creativity in posing and solving objects or problems in a particular technical field. Also, a team of individuals can be addressed as ''person skilled in the art,'' particularly in borderline technical fields.

The question of inventive step is more complicated and ambiguous than the question of novelty. Inventive step considers several issues—e.g., whether the invention uses well-known technologies; whether the invention solves a known problem, only in a different way, via techniques which are known as such or the level of the skill of the artisan.

Inventive step must be proved by the applicant in case the patent examiner or a third party in an opposing procedure raises the issue of lack of inventive step in the invention. An indication of inventive step is an unexpected result proven by comparative examples or improved properties of a new substance. Thus, if a new peptide or

protein shows improved properties over the wild-type protein, an inventive step can be acknowledged.

Requirements of Enablement, Written Description, and Utility

Apart from the essentials of ''novelty'' and ''nonobviousness,'' the invention has to be described in such a manner as to comply with both the written description and the enablement requirement. These requirements are contained in 35 U.S.C. section 112. Similar regulations also exist in other patent laws, as exemplified by the Articles 83 and 84 EPC.

An underlying rationale of the patent system is to grant a patentee an exclusive right for commercialization of an invention, provided, however, that the invention is sufficiently disclosed. Consequently, the purpose of the enablement requirement is to assure that other parties skilled in the art can practice the full scope of the claimed invention without undue experimentation. Claims are typically drafted in broad terms to prevent competitors from circumventing a patented invention. The claims must be sufficiently supported by the patent specification, i.e., claim breadth of the claims and the disclosure (enablement) in the description of the invention should correspond with each other. Otherwise, obstacles in the patent prosecution process will become inevitable and even if a patent is finally issued, it could still be ruled invalid while in the process of being enforced.

To satisfy the written-description requirement, the invention shall be described in sufficient detail so that a person of ordinary skill in the art would recognize that the inventor was in possession of the claimed invention at the time of filing. The requirements of written description and enablement are distinct from each other. This implies that although a patent specification may sufficiently enable a person skilled in the art to practice the invention, it may still be ruled to have failed to comply with the written-description requirement. The case ''The Regents of the University of California vs. Eli Lilly and Co.''[1] provides an example for the significance of the written-disclosure requirement. The disclosure contained the nucleotide sequence of a rat proinsulin cDNA and a general method for obtaining the corresponding human cDNA. The patent claims were broad in scope, covering not only the rat cDNA but also the vertebrate, mammalian, and human cDNA. The latter ones were held invalid because the specification did not provide an adequate written description. In summary, the general tenor in U.S. decisions is that it is not sufficient for obtaining sound patent protection to merely disclose a wish or a plan for obtaining the claimed invention.

In addition, the patent systems typically require that the claimed invention must have a utility (as set forth in 35 U.S.C. section 101) or must be susceptible of industrial application (as set forth in Art. 57 EPC). With regard to genetic patenting, the European Patent Convention explicitly states the industrial application (e.g., function) of a sequence or a partial sequence of a gene must be disclosed in the patent application (see Rule 23e (3) EPC).

WHAT CAN BE LICENSED?

If a result of research in proteomics or genomics shall be licensed, in general a license agreement is concluded. The subject of a license agreement can be know-how or subject matter of an Intellectual Property Right (IPR), in most cases a patent or patent application. Therefore, it is recommended to file a patent application before starting negotiations.

Typically, targets, substances having physiological effects, methods, and technologies, can be subjects of license agreements. Whereas substances having physiological effects are candidates for drug development, so that classical license agreements can be concluded, agreements concerning targets often contain the so-called ''reach-through'' clauses. In the classical case, a license is granted to the drug developing party, which in turn pays royalties and/or down-payments to the licensor. Royalties are based on turnover figures achieved by commercialization of the drug. Targets are research tools for discovering drugs interfering with the target. A particular license agreement can contain clauses obliging the licensee to pay a royalty amount based on turnover figures related to any drug discovered and developed by using the target.

WHAT CAN BE PATENTED IN THE FIELD OF GENOMICS AND PROTEOMICS?

At present, there is no general patent system available under which regime a patent with worldwide extension can be achieved. However, the World Trade Organization (WTO) has issued an international regulation concerning intellectual property rights binding WTO member sates. This regulation is named Agreement On Trade-Related Intellectual Property Rights (TRIPS). TRIPS Article 27 says ''[. . .] patents shall be available for any inventions, whether products or processes, in all fields of technology, provided that they are new, involve an inventive step and are capable of industrial application.''

However, the second and third paragraphs relativize this very general statement by stating

> Members may exclude from patentability inventions, the prevention within their territory of the commercial exploitation of which is necessary to protect order in the public or morality, including to protect human, animal or plant life or health or to avoid serious prejudice to the

> environment, provided that such exclusion is not made merely because the exploitation is prohibited by their law. Members may also exclude from patentability: (a) diagnostic, therapeutic and surgical methods for the treatment of humans or animals; (b) plants and animals other than microorganisms, and essentially biological processes for the production of plants or animals other than nonbiological and microbiological processes. However, Members shall provide for the protection of plant varieties either by patents or by an effective sui generis system or by any combination thereof.

Therefore there are still significant differences in the patent systems of the world, although the TRIPS agreement helps to harmonize the different systems in the future by founding a basis to start with. However, the field of biotechnology, besides the software industry, is still the area most affected by any exceptions of the broad definition according to TRIPS Art 27 (1). The statutes of the European Patent Convention (EPC) contain exclusions from patentability as mentioned in TRIPS Art. 27 (2) and (3). The European Patent Office (EPO) grants patents which are, after grant, administered by the contracting states chosen by the patent applicant. The European Commission issued a Directive 98/44, which was adopted by the European Patent Organization.

One of the most significant feature of the Directive refers to the provisions pertaining to the patentability of biological material. Among other things, it was regulated that an isolated nucleic acid of human origin, an isolated gene of human origin, an isolated protein of human origin, parts of the human body in isolated state, cells of human origin, as well as compartments of cells of human origin could be patented as long as these subject matters were fulfilling all other patentability requirements such as novelty, inventive step, industrial applicability, and sufficiency of disclosure. The requirement of sufficient disclosure of a protein or nucleic acid or gene is only fulfilled if a function of these entities is disclosed. The Directive also regulates that the human body, at various stages of its development, including germ cells, is not patentable. This includes a sequence or a partial sequence of a gene if no function is disclosed. The Directive identifies four classes of inventions to be unpatentable. These include, but are not limited to, processes for cloning human beings; processes for modifying the germ line genetic identity of human beings; use of human embryos for industrial or commercial purposes and processes for modifying the genetic identity of animals which are likely to cause them suffering without any substantial medical benefit to man or animal (this description was adopted from the oncomouse decision).

Before the Directive was issued, the EPO granted patents on transgenic animals following the decision of the Board of Appeals T 19/90 (Oncomouse Decision).[2] Also, transgenic plants are patentable as long as the respective patent does not encompass a plant variety. The Directive has not yet been transformed into national law by eight EU member states, e.g., Germany, Italy, The Netherlands.

The situation in the United States was not as difficult because higher life forms were regarded as patentable. The application concerning the Harvard Mouse issued to US Patent 4,736,866 on April 12, 1988. It issued without difficulty following the ''oyster'' case, Ex Parte Allen (Board of Appeals and Interference, April 3, 1997[3]), which held that polyploid oysters are nonnaturally occurring manufactures or compositions of matter, falling within the definition of invention. Furthermore, subject matter directed to plants and seeds are routinely allowed by the U.S. Patent and Trademark Office, and in general, higher life forms are considered patentable subject matter within the United States. Similarly, in Japan, higher life forms, both plant and animal, are considered allowable subject matter.

Although the patenting issues have widely been resolved as far as the granting proceedings are concerned, there is still an ongoing debate on ethical issues involved with patenting of living material or material derived from living material. Also, little is known-as of yet, how civil courts will handle patent infringement lawsuits concerning biological inventions.

CONCLUSION

Today, most of the basic problems involved in patenting in the field of Genomics and Proteomics are resolved. In all significant industrial regions, a reasonable patent protection is available for inventions concerning substances, compositions of matter, processes, and methods, both in the pharmaceutical as well as the diagnostic industries.

DISCLAIMER

The purpose of this article is to highlight the importance and to explain the general issues of patenting in biotechnology, in particular Genomics and Proteomics. It does not contain definite legal or patent advice and should not be used as a substitute for the advice of your lawyer or patent attorney.

PCR and RT-PCR Analysis in Archival Postmortem Tissues

INTRODUCTION

Most tissues from biopsy, surgery, or autopsy origin are usually fixed and paraffin embedded as a routine procedure in hospital departments of pathology. Tissue storage is a fundamental step in the usual clinical procedure for histopathological investigations. The traditional method of tissue preservation is the fixation of tissues, mostly in formalin, followed by paraffin wax embedding. In this way, biochemical, molecular, and structural integrity is ensured also for future retrospective analyses, because there is no further chemical degradation in paraffin. Usually, these tissues have been stored in the archives of pathology departments for decades. Among the archive tissues, postmortem tissues obtained from autopsy represent an important resource for the study of rare diseases, neuropathology, or molecular epidemiology. For these studies in fact, the analysis of both pathological and normal tissues as control is fundamental. The protocols of tissue storage normally suggest the fixation step in buffered formaldehyde solution in the dark for about 24 hr before paraffin wax embedding. This procedure is habitually maintained for biopsy and surgical samples, but autopsy tissues are usually fixed for longer periods of time. Various factors, such as postmortem interval or the type of fixative and the fixation time, could affect the quality and utilization of nucleic acids from archive tissues. Extensive degradation of nucleic acids is often found in archival tissues older than 20 years because nonbuffered formaldehyde solution was frequently used in the past. The most widely used fixative is neutral formalin, but for special purposes other fixatives may be used in histopathology laboratories. Of these, Bouin's solution and acetone can compromise the PCR amplification efficiency.[1] Longer fixation times could also induce unsuccessful PCR amplification due to enhanced degradation of nucleic acids. Of the parameters involved in the degradation of nucleic acids, the postmortem interval is the most important factor affecting the successful extraction of high-molecular weight DNA from frozen autopsy tissues.[2] The delay between death and tissue collection is referred to as the postmortem interval (PMI). Commonly, a cadaver is refrigerated at 2–4°C within a few hours of death; an autopsy may not be performed for legal reasons before 4 to 36 hr or more have passed, depending on different rules and conditions in use.[2]

Generally, the amount of degraded DNA in frozen autopsy tissues is correlated directly with the duration of the postmortem period.[3] Otherwise, in the same type of tissue PMI does not appear to affect significantly the recovery of total RNA or mRNA.[2] Even if formalin fixation compromises the quality and intactness of nucleic acids, it has already been demonstrated that it is possible to recover and analyze DNA[4] and RNA[5,6] from formalin-fixed and paraffin-embedded postmortem tissues. The use of PCR-based techniques does not require intact nucleic acids for amplification, therefore even an increased degradation may not affect the outcome of the analysis. In our experience, in postmortem tissues, fixed in nonbuffered formalin, DNA fragments longer than 90 bp cannot be amplified. As a consequence of DNA degradation, only very short sequences could be analyzed in postmortem tissues. However, for longer fragment analysis it is possible to perform a partial restoration and reconstruction of DNA length.[4,7] With this procedure it is possible to fill in the DNA breaks and amplify around 300 bp of DNA sequence from autopsy tissues.

As already reported[5,8] it is also possible to extract and analyze RNA from formalin-fixed and paraffin-embedded tissues from autopsy tissues.[5,6] Usually, in routinely treated formalin-fixed material the available fragments of RNA range between 100 and 200 bp. Analysis of RNA obtained from postmortem, formalin-fixed, paraffin-embedded tissues showed higher levels of degradation resulting in an amplification length of not more than 100 bp.

NUCLEIC ACIDS EXTRACTION

The fixation of tissue samples in formalin leads to extensive cross-linking of all tissue components. As a result, the nucleic acids isolated from these specimens are highly fragmented. The extent of fragmentation depends on the tissue type and the condition of fixation. This fragmentation is enhanced in postmortem paraffin-embedded tissues. No modifications of the usual protocol of nucleic acid extraction are needed using postmortem archive tissues. For any type of formalin-fixed, paraffin-embedded tissue there is the possibility to easily isolate single cells or subpopulations of cells by microdissection. Methods for the extraction of DNA[4,9] and RNA[5,8] from archive tissues propose the use of single or multiple 6–8-μm histological sections from the paraffin blocks. The first step in the extraction protocols from paraffin-embedded tissues is the elimination of paraffin. Paraffin is soluble in organic solvents such as xylene. After the deparaffinization, tissues are then washed with ethanol several times to completely eliminate residual xylene, as even small amounts could block the activity of the enzymes used in the next steps.[8] To obtain DNA and RNA for further analysis it is necessary to digest the tissue sections by proteinase K or other proteolytic enzymes to remove the cross-linked proteins. The difference in the protocol for the isolation of RNA and DNA from archival autopsy tissues is the composition of the lysis buffer and proteinase K concentration as previously reported.[4,5,8,9] To purify nucleic acids from proteinase K and proteolysis residues, an extraction with phenol/chloroform is needed, for DNA we use phenol–Tris and for RNA phenol–H_2O. Final samples are obtained by alcohol precipitation using glycogen as a carrier.[4,5,8,9] The concentration of nucleic acids is measured at the absorbance of 260 nm.

RESTORATION TREATMENT AND DNA ANALYSIS

It is possible to amplify even longer DNA sequences of about 300 bp from postmortem formalin-fixed and paraffin-embedded tissues utilizing a simple restoration treatment. The restoration method is based on the fact that DNA degradation is connected with random single-strand breaks. To obtain longer stretches of DNA, a pre-PCR treatment is performed. It consists of a DNA rehybridization step in a specific buffer at 55°C[4] followed by a DNA polymerization at 72°C for 20 min. This single-cycle PCR at the elongation temperature (72°C) restores the nicks in the rehybridized DNA using the other corresponding strand as a template.[4] Because of the random position of the nicks, the fragment reconstruction gives sequences long enough for successive PCR analysis. The treated samples are then normally stored at −20°C until specific PCR analyses. To obtain a PCR amplification with restored DNA in postmortem archive tissues, a denaturation step at 95°C is required before PCR amplification, because in the restoration itself the double-stranded DNA is strongly linked with a more stable secondary structure.[4] As reported in Fig. 1A, the PCR amplification in untreated necropsy tissues was unsuccessful, but in reconstructed and denaturated ones the amplification fragments are evident. The fact that the PCR amplification was obtained in formalin-fixed, paraffin-embedded biopsy specimens (Table 1), even without the restoration procedure, confirms that more extensive DNA degradation is confined to postmortem tissues. This simple restoration/denaturation procedure can overcome the problem of DNA degradation in the analysis of necropsy archive tissue. This could eventually result in better suitability of archival DNA for genetic investigations and would overcome the limit for longer-size PCR fragments for specific needs.

Table 1 Polymerase chain reaction amplification of DNA of autopsy and biopsy origin

Amplicon	Restored and denatured autopsy DNA	No restored biopsy DNA
ApoE[a] (287 bp)	4/4	4/4
TTR1[b] (291 bp)	6/9	9/9
TTR1 (339 bp)	1/9	9/9

[a]Apolipoprotein E.
[b]Human prealbumin gene.

Table 2 Reverse transcriptase polymerase chain reaction amplification of β-actin RNA of autopsy and biopsy origin

β Actin amplicon size	Autopsy RNA	Biopsy RNA
77 bp	4/4	4/4
100 bp	4/4	4/4
120 bp	1/4	4/4
170 bp	0/4	4/4

RNA ANALYSIS

Reverse transcriptase polymerase chain reaction (RT-PCR) has become one of the most widely applied techniques in biomedical research. The ease with which the technique permits a specific mRNA detection and quantification has been a major asset in the molecular investigation of disease pathogenesis. Disease imbalances in the expression of specific mRNAs can be sensitively and quantitatively determined by RT-PCR. Reverse transcriptase polymerase chain reaction also offers some opportunities in diagnostic methods such as the detection of RNA viruses. Different studies have shown the possibility of analyzing RNA extracted from autopsy formalin-fixed, paraffin-embedded tissues[5,10] by RT-PCR analysis. In most of the protocols RNA is firstly transcribed in cDNA and subsequently amplified by PCR. The major concern related to archive postmortem tissues is the enhanced degradation of RNA. Usually, in routinely treated formalin-fixed material of biopsy or surgery origin the amenable fragments of RNA range between 100 and 200 bp. Analysis of RNA obtained from postmortem formalin-fixed, paraffin-embedded tissues showed a higher level of degradation (Table 2). As reported in Fig. 2, amplicons that had been successfully amplified were not longer than 75–100 bp (Fig. 2A and B). In fact, for fragments nearly 150 bp long, the RNA amplification was obtained only in a few samples (Fig. 2C and D). To obtain a successful RT-PCR analysis and maximize the amplification of degraded RNA it is better to amplify short sequences, of about 70–100 bp. It is also possible to perform quantitative RT-PCR analysis using RNAs obtained from necropsy formalin-fixed and paraffin-embedded tissues. Several variables need to be controlled in gene-expression analysis, such as the amount of starting material, enzymatic efficiencies, and differences between tissues. The quantification of RNA from postmortem formalin-fixed, paraffin-embedded tissues presents specific problems that cannot be resolved with a competitive analysis because of RNA degradation in the preserved samples. Because the degradation is presumably random, the quantification in these tissues cannot be resolved using competitive analysis with internal standards. The comparison of different template preparations (standard vs. pathological template) introduces errors. The sample fragmentation due to fixation severely distorts the absolute quantification. In relative quantification the level of the mRNA of interest is related to the amounts of housekeeping genes; these are supposed to be constant both in the tissue and in the pathological situation of interest. As a result, relative quantification is preferred and strongly recommended in postmortem archival tissues. Performing a relative calculation eliminates all distortions due to fixation artefacts or sample impurity. Accurate normalization of gene-expression levels is an absolute prerequisite for reliable results. The purpose of normalization is to remove the sampling differences in order to identify real gene-specific variation. For RT-PCR there is a

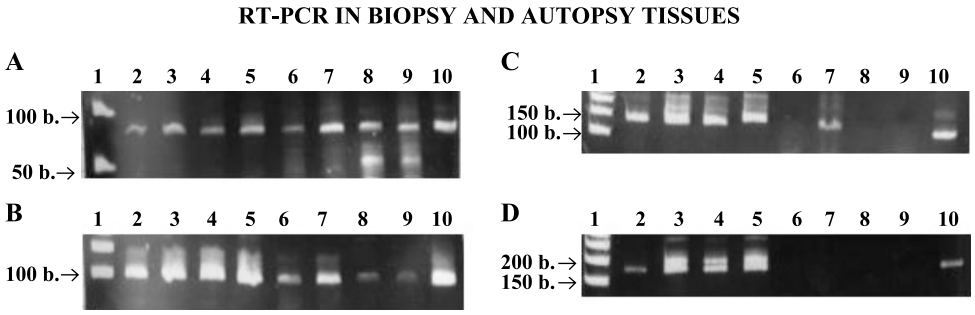

Fig. 2 Reverse transcriptase polymerase chain reaction products in formalin-fixed, paraffin-embedded tissues of autopsy and biopsy origin for β-actin gene. Size marker (lane1), biopsy samples (lanes 2–5), autopsy samples (lanes 6–9), positive control (RT-PCR analysis in RNA obtained from HepG2 cells) (lane 10). (B) RT-PCR analysis for β-actin gene (100 bp). Size marker (lane1), biopsy samples (lanes 2–5), autopsy samples (lanes 6–9), positive (lane 10). (C) RT-PCR analysis for β-actin gene (120 bp). Size marker (lane1), biopsy samples (lanes 2–5), autopsy samples (lanes 6–9), positive control (lane 10). (D) RT-PCR analysis for β-actin gene (170 bp). Size marker (lane1), biopsy samples (lanes 2–5), autopsy samples (lanes 6–9), positive control (lane 10).

general consensus on using a single control gene for normalization purposes. In more than 90% of the cases reported in the literature,[11] GAPDH, β-actin, 18S, and 28S rRNA were used as a single control gene. Different authors have already reported that housekeeping gene expression can vary considerably, so the validity of the conclusions is highly dependent on the control used.[11] Vandesompele et al. strongly recommend the use of at least three control genes for calculating the normalization factor in order to remove nonspecific variation of target genes. Nowadays, there are several analytical approaches to measure the amount of RT-PCR product in archival tissues, including real-time RT-PCR,[12] membrane hybridization,[13,14] capillary electrophoresis,[14,15] PCR-ELISA.[16] All of them are suitable for relative quantification in paraffin-embedded tissues of necropsy origin reducing the amplicon size to less than 100 bp.

CONCLUSION

Formalin-fixed and paraffin-embedded tissues of autopsy origin are an important source for molecular analysis especially in rare diseases, neuropathology, and molecular epidemiology studies because of the availability of either normal or pathological specimens. The major difficulty in using these tissues is the extensive degradation of nucleic acids. The development of a simple treatment for DNA restoration and quantitative RT-PCR opens the autopsy archives for molecular biology analysis. The possibility of performing molecular genetic analysis in autopsy tissues will improve diagnostic procedures and will enable a large number of research studies on various diseases. Retrospective analysis of these archival tissues would provide the means to correlate molecular findings with the response to treatment and clinical outcome. In addition, these findings will guide future prospective studies in analyzing native or freshly frozen tissues.

PCR Chemiluminescent Immunoassay (PCR-CLEIA)

P

Aldo Roda

Monica Musiani
Marialuisa Zerbini
University of Bologna, Bologna, Italy

INTRODUCTION

Polymerase chain reaction (PCR) is a well-established, powerful diagnostic tool that provides rapid, highly sensitive, and specific DNA or RNA detection. The demand for equally rapid and sensitive methods to achieve detection and semiquantitative information on PCR products has brought about the coupling of PCR to enzyme-linked immunosorbent assay (ELISA). These assays involve hybridization of amplicon with specific oligonucleotide probes (thus enhancing the specificity of the method) and detection of the hybridization product with suitable enzyme-labeled antibodies. A further advance of the technique involves the use of chemiluminescence as detection system, yielding PCR chemiluminescent enzyme immunoassay (PCR-CLEIA). This further improves the rapidity and sensitivity of the technique and lets us envisage future developments toward miniaturized and automated high-throughput methods.

In this paper, the principle of the method, applications, and future trends of PCR-CLEIA are presented.

DISCUSSION

PCR, with its extraordinary sensitivity, is the method of choice for the detection of nucleic acids present in very low concentrations in biological specimens. Diagnostic applications of this technique mainly concern analysis of gene amplification, expression in tumors, and expression of etiological agents in human infections. Assays that combine PCR amplification and the immunological chemiluminescent detection of PCR products (PCR-CLEIA) provide high specificity, sensitivity, objectivity, and rapidity. In particular, the use of chemiluminescence as a detection system provides superior assay performance. Chemiluminescence is a versatile analytical tool that offers several advantages over other detection principles, including high detectability, high selectivity, wide dynamic range, and rapidity.[1,2] Thanks to the high sensitivity of chemiluminescence detection, very small volumes of reagents and samples can be used, which results in lower assay costs and the possibility of exploiting high-density formats such as 384-well and 1536-well microtiter plates. This last feature, combined with rapidity, renders chemiluminescence detection suitable for the development of high-throughput methods.

PCR-CLEIA can be very useful in understanding the progression of the disease, monitoring the success of therapy, and evaluating the potential risks of transmission of pathogens. Moreover, PCR-CLEIA can be very useful in the diagnosis of infectious diseases that can persist in the presence of a small number of infectious agents, and in distinguishing low-level innocuous infections from those which may be of clinical relevance.

PCR-CLEIA is based on the following:

1. Direct incorporation of a labeled nucleotide during PCR amplification reaction [mainly by incorporation of digoxigenin (Dig)-labeled dUTP].
2. Hybridization of labeled amplified products with biotin-labeled probes specific for the target (alternatively, the PCR product can be biotin-labeled by performing the amplification reaction in the presence of a biotin-labeled dUTP or primer; in this case, hybridization will be performed with either a Dig-labeled or an enzyme-labeled probe).
3. Capture of hybridized amplicons onto streptavidin-coated white or black microtiter plates (alternatively, the probe can be immobilized onto the solid phase, then the labeled amplicon can be added and hybridization can be performed directly into the wells of the microtiter plate).
4. Detection of immobilized hybridized amplicons by anti-Dig antibodies conjugated to peroxidase or alkaline phosphatase (this step is not necessary in case an enzyme-labeled probe is used).

DOI: 10.1081/E-EDGP 120020691

5. Addition of chemiluminescent substrates with high sensitivity and wide dynamic range.
6. Measurement of chemiluminescent signals by microplate luminometers or imaging systems and correlation to amounts of amplified products.

A schematic representation of the principle of the method is shown in Fig. 1.

With PCR-CLEIA, semiquantitative information on target DNA or RNA is obtained. Moreover, results evaluation is objective, whereas conventional PCR requires a more subjective interpretation; at low DNA concentration, interpretation of results may be doubtful. Unlike conventional PCR, PCR-CLEIA is automatable, able to process simultaneously a large number of samples in reasonable time, and can be applied to DNA or RNA quantification. The chemiluminescent substrate used in amplicon detection permits a large-scale range of measurements compared with colorimetric or fluorometric detection.

To develop a standardized PCR-CLEIA, different steps have to be optimized.

Optimization of PCR-CLEIA Method

Streptavidin-coated microtiter plates able to efficiently adsorb biotinylated nucleic acids are commercially available. To exclude high background luminescence emitted by plate formats, preliminary measurement of phosphorescence emission intensity after exposure to ambient light of the microtiter plate can be performed.

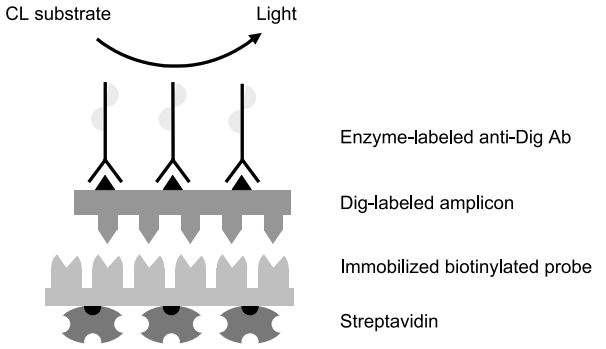

Fig. 1 Microtiter plate hybridization and immunodetection scheme. Schematic representation of the microtiter plate immunochemiluminescent hybridization assay of PCR products: the Dig-labeled PCR product is hybridized with biotin-labeled specific oligoprobes; hybridized amplicons are captured onto streptavidin-coated microtiter plates, then detected by means of anti-Dig antibodies and chemiluminescent detection. CL, chemiluminescent; Dig, digoxigenin; Ab, antibody.

The optimal concentration of target-specific probe has to be determined. PCR products, obtained from serial dilutions of the original sample, have to be hybridized with different concentrations of probe and, subsequently, captured onto the microtiter plate. The chemiluminescent signal intensity from each well is then measured. The oligoprobe concentration that allows to obtain the calibration curve with the lowest limit of detection and the highest sensitivity (slope of the curve) has to be chosen. Usually, no further improvement is obtained by increasing the oligoprobe concentration.

Direct incorporation of a labeled nucleotide during amplification reaction is preferred because it increases the sensitivity of the assay with respect to extension labeling primers.

To overcome differences in DNA or RNA extraction and amplification efficiencies between independent samples, results can be normalized based on a suitable housekeeping gene control.

To enhance the reproducibility of the method, quality control should be performed by including a minimum of two negative controls and two positive controls in each assay.

PCR-CLEIA provides semiquantitative information on the target sequence. However, more accurate quantitative information can be obtained by adding an internal standard consisting of a competitor sequence of target DNA, which can be internally mutagenized. The coamplification of target and internal standard competitor sequences, using the same set of primers and the same physical–chemical parameters, allows the same efficiency of amplification and permits the construction of competitive titration curves for the quantitation of the target DNA.

Limit of Detection

Limits of detection of the PCR-CLEIA methods have to be determined using different concentrations of target nucleic acids. The products of amplification, once hybridized with the immobilized specific probes, are analyzed and the limit of detection for each amplicon is determined as the chemiluminescent signal significantly above cutoff. The criteria for defining the cutoff value and the positivity of samples have to be determined for each protocol based on the expected variability of the results.

Specificity

Serial dilutions of samples containing known numbers of copies of target genomes and negative controls (unrelated genomes) have to be PCR-amplified and hybridized with

target-specific probes. A positive signal has to be detected when target genome PCR amplicons are hybridized with the specific probes. A signal within background range (negative signal) has to be detected when PCR amplicons from unrelated genomes are set for hybridization with target-specific probes.

Precision

To investigate the reproducibility of the PCR-CLEIA method, at least two positive and two negative reference samples have to be amplified, and then assayed with type-specific immobilized oligoprobes in triplicate in three independent assays. Intraassay coefficient of variation (CV) lower than 5% and interassay CV lower than 10% are desirable.

Applications of PCR-CLEIA

PCR-CLEIA has been developed and applied to the detection of PCR-amplified enterotoxin A gene from *Clostridium perfringens* in artificially contaminated ground beef.[3] A biotinylated primer pair was designed for the amplification of a fragment of the *C. perfringens* enterotoxin A gene. PCR-amplified products were detected by hybridization ELISA protocols by applying a streptavidin capture step for the hybridized PCR products to an internal Dig-labeled probe using chemiluminescent detection with Lumiphos 530TM as substrate.

Quantification of circulating human cytomegalovirus (HCMV) in the plasma of severely leukopenic patients was also achieved by PCR-CLEIA through the detection of biotinylated PCR products of the HCMV UL50 region using HCMV-specific enzyme-labeled probes and automated chemiluminescence detection able to reveal 100 HCMV genomes per milliliter of plasma.[4]

A sensitive PCR-CLEIA assay was developed and applied to quantitative detection of enteroviruses in environmental samples.[5] Following reverse transcription (RT), viral cDNA was labeled with Dig-dUTP during the PCR amplification step. The labeled PCR products were then hybridized with enterovirus-specific biotinylated probe, captured in streptavidin-coated microtiter wells, and detected by an anti-Dig peroxidase conjugate using a chemiluminescent substrate and automated measurement. The assay was able to detect 0.01 plaque-forming units (PFU)/mL, proving 10–100 times more sensitive than colorimetric detection or dot blot hybridization.

PCR-CLEIA has proved to be a sensitive and versatile method for the analysis of human and murine cytokine mRNA expression. Indeed, Dufour et al.[6] were able to quantify mRNA for five porcine cytokines: interferon (IFN)-gamma, interleukin (IL)-2, IL-4, IL-10, and IL-18 on peripheral blood mononuclear cells. The main features of the methodology were: RT to obtain DNA sequences, PCR and detection of amplicons for all cytokines simultaneously, cytokine quantification in relation to a housekeeping gene control (glyceraldehyde-3-phosphate dehydrogenase, or GAPDH), detection of amplicons by ELISA using a chemiluminescent substrate with high sensitivity and wide dynamic range, and automation of the detection system for analysis of a large number of samples. This highly sensitive quantitative RT-PCR-CLEIA was able to detect 100–200 cytokines mRNA copies per 7.5×10^4 cells.

Immunochemiluminescent PCR detection of varicella zoster virus (VZV) DNA from the cerebrospinal fluid of 287 patients with meningitis, encephalitis, or other neurological diseases or symptoms improved considerably the detection rate of the VZV–PCR product compared with agarose gel electrophoresis.[7]

Hepatitis G virus (HGV) was recently identified as a new member of the family Flaviviridae, but its clinical significance is still unclear. Because no immunoassay for the diagnosis of HGV is available, to facilitate the detection of the viral genome by mass screening in the clinical laboratory, a sensitive RT-PCR assay with ELISA detection was developed. Sequences within the 5′-noncoding region and within the putative NS5a region were independently amplified in the presence of Dig-dUTP and were detected by hybridization with biotinylated capture probes bound to a streptavidin-coated matrix. Semiquantitative detection via chemiluminescence was performed in microtiter plate format machines. At least 8×10^2 genome equivalents per milliliter of serum using both primer pairs could be detected.[8]

The PCR-CLEIA methods described above were developed using the conventional 96-well microtiter plate format. However, other assay formats can be explored, thanks to the use of chemiluminescence detection, thus enhancing the performance of the method.

For example, using multianalyte assay formats and type-specific probes, PCR-CLEIA can also be easily applied to the simultaneous identification of the different genotypes of pathogens and can therefore be a valid tool to study the prevalence and potential pathogenicity of single genotypes. This is possible, thanks to the use of chemiluminescence as detection system, which allows both quantification and localization of the hybrids captured onto the plate.[9] In particular, to allow multianalyte binding assays, we have developed a novel microtiter plate containing 24 main wells, each divided into seven subwells, and we explored its clinical potential by developing a PCR-CLEIA for simultaneous detection and typing of seven high-oncogenic-risk human

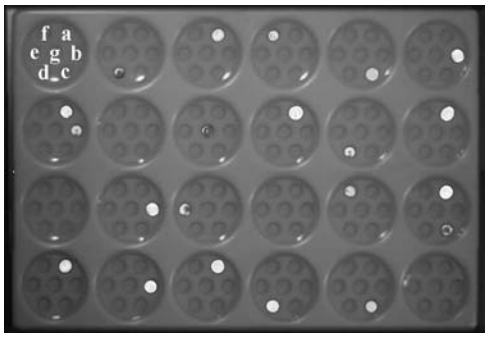

Fig. 2 Multititer plate figure. Analysis of clinical samples [$n=24$; 5 negative and 19 positive (five for HPV 16, three for HPV 18, two for HPV 31, three for HPV 33, one for HPV 35, two for HPV 45, one for HPV 58, one for HPV 16 and 18, and one for HPV 16 and 31)] performed on the novel microtiter plate format for multianalyte assays. Overlay image of the plate live image and the chemiluminescent signal. White letters indicate HPV genotypes detected in the subwells of each main well, based on the immobilized type-specific oligoprobe positions: (a) HPV 16; (b) HPV 18; (c) HPV 31; (d) HPV 33; (e) HPV 35; (f) HPV 45; (g) HPV 58.

papillomavirus (HPV) DNAs in one well. The assay is based on consensus PCR amplification of a conserved sequence of 30 HPV genital genotypes and on the typing of seven HPV DNA using the novel microtiter plate format. Thanks to the possibility of immobilizing seven type-specific capture oligoprobes in separate positions within the same well, typing was performed simultaneously by hybridization followed by a chemiluminescent immunoassay in one well and with one aliquot of the amplification reaction product. The chemiluminescence signal was imaged using an ultrasensitive charge-coupled device (CCD) camera and the light output intensity of each internal subwell was measured. The method proved to be specific and allowed the detection of 50 copies of genome for HPV 16, 18, 33, and 58, and 100 copies of genome for HPV 31, 35, and 45. Intraassay and interassay coefficients of variation of the method were 5.6% and 7.9%, respectively. This new assay format offers advantages in terms of multitest simplification and reductions in reagent volumes and analysis time. The same principle could be applied to the development of single-tube panels of tests for other pathological conditions.

Figure 2 shows the results obtained by analyzing 24 clinical samples with the multianalyte PCR-CLEIA assay, developed using the novel microtiter plate format. In particular, the overlay image of the plate live image and the chemiluminescent signal is shown.

Future trends for PCR-CLEIA mainly involve the development of miniaturized and high-throughput assay formats. With respect to this, we are now developing a PCR-CLEIA on 384-well microtiter plates, which allows to greatly increase the amount of information obtained in one assay. The use of smaller assay volumes allowed us to significantly reduce the amount of samples and reagents, thus providing savings. This format allows the screening of 20 samples for as many as 15 HPV genotypes per sample in one assay and with one 50-μL amplification product aliquot. Moreover, thanks to the high density of the format, it is possible to produce calibration curves for each genotype and to obtain semiquantitative information on the viral load of positive samples. It is worth noting that this assay format provides optimal performance only when chemiluminescence is used as a detection system, thanks to its high detectability even in low volumes.

The use of robotic samples and reagent handling systems will enhance the throughput of the assay and allow the operator to control the analytical steps and the reproducibility of the overall procedure.

CONCLUSION

PCR-CLEIA allows rapid, specific, and sensitive detection of target DNA or RNA sequences. The use of chemiluminescence as a detection system provides optimal performance in terms of sensitivity and linear range of the method, and increases rapidity with respect to conventional spectrophotometric detection. Furthermore, chemiluminescence allows the use of innovative assay formats, such as multianalyte or high-density microtiter plate, thus further enhancing throughput of the method.

Future trends of this technique involve the development of miniaturized and fully automated assays, in particular the use of microarray and microchip technologies, which allow the execution of numerous multianalyte assays in very small sample and reagent volumes and short times. However, at present, these systems are mostly applied to screening purposes because quantification accuracy of each microspot is hampered by the absence of physical separation and cross-talk phenomena.

Personalized Medicine

K. K. Jain
Jain PharmaBiotech, Basel, Switzerland

INTRODUCTION

Personalized medicine simply means the prescription of specific therapeutics best suited for an individual based on pharmacogenetic, pharmacogenomic, and pharmacoproteomic information. Several other terms are used to describe individualization of treatment and include tailored therapy, predictive medicine, and genomic medicine. Individualized treatments that have been used in medicine prior to the discussion of the concept of personalization include blood transfusion, tissue transplantation, and cell therapy. Tissue typing based on genetic markers is used to match the transplant to the recipient individual, and patient's own tumor cells are used in some cancer cell therapies. This concept has now been extended to pharmaceuticals. It is now recognized that patients with the same disease respond differently to drugs depending on their genetic constitution and other factors so that there are marked variations in efficacy and safety of the same drug for different patients.

BASICS OF PERSONALIZED MEDICINE

Important basics of personalized medicine are:[1]

- Pharmacogenetics is a term recognized in pharmacology in the pregenomic era and concerns the study of influence of genetic factors on action of drugs.
- Pharmacogenomics is the application of genomics to drug discovery and development. It involves the study of mechanism of action of the drugs on the cells as revealed by gene expression patterns.
- Pharmacoproteomics is the application of proteomics to drug discovery and development. Subtyping patients on the basis of protein analysis may help to match a particular target-based therapy to a particular marker in a subgroup of patients. Pharmacoproteomics may be considered an extension of genomics and partially overlaps pharmacogenomics.

There is a degree of overlap between pharmacogenetics and pharmacogenomics. The two terms are considered by some as similar but one must recognize the distinction as shown in Table 1.

MOLECULAR DIAGNOSTICS IN RELATION TO PERSONALIZED THERAPY

Several molecular diagnostic technologies[3] are used including single nucleotide polymorphism (SNP) genotyping, haplotyping, gene expression studies by biochip/microarrays, and proteomics. Integration of molecular diagnostics with therapeutics will be important.[4] Relation of molecular diagnostics to personalized medicine is shown in Fig. 1.

Single Nucleotide Polymorphisms

Potential uses of SNP markers include drug discovery and prediction of adverse effects of drugs. Single nucleotide polymorphisms have the following relation to an individual's disease and drug response:

- SNPs are linked to disease susceptibility.
- SNPs are linked to drug response.
- SNPs can be used as markers to segregate individuals with different levels of response to treatment (beneficial or adverse) in clinical settings.

Haplotypes

An alternative approach to SNP genotyping is haplotyping.[5] Gene-based haplotypes are composed of the nucleotides that occur at SNP positions on a single chromosome at the locus of a single gene. Haplotypes are the most precise markers possible for a given gene because they contain all the variations in a gene. Haplotyping is a way of characterizing combinations of SNPs that might influence response and is considered to be a more accurate measure of phenotypic variation. However, SNP-based tests have greater power when the number of causative SNPs (a subset of the total set of SNPs) is smaller than the total number of haplotypes. One limitation of haplotyping is that haplotypes need to be determined for each individual, as SNPs detected from a pool of DNA from a number of individuals cannot yield haplotypes. Clinical trials using haplotyped individuals are the first genetically personalized medical treatments.

Table 1 Pharmacogenetic vs. pharmacogenomic studies

Feature	Pharmacogenetics	Pharmacogenomics
Focus of studies	Patient variability	Drug variability
Scope of studies	Study of sequence variations in genes suspected of affecting drug response	Studies encompass the whole genome
Methods of study	SNP, expression profiles, and biochemistry	Expression profiling
Relation to drugs	One drug and many genomes (patients)	Many drugs and one genome
Examination of drug effects	Study of one drug in vivo in different patients with inherited gene variants	Examination of differential effects of several compounds on gene expression in vivo or in vitro
Application relevant to personalized medicine	Patient/disease-specific healthcare	Drug discovery and development or drug selection

BIOCHIP/MICROARRAYS FOR PERSONALIZED MEDICINE

Biochips play an important role in the development of personalized medicine. Various applications are:[6]

- For storage of the patient's genomic information
- SNP genotyping
- Genetic screening for detection of mutations
- Gene expression profiling
- Diagnosis and prognosis of cancer
- In drug safety for pharmacogenetics and toxicogenomic studies
- Monitoring of pathogens and resistance in infections
- Stratification of patients in clinical trials

Protein chips will be particularly useful for clinical implementation of personalized medicine. Profiling proteins on biochips will be useful for distinguishing the proteins of normal cells from early-stage cancer cells, and from malignant metastatic cancer cells. In comparison with the DNA microarrays, the protein microarrays/chips

offer the possibility of developing a rapid global analysis of the entire proteome leading to protein-based diagnostics and therapeutics.

Diagnostic applications of biochips in healthcare require a time-consuming and expensive validation process but provide the greatest area of potential growth with an emphasis on the point-of-care and personalized medicine. A further refinement of biochip technology using nanoparticles will enable SNP mapping point-of-care hand-held diagnostic devices and biomarker-based drug development as a basis for personalized medicines.

PHARMACOGENETICS

Pharmacogenetics has a threefold role in the pharmaceutical industry, which is relevant to the development of personalized medicines:[7]

1. For study of the drug metabolism and pharmacological effects
2. For predicting genetically determined adverse reactions
3. Drug discovery and development and as an aid to planning clinical trials

It is of considerable importance to know the metabolic status of an individual, particularly when using drugs with a narrow therapeutic range. Differences in metabolism of drugs can lead to severe toxicity or therapeutic failure by altering the relation between dose and blood concentration of the pharmacologically active drug. Inter- and intra-individual variability in pharmacokinetics of most drugs is largely determined by variable liver function as described by parameters of hepatic blood flow and metabolic capacity. Among the factors affecting these parameters are genetic differences in metabolizing enzymes. The most important of these is P450.

Cytochrome P450

The cytochrome P450 (CYP450) enzyme system consists of a large family of proteins, which are involved in the synthesis and/or degradation of a vast number of endogenous compounds such as steroids, cholesterol, vitamins, and retinoic acid, as well as the metabolism of exogenous toxins. Cytochrome P450 enzymes can alter, abolish, or enhance drug metabolism. Genotyping or phenotyping can now be recommended as a complement to plasma concentration determination when aberrant metabolic capacity (poor or ultrarapid) of CYP2D6 substrates is suspected. The current rapid developments in molecular genetic methodology are expected to provide new tools for prediction of the activity of the various drug-metabolizing enzymes. Because cytochrome P450s play key roles in regulating important physiological processes, they are also attractive targets for drug discovery. Inhibitors of P450 enzymes are used clinically or are under evaluation for treatment of a number of diseases. AmpliChip CYP450 microarray (Roche Diagnostics) is commercially available for identification of polymorphisms in CYP2D6 and CYP2C19.

Genotyping

Currently, the most significant polymorphisms in causing genetic differences in Phase I drug metabolism are known, and therapeutic failures or adverse drug reactions caused by polymorphic genes can be predicted for several drugs. Patients are being genotyped in clinical trials. Genotype-based drug dose adjustment information can be useful when the drug is introduced into clinical practice and would enable the dose adjustment for individualized therapy.

Due to the rapid development of cost-effective methods for genotyping and the need to genotype only once in the lifetime of a patient, it would be advisable to include the genotype in the patient's record. It is also desirable to include the genotypes of transport proteins and drug receptors, which can reveal highly predictive genetic information. This would provide the physician with valuable information to individualize the treatment. Besides development of personalized medicines, the impact of genotyping on medical practice would shift the emphasis from present diagnosis-based treatment to detection of disease prior to clinical manifestation and preventive treatment with appropriate medicine and a dose that is most effective and safest for an individual.

ROLE OF PHARMACOGENOMICS IN PERSONALIZED MEDICINE

Molecular genetic methods may be applied both for genetic profiling (polymorphisms, mutations, etc.) of cohorts and for monitoring and guidance of therapies. Such tests can be used by the pharmaceutical companies to help identify suitable subjects for clinical trials, aid in interpretation of clinical trial results, find new markets for current products, and speed up the development of new treatments and therapies. However, only a few pharmacogenomic tests are commercially available and it remains to be seen what impact these will have on the market and on healthcare in general.

Pharmacogenomics in Drug Discovery

Pharmacogenomic analysis can identify disease susceptibility genes representing potential new drug targets. This can lead to novel approaches in drug discovery for individualized application of therapy. It may help focus effective therapy on smaller patient subpopulations which, although demonstrating the same disease phenotype, are characterized by distinct genetic profiles. In other words, personalization of drugs may start at the discovery stage.

Pharmacogenomics in Drug Development

Current applications of pharmacogenomics in drug development include prospective genotyping in Phase I trial to ensure that a subject population is representative with respect to drug metabolism phenotypes. Inclusion and exclusion of patients may be based on genotypes. The banking of genetic material from later stage trials for retrospective studies on drug response is becoming more frequent, but is not yet standard in the industry. Retrospective studies using collections of DNA that supply medical information on specific disease types, drug response, and ethnic composition could build a foundation for the evolution of medicine from diagnosis and treatment toward prediction and prognosis which are important components of integrated personalized medicine.[8]

PHARMACOPROTEOMICS

There is an increasing interest in proteomics technologies now because DNA sequence information provides only a static snapshot of the various ways in which the cell might use its proteins whereas the life of the cell is a dynamic process. Pharmacoproteomics will play an important role in the development of personalized medicine because proteomics-based characterization of multifactorial diseases may help to match a particular target-based therapy to a particular marker in a subgroup of patients. Individualized therapy may be based on differential protein expression rather than a genetic polymorphism. Advantages of using pharmacoproteomics are:

- Pharmacoproteomics is a more functional representation of patient-to-patient variation than that provided by genotyping.
- Because it includes the effects of posttranslational modification, pharmacoproteomics connects the genotype with the phenotype.
- Pharmacoproteomics could increase the predictability of early drug development and identify noninvasive biomarkers of toxicity or efficacy.[9]

ROLE OF BIOINFORMATICS IN PERSONALIZED MEDICINE

The massive amount of information generation by the Human Genome Project, detection of SNPs, and proteomic data would require bioinformatic tools for cataloguing and analysis of information. Bioinformatics will integrate various technologies and sources of information to facilitate the development of personalized medicine as shown in Table 2. Bioinformatic tools will facilitate informed therapeutic decision making by the physicians.

EXAMPLES OF PERSONALIZED THERAPIES

There are numerous examples where currently available genomic technologies are applied to individualize the treatment to patients who are likely to benefit from a

Table 2 Role of bioinformatics in the development of personalized medicine

Table 3 Examples of personalized therapies

Approach to therapy	Comments
Genotyping as a guide to therapy for AIDS	Enables the monitoring of viral load and detection of resistance to treatment in personalized protocols for patients
Autologous cell vaccine is prepared from the patient's tumor and is injected back into the patient	The patient's immune system is better able to recognize, locate, and combat remaining cancer cells
HER-2 gene amplification and overexpression in breast cancer and can be detected by HER-2 breast test (Vysis' PathVysion)	This is an aid in the assessment of breast cancer patients who will respond to treatment with trastuzumab (Genentech's Herceptin)
A validated test that can identify a subgroup of hypertensive patients that should be treated with ACE-inhibitors as first line of treatment	This subgroup (30%) will show a much better response to ACE-inhibitors than the remaining population

certain therapy. There are many potential applications in cancer, genetic disorders, and infections. A few examples are shown briefly in Table 3.

ETHICAL AND SOCIAL ASPECTS OF GENETIC PROFILING

Genetic profiling for pharmacogenetic purposes is less likely to raise objections than genetic testing for primary disease risk assessment. Nevertheless, ethical issues concerning patient confidentiality, possible misuse of genotyping data, and possible harm to patient's social and insurability status need to be resolved before the implementation of pharmacogenetics in healthcare. Holding sensitive information on someone's genetic makeup raises questions of privacy and security and ethical dilemmas in disease prognosis and treatment choices. After all, polymorphisms relevant to drug response may overlap with disease susceptibility, and divulging such information could jeopardize an individual. On the other hand, legal issues may force the inclusion of pharmacogenetic information into clinical practice. Once the genetic component of a severe adverse drug effect is documented, doctors may be obliged to order the genetic test to avoid malpractice litigation.

FUTURE OF PERSONALIZED MEDICINE

Future medicine will be practiced in an environment in which molecular classification of diseases based on genomic analysis will replace the one based on symptoms. Molecular diagnostics to predict the results of therapy will be based on patient's genomic profile. There is still a considerable amount of work to be done before personalized medicine is established in clinical practice. Challenges facing development of personalized medicine are:

- One limitation to the application of pharmacogenomic techniques to personalized medicine is that current knowledge on phenotype–genotype correlation is based on statistical observations that are not totally verifiable on the individual level.
- Not all the treatments can be personalized.
- There is an initiative from the biopharmaceutical industry but little support has come from governments or healthcare organizations.
- There is a great need for education of the health professionals and patients on the advantages and limitations of personalized medicine.
- Ethical, legal, and social problems need to be addressed.
- Management of huge amounts of data needed whereas current bioinformatic manpower is limited.
- Technologies required for implementation of personalized medicine still need refinement.

A thorough understanding of the principles and applications of pharmacogenomics, the most important basic of personalized medicine, will be an indispensable part of the future of drug therapy in clinical practice. Personalized medicine scenario in the year 2010 for prevention could be as follows:

A patient would need to provide only a buccal smear sample in the physician's office for DNA analysis. This will provide information about predisposition to several diseases. This analysis may eventually be performed for a very reasonable cost as the genome chip becomes commercially viable. By identifying genetic predisposition to disease, the physician will focus on risk assessment and develop a comprehensive personalized plan to modify risk factors, and initiate preventive strategies.

Personalized medicine scenario in the year 2010 for treatment could be as follows:

A patient presents in the physician's office with certain symptoms and signs. The patient carries a biochip with record of his/her genetic information. The clinical diagnosis is supplemented with point-of-care molecular diagnostics. The treatment prescribed is personalized according to the patient's genetic makeup and the subtype of the disease and is linked to a diagnostic test.

CONCLUSION

Technological advances, along with new insights into the molecular pharmacology of medications and the functional consequences of polymorphisms in the human genome, are providing the tools needed to elucidate genetic determinants of drug response and translate functional genomics into personalized medicine.[10] Considerable evidence has now accumulated to show that the use of pharmacogenomics and pharmacogenetics as a basis of personalized medicine is feasible. Personalized medicines are available for a few disorders. Knowledge gained from pharmacogenomics and pharmacogenetics is being used to improve the use of currently available medicines and to discover and develop new medicines for specific groups of diseases. Advantages of personalized medicine for patients can be summarized as follows:

- Effective and specific therapies
- Less risk of adverse effects
- No time lost in trial and error with ineffective drugs
- Lower cost of treatment
- Facilitate development of preventive healthcare

Peutz–Jeghers Syndrome

William M. Grady
Andrew M. Kaz
University of Washington Medical Center, Seattle, Washington, U.S.A.

INTRODUCTION

It is estimated that greater than 5% of all colorectal cancers (CRCs) can be directly linked to a specific, inherited allele. The ''polyposis syndromes,'' which are further subdivided into adenomatous and hamartomatous syndromes, comprise approximately 1% of these hereditary cancers.[1] The adenomatous polyposis syndromes consist of familial adenomatous polyposis (FAP) and attenuated FAP. The hamartomatous polyposis syndromes predominantly include Peutz–Jeghers syndrome (PJS), juvenile polyposis, and Cowden syndrome. The genetic etiologies responsible for significant subsets of these disorders have been previously identified.[2]

Peutz–Jeghers syndrome (PJS) is a rare, inherited syndrome characterized by gastrointestinal polyposis and mucocutaneous pigmentation. The histologically distinct polyps of PJS occur throughout the GI tract, but are most consistently found in the jejunum, ileum, and duodenum. Individuals with PJS are at risk for numerous intestinal and extraintestinal malignancies, including small bowel, stomach, breast, and gonadal tumors.[3] In the late 1990s, the genetic etiology of PJS was described by two groups of investigators.[4,5] Germline mutations in a serine/threonine kinase designated *STK11* (also known as *LKB1*), which functions as a tumor suppressor, are likely responsible for roughly half of PJS cases.[6]

This chapter discusses the clinical and genetic aspects of PJS, including the function of the *STK11* gene product, and lists the specific mutations that have been described to date. Special attention is paid to available genetic testing and current surveillance recommendations.

CLINICAL FEATURES OF PEUTZ–JEGHERS SYNDROME

Peutz–Jeghers syndrome is an autosomal dominantly inherited condition with an incidence of approximately 1 in 200,000 births.[2] This rare syndrome is characterized by hamartomatous polyposis of the GI tract, mucocutaneous hyperpigmentation, and a significantly increased risk of developing intestinal and nonintestinal malignancies. Symptoms attributed to PJS are often absent at the time of diagnosis, although patients can present early in life with gastrointestinal emergencies including intussusception, small bowel obstruction, and GI bleeding.[7] The hamartomatous polyps are located in the small bowel (particularly jejunum) in upward of 80% of patients, in the stomach in 40%, and in the colon or rectum in 40%.[1] Peutz–Jeghers syndrome polyps are composed of nonneoplastic tissue with a noticeably distorted architecture. Histologically, they are distinguished by normal epithelium covering frondlike projections that are composed of smooth muscle branching from the muscularis mucosa to the polyp head.[7] This pattern is often designated ''arborization.''

In addition to the characteristic hamartomas that occur in the gastrointestinal tract, pigmented macules along the vermillion border and in the interdigital spaces occur in individuals affected by PJS. Amplified numbers of melanocytes at the epidermal–dermal junction, containing increased basal-cell melanin, account for the blue to brown macules seen in PJS patients. Most commonly affected are the lips, the buccal mucosa, the skin around the eyes and nose, and the digits. The great majority of individuals with PJS (>95%) have evidence of increased melanin deposition. Although the macules on the lips and skin can fade over time, the buccal lesions typically persist.[8]

Requirements for Clinical Diagnosis

According to guidelines set forth by Giardiello et al., PJS can be diagnosed if the following criteria are met: the presence of histopathologically confirmed hamartomatous polyps, plus two or more additional criteria, including a positive family history, mucocutaneous hyperpigmentation, or small-bowel polyps.[9] Peutz–Jeghers can generally be differentiated from other similar syndromes by clinical criteria. Commonly confused conditions are juvenile polyposis (no pigmentation; hamartomas with different histology), mixed hereditary polyposis syndrome (no pigmentation; adenomatous and hyperplastic polyps), and Carney complex (pigmentation present; no GI polyps).[3,7]

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020640

Peutz–Jeghers Syndrome and Cancer Risk

Peutz–Jeghers syndrome is a hereditary cancer-susceptibility syndrome, as evidenced by the development of malignancies in the great majority of patients during their lifetimes, the early age of cancer diagnosis in these family members compared to the general population, and the occurrence of cancers in related individuals in these families. Although the polyps in PJS patients are restricted to the gastrointestinal tract, the malignancies that arise in these families can be found in a variety of organ sites, including the gastrointestinal tract. The gastrointestinal malignancies can occur anywhere in the mucin-secreting portion of the luminal GI tract as well as in the pancreas. Interestingly, although foci of dysplasia can be found in larger Peutz–Jeghers polyps, the hamartomatous polyp of Peutz–Jeghers syndrome is typically a benign neoplasm. Most gastrointestinal cancers are believed to arise from coexisting adenomatous polyps. Nongastrointestinal tumors occur in the skin, thyroid, lung, breast, cervix, ovary, and testis. Of note, the mucocutaneous lesions of PJS are not premalignant.[1]

In regard to the magnitude of the cancer risk in PJS patients, Giardiello et al. reported a cumulative lifetime cancer risk in individuals with PJS of 93% in a recent meta-analysis.[10] These investigators also described the risk of developing pancreatic cancer in individuals with Peutz–Jeghers syndrome to be 100-fold greater than the general population.[9] Boardman et al. observed a 9.9-fold relative risk increase for all cancers; the risk was greatest for neoplasms of the gastrointestinal tract (RR = 151) and breast (RR = 20.3).[11] In another series of PJS patients, Lim et al. observed a 37% cancer risk by age 65 (47% risk in those carrying a *STK11* mutation), and a relative risk of 9.9 (13.2 with a *STK11* mutation)[12] (Table 1).

Neoplasms of the female, and rarely male, genital tract have also been observed with increased frequency in individuals with PJS. These lesions include ovarian sex cord tumors with annular tubules (SCTAT), mucinous ovarian neoplasms, and adenoma malignum of the cervix.[6]

Table 1 Risk of cancer in Peutz–Jeghers syndrome

Site	Relative risk	Reference
All cancers	10–15	[10–12]
Esophagus	57	[10]
Stomach	213	[10]
Small intestine	520	[10]
Colon	84	[10]
Pancreas	100–132	[9,10]
Lung	17	[10]
Breast	14–20	[10–12]
Ovary	27	[10]
Uterus	16	[10]

GENETICS OF PEUTZ–JEGHERS SYNDROME

Peutz–Jeghers syndrome is inherited in an autosomal dominant manner. Birth prevalence rates have been reported anywhere from 1:25,000 to 1:280,000. The disorder can occur in any racial or ethnic group.[3] Penetrance in PJS appears to be variable, and genotype–phenotype correlations are currently poorly characterized. In families with clinically evident PJS, some members appear to demonstrate only mucocutaneous pigmentation whereas others have both pigmentation and polyps. Approximately half of probands have an affected parent, and the other half have no family history of PJS, suggesting the presence of either genetic heterogeneity or modifier genes that can modulate the effects of mutant *STK11*.[3,13] The proportion of individuals who carry de novo mutations is currently unknown.

Amos et al. recently described the risk to family members after the identification of a proband with PJS. Fifty percent of probands will have an affected parent, although family history may appear negative because of lack of signs or symptoms of PJS, or the early death of a parent due to an unrelated cause. Siblings of the proband have a 50% risk of PJS if one parent is affected; if neither parent is affected, the risk appears to be minimal. Children of PJS patients have a 50% chance of inheriting the disorder if a positive family history or a *STK11* germline mutation is identified. The risk to the proband's offspring cannot be accurately determined if the proband has a negative family history or undetectable *STK11* mutation.[3]

STK11 AND PEUTZ–JEGHERS SYNDROME

In 1997, two loci for PJS were identified. The first was mapped to chromosome 19p13.3, near marker D19S886, by genomic hybridization and linkage analyses.[4] Subsequently, a second locus was described on 19q13.4 in the vicinity of D19S891.[14] The following year, two groups pinpointed the PJS gene on 19p13.3. Hemminki et al. noted truncating germline mutations on chromosome 19 in multiple patients with PJS. The gene, called *STK11* (or *LKB1*), is a serine/threonine kinase with strong homology to the Xenopus serine/threonine kinase XEEK1.[15] Jenne et al. described five separate germline mutations in *STK11* in a three-generation Peutz–Jeghers family and concluded *STK11* mutations are responsible for the development of

PJS in at least a subset of PJS families.[16] *STK11* germline mutations have been described in up to 100% of PJS families in some studies, although in other series, *STK11* mutations were absent in 33% to 42% of individuals with clinical manifestations of PJS.[17,18] Boardman et al. analyzed five PJS probands and 23 individuals with sporadic PJS, and found *STK11* mutations in only two and four patients, respectively. Thus PJS appears to demonstrate genetic heterogeneity, and it is likely that other loci will be implicated in this disease.[13]

The Function of the *STK11* Gene Product and Its Role as a Tumor Suppressor Gene

STK11 contains 10 exons spanning 23 kb and is expressed in all human tissues.[16] It encodes a protein kinase that is likely a tumor suppressor, as loss of the normal *STK11* allele has been described in the polyps of PJS patients with germline mutations in the other allele.[15] Peutz–Jeghers syndrome therefore became the first cancer-susceptibility condition described due to inactivation of a protein kinase.

Indeed, Mehenni et al. illustrated that mutant STK11 proteins expressed in COS7 cells demonstrated little or no protein kinase activity when compared with wild-type *STK11* and proposed that STK11's ability to phosphorylate other proteins was related to its role as a tumor suppressor.[19] The consequences of the deregulated kinase activity observed in STK11 mutant appear to be on the regulation of both cell proliferation and apoptosis. Tiainen et al. demonstrated that reconstituting cancer cells that carry mutant *STK11* with wild-type *STK11* resulted in a G_1 cell cycle arrest and the suppression of cell proliferation demonstrating the role of *STK11* as a tumor suppressor gene.[20] STK11 has been shown to regulate cell cycle progression through the induction of the cyclin-dependent kinase inhibitor p21 by a p53-dependent mechanism.[21] In addition to p53-dependent effects on cell cycle arrest, Karuman et al. illustrated the STK11 protein can physically associate with the p53 protein and probably regulates p53-dependent apoptosis.[22] STK11 normally translocates from cytoplasm to nucleus during apoptosis and is significantly upregulated in pyknotic intestinal cells, whereas polyps from PJS patients have been shown to lack STK11 by immunostaining. Thus deficient apoptosis regulation may be an important factor in the formation of intestinal polyps in PJS patients.[22] Consistent with the importance of cellular localization in the function of wild-type *STK11*, some mutations in *STK11* have been shown to affect the normal subcellular localization of STK11. For example, an SL26 mutation found in a PJS family, which results from a small in-frame deletion, produces a protein that retains its kinase activity but only resides in the nucleus, whereas normal STK11 is found in both cytoplasm and nucleus.[23]

Additionally, as demonstrated by Ylikorkala et al., STK11 likely participates in the vascular–endothelial growth factor (VEGF) pathway. Mice with targeted *Stk11* disruption died in midgestation, with evidence of neural tube defects and vascular anomalies. These phenotypes were correlated with noticeably increased levels of VEGF mRNA.[24] Bardeesy et al. generated $Lkb1^{+/-}$ mice and observed the formation of Peutz–Jeghers polyps in these mice and also found that cells from these mice showed loss of culture-induced senescence and modulation of factors related to angiogenesis, extracellular matrix remodeling, and cell adhesion.[25] Finally, other groups have found that STK11 binds to and regulates Brg1, a protein responsible for inducing cell cycle arrest. The inability of *STK11* mutants to mediate Brg1-dependent growth cessation may correlate with the development of the Peutz–Jeghers syndrome.[26]

Specific *STK11* Mutations

Mutations in the *STK11* gene typically lead to truncation of the protein product.[27] DNA sequencing of tissues from individuals with Peutz–Jeghers syndrome has led to the elucidation of over 100 mutations. Stenson et al. in the Human Gene Mutation Database have collected and categorized all 108 reported *STK11* mutations as of March 5, 2004, as follows: 40 missense/nonsense substitutions, 13 splicing substitutions, 30 small deletions, 10 small insertions, 3 small indels, 8 gross deletions, 1 gross insertion and duplication, and 3 complex rearrangements[28] (Table 2).

Table 2 Currently identified mutations in *STK11*

Type of mutation	Total number of mutations
Nucleotide substitutions (missense/nonsense)	40
Nucleotide substitutions (splicing)	13
Small deletions	30
Small insertions	10
Small indels	3
Gross deletions	8
Gross insertions and duplications	1
Complex rearrangements (including inversions)	3
	Total = 108

GENETIC TESTING FOR *STK11*

Genetic testing for germline *STK11* mutations is currently offered at four clinical laboratories.[29] DNA specimens isolated from peripheral blood or the buccal mucosa can be tested utilizing either genetic sequencing of the entire coding region, mutation scanning (e.g., SSCP, DHLPC, DGGE, etc.), or mutation analysis (i.e., assessment for specific mutations). The variability in the types of STK11 mutations identified in PJS families to date suggests that no single currently available mutation analysis technique is likely to be 100% accurate in identifying *STK11* mutations. In addition, at least a subset of PJS families appear to have pathogenic mutations outside of the coding region for the gene, suggesting some mutations will be missed with routine methods used currently in the clinical labs that offer testing.[28] One laboratory also offers prenatal diagnosis. Assaying for loss STK11 expression by immunostaining PJS polyps or cancers has also been proposed as a diagnostic method; however, the accuracy of STK11 immunostaining for the detection of STK11 germline mutation carriers is unknown at this time. In fact, Wei et al., demonstrated that the expression of STK11 in polyps is heterogeneous, even in polyps from a single patient. Furthermore, some polyps and cancers contained both nuclear and cytoplasmic expression of STK11, whereas others showed no evidence of STK11 expression.[30] Thus immunohistochemistry cannot be recommended as an effective adjunct to genetic testing at this time.

The detection rate of *STK11* germline mutations using genetic analysis is variable and depends upon whether a tested individual has a positive family history of PJS. Approximately 70% of individuals tested by sequence analysis who have a positive family history will harbor disease-causing mutations of *STK11*.[3–5,14] If a specific *STK11* mutation has been previously identified in an affected family member, other family members can be tested with accuracy approaching 100%.[1] The detection rate of *STK11* mutations appears to be lower in individuals without a known family history, ranging from 20% to 70%.[3,13]

In general, genetic testing is informative in two situations: 1) to predict whether an ''at-risk'' asymptomatic individual has inherited PJS already clinically diagnosed in a family member; or 2) to confirm the diagnosis of PJS in a patient where the clinical diagnosis is uncertain.[31] Testing of at-risk, asymptomatic family members (which typically involves pre- and posttest genetic counseling) might provide useful information relating to age of onset of PJS, as certain mutations may predispose to earlier development of the syndrome.[3] Additionally, patients harboring distinct *STK11* mutations might have an elevated cancer risk.[12] Testing children for PJS (which can become clinically manifest early in life) is similarly available after an *STK11* mutation has been identified in an affected family member. In all of these cases, genetic testing may allow individuals and their physicians to devise strategies regarding treatment and future cancer surveillance. Prenatal testing for PJS is currently available, although uncommonly performed.

SURVEILLANCE OF PEUTZ–JEHGERS PATIENTS

Because the lifetime cancer risk is significantly elevated in PJS patients compared to the general population, an aggressive cancer surveillance program has been proposed by several groups. In principle, such programs will prevent certain gastrointestinal malignancies and detect other cancers at an earlier stage, which should improve cancer-related mortality. These guidelines, which have not been formally adopted by professional medical organizations, are empiric and based upon expert opinion because of the lack of evidence-based clinical trial data.[1]

Recommendations from the St. Mark's Polyposis Registry, which has been modified by other groups, include the following: annual pancreatic ultrasound exams; annual pelvic ultrasound exams in females, and testicular ultrasound exams in males; biennial upper gastrointestinal endoscopic exams beginning at age 10; biennial colonoscopic exams beginning at age 25; and biennial small bowel X-ray studies starting at age 10. Any gastrointestinal polyps detected should be removed endoscopically and those polyps that cannot be endoscopically resected should be removed surgically via laparotomy with intraoperative endoscopy.[6] In addition, mammography should begin at age 25 and be repeated every 5 years until age 35, then every 2 years until age 50, followed by yearly exams after 50 years of age. Pap smears are recommended every 3 years.[7,32] Family members of PJS patients should be enrolled in surveillance programs if they have clinical evidence of PJS or a detectable *STK11* mutation.

CONCLUSION

The clinical description of Peutz–Jeghers syndrome has evolved over time and now can be defined specifically at the genetic level in a substantial subset of PJS patients. Currently, PJS can be defined as an inherited hamartomatous polyposis syndrome, associated with mucocutaneous lesions and an increased predisposition to numerous gastrointestinal and nongastrointestinal malignancies.

Many cases of PJS occur as a consequence of germline mutations in the *STK11* gene, a serine/threonine kinase that appears to be an important nuclear kinase involved in cell growth and apoptosis pathways. Genetic testing for *STK11* germline mutations is currently available on a clinical basis.

Finally, despite the recent advances in our understanding of PJS, *STK11* mutations do not account for all cases of PJS, and it is likely that additional genes or loci remain to be identified. In addition, further studies of *STK11* genotype/phenotype correlations are required to determine the role of allelic heterogeneity on the clinical manifestations of *STK11* germline mutations. These studies promise to lead to more accurate application of genetic screening and cancer surveillance strategies to PJS family members.

Plasmodium spp.—Detection by Molecular Techniques

Gabriella A. Farcas
Kevin C. Kain
University of Toronto, Toronto, Ontario, Canada

INTRODUCTION

Malaria incidence is increasing, accounting for an estimated 300 to 500 million cases and 3 million deaths annually.[1] In the Americas, malaria incidence has risen dramatically, with as much as a 400% increase in reported cases in the last 20 years.[2] At least 30,000 travelers from industrialized countries are reported to contract malaria each year,[1] and despite treatment between 1% and 4% of those who acquire *Plasmodium falciparum* malaria will die. This fatality rate can climb to 20% or higher in those patients who develop severe malaria or those who are elderly.

MALARIA DIAGNOSTIC METHODS

A variety of diagnostic methods exist to identify the four malaria species and determine parasite burden in clinical samples; however, each method has advantages and disadvantages. Providing rapid and reliable malaria diagnosis continues to be a challenge for laboratories in both endemic and nonendemic countries. The utility and accuracy of the methods described below depend upon the level of technical expertise, training, and quality control as well as on the availability of necessary equipment.

Microscopy

Despite significant advances in the field, microscopic detection of parasites on Giemsa-stained blood smears remains the reference standard for malaria diagnosis in laboratories around the world, as it has been for over a century. It is generally available and relatively inexpensive, and it allows not only the identification of malaria species, but also the assessment of parasitemia. However, the staining and interpretation process is labor intensive and requires considerable expertise, particularly for accurate species identification at low parasitemia or when mixed infections occur. The ability to maintain the required level of expertise in malaria diagnostics is problematic, especially in peripheral medial centers in countries where the disease is not endemic.[3]

Alternative microscopic approaches such as those involving the use of fluorescent dyes (e.g., acridine orange), alone or after centrifugation (QBC; quantitative buffy coat), may be more sensitive but less specific for the diagnosis of *P. falciparum*, yet these methods are not reliable for species identification and require specialized equipment.[4]

Immunochromatographic Antigen Detection Tests

The World Health Organization has recognized the need for simple, cost-effective, and accurate diagnostic tests for malaria which could overcome the expertise-associated limitations of microscopy as well as the changing patterns of accepted morphology of malaria species due to drug pressure, strain variation, or approaches to blood collection.[5]

Nonmicroscopic malaria-diagnostic devices rely on the detection of malaria antigen, such as parasite histidine-rich protein 2 (e.g., NOW ICT *Pf/Pv*™, PATH Falciparum Malaria IC™, and Parasight F™), or parasite LDH (e.g., OptiMAL™) in whole blood. The underlying principle of immunochromatographic procedures utilize conjugated monoclonal antibodies against the malaria antigen of choice as an indicator of infection.

Histidine-rich protein 2 (HRP-2) is a *P. falciparum*-specific antigen, therefore assays limited to the detection of HRP-2 are unable to detect other human *Plasmodium* species. A newer generation of rapid diagnostic assays (RDA) use HRP-2 as well as aldolase, a pan-malarial antigen, to identify nonfalciparum infections, yet they remain unable to differentiate between the nonfalciparum species.

Parasite LDH (pLDH)-based assays take advantage of the species-specific isomers of this enzyme from the parasite glycolytic pathway. Parasite LDH-based RDAs have a *P. falciparum*-specific antibody and two pan-malarial antibodies, which recognize nonfalciparum pLDH.

Compared to microscopy and PCR, RDAs range widely in sensitivity and specificity. One of the latest HRP-2-based assays was 96% sensitive for pure *P. falciparum* and 94% for mixed *P. falciparum* infections

DOI: 10.1081/E-EDGP 120020894

and 84% sensitive for nonfalciparum infections with an overall specificity of 96%.[6] However, for both falciparum and vivax infections, sensitivity fell as parasitemia declined.[6] In a recent evaluation of returning travelers in Berlin, the OptiMal test (a pLDH assay) was found to be 76.2% sensitive and 99.7% specific.[7] In another study, the OptiMAL assay failed to detect malaria infection in 15% of cases.[8] The sensitivity for detection of *P. falciparum* infection was 87%, and for *P. vivax* was 79%. Similar to HRP-2 tests, the sensitivity of the pLDH tests decreased significantly with lower parasite densities (<500/μL).[8]

False negative and false positive results do occasionally occur with these devices, even at high parasitemias, possibly due to prozone effect (false negatives), the possible lack of or alteration in the *hrp 2* gene (false negatives),[9] or the presence of rheumatoid factor (false positives).[10] Importantly, if the clinical suspicion of malaria remains high despite a negative RDA result the assay should be repeated within 12 to 24 hr[9] and these assays should be accompanied by thick and thin blood smears.

Despite some inherent limitations, evidence suggests that rapid malaria diagnostic devices may represent a useful adjunct diagnostic tool to microscopy in a clinical setting while definitive results are sought from a reference laboratory.

Molecular Methods—Radiolabeled Probes

As an alternative approach to the detection and species identification of malaria, species-specific probes were developed in the late 1980s and early 1990s. Hybridization of radiolabeled oligonucleotide probes to complementary species-specific regions of the abundant and stable parasite small ribosomal subunit RNA (ssRNA)[11] seemed promising for the detection of the four species of human Plasmodia. This method of detection is not commonly used as a diagnostic tool.

Molecular Methods—Polymerase Chain Reaction (PCR)

Nested PCR

Polymerase chain reaction-based diagnostic methods for malaria represent a major advancement, surpassing microscopic methods both in sensitivity and specificity. Polymerase chain reaction can detect as few as 1–5 parasites/μL of blood (<0.0001% of infected red blood cells) compared to 50–100 parasites/μL using microscopy or RDAs.[12–14] Furthermore, PCR can readily detect mixed-species infections and may be automated allowing processing of large number of samples.

The multicopy 18S (small subunit) rRNA genes of *Plasmodium* spp. that infect humans have been demonstrated to be highly stable and conserved. Assays to detect them have displayed no cross-reactions to human DNA or other human pathogen DNA/RNA including nonhuman *Plasmodium* spp.[11,13,14] The 18S gene of *Plasmodium* is an ideal molecular target for malaria parasite identification, both for the abundance of the DNA gene targets and because it is composed of a mosaic of conserved and variable regions, allowing the amplification of sequences from samples using primers that are conserved within every member of the genus *Plasmodium*.[15,16] Identification to the species level, however, requires an additional round of PCR, a nested PCR, with species-specific primers.

Although this nested-amplification procedures is highly sensitive and specific, it is more cumbersome and expensive than single PCR assays. Also, because it is an open system (i.e., open transfer of amplicons between tubes) there is an inherent risk of contamination. Amplified products can be detected by gel electrophoresis, Southern or slot blotting followed by hybridization with DNA probes or by a colorimetric detection procedure with an enzyme-labeled antibody and chromogenic substrate in a microtiter format. The detection of amplification products by chemiluminescence hybridization or enzyme immunoassays in microplate format offers better potential for standardized commercial assays and automation.[12,17–19]

Real-time PCR

Despite their superior sensitivity and specificity over microscopy, traditional PCR, and particularly nested PCR, methods[14] are labor intensive with turnaround times that are generally too long for routine clinical application. Moreover, these are open systems that require considerable pre- and postsample handling and therefore special efforts need to be employed in order to prevent false positive assays. Real-time quantitative PCR technology has the potential to overcome these limitations, offering a simple, time-effective, and quantitative diagnostic option. Using DNA binding dyes, such as SYBR green, molecular probes, or hybrids labeled with fluorescent probes, real-time PCR can detect and quantify amplicons in as little as 40 min.

The closed amplification vessels utilized in this system minimize the need for excessive sample handling, particularly when compared to nested reactions, and eliminate additional post-PCR sample handling steps normally required for amplicon detection. These features

significantly reduce the potential for sample contamination. When the real-time assay is combined with the available robotic sample preparation/nucleic acid extraction modules, the process may be fully automated. This combined with their ease of use and rapid turnaround times makes these assays well suited to routine diagnostic laboratories.

Although a number of in-house real-time assays for malaria diagnosis have been developed, few meet the good manufacturing practices (GMP) standards for commercialization. One commercially available real-time PCR assay for malaria diagnosis has recently been evaluated.[20] It contains reagents and enzymes for the specific amplification and detection of a species-conserved 140-bp region of the *Plasmodium* 18S rRNA genes of all four human malaria species. In addition to the hybridization probe used for amplicon detection, the assay contains a second heterologous amplification system to identify potential PCR inhibition in samples. Four quantification standards with known concentrations of cloned gene copies per microliter (equivalent to 70 to 70,000 genome copies per microliter) are used as known positive controls and to generate a standard curve to assess parasite burden.

Direct correlations between parasitemia, as determined by microscopy, and gene copy number, as determined from the standard curve, are somewhat confounded by the multicopy nature of the rRNA genes, by the variable numbers of these genes within each species, and by the presence of multinucleate schizont stages. However, these two approaches represent alternative methods of quantifying parasite burden within a sample and additional clinical trials will be required in order to determine which method is more predictive of clinical outcome.

One limitation of the current generation of real-time assay is their inability to differentiate between the four *Plasmodium* species. In its current form, a positive assay would need to be accompanied by a malaria smear or nested PCR in order to ascertain the *Plasmodium* spp. involved, unless the assay is used primarily as a screening test or to exclude malaria in blood products. The high cost of this state-of the-art technology places real-time PCR-based assays out of reach for developing countries. However, diagnostic laboratories may find the rapid turnaround time, quantitative results, high sensitivity, and the excellent negative predictive value (allowing one to exclude malaria in a patient) to have potential impact on patient care.

Improved real-time PCR malaria diagnostic devices are underway. These utilize fluorescence resonance energy transfer (FRET) technology to differentiate species based on differing melting curve profiles. With a quantification component and an internal control component, this new generation of diagnostic tools will yield sensitive and specific results in under an hour.

Mass Spectrometry

A novel blood-based malaria diagnostic approach has recently been published.[21] Ultraviolet laser desorption mass spectrometry (LDMS) is based on the detection of hemozoin (malaria pigment) formed by the parasites during the intraerythrocytic growth phase. As all four human malaria species catabolize host hemoglobin releasing hemozoin in blood, this by-product becomes a pan-malarial diagnostic biomarker. The LDMS detects the heme within the hemozoin, but not heme bound to intact hemoglobin with a sensitivity of 100 parasites per microliter, comparable to that of an average microscopist. A semiquantitative relationship seems to exist between heme signal and parasitemia, rendering this a quantitative diagnostic assay. Upon further field validation, this could become a powerful, low-cost tool (<U.S.$0.05) for rapid (<5 min) and high-throughput malaria screening by nonspecialists. Although a field-portable version of this assay is currently under development, this assay is limited by its inability to distinguish between *Plasmodium* species.

Microarrays

The publication of the *Plasmodium* genome offers much opportunity in the field of malaria diagnostics. Although at present an expensive technology suited only to reference laboratories, microarrays may play an important role in future infectious disease diagnostics. Species-specific malaria diagnosis will be combined with genetic markers for other febrile infectious diseases to further enhance the diagnostic screening process of patients.

CONCLUSION

Polymerase chain reaction-based assays are increasingly replacing microscopy as reference standards for malaria diagnostic, molecular epidemiological, and treatment studies. The disadvantages and limitations of this procedure are being recognized and addressed in the new generation of PCR-based diagnostic assays such as real-time PCR. Implementation of techniques such as real-time PCR can streamline the routine molecular diagnostic laboratory and can take greater advantage of the recent advances in gene discovery and drug-resistance mutations. As it becomes more affordable and more standardized, microarray technology may well become the future

of molecular detection, characterization, and diagnosis of malaria.

Plasmodium spp.—Detection of Drug Resistance by Molecular Techniques

Gabriella A. Farcas
Kevin C. Kain
University of Toronto, Toronto, Ontario, Canada

INTRODUCTION

The increase in malaria incidence worldwide is due, in large part, to the development and spread of drug-resistant malaria parasites. Resistance has emerged to virtually all classes of antimalarials, although at very different rates. For the oldest antimalarials [quinine (Q) and artemisinin derivatives], resistance has been slow to develop and treatment failure with these drugs is not an operational problem in most malaria-endemic areas. Until recently, there was no confirmed artemisinin resistance; however, Kyle[1] and Peters[2] recently generated a stable isolate of artemisinin-resistant *Plasmodium falciparum* malaria. Although resistance to artemisinin has not yet been reported in natural infections, the use of this drug and its derivatives is associated with a high rate of recrudescence after monotherapy; therefore it must be used in combination with longer-lasting antimalarials.[3]

For newer synthetic antimalarials, resistance has developed much faster, sometimes at an alarming rate. Chloroquine (CQ) was long considered the prophylactic and therapeutic agent of choice for *P. falciparum.* Chloroquine-resistant (CQR) falciparum malaria first emerged in Southeast Asia and South America over half a century ago, and subsequently spread to almost all malaria-endemic areas except Central America, above the Panama Canal, Haiti, and parts of China and the Middle East.[4] CQ resistance occurs both in *P. falciparum* and *Plasmodium vivax*, but the former accounts for most of the global disease burden. CQR *P. vivax* malaria is mostly concentrated in Oceania (Papua New Guinea, Vanuatu, and Indonesia) but has also been confirmed in South America.[4–7] As of yet, no confirmed resistance has been documented for *Plasmodium malariae* or *Plasmodium ovale.*

The advent of CQ resistance led to the development of other synthetic antimalarials including sulfadoxine pyrimethamine (SP), mefloquine (MQ), halofantrine, and atovaquone (ATQ)–proguanil (Malarone™). SP is still used as first-line therapy for treatment of falciparum malaria in much of sub-Saharan Africa and South America, despite evidence for escalating resistance in these regions.[7] MQ is now commonly used in many regions of Southeast Asia, Africa, and South America, and remains an efficacious antimalarial in most endemic regions on the borders of Thailand, with Myanmar and Cambodia where multidrug-resistant falciparum malaria has been the norm since the late 1980s.[4] ATQ–proguanil is the latest antimalarial to be approved for the treatment of falciparum malaria in many western countries. Although presently very efficacious for the treatment of *P. falciparum* in all endemic regions including areas of multidrug resistance, ATQ–proguanil resistance has now been documented in a limited number of cases, primarily travelers returning from Africa.[8,9]

DETERMINANTS OF ANTIMALARIAL RESISTANCE

Many factors may potentially contribute to the establishment and spread of drug-resistant malaria.[10] At the molecular level, drug resistance may arise because of several different mechanisms, including changes in drug accumulation within the parasite, alterations in drug efflux mechanisms, and secondary point mutations within parasite enzymes and other drug targets. Single-point mutations within drug targets often render parasites more ''fit'' under drug pressure. These mutational events are accelerated in the presence of subtherapeutic drug dosing, particularly in the case of drugs with long half-lives.

DETECTION TECHNIQUES

Resistance to conventional antimalarials is escalating, and novel strategies to monitor for resistance are needed. There are no simple bedside methods for assessing antimalarial drug susceptibility. Therapeutic response to antimalarials can be assessed in vivo by using the World Health Organization (WHO) treatment protocols,[11] as well as in vitro by measuring the parasite's sensitivity by inhibition of growth or maturation of blood stages. Both of these strategies have a number of limitations.[12] More recently, a number of studies have begun to elucidate the

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120027605

genetic basis of drug resistance. This information has been translated into molecular assays to characterize malaria isolates for genetic markers of drug resistance. These studies have now been extended, suggesting that these biomarkers can be useful in predicting treatment failures and that they can be used to detect and track global patterns of drug-resistant malaria.[12]

RESISTANCE MARKERS

Molecular markers for drug resistance identified to date include *pfcrt* polymorphisms associated with CQ drug resistance; *dhfr* and *dhps* polymorphisms associated with SP resistance; and *pfmdr1* polymorphisms putatively associated with modulating resistance to CQ, MQ, Q, and artemisinin.[4]

Chloroquine and Quinine

CQ acts by disrupting heme metabolism in the digestive vacuole of *P. falciparum*. CQR parasites survive by preventing the accumulation of CQ within the vacuole; however, the precise mechanism by which this occurs is unknown.[13]

Polymorphisms in two genes of the *P. falciparum* genome have been implicated in molecular CQ resistance studies. The *pfcrt* gene is located on chromosome 7 and codes for PfCRT, a vacuolar membrane transporter protein. Although a number of polymorphisms in this gene are associated with CQ resistance, the substitution of threonine for lysine at position 76 has been shown to be most closely associated with in vivo resistance.[14,15] This association comes with a caveat, namely that some chloroquine-sensitive (CQS) malaria strains also harbor this mutation, suggesting that K76 is required for CQ resistance but that other *pfcrt* polymorphisms must also be involved. However, in vivo outcomes are also clearly influenced by the level of underlying immunity (premunition) to malaria in the individual being treated, and this may limit the ability of mutations in *pfcrt* to predict in vivo outcome following CQ therapy.[16,17] However, the wild-type sequence does reliably predict successful treatment outcome with CQ.

The second *P. falciparum* gene implicated in CQ resistance, *pfmdr1*, is located on chromosome 5 and encodes the p-glycoprotein homologue (Pgh1). The aspartic acid-to-tyrosine point mutation at codon 86 has been associated with CQ resistance, as have a number of other polymorphisms in this gene (Asp 1042, Tyr 1246, Phe 184, and Cys 1034). However, these mutations have not consistently been associated with in vivo CQ resistance, although they may well modulate susceptibility to CQ, MQ, Q, and halofantine.[18] Furthermore, genetic cross-experiments between CQS and CQR parasite lines and parasite transfection studies have not supported a direct role for *pfmdr1* mutations in CQ resistance; rather, these studies have identified mutations in a digestive vacuole transmembrane protein, PfCRT, as causally linked to CQ resistance.[15]

There have been suggestions that *pfmdr1* mutations associated with CQ resistance may also account for reduced parasite susceptibility to Q; however, this needs further confirmatory studies.[19,20]

Mefloquine

The mechanisms of action and resistance to MQ have not been fully elucidated. The *pfmdr1* gene has been investigated as a molecular marker for MQ resistance, but evidence remains controversial. It was suggested that both variations in gene copy number and point mutations at positions 86, 184, 1034, 1042, and 1246 of the *pfmdr1* gene may confer drug resistance, but these findings have been challenged. Some investigations have reported increased sensitivity with the Tyr 86 mutation in *pfmdr1*, whereas others have found no effect.[18] To date, field studies do not consistently support a direct role for these mutations in vivo treatment outcomes.[7]

Sulfadoxine Pyrimethamine (Fansidar™)

The molecular basis of resistance for SP is perhaps the best characterized. Sulfadoxine and pyrimethamine act synergistically, with the former inhibiting dihydroptoate synthase (DHPS) and the latter inhibiting dihydrofolate reductase (DHFR), both of which are enzymes involved in folate synthesis. Point mutations at five *dhps* codons (Gly 437, Glu 540, Gly 581, Ala 436, and Ser 614) have been implicated in resistance to SP by decreasing the binding affinity of the enzyme. Mutations in *dhfr* associated with SP resistance include Ile 51, Arg 59, and Leu 164, with Asn 108 representing the key mutation for SP resistance. The degree of SP resistance increases in a stepwise fashion in response to progressive accumulation of these mutations. In recent in vivo studies in Cameroon and Kenya, the triple DHFR mutation at codons 108, 59, and 51 was associated with early treatment failure,[21] suggesting that these could be useful markers for predicting the therapeutic effectiveness of SP in a given area.[22,23] Of interest, there may be some overlap between existing SP resistance and emergence of resistance to newer antifolate combination drugs such as chlorproguanil dapsone (LAPDAP).[24] Hence, screening of *dhfr* and *dhps* mutations may also provide molecular data to guide the regional implementation of LAPDAP programs.

Atovaquone–Proguanil (Malarone)

ATQ and proguanil operate synergistically. ATQ is a 2-hydroxynaphtoquinolone that disrupts electron transport in the parasite mitochondria at the cytochrome *bc*1 complex and collapses membrane potential, without affecting the host mitochondria.[25,26] Proguanil significantly enhances the ability of ATQ to collapse mitochondrial membrane potential, and the combination drug should slow the emergence of AVQ-resistant parasites. However, mutations in the cytochrome *b*1 gene have appeared and are associated with ATQ/Pro resistance in vitro and in vivo. A *P. falciparum* isolate from a Thai patient with recrudescence after ATQ therapy showed a mutation at codon 268 with a tyrosine-for-serine substitution and an increased IC_{50} of almost 10,000-fold. A small number of ATQ/Pro treatment failures have now been reported primarily in nonimmune patients. Most have involved a N268S mutation, although one patient isolate contained a tyrosine-for-asparagine substitution at the same position.[8,9,27,28] ATQ resistance parasites generated in vitro may possess additional mutations in cytochrome *b*, including mutations at positions 133, 272, and 280, although these mutations impart lower levels of resistance in vitro and have not been observed in patient isolates to date.[29]

MOLECULAR TECHNIQUES FOR THE DETECTION OF ANTIMALARIAL DRUG RESISTANCE

Mutation analysis for antimalarial drug resistance currently includes a variety of strategies including PCR amplification followed by direct sequencing, single-strand conformation polymorphism (SSCP) assays, PCR followed by restriction fragment length polymorphism (RFLP) assays, allele-specific amplification assays, and real-time assays to detect point mutations conferring resistance.

In PCR-RFLP analysis, restriction enzymes are used to cut the PCR product at a specific location, proximal to the mutation site, such that wild-type and mutation-containing fragments display differing digestion patterns on agarose or polyacrylamide gel electrophoresis. SSCP is another gel mobility strategy used to detect single-point mutations in amplified DNA. PCR is used to amplify the region of interest and the resultant DNA is separated as single-stranded molecules by electrophoresis on a nondenaturing polyacrylamide gel. Wild-type and mutant single-stranded DNA fold differently, affecting their motility rate through the gel. The mutations are detected as new bands on autoradiograms (radioactive detection), by silver staining of bands or the use of fluorescent PCR primers that are subsequently detected by an automated DNA sequencer (nonradioactive detection).

Real-time PCR using hybridization probes to identify mutants based on specific melting curve patterns of the amplicon is also being developed.[30] The wealth of genetic information afforded by the completion of the *Plasmodium* genome will certainly help identify new drug targets, further our understanding of the molecular basis of drug resistance, and facilitate the creation of rapid assays for the detection and surveillance of drug-resistant malaria.

CONCLUSION

The predictive value of molecular markers of resistance is best assessed in the context of in vivo field trials using the WHO in vivo model. The association of molecular markers with in vivo resistance is confounded by several factors. First, in vivo studies are often carried out in regions where malaria is hyperendemic and adaptive immunity (premunition) exists. Such immunity may confound the interpretation of drug efficacy because premunition may facilitate clearance of drug-resistant parasites. Second, technical issues may confound interpretation. Many studies fail to check for drug levels to ensure that adequate drug absorption has occurred, thereby overestimating the number of resistant infections. In addition, studies often fail to use techniques to ensure that treatment failures are true recrudescences rather than reinfections.[31,32]

Most current models of resistance assume single-gene models; however, resistance may be multigenic particularly with respect to 4-aminoquinoline drugs such as MQ, and implicated genes and mutations still require further in vivo validation. In contrast, ATQ and SP mechanisms of action are better defined, allowing for a clearer understanding of the role of mutations in key proteins such as CYTb and DHFR/DHPS in mediating resistance. Ultimately, the use of validated genetic markers of drug resistance will facilitate molecular surveillance and global monitoring for emerging drug-resistant malaria, and will potentially serve in predicting treatment outcome.

Platelet Antigen Genotyping

Evelyne Kretzschmar
Heiner Trobisch
Institute for Transfusion Medicine, Duisburg, Germany

INTRODUCTION

Alloantibodies against platelet antigens play an important role in immune-mediated platelet disorders. There are essentially three clinical conditions caused by platelet alloantibodies: platelet transfusion refractoriness, neonatal alloimmune thrombocytopenia (NAIT), and posttransfusion purpura. In NAIT, fetal thrombocytopenia is caused by maternal alloimmunization against antigens on fetal platelets, a condition which may result in life-threatening complications. Typing of the human platelet antigens can be useful for the diagnosis and treatment of these patients. Typing of human platelet antigens is also important for the study of the association of human platelet antigens with an increased probability of developing various diseases. Recently, several studies indicated that polymorphisms underlying platelet antigens might represent genetic risk factors for coronary thrombosis.

In the past two decades platelets were characterized by serological antigen capture assays, such as the monoclonal antibody immobilization of platelet antigens. The introduction of polymerase chain reaction (PCR) technology for amplification of platelet-specific mRNA made the characterization of platelet alloantigens possible at the molecular level and opened the doors for the development of new typing techniques. All but one of the different allelic forms of the human platelet antigens were the result of single nucleotide polymorphisms (SNPs) in the genes encoding the relevant platelet proteins (see below).

In this review, an overview of various genotyping techniques will be presented. New techniques which make human antigen genotyping even more convenient will also be discussed.

HUMAN PLATELET ANTIGENS

Nomenclature

Historically, multiple names existed for the human platelet antigens. In 1990, the Platelet Serology Working Party of the International Society of Blood Transfusion (ISBT) and the International Committee for Standardization in Haematology (ICSH) suggested a numerical terminology which has been widely accepted.[1] The term HPA was introduced to indicate *h*uman *p*latelet *a*ntigen. By convention, ''system'' is assigned to an HPA where both SNP and alloantibodies have been identified. The different antigens are numbered in the order of their discovery. The high-frequency allele of a system is named first (=a) and its low-frequency allele second (=b). The ''W'' after the antigen name is added when alloantibodies for only one allele have been defined. Six biallelic alloantigen systems (HPA-1 to -5 and HPA-15) and the low-frequency antigens HPA-6W to HPA-16W have been described. Table 1 lists HPA types, previous designations, associated nucleotide and amino acid changes, the frequency of each antigen in Caucasians, and the corresponding glycoproteins. Phenotype frequency varies significantly within populations. The Platelet Nomenclature Committee of the ISBT and the International Society of Thrombosis and Haemostasis (ISTH) developed, in 2003, a new nomenclature system.[3] The Platelet Nomenclature Committee maintains a web site with the latest changes, as well as with the positions for the newly assigned single nucleotide polymorphisms.[3]

Most platelet alloantigenic determinants characterized so far were formed by single amino acid substitutions induced by a point mutation of the respective gene. One exception is the rare platelet alloantigen HPA-14W which was formed by one amino acid deletion (Lys611del) of platelet GPIIIa (Table 1).

Some of the ''platelet-specific'' antigens have been detected on other cells as well. Therefore antigens are now called ''platelet associated'' and are divided into two groups: ''platelet-nonspecific'' antigens which are shared by platelets and many diverse cell types, and the ''platelet-specific'' antigens which are uniquely expressed by platelets.

Localization on Platelet Membrane Glycoproteins

The platelet membrane glycoproteins GPIa, GPIbα, GPIbβ, GPIIb, GPIIIa, and GPI-linked CD109 have been

identified as carriers of platelet alloantigenic determinants. Some of these glycoproteins are part of the integrin family and are membrane glycoprotein heterodimers consisting of noncovalently associated α and β subunits. Two platelet membrane receptors that figure prominently in the antigenic profile of platelets, the cohesion receptor GP IIb–IIIa, now called $\alpha_{IIb}\beta_3$, and the collagen receptor GP Ia–IIa ($\alpha_2\beta_3$), are integrins. The GP Ib–IX–V receptor, as another carrier of antigenic epitopes, is an integrin as well. The cohesion receptor is expressed up to 80,000 times on the platelet surface and mediates the common cohesive pathway with adhesive proteins such as the von Willebrand factor and fibrinogen. The platelet collagen receptor plays a major role in the adhesion of platelets to collagens. The Ib–IX–V complex functions as a receptor for von Willebrand factor and enables platelets to interact with blood vessel walls under physiological or stress conditions. Cartoons of GP IIb–IIIa, GP Ia–IIa, and the receptor complex GP Ib–IX–V with major HPA sites are shown in Fig. 1. Their CD nomenclature, their Genbank accession numbers, and their corresponding HPAs are listed in Table 2.

DETECTION OF HUMAN PLATELET ANTIGENS

Many studies have reported successful molecular detection of various HPAs. These techniques are based upon

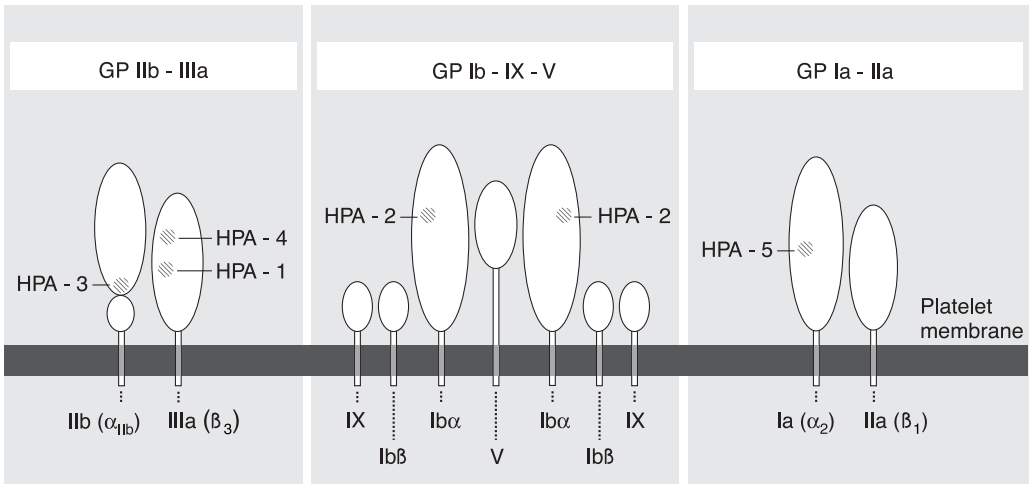

Fig. 1 HPA-1 to -5 on glycoprotein receptors. Three receptor complexes on the platelet membrane with HPA-1 to -5 sites (hatched areas) are shown schematically: the platelet cohesion receptor GP IIb–IIIa, the receptor complex GP Ib–IX–V, and the platelet collagen receptor GP Ia–IIa. The GP Ib–IX–V complex exists on the platelet surface with a suggested stoichiometry of 2:2:2:1 (GP Ibα/GP Ibβ/GP IX/GP V).

conventional PCR where post-PCR steps are required. These conventional techniques will be discussed first and will be followed by discussion of newer techniques not requiring post-PCR steps.

Allele- or Sequence-Specific PCR (SSP-PCR)

Polymerase chain reaction with sequence-specific primers (SSP-PCR) is currently the most widely used technique for HPA genotyping. This approach is based on the principle that a 3′ mismatched nucleotide in a primer-template hybrid will prevent extension during PCR, therefore inhibiting DNA amplification. That is, when the 3′ nucleotide of a primer is complementary to the sequence at the site of allelic variation, a PCR product will be generated. However, when the 3′ nucleotide of the primer is mismatched, the amplification of the template will not occur or will proceed with very low efficiency. For the detection of each HPA allele, two sets of primers are designed, each set containing an allele-specific primer and a common primer. After gel electrophoresis of the PCR product, DNA is stained and analyzed under UV light. The HPA genotype is then determined by the absence or presence of a DNA fragment. As an internal control for the success of the PCR reaction, an additional pair of primers for the amplification of the human growth hormone gene or another gene is usually added to each reaction.

Table 2 Glycoprotein receptors with their subunits and HPAs

Various HPAs have been genotyped by SSP-PCR.[4,5] More references are cited in Ref. [6]. Efforts have been made to standardize the PCR conditions for detecting different polymorphisms. A consensus protocol for genotyping of HPA-1 to -5 and HPA-15 can be found on the platelet immunology pages in the Haematology Division section of the National Institute for Biological Standards and Control web site: http://www.nibsc.ac.uk.

Restriction Fragment Length Polymorphism

Restriction fragment length polymorphism (RFLP) analysis has been implemented for genotyping of platelet antigens in many laboratories. This technique exploits the fact that single nucleotide substitutions may create or abolish a unique enzyme cleavage site. This makes possible allelic discrimination. Genomic DNA is first amplified by PCR using forward and reverse primers flanking the polymorphic region and then subjected to restriction enzyme digestion. The fragments are separated by electrophoresis, stained and analyzed under UV light. The genotype is then interpreted from the restriction pattern.

Polymerase chain reaction–restriction fragment length polymorphism analysis is simple to perform but requires the extra post-PCR step of digestion of the amplified DNA fragment. However, digestion can be incomplete and results in a homozygous individual could be falsely interpreted as heterozygous. Therefore, to avoid undetected incomplete enzyme activity, the amplified DNA fragment should be designed with an additional site for the same restriction enzyme.

Literature for RFLP typing of many HPAs are listed in Ref. [6].

Allele-Specific Oligonucleotide Hybridization

Allele-specific oligonucleotide (ASO) hybridization has been used in several of the initial studies investigating the molecular basis of the HPA alloantigens. This technique utilizes a generic PCR amplification with primers flanking the specific SNP, immobilization on a nylon membrane, and hybridization to labeled allele-specific oligonucleotide probes. Under appropriate hybridization and wash conditions, these probes bind only to their complementary sequence and are able to distinguish single nucleotide differences. The PCR products bound to an allele-specific probe are then detected using a luminescent or chromogenic substrate. Interpretation of the HPA types is based on the presence or absence of positive reactions. Allele-specific oligonucleotide hybridization has been used to detect various HPAs (references are cited in Ref. [6]).

A variation of the ASO technique is the reverse dot-blot hybridization.[7] The ASOs are covalently bound to a nylon membrane and the labeled amplification products are simultaneously hybridized to the probes.

Oligonucleotide Ligation Assay

In the oligonucleotide ligation assay (OLA), gene segments with the polymorphic sites are amplified in a single multiplex PCR. Aliquots of the PCR product are then incubated with pairs of labeled allele-specific probes complementary to contiguous sequences. One probe contains the allele-specific base. Where both probes are bound by complementary sequences, they can be covalently linked by a thermostable DNA ligase to produce a double-labeled product. This double-labeled product can then be detected by an enzyme-linked immunoabsorbent assay (ELISA). If the allele-specific base is absent from the template DNA, annealing of the allele-specific probe is incomplete and ligation cannot occur. No product can then be detected. Oligonucleotide ligation assay does not require the temperature-sensitive hybridization and washing steps used in the ASO technique. The ELISA makes the OLA system suitable for automation. HPA-1 to -5 have been typed with this system (reference in Ref. [8]).

Single-Strand Conformational Polymorphism

The mobility of single-strand DNA in nondenaturing polyacrylamide gels depends on size and tertiary conformation. Single-base changes alter the tertiary conformation such that the single-strand DNA shows a different mobility in the polyacrylamide gels. This is exploited in single-stranded conformational polymorphism (SSCP) to analyze HPA polymorphisms. The method has been used to genotype HPA-1 to -5 and HPA-10W (references are listed in Ref. [8]). The SSCP electrophoresis requires precise temperature control as any variation in temperature can affect single-strand DNA migration.

Preferential Homoduplex Formation Assay

The preferential homoduplex formation assay (PHFA) is based on DNA strand competition between a double-labeled amplicon (a reference double-stranded DNA with each strand separately labeled) and the unlabeled DNA sample. During hybridization with a precisely controlled temperature gradient, preferential formation of a homoduplex occurs more often than a heteroduplex. When

reference DNA and test DNA are identical, heteroduplex formation is favored. If the sequences are not identical, there will be little reduction in the double-labeled population. The reformed double-labeled DNA is immobilized on a microtiter well and detected by ELISA system (for references, see Ref. [8]).

Melting Curve Analysis on the LightCycler®

The new LightCycler PCR technology measures the match of a hybridization probe with the polymorphic region of DNA by melting curve analysis and allows simultaneous detection of both HPA alleles. The LightCycler (http://www.roche-applied-science.com/lightcycler-online/) is a microvolume fluorometer integrated with a thermal cycler that combines rapid thermal cycling for PCR with real-time fluorescence monitoring. First, PCR is performed with two hybridization probes which are labeled with different fluorophores at the adjoining ends. One probe is designed to hybridize to the polymorphic sequence of the PCR templates, and the other hybridizes one to five nucleotides apart on the adjacent region. When these two probes anneal to the PCR template, they are in close proximity, and fluorescence energy transfer (FRET) occurs between the two fluorophores. The emitted fluorescence measured by the LightCycler monitors the amplification process in real time. After the amplification is completed, melting curve analysis allows genotyping. For melting curve analysis, the temperature is lowered below annealing temperature and then slowly increased. At a certain temperature, the probes melt off the DNA template, causing decreased fluorescence. The melting point can then be determined using an algorithm. When probe and PCR product match completely, the melting point is relatively high. A single point mutation, however, makes hybridization weaker and results in a lower melting point. Thus alleles can be easily discriminated. HPA typing on the LightCycler has been accomplished for HPA-1 to -5 and HPA-15.[9–11]

TaqMan® Assay

The TaqMan technology is also based on fluorescent probes. This technique takes advantage of the 5′ nuclease activity of Taq polymerase. TaqMan probes have a reporter dye at the 5′ end and a quencher dye at the 3′ end. The close proximity of the two dyes in the intact probe quenches the fluorescent signal. However, during primer extension, Taq polymerase specifically displaces the annealed probe and allows the 5′-nuclease activity to cleave the probe and release the fluorescent dye. Light is then emitted. Although developed for quantitative real-time PCR, TaqMan technique is suitable for high-throughput SNP analysis. For the biallelic HPA system, two allele-specific probes with two reporter labels, which can be differentiated spectrally, are added into the same PCR mix, allowing single-tube genotyping. References for HPA-1–3 typing are listed in Ref. [8].

CONCLUSION

Once the genetic basis of HPAs had been resolved, a number of techniques for HPA typing were developed. Initially, conventional PCR techniques with elaborate post-PCR steps were introduced. Now, techniques with fluorescent probes have been developed which do not require extra post-PCR steps. These one-tube assays make HPA typing rapid and reliable and less prone to contamination. This makes high-throughput screening an achievable goal. Other techniques, such as minisequencing combined with matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF)[12] or pyrosequencing (http://www.pyrosequencing.com), might become more and more important for large-scale HPA genotyping in the future.

PML/RARA and RARA FISH in Follow-up of Acute Promyelocytic Leukemia

P

Dong Soon Lee
Seoul National University College of Medicine, Seoul, South Korea

INTRODUCTION

Retinoic acid receptor alpha-fluorescent in situ hybridization (RARA FISH) overcomes the drawback of promyelocytic leukemia (PML)/RARA FISH in the follow-up of acute promyelocytic leukemia. This is an analysis on the effectiveness of RARA FISH in acute promyelocytic leukemia (APL) patients during follow-up.

OVERVIEW

Detection of genetic change for t(15;17) is important for the diagnosis of atypical variants of acute promyelocytic leukemia (APL) and for predicting the response to ATRA treatment.[1–4] For this purpose, morphological diagnosis in conjunction with cytogenetics and reverse transcription-polymerase chain reaction (RT-PCR) for promyelocytic leukemia (PML)/retinoic acid receptor alpha (RARA) is generally used. At follow-up after treatment of APL, it is not easy to decide upon remission by morphology. With respect to the discrimination between leukemic promyelocytes and regenerating promyelocytes, many points of discrimination have been suggested;[5] however, the situation is sometimes perplexing. A positive result for RT-PCR in patients with PML after chemotherapy does not mean a persistence of malignant cells, because differentiated leukemic cells by ATRA treatment still harbor the PML/RARA gene rearrangement. Actually, although the majority of APL patients achieve morphological remission after complete remission induced by ATRA, PML/RARA transcripts remain detectable in all cases.[6–8] Hence serial quantitation of leukemic cells harboring the PML/RARA rearrangement is essential in the assessment of complete remission after consolidation.[9]

For the accurate and quantitative detection of minimal residual disease (MRD), real-time RT- PCR is available but is not yet used widely. Furthermore, persistence of PCR positivity in long-term remission without recurrence has been reported,[10] which means those clones with PCR^+ do not always have leukemogenic potential. Therefore the detection of PML/RARA fusion by FISH in the initial follow-up after treatment is very helpful. In addition, there are many factors that can influence the results of PCR, such as the quality of the mRNA, the timing of sampling, and the sensitivity of the RT-PCR assay. Although the sensitivity of FISH (10^{-2}–10^{-3}) is lower than that of PCR (10^{-5}–10^{-6}), the results of FISH are more precise, highly concordant between laboratories, and not influenced by other factors.[11] The only factor that can influence the interpretation of results is the different cutoff value used by laboratories. The scoring of fusion and split signals in FISH may vary by individual, resulting in different cutoff values among laboratories.

Single FISH probes for the PML/RARA fusion gene are commercially available, and the scheme of the PML/RARA probe involves the use of two probes: one from each of the fusion genes, differentially labeled. However, chance of colocalization of differently colored signals in normal specimens can produce some levels of false-positive nuclei with some traditional, two-color, come-together FISH translocation probes. The high normal range of probes with design of the PML/RARA probes is inherent in that design, but extra signal or dual-fusion PML/RARA probes are not available at the present time. This false-positive fusion encountered in normal cells makes it difficult to detect minimal residual disease (MRD) quantitatively, especially during follow-up. If we use RARA probes that are located in the proximal and distal sides of the breakpoint of the RARA gene, the signals would be split, resulting in one green signal, one orange signal, and one fusion signal (1G1O1F), and these probes would enable us to detect the translocations of the RARA gene with any partner chromosomes. The LSI RARA Rearrangement Probe (Vysis, Downers Grove, IL, USA) was originally designed to detect nuclei that have variant rearrangements involving the RARA gene and genes other than PML. However, this probe may also provide better information in the detection of nuclei that have t(15;17), because of its break-apart design.

We performed PML/RARA FISH and RARA break-apart FISH on bone marrow specimen of patients to investigate whether the RARA break-apart probe can overcome the disadvantage of the false-positive fusion signal of the single-FISH (S-FISH) for PML/RARA, and to evaluate the efficiency of RARA break-apart FISH in the diagnosis and monitoring of APL.

MATERIALS AND METHODS

Patient Selection

A total of 78 cases tested for the PML/RARA rearrangement by FISH were retested with a RARA break-apart probe. Of these 78 cases, 27 were examined for the PML/RARA rearrangement by FISH to rule out M3 variant (M3v) at initial diagnosis, 16 cases were typical APL cases, which were positive for the PML/RARA rearrangement by RT-PCR at the time of initial diagnosis, and 21 cases were APL cases for follow-up after induction or consolidation therapy. Fourteen cases with hematological malignancies (non-APL) during the follow-up were included to determine whether there were any cutoff value differences when patients are under chemotherapy vs. the normal controls. To establish the reference range, PML/RARA and RARA FISH were conducted on specimens obtained from bone marrow examinations conducted in 20 normal controls without hematological malignancies (donors for bone marrow transplantation) and from the peripheral blood of 30 healthy persons. We scored the signals in 200 nuclei in each of the samples. Bone marrow mononuclear cells stored in methanol at $-20^{\circ}C$ were used for interphase FISH staining.

Conventional Cytogenetics Study and FISH Study

Bone marrow and peripheral blood samples were processed by conventional cytogenetic procedures with GTG (G bands by trypsin using Giemsa)-banding. Fluorescent in situ hybridization was performed according to the manufacturer's instructions, using an LSI RARA Rearrangement Probe (Vysis Inc.).

Probes of FISH for RARA

The Vysis LSI RARA Dual-Color Rearrangement Probe consists of a SpectrumOrange-labeled probe that

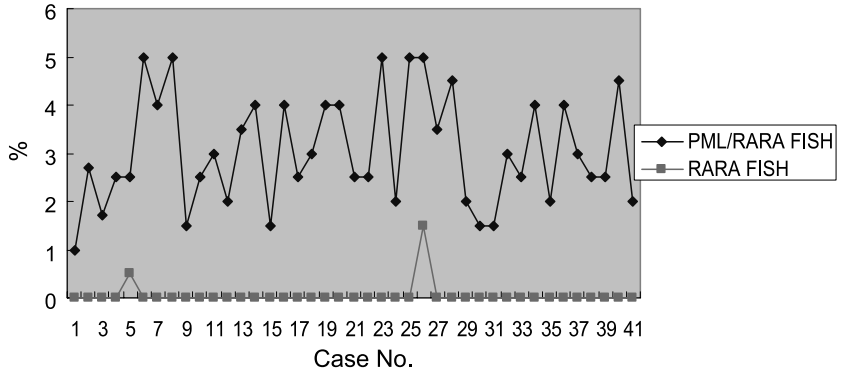

Fig. 2 The quantitative results of PML/RARA FISH and RARA FISH in 21 patients with acute promyelocytic leukemia at follow-up (r=0.75). (*View this art in color at www.dekker.com.*)

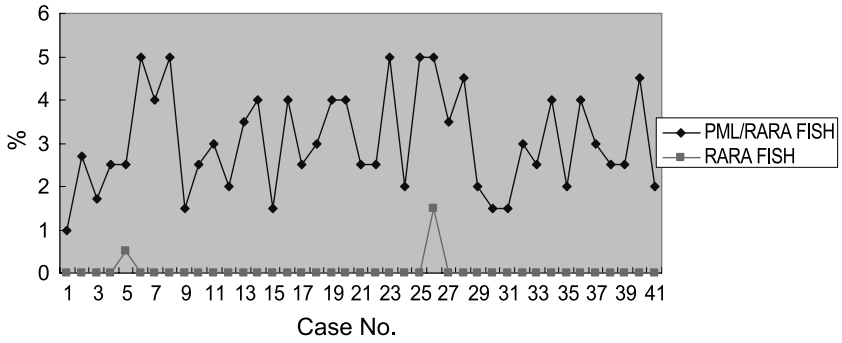

Fig. 3 Comparison of results of PML/RARA FISH and RARA FISH in 41 patients with nonacute promyelocytic leukemia (r=0.233). (*View this art in color at www.dekker.com.*)

hybridizes to a 130-kb region from the breakpoint cluster region (bcr) toward the centromere, and a SpectrumGreen-labeled probe that hybridizes to a 400-kb region. The signal pattern indicative of the RARA gene rearrangement is observed as a separation of the orange and green signals from the normal fusion signal, which indicates that the RARA gene has split.

Probes of FISH for PML/RARA

The Vysis LSI PML/RARA Translocation Probe is a mixture of a PML probe directly labeled with the SpectrumOrange fluorophore and a RARA probe directly labeled with the SpectrumGreen fluorophore.

PML/RARA RT-PCR

Mononuclear cells from the bone marrow or the peripheral blood were separated by dextran centrifugation, and cellular RNA was extracted with RNAsol according to the modified acid guanidium thiocyanate method, and reverse transcripted with avian myelomatous virus reverse transcriptase (Boehringer-Mannheim, Germany) with random primer according to the method of Borrow.[13]

RESULTS

Normal Range of PML/RARA and RARA Rearrangement by FISH

In PML/RARA FISH, the mean signal of 101G1F was 3.12% with a standard deviation of 1.02%, and therefore 6.2% was set as the normal reference range (mean ±3 S.D.). In RARA FISH, the mean signal of 1O1G1F was 0.05% with a standard deviation of 0.35%, and 1.2% was set as the reference range (mean±3 S.D.).

Comparison of PML/RARA, RARA FISH, and Cytogenetic Study in APL Patients at Initial Diagnosis and During Follow-up

The quantitative results of PML/RARA FISH and RARA FISH in 16 patients with acute myeloid leukemia (APL) at initial diagnosis showed good correlation (r=0.83): mean±S.D. was 95.3±6.5% for PML/RARA and 97.0±7.0% for RARA. The quantitative results of RARA FISH were rather higher than those of PML/RARA (Fig. 1). The quantitative results of PML/RARA FISH and RARA FISH in 21 patients with APL at follow-up were well correlated (r=0.75): mean±S.D. was 2.81±3.07%

Table 1 Analysis of the positive cases of RARA rearrangement FISH in comparison with results of PML/RARA translocation FISH

	PML/RARA		Positive RARA
Total (n=62)	≥5%	12 Cases	5 Cases
	< 5%	50 Cases	0 Cases
Initial diagnosis (n=27)	≥5%	3 Cases	1 Cases
	< 5%	24 Cases	0 Cases
Follow-up (n=35)	≥5%	9 Cases	4 Cases
	< 5%	26 Cases	0 Cases

PML/RARA, promyelocytic leukemia/retinoic acid receptor alpha.

for PML/RARA and 0.90±2.07% for RARA. In contrast to the situation at initial diagnosis, the quantitative results of RARA FISH were rather lower than those of PML/RARA at follow-up (Fig. 2). Of 62 cases with the results of PML/RARA fusion (1.0% to 11.6%), 46 cases (74.2%) showed absolute negative results (0%) with RARA split FISH. Interestingly, when we analyzed the results of non-APL patients, the results of PML/RARA and RARA were not correlated well (r=0.23), in contrast to those of APL patients (Fig. 3).

In 21 patients with APL during follow-up after chemotherapy, four cases showed positive signals for PML/RARA FISH over 6.2%, and three of these four cases showed a positive signal for RARA FISH over 1.5% (Table 1). These three cases (9.5%, 2%, and 2.5% positive signal for RARA FISH) showed continued remission by bone marrow examination and normal karyotypes by cytogenetic study after 6 months.

DISCUSSION

The present study differs from previous studies in that the normal control, for setting the reference range for the PML/RARA and RARA signals, included non-APL patients (14 cases) with hematological malignancies at the time of follow-up after chemotherapy, rather than normal individuals. We attempted to determine whether the alignment of chromosomes in the interphase after chemotherapy could affect the interpretation of FISH. Almost no difference was found in the reference ranges for PML/RARA between 20 specimens of normal bone marrow and 14 specimens of the bone marrow of non-APL patients at follow-up (p value=0.17, Student's t test). However, a difference was found in the cutoff values between 30 specimens of peripheral blood (5.47%) and 20 specimens of normal bone marrow (6.21%). The results of normal bone marrow were higher than those of peripheral blood, although the difference was not significant statistically (p value=0.59, Student's t test).

If a normal cutoff of 5% for PML/RARA FISH is applied, which is the same as the remission criterion (5%) by morphology, conducting FISH will not give any additional information. From the aspect of minimal residual disease detection, RARA FISH with a lower reference range of 1.5% would be more informative. Although the reference range of FISH does not usually matter in making a decision about APL at initial diagnosis, this range could significantly affect the clinical determination of complete remission during the treatment of APL, as positive RT-PCR results are frequently obtained after induction therapy, irrespective of the achievement of remission.

According to the results of the present study, the advantages of performing RARA FISH are that 1) false positivity due to the design problem of PML/RARA FISH can be reduced; 2) accurate quantitative results can be obtained; and 3) the interpretation difficulty experienced when the result is around the normal reference range with PML/RARA FISH can be resolved by RARA FISH. Thus at the time of follow-up of APL, employing RARA FISH would be more effective. Nevertheless, as it is important to determine the presence or absence of t(15;17) in the diagnosis of APL, PML/RARA FISH or PML/RARA RT-PCR needs to be considered at the time of initial diagnosis, and when their result is positive, we recommend performing RARA FISH, not PML/RARA FISH, during follow-up. On the other hand, in those cases that are difficult to interpret, because the PML/RARA FISH results are around the reference range, we believe that RARA FISH helps in the interpretation. We also recommend examining quantitative changes through repeated follow-up tests in each case during follow-up, rather than giving significance to only one test.

CONCLUSION

The cutoff value for RARA rearrangement must be changed by using the RARA split probe. In this study, using the RARA split probe, we were able to lower the cutoff value for the RARA rearrangement down to 1.05%, which is significantly lower than the 5–10% of PML/RARA. Actually, 82.7% of cases with PML/RARA positivity by FISH showed absolutely negative results with the RARA split probe.

P

PNA–FISH—Application for Chromosomal Analysis and Other Forms of Genetic Testing

Franck Pellestor
Institute of Human Genetics, Montpellier, France

INTRODUCTION

Both the study and the development of modified oligonucleotides have known a significant upsurge of interest during the last decade and have become a central feature of biotechnology because of the tremendous potential of modified oligonucleotides as therapeutic agents and tools in molecular biology. Among all the synthetic nucleic acid analogs designed, the peptide nucleic acids (PNAs) constitute a remarkable class of nucleic acid mimics with important properties, which have been incorporated into an expanding variety of hybridization-based applications, including genome mapping, antigene therapy, mutation detection, and chromosome analysis.

PNA CHEMISTRY AND PROPERTIES

The first report concerning the design and properties of PNAs was published in 1991 by Nielsen et al.[1] PNAs are synthetic DNA analogs in which the phosphodiester backbone is replaced by repetitive units of *N*-(2-aminoethyl) glycine to which the purine and pyrimidine bases are attached via a methyl carbonyl linker (Fig. 1). The PNA molecules can routinely be labeled with biotin or fluorophores such as fluorescein or rhodamine.

A subsequent generation of PNAs could involve modification of the *N*-(2-aminoethyl) glycine backbone (PNA analogs) or chimeric architecture, such as PNA–peptide chimeras or PNA–DNA chimeras developed to improve the solubility and the cellular uptake of PNAs or to exhibit new biological properties. The synthetic backbone provides PNA with unique hybridization characteristics. Unlike DNA and RNA, the PNA backbone is not charged. Consequently, there is no electrostatic repulsion when PNA hybridizes to its target nucleic acid sequence, giving a higher stability to the PNA–DNA or PNA–RNA duplexes than the natural homo- or heteroduplexes. This greater stability is reflected by a higher thermal melting temperature (T_m) as compared to the corresponding DNA–DNA or DNA–RNA duplexes.

An additional consequence of the polyamide backbone is that PNAs hybridize virtually independently of the salt concentration. This property can be exploited when targeting DNA or RNA sequences involved in secondary structures, which are destabilized by low ionic strength. This facilitates the hybridization with the PNAs. The unnatural backbone of PNAs also means that PNAs are not degraded by nucleases or proteases. Because of this resistance to the enzyme degradation, the lifetime of PNAs is extended both in vivo and in vitro. Also, PNAs are not recognized by polymerases and therefore cannot be directly used as primers or be copied.

Peptide nucleic acids hybridize to complementary DNA or RNA in a sequence-dependent manner, according to the Watson–Crick hydrogen bonding scheme. In contrast to DNA, PNA can bind in either parallel or antiparallel fashion. However, the antiparallel binding is favored over the parallel one. PNA is able to adopt both A- and B-type structures when associating with RNA and DNA, respectively, and PNA–PNA duplexes formed an unusual helix conformation, called P type, and characterized by a large pitch of 18 base pairs.

Peptide nucleic acid probes can bind to either single-stranded DNA or RNA, or to double-stranded DNA (dsDNA). Homopyrimidine PNAs, as well as PNAs containing a high pyrimidine/purine ratio, bind to complementary DNA sequences to form highly stable $(PNA)_2$–DNA triplex helices displaying T_m over 72°C. In these triplexes, one PNA strand hybridizes to DNA through standard Watson–Crick base pairing rules, whereas the other PNA strand binds to DNA through Hoogsteen hydrogen bonds. The resulting structure is called P loops. The stability of these triple helixes is so high that homopyrimidine PNA targeted to purine tracts of dsDNA invades the duplex by displacing one of the DNA strands.[2]

Finally, PNA–DNA hybridization is significantly more affected by base mismatches than DNA–DNA hybridization. A single mismatch in a mixed PNA–DNA 15-mer duplex decreases the T_m by up to 15°C, whereas in the corresponding DNA–DNA complex, a single mismatch decreases the T_m by only 11°C. This high level of discrimination at single-base level has indicated that short PNA probes could offer high specificity and has thus allowed the further development of several PNA-based strategies for molecular investigations and diagnosis.

APPLICATIONS

Since its introduction, an increasing number of applications of PNA technology have been described, confirming the high potential of PNAs as a tool for molecular biology techniques.

Antisense and Antigene Applications

Originally conceived as agents for double-stranded DNA binding, the unique properties of PNAs as a DNA mimics were first exploited for gene therapy drug design. PNAs can inhibit transcription (antigene) and transcription (antisense) of genes by tight binding to DNA or mRNA.

Peptide nucleic acid-mediated inhibition of gene transcription is mainly due to the formation of invaded strand complexes or strand displacement in a DNA target. Several in vitro studies have shown that the binding of PNA or bis-PNA to dsDNA can efficiently block transcriptional elongation and inhibit the binding of transcriptional factors and helicases.[3] PNA targeted against the promoter region of a gene can form stable PNA–DNA complexes that restrict the DNA access of the polymerase, whereas PNA complexes located far from the promoter can block the polymerase progression and lead to the production of truncated RNA transcripts. Nielsen et al.[4] have demonstrated that even an 8-mer PNA can efficiently block transcriptional elongation by $(PNA)_2$–DNA triplex formation.

Peptide nucleic acids are able to interact with mRNA independently of the RNA secondary structure. However, unlike other antisense agents, PNA–RNA duplexes are not recognized by RNase-H. Studies on the mechanisms of antisense activity have demonstrated that PNA inhibits expression differently than antisense oligonucleotides acting through RNase-H-mediated degradation of the mRNA–oligonucleotide hybrid. Because PNAs are not substrates for RNAse, their antisense effect acts through steric interference of either RNA processing, transport into cytoplasm, or translation, caused by binding to the mRNA.

Application of PNAs as antisense reagents was first demonstrated in 1992. The nuclear microinjection of a 15-mer PNA targeting the translation start region of SV40 large T antigen mRNA inhibited transcription in cell extracts.[5] This inhibition was both sequence specific and dose dependent. More recently, Mologni et al.[6] reported the effect of three different types of antisense PNAs on the in vitro expression of PML/RARalpha gene. It was also reported that intron–exon splice junctions are very sensitive targets for PNA antisense probes because correct mRNA splicing can be altered by PNA binding.[7]

Although these in vitro results strongly emphasized the potential of PNAs for antigene and antisense applications, the limiting factors for in vivo use of PNAs are the weak uptake of PNAs by living cells. Several modifications of PNAs have led to significant improvements. Cellular uptake can be speeded up by coupling PNA to DNA oligomers, to receptor ligands, or more efficiently, to peptides such as cell-penetrating peptides that are rapidly internalized by mammalian cells. Reports have demonstrated that PNAs conjugated to such peptides are efficiently taken up by eukaryotic cells.[8,9] Another strategy adapted to improve the in vivo delivery of PNA can be their incorporation into liposomes.

PCR and Q-PNA PCR

Peptide nucleic acid probes have no direct interaction with DNA polymerase but PNAs can terminate the elongation of oligonucleotide primers by binding to the template or competing with the primers.[10] Moreover, PNA–DNA chimeras can be recognized by the DNA polymerase and can thus be used as primers for PCR reactions.[11] The high-affinity binding of PNAs has also been used for detecting single base pair mutations by polymerase chain reaction (PCR). This strategy, named PNA-directed PCR clamping, uses PNAs to inhibit the amplification of a specific target by direct competition of the PNA targeted against one of the PCR primer sites and the conventional

PCR primer.[12] More recently, novel automated real-time PCR has been developed using PNAs. In this method, named Q-PNA PCR, a generic quencher labeled PNA (Q-PNA) is hybridized to the 5′ tag sequence of a fluorescent-dye-labeled DNA primer to quench the fluorescence of the primer. During PCR, the Q-PNA is displaced by incorporation of the primer into amplicons and the fluorescence of the dye label is liberated.[13]

Nuclear Acid Capture

Peptide nucleic acids can be used for sequence-specific capture of single-stranded nucleic acids, taking advantage of the tight complex formation at low ionic strength, which destabilizes nucleic acid secondary structure. Several studies have reported such applications of PNAs. Short PNA probes can then be used as generic capture probes for purification of nucleic acids.[14]

Solid-Phase Hybridization Techniques

Peptide nucleic acids can be used in many of the same hybridization applications as natural or synthetic DNA probes but with the added advantages of tighter binding and higher specificity. This leads to faster and easier procedures in most standard hybridization techniques, such as Southern and Northern blotting. An alternative to Southern analysis is also the PNA pregel hybridization process, which significantly simplifies the procedure of Southern hybridization.[15] Labeled PNAs are then used as probes, allowing hybridization to a denatured dsDNA sample at low ionic strength before loading on the gel. The method is sensitive enough to detect a single mismatch in a DNA sample. Another gel-based strategy, known as affinity electrophoresis can be exploited with PNA probes. In this case, the slowdown of DNA during electrophoretic passage is related to its hybridization with a complementary PNA probe entrapped in the gel matrix. Likewise, hybridization PNA-based biosensor procedures have been developed in which a single-stranded PNA probe is immobilized onto optical or mass-sensitive transducers to detect the complementary strand or corresponding mismatch in a DNA sample solution. The hybridization events are converted into electric signals by the transducers.[16]

Fluorescence In Situ Hybridization (PNA–FISH)

The efficiency of PNAs as hybridization probes has also been demonstrated in fluorescence in situ hybridization (FISH) applications. The properties of PNAs have allowed the development of fast, simple, and robust in situ assays. Because of their neutral backbone, PNA probes present in situ high specificity and require low concentrations and short hybridization time. Additional in situ benefits of using PNA probes are reduced background binding, low photobleaching, and mild washing procedure. In situ labeling can efficiently be obtained with a single 15-mer PNA oligomer carrying a single label.

The PNA–FISH technique was first developed for quantitative telomere analysis. Using a unique fluorescein-labeled PNA probe, Lansdorp et al.[17] performed the in situ labeling of human telomeric repeat sequences and the data obtained allowed accurate estimates of telomere lengths. Subsequently, telomeric PNA probes were used in several in situ studies of cancer and aging.[18] Further developments were focused on the in situ specific identification of human chromosomes on both metaphases and interphase nuclei, using PNA probes specific for satellite repeat sequences of various chromosomes. Multicolor PNA experiments were thus reported on lymphocytes (Fig. 2), amniocytes, and fibroblasts from normal subjects and patients with numerical abnormalities.[19,20] These experiments demonstrated the superiority of PNA probes over satellite DNA probes in both intensity and sequence discrimination. Chen et al.[21] reported that PNA probes could discriminate in situ between two centromeric DNA repeats that differ by only a single base pair. The discriminating power of PNA could be very useful for the study of chromosomal variations and

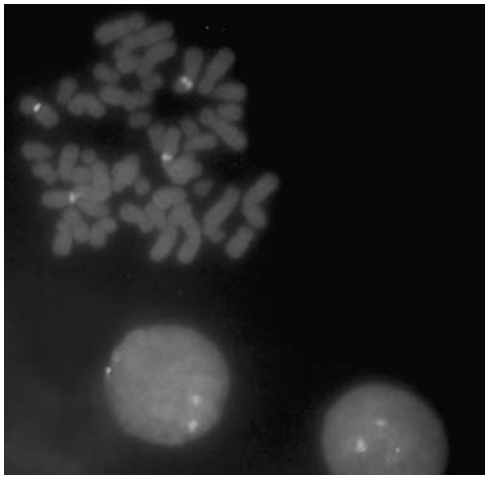

Fig. 2 In situ identification of chromosomes 1, X, and Y on human metaphase and interphase nuclei using multicolor PNA–FISH procedure with satellite-specific PNA probes. Chromosome 1 is labeled in blue, chromosome X in red, and chromosome Y in green. (*View this art in color at www.dekker.com.*)

polymorphisms. Recently, PNA–FISH has been adapted to in situ chromosomal analysis of the human sperm.[22] This adaptation constituted an interesting challenge because of the particularities of human spermatozoa nuclei in terms of genomic compaction and accessibility of DNA sequences. Comparative estimates of disomies X, Y, and 1 were performed in sperm from healthy subjects using FISH, primed in situ labeling (PRINS), and PNA procedures in parallel. Equivalent quality of in situ nuclear labeling and similar results was obtained with the three methods. However, the hybridization timing of PNA probes (i.e., 45 min) appeared to be significantly shortened in comparison with FISH reaction on sperm. The fast hybridization kinetics of PNA was similar to the kinetics of PRINS reaction.[23] The similarity between PNA and PRINS might be essentially due to the small size of both PNA probes and PRINS primers, which do not exceed 30 bases in length. This finding points out the importance of the probe size for in situ assays and, consequently, the great potentiality of the PNA approach, because high specific binding can be obtained with a short, unique PNA oligomer. This study also demonstrates the efficiency of multicolor PNA procedure on male gametes and shows that PNA could be a powerful alternative to FISH and PRINS for in situ chromosomal investigations.

CONCLUSION

Since their invention, PNAs have quickly evolved from basic research to the application of PNA technology to diagnosis procedures. PNA-based applications benefit from the unique physicochemical properties of PNA molecules, enabling development of simple and robust assays. The data presented here illustrate the large number of PNA applications in genetics and cytogenetic testing. Very powerful applications of PNAs have also emerged in microbiology, virology, and parasitology. New chemical modifications of the original PNA backbone may contribute to increasing the potentialities of PNAs and lead to the development of novel applications and PNA-dependent projects in many areas of biology and biotechnology.

PNA–FISH—Applications for Rapid Diagnosis of Bloodstream Infections

P

Henrik Stender
AdvanDx, Inc., Woburn, Massachusetts, U.S.A.

INTRODUCTION

Bloodstream infections have become an important ''disease'' in the industrialized world and are associated with significant morbidity and mortality. Each year, an estimated quarter million hospital-acquired bloodstream infections and a similar number of community-acquired bloodstream infections occur in the United States alone. The ''disease'' has further intensified due to the emergence of methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and an increasing number of fungemia caused by non-*Candida albicans* yeasts—all associated with increased costs and mortality.

Today, the diagnosis of bloodstream infections is based on Gram staining of positive blood culture bottles; however, the final identification and susceptibility results are not available until 1–3 days later. Therefore, meanwhile, patients are often treated empirically, and delayed laboratory results have little impact on patient therapy, leading to an inappropriate use of broad-spectrum antibiotics.

Peptide nucleic acid fluorescence in situ hybridization (PNA–FISH) is a novel in vitro diagnostic platform, which has recently been applied for rapid and accurate diagnosis of bloodstream infections. Benefiting from the unique features of PNA probes, PNA–FISH assays enable clinical microbiology laboratories to report important information for patient therapy within a time frame not possible using current methods.

THE PNA–FISH PLATFORM

PNA Probes—A Superior Probe Molecule For Diagnostics

PNA probes hybridize in a sequence-specific manner to DNA and RNA by obeying Watson–Crick base-paring rules.[1] However, because of their structure, PNAs have significant advantages compared with DNA probes, as outlined below:

- *Higher sensitivity*: PNA binds stronger and faster to complementary RNA or DNA, thereby facilitating the development of more rapid and sensitive diagnostic tests. Where DNA probes often require overnight incubation, reactions with PNA are completed within a few hours.[2]
- *Higher specificity*: PNA probes are particularly well suited for discriminating closely related sequences, even single nucleotide differences, thus making PNA-based assays 100% definitive.[3]
- *Robust assays*: PNA is a synthetic molecule resistant to nucleases and proteases. It is extremely stable in prepackaged kit formats, as well as during the actual assay when in contact with the sample.[4]
- *Novel assay formats*: The unique properties of PNA enable the development of assay formats that go above and beyond the possibilities of DNA probes, thereby reducing the complexity related to the performance of molecular diagnostic tests.[5]
- *No target limitation*: The noncharged backbone allows PNA probes to hybridize under conditions that are destabilizing to DNA and RNA. Attributes that enable PNA probes to access targets, such as highly structured rRNA and double-stranded DNA, are known to be inaccessible to DNA probes.[6]
- *In situ hybridization*: The hydrophobic nature of PNA relative to DNA makes PNA probes superior for in situ hybridization assays where the probes must penetrate the hydrophobic cell wall prior to hybridization.[7]

rRNA—A Superior Phylogenetic Marker

Comparative ribosomal RNA (rRNA) sequence analysis has become a widely accepted method for establishing phylogenetic relationships between bacterial species, and rRNA sequence information has become a well-established method for microbial identification.[8]

rRNA sequence differences between closely related species enable the design of species-specific probes targeting almost any microorganism. Such probes are obvious reagents for microbial identification and enable diagnostic microbiology to be based on a single genetic marker rather than a series of biochemical tests.

PNA–FISH—An Intelligent Stain

PNA–FISH is a novel technique that combines the simplicity of current staining methods such as Gram staining with the specificity of molecular techniques (Fig. 1).[9] In this way, presumptive detection of the causative agent routinely performed by microscopical examination can be improved to provide final identification. Importantly, PNA–FISH is performed directly on smears fixed onto microscope slides by standard methods, such as flame fixation, methanol fixation, or heat fixation, without any other pretreatment or permeabilization steps known from DNA-based tests.

PNA–FISH uses rRNA as target not only because of its phylogenetic superiority as described above, but also because each microorganism harbors several thousand rRNA molecules. This abundance of rRNA target molecules allows individual cells to be detected and identified directly by fluorescent-labeled probes, also called ''phylogenetic stains''[10]—attributes that make the PNA–FISH technology extremely simple and user-friendly compared with polymerase chain reaction (PCR) and other molecular technologies.

Moreover, the PNA–FISH concept is directly compatible with a variety of sample types.[9] Blood cultures, as will be reviewed later, are one example where the complex medium contains well-known inhibitors and interference substances, such as sodium polyanetholesulfonate, charcoal particle, or resins, for diagnostic procedures. Numerous attempts to perform blood culture identification directly from the positive blood culture bottles have been reported in the past, but with variable sensitivities and specificities, and have often only been evaluated on a single blood culture medium and rarely on highly complex media with charcoal or resins. In contrast, PNA–FISH is compatible with all major blood culture media[11]—a key feature that is ascribed to the inert and synthetic PNA probe molecule.

IN VITRO DIAGNOSTIC APPLICATIONS

The generic PNA–FISH assay procedure allows PNA–FISH to be applied for various blood pathogens without procedural changes, such that separate tests can be performed in parallel. Using the results from Gram staining, appropriate PNA–FISH tests can be selected to identify or rule out relevant pathogens (Fig. 2).

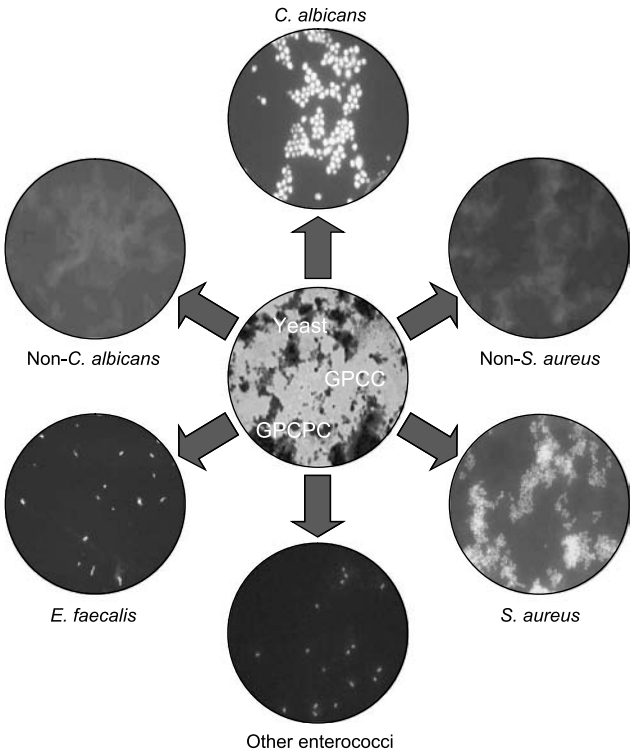

Fig. 2 Application of PNA–FISH tests for direct identification of positive blood culture bottles. The result of the Gram stain provides a basis for the selection of appropriate PNA–FISH test. GPCC: *S. aureus* PNA–FISH is used to identify *S. aureus*. Negative test results are indicative of coagulase-negative staphylococci. GPCPC: *Enterococcus faecalis* PNA–FISH is used to distinguish *E. faecalis* from other enterococci. Negative test results (not shown) are indicative of streptococci. Yeast: *C. albicans* PNA–FISH is used to identify *C. albicans*. Negative test results are indicative of non-*C. albicans* species. (*View this art in color at www.dekker.com.*)

Identification of *S. aureus* in GPCC-Positive Blood Culture Bottles

S. aureus bacteremia is both a serious and frequent nosocomial and community-acquired infection that is further complicated by the emergence of methicillin-resistant *S. aureus* and, recently, vancomycin-resistant *S. aureus*[12] which are ascribed to the widespread use of these antibiotics in healthcare settings. *S. aureus* is preliminary identified as gram-positive cocci in clusters (GPCC) along with other staphylococci; however, whereas *S. aureus* is often clinically significant, other staphylococci, such as *Staphylococcus epidermidis*, are often contaminants and not clinically significant. Therefore, rapid identification of *S. aureus* and differentiation from other staphylococci directly from positive blood culture bottles are important for patient diagnosis and selection of appropriate therapy to reduce empirical therapy with broad-spectrum antibiotics, such as ampicillin and vancomycin.

S. aureus PNA–FISH is based on a fluorescein-labeled PNA probe targeting *S. aureus* rRNA for both rapid and accurate identification of *S. aureus*. The performance of *S. aureus* PNA–FISH has been reviewed elsewhere[9] and showed 97.3–100% sensitivity and 98.9–100% specificity in four separate studies.[11,13–15]

Identification of *E. faecalis* in GPCPC-Positive Blood Culture Bottles

VRE have become a serious nosocomial pathogen because of the widespread use of vancomycin and require aggressive therapy with novel antibiotics, such as linezolid and quinupristin/dalfopristin. Resistance to vancomycin and also ampicillin among enterococci is primarily associated with *Enterococcus faecium* and a few other rare-occurring *Enterococcus* species, whereas *E. faecalis*, the most frequent species accounting for approximately two thirds of enterococcal isolates, is rarely resistant to these antibiotics. Therefore rapid identification of *E. faecalis* and differentiation from other enterococci directly from positive blood culture with gram-positive cocci in pairs or chains (GPCPC) are important to institute appropriate antibiotic therapy and to limit aggressive therapy to *E. faecium* and others with increased resistance to ampicillin and vancomycin.

E. faecalis PNA–FISH is a novel dual-color approach using a fluorescein-labeled PNA probe targeting *E. faecalis* and a rhodamine-labeled PNA probe targeting other enterococci, including *E. faecium*. Negative results are indicative of streptococci. The performance of *E. faecalis* PNA–FISH has been reviewed elsewhere[9] and showed 92.8–100% sensitivity and 88.9–100% specificity in two separate studies.[16,17]

Identification of *C. albicans* in Yeast-Positive Blood Culture Bottles

The number of candidemia cases has increased during the past decade because of the increasing population of immunocompromised patients, organ transplantations, and the common use of intravascular devices. Furthermore, species distribution is changing such that the prevalence of *C. albicans* is decreasing because of the emergence of other *Candida* species, in particular *Candida glabrata* and *Candida parapsilosis*.[18] Whereas *C. albicans* is often susceptible to fluconazole, *C. glabrata* and other emerging species, such as *Candida krusei*, have a different resistance pattern. Therefore rapid and accurate methods for species identification of yeast in blood cultures are important for the selection of appropriate antifungal therapy. Rapid identification of *C. albicans* and differentiation from other yeast species are particularly important as they allow the majority of cases caused by *C. albicans* to be treated safely and cost-effectively with fluconazole, such that only the remaining cases caused by other *Candida* species require ''empirical'' treatment with amphotericin B, a broad-spectrum but nephrotoxic drug, until further identification and susceptibility results become available.

C. albicans PNA–FISH contains a fluorescein-labeled PNA probe targeting *C. albicans* rRNA that can distinguish *C. albicans* from the closely related *Candida dubliniensis* often identified as *C. albicans* by standard methods. The performance of *C. albicans* PNA–FISH has been reviewed elsewhere[9] and showed 100% sensitivity and 100% specificity in two separate studies.[19,20]

UNLIMITED OPPORTUNITIES

The applications reviewed previously were all related to rapid and accurate identification of blood culture bottles with yeast or gram-positive bacteria; however, PNA probes for important gram-negative bloodstream pathogens, such as *Escherichia coli* and *Pseudomonas aeruginosa*, have also been described[21] and are obvious candidates for an almost complete test panel for blood culture identification. The PNA–FISH platform has also been studied in several other applications, such as *Mycobacterium tuberculosis* in acid-fast bacilli (AFB)-positive sputum samples,[7] cultures,[22] and biopsies,[23] and *Trypanosome brucei* in blood smears,[24] with the latter being the first PNA–FISH application on parasites and yet another example of the broad applicability of the PNA–FISH platform.

Therefore, PNA–FISH offers almost unlimited opportunities for novel diagnostic applications to not just

replace existing tests, but also to offer attractive solutions to unmet diagnostic needs that potentially lead to better patient therapy and management.

CONCLUSION

Rapid and accurate diagnosis of bloodstream infections by PNA–FISH is an important application utilizing the unique attributes of PNA probes to provide important diagnostic information in time to support the selection of appropriate antibiotic therapy. Furthermore, PNA–FISH has several similarities to standard staining technique, making it easily adaptable for routine testing without the need for specialized equipment, laboratory facilities, or personnel, as often required for molecular techniques.

It is well accepted that empirical use of antibiotics plays an important role in the spread and emergence of antibiotic resistance, and that a more appropriate use of antibiotics requires new and rapid diagnostic tests to change from empirical treatment practices based on clinical symptoms and worst-case scenarios to more personalized therapies based on individual diagnostic information. The speed and accuracy, combined with the simple and universal assay procedure, make PNA–FISH a promising tool for the development of therapy-directing diagnostics—the new generation of diagnostics.

Pneumocystis jiroveci

Hans Henrik Larsen
Jannik Helweg-Larsen
Bettina Lundgren
Hvidovre University Hospital, Hvidovre, Denmark

INTRODUCTION

Pneumocystis is an unusual opportunistic fungus which causes a severe and—if untreated—lethal pneumonia (*Pneumocystis* pneumonia, or PCP) in immunocompromised humans and mammals.

Two major difficulties have hampered the study of PCP. First, no reliable in vitro system for the cultivation of *Pneumocystis* exists, and although animal models are widely used, considerable genetic difference between human *Pneumocystis* (*Pneumocystis jiroveci*) and *Pneumocystis* spp. infecting other mammalian species exists. Second, live organisms have never been detected outside its hosts, and clinical samples containing large quantities of *P. jiroveci* organisms are not easily obtained. As a consequence, the study of the organism and the infection has relied greatly on molecular and immunological approaches. These have led to the identification of clinical relevant antigens and enzymes, and have enabled typing. The latter is of outmost importance in elucidating the epidemiology of human pneumocystosis.

The standard method for diagnosis of PCP is microscopical examination of invasive lower respiratory tract specimens. Molecular detection systems have the potential to provide a higher degree of sensitivity than microscopy. Therefore PCR methods have been applied to clinical specimens for diagnosing PCP, and oral wash examination by PCR may be an alternative as a noninvasive diagnostic test.

PNEUMOCYSTIS—THE ORGANISM

Pneumocystis is a eukaryotic extracellular lung pathogen that has been detected in almost every mammalian species evaluated for its presence.

Pneumocystis was long considered as a protozoan based on morphological features and its resistance to classical antifungal agents. However, in the late 1980s, *Pneumocystis* was included in the fungal kingdom based on phylogenetic analysis of ribosomal RNA (rRNA) sequences and observations of genome size. This position was substantiated by functional and phylogenetic comparisons of several other genes.[1]

Pneumocystis organisms were first identified and named *Pneumocystis carinii* in the beginning of the last century. Studies including chromosomal karyotyping, nucleotide sequence analysis, antigenic characterization, and experimental transmission of infection have shown that *Pneumocystis* has considerable genetic diversity and host specificity. Thus an interim trinomial name change was adopted to reflect the diversity (e.g., *P. carinii* f. sp. *hominis* for *Pneumocystis* infecting humans). Finally, in recognition of the special forms' genetic and functional distinctness as separate species, human *Pneumocystis* was renamed *P. jiroveci*.[2]

In the lungs, two major forms of the organism can be identified by light microscopy: the cystic form (cysts) and the trophic form (trophozoites). The cystic form (sporangium) is thick-walled, oval, approximately 5–8 μm in diameter, and contains up to eight intracystic bodies (endospores), which will become trophic forms after excystation. The trophic form (yeast) is small (2–5 μm), thin-walled, pleomorphic, and often has an eccentric nucleus. The trophozoites are often seen in clusters. Not much is known about the lifecycle, and the mode of replication has not been definitely established, but both asexual and sexual life cycles have been proposed.

CLINICAL MANIFESTATIONS

Pneumocystis is primarily an opportunistic pulmonary pathogen, causing PCP. Extrapulmonary pneumocystosis is very rare.

PCP was an uncommon disease occurring in immunocompromised patient populations until the beginning of the 1980s, when it emerged as a significant cause of morbidity and mortality among human immunodeficiency virus (HIV)-infected patients.[3] PCP remains one of the most common acquired immunodeficiency syndrome (AIDS)-defining events, despite the use of prophylaxis and highly active antiretroviral therapy (HAART).[4]

The major presenting symptoms of PCP are shortness of breath, fever, and nonproductive cough. Immunosuppressed, HIV-uninfected patients are typically sick for days to 2 weeks before seeking medical attention, whereas PCP in HIV-infected patients typically has a more

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020895

insidious onset, with symptoms lasting several weeks. The organism burden is higher, but the lung damage less severe in HIV-infected patients.

On physical examination, tachypnea and tachycardia are found in acutely ill patients. Although lung auscultation is usually not helpful, the chest radiograph classically exhibits diffuse bilateral interstitial infiltrates. Atypical findings range from normal examination to unilateral localized findings.

The magnitude of impaired arterial oxygenation is used to evaluate the severity of the disease, with a p_aO_2 of 70 mmHg discriminating between mild to moderate disease and severe disease. In addition, serum lactic dehydrogenase levels can be of some help in evaluating the severity of lung injury, but the analysis is nonspecific for PCP and lung injury.

TREATMENT

Management of PCP has improved over the past decades: chemoprophylaxis is used routinely during periods of immunological susceptibility in various patient populations, and if an episode of PCP does occur, the prognosis is improved because of earlier diagnosis and earlier institution of therapy. The use of adjunctive corticosteroid treatment for moderate to severe PCP has also led to a decrease in mortality.

Few advances in drug treatment have occurred during the past 20 years. The major chemotherapeutic agents available for treatment of PCP in the pre-HIV era were parenteral pentamidine and trimethoprim sulfamethoxazole (TMP-SMX). To date, TMP-SMX remains the drug of choice for both treatment and prophylaxis of PCP because of its well-established safety and efficacy, as well as its low cost. Alternatives, if the patient is intolerant or fails TMP-SMX, include dapsone-containing regimens, pentamidine (intravenous form for treatment and aerosolized form for prophylaxis), atovaquone, and clindamycin/primaquine (treatment only).

The oral route can be used to treat mild to moderate cases of PCP when no obvious gastrointestinal dysfunction is apparent. All patients with severe disease should be placed on an intravenous regimen and should receive adjunctive corticosteroid therapy.

MOLECULAR CHARACTERIZATION OF *PNEUMOCYSTIS*

The genomes of *Pneumocystis* species infecting mice, humans, rats, and ferrets have been estimated to be 6.5, 7.0, 7.7, and 11 Mb of DNA, respectively, which are relatively small genome sizes for a fungus when compared with, for example, the 12-Mb *Saccharomyces cerevisiae* genome. Chromosome organization has not been definitely determined because extensive chromosome polymorphism has been characterized among different strains of rat *P. carinii*. By pulsed field gel electrophoresis (PFGE), the estimation is that the genome of rat *P. carinii* is likely divided into 15 chromosomes of 0.3–0.7 Mb size.[5] There is an ongoing sequencing project with a goal to provide physical maps and gene sequences for the entire genomes of rat *P. carinii* and human *P. jiroveci* (http://biology.uky.edu/Pc/).

Phylogenetic analysis based on nuclear 16S-like RNA has not identified any close relatives, but fungal organisms on neighboring branches include the fission yeast, *Schizosaccharomyces pombe*. However, in contrast to most other fungi, *Pneumocystis* has a fragile cell wall and contains little or no ergosterol.

The typical *Pneumocystis* gene is rich in A and T (60–65%), and contains numerous (up to nine) introns of less than 50 bp length.[5]

To date, the major surface glycoprotein (MSG; also called glycoprotein A) is the only antigen of human *P. jiroveci* that has been well characterized.[6] MSG is the most abundant surface protein present in all *Pneumocystis* strains examined to date. The 95- to 140-kDA MSG is encoded by a multicopy gene family, distributed among all chromosomes. This protein has a crucial role in interactions with the host, possibly by acting as an attachment ligand to lung cells, and in elicitation of an immune response. MSG shows a high level of antigenic variation by switching the expression of MSG genes using a single expression site termed the upstream conserved sequence (UCS).[7] It is likely that it serves for evasion of the host immune response by use of antigenic variability.

Recombinant MSG fragments have been generated, which could be used in serological studies investigating the epidemiology of human pneumocystosis.[8,9]

A number of genes encoding enzymes have been described. Of particular potential clinical interest is the dihydropteroate synthase (*DHPS*) gene encoding the target enzyme of sulfa drugs. Nonsynonymous mutations occurring at six nucleotide positions, resulting in amino acid changes, have been reported.[10] Two of these mutations, encoding amino acids at positions 55 and 57, are located in the active site of the enzyme, and mutations at homologous positions have been shown to cause sulfa resistance in other organisms. Most studies have found a correlation of these two *DHPS* mutations with prior sulfa exposure, suggesting evolutionary selective pressure of sulfa drugs and hence a pharmacologically significant effect. The clinical significance of *DHPS* mutations still has to be elucidated.

Because *P. jiroveci* cannot be readily cultured,[11] one can speculate that molecular methods could eventually

provide the means for assessing the antibiotic susceptibility of a particular *Pneumocystis* ''isolate.''

MOLECULAR TYPING OF *PNEUMOCYSTIS*

Pneumocystis is likely transmitted through the respiratory route. The reservoir for *P. jiroveci* is unknown, but could include other human or environmental sources, whereas animal reservoirs are unlikely due to host specificity.[12] Serological studies suggest that a high proportion of healthy individuals has had a primary infection during childhood.[13] It is still debated whether PCP is caused by reinfection or reactivation of latent infection.

Development of a typing system for *P. jiroveci* is critical for investigating the transmission and epidemiology of PCP. Clinical samples contain relatively small amounts of organisms mixed with host DNA, and pure extractions of the organism are difficult or impossible to obtain. Therefore, standard genetic methods such as karyotyping or random amplification of polymorphic DNA cannot be performed. Thus, investigation of the epidemiology has relied on PCR-based DNA sequence analysis.

Different sequence types of *P. jiroveci* have been identified in a number of genetic loci (Table 1). Because of the relatively low discriminatory power of several of these loci, alternatives were sought. The internal transcribed spacer (ITS) regions, ITS1 and ITS2, of the rRNA locus have been central to the study of genomic variations and taxonomic relationships in fungi and other species. In contrast to other fungi, *Pneumocystis* possesses only one

Table 1 Genes used in the typing of *P. jiroveci*

copy of this locus. Studies have revealed that several ITS types exist (Table 1).

Single-strand conformation polymorphism (SSCP) analysis and restriction fragment length polymorphism (RFLP) assays have been investigated as alternatives to DNA sequencing.[14,21] These methods require prior characterization of the polymorphisms to be analyzed.

Although application of these typing methods has not yet provided unequivocal data on the mode of transmission and epidemiology of human pneumocystosis, studies continue to address these questions. At this point, molecular approaches seem to be the most promising way to investigate the epidemiology of *Pneumocystis*.

MOLECULAR TESTING FOR *PNEUMOCYSTIS*

The standard method for diagnosis of PCP is direct microscopical visualization of *Pneumocystis* organisms in invasive lower respiratory tract specimens (e.g., bronchoalveolar lavage, or BAL).

Upper respiratory specimens usually present insufficient numbers of organisms to enable diagnosis by microscopy, but PCR increases the sensitivity.[22] Even oral washes, which are easily obtained by gargling the mouth with sterile saline, are suitable for PCR diagnosis.[23] Various PCR assays targeting different genes and the use of nested PCR, in which a second round of PCR reamplifies the primary PCR product, have been investigated.[24] However, some of these PCR techniques employed have been too complicated for routine use in a clinical laboratory. Single-round PCR is to be preferred for diagnostic purposes because nested PCR offers a limited increase in diagnostic sensitivity with an increased risk of biological false-positive results (carryover contamination). Choosing a multicopy gene target provides increased sensitivity compared with a single-copy target. Furthermore, employment of touchdown PCR may increase the sensitivity. An internal inhibitor control is recommended to be included in a diagnostic assay. Oligonucleotide sequences and PCR conditions for three different PCR assays are presented in Table 2.

Although PCR methods have the potential to be very sensitive, specimens have been reported to be positive by PCR in patients without clinical PCP, who are presumed to be colonized with *Pneumocystis*. Recent research suggests that organism burden, as assessed by quantitative PCR, is higher in cases of PCP compared with cases of colonization.[25] If these findings are supported by further investigation, quantitative real-time PCR could improve the specificity by distinguishing between infection and colonization.

In addition, the viability of *P. jiroveci* organism may be assessed by the study of *Pneumocystis* mRNA, which could offer a potential method for monitoring treatment.[26]

CONCLUSION

Pneumocystis is an unusual organism, which has been determined to be a fungus by phylogenetic analysis of DNA sequences.

Because of our inability to culture the organism in vitro, molecular and immunological techniques have had

Table 2 Selected PCR assays, targeting three different multicopy genes using touchdown PCR

great impact on our understanding of the organism itself and of PCP.

The main fields of research that have benefited from the development of these techniques include characterization of the basic biology of the organism, biology and epidemiology of PCP, and diagnosis of PCP. Although much is still to be learned about this organism and PCP, it is likely that molecular approaches will continue to be among the most important tools available. The ongoing project to sequence the genome will, when finished, provide important information for investigators conducting research on *Pneumocystis*.

Point-of-Care Testing (POCT)—Nucleic Acid-Based Testing in a Point-of-Care Setting

Jürgen Fuchs
Maurizio Podda
J.W. Goethe University, Frankfurt, Germany

INTRODUCTION

The latest achievements in molecular biology and medicine and the evolution of new diagnostic microdevices are driving the implementation of nucleic acid-based technologies (NABT) in the medical laboratory and are contributing to the emerging utilization of point-of-care testing (POCT). These developments will be changing the medical laboratory and medicine in general. With the increasing recognition of new infectious diseases, the potential threat of global bioterrorism, the evolving identification of genetic markers for disease risk and drug side reactions, and new technology available, there is an increased interest in the potential applications of nucleic acid-based tests in a point-of-care setting. Several years ago nucleic acid-based technologies (NABT) seemed to move only slowly into the medical laboratory,[1] but currently several nucleic acid-based tests have already replaced traditional assays and turned into gold standard, in particular in the field of diagnostic microbiology.[2] Differentiating POCT from regular laboratory testing is somewhat artificial, but is a useful simplification from the health-care management perspective to describe testing by nonlaboratoty staff using specialized diagnostic equipment adapted for near-patient applications. Point-of-care testing has a number of names and definitions: ancillary testing, bedside testing, alternate site testing, and decentralized testing all mean POCT. Point-of-care testing includes simple self-care tests that patients can perform by themselves at home, tests that are performed in the doctor's office, and tests that are performed by personnel, e.g., in the intensive care unit, the emergency room, the ward, or in the battlefield area.

HISTORIC DEVELOPMENTS

Before clinical laboratories evolved in the late 19th and 20th century, simple laboratory testing was performed next to the patient, such as organoleptic analysis (perceived by a sense organ) of body fluids and excrements. An archaic example of POCT from ancient times is tasting the patients' urine to analyze the presence of glucose indicative of diabetes. With the beginning of modern clinical chemistry centrally located laboratories emerged, and later laboratory testing transformed medicine fundamentally when it became available on a broad scale and even more so as it became automated. The trend toward miniaturization, portability, and simplicity of use in combination with the advance of a black-box technology is again changing medicine fundamentally,[3] allowing personnel who do not have intensive training in laboratory medicine or molecular biology to run moderately or highly complex analytical tests. This will result in some reembodiment of laboratory testing in the primary health-care provider's hand, but in contrast to prelaboratorian times, the personnel will be equipped with the finest technology on the market.

QUALITY ISSUES

Point-of-care testing has many advantages and disadvantages, and numerous arguments have been raised in support of and against it.[4–6] A discussion of this topic is out of the scope of this contribution, but data indicate that POCT has (may have) a positive benefit on morbidity and mortality.[7–9] The cost of POCT is usually greater than traditional laboratory testing, but the increased cost may be offset by improvements in the management of patient care, improvements in patient outcomes, and decreased utilization of the health-care system.[7,9] An underestimated aspect of POCT is the importance of established quality-management procedures. These procedures have to ensure that POCT results are accurate, reliable, and performed by competent personnel, and that regulatory compliance is achieved.[10,11] Concerns over the quality of POCT have resulted in a hierarchy of laboratory regulations, and POCT guidelines are appearing in a number of countries worldwide.[12,13] In the United States, all laboratories are required to be CLIA (Clinical Laboratory Improvement Amendments) certified (http://www.cms.gov/clia), and several physician's office laboratories have been forced to close their doors in

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120040338

response to regulatory restrictions.[14] The continuing integration of nucleic acid-based POCT in the health-care system is considerably affected by quality-regulations matters, and these measures serve as an excellent controlling instrument.

BLACK-BOX TECHNOLOGY

The development of microfluidic systems,[15] nanotechnology-based lab-on-a-chip devices,[16] micro-total analysis systems (uTAS),[17] and microelectromechanical systems (MEMS)[18] is one of the driving forces for the implementation of nucleic acid-based testing in the point-of-care setting. For example, microelectromechanical systems (MEMS) can revolutionize the commercialization of diagnostic tests by development of compact, potentially disposable, automated diagnostic systems that could be used to perform molecular diagnosis in a point-of-care setting. These systems can be used for automated sample preparation and analysis, such as cell separation, nucleic acid purification, nucleic acid amplification and detection.[18] It was predicted that the health-care implications of successfully developed MEMS are enormous, including rapid identification of disease and risk condition, as well as more accessible health-care delivery at a lower total cost.[19] Recently, a biochip device was developed that integrates sample preparation with PCR and DNA microarray. The on-chip analysis starts with the preparation process of a whole-blood sample, which includes magnetic bead-based target cell capture, cell preconcentration and purification, and cell lysis, followed by PCR amplification and electrochemical microarray-based detection. This biochip performs pathogenic bacteria detection or hemochromatosis genotyping from a whole-blood sample within about 4 and 3 hr, respectively.[20] Another example is the Verigene™ device from Nanosphere, Northbrook, USA. The Verigene™ is a handheld nucleic acid analyzer, which performs clinical sample processing and real-time PCR detection in one instrument, and is scheduled to be available for use at the end of 2004.

ROLE OF NUCLEIC ACID-BASED TECHNOLOGY IN POCT

Nucleic acid-based technology is considered to be of critical importance to public health worldwide and is transforming clinical microbiology, pathology, genetics, pharmacogenetics, prenatal, and preimplantation medicine.[21] Nucleic acid-based technology will also have a significant impact on forensic diagnostics, veterinary medicine, food hygiene and technology, and monitoring of genetically modified agricultural products.

Genetics

Primary-care physicians are playing an increasing role in selecting and counseling patients, and in interpreting genetic test results, which are usually performed in specialized genetic laboratories. Currently, the number of laboratory tests to diagnose monogenic diseases is slowly increasing, and DNA testing is now available for more than 1000 inherited diseases (694 clinical testing and 345 research-only testing) (http://www.geneclinics.org). Mass screening has already commenced for a few of these diseases such as cystic fibrosis, sickle cell disease, hereditary hemochromatosis, and thrombophilias, which have a high prevalence and penetrance. The real challenge lies in the molecular diagnosis and prognosis of complex, multifactorial diseases, but testing for most of these disorders is still experimental. Because of the highly sensitive nature of genetic testing, professional practice guidelines have been developed, and, in addition to these general guidelines, special laboratory guidelines have been developed. It was proposed that testing for disease-causing mutations will become routine, and in time will be used massively in both hospital and community medicine,[22] but currently the implementation of POCT for hereditary diseases is impeded by strict regulations.

Pharmacogenetics

Much of the individual variation in drug response is due to genetic polymorphisms of drug-metabolizing enzymes, and genomic testing for drug-metabolizing enzymes has significant potential for improving the efficiency of drug treatment and reducing adverse drug reactions and thus promises to improve future health care in a number of ways. It is very likely that these tests will make up a significant proportion of total nucleic acid-based testing in the coming years.[23] Currently, however, only a few pharmacogenetic tests and associated products are commercially available, and most are for research use only. Pharmacogenetic tests pose fewer risks for the patient than genetic tests for disease mutations; however, these tests still raise several ethical, economical, and regulatory issues that need to be addressed before they can be integrated into medicine in a large scale.[24]

Microbiology

Molecular theranostics is an emerging concept in clinical microbiology in which molecular biology tools are used to provide rapid and accurate diagnostic assays to enable better initial management of patients and more efficient use of antimicrobials.[25] These applications will probably evolve into standard laboratory and POCT protocols.

Especially in virology, the application of both qualitative and quantitative nucleic acid detection techniques has had a major impact on diagnostics.[26] Point-of-care testing for biological warfare agents by ''nontrained'' personnel using devices such as the RAPID™ (Idaho Technology, Salt Lake City, USA), and handheld instruments such as the RAZOR™ (Idaho Technology), or the BioSeeg™ (Smiths Detection, Edgewood, USA) is already the reality.[27] It seems to be just a matter of time when this kind of technology will become available for primary-care providers for routine microbiological testing in the point-of-care setting.

Pathology

Nucleic acid-based tests have found major applications in pathology, particularly in oncology, and the number of clinically useful molecular assays in the routine clinical pathology laboratory is continuously expanding.[28,29] One example is human papillomavirus (HPV) testing by nucleic acid-based methods, which is becoming an integral part of cervical cancer screening.[30,31] However, several issues still need to be clarified before HPV screening can be recommended unequivocally.[32,33] Another example is evaluation of molecular alterations in fecal DNA, which is a potential, noninvasive, alternative tool for the detection of colorectal cancer and may be suitable for POCT. Stool testing by a multitargeted DNA-based assay has the potential to improve the effectiveness and efficiency for colorectal cancer screening, but the clinical value of this nucleic acid-based test still needs to be assessed by further studies.[34]

POCT MARKET ANALYSIS

The POCT market is expected to be a rapidly increasing and very lucrative market. The spectrum and the total volume of POCT are continuously expanding, and the market of POCT devices is growing at a 5% rate per year. It was estimated that in the developed world just 25% of laboratory testing took place outside the central laboratory in 1998, but this figure is estimated to grow to 45% by 2008.[35] This increase will be most prominent in the United States, but similar trends exist in Europe, Australia, and Asia.[36] In addition, there is a tendency to move laboratory testing away from the clinical chemical laboratory to other diagnostic laboratories, e.g., to pathology, hematology, or oncology. It was estimated that the diagnostic molecular pathology laboratory of the early 21st century will perform 5–10% of the volume of all laboratory testing.[35] Aging of the population in the industrialized Western world will cause a substantial increase in home health care, and in association with telemedicine, POCT is believed to have a significant impact on the management of these patients.[37,38] Many drug stores and supermarkets sell over-the-counter POCT kits intended for home use. These developments will move away test volume from the central laboratory to the point-of-care setting and thus shifting financial volumes away from the laboratory to POCT providers, triggering a distribution conflict. ''POCT is a game of tug-of-war, it's pulled and pushed and shoven between laboratorians, physicians, nurses and other health care providers'' (Karen Titus, contributing editor and comanaging editor of *CAP TODAY*, 2004). Various government guidelines and legislation impact the use of POCT and some of these regulations can be considered strategies in a turf war between the traditional provider of laboratory tests and the new incoming POCT providers.

CONCLUSION

Point-of-care testing is a fact of life in nearly every health-care institution in the Western world. Point-of-care testing is definitely not a replacement for conventional laboratory service but a supplement. It seems realistic that some parts of diagnostics will inevitably leave the central clinical laboratory to be performed instead at the bedside, in the doctor's office, or even at the patient's home. Miniaturization of in vitro diagnostics and NABT will play a significant role in this scenario. Many clinical disciplines deal with a wide spectrum of nucleic acid-based diagnostic assays, including tests for infectious diseases, neoplasias, and inherited diseases, which have the potential to be used at the point-of-care setting. Examples are pathology,[28,29] hematology,[39] oncology,[40] urology,[41] dermatology,[42] obstetrics and gynecology,[43,44] pediatrics,[45] and STD specialty.[46] With the development of prenatal and preimplantation diagnostics, ''obstetrics has been claimed to have assumed a natural leadership position in molecular diagnostics, not only in terms of applied technology, but also in the social, clinical, economical, and political ramifications of these technologies.''[47] The integration of POCT in the health-care system, particularly the implementation of NABT in the point-of-care setting, and finally patient care, will profit more from an inter- and multidisciplinary management approach between equals than by the ''natural leadership position'' of an individual discipline. It remains to be seen what the health-care system will look like when all the critical issues of POCT and NABT have

been resolved, and what impact these changes will have on medical practice in general, laboratory medicine, and on the individual patient in particular.

Polymer Nonviral Delivery Vehicles

P

Ernst Wagner
Ludwig-Maximilians-Universität, Munich, Germany

INTRODUCTION

Polyplexes are based on the condensation of negatively charged DNA by electrostatic attraction with polycationic condensing compounds. The resulting compact particles protect the nucleic acid and also improve the uptake into the cells. Numerous polycations have been used for formulating DNA into complexes. Ideally, the cationic polymer will carry out multiple tasks which include compacting DNA into particles that can migrate to the target tissue, shielding the particles against degradation and undesired interactions, and enhancing cell binding and intracellular delivery into cytoplasm and the nucleus. In practical terms, the polymer is unable to carry out all these tasks. Additional functional domains have to be integrated into the formulation. Advantageously, polymers can be chemically linked to molecules such as cell-targeting ligands, including proteins (antibodies, growth factors) and small molecules (carbohydrates, peptides, vitamins). Various polymer–ligand gene delivery systems have been demonstrated to facilitate receptor-cell-mediated delivery into cultured cells. Targeted delivery to the lung, the liver, or tumors has been achieved in experimental animals, either by localized or systemic application.

TARGETED POLYPLEXES FOR GENE THERAPY

Polycations for DNA Complex Formation

DNA-binding polycations include synthetic polymers such as polylysine, polyethylenimine, cationic dendrimers, carbohydrate-based polymers such as modified chitosan or dextran, and natural DNA-binding proteins such as histones or protamines. The characteristics of these polymers and their use in transfections have been reported extensively.[1–3] Of the ''first-generation'' cationic polymeric carriers evaluated, polyethylenimine,[4] also termed PEI, has the highest transfection efficiency. This can be explained by its intrinsic ability to facilitate endosomal release. The polymer acts as a ''proton sponge,'' containing protonable amines which after endocytosis slow down endosomal acidification, triggering enhanced endosomal chloride accumulation followed by osmotic swelling and breaking up of endosomes.[5] Biocompatible and biodegradable polymers with further enhanced efficiency would be advantageous. Approaches currently under evaluation include the use of low-molecular weight polymers oligomerized into larger polymeric structures by biodegradable, connecting disulfide linkages[6] or esters.[7,8]

In Vivo Applications of Polyplexes

For targeted delivery into a distant organ, the following factors have to be taken into account (Fig. 1): ideally 1) DNA polyplexes are stable and inert in blood; 2) they must be able to reach their target tissue and therefore to cross different biologicals barriers, including vascular endothelium, extracellular matrix, and others; 3) once reaching the target cell they should internalize; 4) should disassemble at the right moment, but still protect the DNA against intracellular degradation; 5) release the DNA into the nuclear compartment; 6) they must elicit as low an inflammatory or immune response as possible. Although no polyplex or other nonviral gene transfer system exists which would fulfill all these requirements, targeted delivery to the lung, the liver, or tumors has already been achieved in experimental animals (Table 1).

Several strategies have been evaluated for gene transfer to the lung. Systemic application of PEI polyplexes resulted in very high gene transfer to the lung.[9] In this application, the linear polymer form of PEI mediates a much higher transfection activity than branched PEI of similar molecular weight.[10] However, a positive charge ratio (cation of polymer to DNA phosphate anion ratio) is required, with a narrow window between efficiency and severe toxicity, as PEI/DNA activates the lung endothelium and forms small aggregates.

As an alternative approach, Ferkol and colleagues generated polylysine polyplexes for targeting the polymeric immunoglobulin receptor by using an antibody Fab fragment as ligand conjugated with polylysine. Systemic delivery of these polyplexes in rats resulted in reporter gene expression in cells of the airway epithelium and submucosal glands.[11] Also, different lung-targeted ligand–polylysine polyplexes were evaluated, using a

synthetic peptide ligand for the serpin–enzyme complex receptor. These polyplexes upon nasal administration were able to transiently correct the chloride transport defect in the nasal epithelium of CF mice.[12]

Targeted gene transfer to the liver was reported by Wu and Wu.[13] DNA/asialoorosomucoid–polylysine complexes were administered for targeting to the hepatocyte-specific asialoglycoprotein receptor, and intravenous (i.v.) injection in rats resulted in marker gene expression in rat livers. This work was the very first successful in vivo application of a targeted polyplex system for gene transfer. Using the same type of formulation, Nagase analbuminemic rats were injected with a human albumin expression plasmid, followed by partial hepatectomy.[14] Circulating human albumin increased in concentration to a maximum by 2 weeks postinjection and remained stable for further 2 weeks.

A synthetic hepatocyte-directed, multifunctional polyplex system was applied by the group of Nishikawa et al.,[15] consisting of DNA complexed with polyornithine which was modified with galactose (to serve as asialoglycoprotein receptor ligand) and a fusogenic peptide derived from the influenza virus hemagglutinin subunit HA2 (to serve as endosomal release domain). Upon intravenous injection in mice, a large amount of a marker gene product was detected in the liver, with the hepatocytes contributing more than 95% of the total activity in all tissues. In another approach, a conjugate of low-molecular weight PEI with Pluronic 123 (a block copolymer of polyethylene oxide and polypropylene oxide) was synthesized by the group of Nguyen et al.[16] In combination with unmodified Pluronic 123 and DNA, the conjugate forms small and stable complexes which after i.v. injection into mice exhibit highest gene expression in liver.

Targeting tumors might present a unique opportunity to reach and attack multiple-spread metastases. Direct intratumoral delivery of PEI polyplexes has been investigated. Expression levels were low, and a special form of administration, the local infusion of PEI polyplexes into the tumor mass by a micropump,[17] had to be applied to obtain satisfactory results. As an alternative for lung tumors, Gautam and colleagues successfully delivered PEI polyplexes to lung metastases of melanoma as aerosol through the airways.[18]

A series of targeted DNA polyplex formulations with the potential of systemically targeting tumors have been established. A charge-neutral surface of the DNA particles is essential to minimize nonspecific interactions with blood components, allowing greater intravenous circulation time for the vector to reach its target, and also reducing vector toxicity.[4] The hydrophilic shielding agents investigated include the serum protein transferrin and hydrophilic polymers such as hydroxypropyl methacrylate or polyethylene glycol (PEG). For example, transferrin-shielded polyplexes[19] or PEG-shielded polyplexes[20,21] demonstrated potential for systemic in vivo targeting of tumors. Intravenous injection resulted in gene transfer into distant subcutaneous neuroblastoma tumors of syngeneic mice[19–21] with luciferase marker gene expression levels in tumor tissues approximately 100-fold higher than in other organ tissues. Specificity was confirmed by luciferase imaging in living mice.[22] In analogous manner, EGF–PEG-coated polyplexes were successfully applied for systemic targeting of human hepatocellular carcinoma xenografts in SCID mice.[23] Similar observations of in vivo hepatoma targeting were made with polylysine polyplexes linked with EGF-derived peptides and an endosomally active peptide.[24]

Table 1 In vivo delivery of polyplexes

Polyplex system	Delivery mode	Target organ	Results	Reference
PEI	Intravenous	Lung	High lung gene expression, toxicity	[9]
Anti pIgR–polylysine	Intravenous	Lung	Highest expression in lung; also in liver	[11]
SECR ligand–polylysine	Intranasal	Nasal epithelium	Functional CFTR gene transfer	[12]
ASOM–polylysine	Intravenous	Liver	First demonstration of targeted gene transfer	[13]
Galactose–polyornithine–HA2 peptide	Intravenous	Liver	Hepatocyte-targeted gene expression	[15]
Pluronic–PEI	Intravenous	Liver	Highest gene expression in liver	[16]
PEI	Infusion into tumor	Tumor	Micropump required	[17]
TfR-targeted, shielded PEI	Intravenous	Tumor	Up to 100-fold higher expression in tumor	[19,21]
EGF–PEI, PEG shielded	Intravenous	Hepatoma	Up to 100-fold higher expression in tumor	[23]

ASOM, asialoorosomucoid; EGF, epidermal growth factor; PEG, polyethylene glycol; PEI, polyethylenimine; SECR, serpine–enzyme complex receptor; TfR, transferrin receptor.

Therapeutic Approaches Using Polyplexes

Table 2 lists an example of therapeutic concepts evaluated in animal models. Using the first targeted in vivo gene delivery system developed,[13] Wu and colleagues demonstrated hepatocyte-specific gene transfer of the LDL receptor in a rabbit animal model for familial hypercholesterolemia. This resulted in a temporary amelioration of the disease phenotype.[25] In analogous manner, the albumin serum levels of Nagase analbuminemic rats were transiently raised by human albumin gene delivery.[14]

For cancer, Gautam and colleagues[18] successfully delivered PEI polyplexes expressing the p53 gene as aerosol through the airways to established melanoma lung metastases, which, especially in combination with 9-nitrocamptothecin chemotherapy, resulted in tumor growth inhibition.

Polyplexes with appropriate surface shielding can target the tumor tissue and exploit the unique neovasculature for extravasation from the blood stream (compare Fig. 1) and delivery of therapeutic genes into the tumor tissue. Repeated systemic application of transferrin- and/or PEG-shielded polyplexes encoding tumor necrosis factor alpha (TNF-alpha) into tumor-bearing mice induced expression in tumor cells close to the feeding blood vessels, which triggers TNF-mediated destruction of the tumor vasculature, tumor necrosis, and inhibition of tumor growth as demonstrated in several

Table 2 Examples for therapeutic strategies using polyplexes

Polyplex system	Delivery mode	Gene (target organ)	Therapeutic result	Reference
ASOM–polylysine	Intravenous (rat)	Human albumin (liver)	Human albumin in serum of Nagase rat	[14]
ASOM–polylysine	Intravenous (rabbit)	LDL receptor (liver)	Reduced hypercholesterolemia	[25]
PEI	Aerosol (mice)	p53 (lung metastases)	Growth inhibition of established lung metastases	[18]
TfR-targeted, shielded PEI	Intravenous (mice)	TNF-alpha (tumors)	Tumor necrosis, inhibition of tumor growth	[21]
EGFR-targeted polylysine	Intravenous (mice)	p21WAF-1, GM-CSF (hepatoma)	Inhibition of hepatoma growth	[24]

ASOM, asialoorosomucoid; EGFR, epidermal growth factor receptor; GM-CSF, granulocyte macrophage-colony stimulating factor; LDL, low density lipoprotein; PEI, polyethylenimine; TfR, transferrin receptor; TNF, tumor necrosis factor.

murine tumor models.[21] The gene expression of TNF-alpha was localized within the tumor; no significant systemic TNF-related toxicities were observed. Systemic administration of combined p21(WAF-1) and GM-CSF genes formulated into EGF receptor-targeted polyplexes inhibited the growth of subcutaneous hepatoma cells and increased the survival rate of tumor-bearing mice.[24] It remains to be demonstrated whether encouraging findings such as those obtained in mice can be transferred to studies in larger animals and humans.

CONCLUSION

Targeted delivery to the lung, the liver, or tumors has been achieved in experimental animals, either by localized or systemic application. Therapeutic effects have been demonstrated, although efficiencies currently appear to be still too low to justify clinical use. The limitations of first-generation polymeric carriers (modest activity and significant toxicity) have to be overcome by developments of new biodegradable polycationic polymers, incorporation of targeting and intracellular transport functions, and polyplex formulations that avoid unspecific adverse interactions with the host. A key future step will be the further development of polyplexes into ''artificial viruses,'' i.e., polyplexes possessing viruslike entry functions which are presented by smart polymers and conjugates. These ''smart'' polymers in contrast to conventional polymers have to respond in a more dynamic and controlled manner to alterations in their biological microenvironment such as pH or redox environment, and have to undergo programmed structural changes, to more accurately switch on the individual delivery functions only when required in the individual steps (Fig. 1) of the delivery process.

INTRODUCTION

This brief presentation cannot replace in-depth textbooks (e.g., Gelfand et al.).[1] The principle of the polymerase chain reaction (PCR) method is outlined in Fig. 1. Although it looks simple, a genius like Kary Mullis was needed for its invention, initially using the heat-labile Klenow enzyme as DNA polymerase, which had to be replenished in each amplification cycle.[2] Mullis, at that time employed by Cetus Corporation in California, was awarded the Nobel Prize in Chemistry in 1993. Since then, PCR technology has radically changed the face of medicine and biology. The basics of the method and some special applications will be outlined.

BASICS OF PCR TECHNOLOGY

The original goal of the PCR inventors was to develop a new diagnostic technology for the detection of an otherwise hardly traceable virus. The intended amplification procedure should work with tiny amounts of DNA, generating millions of amplicons from a single copy of the virus genome. Optimization of basic PCR protocols[1] for the amplification of specific targets involves several steps:

1) *Considerations for the amount of input PCR template*: In theory, a single target copy can be amplified (30 PCR cycles will yield up to a billion-fold amplification or femtomole amounts of amplified PCR product). But statistical variations will always result in undesired blank samples, and a threshold of 3–10 copies is a more practical lower limit. But there is also a maximum of input target, which should not exceed 10^5–10^6 copies. Apart from rapid consumption of all PCR components, rapid reannealing of both DNA strands leads to kinetic interference with primer hybridization or elongation, and PCR products can act as primers. As a drastic consequence, only a smear of PCR products with divergent sizes will be observed due to premature polymerase termination and staggered priming of PCR products.
2) *Primer design*: Length should be between 18 and 30 nucleotides with a GC content in the range of 40–60%. The following features should be avoided: complementarity of two or more nucleotides at the 3′ ends of primer pairs (to reduce formation of primer dimers); T at the 3′ end (3′-terminal T increases mismatch tolerance); complementarity within the primers and between primer pairs (detailed help is available from numerous software programs, e.g., the free *primer3* at www-genome.wi.mit.edu/genome_software/other/primer3.html or the commercial PrimerExpress® from Applied Biosystems).
3) *Adjustment of primer annealing temperatures*: The simplified formula of T_m [°C] = 2*x*(A:T) + 4*x*(G:C) can be used as a guideline. Whenever possible, use primer pairs with similar T_m values and optimize the PCR protocol by a stepwise increase of the annealing temperature, starting about 5°C below the calculated T_m value.
4) *Variety of cycling conditions*: In general, three-step amplification cycles are used (Table 1). If high annealing temperatures can be used, two-step amplification cycles are possible (Table 2), and some reports[3,4] suggest that this can result in less premature termination and the formation of more defined PCR products.
5) *Optimized concentrations of dNTPs and buffers (especially the divalent cation Mg^{2+}), as well as the use of reaction additives*: Some commercial suppliers (e.g., Q-solution from Qiagen with a mixture of monovalent K^+ and NH_4^+ ions) offer solutions with a wider window for optimal annealing temperatures, as well as Mg^{2+} and dNTP concentrations (Table 3).
6) *Choice of commercial thermocyclers*: A wide range is available, including instruments with several independently operated heating/cooling blocks or with gradient blocks that permit analysis of a temperature series in a single experiment. Blocks are available for your preferred PCR reaction tubes and sample numbers (brief overview in Table 4).
7) *''Hot-start'' PCR or heat-activated DNA polymerase*: If highly stringent PCR conditions are desired, consider using ''hot-start'' PCR or heat-activated

Encyclopedia of Diagnostic Genomics and Proteomics

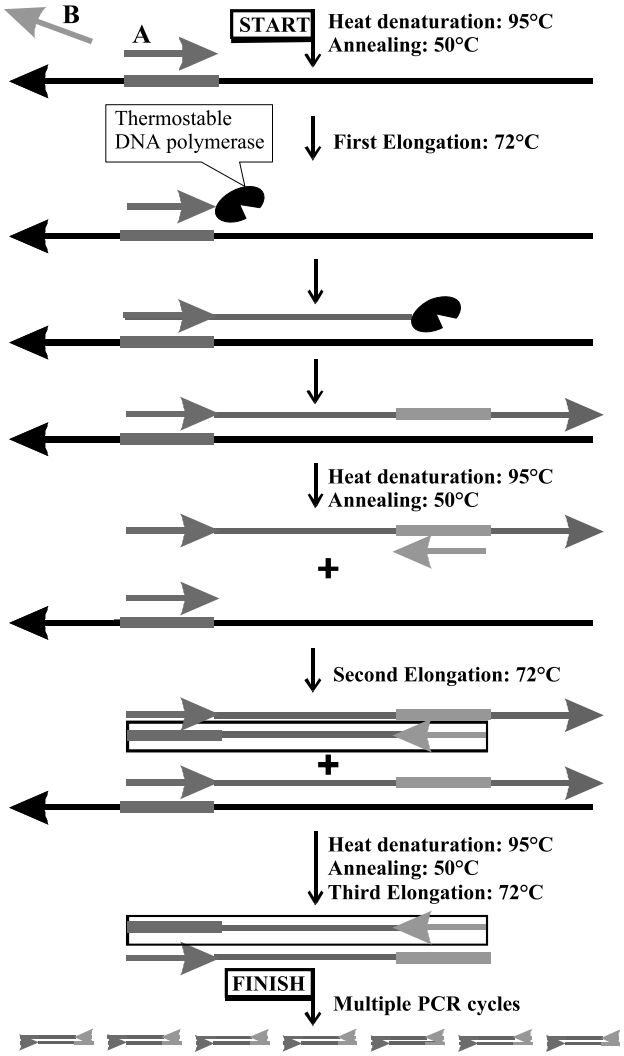

Fig. 1 Principle of PCR technology. Technology for the amplification of a single-stranded DNA target is outlined. *Start*: After heat denaturation (95°C), primers are annealed at a lower temperature (e.g., 50°C). Initially, only primer A can anneal to its complementary sequence (thick red line) in the target DNA. *First elongation*: The optimal reaction temperature for the thermostable Taq DNA polymerase is 72°C, and the annealed primer A is elongated, in principle, all the way to the end of the target DNA, including the sequence (thick green line) complementary to primer B. *Second elongation*: After heat denaturation and annealing, this step generates the first *specific PCR product* with a defined length, containing only the sequence stretch flanked by the two primer sequences (boxed product with green arrow, blue stretch, and thick red line). *Finish*: Multiple copies of the *specific PCR product* are generated (shown as smaller schemes). Primer A (red arrow), primer B (green arrow), target DNA (black), and PCR-generated DNA (blue). (*View this art in color at www.dekker.com.*)

DNA polymerase. The thermostable DNA polymerases have a high temperature optimum but they are not completely inactive at room temperature, and this can lead to elongation of misannealed primers or excessive primer dimer formation. These low-temperature products can be avoided by hot-start PCR: An essential component such as polymerase or magnesium solution is added only after the ''initial template denaturation'' step, during the ''primer annealing'' step (Tables 2 and 3). Another, more convenient option is the use of inactivated DNA polymerase enzyme (commercially available, using heat-labile chemical modification, e.g., from Qiagen; or by antibodies, e.g., from Roche Diagnostics). The enzyme activation requires an extended heat treatment and, for this purpose, the ''initial template denaturation'' at 95°C can be extended to 10 min.

After solving the basic problems of the PCR procedure, one serious practical problem is the occurrence of PCR inhibition, leading to false-negative results. This can be avoided by the inclusion of a separately amplified PCR target as internal control (Fig. 2).[5] A further complication derives from the required high precision in diagnostics. This means that the occurrence of an amplicon with the expected size is not sufficient proof for the positive detection of the targeted pathogen, considering the far-reaching consequences. Therefore in all diagnostic procedures, a sequence-specific identification was and still is a mandatory additional requirement to confirm the amplification of the desired target. Two basic procedures can be applied:[6] 1) Southern hybridization involves transfer (blotting) of the PCR products (with or without prior gel electrophoresis) to nitrocellulose or nylon membranes, followed by hybridization with a labeled probe. Stringent washes remove all nonspecifically bound probes. Finally, the specifically bound, labeled probe is detected. Different types of labels can be used: direct labels are radioactive isotopes (detected with X-ray film, or phosphoimager) or fluorescent dyes (detected with flourimager). Indirect labels are biotin or digoxigenin, combined with enzymes (phosphatase or peroxidase), which carry the corresponding haptens—streptavidin for biotin or antidigoxigenin antibodies for digoxigenin. A wide variety of enzyme substrates are available, which can be converted to fluorescent or nonfluorescent dyes, or produce a chemiluminescent reaction. The multiple turnover of substrates results in much higher sensitivity of these enzyme-coupled detections. Products and detailed protocols are available from many commercial suppliers (e.g., Amersham and Roche Diagnostics). 2) Higher throughput and automation are possible by a combination of capture and detection probes. Both probe sequences must be present in the PCR amplicons. First, amplicons

Table 1 General PCR conditions

Useful range of template copies	Primers	dNTP/$MgCl_2$	Thermostable DNA polymerase	Additives
Theoretical lower limit: one single copy (30 cycles can generate up to 1 billion copies)	5–50 pmol	20–300 μM/1.5 mM[a]	0.2–5 U *Taq* DNA polymerase (from *Thermus aquaticus*; no proofreading)	Increased annealing stringency: 2–5% DMSO, 5% formamide
Upper limit: 100,000 to 1 million copies	0.1–1 μM	20–400 μM/2–4 mM[a]	Pfu DNA polymerase (from *Pyrococcus furiosus*; with proofreading)	Increased efficiency and specificity: 1–10% glycerol, or nonionic detergents such as Tween, Nonidet, CHAPS, Triton

[a]A surplus of free Mg^{2+} is required. Therefore higher dNTP concentrations require higher Mg^{2+} concentrations.

are hybridized to an immobilized capture probe (on membrane or paramagnetic beads), followed by hybridization with a labeled detector probe, stringent washes, and detection, as described above.

This means that the nowadays fully automated and straightforward PCR is complicated by these extra steps after PCR completion, which include the risk of spreading the multimillion-fold amplified DNA segment. If high numbers of samples are analyzed in parallel, laboratory contamination can lead to many false-positive results. Therefore in routine diagnostics, conventional PCR is now widely replaced by sequence-specific real-time PCR techniques (see ''Real-Time PCR Technology'').

Exciting applications in molecular biology derive from the use of composite primers (principle in Fig. 3), combining a 3′-terminal segment with the usual target-specific primer sequence and an unrelated 5′ track that can introduce functional DNA sequence recognition sites. Examples are cleavage sites for restriction enzymes in cloning applications, or a promoter sequence of an RNA polymerase for the production of large amounts of PCR-designed RNA transcripts,[7] useful for in vitro translation, RNA processing, tRNA charging, ribozyme studies, etc. For cloning applications, it is important to keep in mind that the most widely used thermostable *Taq* DNA polymerase has an error rate of about 1:1000.[1] If the PCR-generated mixture of millions of amplicon molecules is used directly (e.g., in sequencing, or for the generation of RNA transcripts), the mutated molecules can be ignored. However, if PCR products are cloned, these clones are derived from individual amplicon molecules. This means that, if only one clone is analyzed, the derived sequence can have one or several mutations. Therefore multiple clones have to be sequenced, and a functional PCR construct (e.g., for overexpression of a protein) with the correct sequence has to be selected.

The aim to perform quantitative PCR analysis is a major challenge in conventional PCR. In principle, the amount of PCR product (*P*) is directly related to the

Table 2 General thermoprofile for three-step PCR

Number of cycles	Temperature [°C]	Time range	Description
1	94	2 min	Initial template denaturation
25–35	45–65	5–60 sec	Primer annealing
	72 (68 for very long PCR products)	20 sec–10 min	Extension/ elongation
	94	5–20 sec	Template denaturation
1	72	2–10 min	Final elongation for complete dsDNA PCR product

Table 3 General thermoprofile for two-step PCR

Number of cycles	Temperature [°C]	Time range	Description
1	94	2 min	Initial template denaturation
25–35	60–69	60 sec–10 min	Primer annealing and extension/ elongation
	94	5–20 sec	Template denaturation
1	72	2–10 min	Final elongation for complete dsDNA PCR product

Table 4 Some commercially available thermocyclers—a brief overview

Supplier	Instrument name	Number of heating blocks (change possible)	Block options	Heating (cooling) rate [°C/sec]	Temperature uniformity [± °C]	Gradient temperature range [°C]	Storage capacity: programs (steps per program)
Applied Biosystems	GeneAmp 9700	1 (Yes)	96 × 0.2 mL, 60 × 0.5 mL of MTP	Up to 5	0.5	No	100 (99)
	Dual GeneAmp 9700	2 (Yes)	2 × 96 × 0.2 mL of MTP	1 (1.5)	0.5	No	100 (99)

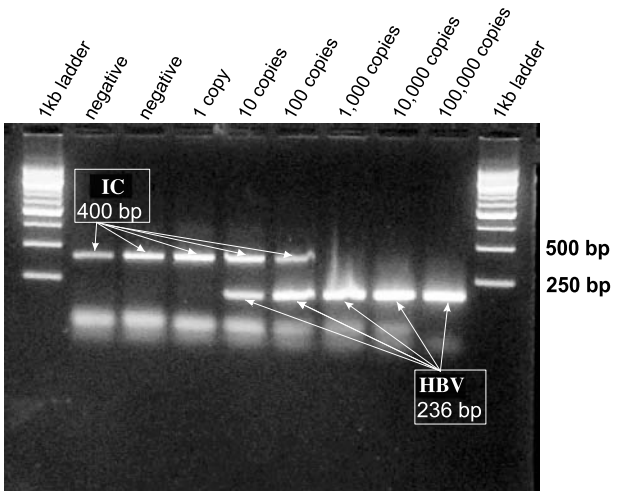

Fig. 2 Coamplification of internal PCR control. All PCR reactions contain primers for the specific pathogen (here, a 236-bp segment of hepatitis B virus, or HBV, is amplified) and for the internal PCR control template IC (here leading to a 400-bp amplicon). The IC sequence and primers are unrelated to the target pathogen and all PCR reactions are spiked with a defined amount of IC. In the absence of the pathogen (negative controls and negative samples), amplification of IC indicates proper PCR conditions and the absence of PCR inhibitors. These inhibitors frequently occur in biological samples and have to be removed during isolation of the DNA, prior to PCR analysis. Theoretical dilution down to one HBV copy per reaction frequently leads to no copy and thus to negative results. At low HBV titers (up to 100 copies per PCR reaction), amplicons from IC and HBV are observed. At higher HBV titers (1000 copies and more), only the HBV-specific amplicon is generated due to competition for reaction compounds. (*View this art in color at www.dekker.com.*)

number of input target copies (T): $P=TE^n$ (E=PCR cycle efficiency, ideally 2.0; n=number of PCR cycles).[8] However, this calculation is based on a constant value for E, and this requirement is met only for a limited number of cycles, the logarithmic or exponential phase. With increasing product concentration and stepwise consumption of primers and other reaction components, E will decrease and, finally, a plateau phase is reached with $E=1$ (Fig. 4). In consequence, product quantities reflect the initial target amounts only until certain cycle numbers are reached, whereas this relation is lost at higher cycle numbers (Fig. 5). In practice, unknown target amounts require the comparative quantitative analysis of PCR products after the completion of several different PCR cycle numbers. Again, real-time PCR techniques are preferred in routine applications. However, the previously mentioned sequence-specific detection is not mandatory and a simplified and much cheaper detection of amplicons by means of intercalating dyes such as ethidium bromide or SYBR Green is sufficient (see ''Real-Time PCR Technology'').

TROUBLESHOOTING

Problem: No PCR Product

Check the quality of primers and template.
Increase the number of cycles (by steps of five).
Increase template DNA by 50-ng increments.
Increase enzyme concentration (up to 5 U/50 μL).
Check if the PCR tubes fit the thermocycler used. Poor thermal contact prevents effective temperature transfer.
Check for air bubbles trapped after mixing the PCR components. Air bubbles prevent homogenous temperature distribution throughout the reaction volume.

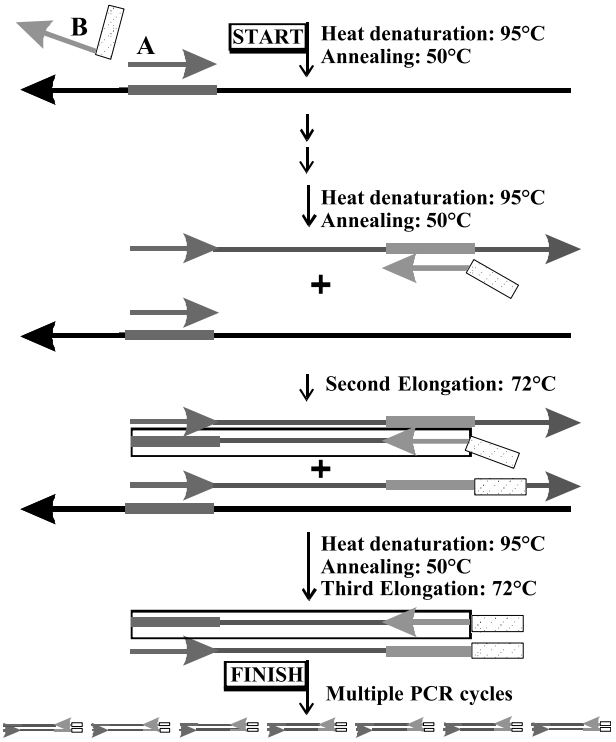

Fig. 3 PCR with functional primer(s). The procedure is as outlined in Fig. 1, but one or both primers contain an extra 5′-terminal functional segment. Here, it is shown only for primer B, indicated by a striped box and shown as tilted element for easier perception. During annealing of primer B, this box does not find a complementary target and sticks out, essentially without affecting PCR performance. After the third elongation step, this box is fully integrated in the *specific PCR product* and further amplified as shown before. (*View this art in color at www.dekker.com.*)

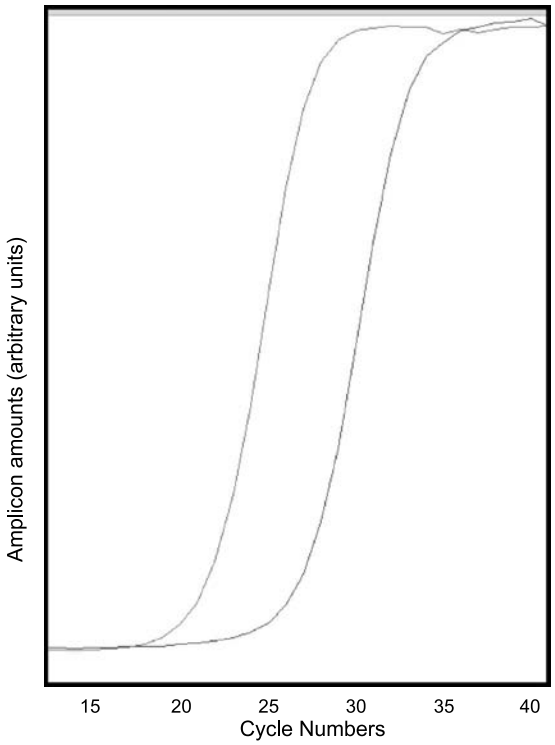

Fig. 4 Quantitative dynamics in PCR amplicon generation. After a certain number of PCR cycles, detectable amplicon amounts are generated (with the target amounts used here, after about 18 and 24 cycles, respectively). These amounts are amplified logarithmically for only about five subsequent PCR cycles, and, finally, a static plateau phase is reached (at about 26 and 32 cycles, respectively). (*View this art in color at www.dekker.com.*)

Problem: Low Amount of Defined PCR Product on High Background Smear

Reduce the number of cycles by steps of two.
Reduce template DNA by decrements of 50 ng.
Increase the time of the elongation step.
Check the ratio of magnesium ions/dNTP. A surplus of free Mg^{2+} is required; therefore a final dNTP concentration at 500 μM requires 2.5 mM Mg^{2+}.
Reduce the amount of enzyme in decrements of 0.2 U.
Increase the concentration of magnesium ions up to 3.5 mM in 0.25 increments if more than 500 ng of template DNA, or more than 500 μM dNTPs is used.

Problem: Low Yield of PCR Product

Increase the final buffer concentration in the reaction assay to 1.6×.
Increase the number of cycles (especially for complex genomic targets and GC-rich targets).
For GC-rich targets, consider replacing dGTP by base analogs with reduced T_m, such as deaza-dGTP or dITP.
Increase the amount of template DNA per reaction by increments of 50 ng.
Increase the amount of enzyme (up to 5 U/50 μL).
Increase the magnesium ions (up to 3.5 mM).

Problem: Nonspecific Products

Try higher annealing temperatures in increments of 5°C.
Reduce the annealing time down to 8 sec in 2-sec decrements.
Reduce time of the elongation step.
Decrease the enzyme amount per reaction in decrements of 0.2 U.
Reduce the amount of template DNA.
Reduce the number of cycles by steps of two.
Add 2–5% dimethyl sulfoxide (DMSO) to the PCR reaction.
Design new (maybe longer) primers.

CONCLUSION

Although conventional PCR has lost ground in the detection of pathogens for diagnostic applications, it remains the workhorse, with many applications in molecular biology. Future developments might reintroduce large-scale diagnostic applications of conventional PCR where cross-contamination and false positives are much less important, such as in tests for mutation(s) in one specific gene involved in a genetic disease and for single nucleotide polymorphism (SNP) analyses. Here, the target of interest is always present and amplified; only the subsequent detection of sequence variations is important. Beyond the scope of this entry are emerging combinations with advanced detection technologies suitable for automation and high throughput, such as pyrosequencing[9] and the rather complex mass spectrometry.[10]

Prader–Willi Syndrome

Milen Velinov
Edmund C. Jenkins
W. Ted Brown
New York State Institute for Basic Research in Developmental Disabilities, Staten Island, New York, U.S.A.

INTRODUCTION

Prader–Willi syndrome (PWS), a condition initially described by Prader, Labhard, and Willi in 1956,[1] is a neurodevelopmental disorder with a clinical presentation that includes neonatal hypotonia, obesity, mental retardation, and behavioral abnormalities. After introduction of high-resolution chromosome analysis, PWS was the first abnormal phenotype found to be associated with a submicroscopic chromosomal deletion.[2] The PWS-associated microdeletion spans about 4 Mbp in the chromosomal region 15q11q13 and always affects the paternally derived chromosome. In this chromosomal region several genes are imprinted—only their paternally derived alleles are functional. Among them, candidates for major gene contributors for the PWS phenotype are the unusual polycistronic gene *SNURF-SNRPN*, the gene *NDN*, and others.[3] Four main molecular mechanisms may lead to deficiencies of genes located in the PWS area. In all PWS cases, with the exception of the rare cases of chromosomal balanced translocations, DNA methylation abnormalities can be detected and are used for diagnostic evaluations. Although in most cases the recurrence risk in the family is lower than 1%, complete diagnostic evaluation and determination of the particular PWS type is always appropriate because in some rare instances the recurrence risk is increased. The management of PWS is generally supportive. One useful recent development in PWS therapy is the use of growth hormone (GH) to counteract obesity and short stature.

PREVALENCE

Most frequently reported prevalence of PWS is in the range of 1:10,000–20,000.[4,5]

CLINICAL FEATURES

Patients with PWS have central muscle hypotonia that is manifested prenatally as decreased fetal movements, abnormal fetal position, and difficult delivery. The hypotonia is evident in the newborn period, accompanied by poor sucking and failure to thrive. Hypogonadism resulting in cryptorchidism and scrotal hypoplasia in males and labial hypoplasia in females are also seen in the newborn period.

Hyperphagia and food-seeking behavior start at about 1 year of age and lead to obesity by 1–6 years. The obesity is central and tends to spare the distal extremities. There is mild facial dysmorphism consisting of almond-shaped palpebral fissures and thin upper lip with downturned mouth. Most patients with PWS have small hands and feet, as well as strabismus. About one third have hypopigmentation.[6]

In addition to the prominent motor delay, there is cognitive developmental delay and, ultimately, mild mental retardation in most cases. The verbal skills are relatively spared.

Characteristic behavioral abnormalities with tantrums, stubbornness, and obsessive–compulsive characteristics are seen in the early childhood. True psychoses later develop in up to 10% of patients.

Clinical diagnostic criteria have been established for PWS to assist clinicians with making clinical diagnosis[4] (Table 1). Laboratory confirmation (see Laboratory Testing) is necessary for all suspected cases and will identify all true PWS cases.

MOLECULAR BASIS AND GENETIC COUNSELING

PWS is the result of deficiency of one or more genes that map on the proximal long arm of chromosome 15 (Table 2). These genes are imprinted. Only their paternally derived alleles are functional.[3] The genomic imprinting on chromosome 15 is reflected in the patterns of cytosine methylation in the CpG islands of this region. These cytosines are methylated only in the maternally derived sequences in the imprinted area. These detectable differences can be used for the diagnostic workup of individuals with suspected PWS. Four mechanisms

DOI: 10.1081/E-EDGP 120025779

Table 1 Consensus clinical diagnostic criteria for PWS

Major criteria (one point each)
Neonatal/infantile central hypotonia
Feeding problems, failure to thrive
Rapid weight gain between 1 and 6 years
Characteristic facial features
Hypogonadism
Developmental delay/mental retardation
Minor criteria (1/2 point each)
Decreased fetal movements
Abnormal behavior
Sleep disturbances/sleep apnea
Short stature
Hypopigmentation
Small hands/feet
Narrow hands with straight ulnar border
Esotropia, myopia
Thick viscous saliva
Speech articulation defects
Skin picking
Supportive findings
High pain threshold
Decreased vomiting
Temperature instability
Scoliosis/kyphosis
Early adrenarche
Osteoporosis
Unusual skill with jigsaw puzzles
Normal neuromuscular studies

The diagnosis of PWS is strongly suspected in children under 3 years of age with five points (three from major criteria) and above 3 years of age with eight points (four from major criteria).
Source: Adopted from Refs. [4] and [15].

can lead to PWS. (All but Type IIb among those listed below have DNA methylation abnormalities and can be diagnosed using DNA methylation analysis; see Diagnostic Methods.)

Type I: Chromosome 15q Deletion

About 70% of all PWS cases are the result of a de novo interstitial deletion involving the 15q11q13 region.[2] Most cases have similar/identical common deletion of about 4 Mbp with the same distal breakpoint and two alternative proximal breakpoints.[3] The deletion always involves the paternally derived chromosome 15. The same deletion is observed in patients with Angelman syndrome (AS) (see Angelman Syndrome), but in those cases the deleted chromosome is maternally derived.[7] The 15q deletion cases typically occur de novo and the recurrence risk for subsequent pregnancies is less than 1%.

Type II

Chromosomal rearrangements are seen in less than 1% of the PWS cases.

Type IIa: Unbalanced translocation affecting chromosome 15.[8,12] In these cases, if the transmitting parent has a balanced translocation, the recurrence risk for PWS in the family can be as high as 50%.

Type IIb: De novo balanced translocations affecting the paternally derived chromosome 15. Five such cases that resulted in PWS were reported.[3] In all cases of balanced translocations the translocation breakpoint lies within the locus of the gene *SNURF-SNRPN*. The balanced translocation cases do not have imprinting/DNA methylation abnormalities (see Diagnostic Methods). The mechanism here appears to be the disruption of sequences in the *SNURF-SNRPN* locus and subsequent deficiency of one or more of the multiple transcripts that originate from this locus (see The PWS/AS Chromosomal Region).[3] For these de novo translocations the recurrence risk is less then 1%.

Type III: Maternal Uniparental Disomy 15

Most of the deletion-negative PWS cases (about 25% of all cases) are due to maternal uniparental disomy 15 (UPD 15) inheritance of both chromosome 15s from the mother with resulting deficiency of paternally derived alleles in the imprinted 15q11q13 region.[9,10] Paternal UPD 15 is also observed and leads to Angelman syndrome (see Angelman Syndrome). However, the paternal UPD is not as frequent as the maternal (only 2–3% of the AS cases are the result of UPD). It appears that the mechanism of UPD occurrence differs in PWS, and AS maternal UPD in PWS occurred in most cases in meiosis I, whereas most paternal UPD cases that resulted in AS occurred postzygotically.[11] Although the recurrence risk for PWS in cases of UPD (Type IIIa) is generally low, chromosomal rearrangements in the parents involving chromosome 15 (Type IIIb) may increase the risk for maternal UPD 15 and PWS in the offspring.[12]

Type IV: Imprinting Defect

About 1% of individuals with PWS have neither a FISH identifiable 15q deletion nor UPD 15, but have DNA methylation abnormalities as if they had only maternally derived chromosome 15s. Up to 20% of these individuals (Type IVa) have a small deletion at the 5′ end of the *SNURF-SNRPN* locus, involving its first exon.[13] This region is referred to as imprinting center (IC) because it seems that this locus takes part in the regulation of the imprinting in a large (about 2 Mbp) imprinted region on the proximal 15q. A small proportion of the patients with

Table 2 Molecular types of PWS

Type	Mechanism	Laboratory testing	Proportion of all (%)	Recurrence risk
I	De novo Del 15q11q13	MT+[a] FISH+	70	<1%
IIa	Chromosomal unbalanced translocations	Chromosome analysis—abnormal MT+	<1	Up to 50%
IIb	Chromosomal balanced translocations	MT−, FISH− Chromosome analysis—abnormal	<1	<1% (de novo occurrence)
IIIa	Maternal UPD	MT+, UPD analysis+	25	<1%
IIIb	Uniparental disomy and chromosomal aberration	Chromosome analysis—abnormal MT+ UPD study+	<1	? Increased, but limited data
IVa	Imprinting defect with IC deletion	MT+, FISH− UPD−, IC del+	<1	Up to 50%
IVb	Imprinting defect without IC deletion	MT+, FISH− UPD−, IC del−	1	<1%

[a]MT = DNA methylation testing.

AS also have deletions in this region. However, the analysis of patients with imprinting mutations resulting in PWS or AS showed that the smallest regions of overlap for the imprinting mutations are not the same for the two groups of individuals. The IC is thus a bipartite structure with one proximal region of about 880 bp that regulates the paternal-to-maternal imprinting switch, and when disrupted may lead to AS, and another, distal 4.3-kb region that when disrupted results in PWS[14] (see Angelman Syndrome). The imprinting center deletions are also identified in the fathers of the affected individuals, and are associated with a 50% recurrence risk for subsequent pregnancies. On the other hand, the imprinting defects without identifiable IC deletions (Type IVb) are considered sporadic, and are not associated with greater recurrence risk.[13] A summary of Types I–IV is given in Table 1.

THE PWS/AS CHROMOSOMAL REGION

The common deletion in PWS spans about 4 Mbp on the proximal long arm of chromosome 15 (for a review, see also Ref. [3]). The imprinted region consists in about 2 Mbp within the commonly deleted region. One gene in the region, *UBE3A*, functions only with its maternally derived allele in the brain, and its deficit leads to AS (see Angelman Syndrome). A *UBE3A* mutation alone can produce the whole AS phenotype. On the other hand, there are at least five genes that are expressed only by their paternal alleles. Thus, in PWS the relative contributions of different gene deficiencies for the phenotype is unclear. Among the imprinted genes that are deficient in PWS one important candidate for a major phenotype contributor is *SNURF-SNRPN*, which is a very complex, polycistronic gene coding for two independent proteins. One of them, the protein SmN, translates off exons 4–10, and is a core spliceosomal protein that participates in the process of mRNA splicing in the brain. The five reported balanced translocations (see Type IIb PWS) that resulted in PWS had their breakpoint within the *SNURF-SNRPN* locus, thus suggesting the gene's major role in the PWS phenotype. However, mouse models with altered *SNURF-SNRPN* sequence do not seem to show the PWS-like phenotype. SmN's function in the brain overlaps with the SmB/B proteins. The SmB/B proteins have elevated levels in the mouse model with an ablated SmN sequence, thus supporting the idea that the SmB/B proteins can compensate for the SmN deficiency in the mouse model. SNRPN upstream reading frame (SNURF) (exons 1–3) encodes another protein that may be involved in the regulation of SmN or in the process of imprinting because its locus overlaps with the IC. In addition, there are genes for many small nucleolar RNAs located within the *SNURF-SNRPN* introns. The impaired transcription of these RNA molecules may also be an important contributor for the PWS phenotype.[15]

Finally, another major candidate contributor for the PWS phenotype is the gene *NDN* whose products are predominantly expressed in the brain.[3]

PHENOTYPE–GENOTYPE CORRELATIONS

The different PWS molecular subtypes have very similar phenotypes with only minor differences noted by some

studies. Patients with UPD tend to lack facial dysmorphisms, and African–American PWS patients often are of normal height and do not have small hands.[16] One recently reported important phenotype–genotype correlation is the higher prevalence of psychotic disorders among the patients with UPD compared to the other PWS types.[17] The molecular basis of this finding is currently unclear.

DIAGNOSTIC EVALUATION

The diagnostic tests bellow are listed in order of their application for diagnostic evaluation:

G-banded chromosome analysis is undertaken in every individual with suspected PWS to rule out chromosomal abnormalities leading to PWS or producing similar phenotypes.

DNA methylation testing is done as an initial evaluation for all patients with suspected PWS and will identify all patients except the ones with balanced chromosomal translocations. (For more detailed explanation of DNA methylation testing, see Angelman Syndrome).

Fluorescence in situ hybridization (FISH) analysis using commercially available probes specific for the SNRPN locus is done to look for 15q11q13 deletions after positive DNA methylation testing,[18]

UPD analysis is done in cases of abnormal DNA methylation and normal FISH analysis. This testing protocol uses DNA polymorphisms to trace the inheritance of chromosome 15. DNA specimens from both parents are necessary.

IC mutation screening. In methylation-positive and FISH- and UPD-negative cases a search for an IC deletion can be done, but is not currently available for routine use.

For patients with negative DNA methylation analysis and normal chromosome analysis the diagnosis of PWS is ruled out.

MANAGEMENT

The management of PWS is supportive and problem oriented.[16] The following more important disease aspects are usually addressed:

Developmental delay/mental retardation is managed by early intervention, special education, and occupational therapy.

Obesity is an important morbidity and mortality contributor in PWS. Its management includes low calorie diet, exercise, and limiting the access to food.

GH deficiency. GH therapy was recently recommended for PWS because GH deficiency is well documented in patients with PWS.[19] The favorable effect of GH therapy on linear growth and body composition was later reported, although issues of the priority of such therapy given the presence of more important PWS-associated problems was also discussed by Paterson and Donaldson.[20] Finally, several fatalities of children with PWS after initiation of growth hormone therapy were reported by Pfizer Inc. (the manufacturer of recombinant growth hormone; see www.pharmacia.com). The fatalities had one of the following complications: severe obesity, history of respiratory impairment/sleep apnea, or unidentified respiratory infection. These risk factors are now considered contraindications for growth hormone therapy in PWS.

Support and information for families with affected members can be obtained from the website of the PWS Association (USA) at www.pwsausa.org.

CONCLUSION

PWS is the result of the deficiency of imprinted gene(s) in the chromosomal region 15q11q13. Although no single gene was shown to be a major contributor for the phenotype, *SNURF-SNRPN* and *NDN* are strong candidates. The typical PWS phenotype is most likely the result of deficiency of more than one gene, and thus fits the definition for continuous gene syndrome. DNA methylation testing in combination with chromosome analysis will identify all PWS cases, but further testing may be required to determine the patient subtype. Future research on this condition may address the higher prevalence of psychotic manifestations in PWS patients with UPD. In addition, the long-term effects of growth hormone therapy on PWS need to be evaluated.

Preimplantation Genetic Diagnosis—An Overview

P

The-Hung Bui

Karolinska Institutet/Karolinska Hospital, Stockholm, Sweden

INTRODUCTION

Couples known to be at increased risk of transmitting a specific monogenic disorder or chromosomal imbalance to their offspring will find increasing use of preimplantation genetic diagnosis (PGD) as an alternative to conventional prenatal diagnosis by invasive procedures during pregnancy. Routine assisted reproductive technologies [in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI)] are needed for PGD. Genetic tests are performed before embryo transfer, thus allowing the selection of unaffected embryos before a pregnancy has been established. This approach has the advantage that the couple avoids having to consider termination of pregnancy because of an affected fetus. More recently, PGD for aneuploidy screening (PGD-AS) has been used in an attempt to improve the pregnancy rates in infertile couples treated by IVF.

This chapter focuses on the current status of clinical PGD, the technical limitations, and further prospects of this technology.

EMBRYO AND POLAR BODY BIOPSY

Currently, most centers performing PGD use cells obtained from the six- to eight-cell cleavage stage (day 3 of embryonic development).[1] Embryo biopsy is a two-step procedure in which a hole is first drilled in the zona pellucida surrounding the embryo at this stage, and next, one or two cells are aspirated through it (Fig. 1). The hole made in the zona pellucida is usually 30–50 μm, and it is believed that a larger hole may be detrimental to embryo development and viability.[2] Until recently, most centers used acidified Tyrode's solution for zona drilling, but a noncontact laser method has become very popular and is also widely used for assisted hatching (references in Ref. [1]). No controlled randomized studies have yet been conducted to compare the effects of acid Tyrode's solution or the laser on embryo viability. However, comparative data from the ESHRE PGD Consortium and others have shown no difference in pregnancy rates between these two methods.[1,3] Another controversy is whether taking two cells rather than one is detrimental to embryonic development.

Sequential or simultaneous biopsies of the first and second polar body have also been performed for PGD (Fig. 2). The main application has been for age-related aneuploidy screening (PGD-AS), but this strategy has also been used in some cases of PGD for single-gene defects and female carriers of chromosomal abnormalities.[1] Genetic analysis of the polar body is restricted to maternally derived diseases, as information of the paternal genetic contribution cannot be obtained by this approach.

CHROMOSOME ANALYSIS OF PREIMPLANTATION EMBRYOS

Karyotype analysis of early embryos is difficult because of limitations in culturing and obtaining metaphase spreads from biopsied embryo cells. This is circumvented by the use of fluorescent in situ hybridization (FISH) with locus-specific DNA probes on interphase nuclei.

FISH for Sexing and Inherited Chromosomal Abnormalities

Any X-linked disease, for which no specific single-cell polymerase chain reaction (PCR) test is available, may be considered for PGD sex selection. By using DNA probes for the sex chromosomes and an autosome as a hybridization control, the sex of embryos can be determined and only female embryos are transferred to the woman. For this particular application FISH is more advantageous and robust than PCR; it can additionally detect potential aneuploidy for the analyzed chromosomes while the problem with allele dropout (ADO) associated with PCR is entirely avoided. The first application of FISH in PGD was for sex selection and it remains the method of choice for this indication. Nevertheless, sexing and transfer of only female embryos cannot be regarded as the optimal treatment for carriers of an X-linked disorder as theoretically half of the discarded male embryos are unaffected. On the other hand, the workup of a new diagnostic test for every X-linked disease is very

expensive and time-consuming, thus sexing is still considered a reasonable option for these patients.

Fluorescent in situ hybridization is also used for PGD of inherited structural chromosomal abnormalities. Previously, the limiting factor was the need to design unique probes for every case as most structural chromosome abnormalities are ''private'' with patient-specific breakpoints. However, this has to a large extent been solved by the recent publication and subsequent commercial availability of subtelomeric probes from all chromosomes. The majority of reported cases of PGD for structural chromosomal abnormalities concern carriers of balanced translocations.[3] Two types of translocations are known: Robertsonian translocations, the centric fusion of two acrocentric chromosomes, and reciprocal translocations, an exchange of segments from at least two chromosomes. To discriminate between embryos showing balanced and unbalanced chromosome content, a minimum dual-color FISH assay with one DNA probe from each q-arm of the chromosomes involved is required for Robertsonian translocations (Fig. 3). Generally, a three-color FISH assay is used for reciprocal translocations with one probe from each side of the breakpoint on either of the chromosomes involved and one probe located anywhere on the other chromosome. However, this diagnostic approach does not allow distinguishing between normal and balanced embryos. To be able to discriminate between them, the DNA probes used need to span or flank the translocation breakpoints. Such a strategy will be restricted by the time required to develop specific probes for each translocation carrier and the additional costs. Also, as both normal and balanced embryos will result in normal offspring it is ethically questionable whether only normal embryos should be transferred and not balanced translocation carriers. Preimplantation genetic diagnosis has also been successfully applied for other structural chromosomal abnormalities including inversions and deletions.[4]

FISH for Aneuploidy Screening

Cytogenetic studies have shown that up to 60% of the early spontaneous abortions in humans are caused by numerical chromosomal abnormalities and that as many as 70% of all human preimplantation embryos may contain aneuploid cells.[5] This prompted the development of PGD for aneuploidy screening of oocytes and preimplantation embryos (PGD-AS). Fluorescent in situ hybridization is

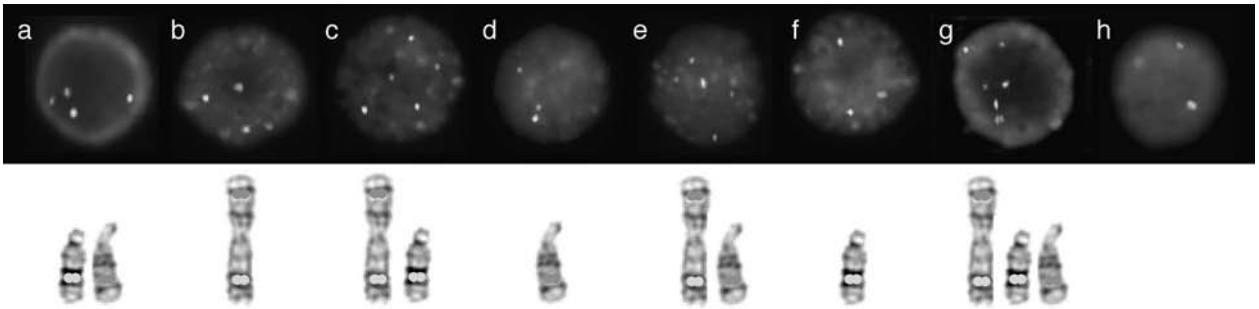

Fig. 3 Preimplantation genetic diagnosis for a Robertsonian translocation. Upper row: Blastomeres, obtained by biopsy of eight different embryos, analyzed by FISH using locus-specific probes (green for chromosome 13 and red for chromosome 14). The embryos were the result of fertilization of gametes from a carrier of a Robertsonian translocation, der(13;14)(q10;q10). Bottom row: Corresponding, and also all possible gametes in a der(13;14)(q10;q10) carrier, only chromosomes 13, 14, and der(13;14)(q10;q10) being depicted. Only embryos whose blastomere demonstrates two signals of each probe will result in an unaffected child. These embryos will be either noncarrier (a) or balanced carrier (b); the remaining embryos are unbalanced (c–h). (*View this art in color at www.dekker.com.*)

performed with enumerating probes for an increasing number of different chromosomes to select embryos that are more likely to implant and thereby enhance IVF success. However, there are limits to the number of probes used simultaneously in interphase FISH as this may result in signal overlapping. New technologies, such as comparative genomic hybridization (CGH), which enable full karyotyping of single cells, may solve these problems.[6]

Several reports have suggested an increased pregnancy rate using PGD-AS for patient groups with poor prognosis including those with increased maternal age, recurrent pregnancy losses, or IVF failures.[5] For this reason, PGD-AS is already practiced and is the most common reason for embryo diagnosis.[7] However, the first randomized, prospective study evaluating PGD-AS in these three high-risk groups could not find proof for an added benefit for any of them.[8] Thus there is an urgent need for further evaluation of this technology with additional large, controlled, randomized studies.

The presence of mosaicism shown in human preimplantation embryos can result in diagnostic difficulties as the biopsied blastomere may not be representative of the embryo. The risk of misdiagnosis could be assessed by reanalysis of nontransferred embryos. Data from PGD-AS indicate a misdiagnosis rate of 7.2%, of which 5.6% was attributable to mosaicism.[9] The estimated risk for false negative diagnosis was 4.3%. However, this may be reduced if two cells are analyzed.

PGD FOR SOCIAL SEXING AND HLA TYPING

Preimplantation genetic diagnosis for family balancing purpose, also known as social sexing (PGD-SS), is currently offered by a couple of PGD centers worldwide and 78 cycles were reported by May 2001.[3] This is a highly controversial application and a matter of contention. The vast majority of PGD centers registered with the ESHRE PGD Consortium does not offer PGD-SS.[3]

For a number of hematological diseases, transplantation of hematopoietic stem cells is the only curative treatment. Some parents with an affected child may contemplate PGD in the hope of conceiving an HLA-identical donor sibling. This issue is also much debated. However, if the child to-be is at risk of having the same disease and a specific PGD analysis is performed along with the HLA analysis, the added benefits of possibly saving the life of the sibling have been generally considered to outweigh the disadvantages.[10] A detailed account of the ethical issues of PGD is outside the scope of this chapter and these are discussed elsewhere.[10]

PGD OF SINGLE-GENE DISORDERS USING PCR

Preimplantation genetic diagnosis has been developed for an increasing number of single-gene disorders and in most cases a PCR-based method is used.[3,11,12] The sample is lysed in order to release the nuclear DNA and the 5–10 pg of DNA contained in a single cell needs to be amplified before mutation analysis can be performed using restriction enzyme digestion, single-strand conformational polymorphism (SSCP), sequencing, etc.[12] Nested PCR, a two-step PCR procedure, was introduced to achieve specific PCR products in large enough amounts. The more recent introduction of fluorescent PCR allowed for a more sensitive detection of PCR products (1000-fold more sensitive) and thus facilitates single rounds of PCR.[13] In

addition, primers can be tagged with different fluorescent molecules that facilitate amplification and simultaneous detection of several different DNA sequences.

Problems with Single-Cell PCR

Single-cell PCR is technically demanding, with high risks of contamination and ADO. Contamination can occur from the operator's DNA or carryover of previous PCR products. This type of contamination can be avoided by working in sterile manners, using different pre- and post-PCR rooms and materials dedicated only for the setup of single-cell PCR. Another source of contamination is genomic DNA from the patients, e.g., maternal cumulus cells or sperms sticking to the zona pellucida accidentally sampled during biopsy procedures. To avoid the risk of paternal contamination, ICSI should be used to achieve fertilization in all cases of PCR-based PGD. Allele dropout is a phenomenon observed when one of the examined alleles fails to amplify during the PCR reaction. This can result in diagnostic errors, especially for autosomal dominant disorders, as ADO of the mutated allele would wrongly diagnose an affected embryo as healthy.

Strategies for Avoiding Misdiagnosis

There are different ways to optimize the PCR to avoid or detect contamination and ADO in PGD.[14] The use of fluorescent PCR has reduced the observed frequency of ADO due to the increased sensitivity. In addition, most recent protocols use multiplex PCR with fluorescent tagged primers. Contamination can be detected by the simultaneous amplification of the DNA fragment encompassing the mutation and any informative polymorphic marker. The biopsied blastomere should show one marker allele from each parent; any other pattern will be indicative of contamination. Multiplex PCR of the DNA fragment encompassing the mutation and a linked polymorphic marker makes it possible to detect ADO by comparing the results of the two loci. This strategy doubles the chance of identifying the mutation, as one of the marker alleles will be linked to it, and thus decreases the risk for misdiagnosis due to ADO by half. Another advantage of multiplex PCR is that a combination of linked markers can be used for diagnosis. Linkage analysis could be an alternative strategy for PGD especially for diseases exhibiting wide mutation spectra such as cystic fibrosis.

Clinical Applications

The list of monogenic disorders for which single-cell PCR has been developed is continuously extending. So far, the largest number of PGD cycles has been performed for cystic fibrosis, myotonic dystrophy, Huntington's disease, beta-thalassemia, spinal muscular atrophy, the fragile X syndrome, Charcot–Marie–Tooth type 1A or 2A, and Duchenne's muscular atrophy.[3]

OUTCOME OF PGD

Preimplantation genetic diagnosis has been used clinically for more than 10 years and is presently offered by more than 50 centers worldwide. Although more than 5000 cycles have been performed and over 1000 babies born,[11] the impact of PGD is still low in comparison to conventional invasive prenatal diagnosis. This is due to the complexity of the procedure and the relatively low pregnancy rate following IVF. Two forums have been established to evaluate the clinical outcome of PGD, the ESHRE PGD Consortium and the International Working Group, IWGPG (Yury Verlinsky, Reproductive Genetics Institute, Chicago, U.S.A.). The most recent data collection from the ESHRE PGD Consortium included 1670 embryo transfer cycles from 25 different centers.[3] These data show a pregnancy rate of 17% and 25% per oocyte retrieval for PGD and PGD-AS, respectively, with 279 babies born. Children born after PGD have not been found to have malformations or complications to a higher extent than children born after IVF with ICSI.[15]

A few misdiagnoses are unfortunately still being made. Until now eight cases out of 451 pregnancies have been reported to the ESHRE PGD Consortium.[3] The total rate of misdiagnosis is 1.8%, with a higher incidence for PCR (3.4%) than for FISH (0.9%).

FUTURE PROSPECTS

For PGD-AS, CGH is an attractive method as it displays all the chromosomes at the same time. Although single-cell CGH has been applied on early embryos for research purposes,[16,17] its clinical application is not straightforward. All present CGH protocols have a time requirement of 4 to 5 days that is impossible to fit into the PGD situation with biopsies at day 3 and embryo transfer on day 4 or 5. However, one group has reported the use of CGH in PGD-AS, resulting in the birth of a healthy baby.[6] The obstacle was overcome by cryopreservation of the embryos after biopsy while awaiting the results. Alternatively, an accelerated protocol with polar body biopsy at day 1 could be used.[18]

The main disadvantage of CGH is that it is labor intensive and demands the knowledge of karyotyping. In microarray-CGH the target for hybridization are arrays of genomic clones spotted to glass slides. This setting allows

for automation as well as improved resolution, down to 100–200 kb depending on the number and density of clones present on the slide, compared to 2–20 Mb for conventional CGH. The use of microarrays in PGD for monogenic disorders will probably have a limited value because in most cases only one or two mutations have to be identified.

CONCLUSION

Preimplantation genetic diagnosis is a developing technology introduced in 1990 as an alternative to invasive prenatal diagnosis. The issue of pregnancy termination is avoided as genetic tests are performed before embryo transfer. Many would consider PGD ethically acceptable for cases where prenatal diagnosis would be offered. However, the clinical indications for PGD will widen and those performed for family balancing (sex selection) or other nondisease conditions (e.g., HLA-typing) are the most controversial. Whether PGD for aneuploidy screening will increase the success rate for IVF treatment is still being investigated.

Development in the field of PGD has been focusing on methods to eliminate any risks of misdiagnosis. For chromosome analysis, mosaicism is problematic and analysis of two blastomeres may increase the chance of detecting it. Ideally, a full chromosome analysis should be performed and techniques such as CGH are being adapted for PGD. In PCR, diagnostic errors can be reduced by using fluorescent PCR and informative markers in a multiplex reaction.

The overall impact of PGD is still low because of its complexity and relative costs. However, for couples at high risk of having an affected child, PGD may be an attractive alternative to prenatal diagnosis. For some couples PGD could even be the only available method that will enable them to have unaffected children.

Preimplantation Genetic Diagnosis—Single-Cell DNA and FISH Analysis

Anver Kuliev
Yury Verlinsky
Reproductive Genetics Institute, Chicago, Illinois, U.S.A.

INTRODUCTION

Preimplantation genetic diagnosis (PGD) is a principally new approach for genetic testing before pregnancy is established. In contrast to prenatal diagnosis, performed already after the pregnancy, PGD avoids the need for pregnancy termination, which is the major limitation of prenatal diagnosis. Preimplantation genetic diagnosis has become realistic only after introduction of polymerase chain reaction (PCR), which made it feasible to perform genetic analysis in single cells biopsied from preimplantation embryo. This was first performed 13 years ago by testing single blastomeres, removed from the cleaving embryos, or the first polar bodies removed from the mature oocyte.

Since then, more than 7000 PGD cases have been performed in the framework of assisted reproduction and genetics practices, demonstrating an increasing acceptance of PGD in different populations around the world. A wider use of PGD has also been due to offering it to IVF patients of advanced reproductive age and application of FISH technique for a possible preselection and avoidance from transfer of oocytes and embryos with common aneuploidies and translocations.

SINGLE-CELL DNA ANALYSIS

Because PGD for single gene disorders is based on single-cell genetic analysis, its accuracy depends largely on the limitations of single-cell DNA analysis, which may potentially cause misdiagnosis. One of the key contributors to misdiagnosis is the phenomenon of preferential amplification, also known as allele-specific amplification failure [allele dropout (ADO)], requiring the application of special protocols to ensure the highest ADO detection rate.[1,2] A few previously reported misdiagnoses, involving PGD for cystic fibrosis (CF), myotonic dystrophy (DM), and fragile-X syndrome (XMR1), might have been due to this phenomenon, which has not initially been fully realized.[3,4]

It has been demonstrated that ADO rates in single cells might be different for different types of heterozygous cells.[5] The ADO rate may exceed 20% in blastomeres, compared with ADO rate in single fibroblasts and PB1, which was shown to be under 10%. A high rate of ADO in blastomeres may lead to an obvious misdiagnosis, especially in compound heterozygous embryos. As mentioned, most misdiagnoses, especially those at the initial stage of application of PGD for single gene disorders, were in the cases of blastomere biopsy from apparently compound heterozygous embryos. To avoid a misdiagnosis because of preferential amplification, a simultaneous detection of the mutant gene together with up to three highly polymorphic markers, closely linked to the gene tested, was introduced.[1,2] Each additional linked marker reduces the risk for misdiagnosis significantly, which may practically be eliminated with the application of three markers. So a multiplex nested PCR analysis is performed, with the initial PCR reaction containing all the pairs of outside primers, so that following the first-round PCR, separate aliquots of the resulting PCR product may be amplified using the inside primers specific for each site. Only when the polymorphic sites and the mutation agree are embryos transferred. So the multiplex amplification allows detecting ADO and preventing the transfer of misdiagnosed affected embryos.

Another efficient approach for avoiding misdiagnosis is a sequential genetic analysis of the PB1 and PB2 in PGD for maternally derived mutations.[1] Detection of both mutant and normal alleles in the heterozygous PB1, together with the mutant allele in the corresponding PB2, leaves no doubt that the resulting maternal contribution to the embryo is normal, even without testing for the linked markers as a control. However, it is ideal to test simultaneously at least for one linked marker to confirm the diagnosis. Alternatively, the mutation-free oocytes may also be predicted when corresponding PB1 is homozygous mutant, in which case the corresponding PB2 should be hemizygous normal, similar to the resulting maternal pronucleus. However, the genotype of the resulting maternal contribution may be quite opposite, i.e., mutant, if the corresponding PB1 is in fact

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020746

heterozygous but not detected because of ADO of the normal allele.

The other method with the proved potential for detecting and avoiding misdiagnosis because of preferential amplification is fluorescence PCR (F-PCR), which may allow detecting of some of the heterozygous PB1 or blastomeres misdiagnosed as homozygous in conventional PCR.[2] In addition, the method also allows a simultaneous gender determination, DNA fingerprinting, and detection of common aneuploidies.

Finally, because of high rate of chromosomal mosaicism at the cleavage stage, testing for the chromosome, in which the gene in question is mapped, is of an obvious value to exclude the lack of mutant allele because of monosomy of this chromosome in the biopsied blastomere. As mentioned, aneuploidy testing is technically feasible and may be performed by adding primers for chromosome-specific microsatellite markers to the multiplex PCR protocols worked out for specific genetic disorder.[6]

Because of need for the development of a custom-made PGD design for each mutation and each couple, a preparatory work has become an integral part of PGD for single gene disorders to ensure avoiding the potential misdiagnosis. For example, in some cases, a particular set of outside primers has to be designed to eliminate false priming to the pseudogene, as described in PGD for long-chain 3-hydroxyacyl-Coa dehydrogenase deficiency.[7] In addition, the preparatory work may frequently involve a single sperm typing needed for establishing paternal haplotypes, so that linked marker analysis could be performed in addition to mutation analysis, especially in cases of paternally derived dominant conditions or PGD combined with preimplantation HLA matching.[8]

SINGLE-CELL FISH ANALYSIS

Preimplantation genetic diagnosis for the age-related aneuploidies is currently performed by FISH analysis using commercially available chromosome-specific probes (Abbott, Downers Groves, IL). It was first applied in 1991 for gender determination using DNA probes specific either for the X or Y chromosome.[9] Because testing for only one of the sex chromosomes could lead to misdiagnosis of gender because of a possible failure of hybridization, a dual FISH was introduced, involving the simultaneous detection of X and Y, each in different color.[10] Furthermore, the dual FISH analysis was combined with a ploidy assessment by adding a centromeric probe specific for chromosome-18.[11] Testing was then extended to up to 5 autosomes, including chromosomes 13, 16, 21, and 22, and then to up to 12 chromosomes, using additional rounds of rehybridization.[12]

The reliability of the FISH technique for aneuploidy detection in blastomeres has been extensively studied. However, a high rate of mosaicism was observed at the cleavage stage, which was particularly high in slow embryos exhibiting an arrested development.[13–15] According to the present data, approximately half of all preimplantation embryos are mosaic, suggesting that the biopsied blastomere might not represent the genotype of the embryo. As the origin of mosaicism in preimplantation embryos is still not well understood, it may be useful to test the chromosomal status of both oocyte and the resulting embryo, at least to exclude the majority of chromosomal aneuploidies originating from female meiosis.[16]

The overall experience of preimplantation FISH analysis currently involves more than 5000 clinical cycles, approximately half performed by FISH analysis of blastomeres and half by FISH analysis of PB1 and PB2, which resulted in hundreds of unaffected pregnancies and healthy children born at the present time. The follow-up confirmation studies of the preselected abnormal embryos, and the babies born following the procedure, demonstrated an acceptable accuracy of the FISH analysis.[3,17]

Preimplantation genetic diagnosis for aneuploidies was also achieved by comparative genome hybridization (CGH), which is a PCR-based method for testing of chromosomal abnormalities in a single cell. The method was designed for the detection and exclusion from the embryo transfer of the aneuploid embryos of which a sizable proportion could be misdiagnosed as normal by the commercially available five-color probe. The standard CGH protocol, which takes 5 days to complete, has presently been applied in 20 frozen cycles for poor prognosis IVF patients, resulting in a few unaffected clinical pregnancies.[18] The major limitation of CGH protocol involves a 3-day duration of the procedure incompatible with the current laboratory framework for PGD, which has presently been overcome either by performing the polar body CGH or by accelerating the procedure to be completed in 38 hr.[17,19] However, the accuracy and practical usefulness of CGH for PGD need to be further evaluated.[20]

PREIMPLANTATION GENETIC DIAGNOSIS APPLICATIONS

Preimplantation genetic diagnosis has presently been applied for more than 50 different conditions, among which the most frequent ones were cystic fibrosis and hemoglobin disorders.[3,4,17] In contrast to prenatal diagnosis, the

indications for PGD include inherited predisposition to late-onset disorders, such as inherited cancer predisposition and Alzheimer disease.[21,22] Most recently, PGD was applied for congenital malformations, including Sonic Hedgehog mutation and Crouzon syndrome.[8,23] The most controversial application of PGD has been HLA matching as a tool for the preselection of a potential donor progeny for bone marrow transplantation.[24] Previously, this was applied to the Fanconi anemia (FA) case, in which the preselection and transfer of unaffected embryos with HLA matched for the affected sibling yielded a clinical pregnancy and birth of a healthy carrier of FA gene, whose cord blood was transplanted to the affected sibling, resulting in a successful hematopoietic reconstitution. The method has currently been applied for the HLA genotyping for thalassemia, Wiskott–Aldrich syndrome, hyperimmunoglobulin M syndrome, X-linked adrenoleukodystrophy, and for leukemia, which resulted in the preselection and transfer of 19% of the HLA-matched embryos, demonstrating the practical usefulness of PGD for HLA typing.[25,26]

Finally, the most practical application of PGD is currently the preselection of aneuploidy-free embryos for IVF patients of advanced reproductive age and also detection of normal or balanced embryos in carriers of chromosomal translocations.[3,17] The usefulness of PGD in assisted reproduction is obvious from the data on the prevalence of chromosomal abnormalities in the oocytes of women of 35 years and older, which is over 50% even by testing for only 5 chromosomes (chromosomes 13, 16, 18, 21, and 22).[16] This is comparable to those detected in preimplantation embryos in PGD for aneuploidies at the cleavage stage, taking into consideration additional fertilization-related abnormalities and paternally derived meiotic errors, which was shown to be as high as 60%. As mentioned, the origin of high frequency of mosaicism, comprising approximately half of the chromosomal abnormalities at the cleavage stage, is still unclear. A significant proportion of mosaic embryos may originate from the oocytes that are aneuploid from the onset through a process similar to that known as a phenomenon of aneuploidy ''rescue.''

The overall experience of PGD for chromosomal disorders indicates a positive impact of the procedure on the clinical outcome in terms of the improved pregnancy and implantation rates, which may be almost doubled, as well the improved outcome of pregnancies through the statistically significant reduction of spontaneous abortions in IVF patients of advanced reproductive age, and other poor prognosis patients, including those with repeated IVF failures and repeated spontaneous abortions.[27,28] The clinical impact of PGD is even more significant for the carriers of balanced translocations who have an extremely poor chance of having an unaffected pregnancy. The data suggest a more than threefold reduction of spontaneous abortion rate in PGD patients with balanced translocations.[29,30]

The data show that single-cell DNA and FISH analysis has presently become an important tool for application of PGD in assisted reproduction and genetic practices, providing an important option for couples at the genetic risk to avoid the birth of an affected child and have a healthy child. In addition, the application of the technique has been extended to nondisease testing, such as the preselection of an HLA-compatible donor progeny for treatment of affected siblings requiring stem cell transplantation.

CONCLUSION

Preimplantation genetic diagnosis has been expanded to a variety of conditions, which have never been considered as an indication for prenatal diagnosis, including the late-onset disorders with genetic predisposition and preimplantation nondisease testing. Preimplantation genetic diagnosis has become a useful tool for the improvement of the effectiveness of in vitro fertilization (IVF), through avoiding the transfer of chromosomally abnormal embryos, representing more than half of the embryos routinely transferred in IVF patients of advanced maternal age and other poor prognosis patients. Preimplantation genetic diagnosis is of particular hope for the carriers of balanced chromosomal translocations, allowing accurately preselecting a few balanced or normal embryos, resulting from an extremely poor meiotic outcome. With the current progress in PCR-based detection of chromosomal abnormalities in oocytes and embryos, PGD may soon be performed for both chromosomal and single gene disorders using the same single cell, which is frequently required with the current expansion of PGD application. More than 1000 children have already been born following PGD, further confirming the accuracy and reliability of DNA and FISH analysis in single cells.

Prenatal Diagnosis of Fetal RhD Status by Molecular Analysis of Maternal Blood

Jean-Marc Costa
American Hospital of Paris, Neuilly, France

Alexandra Benachi
Hôpital Necker Enfants Malades, Paris, France

INTRODUCTION

Hemolytic disease of the newborn (HDN) affects the fetus or neonate and results from the transplacental passage of maternal alloantibodies directed against fetal red cell antigens inherited from the father. Over 90% of all cases of clinically significant HDN affect rhesus D (RhD)-positive infants born to RhD-negative mothers. When fetomaternal hemorrhage occurs antenatally or at delivery, maternal B lymphocyte clones that recognize the RhD antigen are established. In a subsequent pregnancy, if stimulated by the RhD antigen on fetal red cells, they proliferate and produce immunoglobulin (Ig) G antibodies that cross the placenta and destroy any RhD-positive red cell, resulting in fetal anemia.[1] The incidence of HDN has dropped dramatically (1–6/1000 live births) since 1968, when effective prophylaxis by anti-D Ig injection to the mother become available. In the United States, anti-D Ig is systematically administrated at 28 weeks' gestation and at delivery, or if an identifiable risk event occurs to RhD-negative mothers. Administration of blood derivative is not devoid of risk, and every effort should be made to improve techniques that reduce the number of injections.[1] In 1991, the RhD locus was localized to the short arm of chromosome 1. The elucidation of the molecular basis of the various blood group system alloantigens allowed the development of polymerase chain reaction (PCR)-based assay for blood group typing. These assays can be performed with fetal DNA obtained from amniocentesis or chorionic villus sampling.[2] In 1998, Lo et al.[3] and Faas et al.[4] discovered that fetal DNA was present in maternal blood and that fetal RhD status could be determined by a noninvasive method.

For clinical purposes, fetal RhD genotyping using PCR is a significant advancement. In case of a heterozygous father, fetal RhD genotype determination early in pregnancy is useful in the management of RhD-negative sensitized women. Amniocentesis is now accepted as the primary modality that is used to test fetal blood type.[5] Chorionic villous sampling can also be used, but it should be discouraged in patients who wish to continue the pregnancy if the fetus is found to be RhD-positive. Disruption of the chorionic villi during the procedure can result in fetomaternal hemorrhage and an anamnestic response in maternal titer, thereby worsening the fetal disease. This phenomenon can also occur during amniocentesis, and all attempts should be made to avoid transplacental passage.[1] Although the quantity and quality of DNA obtained from fetal sampling are less than those of leukocytes, many groups showed concordant results with serology, although the importance of testing more than one region of the gene was established.[2] Moreover, these sampling procedures are invasive, resulting in an increase risk of fetal loss (2%). Fetal RhD genotyping is also useful in RhD-negative pregnant women at risk for RhD immunization [American College of Obstetrics and Gynecology (ACOG) practice bulletin, 1999] to adapt prophylactic anti-D Ig infusion, to avoid unnecessary administration in case of an RhD-negative fetus.

Many groups have worked on a reliable noninvasive approach to determine fetal RhD genotype. Recovery of fetal cells from maternal blood or cervical mucus has been reported, but techniques require isolation and enrichment of fetal cells, and questions regarding sensitivity and cost-effectiveness are still unresolved for routine use.[6,7] An RNA-based assay on fetal erythroblasts isolated from maternal blood was also evaluated, but results were not conclusive.[8] Moreover, the persistence of fetal cells from previous pregnancies renders this approach susceptible to false-positive results. Despite the fact that many studies have shown that it is theoretically possible to isolate fetal cellular DNA from maternal blood, none of the techniques used meets the accuracy needed for clinical usage.[2]

DISCUSSION

Fetal DNA has been known to be present in maternal blood since the work of Lo et al.[9] in 1997. They first

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120021017

showed that Y-chromosomal sequences could be amplified from DNA isolated from the plasma of pregnant women carrying a male fetus. Fetal DNA is present in maternal serum at 5 weeks' gestation[10] and the concentration of fetal DNA increases with gestational age. Fetal DNA represents 3.4% (0.4–12%) and 6.2% (2.3–11.5%) of total plasma DNA in the first and third trimesters of pregnancy, respectively.[11] The origin of fetal DNA is still unclear. One or more mechanisms might be involved in this process: Fetal DNA might be released from apoptotic fetal cells circulating in maternal blood, or by trophoblasts (by lysis of the cells at the fetal–maternal interphase, or after entrapment in the maternal lung); it could also passively cross the placenta. Regardless of its origin, fetal DNA is rapidly cleared (mean half-life, 16 min)[12] and it has been shown not to persist in maternal blood after pregnancy.[13]

Although anecdotal diagnosis has been made using circulating fetal DNA (myotonic dystrophy;[14] achondroplasia.[15]), most of the studies on the accuracy of PCRs based on fetal circulating DNA have focused on Y-chromosome and RhD. In the past few years, studies have reported a 100% accuracy in fetal sex detection using a PCR technique in the first trimester.[16,17] This technique has now modified the prenatal diagnosis of X-linked disorders,[18] as well as the management of pregnancies at risk for congenital adrenal hyperplasia.[19] The use of cell-free DNA in maternal plasma and serum for noninvasive fetal RhD genotyping has been achieved independently by five groups.[3,4,20–22] Faas et al.[4] reported a highly sensitive but conventional PCR specific for *RHD* exon 7. The RhD genotype was correctly predicted in 31 second-trimester pregnancies. Lo et al. used a real-time *RHD* PCR technique on exon 10 in 57 RhD-negative women at different gestational ages. Two false-negative results were obtained in the first trimester. Results of Bischoff et al.[20] were less accurate, with 30% false negatives. In their PCR, input DNA was isolated from only 10 μL of serum, and this could explain the low sensitivity observed in this study.[2] Zhong et al.[21] analyzed 22 pregnancies and obtained one false-positive result, but they used a multiplex nested PCR using Y-chromosome-specific and RhD-specific primers. Our team studied 106 sera from RhD-negative pregnant women in the first trimester, and maternal serum results were in complete concordance with those obtained on fetal cells isolated from amniotic fluid and with the RhD serotype of the newborn.[22]

The assay was based on real-time PCR targeted at the 3′ end (exon 10) region of the *RHD* gene. Being a closed-tube system, real-time PCR offers, to date, the highest level of safety and represents the most secure amplification procedure. Total DNA was extracted

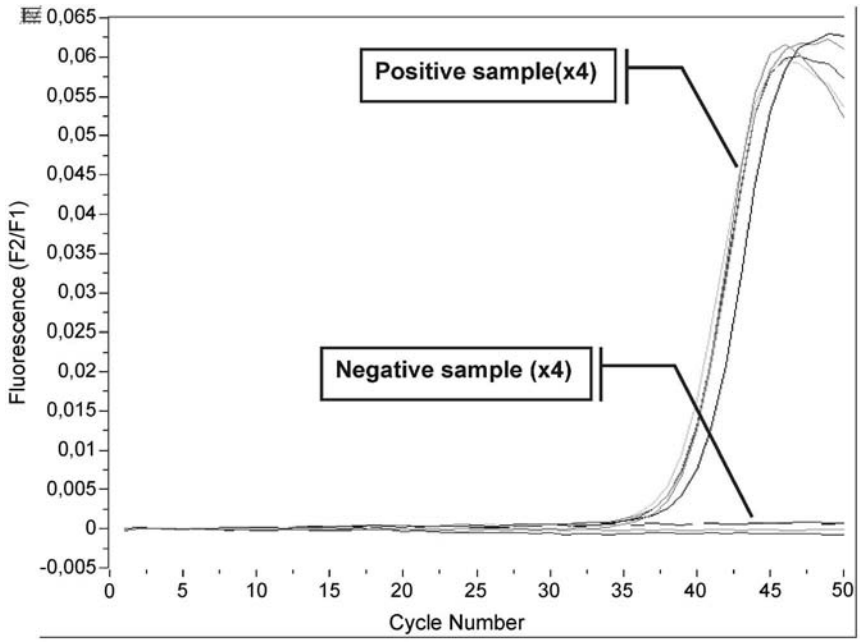

Fig. 1 Detection of the *RHD* gene in maternal serum using real-time PCR. Two patients' samples are tested in quadruplicate—one giving a positive result, and the second giving a negative one. (*View this art in color at www.dekker.com.*)

from 400 μL of serum using a silica-based commercial procedure and was then eluted with 50 μL of an elution buffer, of which 10 μL was used for the assay. Amplification as carried out in a LightCycler® instrument for 50 cycles. Each sample was analyzed, in duplicate, by different DNA extraction methods. Figure 1 illustrates typical results.

Van Der Schoot et al.[2] report a 100% concordance over 100 plasma samples (details on gestational age are lacking). The discrepancy on first-trimester determination of fetal RhD status might be a result of poor amplification efficiency. The real-time PCR assay (our team uses FRET instead of TaqMan technology) achieves a high level of sensitivity associated with a high level of safety because it is a closed-tube system; no false-positive results related to PCR product carryover are observed.[22] Poor efficiency of DNA recovery, or an inhibitor effect of DNA extract may also explain low sensitivity. As a control for amplifiability, the use of an endogenous gene (such as β-globin gene) seems inappropriate[3] because it evaluates mainly maternal DNA, which is present in large amounts in the plasma. For this reason, our group has proposed the addition of a low amount of a heterologous DNA as an internal control. Finally, the use of maternal serum instead of plasma used by Lo et al. may also explain these discrepancies.

One of the concerns for this technique is the internal control for the presence of fetal DNA. We postulate that fetal DNA was always present in maternal serum and that this control was not necessary. Van Der Schoot et al. consider that when no RhD-specific signal is obtained, the presence of fetal DNA in the plasma has to be confirmed by another fetus-specific DNA sequence from a highly polymorphic paternal antigen (STR markers) or from the Y-chromosome (e.g., *SRY*), which could be used only in women bearing a male fetus. However, most of those assays that have already been described are multiplex PCRs in which sensitivity is low because paternal alleles are difficult to detect within the high background of maternal alleles and because of poorer amplification.[21] Notwithstanding this, Pertl et al.[23] successfully applied multiplex fluorescent PCR of STR on fetal DNA in maternal plasma, but gestational age in this study was 34 weeks and over—a time when fetal DNA is particularly high in maternal serum, which is not the case in the first trimester.[2] To Van Der Schoot et al.'s point of view, only positive results are meaningful until allele-specific amplification strategies allow more sensitive systems. We do agree in theory with this statement, but our personal experience (over 250 cases with 100% accuracy) has shown that if internal control of the amplification is used, negative result is still of clinical value.

Another issue is genotyping errors caused by rare variants of the *RHD* gene. These variants could lead to false-positive or false-negative results. A fetus carrying an RhD-negative allele might be typed RhD-positive when the RhD-specific PCR assays are based on polymorphic sites still present in the silent allele. In already sensitized RhD-negative pregnant women, a false-positive result will not have much consequences as maternal IgG titer will be followed as usual and will not lead to any invasive intervention. In case of unsensitized women, unnecessary Ig injection will be performed if needed, which is acceptable. In the Caucasian population, RhD negativity is usually caused by deletion of the *RHD* gene, but negativity could also result from aberrant *RHD* alleles that do not lead to RhD expression. In the African black population, the variant *RHD* genes r′s (=Cde^S) and *RHDψ* can underlie serologic RhD negativity.[2] In the Caucasian population, 14 different RhD-negative *RHD* alleles have been described,[24] but the frequency of these alleles is extremely low (1/1500); therefore they do not influence the accuracy of *RHD*-specific PCR assays. It has been suggested that different regions of the *RHD* gene should be examined to increase the accuracy of RhD genotyping. However, the assay described by our group was only targeted at the 3′ untranslated region specific to the *RHD* gene (exon 10) and no false positive was detected. Lo et al.[3] and Zhang et al.[25] also used single *RHD* gene region assay on exons 10 and 7, respectively. The population of those studies is mainly Caucasian, which could explain the absence of false positives. Van Der Schoot et al.[2] have designed primers and probes located in exon 7. This exon is present in almost all RhD-positive *RHD* alleles (except some rare variants). False-positive results will be obtained, such as with the primers used by our team located in exon 10, in fetuses carrying only the silent *RHDψ* gene.

RhD positivity might be missed when the fetus is carrying an aberrant allele, which still leads to RhD positivity, although not all RhD-specific polymorphic nucleotides are present.[2] This kind of variant might lead to alloimmunization in an RhD-negative mother, but HDN in a fetus whose red blood cells have a partial D antigen is rare. Van de Schoot et al. suggest that for immunized mothers, no aberrant RhD alleles should be missed; therefore a multiplex PCR approach on more than one region of the *RHD* gene has to be taken and the *RHDψ* gene has to be recognized. From our point of view, the sensitivity of a multiplex PCR will be less than the actually reported protocols, and the frequency of these aberrant alleles is so small that sensitivity of the test should be preferred. However, in a non-Caucasian population, the existence of those variants should be kept in mind.

CONCLUSION

The high level of accuracy of fetal RhD genotyping obtained by different groups could enable this technique to be offered on a routine basis for the management of RhD-negative patients during the first trimester of pregnancy. This strategy offers many advantages. The potential risk for maternal infection from contaminated anti-D Ig has to be taken into consideration, and women should be informed of the risk involved.[22] Even if anti-D product was safe with regards viral transmission, the risk could not be formally excluded. Moreover, as unnecessary infusion of anti-D Ig would be avoided, this strategy could contribute to saving this limited product until clonal anti-D becomes available. First-trimester determination of RhD fetal status is of interest because several clinical events may be responsible for RhD alloimmunization very early in pregnancy, such as therapeutic or spontaneous abortion and bleeding. In case of an RhD-negative fetus, no further biological and clinical investigations should be performed during the rest of the pregnancy.

First-trimester pregnancy is a critical period for prenatal diagnosis using noninvasive and invasive procedures. The PCR assays actually used need to be evaluated on a large-scale population,[2,22] and could lead to a combined systematic analysis of fetal RhD genotyping in RhD-negative women in the first trimester, in conjunction with fetal nuchal translucency and Down's syndrome screening test by serum biochemical markers.

Prenatal Diagnosis Using Fetal Cells and Cell-Free Fetal DNA in Maternal Blood

INTRODUCTION

The development of safe and efficacious methods for prenatal diagnosis has been the subject of intense research in the past decade. This has, in part, been spurred by a dramatic shift in population demographics in developed nations, typified by a significant increase in maternal age (>30 years) and a concomitant reduction in parity, with most couples opting only for one child. Because an increased maternal age is associated with an elevated risk for bearing a fetus with a chromosomal anomaly, this demographic change has led to an increased need for prenatal diagnoses, which can currently only be reliably performed using invasive practices, such as amniocentesis or chorionic villus sampling. As these procedures are associated with a significant risk for fetal loss (on the order of 0.1%), the need for safe alternatives has been voiced, as many couples were reluctant to expose their long sought-after unborn child to this risk.

FETAL CELLS: BRIEF HISTORICAL OVERVIEW

Even though the first description concerning the deportation of trophoblast cells into the maternal periphery was made by Schmorl at the turn of the 19th century, it was only in the late 20th century that the tools were developed, which permitted the enrichment of rare circulatory fetal cells (frequencies as low as 1×10^7 nucleated maternal cells). The main proponents were fluorescence-activated cell sorting (FACS) and magnetic cell sorting (MACS). Common consensus indicated that the target fetal cell of choice was the fetal erythroblast, also termed nucleated red blood cell (NRBC) because of the high prevalence of this cell in the fetal circulation (up to 50% of all nucleated fetal cells), its expression of potentially fetal-specific molecules (fetal and embryonic hemoglobin chains), and its short life span, which excluded cells from previous pregnancies from being analyzed.[1,2]

Further innovations that accelerated the pace of research in this field were the developments of fluorescent in situ hybridization (FISH) and polymerase chain reaction (PCR), both of which permit genetic analysis of individual cells. By use of these technologies, proof-of-principle studies demonstrated that fetal aneuploidies as well as single-gene Mendelian disorders, such as hemoglobinopathies, could be determined from the analysis of enriched circulatory fetal erythroblasts.[1,2]

FETAL CELLS: CLINICAL STUDIES

These promising results encouraged the instigation of at least two large-scale studies, the largest of which was conducted under the auspices of the National Institutes of Health (NIH)—the so-called NIFTY Study.[3] In this study, close to 3000 samples were recruited from pregnant women about to undergo invasive prenatal diagnostic testing because of an elevated risk for bearing a fetus with a chromosomal anomaly. These samples were then either processed by MACS or FACS and analyzed by multicolor FISH. All experimental results were compared to karyotypes obtained from the invasive procedure—the current gold standard. The results from this study, which were published in 2002, were in stark contrast to the euphoria that reigned a few years previously, in that fetal cells could, at best, be detected with a sensitivity of 48% using MACS and below 15% using FACS.[3] Consequently, the NIFTY Study reiterated the importance of large-scale well-designed and conducted studies in order not to be misled by short case reports such as high-profile publications.

An important aspect of the NIFTY Study that is frequently disregarded in other clinical studies is that it specifically addressed psycho-social issues concerning the introduction of a new noninvasive method for prenatal diagnosis, especially the potential problem of coercion. This part of the NIFTY Study clearly showed that coercion would not be an issue, and the introduction of such a noninvasive test would be especially welcomed by couples involved in assisted reproduction (ART) programs.[4,5]

DOI: 10.1081/E-EDGP 120021949

FETAL CELLS: DIAGNOSIS OR SCREENING?

The scarcity of fetal cells in the maternal circulation and the failure to reliably retrieve these cells from maternal blood samples are amply underscored by the sobering results of the NIFTY Study. As even more disappointing results were obtained in the study initiated by Applied Imaging, which used state-of-the-art technology for the automated detection of putative fetal erythroblasts,[5] questions have been raised as to whether the pursuit of fetal cells can have any future diagnostic value.[1] Although it is clear that current technologies are not suited to clinical applications, there are other facets worthy of future exploration. Among these is the observation that the trafficking of fetal cells into the maternal periphery appears to be greater in pregnancies with aneuploid fetuses, particularly in cases with trisomy 21.[6] Furthermore, reports indicating that trophoblast cells may be more prevalent in the maternal circulation than previously thought[7] suggest that unnecessary constraints may have been made in restricting previous studies solely to fetal erythroblasts. Therefore it is possible that a greater degree of success may be attained by casting the net out to catch a wider variety of fetal cells. Furthermore, a sensible strategy may be to move away from a diagnostic setting to a screening one. In such a scenario, the focus would be shifted to the detection of fetal cells only in those instances where suspicion of a fetal aneuploidy exists. These results are used in combination with those obtained from ultrasound and/or serum analyte examination to reduce the relatively high false-positive rate of other methods, or, at best, to obviate the need for any further confirmatory invasive procedures.

EXTRACELLULAR CIRCULATORY FETAL DNA

Possibly the observation that has changed future prospects for the noninvasive diagnosis of fetal genetic traits the most was that describing the presence of extracellular fetal DNA in maternal plasma and serum.[8] This analysis was prompted by reports indicating that cell-free tumor-derived DNA was readily detectable in the plasma of cancer patients.[9] By arguing that the placenta shares many similarities with tumors (high rate of cell turnover, tissue invasion), it was hypothesized that placenta-derived cell-free fetal DNA may be present in the maternal circulation. This indeed turned out to be the instance, with cell-free fetal DNA being readily detectable by conventional PCR assays. However, a caveat of this fetal genetic material is that, because cell-free maternal DNA is also present in the maternal circulation, only paternally inherited loci absent from the maternal genome can be reliably detected. Consequently, most studies have focussed on the detection of such facile fetal genetic loci such as Y chromosome-specific sequences.[10]

An advantage of cell-free fetal DNA is that the concentration of this material in maternal samples can be reliably quantified by the use of real-time PCR. Studies employing this technology indicated that this analyte had a very short half-life (on the order of 15 min) and rapidly disappeared from the maternal periphery postdelivery.[11] It was also shown that cell-free fetal DNA constitutes approximately 5% of the total circulatory cell-free DNA, and that the number of copies of this fetal material was approximately 100-fold higher than the estimated number of circulatory fetal cells. Current consensus is that cell-free fetal DNA is almost exclusively derived from the placenta.

Furthermore, by the use of such quantitative PCR technology, it was clearly demonstrated that the concentrations of this fetal analyte were elevated in pregnancies with aneuploid fetuses (again most notably with trisomy 21),[12,13] or those affected by preterm labor and preeclampsia.[14–16] A valuable aspect of these studies is that, by being performed independently, they verified the soundness of the initial observation and, for the first time, introduced a high degree of reproducibility into this research arena.

EXTRACELLULAR FETAL DNA: CLINICAL APPLICATIONS

The discovery of cell-free fetal DNA quickly led to a clinical application, namely the determination of the fetal RhD genotype in pregnancies at risk for hemolytic disease of the fetus and newborn (HDN).[10] This is largely because of the fortunate constellation existing in Caucasians where the *RhD* gene is generally absent in RhD individuals. Therefore the analysis of the fetal RhD genotype in pregnancies with an RhD constellation (father RhD, mother RhD) is similar to the facile detection of Y chromosome-specific sequences in a maternal background. Several large-scale studies have indicated that fetal loci such as the SRY locus on the Y chromosome and the *RhD* gene could be detected with sensitivities approaching 95%, coupled with 100% specificity.[17] Consequently, a few European centers have started offering this service in a clinical setting (i.e., either the determination of the fetal RhD status in pregnancies at risk for HDN, or fetal sex in pregnancies at risk for an X-linked disorder). The significance of this development truly becomes apparent when comparing the speed with which this transition from bench to bedside has occurred to more than a decade invested into circulatory fetal cells, where no similar test is yet in sight.

Despite this premise, other tests have been slow to follow, especially those for the detection of paternally inherited mutant alleles for heterozygous compound Mendelian disorders (e.g., hemoglobinopathies, cystic fibrosis). Such tests would be of importance in cases where the mother and father do not share the same disease allele. In this manner, the detection of the paternal mutant allele can serve to indicate that the fetus may be affected, whereas its absence would indicate that it is not affected, and thereby obviate the need for an invasive prenatal diagnostic procedure. It appears that the major factor hindering these assays is the predominance of maternal cell-free DNA over that of the fetus (at least 25:1), in that many of the allele-specific PCR assays are no longer capable of reliably determining single base changes under such conditions. It is clear that alternative strategies will have to be sought to overcome this problem.

EXTRACELLULAR FETAL RNA

A recent discovery, once again inspired by oncological observations concerning tumor-derived mRNA transcripts, is that placenta-derived mRNA species are present in maternal plasma samples.[18] Unlike their cell-free fetal DNA counterparts, which are truly acellular, these mRNA molecules are contained in small membrane particles. This difference becomes apparent when filtering the plasma sample, in that the mRNA containing particles are retained by the filter, whereas the cell-free DNA passes through. Disruption of the protective membrane particles renders the mRNA highly labile, and it is rapidly degraded by nucleases in the plasma sample. Consequently, stored or frozen samples are not suitable for these studies. Current analyses have focused on mRNA transcripts expressed in the placenta such as human placental lactogen (hPL), human chorionic gonadotropin (βhCG) or corticotropin-releasing hormone (CRH). In the latter instance, quantitative PCR analyses have indicated that the level of CRH mRNA species is elevated in pregnancies with manifest preeclampsia.[19] The immediate advantage of studying mRNA species is that it permits fetal sex-independent analysis in that the study is not restricted to the detection of Y chromosome-specific DNA sequences.

CIRCULATORY NUCLEIC ACIDS: ROLE IN DETECTING HIGH-RISK PREGNANCIES?

The observation that cell-free fetal DNA concentrations are elevated in pregnancies with certain fetal aneuploidies or pregnancy-related disorders, such as preeclampsia, have led to the suggestion that this may serve as a marker for such pregnancies. This is further supported by two independent studies, which have indicated that the levels of circulatory fetal DNA are elevated early (second trimester) in those pregnancies that later develop preeclampsia.[20,21] Unfortunately, these studies are too small to provide any indication of the possible predictive value. An examination of second-trimester fetal DNA levels has indicated a minimal increase in sensitivity for the detection of trisomy 21 fetuses when combined with the analysis of other serum analytes. The proposal that the analysis of circulatory fetal DNA could aid in the distinction between true and false preterm labor (i.e., those that do not respond to tocolytic treatment and still deliver prematurely, and those that respond and deliver at term) could, unfortunately, not be confirmed in a larger study.

It is perhaps in this area that the analysis of circulatory mRNA species will come to the fore, as apart from not being restricted by fetal sex, the description of mRNA species overtly expressed in the placenta of trisomy 21 placentae[22] may aid in the development of aneuploidy-specific screening tests. It is also possible that preeclampsia may be associated with the upregulation of different mRNA species when compared to other pregnancy-related disorders, such as preterm labor. This distinction may lead to the development of specific diagnostic or screening markers.

CONCLUSIONS

The conundrum facing research into the potential use of circulatory fetal cells for prenatal diagnostic purposes is whether it will be possible to develop a test that is rapid, reliable, and cheap enough to compete with the current high levels of sensitivity (>90%) and very low false-positive rate (<1%) for the detection of trisomy 21 fetuses, obtained by a combination of different ultrasound markers (nuchal translucency and nasal bone) and serum analytes.[23]

However, it is likely that once the hurdles regarding the detection of subtle fetal genetic alterations in a high background of maternal circulatory DNA have been overcome, the analysis of cell-free fetal DNA will further establish itself in day-to-day clinical practice. The usefulness of circulatory RNA species remains to be determined, but it is highly probable that by the inclusion of genomic methodologies, new markers may be identified for the screening of a number of high-risk pregnancies. In either instance, it appears that current challenge can only be met by an integrated approach that incorporates a wide range of disciplines and expertise.

Protein Microarrays

Lance A. Liotta
Virginia Espina
National Cancer Institute, Bethesda, Maryland, U.S.A.

INTRODUCTION

Protein microarrays, in the simplest sense, are immobilized protein spots on a substratum. Individual protein spots may be heterogeneous or homogeneous, and may consist of cell or phage lysates, an antibody, a nucleic acid, drug, or recombinant protein. These immobilized bait molecules are detected by probing the microarray with a signal-generating molecule such as a tagged antibody, ligand, serum, or cell lysate. The tagging molecule generates a pattern of positive and negative spots. The signal intensity of each spot is proportional to the quantity of applied tagged molecules bound to the bait molecule. The spot pattern image is captured, analyzed, and correlated with biological information.

Protein microarrays have broad applications for discovery and quantitative analysis. Protein microarray technology may be applied to drug discovery, biomarker identification, and molecular profiling of cellular material. It is expected that the clinical utility of protein microarrays will depend on their ability to provide a map of known cell signaling proteins and to provide crucial information about protein posttranslational modifications. Protein microarrays help to provide a view of the disrupted cellular machinery governing disease. Identification of critical nodes, or interactions, within these networks is a potential starting point for drug development and/or design of individual therapy regimens.

CELLULAR SIGNALING PATHWAYS

Information Flow Through a Cell

Proteomics is considered the characterization of the entire cellular protein content. This broad categorization of cellular proteins may not yield immediate, clinically useful information because protein function is closely related to specific cell–cell interactions and the cellular microenvironment. Proteins relay information from the extracellular environment through a series of complex protein–protein interactions, allowing protein complexes to coalesce, then dissolve after the signal is gone, or by changing the shape of a receptor protein. As an example, some types of signaling mechanisms are mediated by phosphorylation events, cleavage events, or alteration of a protein's conformation. Characterization of these events may allow the elucidation of the information flow through a cell, which in turn can point to critical nodes or pathways required for cell survival.

Examples of functional proteomic information can be found in the phosphorylation states of signaling proteins and the flow of information within a cell and the organism. The ability to discern these specific interactions, or pathways, is a goal of clinical proteomics. The utility of protein microarrays is expected to be their ability to recapitulate the in vivo cellular signaling network, based on specific phosphorylation events, at any given point in time for a cell population.[1–13] Specific protein phosphorylation events are just one example of many types of posttranslational modifications that may affect information flow through a cell. Information concerning protein posttranslational modifications is not reflected in gene microarrays. Completion of a detailed protein network map, even for a subset of cellular processes or critical nodes comprising a network, coupled with detailed genomic and biologic insights, is expected to lead to the design of treatment targeted toward a specific cellular pathway or pathways.[14,15]

Tissue Microenvironment

The tissue microenvironment comprises multiple cell types, in a miniature ecosystem, permitting numerous interactions between diseased and disease-free cells. Host interactions, nutritional status of the individual, and immune system function influence the cell's microenvironment. Examples of molecules mediating cell–cell interactions include secreted factors, cell surface receptors, and adhesion molecules.[16–18] Cells carrying a constitutive genetic defect may express a variety of proteins depending on the context of the microenvironment. Thus cells, specifically diseased cells, are a product of their microenvironment as well as their genetic constitution.

A comprehensive analysis of the molecular basis of cancer and other disease states requires integration of the distinct, but complementary knowledge, garnered from the fields of genomics and proteomics. Genetic

DOI: 10.1081/E-EDGP 120020816

defects ultimately lead to altered functional proteins that confer survival advantages for tumor cells or disrupt normal cellular function.[19,20] Genomics and DNA microarrays point toward potential genetic defects that may cause disruptions in cell signaling pathways. On the other hand, protein microarrays help to provide information detailing the specific phosphorylation states of proteins. Changes in phosphorylation states may have inhibitory, activating, or neutral effects on a protein depending on the specific site of the phosphorylation event. Protein posttranslational modifications are not solely limited to phosphorylation events, but rather represent one molecule capable of indicating changes in signaling proteins that may reflect changes in the activation state of the protein.

Redundancy in Signaling Pathways

Cancer is an example of a genetically based disease process, but on a functional level, it is a proteomic disease. This genetic alteration is translated into a defective or altered protein that guides the survival of the diseased cell population. The genetic defect of the cancer cell selectively offers a survival advantage for the cell by altering cellular signaling pathways, possibly driving tumor invasion and metastasis.[17,19,21] As expected, these pathways are fluid and dynamic, adapting to the changing microenvironment.[15,22–26] Cellular survival mechanisms include redundancy and collateral signaling pathways. Recurrent tumors are prime examples of a completely natural and normal function of the cell's capacity to adjust to its microenvironment. The need for individual molecular profiling quickly becomes apparent in this context of redundancy and dynamic signaling pathways.

PROTEIN MICROARRAY TECHNOLOGY

Technology Overview

One means of profiling a protein network via protein microarrays is accomplished by comparing the proportion of total protein (phosphorylated and nonphosphorylated) to the phosphorylated protein. Comparison of a selected set of protein phosphorylation events, coupled with knowledge of the biology of the phosphorylation event, may allow us to infer information concerning the activity level of the protein(s). Monitoring the total and phosphorylated proteins before, during, or after treatment, or periodically over time, or between disease and disease-free states, may allow us to infer information concerning the activity levels of the proteins in real time for a

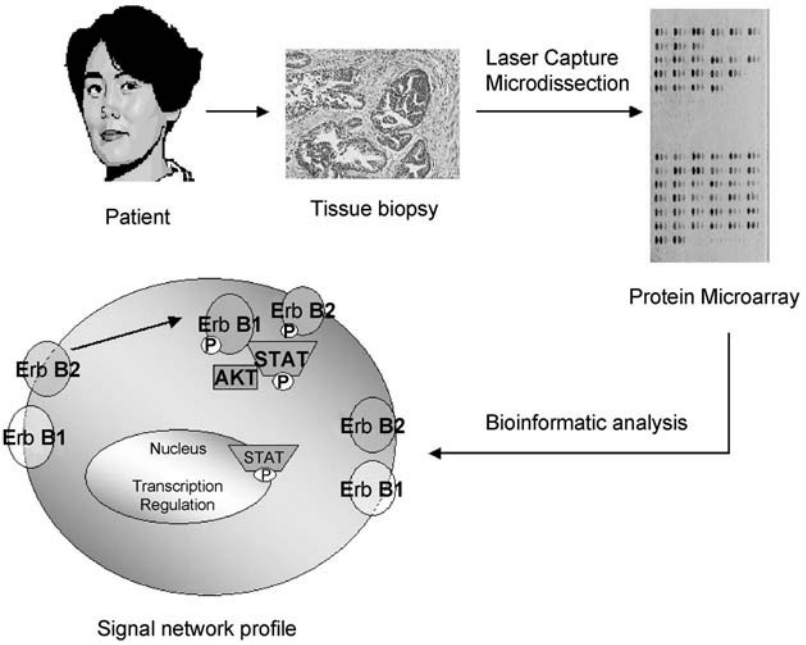

Fig. 1 Protein molecular profiling. Patient biopsy samples are applicable for molecular profiling via laser capture microdissection (LCM), protein microarray, and bioinformatic analysis. A heterogeneous biopsy is the starting point for cell procurement. LCM enhances the procurement of pure cell populations. Whole-cell protein lysates are prepared from the microdissected cells and printed on a microarray. Bioinformatic analysis reveals the activation state of key signaling proteins. The pattern of activated or phosphorylated proteins is developed into a signaling network profile for that particular patient sample.

particular protein pathway.[14,15] It is conceivable that this technology concept could be applied to other posttranslational modification events such as glycosylation, lipidation, or myristalization.

Microarray Formats

Forward phase microarray

There are currently two approaches to producing arrays capable of generating this type of network information. The first format is the forward phase array, in which a labeled bait molecule, typically an antibody, is immobilized on the substratum.[1–6] Each spot represents only one type of bait molecule or antibody. The array is incubated with only one test sample containing several different analytes of interest. The captured analytes are detected with a second tagged molecule that recognized the captured analyte or by labeling the analyte directly.

Reverse phase microarray

Reverse phase microarrays consist of immobilized analyte molecules, with multiple analytes in each spot (Fig. 1). Each spot represents an individual test sample, allowing an array to be comprised of multiple, different samples, such as clinical biopsy samples. The reverse phase array is probed with a single detection molecule, and a single analyte is measured for each spot on the array, across multiple samples. This format allows multiple samples to be analyzed under the same experimental conditions for any given analyte. The arrays are probed separately with two different classes of antibodies to specifically detect the total and phosphorylated forms of the protein of interest. Comparison of the proportion of phosphorylated proteins across patients on the same array provides insights into the cellular signaling network for individual patients. Each slide microarray is probed with a different antibody, generating a set of microarray slides for each set of probe antibodies. Construction of reverse phase

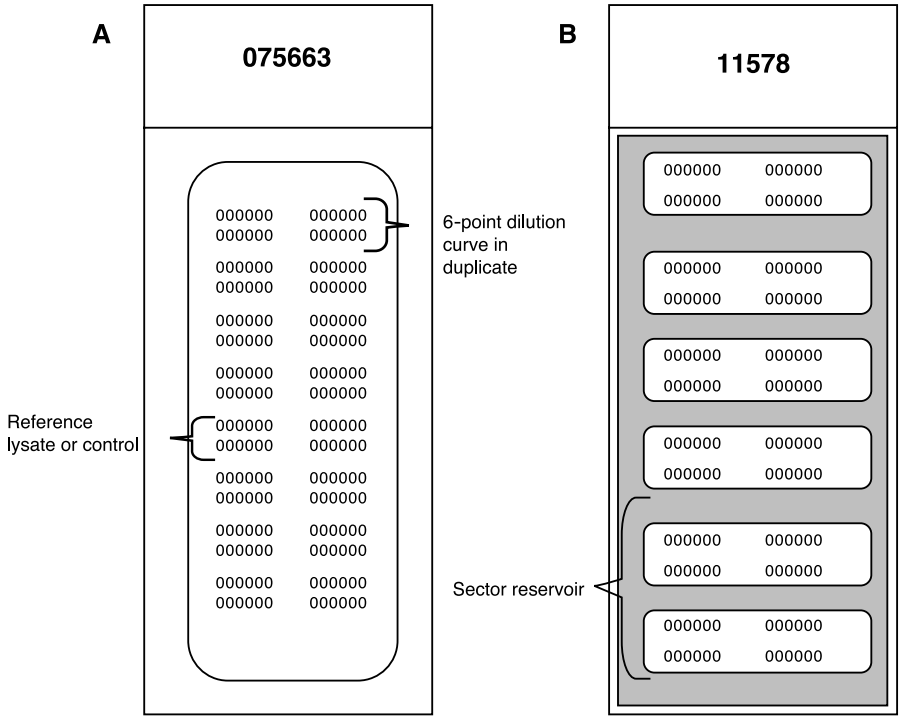

Fig. 2 Reverse phase protein microarray design. Protein microarrays may be designed as a single pad (A) or as sectors (B). The single pad design represents multiple samples, probed with a single antibody, on one microarray slide. Each sample is arrayed in duplicate in a 6-point dilution curve representing undiluted, 1:2, 1;4, 1:8, 1:16 dilutions, and a blank or negative control spot. Inclusion of a reference or control lysate permits process quality control within each slide. The single pad array design (A) allows multiple patient samples to be compared across arrays. Sector microarrays (B) represent one individual sample printed in multiple sectors and probed with a different antibody in each sector. The sample is prepared in a dilution curve in the same manner as for a single pad microarray. The removable reservoir effectively miniaturizes the assay, thus decreasing the volume of reagents for any particular assay. The sector array design allows analysis of multiple proteins for an individual patient on one microarray.

microarrays follows these general protocols: sample collection, sample preservation, preparation of frozen tissue sections, isolation of pure cell populations, protein extraction, microarray printing, and protein detection.

Reverse Phase Microarray Design

A typical array layout consists of a series of 4–6 horizontal spots, representing a mini dilution curve of each sample (Fig. 2). Multiple samples may be printed on each slide, representing before- and after-treatment samples or normal and malignant tissue lysates. The use of multiple sample dilutions ensures the protein of interest is within the linear dynamic range of the assay, based on the antibody sensitivity and affinity.[6]

Sector microarrays

Protein arrays may also be printed in sector formats. A sector array consists of multiple small pads of substratum on a slide. A reservoir placed around each sector permits a different antibody to be used for probing the samples. The sector format miniaturizes the array, providing an increased signal/noise ratio, and is well suited to individual patient assessments. Through the sector array, multiple antibody probes can be multiplexed on a single slide. Thus on one slide, a complete set of analytes can be characterized and used to support a therapy decision for a single patient. For example, a sector array can be probed with antibodies spanning a key cell growth or apoptosis pathway targeted for therapy.

Sensitivity Requirements and Clinical Samples

Clinical applications of protein microarray technology require systems that: 1) are capable of detecting a broad dynamic range of analyte concentrations; 2) exhibit adequate sensitivity (in the femtomolar range) and specificity for detecting low abundance proteins; and 3) are capable of limiting interference from contaminating biologically active molecules such as peroxidases, biotin, avidin, and immunoglobulins.

Protein microarray technology may be directly applied to biopsies, tissue cell aspirates, or body fluid samples.[1,27,28] The total number of cells required for microarray construction is dependent on the number of analyte molecules, the sensitivity of the detection system, and the number of analyte molecules/mole.[6]

Laser Capture Microdissection

Accurate interpretation of signaling pathways is dependent on the proportion of cells contributing to the total signal for a given cell population. Laser capture microdissection (LCM) is an established technique for procurement of pure cell populations from heterogeneous tissue sections.[29,30] Microdissection permits procurement of cells from any designated area of a tissue biopsy, such that cells representing normal, diseased, or stromal tissue may be obtained in relation to their microenvironment. Proteins from neighboring, contaminating cells will not be microdissected, thus limiting their contribution to the overall repertoire of proteins in the population of cells to be studied. Protein microarray construction may be performed with as few as 5000 microdissected cells/15 μL of extraction buffer.

Antibody Validation

A limiting factor for the successful application of this reverse phase protein microarray technology for monitoring phosphorylation events is the availability of specific, high-affinity antibodies.[6,12] DNA probes have been manufactured with known specific affinity constants. On the other hand, antibodies, aptamers, and ligands utilized for protein microarrays cannot be manufactured with predictable affinity or specificity. Reproducible protein microarray analysis relies on antibodies that are specific for the protein of interest. Validation of antibodies via Western blotting is typically performed with a complex biologic sample similar to the sample that will be used on the microarray. A validated antibody should reveal a single, specific band at the expected molecular weight, thus indicating its specificity.

Table 1 Comparison of contact and noncontact microarray printing technologies

	Technology	Types	Determination of spot size	Sample delivery volume
Contact printing	Direct contact of print head with substratum	Ink jet, pin and ring, quill	Pin diameter	0.3–2.0 nL
Noncontact printing	Fluid contact only	Piezoelectric, solenoid	Droplet volume	0.1–0.3 nL piezoelectric; 4.0–8.0 nL solenoid

Protein Extraction

Molecular profiling for elucidation of cell signaling networks requires liberation of the entire cellular proteome. Previously unidentified cell signaling partners could potentially be overlooked if a subcellular compartment was excluded from the extraction protocol. Thus extraction buffers with ionic and nonionic detergents will solubilize cells, generating proteins that are acceptable for use with microarray techniques.

Substratum and Arraying Devices for Reverse Phase Protein Microarrays

Protein microarray substrata may be nylon, nitrocellulose, or silanized silica.[31–33] The substratum requirements for protein arrays are as follows: 1) high binding capacity; 2) should not alter the protein structure; and 3) low background signal. Nitrocellulose-coated glass slides are a common substratum for protein arrays. Proteins bind to nitrocellulose via electrostatic interactions in an irreversible manner, limiting the number of probes that can be used with any one set of immobilized proteins.[32,33] The nitrocellulose slide format allows multiple slides to be printed for each set of samples, thus permitting multiplex analysis with a set of antibody probes (Fig. 1). Chromogenic, fluorometric, and luminescent detection methods may be used with an adequate signal/noise ratio.[33,35–44]

Microarray printing technology currently exists in two forms: contact and noncontact devices. Contact printing is accomplished by direct contact between the print head and the substratum. Noncontact printing dispenses a minute volume of sample above the substratum.[34] A comparison of printing devices is shown in Table 1. Selection of a printing device depends on the viscosity of the material to be printed, the throughput required, the space, and the ability to print replicate samples.

CONCLUSION

Protein microarray applications are being applied to address the challenges of translational medicine. Mapping pathophysiological defects, via protein microarrays, is enhancing our ability to discern treatment effectiveness at an early time point during treatment, thus hopefully leading to early intervention and positive patient outcomes. The need for discovery and quantitative analysis of protein–protein interactions and posttranslational modifications will undoubtedly benefit from this technology. Protein microarrays are proving useful for penetrating into phosphorylation events that are not related to gene expression. The ability to draw a functional map of the state of key protein pathways within a patient's tumor cells will hopefully become the starting point for individualized therapy. Under this scenario, therapy may be tailored to the individual tumor's molecular defect, making it feasible to administer combination therapy targeting multiple interdependent points along a pathogenic pathway or targeting separate pathways.

Protein Truncation Test (PTT)

Sadanand Gite
Alex Garvin
Kenneth Rothschild
AmberGen Inc., Boston, Massachusetts, U.S.A.

INTRODUCTION

The protein truncation test (PTT) is a mutation detection technique that specifically detects mutations leading to the premature termination of protein translation. An increasing number of genes implicated in disease processes (primarily cancers) have been identified where the majority of the mutations result in premature termination of translation leading to an incomplete and nonfunctional protein product. These include the *APC* gene,[1,2] *BRCA*1 and 2,[3] *PKD*1,[4] *NF*1,[5] *TSC*1 and 2,[6] and *DMD*.[7] Protein truncation test was first reported in 1993[1,8] and has been used mainly in clinical research settings (http://www.genetest.org). However, until recently the PTT had not significantly advanced beyond its original form and has not gained wider acceptance because of several limitations that include 1) slow readout because of the use of electrophoresis followed by radioactive detection; 2) errors in the visual detection of mobility shifts on a gel (which depend on the level of the training of the technician); 3) safety issues involved with the use of radioactivity; and 4) the difficulty in automating SDS-PAGE. We describe here recent advances in the PTT including the introduction of an ELISA-based PTT (ELISA-PTT), and how these advances might lead to wider acceptance of this promising yet underutilized technique.

TECHNICAL DESCRIPTION OF PTT

PTT Protocol

The workflow for the standard-PTT and ELISA-PTT[9] is outlined in Fig. 1. The first step involves the isolation of genomic DNA/mRNA and amplification of specific regions of coding sequences from the target gene using PCR/RT-PCR. These PCR products are then used as template for in vitro (cell-free) translation and the synthesized proteins are traditionally analyzed by SDS-PAGE/autoradiography. Shorter protein products of mutated alleles are distinguished from the full-length protein products of normal alleles due to mobility differences. In the case of ELISA-PTT (Fig. 2A), a reduced C- to N-terminal ratio (C/N) indicates the presence of mutations.

Designing Primers for PTT

Several factors are important when designing PCR primer pairs for PTT. Proper design of the forward primer is the most critical factor. This primer contains four specific regions that are essential for efficient in vitro translation of the PCR amplicon. The 5′-primer must have a promoter sequence at the 5′-end (generally for T7 polymerase) followed by a 5–7-bp spacer sequence, a eukaryotic translation initiation sequence (Kozak sequence) including the ATG start codon, and at the 3′-end, a region of the target gene sequence ($\sim$17–24 bp) in-frame with the ATG codon. In addition, for ELISA-PTT, the 5′-primer also contains sequences coding for the N-terminal detection tag (epitope) and/or binding tags. The 3′-primer must be complementary to the 3′-end of target sequence and for ELISA-PTT must also contain a sequence encoding the C-terminal detection tag.[9] To ensure that truncation mutations near the beginning or at the end of a fragment (i.e., at the 5′- or 3′-end) are not missed, flanking segments for a large region of coding sequence should have an overlap of 350–500 bp. When RNA-based PTT is used, primers from overlapping segments should be located in different exons to reduce the possibility that a mutant allele having a deletion or splicing defect does not amplify with any of the primer sets.

Template Considerations for PCR Amplification

Although transcription/translation of PCR products up to 3 kb is not difficult, best results are obtained using fragments of 1.3–2.0 kb size. If a gene contains several kilobases of coding sequence, it is necessary to divide it into multiple segments. Most published PTT reports use genomic DNA as the template to analyze large exons, e.g., exon 11 of *BRCA*1 and exon 15 of the *APC* genes.[1,3]

DOI: 10.1081/E-EDGP 120020757

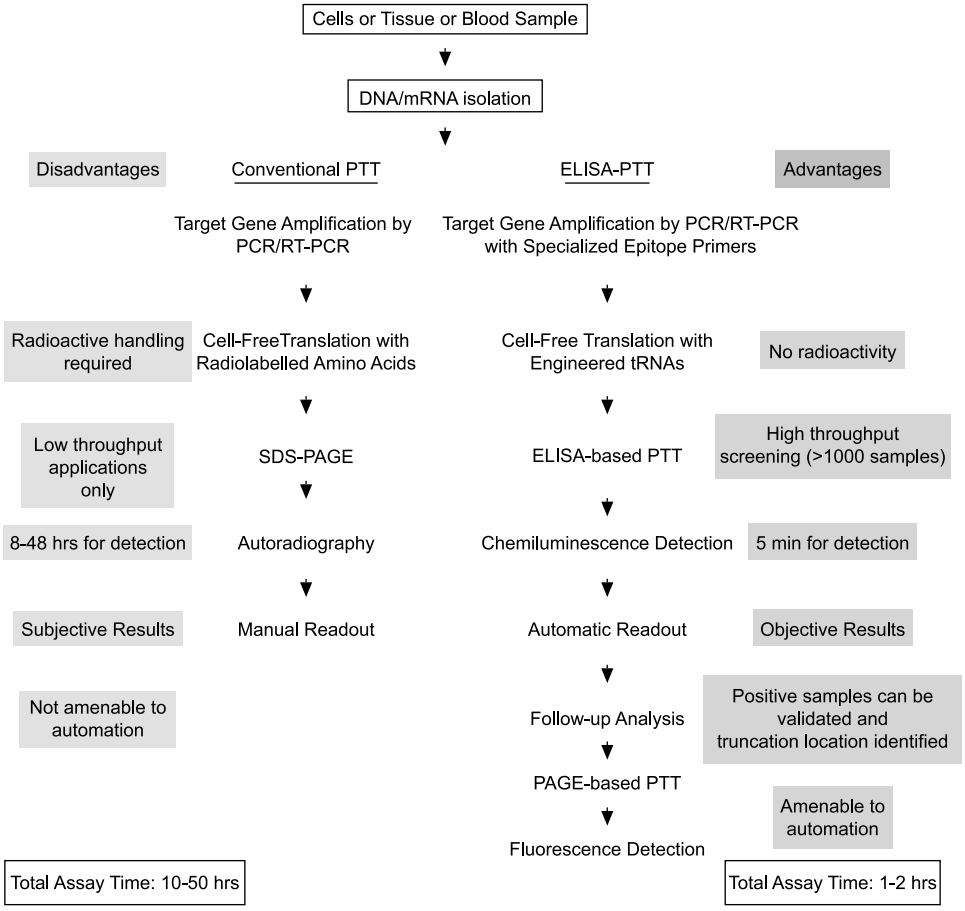

Fig. 1 Various steps involved in typical protein truncation test. (*View this art in color at www.dekker.com.*)

In addition, several attempts have been made to scan entire genes for truncating mutations using a combination of genomic DNA and mRNA (Table 1). In the case of RNA-based PTT, mRNA is first reverse transcribed to cDNA, which then functions as a template for amplification. The best source of RNA is cells in which the target gene is abundantly expressed. However, for practical reasons RNA is generally isolated from freshly drawn peripheral blood lymphocytes.

PCR Amplification

High-fidelity polymerase such as PFU (Stratagene) or Phusion (MJ research) should be used to reduce the possibility of PCR errors. In addition, PCR products should be analyzed by agarose gel electrophoresis prior to the transcription/translation. Direct analysis of the PCR products can indicate the presence of an abnormally sized amplicon suggesting a splicing error or genetic rearrangements such as deletions or duplications. However, purification of the PCR amplicon of the correct size is not necessary and should be avoided, because the aberrant-sized PCR products are often derived from mutant alleles.

In Vitro Transcription/Translation and Analysis of Translated Protein

The TNT® T7 Quick Coupled Transcription/Translation System (Promega, Madison, WI) is convenient for PTT as both transcription and translation are performed simultaneously in a single tube using the PCR product as a template. There are several ways to detect the newly synthesized proteins. The most common method is incorporation of radiolabeled amino acids (e.g., ^{35}S-methionine or ^{13}C-leucine). For separation of the translation products, appropriate SDS-PAGE conditions must be chosen for simultaneous detection of both full-length and smaller products. After electrophoresis, gels are dried and protein bands are detected using either X-ray film or a phosphorImager screen. In general, a wild-type sample will have a strong band at the expected size

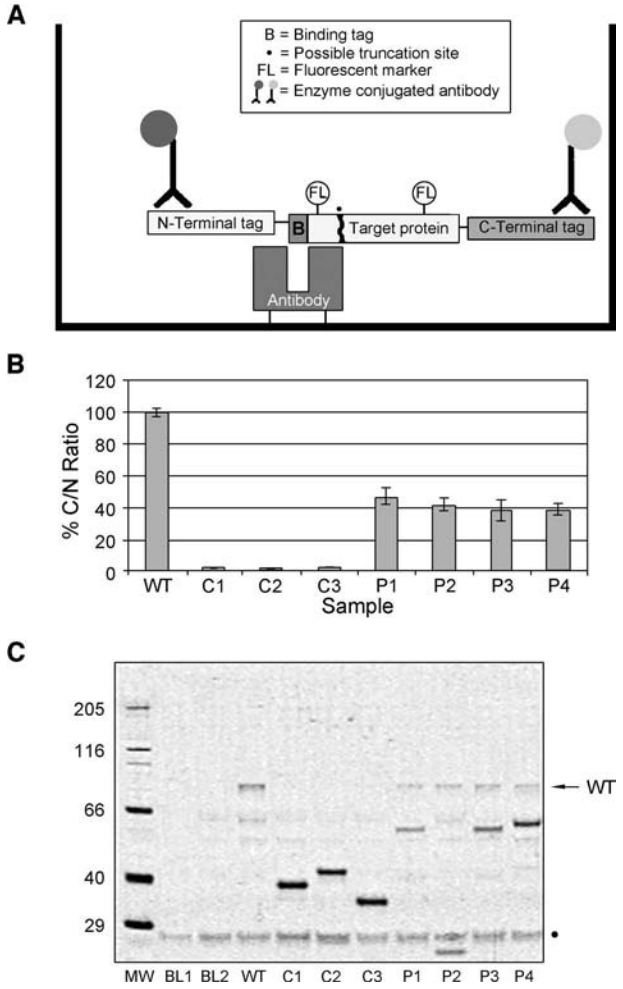

Fig. 2 ELISA-PTT. Panel A: Schematic representation of an ELISA-based Protein Truncation Test (ELISA-PTT). Unlike conventional PTT, the test uses a solid-phase ELISA format. B, Binding tag (either biotin which is incorporated randomly along the sequence using misaminoacylated tRNAs or epitope tag incorporated at N-terminal) acts to immobilize the cell-free synthesized fragments on the well surface. N- and C-terminal epitopes are detected by corresponding antibodies allowing for an estimate of the relative amount of truncated protein while simultaneously controlling for the level of translation. FluoroTags (FL) provide an independent confirmation of truncation and estimate of the fragment size by using fluorescence readout of gels. Panel B: Detection of various truncation mutations in the APC gene using ELISA-PTT. Panel C: Validation of ELISA-PTT result by gel-based fluorescence PTT. WT is wild-type, C1–C3 are mutant homozygous DNA samples from cell lines, and P1–P4 are the heterozygous DNA samples from patients prediagnosed with FAP. BL1 corresponds to a cell-free translation performed lacking both the added tRNAs and DNA. BL2 corresponds to a cell-free translation performed lacking only the added DNA. MW is molecular weight markers. The asterisk indicates the position of an autofluorescent protein band present in the cell-free translation extract. (*View this art in color at www.dekker.com.*)

of the full-length translation product compared to bands corresponding to smaller proteins. Ideally, these weaker bands correspond to truncated protein fragments derived from mutant template. However, weaker bands can also originate from internal weak translation initiation sites (AUG) and proteolytic degradation products. In some cases these bands can obscure the analysis and/or detection of the truncated fragments derived from a mutant template.

In addition to radiolabeling, methods have been reported which use nonisotopic detection. In one approach, biotin was incorporated during translation using biotin–lysine–tRNA and was detected by Western blotting.[10] Similarly, Kahmann and coworkers[11] used Western blotting to detect engineered epitope tags. Radioisotope labeling can also be eliminated by incorporating fluorescent labels using fluorescently labeled tRNAs.[9,12,13] Although these nonisotope-based methods have clear advantages compared to radioactive detection, they still suffer from the intrinsic throughput problems associated with electrophoresis. In order to overcome these limitations, ELISA-PTT has been developed which provides higher throughput and lower cost because it circumvents electrophoresis.[9]

The basic ELISA-PTT approach is illustrated in Fig. 2A. Specially designed primers, which incorporate N- and C-terminal epitopes, are used for amplification of target sequences. In addition to these epitopes, additional tags can be incorporated randomly along the protein chain for detection and capture purposes. This is accomplished using mis-aminoacylated tRNAs (e.g., biotin–lysine–tRNA or/and BODIPY–lysine–tRNA) which are added to the reaction mixture. A capture tag can also be incorporated into the protein by using a specially designed primer. After translation, the test proteins are captured in a single-well of a microtiter plate, and the N- and C-terminal epitope tags are detected using appropriate antibodies. The signals obtained are used to compare the total amount of target protein captured (N-terminal signal) vs. the fraction that is full length (i.e., has a C-terminus).

The results of ELISA-PTT for the *APC* gene are shown in Fig. 2B. In this experiment, DNA derived from normal controls, familial adenomatous polyposis (FAP) patients as well as cell lines with known mutations in the *APC* gene was analyzed. The C/N terminal ratio of wild type was normalized to 100% and the values obtained for all other samples are expressed as a fraction of the wild type. For cell line DNA (homozygous APC mutant), the C/N terminal ratio was close to 0%, as expected. The C/N terminal ratio for heterozygote samples derived from individuals with FAP ranged from 37% to 47% relative to the wild type (Fig. 2B). It is possible to validate the ELISA-PTT results and localize the mutation within the protein using the fluorescent labels incorporated into

Table 1 Top ten diseases where PTT is applicable

No.	Disease	Gene	% Truncated mutations	Ref.
1	Breast cancer	BRCA1/2	90	[3]
2	Colorectal cancer	APC	95	[21]
3	Familial adenomatous polyposis	APC	97	[1]
4	Hereditary nonpolyposis colon cancer	MSH2/ MLH1	70–80	[22]
5	Neurofibromatosis	NF1/2	60–75	[5]
6	Polycystic kidney disease	PKD1/2	95	[4]
7	Duchenne muscular dystrophy	DMD	95	[7]
8	Cystic fibrosis	CFTR	50	[23]
9	Ataxia telangiectasia	ATM	90	[24]
10	Tuberous sclerosis	TSC1/2	75–98	[6]

the in vitro translated proteins. Figure 2C shows results obtained from fluorescent imaging after SDS-PAGE using aliquots of the same translation mixtures used in Fig. 2B. The wild-type sample produces a band of the expected molecular mass (~70 kDa), whereas the homozygous mutant cell line samples exhibit single bands at approximately 35, 40, and 32 kDa (C1–C3, respectively). Samples derived from FAP individuals heterozygous for a mutation exhibited two bands corresponding to both wild-type and mutant alleles (lanes P1–P4).

ELISA-PTT does not require electrophoresis for the primary screen, but does require electrophoresis for sizing the proteins in order to locate and confirm the mutation in the amplicon. In contrast, Garvin et al.[14] reported a method to size in vitro synthesized proteins by mass spectrometry, thereby eliminating the need for electrophoresis. Experiments were carried out using a short sequence (21 bases) of the *BRCA*1 gene. After in vitro translation, the test peptide was purified using a FLAG-epitope and subjected to MALDI-TOF mass spectroscopy. Truncating mutations in heterozygotes are easily detected, and importantly, single amino acid substitutions are also detectable because of the high resolution of mass spectroscopy. Although this process can be multiplexed and is amenable to automation, the small test sequence size reduces its effective throughput compared to gel-PTT or ELISA-PTT.

GENERAL CONSIDERATIONS OF PTT

Sensitivity of PTT

The PTT is most often used to detect truncating mutations in tumor suppressor genes from patients that are heterozygous for the mutation, using genomic DNA as starting material. The mutant allele represents 50% of the alleles present in the sample, and the PTT, like all other scanning methodologies, can easily detect mutations at the 50% level. There are other applications, however, where the mutant allele is present at much less than 50% (e.g., in a tumor biopsy or fecal material from a colorectal cancer patients) and in these cases sensitivity becomes an issue. In comparison with other mutation detection techniques, the sensitivity of gel-PTT is high and is capable of detecting mutant alleles at one part in five. Recently, Traverso et al. have demonstrated detection efficiencies of chain truncation mutations as low as 0.4% relative to WT.[15] This was achieved by first diluting genomic DNA samples so that no more than two to four DNA templates are present in each sample prior to PCR amplification. This is followed by translation of the amplified DNA for approximately 144 samples and detection using radioactive gel-based PTT. As discussed previously,[9] ELISA-PTT is ideal for such an application as radioactive gel-based detection is not suitable for automation.

Advantages and Disadvantages of PTT

Despite the fact that chain-truncating mutations can be detected by conventional scanning methods such as DNA sequencing or single-strand conformation polymorphism analysis (SSCP), PTT remains the method of choice for many laboratories. This is primarily due to its ability to accurately scan a large sequence (as large as 3 kb) in a single reaction. Once a chain truncation is identified and its position on a gel is known, a much smaller region of DNA can be scanned by sequencing to confirm and characterize the mutation. Although PTT detects only chain truncating mutations, these mutations are invariably associated with disease, especially in the case of tumor suppressor genes because truncated proteins are almost always nonfunctional. In contrast, gene variants that result only in an amino acid substitution are often difficult for the clinician to interpret without additional information.

However, there are a variety of limitations for the PTT approach. First, PTT is usually only appropriate for those genes that contain a high proportion of protein truncating

mutations. In addition, it is only effective for large exons as protein fragments encoded by smaller exons are not easily analyzed by SDS-PAGE. This limitation can be overcome by using mRNA as the starting material. However, there are handling and storage concerns with the use of mRNA due to nonsense-mediated mRNA decay[16] and the lack of mRNA expression in accessible tissue (peripheral blood). In addition, PTT cannot detect mutations occurring outside the coding region, such as those that affect control of gene expression.

A number of problems can arise during the PCR amplification step used in PTT. For example, if the mutated allele has a large insertion in the amplicon or if the mutation is a deletion that includes the primer binding site, the mutant allele will not amplify. Also, polymerase error in the first few cycles can lead to an artifact that can be mistaken for an authentic mutation. Artifacts can also be produced from in vitro translation and include false-initiation from internal ATG codons (which is more severe in *Escherichia coli*-derived reaction mixtures) and proteolytic degradation of the full-length protein by endogenous proteases present in the in vitro synthesis lysate. These and other factors can give rise to background bands in the wild type control samples which can interfere with detection of an overlapping mutant band.

ALTERNATIVE METHODS FOR DETECTING CHAIN TRUNCATIONS

Many genotyping methods exist which can detect chain truncating mutations as well as other types of mutations. DNA sequencing is considered the gold standard for genotyping as it can detect any mutation that can be amplified by PCR including those that have never been previously described. However, it is expensive and time consuming to carry out complete gene sequencing even with high-throughput automated capillary sequencers. Furthermore, this method is not able to detect a mutant sequence that represents less than 25% of the sample because of the presence of the wild-type signal at every position.[17] Hybridization-based approaches for detecting mutations such as TaqMan® (Applied Biosystems), Invader (Third Wave Technology), and high-density chip arrays (Affymetrix) are high-throughput methods that are only capable of detecting previously identified mutations and will miss de novo mutations.[18] In one study,[19] five different mutation detection methods to detect truncation mutations in *BRCA*1 were compared. These included four DNA-based methods: two-dimensional gene scanning (TDGS), denaturing high-performance liquid chromatography (DHPLC), enzymatic mutation detection (EMD), SSCP, and PTT. Analysis of 21 samples showed that PTT correctly identified all 15 deleterious mutations. Not surprisingly, the DNA-based techniques did not detect a deletion of exon 22, and five truncating mutations were missed by SSCP. In another study,[20] researchers compared the effectiveness of PTT and SSCP for detecting *BRCA*1 mutations and concluded that PTT is a superior screening test as the specificity of PTT was 100% and sensitivity was 82.6%, whereas for SSCP, the specificity was 99% but the sensitivity was only 60.9%.

CONCLUSION

The protein truncation test is currently the fastest method in general use for detecting previously unidentified truncating mutations in tumor suppressor genes. In addition, by only identifying disease-causing truncation mutations, PTT analysis is not hampered by false-positive signals derived from phenotypically silent variants such as polymorphisms. Finally, the size of the truncated product localizes the DNA mutation and thus enhances sequence analysis for confirmation. In recent years, the identification of truncating mutations in tumor suppressor genes has greatly benefited from PTT. Improvements in the PTT, such as ELISA-PTT,[9] multicolor-PTT,[12] and mass spectrometry-based PTT,[14] should allow this method to gain wider acceptance.

INTRODUCTION

Pseudoxanthoma elasticum (PXE) has long been considered a prototype of connective tissue diseases as it visibly alters the elastic fiber network of skin. Two French physicians, Felix Balzer in 1884 and Marie-Anatole Chauffard just five years later, first described the characteristic skin changes. The first of them also noted ''broken elastic fibers'' on histological specimen of the skin and heart. In his monograph about PXE, Neldner summarizes in 1988 that ''in both cases, efforts to indict the liver, often the target of blame for poor health amongst the French, were unsuccessful, although it was still a suspect.'' With the advent of molecular genetic research in general and the recent detection of the hepatic transmembrane transporter protein MRP6 as the affected gene product in particular, the suspicion of the French physicians was proven correct about 100 years later.

EPIDEMIOLOGY

Pseudoxanthoma elasticum is a rare heritable disorder of connective tissue. Its estimated prevalence varies between 1 in 25,000 and 1 in a million. Women seem to be slightly more often affected than men (3:2), although some investigators have attributed this to cosmetic bias. Age of onset of clinical symptoms may vary from infancy to over 50 years of age, and severity differs not only between families but also among members of the same family.[1]

MODE OF INHERITANCE

Pseudoxanthoma elasticum is caused by mutations in the *ABCC6* gene.[2–4] It is inherited in an autosomal recessive fashion, but is most frequently encountered sporadically.[1] However, affected individuals in two generations, suggesting autosomal dominant inheritance, have been frequently reported. In addition, a limited phenotype, often reflected only by positive histopathology at predilection sites of skin and by asymptomatic eye findings, has been reported in presumed obligate heterozygous carriers within PXE families. Molecular evaluation of some of these families revealed the presence of at least two different compound heterozygotes with segregation of a total of three different mutations[5] (Fig. 1). The disparities in phenotype within those families may well be explained by the difference in the set of mutations inherited. The mild phenotype was often associated with at least one missense mutation in the *ABCC6* gene, which would predict in some cases residual activity of the gene product. In other multigenerational families, consanguinity accounted for the pseudodominant inheritance of PXE. Refined mutation screening techniques led to the detection of two mutated alleles in almost all affected individuals, thus contradicting the existence of autosomal dominant forms of PXE. In fact, the mode of transmission is autosomal recessive in all affected individuals elucidated thus far at the molecular level.[5]

CLINICAL FEATURES

Pseudoxanthoma elasticum clinically affects three different organs of the body, namely, the skin, the eye, and the cardiovascular system. Initially, manifestations on the skin include yellowish papules, which tend to coalesce into larger plaques in the predilection sites, such as the lateral neck, the axillae, groin, antecubital, and popliteal fossae, and which typically are present at puberty. In long-standing lesions, sagging of the skin may be observed, which presents a major cosmetic problem. Involvement of the eyes can be severe as newly formed, fragile blood vessels along fractures (angioid streaks) in the elastic fiber-rich Bruch's membrane behind the retina often rupture and bleed, which leads to loss of central vision around the age of 40. Calcification in the cardiovascular system causes atherosclerotic disease often with morbid consequences beginning in young adulthood. While age of onset is variable and clinical manifestations are protean and differ significantly even within families, no racial or ethnic predilection has been observed.[1,6]

GENOTYPE–PHENOTYPE CORRELATION

To date, over 100 loss-of-function and missense mutations in *ABCC6* have been reported. Currently, it is unclear how consequences of mutations at the level of the

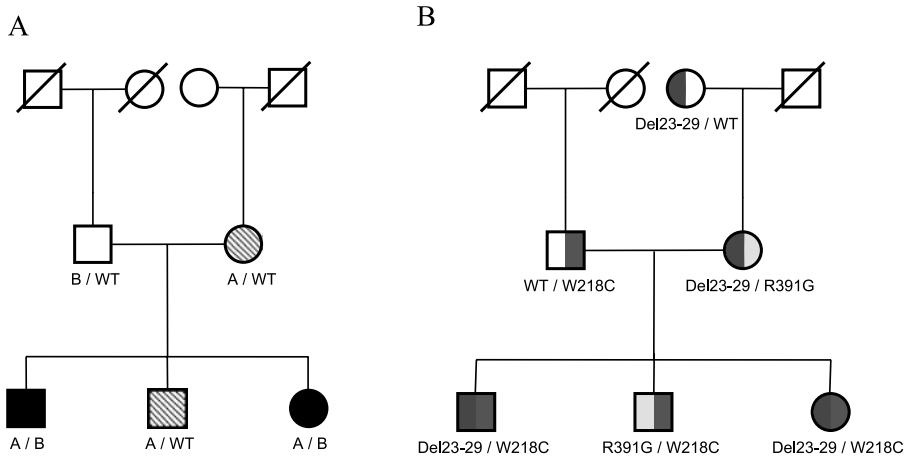

Fig. 1 A. Pseudodominant pedigree with clinically affected individuals (blackened) and presumed obligate heterozygous carriers with only histopathological evidence of PXE (shaded). Letters A and B designate the assumed mutations and their distribution prior to molecular analysis. B. Mutation analysis in the same pedigree reveals a total of three different mutations on three different alleles (colored symbols). Both affected and minimally affected obligate heterozygous carriers are compound heterozygous for mutations in *ABCC6*, WT: wild type. (*View this art in color at www.dekker.com.*)

encoded protein, MRP6, determine a particular phenotype ranging from mild to severely debilitating disease with a broad spectrum of cardiovascular involvement. The high prevalence of cardiac abnormalities in otherwise unaffected members of families or individuals with PXE also suggests the possibility of a dominant effect of specific mutations or polymorphisms on the cardiovascular system.

PATHOPHYSIOLOGY

Mutations in the *ABCC6* gene have recently been found to underlie PXE in nearly all affected individuals.[2–4,7–9] *ABCC6* is located on chromosome 16p13.1, and its 31 exons are dispersed over 73 kb of genomic sequence.[2] Its translated region spans 4.5 kb and encodes multidrug resistance-associated protein 6, MRP6,[10,11] an ATP-dependent efflux pump that is expressed at the basolateral membranes of hepatocytes and the proximal tubules in the kidneys.[12] The protein is composed of three transmembrane domains and two nucleotide-binding folds with ABC motifs located in the intracellular space. Mutations in *ABCC6* are mostly private with the exception of two frequently recurring mutations, R1141X and del exons 23–29, in patients of Northern European descent.[2,8] They are dispersed over the entire gene but the majority of mutations are predicted to interfere with proper function of the second nucleotide-binding fold, the site of substrate binding in ABC transporters. To date, no physiological substrate for MRP6 has been identified.[13–15] MRP6 is 45% homologous to the prototype within this family of proteins, MRP1.[3,10,11] The latter is instrumental to cellular detoxification, a property apparently not shared by MRP6, and has a capacity to confer chemotherapy resistance to the cells. While the exact pathomechanisms leading to abnormalities in the elastic fiber network of the target organs are poorly understood, deposition of calcium is considered merely a secondary change that can occur after trauma to elastic fibers. As a result of calcification, fragmentation or disorganization of elastic fibers in the midreticular dermis and the medium-sized arteries and veins as well as the fractures in Bruch's membrane behind the retina occurs. In the skin, this leads to inelasticity, loss of recoil, and subsequent sagging of the skin. In the eye, neovascularization occurs at sites of fracture due to calcium deposits. These newly formed vessels are fragile and often rupture with trauma. In the arteries, alteration of elastic fibers leads to calcification of the elastic media and later the intima, which facilitates atherosclerotic peripheral vascular disease.

DIAGNOSIS—CLINICAL AND LABORATORY FINDINGS

A trained dermatologist can often diagnose PXE clinically without difficulty, but skin biopsy confirms the clinical suspicion, especially in less obvious clinical scenarios. A punch biopsy should be obtained from the lateral neck or axillae even in the absence of obvious skin lesions. When lesions are clinically obvious, hematoxylin and eosin (H&E) stain usually demonstrates calcium deposits in the midreticular dermis. Otherwise, silver stains for elastin (Verhoeff–van Giesson) or calcium (von Kossa) may be necessary for visualization of microscopic anomalies in

Underlined nucleotides eliminate the amplification of both pseudogenes, underlined nucleotides in bold eliminate ABCC6-ψ 2, underlined nucleotides in italics eliminate ABCC6-ψ1.

the dermis. Diagnosis has been challenging in presumed obligate heterozygous carriers, which have been found to display minimal clinical manifestations and have positive skin biopsies.[16–18] The recent discovery of *ABCC6* as the gene harboring causative mutations for PXE and the ability to perform mutation analysis have significantly improved our ability to render a definite diagnosis.

MOLECULAR GENETICS

Mutation detection strategies were initially complicated by the presence of two partial pseudogenes, *ABCC6-Ψ1* and *ABCC6-Ψ2*, in the human genome. They are both products of large genomic duplications containing 5′ portions of *ABCC6* as well as part of the neighboring *pM5* gene, located upstream of *ABCC6*. *ABCC6-Ψ1* contains the promoter region as well as the first nine exons of *ABCC6*, whereas *ABCC6-Ψ2* is nearly identical to the 5′ untranslated region and exons 1–4. They are located in close proximity to *ABCC6* on the short arm of chromosome 16. Both are highly homologous to their origin and differ only in a few nucleotide positions.[19] Current mutation detection methods employ gene-specific primers (Table 1) which allow detection of over 70% of mutations using denaturing high-performance liquid chromatography (dHPLC) through WAVE technology (Transgenomic™) as a screening technique[20] and over 80% with direct sequencing of the entire *ABCC6* coding region. Mutation detection has not only solved a historical debate about the mode of inheritance in PXE but allows timely and presymptomatic detection of affected individuals who may be counseled to avoid risk factors that would exacerbate their eye or cardiovascular disease. In addition, mutation detection has significantly improved genetic counseling and offers the possibility for prenatal diagnosis.

MANAGEMENT

The most important measure is prevention of severe cardiovascular or ophthalmologic disease. Biannual or annual evaluation by a cardiologist is recommended. Smoking should be avoided at all costs and regular low-impact exercise, e.g., running, biking, and swimming, is encouraged. The use of acetylsalicylic acid is controversial as it lowers the risk of myocardial infarction yet may facilitate serious complications in case of gastric or intestinal hemorrhage. Calcium intake should be appropriate for development and age but excess should be avoided as it may worsen the clinical symptoms. Claudication may be treated with pentoxyfylline (Trental) 400 mg tid or cilostazol (Pletal) 50 or 100 mg bid. Biannual ophthalmologic examinations, avoidance of head trauma, and regular use of an Amsler grid are crucial. When angioid streaks become symptomatic, laser surgery may improve symptoms in about 50% of patients treated. Photodynamic therapy and macular translocation are fairly novel techniques that should be reserved for the most seriously affected. Skin changes are disfiguring and may occasionally respond to plastic reconstruction. While wound healing is not impaired, scars may spread as a result of the loss of elastic properties of the skin. The use of oral phosphate binders is currently under investigation.

CONCLUSION

About 100 years after the first formal description of PXE, a major milestone has been reached with the discovery of the causative mutations in the *ABCC6* gene. However, the unsuspected role of a transmembrane transporter protein in liver and kidneys, far away from the affected organs, has raised many questions that remain to be answered.

Current hypothesis favors a metabolic pathway of disease development. Impaired excretion of a yet unidentified substance via urine or bile may lead to its resorption into the systemic circulation with adherence and subsequent trauma to the elastic fiber network and secondary deposition of calcium. Alternatively, a nonfunctional MRP6 pump may switch on an alternative mechanism of excretion in liver and kidneys that indirectly causes trauma to the elastic fiber network by removal of essential factors.

In addition, there is currently little evidence to suggest that certain mutations or combinations thereof elicit a specific phenotype. These observations emphasize the role of possible environmental factors as determinants of disease extent and severity, a question that may be resolved once adequate animal models for PXE become available.

Pulsed Field Gel Electrophoresis (PFGE)

P

Fann Wu

INTRODUCTION

Pulsed field gel electrophoresis (PFGE) was first described in the early 1980s and has proven to be one of the most powerful techniques in modern molecular epidemiology for genotyping microorganisms. The applications of this technology include determining genetic relatedness among microbial strains in industrial, agricultural, and hospital settings, as well as understanding the dynamics of antimicrobial resistance and epidemiological investigations. This chapter will focus on the clinical applications of PFGE, assessing its strengths and limitations.

THE HISTORY OF PULSED FIELD GEL ELECTROPHORESIS TECHNOLOGY

The Electrophoretic Separation of DNA Molecules

Conventional gel electrophoresis is based on the principle that negatively charged DNA fragments below 50 kb can be separated when subjected to a unidirectional electric field. The DNA samples are added to wells in an agarose matrix and migrate in the direction of the field at a rate that is inversely proportional to size, i.e., the larger the DNA fragments, the slower their rate of migration in the electric field. However, when DNA molecules are larger than the threshold size of 50 kb, all fragments exhibit size-independent mobilities.[1] This significant practical problem limited the use of electrophoresis for the study of megabase-sized molecules, such as the bacterial chromosomal DNA.

In 1984, Schwartz and Cantor introduced the concept of pulsed field gel electrophoresis by using two alternating electric fields, to separate large DNA fragments (50 to 2000 kb) within agarose gels.[2] Subsequently, a variety of alternative electrophoretic configurations, using currents ''pulsed'' in different directions over controlled time intervals, have been developed. These included orthogonal field alternation gel electrophoresis,[3] vertical alternating field gradient gel electrophoresis,[4] periodic field inversion gel electrophoresis,[5] and contour-clamped homogeneous electric field electrophoresis (CHEF).[6]

In PFGE, chromosomal DNA can be treated with a restriction endonuclease, resulting in DNA fragments that vary in size from 50 to 2000 kb. It is a powerful molecular typing technique for comparing and analyzing bacterial chromosomal DNA fragments. The two most common pulsed field methods used in DNA fingerprinting laboratories are the CHEF and the programmable autonomously controlled electrode gel electrophoresis (PACE).[7] Both systems contain three major components: a power module to generate the electrode voltages and store switching function parameters, a cooling module to keep the temperature at 14°C, and an electrophoresis chamber. The chamber contains 24 horizontal electrodes, some of which are clamped to eliminate DNA lane distortion. The electrodes are arranged in a hexagon, thus providing reorientation angles of 60° or 120° in contrast to traditional orthogonal field alternation gel systems with two perpendicular electrodes. The resolution of PFGE is dramatically affected by the number and configuration of the electrodes used, because these alter the shape of the applied electrical field. For high-resolution separation, the most effective electrode configurations yield angles of more than 110°.[8] In PACE, each electrode's voltage is independently controlled and can generate an unlimited number of electric fields of different voltage gradients, orientations, and intervals sequentially in time. However, the traditional CHEF systems are limited to two alternating electric fields at a fixed reorientation angle. The two leading PFGE technologies, CHEF and PACE, have been combined into a CHEF Mapper system (BioRad Inc.) which is widely used by molecular epidemiologists. It has the advantage of containing protocols embedded on a microchip, thus eliminating trial and error in setting parameters for obtaining good resolution of band patterns.

Sample Preparation for PFGE

Standard sample preparation procedures for DNA isolation involving mechanical forces are inappropriate for the

analysis of fragile, high-molecular weight DNA molecules that easily break into small pieces. To prevent DNA damage, intact cells mixed with warmed, liquid agarose are pipetted into plug molds, $10 \times 5 \times 1.5$ mm in size. Cells embedded in the agarose plugs are lysed in situ by detergents and enzymes. The agarose matrix keeps the large DNA molecules intact, while permitting diffusion of lysed cellular components from the plug. Infrequent-cutting restriction endonucleases are used to digest the DNA. The choice of restriction enzyme is critical because it should generate between 10 and 30 numbers of DNA fragments necessary for strain discrimination. A list of endonucleases for typing specific microorganisms have been published.[9] After restriction enzyme digestion, the plugs are cut into appropriate sizes based on the DNA concentration and loaded into the wells of an agarose gel. The gel is then placed in the electrophoresis chamber, and pulsed field conditions are chosen based on the expected size range of the DNA. To separate 40–2000-kb-sized DNA fragments, PFGE is usually run for 18–48 hr. After staining with ethidium bromide, bands are visualized and photographed. Several commercially available software packages are available that provide computerized gel scanning and data analysis capabilities. They enable the clustering pattern of each gel to be represented as a dendrogram that shows the percent similarity obtained through Dice coefficient and the unweighted pair group method with arithmetic average. Pulsed field gel electrophoresis patterns can also be stored for future strain comparisons.

Performance Characteristics

The performance requirements for a good molecular typing system include a high index of strain discrimination (>0.95) and assay reproducibility, and the ability to provide results for a diverse group of microorganisms.[10] Pulsed field gel electrophoresis technology satisfies these criteria and therefore is the most frequently used molecular typing method in molecular epidemiology. The PFGE band patterns represent the entire microbial chromosome profile (>90%).[11] All manipulations for DNA extraction and restriction digestion are performed inside the agarose plug, which protects DNA from shearing forces during sample preparation. Pulsed field gel electrophoresis typically yields 10 to 30 well-separated, easy-to-read chromosomal DNA bands after digestion with infrequent-cutting restriction endonucleases. It has significant advantages compared with conventional electrophoresis techniques for analysis of restriction endonuclease digested chromosomal DNA. The latter when applied to conventional electrophoresis cannot separate large fragments, and treatment with frequent-cutting restriction endonucleases will generate hundreds of uninterpretable bands. Therefore conventional electrophoresis is best suited to the analysis of relatively small-molecular weight (<50 kb) DNA fragments of plasmids. The comparison of the procedural features of conventional electrophoresis and pulsed field gel electrophoresis is summarized in Table 1.

The major disadvantages of PFGE compared to other DNA-based typing methods include the relatively high cost and the labor-intensive techniques that can take 4 to 5 days to complete.[12] DNA fragments smaller than 50 kb cannot be reliably separated by PFGE, because the system is not able to switch the field orientation quickly enough to separate these smaller molecules. Furthermore, certain organisms such as *Clostridium difficile* and *Aspergillus* spp. may not be typeable by PFGE as their DNA cannot be isolated intact. Strain differentiation may not be possible for some bacterial species because of inherent nuclease contamination that can degrade DNA.[13]

Many different protocols have been developed in laboratories using PFGE, leading to variability in assay design and reproducibility. It is important to standardize the PFGE protocols, especially, some critical elements, such as the concentration and the integrity of the DNA in the plug, the effectiveness of specific restriction enzymes for digestion, and the electrophoresis conditions including gel volume and agarose concentration, ionic strength and volume of the buffer, and running conditions including voltage, switching times, reorientation angle, and total run times of electrophoresis.[14,15] To insure high-quality gels and consistent reproducibility, we recommend including a quality-control strain with each run for gel comparison.

Table 1 Comparison of the procedural features of conventional electrophoresis and PFGE

Procedural characteristics	Conventional gel electrophoresis	PFGE
Sample preparation	No specific requirement	Intact cells embedded in agarose
Restriction endonuclease	Frequent-cutting enzyme	Infrequent-cutting enzyme
Electric field	Single homogeneous	Pulsed homogeneous
Resolution in DNA size	<50 kb	50–2,000 kb
Typical run times	1–4 hr	18–48 hr
Instrument cost	<$2,000	>$15,000

Interpretation of strain relatedness can be performed by visual inspection of the PFGE bands. Criteria for PFGE interpretation have been proposed for epidemiological investigations[16] in the following manner: bacterial isolates yielding the same PFGE pattern are considered ''indistinguishable;'' isolates differing by one to three bands (a single genetic change) are considered ''closely related;'' isolates differing by four to six bands (two independent genetic changes) are considered ''possibly related.'' Six or more band differences represent three or more genetic changes and such isolates are considered ''unrelated.'' More recently, various computer-assisted programs have become available to enhance the capability of comparing DNA fragment patterns present on multiple gel sets. Using this approach, investigators can create a searchable database of PFGE fragment patterns and easily perform cluster analyses.[17]

APPLICATIONS

Pulsed field gel electrophoresis has a wide range of applications in the analysis of microorganisms and human or other mammalian DNA. Because of its high reproducibility and discriminatory power, PFGE has been utilized in genetic and epidemiological analyses of at least 98 different pathogens, including gram-negative and gram-positive bacteria and fungi.[18] Here we highlight some clinical applications of PFGE genotyping of bacterial pathogens to study hospital-related epidemiological investigations and international surveillance efforts to understand and contain the spread of antimicrobial resistant microorganisms.

Nosocomial Infections

An important application of PFGE is the comparative analysis of nosocomial pathogens. It is clear that specific etiological agents can be transferred between patients in hospital settings and cause nosocomial infections. Rapidly assessing the clonal relatedness of these isolates is critical in determining the extent of outbreak spread and the strategies for containment. Pulsed field gel electrophoresis is most often considered the typing technique of choice to examine the true genetic identity of the bacterial isolates in an outbreak investigation.[11] Figure 1 shows a variety of PFGE patterns that were generated when methicillin-resistant *S. aureus* (MRSA) chromosomal DNA was digested with *Sma*I restriction enzyme. These results were obtained from a published study describing an outbreak investigation in our hospital, which involved four cases of postpartum mastitis caused by nosocomial spread of a virulent strain of community-acquired MRSA.[19] The outbreak strains were found to be indistinguishable from each other by PFGE (lanes 1 to 4), and were distinct from other groups of hospital-acquired MRSA strains that were collected from different hospital units (lanes 5 to 9).

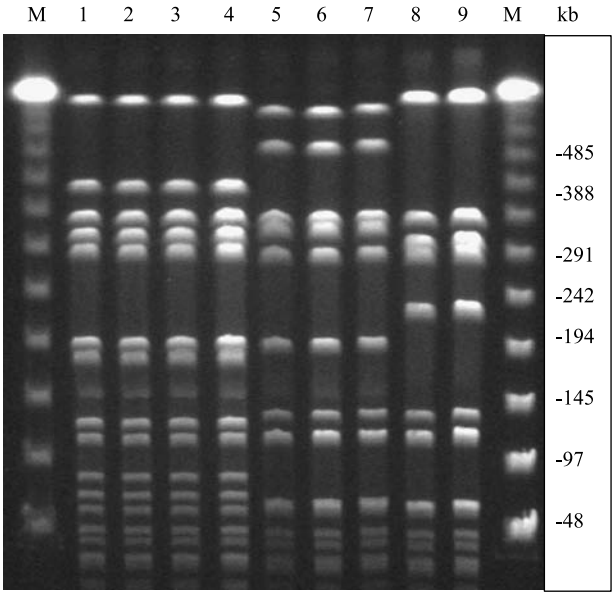

Fig. 1 PFGE of *Staphylococus. aureus* isolates. Genetic profiles were obtained by digestion of *S. aureus* chromosomal DNA with *Sma*I restriction endonuclease. Lanes 1 to 4 show chromosomal DNA from *S. aureus* isolates obtained during the outbreak. Lanes 5 to 9 show chromosomal DNA from unrelated *S. aureus* isolates obtained from other hospital units during the course of the outbreak. Lanes marked M show the lambda molecular weight standard with corresponding molecular weights in kilobase indicated on the right side of the gel.

Community-Acquired Infections: Colonization vs. Infection

Pulsed field gel electrophoresis has been successfully used as a tool to investigate community-acquired infections or colonizations and the epidemiological relatedness of strains within the community, school, or day-care centers.[20,21] We conducted an epidemiological study of multidrug-resistant *Acinetobacter baumannii* in our community.[22] A total of 103 isolates from patients in two Manhattan hospitals were compared with 23 isolates from the hands of community residents by analysis of antimicrobial resistance patterns and PFGE genotyping. The antibiogram results showed that 36.6% of hospital isolates were multidrug resistant, whereas those from the community were not ($p<0.005$). Pulsed field gel electrophoresis genotyping indicated that more than half of the isolates from both hospitals were either indistinguishable or closely related. However, hospital strains were found to be unrelated to most of the community isolates ($p<0.001$).

The results showed that *Acinetobacter* strains recovered from patients in the hospitals were not acquired from the community and suggested that the hospital environment harbored a reservoir for epidemic *A. baumannii* strains.

Public Health Surveillance

Pulsed field gel electrophoresis is the most commonly used molecular typing method for epidemiological investigations by national and international surveillance networks. Pathogens, such as *Salmonella*, *E. coli* O157, *Shigella*, and *Legionella*, often cause food or water-associated multicommunity outbreaks that require comprehensive public health measures.[23–25] Appropriate surveillance and timely detection of the outbreak sources are necessary for interruption of pathogen transmission. The strategy is that selected isolates from ongoing outbreak sources are submitted to a designated laboratory where PFGE genotyping is routinely performed. When a cluster of identical genomic profiles of the isolates are determined by PFGE, the local health authorities are immediately notified and an investigation is conducted. The implementation of PFGE typing technology enables reliable tracking of epidemic clones and determines the extent of the outbreak.

CONCLUSION

Pulsed field gel electrophoresis is widely used for genotypic characterization. It has been considered the method of choice for the analysis of most bacterial pathogens because of its high reproducibility and discriminatory power. The limitations include its labor-intensive nature, delayed turn-around time to results, and the inability to genotype some microorganisms. For the latter, a combination of PFGE and amplification-based technique may provide the best discriminatory power. Efforts are underway to simplify and standardize the methodology for broad applicability and interlaboratory comparisons.

Pyrosequencing

Dong-chuan Guo
Dianna M. Milewicz
University of Texas-Houston Medical School, Houston, Texas, U.S.A.

INTRODUCTION

Pyrosequencing is a high-throughput technique for single nucleotide polymorphism (SNP) genotyping and DNA sequencing that is inexpensive, accurate, and easy to optimize. The pyrosequencing technique uses a non-electrophoresis-based bioluminometric DNA sequencing method that employs a cascade of luciferase-based enzymatic system that monitors DNA synthesis in real time. In the pyrosequencing assay, a sequencing primer is hybridized to a single-stranded, PCR-amplified DNA template and is then incubated with enzymes and their substrates. During the DNA sequencing, one of the four deoxyribonucleotide triphosphates (dNTPs) is added to the reaction system in an order that is preprogrammed. If the nucleotide is complementary to the nucleotide in the template, DNA polymerase catalyzes the incorporation into the DNA strand. When an incorporation event occurs, it is accompanied by the release of an inorganic pyrophosphate (PPi) in an equimolar amount to the incorporated nucleotide. The inorganic pyrophosphate produced is then converted to ATP by sulfurylase and is immediately utilized in a subsequent luciferase-based light-producing reaction. The pyrosequencer detects the visible light generated by luciferase during DNA synthesis, which is proportional to the number of nucleotides incorporated. The DNA sequence is then determined by monitoring the visible light produced from the reaction as each dNTP is added. The unincorporated nucleotides are degraded by apyrase, which allows the iterative addition of nucleotides in the following steps.

$$(\mathrm{DNA})_n + \mathrm{dNTP} \xrightarrow{\text{DNA polymerase}} (\mathrm{DNA})_{n+1} + \mathrm{PPi}$$

$$\mathrm{PPi} + \text{adenosine } 5' \text{ phosphosulfate} \xrightarrow{\text{ATP sulfurylase}} \mathrm{ATP}$$

$$\mathrm{ATP} + \text{luciferin} \xrightarrow{\text{luciferase}} \mathrm{AMP} + \text{oxyluciferin} + \boldsymbol{hv}$$

$$\mathrm{ATP} + \mathrm{dNTP} \xrightarrow{\text{apyrase}} \mathrm{ADP} + \mathrm{dNDP} + \mathrm{dNMP} + \mathrm{Pi}$$

SNP GENOTYPING

Single nucleotide polymorphisms are alterations in the DNA sequence at a single nucleotide and can serve as genetic markers. These genetic markers have been used extensively for population genetics, medical genetics, pharmacogenomics, and forensic DNA analysis. The technologies for analyzing SNPs have focused on rapid and efficient detection of these alterations. Pyrosequencing is one of the newer technologies that have allowed for a high-throughput SNP genotyping technique that performs DNA sequencing in real time. This methodology also creates an internal control for monitoring the specificity of SNP assays by reading a few base pairs of DNA sequence flanking the SNP.

Pyrosequencing begins by purifying PCR-generated single-stranded DNA as a sequencing template followed by annealing with a sequencing primer to perform real-time DNA sequencing. A biotin-labeled DNA fragment is generated by PCR amplification using a biotin-labeled PCR primer. The biotin-labeled strand is immobilized to streptavidin-coated magnetic beads to isolate the single-stranded DNA after denaturation of the double-stranded PCR product. The pyrosequencing primers are designed using the SNP Primer Design Software (http://www.biotage.com). The real-time sequencing reactions are performed and monitored on a Pyrosequencer^{TM} with the SNP Reagent Kit (Biotage AB and Biosystems, Sweden). A methodology of universal biotinylated primers has recently been developed to generate biotin-labeled sequencing templates, which tremendously reduces the cost of synthesizing biotin-labeled-specific PCR primers.[1]

Figure 1 depicts an example of SNP genotyping using the pyrosequencing assay. The C-to-G SNP and the flanking DNA sequence are C/G-A-A-C-G. Figure 1A shows the pyrosequencing result of the homozygous C/C genotype. The first position (T) and the position following SNP (the second T) are automatically assigned by the pyrosequencing as blank controls. The full peak height of the first C position followed by no signal in the G position indicates that it is a homozygous C/C genotype. The third peak in the A position indicates that the adenines follow the C/G SNP and the height of this peak indicates that there are two adenines in this position because the light signal is proportional to the number of nucleotides incorporated. The fourth and fifth peaks indicate that a cytosine and a guanine follow the adenines. Similarly, the half height of the peak in the first C and second G position in Fig. 1B and no signal in the first C and full height of

peak in the second G position in Fig. 1C indicate that they are the heterozygous C/G genotype and homozygous G/G genotype, respectively.

High-throughput detection of small genomic insertions and deletions can be achieved by the pyrosequencing SNP assay program. Small insertions and deletions of nucleotides are common causes of polymorphic variations and can result in a predisposition to particular diseases. Although conventional DNA sequencing techniques can analyze these variations, it is costly and time consuming. The pyrosequencing technique can detect these variations without sequencing an entire region of chromosome DNA. The most critical factor for detecting these variants is to preprogram the appropriate sequences for the pyrosequencing assay. The order of nucleotide preprogrammed should depend on the normal allele and the boundaries of the deleted nucleotide sequences, which maximizes the differentiated patterns of the pyrosequencing results among the different genotypes. It has been demonstrated that this technique can analyze up to 100 bp nucleotide insertions and deletions along with complicated genomic rearrangements.[2] The pyrosequencing SNP assay program greatly reduce the timing and cost for detecting small insertion and deletion of nucleotides while increasing the throughput for the assay.

To further reduce the cost and time and increase the throughput of this analysis, the pyrosequencing assays can be multiplexed. This can be performed on a single template which contains multiple SNPs or on multiple templates.[3,4] To ensure the accuracy of SNP genotyping, the assays require carefully designing sequencing primers and preprogramming the sequences. Interpretation of peak intensities and proper base assignment may be difficult when multiplexing assays on multiple templates because PCR amplification efficiencies may be different for different amplicons. Multiplexing pyrosequencing can yield better results when the multiple SNPs exist within a few hundred base pairs in the genome.[3,4]

Multiplexed pyrosequencing assays on a single template have been applied to SNP haplotyping. Traditionally, construction of SNP haplotypes is performed by computational analysis or cloning techniques. Pyrosequencing SNP haplotyping is based on the combination of allele-specific PCR with pyrosequencing SNP assays.[5] Utilizing an existing SNP, allele-specific PCR primers are designed to specifically amplify genomic DNA flanking each allele of the SNP. The allele-specific PCR products serve as templates for the pyrosequencing assays to detect other SNPs located within the PCR fragments. This method has been proven to be highly reliable for detecting SNP haplotypes. However, the pyrosequencing-based SNP haplotyping can only detect the haplotypes of SNPs located within a few kilobase pairs on a chromosome because amplification of large PCR fragments tends to reduce the specificity of allele-specific PCR and increase the background noise of the pyrosequencing assay. To reduce the background noise of the assay, linked SNPs can be amplified using allele-specific PCR followed by a nested PCR of each associated SNPs for pyrosequencing assays.[6]

DNA SEQUENCING

Pyrosequencing can be used as an alternative to the traditional Sanger dideoxy sequencing method. The sequencing assay is performed by a reiteration of steps in which one of the four nucleotides is added and tested sequentially for incorporation into the nascent nucleotide chain. When the nucleotide added is complementary to the DNA template, it incorporates into the DNA strand and a light signal is generated. The intensity of the light signal reflects the number of incorporated nucleotides in a single nucleotide repeat region. Compared to the Sanger sequencing method, the pyrosequencing technique is

limited to read up to 100 nucleotides.[7] However, the pyrosequencing technique has several unique advantages over Sanger sequencing. For example, the results of heterozygous genotypes or multiplexing assays by Sanger dideoxy sequencing show overlapping signal peaks in a single position, which may result in sequence misreading. Conversely, pyrosequencing obtains sequencing data from each allele independently, which allows it to simultaneously sequence multiplex loci of a gene family.[8] Additionally, pyrosequencing is able to capture the first base following the sequencing primer.

Pyrosequencing DNA sequencing is being used for a wide variety of disciplines.[9,10] Pyrosequencing has been employed to obtain 50–100-bp sequence data in the variable region of the 16S rRNA using PCR primers based on the conservative region for amplification. This sequencing assay allows for the rapid identification of bacteria.[11] Similarly, the pyrosequencing technique has been applied for yeast and virus typing, and mutation testing.[12,13]

The pyrosequencing assay is also used for human leukocyte antigen (HLA) genotyping, which is essential for matching the HLAs of a recipient and an unrelated donor to decrease graft rejection and transplant-related mortality. The genetic complexity of HLA genes results in extreme difficulty in genotyping the donor and recipient HLA haplotypes by traditional methods. Sequence-based genotyping is necessary because it provides critical information for HLA matches considering that histocompatibility between recipient and donor is inversely correlated with the number of mismatches. The high-throughput pyrosequencing technique can be used to obtain high-resolution sequencing information of HLA genotyping that overcomes these problems.[8,14]

ALLELE QUANTITATION

Pyrosequencing is a quantitative DNA sequencing technique because the intensity of a light signal is accurately correlated to the amount of nucleotide incorporated. This fact enables pyrosequencing to be applied to quantifying allele frequencies of SNPs,[15] estimating global DNA methylation,[16] and detecting variations in the copy numbers of duplicated genes.[17] The pyrosequencing SNP software automatically analyzes SNP genotyping data and quantifies the allele frequencies of SNPs.

Linkage disequilibria of SNPs have been employed to identify susceptibility genes for complex diseases. Although high-throughput techniques have been applied for accuracy and large-scale SNP genotyping, using individual genotyping is expensive and time-consuming for assays with large sample sizes and that also scan for numerous alleles. Directly assaying SNP allele frequencies in pooled DNA samples provides the advantages of higher throughput and lower cost. An accurate and reproducible assay is critical for determining SNP frequencies using DNA pools. The ability to quantify the amount of incorporated nucleotide enables pyrosequencing to accurately estimate the SNP allele frequencies in DNA pools. The correlation coefficients between estimated SNP allele frequencies in DNA pools and that of true allele frequencies were demonstrated to be between 0.979 and 0.996.[15,18] Scanning SNP allele frequencies in DNA pools allows the rapid estimation of the linkage disequilibria of SNPs in susceptibility genes in the genetic study of complex diseases.

DNA methylation is an epigenetic modification of DNA that plays an important role in controlling gene expression, regulating X-chromosome inactivation, DNA repair, and tumorigenesis.[19,20] In mammals, DNA methylation occurs at the 5-position of the pyrimidine ring of cytosine in the context of dinucleotide CpG. Quantifying global DNA methylation or DNA methylation in a specific locus is important for understanding the regulation of gene expression and inactivation of genes throughout the genome. The pyrosequencing technique has been demonstrated to be an accurate and high-throughput method for quantitating DNA methylation.[16,20] This method is based on bisulfite treatment of genomic DNA, which converts unmethylated cytosines to uracils, such that the ratio of methylated cytosines to unmethylated ones can be quantified as C/T SNP using the pyrosequencing allele frequency analysis program.

TECHNICAL CHALLENGES

A technical challenge for pyrosequencing is the limited annealing specificity for the sequencing primers to the templates as the pyrosequencing assay is performed at 28°C because of the low thermostability of firefly luciferase. Measures have been applied to minimize the background noise due to the nonspecific binding of the sequencing primers and the formation of 3′-end loops. Glycine betaine has been used to stabilize the luciferase so that the pyrosequencing assay can be performed at 37°C.[21] Single-stranded DNA-binding protein has also been tested to enhance specific hybridization between sequencing primers and templates, therefore reducing background noise and increasing the accuracy and intensity of the assays.[22] Increasing the annealing specificity would allow the pyrosequencing assay to be directly performed on double-stranded DNA and longer templates, therefore reducing the cost and time of assay.

Another disadvantage of pyrosequencing is the cost and time associated with purifying single-stranded DNA templates. A methodology has been developed to reduce the cost of generating biotin-labeled pyrosequencing templates.[5] This methodology uses a universal

biotinylated primer and two sequence-specific primers. One of the sequence-specific primers contains a 5′ tail that is complementary to the universal primer. During PCR amplification, a sequence-specific primer pair initiates PCR amplification of the genomic DNA. The resulting amplified fragments serve as templates for the universal biotinylated primer and a sequence-specific primer in subsequent amplifications, thus producing labeled amplicons. The cost savings result from ordering large amounts of the biotin-labeled universal primer rather than the biotin-labeled sequence-specific primers.

CONCLUSION

Pyrosequencing is a new DNA sequencing methodology and has been applied to SNP genotyping, DNA sequencing, and allele-specific DNA quantitation. This technique has the potential advantages of high-throughput, accuracy, flexibility, and can easily be automated. Future improvements in both chemical and instrumentation of pyrosequencing will reduce cost and improve specificity of primer hybridization, and will allow its widespread use in genomic and genetic studies. Developing a microarray-based pyrosequencing technique will enable performing genomewide SNP genotyping and DNA sequencing.

INTRODUCTION

A modern-day technique has enabled tens of thousands of genes to be printed on a single microscope slide—high-density microarrays. The development of these arrays has boosted genomics research, exploiting the huge amount of data made available by the human genome project because all known genes could now be included. Complete RNA expression profiles can be acquired from tissue samples as small as those obtained by laser dissection microscopy using RNA amplification. Expression profiles can be clustered and related to disease status. From these clusters, a molecular profile or ''signature'' of the disease can be extracted. Thus research can take full advantage of developments in microarray technique to find diagnostic and prognostic profiles for various diseases. A major challenge is to implement these signatures as diagnostic or prognostic tools in the clinic.

Despite the availability of a number of commercial platforms, many institutes have raised core facilities that provide them with homemade microarrays to minimize cost and to maximize flexibility. Because all these facilities use their own combination of probes, slides, printing and scanning equipment, hybridization conditions, and sample preparation, this gives rise to a huge variability in quality. Because regulatory federal and state agencies will allow only excellent quality microarrays to be used for diagnostics, many of today's platforms will not pass.

Many statistical ''tricks'' are being applied to correct for artifacts in the results of microarray experiments. In this review, we will indicate ways to solve these artifacts by techniques rather than by statistics. We will pinpoint essential steps to raise the quality of microarrays produced in core facilities to the perfection required for diagnostics or prognostics.

MICROARRAYS FOR DIAGNOSTIC PURPOSES

The development of high-density microarrays offers an enormous potential for diagnostics. Where standard pathological and molecular techniques cannot distinguish between tumor subclasses, molecular profiles are now able to predict clinical behavior.[1–3] The Dutch Cancer Institute has developed a signature set of 70 genes that can predict the 5-year survival chance of breast cancer patients and is planning to use this information to decide whether or not to start chemotherapy treatment.[2] A set of 37 genes can discriminate between two lymphoma types of diffused large B-cell lymphomas.[4] Furthermore, the clinical outcome of children with medulloblastomas is highly predictable based on the gene expression profiles of their tumors at diagnosis.[5]

It goes without saying that the quality of microarrays used in diagnostics should be nothing less than excellent. Regulatory federal and state agencies require absolute confidence about all key issues in a microarray experiment, such as gene identity, sample preparation, hybridization procedures, and array analysis. Tests used for diagnosis must also be highly standardized, reproducible, and reliable. Here we present some ideas to raise the quality of microarrays provided by in-house facilities to a level essential for diagnostic tests.

FROM ARRAY TO HIGH DENSITY: LET ROBOTS DO THE WORK

Low-density arrays in the past used to be produced by simple methods such as slot or spot blotting on filters used with radioactively labeled probes. Nowadays, robotics has taken over, spotting tens of thousands of genes on a single microscope slide with high accuracy. The first robotic arrayers used solid titanium pins that spotted relatively slow and with medium density (spot–spot distance of 300 μM or more). Currently, most people use quill pins, which provide fast printing with high density (spot–spot distance of 200 μM or less). Nevertheless, quill pins have a number of disadvantages that prevent the microarray technique from developing to perfection.[6] As the pins spot the DNA solution, they touch the surface of the slide, which may damage the pins and the slide surface coating where the DNA probe is to be immobilized. As most

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020785

arrays will be printed using more than one pin, there will be slight differences in spot morphology caused by pin-to-pin variation. Moreover, the number of slides that can be printed with one dip of a pin in the DNA solution is limited and dependent on the nature of the spotting buffer. Pins may fail during a run by picking up a dust particle or obstruction in the print head causing the whole—or part of the—subarray to drop out. Finally, it appears that thorough washing of the pins between dips is not invariably perfect, causing small amounts of carryover from one spot into the next one.[6]

It is important to notice that when an experimental set of arrays is analyzed, the variation in expression of a single gene across all arrays is analyzed, but not the variation of expression within an array. This implies that localization, pin-to-pin variation, or dye effects do not necessarily need to be corrected for as long as they are reproducible across an experimental set of arrays.

Most of these disadvantages have been overcome by noncontact printers, which are in development. Such printers use ''ink jet'' technology to deposit microdrops on a slide without touching it. Its tips can aspirate enough DNA solution to print thousands of spots, so all arrays within one print run will have identical quality. As the tips do not touch the glass surface, pin-to-pin variation is mostly eliminated and spot morphology is very even. In addition, ink jet technology allows detection of malfunctioning tips using a camera. Afterward, missing spots can be inserted, resulting in 100% complete arrays (Fig. 1).

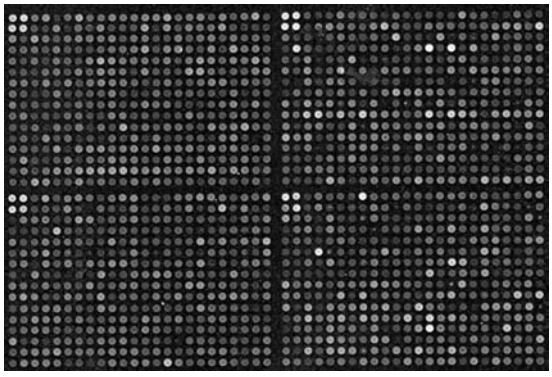

Fig. 1 Part of a microarray printed using the SpotArray™ Enterprise piezoelectric noncontact printer (PerkinElmer) showing complete arrays with very even spot morphology. The array has been constructed using the rat 5 K oligolibrary from Sigma/Compugen (www.cgen.com) on CodeLink slides. (From Ref. [7].) Target labeling, automated hybridization (Hybstation12; Perkin Elmer), and scanning were performed according to the protocols described on our website (www.vumc.nl/microarrays). Samples were from rat brain cerebellum (Cy3) and rat brain cortex (Cy5). (*View this art in color at www.dekker.com.*)

Finally, noncontact printing provides much more flexibility in designing arrays. It is much easier, for instance, to create replicates by set, rather than consecutively on the array, which introduces more statistical power to the array result as localization effects can be ruled out. In addition, the possibility to print a series of small arrays on one slide aids in the cost-effectiveness needed for diagnostic tests.

MICROARRAYS BY DESIGN: FROM cDNA TO OLIGONUCLEOTIDES

High-density microarrays were developed using spotted cDNA. At present, cDNA microarrays are still a major source for the production of valuable data, and they have the advantage that sequence analysis of the clones is not essential.[1] If one would like to perform an array on some exotic creature, a cDNA library can be printed and significant clones can be sequenced afterward. However, cDNA microarrays have a number of disadvantages that prevent the development of high-density microarrays to perfection. First and most important, cDNA clones used for microarrays are not all verified by sequence analysis, resulting in up to 25% of clones not representing what they should.[8] Such uncertainties are unacceptable for diagnostic microarrays. Second, cDNA clones have different lengths and basepair compositions resulting in different melting temperatures. Therefore it is impossible to achieve optimal hybridization conditions for all clones during a single hybridization experiment. Third, because most cDNA clones will have products of several hundreds of basepairs long, there is a major risk of cross-hybridization.

The best answer to these problems has proven to be the use of oligonucleotides to replace cDNA clones.[6,9,10] Oligonucleotides 50–70 nucleotides long have the advantage of being synthetically synthesized, thus they can be designed and customized for optimal performance (Compugen; www.cgen.com). They do not need to be sequence-verified and can be designed to minimize cross-hybridization and at similar melting temperatures. Furthermore, they can be designed to avoid known single nucleotide polymorphisms. Nowadays, most, if not all, of the commercial companies that offer high-density microarrays have platforms based on oligonucleotide technology.

SMALL SAMPLES: RNA AMPLIFICATION OR NOT?

The use of microarrays in diagnostic research requires that small samples give high-quality reproducible results. The size of a tumor sample or fine-needle biopsy can be limited, and researchers wish to perform microarray

analysis on microdissected material. One way to deal with this is to amplify the RNA of the sample, either using a homemade RNA amplification method[11] or one of the commercially available kits (i.e., www.agilent.com). The most challenging, yet difficult, part of amplifying an RNA sample is to do it linearly—meaning that the relative amount of all different RNA in the amplified sample is the same as in the original sample. Although many RNA amplification kits claim to perform linear amplification, in reality, when an unamplified sample is compared with its amplified RNA for many genes, a ratio other than 1 is obtained. As long as the nonlinearity is reproducible among all amplified samples that are compared in an array experiment, such an experiment will produce valid results. However, one should realize that all manipulations performed on the RNA samples will introduce extra noise in the results due to the limited stability of the RNA molecule. Moreover, the oligonucleotide libraries offered by various companies have been designed using the sense coding strand of the RNA. Using amplified RNA on these oligonucleotides enforces hybridization with unstable RNA, instead of cDNA. Although methods have been published to amplify even degraded RNA,[12] we would argue to avoid RNA amplification, if at all possible.

Instead, another approach used to deal with small size samples could be optimizing the yield of the cDNA labeling reaction and lowering the threshold for the amount of input RNA needed to achieve reasonable results in a microarray experiment. By optimizing column purification steps and hybridization conditions, we have scaled down the amount of input RNA by more than 10-fold—to as low as 4 μg of total RNA with very limited loss of signal intensity and reproducibility of the data. Whereas many researchers are using cover slips for their hybridization or hand-made hybridization chambers, automated hybridization, which enables moving targets in low volumes and very efficient washing, has been developed. All these measures increase the sensitivity of

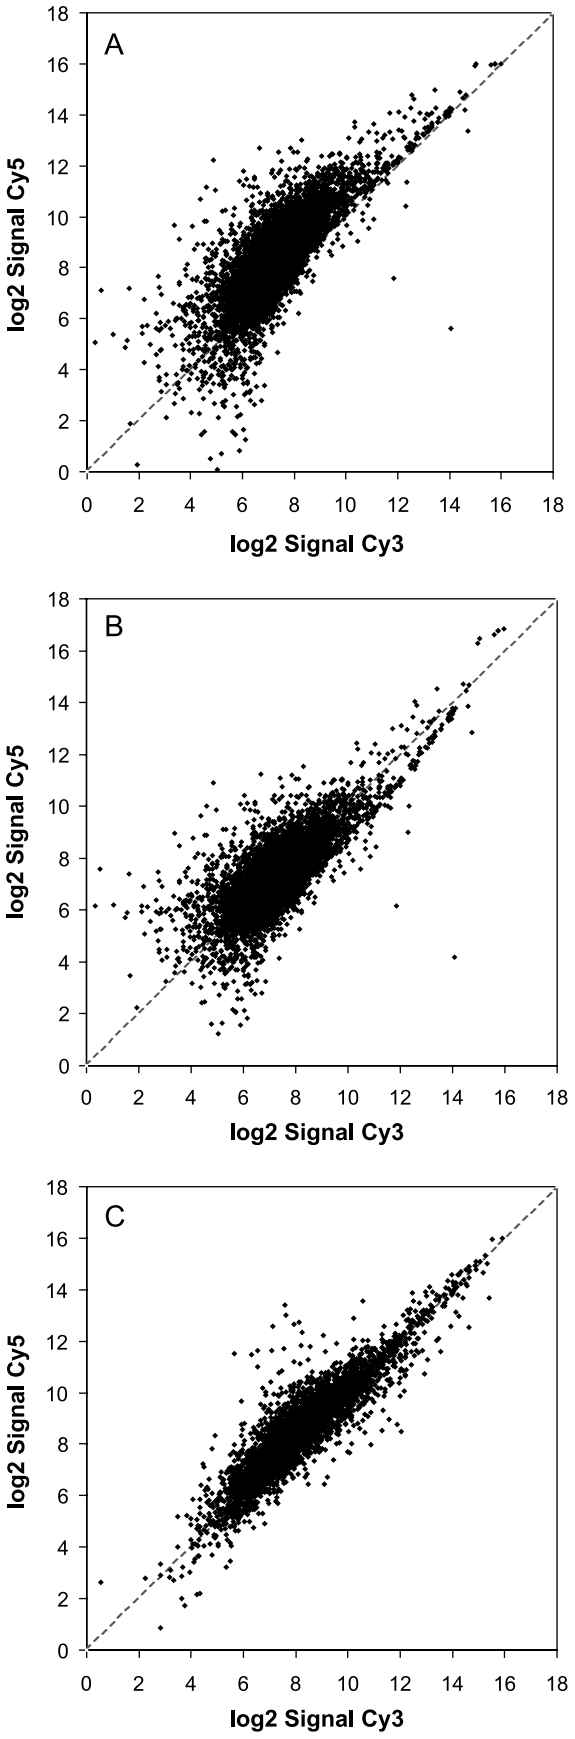

Fig. 2 Channel balancing omits the need for Lowess correction. Scatter plots showing the results of two microarray experiments using a human tumor cell line (Cy3 channel) and Human Universal Reference RNA (Stratagene) (Cy5 channel). The first experiment was performed without channel balancing (A) and results were corrected by Lowess smoothing (B). (From Ref. [15].) The second experiment was performed with channel balancing (C) showing that Lowess correction is not necessary. Arrays were performed by manual hybridization on 19 K human oligo arrays (Sigma/Compugen) as described in the legend of Fig. 1. (From Ref. [16].) Spots were measured using ImaGene software (BioDiscovery, USA). All plots have been constructed using signal mean values and all spots including flagged ones are included on the plots. (*View this art in color at www.dekker.com.*)

microarray experiments, thus omitting the need for RNA amplification. Currently, amplification is necessary for RNA samples smaller than 4 μg.

Another way of dealing with a limited size of samples is downscaling the size of the microarrays. Subsequent to the initial diagnostic research that has been performed on large, whole genome arrays, often a ''signature'' set of a limited number of genes that is specific for predicting a disease condition can be identified.[1,2,4] So if the size of the array can be downscaled from thousands to several hundred of genes, an enormous reduction of sample size can be obtained. In addition, there is technical room to decrease spot size by optimizing spotting solution in combination with the slide surface, or by other printing methods using capillary tips as currently being developed at the UCSF Cancer Center (cc.ucsf.edu). As a welcome advantage, this would also reduce the cost of a microarray experiment, thus rendering microarrays suitable for diagnostic purposes. The breast cancer study by Van't Veer et al.[2] has now led to the foundation of the first company that offers commercial microarray-based testing for diagnostics (Ref. [13]; www.agendia.com).

Investigations in which the RNA quality or quantity is not sufficient for expression profiling may be approached by microarray comparative genome hybridization (CGH)[3,14] because the more stable DNA is used as target instead of RNA.

FROM HIGH QUALITY TO PERFECTION

Many researchers perform all kinds of statistical ''tricks,'' such as Lowess correction,[15] to obtain valid data. It is our opinion that by using such tricks, valuable information is lost and that one should strive to solve array artifacts by the technique, rather than by statistics. As an example of this, Fig. 2 shows that ''channel balancing,'' a well-estimated chemical balance between the signal strength in both channels on the array, omits the need for high normalization factors and appears to have an enormous impact on data quality. Such a ''technical'' normalization can be achieved by measuring the amount of label incorporation in both channels and adjusting that for the hybridization. Rather than a conventional spectrophotometer, a Nanodrop (www.nanodrop.com) is an excellent piece of equipment for such measurements because it is highly reproducible and needs only tiny amounts of materials. A scatter plot of an array performed without channel balancing shows some sort of ''banana'' shape (Fig. 2A) that could be corrected by Lowess smoothing (Fig. 2B). An array performed with channel balancing (Fig. 2C) does not need such correction.

A second example is the improvement of hybridization conditions by going from a hand-made hybridization chamber[16] to an automated hybridization station (Hybstation12; PerkinElmer, USA). It is our experience that this alleviates the need for localization corrections such as border effects seen in the results of manual hybridizations.

To obtain the best hybridization results, it is essential to estimate hybridization stringency (ΔT). This is measured by the difference between the hybridization temperature (T_{exp}) and the melting temperature (T_m): $\Delta T = T_m - T_{exp}$. According to the equation by which T_m can be calculated, the four variables that affect melting temperature are: sodium concentration, formamide concentration, oligonucleotide length, and GC content.[17] If ΔT is too large, the chance of cross-hybridization and background signal is increased. If ΔT is too small, when the hybridization temperature approaches the melting temperature, too much signal is lost. Thus using the right ΔT during hybridization and washing can enhance reliability. For our homemade oligo arrays, we use a ΔT of 15°C. Compare it with a ΔT of approximately 35–40°C used in Southern blotting to detect gene families and 15–20°C to detect single genes.[17] Thus a ΔT of 15°C should completely abolish cross-hybridization as long as the design of the oligonucleotides is correct. The design of the oligonucleotides will keep pace with the quality of sequence data in the human genome databases. One should realize that things such as time, area, and nature of the surface (i.e., glass or nitrocellulose) are not in the ''T_m equation'' and thus will not affect hybridization stringency.

Finally, RNA quality is of crucial importance to the outcome of an array experiment. An RNA sample that has an excellent quality as judged by the ratio of the 28S and 18S ribosomal RNA bands and, an A_{260}/A_{280} ratio of 2.0 at a pH 7 usually guarantees good-quality microarray data, provided no phenol traces are present in the RNA samples, which severely affect enzymatic reactions that follow.

DATA ANALYSIS: HOW WAS THE EXPERIMENT SET UP?

Maybe the most underestimated consequence of high-density microarrays is the fact that every single experiment will generate thousands of results.[6] So the question is how to approach the analysis of series of tens or hundreds of microarray data. Although a huge number of both free and commercial software packages are available, this is no guarantee that a researcher will select the right analysis decisions. For example, clustering will always result in a number of clusters, but there is no assurance that these have a significant biological meaning. In some cases, unsupervised clustering using just the raw data is the best choice for analysis. In other cases (i.e., when the number of variables is small and the experiment has been

well set up), supervised clustering could lead to the desired results.

The major determinant in the analysis strategy is the experimental design of the study. If the experiment has been set up well and the quality of the RNA and arrays is optimal, then the analysis is straightforward. Often, researchers only find out how the experiment should have been set up when they run into difficulties while analyzing their results.

CONCLUSION

The development of high-density microarrays is having a great impact on diagnostic research. An increasing number of investigations are being published, showing that microarrays can classify tumor types based on specific ''signature'' sets that can be used as diagnostic or prognostic tools. The time has now arrived to let patients benefit from these tests. We believe that in-house facilities can raise the quality of their microarrays to diagnostic standards by implementing the latest technological developments and optimizing their protocols. Researchers will benefit from this by getting more reliable and reproducible data out of their microarray experiments.

Ramification Amplification

R

David Y. Zhang
Josephine Wu
Wandi Zhang
Fei Ye
Mount Sinai School of Medicine, New York, New York, U.S.A.

INTRODUCTION

Ramification amplification (RAM), also termed hyperbranched rolling circle amplification or cascade rolling circle amplification, utilizes a closed circular probe (C-probe) or padlock probe and a DNA polymerase with a high processivity. The C-probe can be exponentially amplified under isothermal conditions, eliminating the need for a thermal cycler. This type of amplification offers superb detection sensitivity for target DNA, RNA, or proteins.

OVERVIEW

Technical Description

Ramification amplification (RAM),[1,2] also termed hyperbranched rolling circle amplification[3] or cascade rolling circle amplification,[4] utilizes a closed C-probe or padlock probe and a DNA polymerase under isothermal conditions. The choice of DNA polymerase is based on the following requirements: a good strand displacement activity in order to separate downstream DNA from the template strand and a high processivity (i.e., incorporating nucleotides continuously on a given primer without dissociating from the template), allowing the polymerase to synthesize several thousand nucleotide-long ssDNA from the ligated C-probe. In this type of amplification, two primers, one complementary to the C-probe (forward) and the other identical in sequence to a second binding site in the C-probe (reverse), are added to the reaction. An initial rolling circle primer extension process is initiated and a single-stranded DNA (ssDNA) molecule is generated (rolling circle amplification). As the ssDNA molecule grows, multiple reverse primers are able to bind to the ssDNA and initiate a second ''round'' of primer extension templated by the initial ''rolling circle'' products. Once an upstream primer-extension strand ''bumps into'' a bound downstream primer, the polymerase displaces the downstream bound primer along with any extended sequence that is attached to it. The displaced dsDNAs serve as templates for further primer extension and amplification (Fig. 1). Like the constant unfurling of streamers, multiple primer extensions are simultaneously in progress, resulting in a large ramified complex. The reaction end-products are multimeric dsDNAs of various lengths, including smaller units such as monomers, dimers, trimers, and so on. Because the displaced DNAs are single-stranded, primers can bind to them at a constant temperature, eliminating the need for thermal cycling to generate ssDNA (as in the case of polymerase chain reaction, PCR).

The power of the exponential amplification of RAM can be expressed using the following formula: $x(2^U)$ where U is the number of repeats generated from the initial closed C-probe and where x is the number of the primer pair used.[1] For example, if one primer pair is used (one forward and one reverse), the formula is 2^U, indicating that RAM is an exponential amplification. Compared to PCR that can be expressed as 2^N, where N is the number of temperature cycles, RAM has an equivalent power of amplification. However, adding additional primer pairs can further enhance amplification. With three primer pairs (three forward and three reverse), the formula is $3(2^U)$, indicating that RAM can result in a far greater magnitude of amplification.[5] When using the RAM assay, the limiting factor is the length of the initial ssDNA generated from the closed C-probe; at least 20 repeats of ssDNA from the closed C-probe are required to achieve 1 million-fold amplification.

The two most important factors that affect amplification rate are stability of the DNA–polymerase complex and accessibility of the primer to its binding sites as soon as they are available. It is possible that formation of the large ramifying DNA–polymerase complex may interfere with the interaction of primers to their binding sites and disrupt the DNA–polymerase complex. Therefore the organic solvent dimethyl sulfoxide (DMSO, which stabilizes the DNA polymerase)[6] and a protein co-factor T4 gene 32 protein (which stabilizes single-stranded regions of DNA)[7] can be added to enhance primer binding to the growing ssDNA and stabilize the DNA–polymerase complex. The addition of these agents

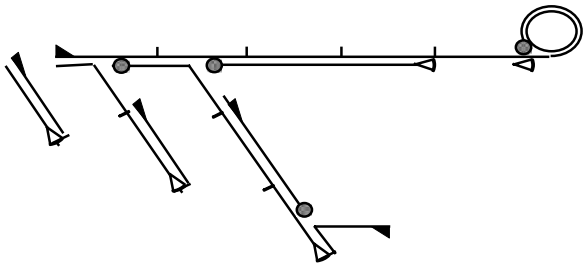

Fig. 1 Schematic representation of RAM. A forward primer (▶) bound to a C-probe is extended by a DNA polymerase (●), generating a long ssDNA. Multiple reverse primers (◁) bind to the nascent ssDNA as their binding sites become available. Each bound reverse primer extends and displaces the downstream primers and their extended products. The forward primer binding sites of the displaced ssDNA are then available for the forward primers to bind and extend similarly, thus forming a large ramifying DNA complex (RAM).

significantly stimulates DNA synthesis of many DNA polymerases such as 29 DNA polymerase[5] and Bst DNA polymerase.[2] Other components that can also stimulate DNA synthesis of DNA polymerases in RAM include Triton X-100 and 5% tetramethyl ammonium oxalate.[8]

The RAM assay offers many advantages over other amplification techniques. Primers can readily bind to ssDNAs displaced by DNA polymerase, enabling the reaction to be carried out under isothermal conditions, obviating the need for a thermal cycler. A multiplex assay can be designed using generic primers to amplify different probes with equal efficiency, resulting in a better multiplex capability than conventional PCR.[1,9] The RAM assay offers a uniform platform for both RNA and DNA detection with the ability to ligate both ends of the padlock probe regardless of the nature of target (DNA or RNA) eliminating the need for reverse transcription for detecting RNA.[9] Finally, ligation requires that both probe termini perfectly match in order

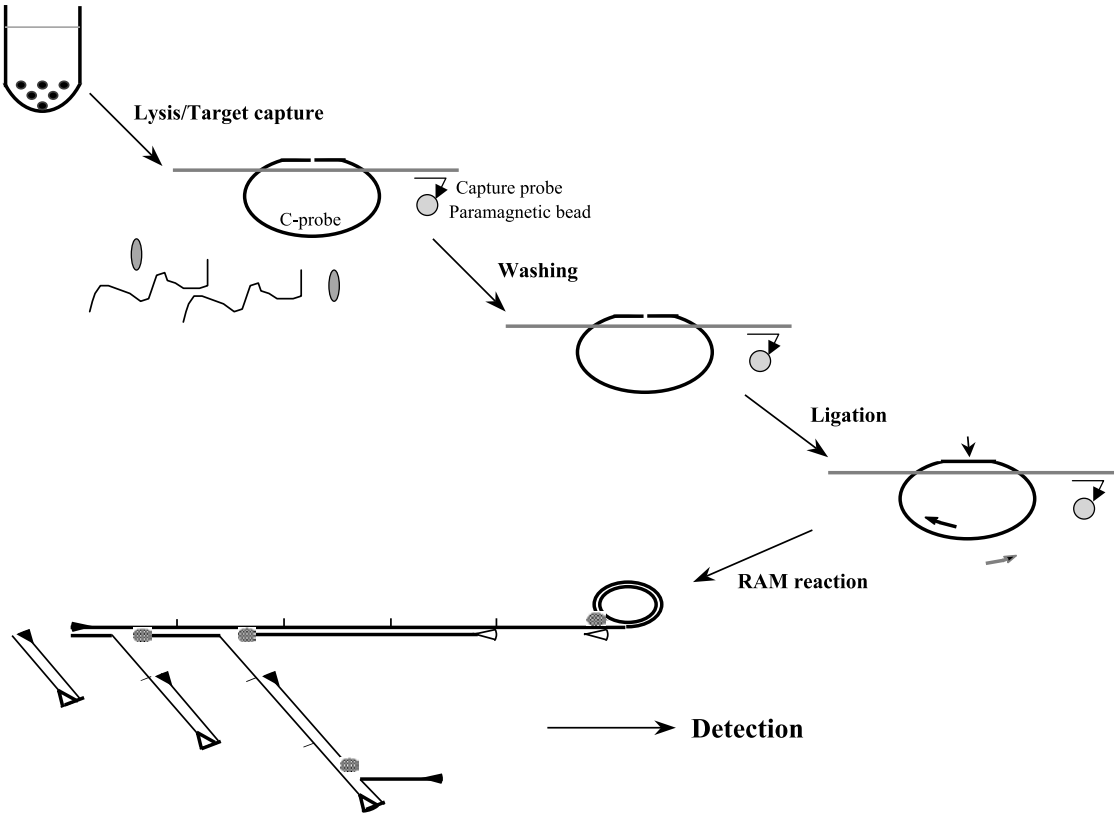

Fig. 2 Ramification amplification assay procedure. A clinical sample is lysed in a lysis buffer in the presence of capture probe, C-probe, and paramagnetic bead, and target DNA together with the bound C-probe are captured on a paramagnetic bead, allowing extensive washing to remove unbound C-probe and other components in the sample. The C-probe aligned on the target is linked together by a DNA ligase. RAM amplification is then carried out by the addition of forward and reverse primers and DNA polymerase. (*View this art in color at www.dekker.com.*)

for hybridization to occur, permitting the detection of a single nucleotide polymorphism.

Application

The practical uses of RAM assay to detect target nucleic acids in clinical samples have been demonstrated in several studies (Fig. 2). Zhang et al. have applied the RAM assay to detect *Chlamydia trachomatis*, a leading cause of sexually transmitted disease (STD) in the United States, in cervical specimens collected in PreservCyt cytological solution.[10] They demonstrated the RAM assay can detect as few as 10 *C. trachomatis* elementary bodies in less than 2 hr, comparable with those of Amplicor PCR and ligase chain reaction (LCR), and they further tested 30 clinical specimens and detected all positive samples confirmed by PCR and LCR. The RAM assay can be an alternative to PCR and LCR to detect sexually transmitted agents because of its simplicity and isothermal amplification nature. Furthermore, it is possible to screen simultaneously cervical intraepithelial lesions and to detect STD agents in a single collection vial. Zhang et al. have also successfully applied the RAM assay for detection of Epstein–Barr virus in human lymphoma specimens.[2] They demonstrated the feasibility of RAM to detect a rare DNA target in clinical specimens and achieved an analytical sensitivity of as low as 10 molecules, comparable to that of PCR.

Fluorescent-based RAM assays have been developed to monitor and quantify the RAM products in a real-time fashion in a homogeneous reaction. Zhang et al. have demonstrated that RAM products can be monitored in the presence of SYBR green, and SYBR green can be incorporated into RAM reaction for the real-time detection of RAM products. The major limitations of intercalating dyes are that it can only detect one target per reaction, and that the signal can also be generated from nonspecific polymerization products. Fluorescent molecular beacons can also be used for real-time RAM assay.[8,11] Amplifluor is used as a primer and the reverse sequence displaces the stem structure, resulting in the release of fluorescence.

The RAM mechanism has been applied to amplify large, circular DNA such as the M13 phage (30,000 bp) or plasmid DNA from single colonies or plaques.[8] Dean et al.[12] showed that using random primers and 29 DNA polymerase, circular DNA templates can be amplified up to 10,000-fold in a few hours. This procedure removes the need for lengthy growth periods for phage and plasmid as well as traditional DNA isolation methods. The amplified products can be used directly for DNA sequencing, in vitro cloning, library construction, and other molecular biology applications.

The RAM mechanism can also be used to amplify linear DNA, such as genomic DNA. Dean et al.[12] recently demonstrated that whole genomic DNA can be amplified with 3′ thiophosphate-modified random hexamer and 29 DNA polymerase. About 20–30 μg DNA can be generated from as few as 10 copies of genomic DNA in about 6 hr of incubation at 30°C; the average product length was >10 kb. The products can be used directly for sequence analysis, SNP detection, comparative genome hybridization, or loss of heterozygosity analysis.

CONCLUSION

In summary, RAM represents a novel, isothermal, exponential amplification method of nucleic acid and protein based on primer extension, displacement, and ramification. The inherent simplicity will allow RAM to be used in a wide variety of clinical and research applications.

Real-Time PCR

Stephen A. Bustin
University of London, London, U.K.

INTRODUCTION

The real-time polymerase chain reaction (PCR) uses fluorescent reporter molecules to monitor the production of amplification products during each cycle of the PCR reaction. This combines the DNA amplification and detection steps into one homogeneous assay and obviates the need for gel electrophoresis to detect amplification products. Appropriate data analysis and/or use of apposite chemistries also eliminates the need for Southern blotting or DNA sequencing for amplicon identification. Its simplicity, specificity, and sensitivity, together with its potential for high throughput and the ongoing introduction of new chemistries, more reliable instrumentation, and improved protocols, has made real-time PCR the benchmark technology for the detection of DNA.

THE ASSAY

The concepts underlying fluorescence-based real-time PCR are straightforward and are described in detail in the accompanying review on real-time reverse transcription-PCR. Real-time PCR technology is based on the detection of a fluorescent signal produced proportionally during the amplification of a DNA target (Fig. 1). Rather than having to look at the amount of DNA target accumulated after a fixed number of cycles, real-time assays determine the point in time during cycling when amplification of a PCR product is first detected. This is determined by identifying the cycle number at which the reporter dye emission intensity rises above background noise. That cycle number is referred to as the threshold cycle (C_t). The C_t is determined at the exponential phase of the PCR reaction and is inversely proportional to the copy number of the target. Therefore the higher the starting copy number of the nucleic acid target, the sooner a significant increase in fluorescence is observed, and the lower the C_t. Real-time PCR assays are highly reproducible (Fig. 2A) and can easily discriminate between twofold differences in target numbers (Fig. 2B).

At its simplest, real-time PCR can be used as a qualitative assay. However, as fluorescence output is linear to sample concentration over a very broad range, this linear correlation between PCR product and fluorescence intensity can be used to calculate the amount of template present at the beginning of the reaction.

There has been an explosion of protocols, instruments, and chemistries, which on the one hand is evidence for the popularity and ubiquity of the assay, but also highlights the need to be aware of problems associated with the use of nonstandardized assays for diagnostic assays.[1]

CHEMISTRIES

Real-time PCR can utilize general nonspecific DNA-binding fluorophores (e.g., SYBER Green I), fluorophore-labeled primers (e.g., LUX™), or sequence-specific probes (e.g., Scorpions™).

Nonspecific Chemistries

An important advantage of nonspecific chemistries is that the design and setup of the assays is straightforward and, except for the cost of the real-time PCR apparatus, material costs are low. This makes them particularly attractive for the analysis of single nucleotide polymorphisms (SNP), which have become the markers of choice for identifying the multiple genes associated with complex diseases such as cancer or diabetes. Biallelic polymorphisms can be detected by combining allele-specific amplification with the detection of SYBR Green I. Allele-specific amplification takes advantage of the relative inability of *Taq* polymerase to extend primers that are mismatched to their targets at the 3′ end. The assay is carried out in two separate tubes, each of which contains a primer pair specific to one or the other allelic SNP variant.[2] Although there will be amplification of the mismatched allele, this occurs much less efficiently than that of the matching allele, delaying amplification and resulting in a much higher C_t being recorded. The specificity of the assay can be improved by using hairpin primers for the allele-specific PCR, as they are better than linear ones at discriminating between closely related sequences.[3]

The use of dissociation curve analysis to identify different amplicons obviates the requirement for two

DOI: 10.1081/E-EDGP 120020684

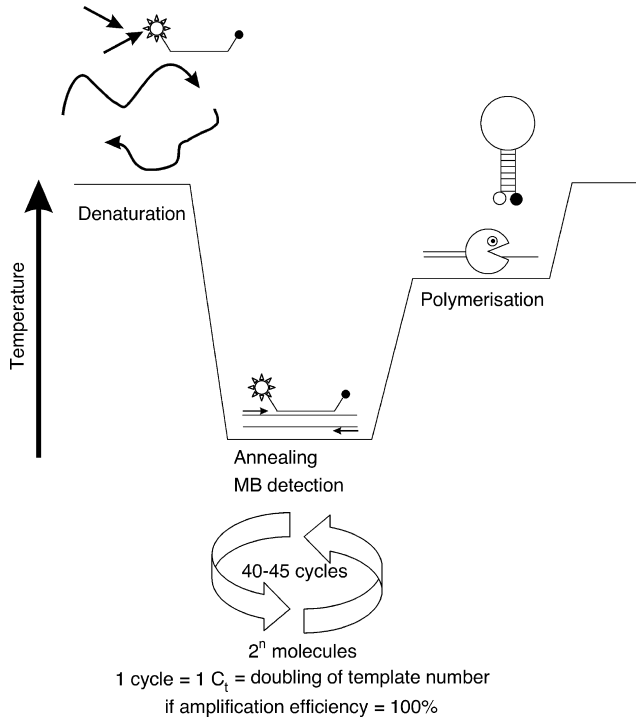

Fig. 1 Schematic representation of a real-time PCR assay using MB probes. At the annealing temperature, MB bind to their complementary target and fluorescence readings are taken. At the polymerization temperature MB dissociate from their target allowing *Taq* polymerase to read through and replicate the amplicon. A well-designed assay has an amplification efficiency of near 100% at the time fluorescence is first detected. Hence, any twofold difference in initial template concentration is reflected in a ΔC_t of 2.

separate amplification reactions. Following the PCR assay, double-stranded (ds) DNA product is melted into single-stranded (ss) DNA by a stepwise increase in temperature, with fluorescence data being collected at each temperature step. The magnitude of the reduction in fluorescence intensity of the SYBR Green dye due to its release from dsDNA provides an indicator of the amount of dsDNA dissociated at each step in the dissociation curve (Fig. 3). Furthermore, as different amplicons will melt at different temperatures, SYBR Green I can be used to distinguish different alleles through their melting temperatures (T_m). For example, Huntington's disease is caused by an expanded number of CAG repeats in the Huntington gene and the dissociation curve of a normal subject shows a single melting peak, whereas that of an affected individual has two.[4] Several closed-tube systems have been developed that can be used in combination with melting analysis of PCR products to identify both heterozygous and homozygous sequence variants,[5] and it has even been possible to develop triplex assays that use SYBR Green I and dissociation curves to identify different gene targets in the same tube.[6]

Fluorophore-Labeled Primers

Despite their attraction, there are several problems associated with the use of nonspecific dyes. In particular, there is a broadening of the melting transition and T_m compression among genotypes, which can lead to ambiguous results. Furthermore, dsDNA-specific dyes may redistribute during melting causing the release of dye from low-melting heteroduplexes and redistribution to higher melting heteroduplexes. The use of labeled primers for melting analysis avoids these problems while retaining the advantage of not having to use specific probes for each assay. The use of one fluorophore-labeled and one unlabeled primer enables melting profiles of the amplicon to be obtained immediately after completion of the PCR reaction and results in distinct melting curve shapes for different alleles, including those that differ by only a single base.[7]

Another method makes use of the principle of fluorescence resonance energy transfer (FRET). This is a distance-dependent interaction between the excited states of two dye molecules in which excitation is transferred from a donor molecule to an acceptor molecule at distances up to 70–100 Å without emission of a photon. As a result, the emission of the reporter fluorophore is quenched. In this approach, one of the amplification primers has a reporter and a quencher moiety attached to a hairpin structure at its 5′ end (Fig. 4A). When in solution, fluorescence emission from the reporter is quenched. A fluorescent signal is generated only when the labeled oligonucleotides are incorporated into the ds amplification product.[8] Labeled primer synthesis has been simplified recently by using the same type of hairpin primer, but only a single reporter fluorophore whose fluorescence emission is self-quenched based on sequence context.[9] These primers, also known as LUX™, quench when free in solution, fluoresce weakly when denatured, and emit light strongly when incorporated into DNA (Fig. 4B). Differential fluorescence labeling of primers allows the use of allele-specific PCR in a single tube.

Target-Specific Probes

Despite the evident usefulness of these chemistries, the specificity of these assays remains dependent on the specificity of the primers. Therefore the use of chemistries employing hybridization probes remains the reference method for genotyping. Two fluorogenic probes, labeled with two spectrally distinct dyes, are used to discriminate between the wild-type and mutant alleles. If amplification

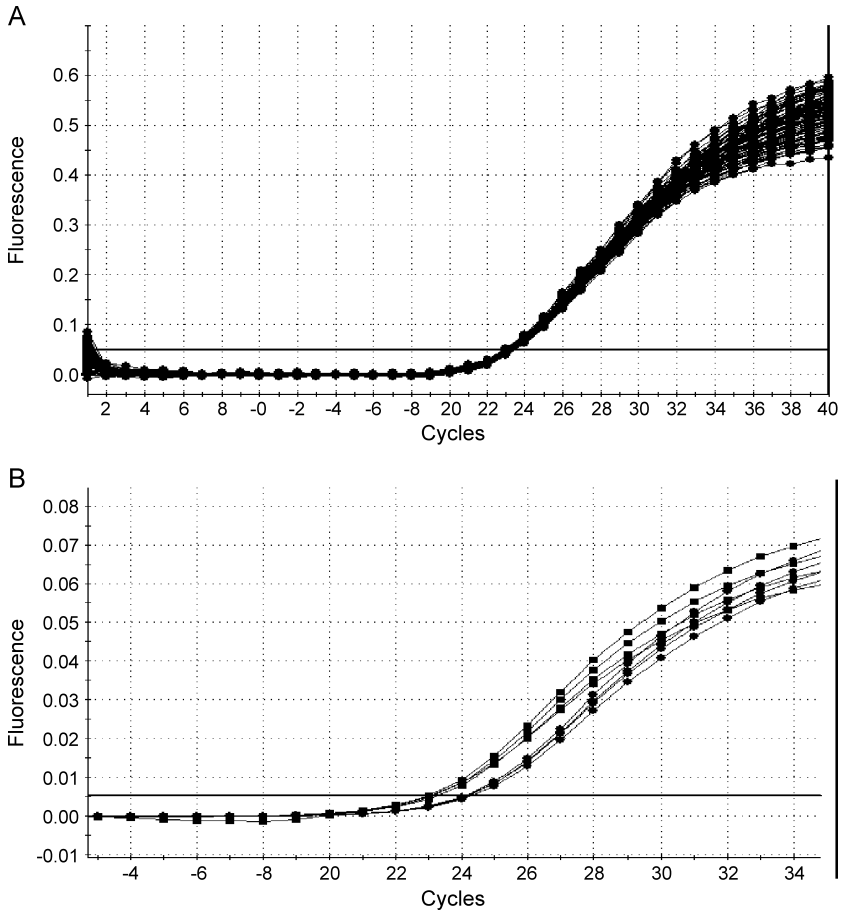

Fig. 2 Reproducibility and accuracy of real-time PCR. (A) Analysis of a 96-well plate containing replicates of a single template/mastermix. The assay was carried out on a Stratagene MX 4000 instrument using TaqMan™ chemistry. The average C_t for all 96 reactions is 23 ± 0.3. (B) Two reaction mixes were set up in triplicate. One contained 1×10^3 copies of template DNA and recorded a C_t of 23.1 ± 0.15. The other contained 2×10^3 copies and recorded a C_t of 24.1 ± 0.1. This corresponds exactly to the expected ΔC_t of 1.

in an unknown DNA sample is detected for the fluorophore identifying the wild-type allele but not for the one identifying the mutant allele, the sample is designated as wild-type homozygous. If amplification in an unknown DNA sample is detected for the fluorophore identifying the mutant allele but not for the dye identifying the wild-type allele, the sample can be designated as mutant homozygous. If the sample generates intermediate values for both dyes, it is designated as heterozygous for the two alleles (Fig. 5).

Assays based on the 5′-nuclease (''TaqMan'') use two allele-specific oligonucleotides that are labeled with different fluorophores at their 5′-ends. During PCR, fluorescence is generated after cleavage of the annealed probes by the 5′ nuclease activity of the Taq polymerase. Different sequences can de distinguished from one another by the differential fluorescence emission of the two reported dyes.[10]

Another assay, most commonly used on Roche's LightCycler™, uses two sequence-specific probes that bind adjacent to each other on the amplicon in a head-to-tail arrangement. One has a donor dye at its 3′-end, and the other has an acceptor dye on its 5′-end and is blocked at its 3′-end to prevent its extension during the annealing step. In solution, the two dyes are apart and only background fluorescence is emitted by the donor. Following the denaturation step, both probes hybridize to their target sequence in a head-to-tail arrangement during the annealing step. The reporter is excited and passes its energy to the acceptor dye through FRET. For SNP/mutation detection one probe is positioned over the polymorphic site and the mismatch causes the probe to dissociate at a different temperature to the fully complementary amplicons. Melt curve analysis after the PCR reveals which alleles are present as one probe dissociating from the amplicon causes a decrease in fluorescence as FRET can no longer occur.[11]

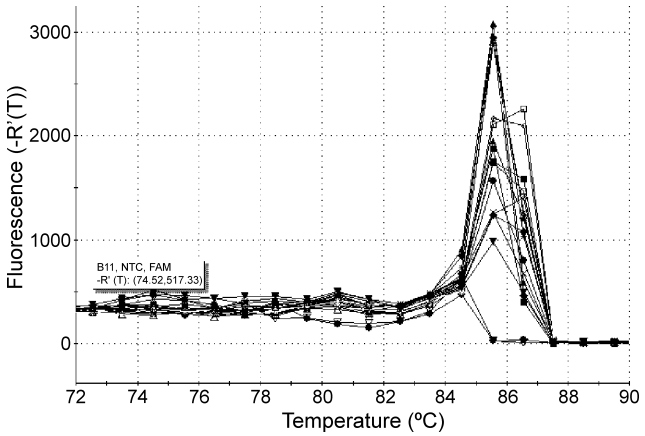

Fig. 3 Analysis of SYBR Green 1 dissociation curve. The first derivative view with respect to temperature provides a clear view of the rate of SYBR Green 1 loss and the temperature range over which this occurs. The example shows a view of data between 72°C and 90°C. The small peak at 74.5°C is probably due to primer dimer product formation as this is the only peak to occur in the NTC sample. The main peaks occur around 85.55°C although there are some with a distinctly different profile and a peak at 86.55°C. These distinct profiles represent different products in the final PCR product.

Molecular beacons (MB) and Scorpions are based on stem-loop hairpin structures, and MB in particular have found wide-ranging application as diagnostic tools.[12] Molecular beacons consist of a hairpin loop structure, with the loop complementary to a target nucleic acid and the stem formed by the annealing of complementary termini (Fig. 6A). One end of the stem has a reporter fluorophore attached and the other a quencher. In solution, free MB adopt a hairpin structure and the stem keeps the arms in close proximity, resulting in efficient proximal quenching of the fluorophore. During the denaturation step, the MB assume a random-coil configuration and fluoresce. At the annealing temperature, MB bind to any target amplicons as the probe/target duplex is designed to be thermodynamically more stable than the hairpin structure at that temperature. Once the probe binds to its target the hairpin is opened out and the fluorophore and quencher are separated, resulting in fluorescence. A major strength of this technology is the high specificity of the MB in recognizing nucleotide sequence mismatches in DNA and RNA. The hairpin shape of the MB causes mismatched probe/target hybrids to easily dissociate at significantly lower temperatures than exactly complementary hybrids. This is because the thermodynamic properties of the MB favor the formation of a hairpin form rather than continued hybridization to a less than perfectly matched target sequence. When the temperature is raised to allow primer extension, the MB dissociate from their targets and do not interfere with polymerization. A new hybridization takes place in the annealing step of every cycle, and the intensity of the resulting fluorescence indicates the amount of accumulated amplicon. Again, as this is a reversible process, melt curves can be used to analyze the dynamics of the reaction and determine the best temperature for fluorescent acquisition (Fig. 6B). There is some evidence to suggest that the measured signal ratios

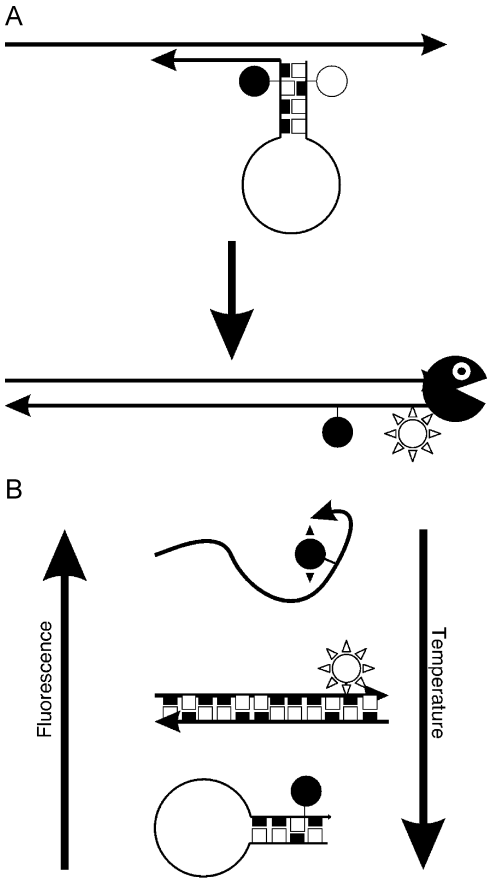

Fig. 4 Fluorophore-labeled probes. (A) The original design used a primer with a hairpin structure at its 5′-end that contained a fluorophore and quencher at opposite ends of the hairpin. During the first cycle of PCR the primers are extended and become templates during each subsequent cycle. This linearizes the hairpin, separates the donor and acceptor moieties, and results in fluorescence emission from the fluorophore. (B) LUX™ primers. One primer contains a fluorophore, the other one is unlabeled. The fluorogenic primer has a short sequence tail of 4–6 nucleotides on the 5′-end that is complementary to the 3′-end of the primer. The resulting hairpin secondary structure provides optimal quenching of the attached fluorophore. When the primer is incorporated into the double-stranded PCR product, the fluorophore is dequenched and a signal is reported.

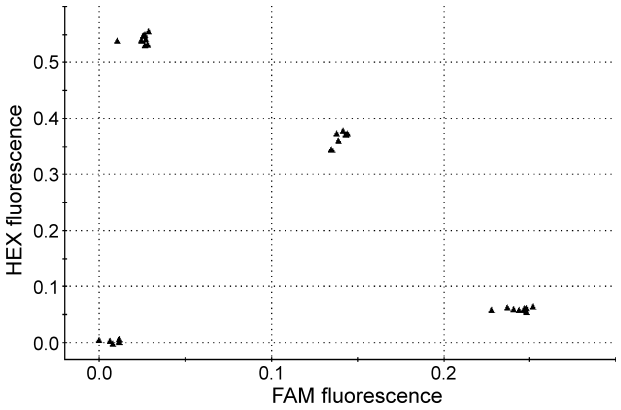

Fig. 5 Scatter plot for real-time SNP analysis using MB. Fluorescence is reported during each annealing step when the MB is bound to its complementary target and the C_t value for each dye in the sample is used to determine the genotype of the samples. A C_t value equal to the final cycle of the PCR reaction (typically 40 or 45) indicates the absence of a specific allele. Each plotted point represents the coordinates of the C_t values for the two dyes in a single well. Here the x axis corresponds to FAM C_t whereas the y axis corresponds to HEX C_t and the plotted points (x,y) correspond to the coordinates describing the two C_t values determined for a given well. The position of the data point for a given well on the scatter plot indicates the presence or absence of each allele, providing a rapid method for clustering the samples that are homozygous for either of the two alleles or are heterozygous. If a highly quantitative measurement of copy numbers is not necessary, it is also possible to measure fluorescence when cycling is complete.

with MB assays are proportional to the amount of the minor allele over a wider range than with the TaqMan assay.[13] Multiplexing of MB is enhanced by the use of wavelength-shifting MB (Fig. 6C).[14] These extend the range of fluorophore/quencher pairs that will function at a given wavelength and contain a generic harvester fluorophore, a probe-specific emitter fluorophore, and a quencher. Scorpions were originally made up of a single oligonucleotide containing a 5′ fluorophore, a stem-loop structure containing the probe, a quencher, and a PCR blocker to prevent read-through by DNA polymerase and primer. In the presence of a target, the specific probe sequence folds back on itself to bind its complement within the same DNA strand, opening up the hairpin loop and separating the fluorophore and quencher. This unwieldy structure was replaced by the second-generation Scorpions that are made up of two oligonucleotides. One contains the fluorophore-coupled probe, the other a quencher-coupled complementary sequence. For SNP analysis, the fluorescence is monitored above the T_m of the mismatch probe/target duplex and below the T_m of the fully complementary probe/target duplex. Under these conditions the mismatched probe reassociates with the quencher element to become nonfluorescent, whereas the hybridized wild-type probe is separated from the quencher element and is fluorescent. Because the hybridization of probe sequence to amplicon is intramolecular, Scorpion probes are more efficient than binary systems such as MB and as a result generate significantly greater signal intensities.[15]

There are many more probe chemistries available, all with their own advantages and disadvantages. These include Hybeacons, which require only a single fluorophore and make use of the quenching properties of DNA. This makes them easy to design and synthesize.[16] Light-up probes are composed of thiazole orange conjugated to peptide nucleic acid (PNA) (see below) and combine the excellent hybridization properties of PNA, which allows the use of shorter probes, with the extraordinary fluorescence enhancement of asymmetric cyanine dyes upon binding to nucleic acids.[17] Eclipse™ probes are linear probes that have a minor groove binder (MGB) and quencher on the 5′-end and the fluorophore on the 3′-end.[18] This is the other way round compared with hydrolysis probes, and the presence of the MGB at the 5′-end prevents cleavage of the Eclipse probe by *Taq* polymerase. Other chemistries are described in detail elsewhere.[19]

Real-time PCR assays generally use symmetric primers. However, this results in the reactions typically slowing down and entering the plateau phase in a stochastic manner, because reannealing of the template strands gradually outcompetes primer and probe binding to the template strands. This is a particular problem when the aim is to detect specific DNA targets down to alleles of single-copy genes in single cells. Asymmetric PCR potentially circumvents the problem of amplicon strand reannealing by using unequal primer concentrations. However, asymmetric amplification is much less efficient and requires extensive optimization to identify the proper primer ratios, the amounts of starting material, and the number of amplification cycles that can generate reasonable amounts of product for individual template/target combinations. A recent innovation termed linear-after-the-exponential-PCR (LATE-PCR) uses unequal primer concentrations but takes into account the effect of the actual primer concentrations on primer T_m.[20] It corrects for the fact that the T_m of the limiting primer is often several degrees below the T_m of excess primer and allows the asymmetric PCR to proceed as efficiently as symmetric PCR. Furthermore, ss amplicons are generated with predictable kinetics for many cycles beyond the exponential phase. This permits uncoupling of primer annealing from product detection. As a result, the T_m of the probe no

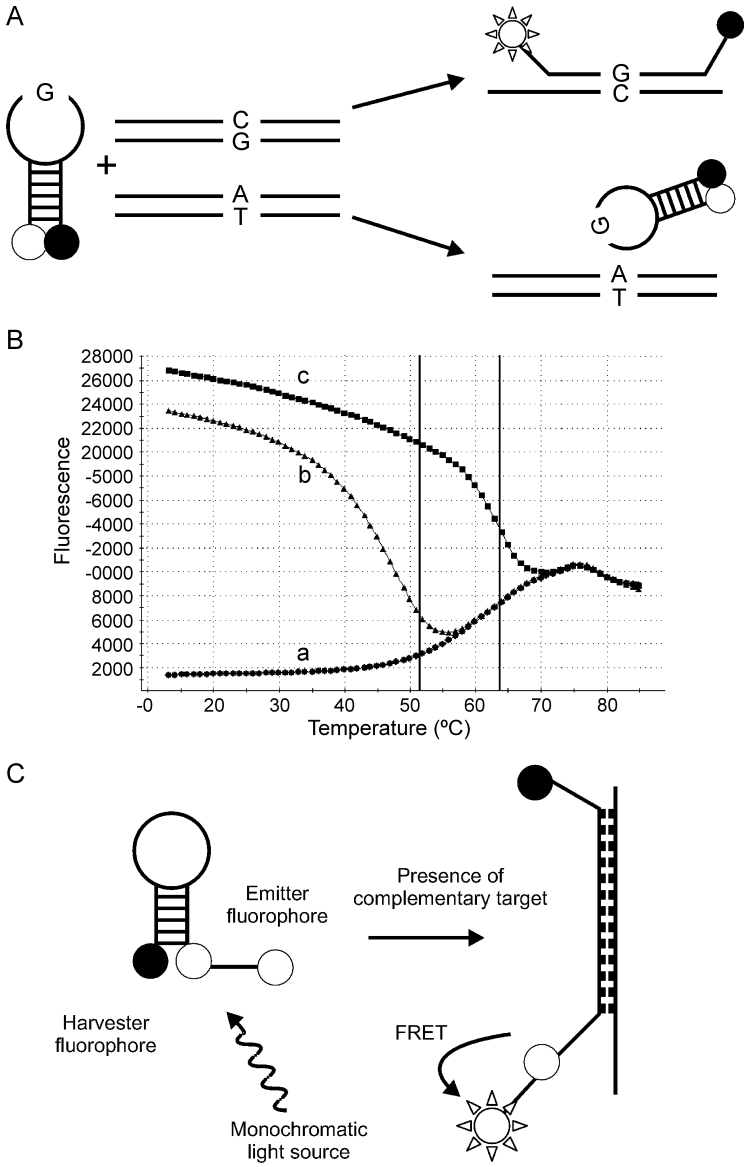

Fig. 6 Molecular beacons and melting curves. (A) Structured probes are better at discriminating single base-pair mismatches than linear ones such as TaqMan™. Only one MB is shown, which hybridizes to its perfect complement and emits fluorescence but remains closed and unbound to a target with a single nucleotide mismatch. (B) Molecular beacon melting profile for allelic discrimination. Three melting curves are visible. One for MB alone (a), a second one for MB and its perfectly complementary single-stranded oligonucleotide target (b), and a third one for MB plus a single-strand target that produces a probe/target hybrid containing a single mismatched base pair (c). The two vertical bars indicate the optimal annealing temperature range in which the perfectly matched MB will have greater fluorescence than the mismatched MB, with background fluorescence still low. (C) Wavelength shifting MB. The MB has two fluorophores on one end, a ''harvester'' and an ''emitter,'' and a quencher on the other end. In the hairpin loop structure, the quencher forms a nonfluorescent complex with the harvester. Upon hybridization of the MB to a complementary sequence, quenching of the harvester fluorophore is relieved, and it transfers energy via FRET to the emitter, which emits fluorescence.

longer needs to be higher than the T_m of either primer. This permits the use of low-T_m probes, which are inherently more allele-discriminating, generate lower background, and can be used at saturating concentrations without interfering with the efficiency of amplification.

Another important advantage of using probe-based chemistries is that it is possible to multiplex, i.e., amplify multiple targets in a single tube, as fluorescent dyes with different emission spectra may be attached to the different probes (Fig. 7). Probes afford a level of discrimination

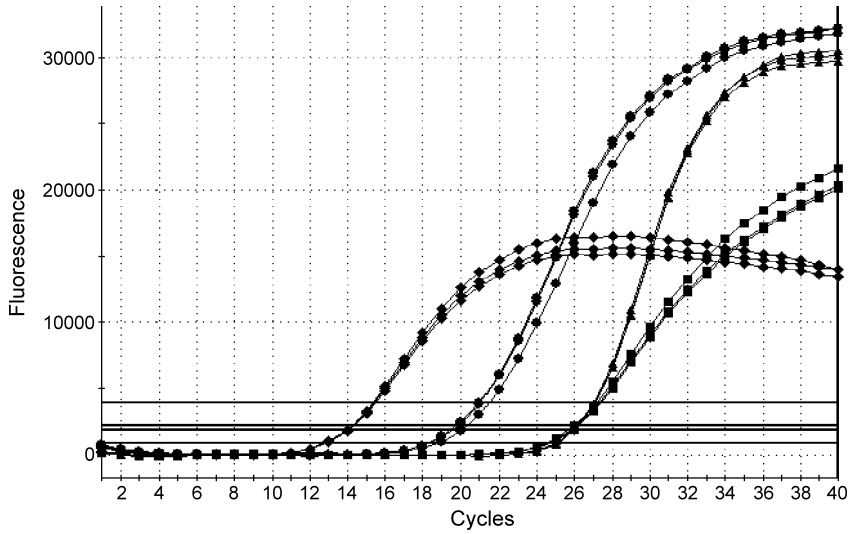

Fig. 7 Multiplex PCR. Four TaqMan™ probes were labeled with FAM, HEX, ROX, or Cy5, and a PCR assay was performed using the Stratagene ''Brilliant® Multiplex QPCR'' master mix on the MX4000 real-time PCR system. Each sample was analyzed in triplicate. The four horizontal lines indicate the four thresholds calculated for the individual fluorophores. The four targets differ by 14 C_ts, which translates into a 1.6×10^4-fold difference in target abundance.

impossible to obtain with SYBR Green, as they will only hybridize to true targets in a PCR and not to primer–dimers or other spurious products.

DNA ANALOGUES

A recent development has been the use of probes incorporating peptide nucleic acid (PNA) or locked nucleic acid (LNA™). In PNA the entire deoxyribose phosphate backbone is replaced by a structurally homomorphous backbone consisting of repeating *N*-(2-aminoethyl)-glycine units linked by peptide bonds. As the PNA backbone is not charged, hybridization is not affected by intrastrand repulsion, and no salt is necessary to facilitate and stabilize the formation of PNA and DNA or RNA duplexes. Furthermore, the ΔT_m of a single PNA/DNA mismatch is significantly higher than that of a DNA/DNA mismatch, making PNA probes useful for mismatch detection. PNA technology has been used in an ingenious approach utilizing quencher-labeled primers. This system uses two labeled molecules: 1) a quencher-labeled PNA probe with a C-terminal DABCYL group; and 2) a primer with a target-specific sequence at its 3′-end and a fluorophore and a PNA-probe-complementary sequence tag at its 5′-end.[21] The PNA/primer duplex has a T_m higher than the primer annealing temperature, but lower than the T_m of the primer/amplicon duplex. This ensures that excess primer is quenched at the annealing temperature and the fluorescence measured during the annealing step indicates the amount of primer hybridized to amplicon, plus any full-length ds amplicon as the end result is a fluorescently labeled ds amplicon. The main disadvantage with PNA probes is that they can aggregate and precipitate.

In LNA the furanose ring conformation is restricted by a methylene bridge that connects the 2′-oxygen position of ribose to the 4′-carbon. This bridge reduces the conformational flexibility of the ribose, which imparts superior affinity and specificity in binding complementary sequences of DNA or RNA. In addition, the change in T_m caused by a mismatch is significantly greater with a LNA/DNA duplex than with of a DNA/DNA duplex, resulting in enhanced specificity for SNP/mutation analyses.[22] Using appropriate dyes, it is possible to use probes as short as 7 nucleotides long for mismatch discrimination, making it possible to generate universal genotyping reagents. Unlike PNA, there is no problem with solubility of LNA molecules.

OTHER APPLICATIONS

The real-time PCR-based focus on pathogen genotype is having a significant impact on the detection of viruses, bacteria, and parasites in diagnostic microbiology.[23] The biggest application of real-time technology is probably in virology, where these assays have been used to investigate the role of viruses in a range of human diseases. The ability to multiplex has allowed the reliable measurement

of different viral nucleic acid targets within a single sample, and the discrimination of multiple viral genotypes within a single reaction tube. A major application is in the detection of viral load, and real-time assays have become very useful as indicators of the extent of active infection, host/virus interaction, and the efficacy of antiviral treatment. Other uses include the assessment of viral gene therapy vectors before their use in clinical trials and the study of new and emerging viruses and clinical symptoms experienced by patients.[24]

A major benefit lies in the rapidity with which results can be obtained. This is of major importance when detecting bacterial pathogens, as it allows a specific and timely application of antibiotics. Real-time assays are ideal for distinguishing between different serotypes of a single bacterial species,[25] for detecting and monitoring drug resistance among clinical isolates,[26] for detecting pathogens in food,[27] and not least for identifying microbes used as agents of biological warfare.[28]

The worldwide approval of a large number of genetically modified organisms (GMOs) among countries, and the associated labeling requirements, has resulted in the development of real-time PCR-based methods for the detection of the presence of GMO in food or food additives.[29] Genetically modified organism detection through PCR relies on parallel amplification of the transgene and of an endogenous reference gene that provides a control both for the lack of inhibition and for the ability to amplify the target DNA in the sample. Additionally, for quantitative analyses, amplification of the reference gene provides an estimation of the total amount of target DNA present in the sample. Targeting the DNA is particularly appropriate, because of the high stability of this molecule under the extreme conditions used during processing of some food products.

CONCLUSION

These examples are but a few of the huge number of applications that have benefited from the introduction of real-time fluorescence-based PCR assays and that have contributed to the transformation of this technique from an experimental tool into the scientific mainstream.[30] The advances in robotic nucleic acid extraction and liquid-handling systems, together with the continuous introduction of less expensive, yet more capable thermal cyclers make real-time PCR an attractive and essential technology for routine diagnostics. Recent developments in multiplexing make it possible to envisage easy identification, genotyping, and quantification of DNA targets in single, rapid reactions. However, the technology is only as reliable as the accompanying controls and associated quality-assurance programs. This includes the quality of standards, the use of suitably controlled standard curves, and the need to fully optimize, validate, and evaluate each new assay against previously standardized assays. Nevertheless, it is clear that real-time PCR is a technique whose time has come.[31]

Real-Time PCR Platforms

Mikael Kubista

TATAA Biocenter AB, Göteborg, Sweden

INTRODUCTION

During the last decade, the scientific community has undergone a technology shift in studying nucleic acids in biological samples. With the development of real-time polymerase chain reaction (PCR), it became possible to quantify the amount of specific nucleic acids target in virtually any biological sample with unprecedented accuracy, sensitivity, and specificity. Real-time PCR combines the exponential amplification of the PCR with optical detection using fluorescent dyes or fluorescent probes, which makes it possible to measure the amount of product after each cycle of the reaction. From this information, the initial amount of template can be determined. During the last years, real-time PCR has been used in a variety of applications such as human[1] and veterinary[2] diagnostics; detection of pathogens in food,[3] water,[4] and soil;[5] and gene expression studies.[6] To meet the various demands for real-time PCR instruments and the large variety of applications, several instrument platforms have been developed, many with specific properties. A real-time PCR instrument must have certain components to perform its intended function. The sample must be contained in a container that can be heated and cooled rather rapidly. An optical unit that illuminates the sample and records the emitted fluorescence is also required. In this article, we will briefly describe the variety of different components used in the most common real-time PCR machines.

HEATING AND COOLING MECHANISMS

To perform PCR, the unit must thermocycle the sample and heat it to temperatures close to 100°C. This is typically done using either Peltier elements, resistive heating, and/or airflow.

Peltier Elements

Peltier elements are solid-state heat pumps that make use of the Peltier effect to create a hot side and a cool side of the element. Peltier elements are common in electronic components in laboratory equipment. They are relatively small, silent, and have no moving parts. This makes them reliable. Peltier elements are operated by a direct current (d.c.) and, by reversing the polarity of the current, one can alternate heating and cooling. The amount of heat transferred is proportional to the current that flows through the element. The block temperature may not be uniform throughout the element, particularly the corners may deviate, which might affect reaction efficiency. Temperature variations within the block are usually within ±0.5°C after holding at constant temperature for a certain amount of time. Peltier elements can create temperature gradients, giving extra flexibility when, for example, optimizing annealing temperatures in PCR. Instruments that use Peltier elements usually have rather slow heating and cooling ramp rates. They are typically of 1–5°C/sec because of large thermal inertia, which cause a regular PCR run of 40 cycles in approximately 90 min. Real-time PCR instruments that use Peltier elements include the Bio-Rad iCycler and MyCycler, ABI, real-time PCR instruments, MJ Research DNA Engine Opticon, Techne Quantica and Stratagene Mx4000/Mx3000p.

Air

Using air as media for transfer of heat requires mechanisms to maintain sample temperature uniformity. This usually entails either the samples being spinned, or the air being thoroughly mixed using fans. Air has low heat capacity and, in direct contact with the reaction vessel, ensures efficient thermal transfer. Ambient air is heated with a resistive coil and is transferred to the reaction chamber using fans. Therefore for cooling, ambient air is used directly and samples cannot be cooled below room temperature. Instruments that use air for thermocycling include Corbett Research Rotorgene 2000/3000, Roche LightCycler, and also in the fast real-time PCR instrument under development by AlphaHelix.

Conductive Polymers

Recently, conductive polymers have been introduced for thermocycling to further reduce the thermal barrier

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020685

between the heating/cooling material and the reaction media. Using electrically conductive polymers as reaction vessel, each reaction can be temperature-controlled independently using infrared temperature sensors. This results in high-temperature uniformity between samples and increased flexibility by allowing individual temperature cycling for different tubes in the same plate. Direct heating of the reaction tubes results in temperature transfer rates up to 15°C/sec,[7] enabling shorter cycling times. The BioGene InSyte uses conductive polymers for thermocycling.

EXCITATION SOURCES

Lasers

Laser excitation results in a highly intense and monochromatic signal. Therefore lasers are reliable, but they are expensive to manufacture and usually included in the more expensive range of real-time PCR instruments. Conventional lasers are also bulkier than other illuminating sources and are found only in larger instruments.

Halogen Lamp

Halogen lamp as illumination source requires the use of filters to excite fluorophores at the appropriate wavelength. Halogen lamps emit light between 350 and 750 nm. Light intensity is lower than from lasers and may result in lower sensitivity. They are cheap but have a limited lifetime and must be replaced regularly.

Light-Emitting Diodes (LEDs)

LEDs are small and cheap and, in combination with filters, can deliver narrow bandwidth illumination source. LEDs consist of two electrodes surrounding semiconductor elements and convert electric energy into light energy.

DETECTORS

Photomultiplier Tubes (PMTs)

A typical PMT consists of a photocathode followed by focusing electrodes, electron multipliers, and an electron collector. When light enters the PMT, photons hitting the photocathode emit electrons into the tube and are directed toward the multiplier electrodes by the focusing electrodes' voltage. The electrons are multiplied at each electrode and finally detected as an electric signal from the anode. Because each photon gives rise to a cascade of electrons, PMTs are highly sensitive detectors that generate signals with very low noise. PMTs are not

Table 1 Summary of common real-time PCR instruments' reaction vessels and thermocycling mechanisms

Instrument	Company	Heating mechanism	Heating/cooling rate (°C/sec)	Reaction vessel	Number of samples	Volume (μL)
7000/7700/7900	ABI	Peltier	1.5/1.5	Tubes/plates	96 (394 for 7900)	Up to 100
iCycler/myCycler	Bio-Rad	Peltier	3.3/2.0	Tubes/plates	96	15–100
LightCycler	Roche	Air	20/20	Glass capillaries	32	10–20
LightCycler 2.0	Roche	Air	20/20	Glass capillaries	32	10–20 or <100
Rotorgene 3000	Corbett Research	Air	2.5/2.5	Tubes	72	10–100
SmartCycler	Cepheid	I-CORE™	10.0/2.5	Plastic capillaries	16	25–100
Mx4000/ Mx3000P	Stratagene	Peltier	2.2/2.2	Tubes/plates	96	10–50
Opticon 2	MJ Research, Inc.	Peltier	3.0/2.0	Tubes/plates	96	10–100
InSyte	BioGene	Conductive polymer	15/15	Conductive polymer plate	96	Up to 50
7300/7500	ABI	Peltier	1.5/1.5 (7500 block upgradable to faster ramping block)	Tubes/plates	96	25–100
Quantica	Techne	Peltier	2.6/2.6	Tubes/plates	96	15–50

Table 2 Summary of common real-time PCR instruments' optical properties

Instrument	Company	Illumination source	Excitation wavelengths	Detector	Detection wavelengths
7000/7700/7900	ABI	7000: Halogen lamp; 7700/7900: argon laser	7000: 350–750; 7700/7900: 488 and 545	CCD	7000: 520, 550, 580, and 602; 7700/7900: 500–650
iCycler/myCycler	Bio-Rad	Halogen lamp	400–700/400–585	CCD	Variable filters available
LightCycler	Roche	LED	470	Photodiodes	530, 640, 710
LightCycler 2.0	Roche	LED	470	Photodiodes	530, 560, 610, 640, 670, 710
Rotorgene 3000	Corbett Research	LED	470, 530, 585, 625	Photodiodes	510, 555, 610, 580 hp, 610 hp, 660 hp
SmartCycler	Cepheid	LED	450–495, 500–550, 565–590, 630–640	Photodiodes	510–527, 565–590, 606–650, 670–750
Mx4000/Mx3000P	Stratagene	Halogen lamp	350–750	PMT	350–850
Opticon 2	MJ Research	LED	470–505	PMT	523–543, 540–700
InSyte	BioGene	Blue laser	473	PMT	520–720
7300/7500	ABI	Halogen lamp	7300: Single broad excitation 7500:5 filters for FAM/SYBR/VIC/JOE, NED/TAMRA/Cy3, ROX/Texas Red and Cy5	CCD	7300: Filters for FAM/SYBR, VIC/JOE, TAMRA and ROX 7500: Filters for FAM/SYBR, VIC/JOE, NED/TAMRA/Cy3, ROX/Texas Red and Cy5
Quantica	Techne	Halogen lamp	470–650 (up to 4 user selected filters)	PMT	500–710 (up to 4 user selected filters)

Source: Refs. [7–16].

wavelength-discriminative and must be used in combination with filters. Therefore instruments equipped with PMTs have only one PMT alternatively, one PMT per detection wavelength, and can only measure one sample at a time. Reading out of many samples requires moving parts. It can be achieved by rotating the sample holder, or by moving an optical fiber across the different samples.

Photodiodes

Photodiodes are electrical components that convert incident light to electric current. The photodiode consists of a positive electrode, a P-layer, a neutral layer, and an N-layer followed by a negative electrode. When light hits the P-layer, electrons in its crystal structure are excited and, in an electric field, accelerate toward the N-layer, creating a current. Photodiodes are cheap; there may be several diodes in a single instrument. Photodiodes can also be wavelength-discriminative; different diodes are used for different wavelengths.

Charged Coupled Device (CCD) Cameras

CCD cameras are basically a large array of photodiodes containing many spots—pixels—which convert light to an electric signal. The higher is the amount of spots, the higher is the resolution of the camera. CCD cameras are, in general, not as sensitive to light as PMTs, and this may affect the sensitivity of the instrument. Instruments equipped with a CCD camera will measure all samples simultaneously for each wavelength and must be used together with filters. The excitation and detection wavelengths of some instruments are set for certain fluorescence detection chemistries, which reduce the flexibility of the instrument and may lead to higher running costs.

REACTION VESSELS

Capillaries

Glass capillaries have the best optical properties for fluorescence measurements. They also have a large surface-to-volume ratio, leading to fast temperature ramping rates as well as being highly suitable as fluorescence measurement vessels. The high surface-to-volume ratio also increases the adsorption of reaction components to the glass walls, and protocols intended for plastic containers may need reoptimization. LightCycler capillaries have an outer diameter of 1.5 mm and a length of 3 cm, and can hold sample volumes of 5–20 μL.[8] The new LightCycler 2.0 instrument can also use new 100-μL capillaries in a special sample carousel. The shape of the capillaries concentrates the fluorescent signal to the tip, where emitted light is collected. The capillary has three parts: the actual capillary, a sample deposit chamber from where the reaction mix is centrifuged into the capillary, and a plastic cover to seal the capillary. Glass capillaries are rather expensive and containers are a major cost component of each PCR reaction run. The capillaries are also fragile and may break during handling.

Tubes/Plates

Tubes and plates are the most common reaction containers and are usually sealed with optical caps or optical film for head on detection. It is important to have plasticware that is thermally stable to avoid evaporation. Optical-grade plastic tubes and plates are available from a number of manufacturers, which have pressed prices, making them the most cost-efficient reaction vessel for real-time PCR. The ABI, Stratagene, Bio-Rad, and MJ Research instruments recommend a reference dye not participating in the reaction to be present. The reference dye is usually ROX or fluorescein in the reaction mix and is used to compensate for detection differences across the plate.

Special Containers

Certain real-time PCR instruments require special containers. These include electrically conductive polymer tubes/plates of the BioGene InSyte and the special plastic small-volume containers of the Cepheid SmartCycler. The cost of these containers is significantly higher than that of regular tubes and plates. Both containers are designed to achieve fast cycling times.

CONCLUSION

Combining various technologies for heating/cooling and illumination/detection has given rise to a large selection of real-time PCR instruments that have unique advantages, making them the preferred choice for certain applications, but they also have limitations. Tables 1 and 2 summarize the most common real-time PCR instruments available today and their properties.

Development in real-time PCR instrumentation is branching into high-throughput instruments for routine diagnostics, research instruments with maximum flexibility, and battery-operated instruments for field use. The high-throughput instruments are developing into fully automated machines, with miniaturized reactions enabling many hundreds of samples to be run simultaneously. The instruments are also becoming increasingly integrated with sample preparation robots.

Although the main use of real-time PCR is in diagnostics, the technique is rapidly becoming popular in gene expression profiling. Today, real-time PCR is mainly used to validate results from microarray expression experiments. With the introduction of high-throughput automated instruments, the unsurpassed sensitivity, accuracy, and specificity of real-time PCR are likely to make real-time PCR the method of choice also for large-scale gene expression studies. We think that development will eventually lead to a merger of real-time PCR and microarray platforms, resulting in real-time PCR microarrays with the throughput of today's microarrays and the sensitivity, accuracy, and specificity of real-time PCR.

Real-Time Reverse Transcription PCR

Stephen A. Bustin
University of London, London, U.K.

INTRODUCTION

Real-time, fluorescence-based reverse transcription polymerase chain reaction (RT-PCR)[1] has been transformed from an experimental technology into a mainstream scientific tool for the detection of RNA.[2] This is because of several factors: 1) it is a homogeneous assay, which eliminates the requirement for post-PCR processing; 2) it has a wide dynamic range; 3) there is little interassay variation; and 4) it realizes the inherent quantitative capacity[3] of PCR-based assays, making it a quantitative, rather than a qualitative, assay. These properties match the evident requirement in molecular medicine for quantitative data (e.g., for measuring viral load,[4] monitoring of occult disease in cancer,[5] or examining the genetic basis for individual variation in response to therapeutics through pharmacogenomics).[6]

THE ASSAY

The principle of fluorescence-based real-time RT-PCR assays is simple: reverse transcription of RNA is reverse-transcribed into cDNA; a suitable detection chemistry reports the presence of PCR products; an instrument monitors the amplification in real time; and an appropriate software analyzes the data.[7] Because the quality of the RNA template is the single most important determinant of the reproducibility of RT-PCR results,[8] it is essential to ensure that no inhibitors copurify during the RNA extraction process.[9]

Real-time RT-PCR can be either a one-tube assay using a single buffer, or a two-tube assay where both first-strand cDNA synthesis and the subsequent PCR step are performed separately under optimal conditions for the respective polymerases. The former is more convenient and reduces the risk of cross-contamination;[10,11] the latter may be more sensitive and more reproducible.[12]

The priming of the cDNA reaction from the RNA template is best performed using oligo-dT or target-specific primers. Although random primers yield the most cDNA, they initiate transcripts from multiple points along the RNA, including ribosomal RNA (rRNA), thus producing more than one cDNA per original target. Oligo-dT priming results in a faithful cDNA representation of the mRNA pool, but it is not a good choice for poor-quality RNA from formalin-fixed archival material. Target-specific primers synthesize the most specific cDNA and provide the most sensitive method of quantification,[13] but require separate priming reactions for each target.

Viral RTs, used mainly in two-step assays, have a relatively high error rate and a strong tendency to pause, hence producing truncated cDNA.[14] Avian Myoblastosis Virus-RT (AMV-RT) is more robust and processive than Moloney Murine Leukemia Virus-RT (MMLV-RT)[15] and retains significant polymerization activity up to 55°C,[16] whereas native MMLV-RT has significantly less RNaseH activity than native AMV-RT[17] but is less thermostable. Several DNA-dependent DNA polymerases exhibit both RNA- and DNA-dependent polymerization activities in the presence of Mn^{2+}.[18,19] It is also possible to use blends of reverse transcriptases in RT-PCR reactions, which can result in higher reverse transcription efficiencies than the individual component enzymes.

CHEMISTRIES

Detection chemistries fall into two groups:

1. Nonspecific chemistries usually involve the detection of an intercalating dye (e.g., SYBR green I) (Fig. 1A).[20] The PCR product can be verified by plotting fluorescence as a function of temperature to generate a melting curve of the amplicon.[21] Because the melting temperature (T_m) of the amplicon depends markedly on its nucleotide composition, it is possible to identify the signal obtained from the correct product. A characteristic melting peak at the amplicon's T_m will distinguish it from amplification artefacts that melt at lower temperatures in broader peaks.
2. Specific chemistries make use of template-specific fluorescent probes for each PCR assay. These probes can be structured (e.g., Scorpions, Molecular Beacons) or linear (e.g., TaqMan, Light-Cycler probes). Probes may contain reporters and quenchers, or make use of the quenching properties of the DNA. All operate on the same principle: A fluorescent signal is only generated if the amplicon-specific probe hybridizes to its complementary target (Fig. 1B).

DOI: 10.1081/E-EDGP 120020680

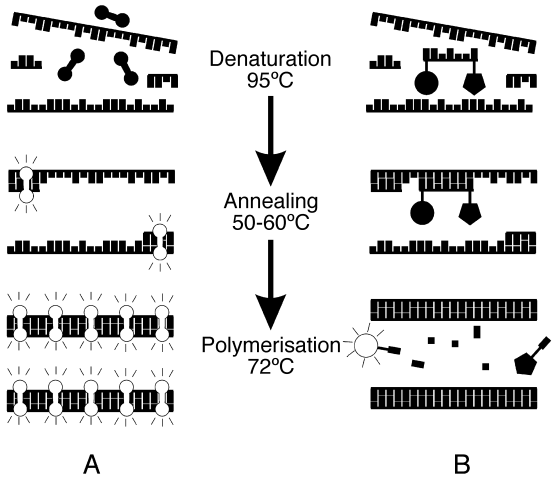

Fig. 1 Real-time detection chemistries. (A) Nonspecific (e.g., SYBR green I). In solution, the unbound dye exhibits little fluorescence; during the PCR assay, increasing amounts of dye bind to the nascent double-stranded DNA. When monitored in real time, this results in an increase in the fluorescence signal as the polymerization proceeds, and that falls off during the denaturation step. Consequently, the increasing amounts of amplified DNA can be monitored by measuring the fluorescence measurements at the end of each elongation step. (B) Specific (e.g., 5′-nuclease; TaqMan). Although the fluorophore (circle) and a quencher (pentagon) are bound to the same probe molecule, any light emitted by the fluorophore on excitation is quenched. When the polymerase displaces and cleaves the probe, the fluorophore and the quencher become physically separated, and emissions from the fluorophore can be detected.

INSTRUMENTATION

Instruments used for real-time PCR use: 1) an excitation light source, to excite the fluorophores; 2) a detector, to register photon emissions that are proportional to the concentration of the amplification product being measured; and 3) a software, which allows analyses of the data.

Fluorescence emission data are collected from each tube and the levels of background fluorescence detected by the fluorimeter are established. Platform-specific algorithms are used to define a fluorescence threshold. Finally, the algorithm searches the data from each sample for a point that exceeds the baseline. The cycle at which this point occurs is defined as C_t (Fig. 2) and is used to calculate the amount of template present at the beginning of the reaction.[22]

DATA ANALYSIS

Results obtained using real-time RT-PCR assays are significantly less variable than conventional RT-PCR protocols, which can be subject to significant error.[23] In principle, quantification by real-time assays is easy: the more copies of mRNA there are at the beginning of the assay, the fewer cycles of amplification are required to reach the C_t. In practice, there are some problems in converting a C_t value into a biologically meaningful copy number.[24]

Relative Quantification

Relative quantification expresses the changes in steady-state mRNA levels of a gene relative to the levels of a coamplified internal control mRNA.[25] Target C_t values are compared directly to an internal reference C_t and results are expressed as ratios of the target-specific signal to the internal reference. This produces a corrected relative value for the target-specific mRNA product, which can be compared between samples and allows an estimate of the relative expression of target mRNA in those samples. Amplification efficiencies of a target and a reference must be similar because they directly affect the accuracy of any calculated expression result and must be incorporated into copy number calculations.[26,27] However, because the expression of the internal control itself is often variable, relative quantification can be misleading.[28]

''Absolute'' Quantification

''Absolute'' quantification is not really absolute, but is relative to an external standard curve.[2] A standard dilution series with a known concentration of initial target

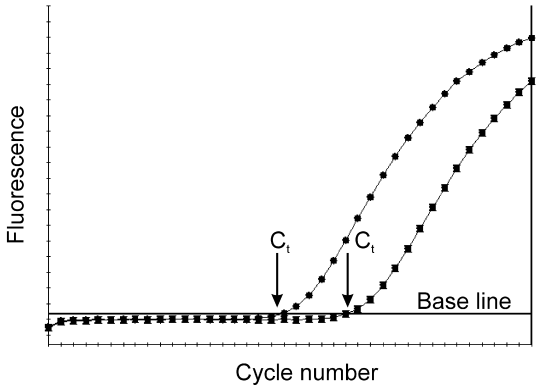

Fig. 2 Threshold cycle C_t. The threshold cycle is defined as the number of PCR cycles where the fluorescence generated from the amplification product first exceeds a baseline level. It depends on the sensitivity of the detection system and can vary significantly depending on assay-specific background levels. The two amplification plots have C_t values that differ by six cycles (i.e., represent an approximately 100-fold difference in template starting copy numbers).

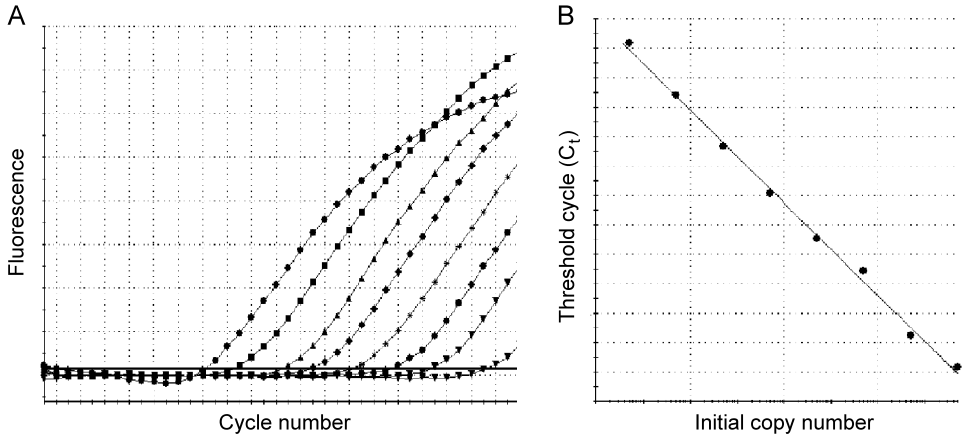

Fig. 3 Preparation of a standard curve. (A) Sense-strand amplicon-specific oligonucleotides are serially diluted from 1×10^8 to 10 copies, and their respective C_t values are recorded. (B) A plot of C_t against the log of the initial oligonucleotide copy number results in a straight line that is linear over at least seven orders of magnitude, and linear regression analysis permits the calculation of the ''absolute'' copy number of any unknown target relative to that standard curve.

copy number is used to generate a standard curve by plotting the C_t values against the logarithm of the initial copy numbers (Fig. 3).[29] Its dynamic range must include the C_t values expected for the experimental RNA samples. The copy numbers of unknown samples can be calculated from the linear regression of that standard curve, with the slope providing the amplification efficiency. Standard curves can be constructed from PCR fragments, in vitro T7-transcribed RNA, single-stranded sense-strand oligodeoxyribonucleotides, or commercially available universal reference RNAs.[30]

Absolute quantification is most obviously used for quantifying tumor cells or infectious particles such as viruses or bacteria in body fluids, but it is also usefully applied to quantitate changes in mRNA levels. The accuracy of absolute quantification depends entirely on the accuracy of the standards. However, external standards cannot detect or compensate for inhibitors that may be present in the samples.

Data Reporting

RT-PCR-specific errors in the quantification of mRNA transcripts are easily compounded by any variation in the amount of starting material between samples.[31] This is especially relevant when dealing with in vivo samples that have been obtained from different individuals, or when comparing samples from different tissues.

The most common method for minimizing these errors and correcting for sample-to-sample variation is to amplify a cellular RNA specified by a housekeeping gene that serves as an internal reference against which other RNA values can be normalized.[32] However, because there is no single mRNA with a constant expression level among different tissues of an organism,[33] its use as an internal calibrator is inappropriate.[34] rRNA has been proposed as an alternative normalizer,[35] but there are serious concerns regarding its expression levels, transcription by a different RNA polymerase, and possible imbalances in relative rRNA-to-mRNA content in different cell types that caution against its use as a normalizer.[36] Copy numbers can also be normalized to total cellular RNA and reported as copies per microgram of total RNA.[24] However, total RNA levels may be increased in highly proliferating cells, and this will affect the accuracy of any comparison of copy numbers between normal and tumor cells.

BIOLOGICAL RELEVANCE

Biopsies contain a range of different cell types—a problem exacerbated in heterogeneous tumor samples that include normal and inflammatory cells as well as diversely evolved cell populations. In addition, normal cells adjacent to a tumor may be phenotypically normal but genotypically abnormal, or exhibit altered gene expression profiles because of their proximity to the tumor.[37] Hence expression profiling of such biopsies provides a composite of the whole population, and this may result in the masking of the expression profile of a specific cell type, or it may be ascribed to and dismissed as illegitimate transcription.[38]

Laser capture microdissection (LCM) is useful for accurate expression profiling from such biopsies[39] and has become a powerful technique for extracting pure subpopulations of cells from heterogeneous in vivo cell samples for detailed molecular analysis.[40] Isolation of

RNA from such small samples is possible, and mRNA expression levels can be accurately and reproducibly quantified,[41] even from archival paraffin-embedded tissue specimens[42] and after immunohistochemical staining.[43]

APPLICATIONS

The increasing utility of real-time RT-PCR promises a paradigm shift in molecular clinical diagnostics. Its ability to detect the nucleic acid of a pathogen allows it to identify the actual causes of a disease, as opposed to merely detecting its symptoms. Alterations in mRNA expression profiles are associated with a tissue's reaction to pathological states or drug treatments, and are likely to prove useful for more accurate postoperative staging of cancer patients. Its speed, simplicity, specificity, and sensitivity make this technique ideally suited for this task, making it a cost-effective and time-efficient assay that could become part of a routine protocol of specimen processing.

However, it is important to be aware that issues such as sample processing, assay standardization, and reproducibility, as well as the use of appropriate diagnostic controls, remain to be resolved before real-time RT-PCR can become a realistic practical diagnostic assay. Furthermore, because data interpretation remains highly subjective, there is a need for strict quality control of the reported results to achieve a consistent, standard, and valid diagnosis based on real-time RT-PCR.

CONCLUSION

Real-time technology has revolutionized the use of, and applications for, RT-PCR assays. However, considerable doubts remain about the reproducibility of real-time RT-PCR data, and statistical analyses of the numerical data may obscure the actual results, leaving considerable scope for misinterpretation. Although there can be no doubt of its value as a research tool, its use as a routine clinical diagnostic tool remains unproven.

Restriction Fragment Length Polymorphism (RFLP)—Application for Mycobacteria Typing

Institute of Tropical Medicine, Antwerp, Belgium

INTRODUCTION

Outbreaks of infectious diseases often result from exposure to a common source of the etiologic agent. Generally, the etiologic agent involved in an outbreak of disease is derived from a single cell whose progeny are genetically identical or closely related to the source organism. In epidemiological terms, the organisms involved in the outbreak are clonally related; that is, they have a common origin. Clonally related organisms are members of the same species that share virulence factors, biochemical properties, and genomic characteristics. However, there is sufficient diversity at the species level that organisms isolated at different times and in different geographical areas may be differentiated or classified into subtypes or strains.

OVERVIEW

The process of subtyping is epidemiologically important for recognizing outbreaks of diseases, detecting the cross-transmission of nosocomial pathogens, determining the source of infection, and in some cases recognizing particularly virulent strains of organisms.

Subtyping or strain classification has been accomplished by a number of different approaches. In recent years, the development and extensive use of high-resolution molecular typing systems based on direct analysis of genomic polymorphism have greatly improved the understanding of the epidemiology of infectious diseases.[1,2] These molecular typing methods can be applied to answer a number of different questions, such as:

In an outbreak, what is the extent and mode of transmission of the epidemic clone(s)?

In long-term surveillance, what is the prevalence over time and the geographic spread of epidemic and endemic clones in the population?

A large number of molecular typing methods are available for a wide range of microorganisms and can provide a good epidemiological tool. However, the rapid diversification and incomplete comparative evaluation of some of these methods leave the microbiologist and the epidemiologist faced with a number of questions dealing with selection of appropriate typing system(s), to address a particular problem, as well as a lack of consensus about interpretation and communication of results.

Several criteria have been proposed for evaluating the performance of typing systems.[1,2] These criteria include typeability, reproducibility, stability, and discriminatory power.

- *Typeability*. Typeability refers to the proportion of isolates that can be scored in the typing system and assigned to a type.
- *Reproducibility*. Reproducibility refers to the ability of the typing system to assign the same type on repeated testing of the same strain.
- *Stability*. Stability is based on the biological features of clonally derived isolates to express constant markers over time and generations.
- *Discriminatory power*. This is a key characteristic of typing systems, as it estimates the probability that isolates sharing identical or closely related types are truly clonal and part of the same chain of transmission.

Additional comparative studies are needed to establish the relative value of systems currently used for typing microbial pathogens. Moreover, there are important variations in the performance of any given method depending on the species and on modifications of the procedure as applied by different investigators.

SOUTHERN BLOTTING AND RESTRICTION FRAGMENT LENGTH POLYMORPHISM (RFLP) METHODS

Technical Description

Southern blotting has been used for many years to detect and locate genomic sequences from a variety of prokaryotic and eukaryotic organisms. For gene detection, whole chromosomal DNA is digested with a restriction enzyme, and the fragments are separated by electrophoresis through an agarose gel. The separated fragments are transferred from the agarose gel to either a nitrocellulose or a nylon membrane by Southern blotting (Fig. 1). The membrane-bound nucleic acid is then hybridized to one or more labeled probes homologous to the gene to be examined. Probes can be labeled with a number of detectable moieties, including colorimetric and chemiluminescent enzymes to bus with the appropriate substrates. This classical method has been adapted to differentiate bacterial strains on the basis of the observation that the location of various restriction enzyme recognition sites within a particular genetic locus of interest can be polymorphic from strain to strain, resulting in gel bands that differ in size between different strains. Thus the name restriction fragment length polymorphism (RFLP) refers to this polymorphic nature of the locations of restriction enzyme sites within defined genetic regions. Only the genomic DNA fragments that hybridize to the probes are visible in RFLP analysis, which greatly simplifies the analysis. Different types of nucleic acid probes can be used for typing: 1) genes encoding metabolic, virulence or resistance functions; 2) multicopy elements, including insertion sequences (IS) and transposons. Insertion sequences typing technique using insertion sequences as a probe are in general very reproducible and can provide a highly discriminating typing tool. Discrimination is related to the presence of multiple copies of these elements at diverse locations in the chromosome. However, RFLP is a slow and labor-intensive technique requiring specialized equipment and expertise. Besides, careful selection and optimization of probe sequence, restriction endonucleases, electrophoresis, and hybridization conditions need to be developed for each species or pathovar to be typed. Furthermore, large-scale application of RFLP analysis requires international standardization of the technique, reagents, type strains, and nomenclature. In the field of *Mycobacterium tuberculosis* this was established by several public health reference laboratories for IS*6110* RFLP-fingerprinting, which integrates standard computer analysis of patterns and a common database, and it is now widely applied for large-scale surveillance of tuberculosis.[3]

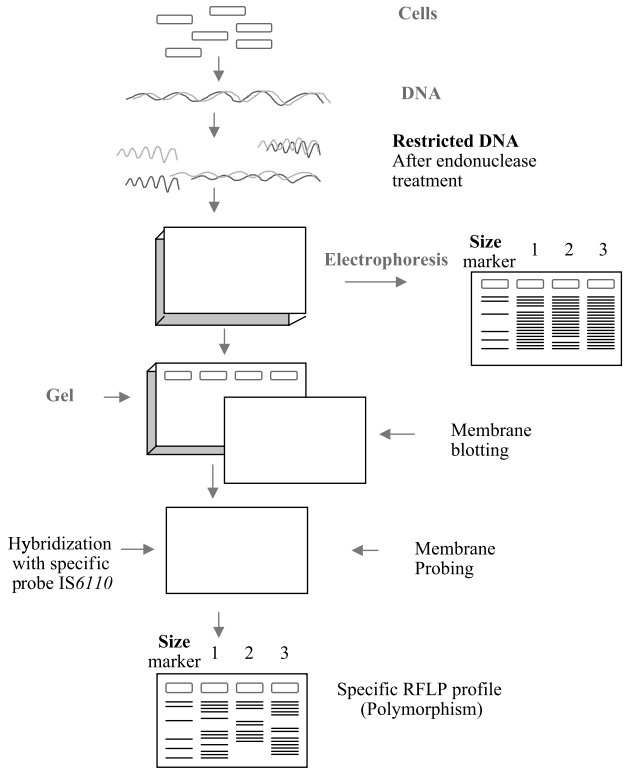

Fig. 1 Schematic representation of RFLP technique. (*View this art in color at www.dekker.com.*)

Example of Application of RFLP (*Mycobacterium tuberculosis*)

The most commonly used typing system for *M. tuberculosis* is IS*6110*-based RFLP,[4] so far considered the gold standard for TB typing. IS*6110* is an IS3-like element, also known as IS*986* or IS*987*. It occurs at various locations in the genome of *M. tuberculosis* in variable copy numbers.[5,6] As its sequence is apparently invariant,[7] it is an ideal target sequence. The copy number of the element ranges from 1 to 25 copies per genome, although rare *M. tuberculosis* cultures have been reported with no inserts. To visualize IS*6110* RFLP patterns, DNA is extracted and purified from bacterial culture. Thereafter, the DNA is digested with the restriction enzyme *Pvu*II, the restriction fragments are separated on an agarose gel and transferred to a DNA membrane. A peroxidase-labeled probe with a DNA sequence complementary to the IS*6110*-DNA sequence is added in order to visualize the IS*6110* containing restriction fragments, by chemiluminescence, which is initiated by adding two substrates. Restriction fragment length polymorphism

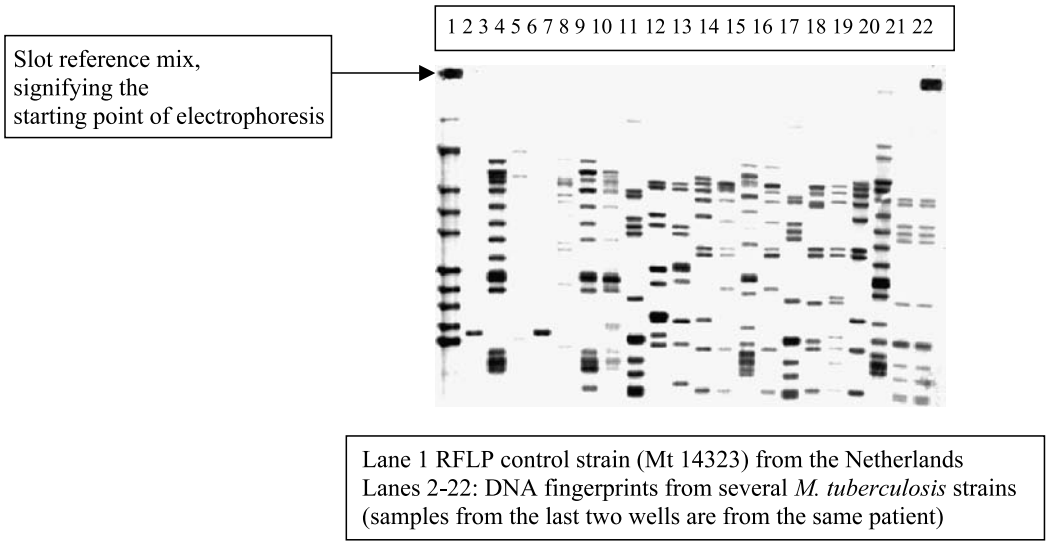

Fig. 2 Representative RFLP profiles of *M. tuberculosis* using IS*6110* as a probe.

patterns are detected by placing a light-sensitive film on the wrapped membrane in a light-blocked cassette[8] (Fig. 2). Restriction fragment length polymorphism has been used to confirm outbreaks of tuberculosis or incidents of suspected laboratory cross contamination,[9] to investigate the question of reinfection vs. reactivation, to examine the existence of multiple infections, and to track the spread of multidrug resistance.[10] DNA fingerprints of *M. tuberculosis* do not change during the development of resistance to various antituberculous drugs.[11] However, there are a number of notable limitations with standard IS*6110* typing. For example, it is labor intensive and thus costly. The typing patterns produced have varying numbers of bands which may also vary in position, so that sophisticated software is needed to analyze large numbers of patterns and to compare results between laboratories.[12] Furthermore, RFLP typing of strains with a low copy number of IS*6110* is not sufficiently discriminatory.[6,13,14] Additional genetic typing method in cases where *M. tuberculosis* isolates contain fewer than five IS*6110* copies is necessary.

In addition to IS*6110*, many other different DNA sequences that have been used as probes for typing *M. tuberculosis* complex strain by RFLP include the major polymorphic tandem repeat (MPTR), the polymorphic GC-rich sequence, the direct repeat region, $(GTG)_5$, repetitive DNA elements, and rDNA (ribotyping).[6,15,16]

Application for Other Organisms

Ribotyping is the most versatile and the most widely used strategy of Southern blot analysis of bacterial genome polymorphism. The evolutionary conservation of ribosomal RNA makes it applicable as a universal bacterial probe. Many important pathogens, including *Enterobacteriaceae*, *Listeria*, *Pseudomonas* spp., and staphylococci have more than five ribosomal operons and thus produce ribotype patterns of 5 to 15 bands.[17] Ribotyping is a robust method that exhibits excellent reproducibility and stability, during the course of the outbreaks. It is commercially available and fully automated and well standardized. However, its discriminatory power is only moderate, and this is related to the fact that ribosomal operons cover less than 0.1% of chromosomal length and tend to cluster in one particular region of the genome. Discrimination of ribotyping depends on the species and on the choice and number of restriction endonucleases used. No consensus has been achieved on optimal procedure and no general rules are available for interpretation of technically problematic results, such as weakly hybridizing fragments.

LOCUS SPECIFIC PCR-BASED RFLP

Technical Description

In recent years, a number of PCR-based strategies have been developed for strain discrimination of microbial pathogens. In PCR *gene* RFLP *typing*, a target sequence, 1 to 2 kb long and known to show polymorphism among strains of species of interest, is amplified at high stringency. The amplified product is cut with restriction endonucleases and isolates are compared by RFLP pattern on an agarose gel after staining with ethidium bromide avoiding the need for Southern blot.

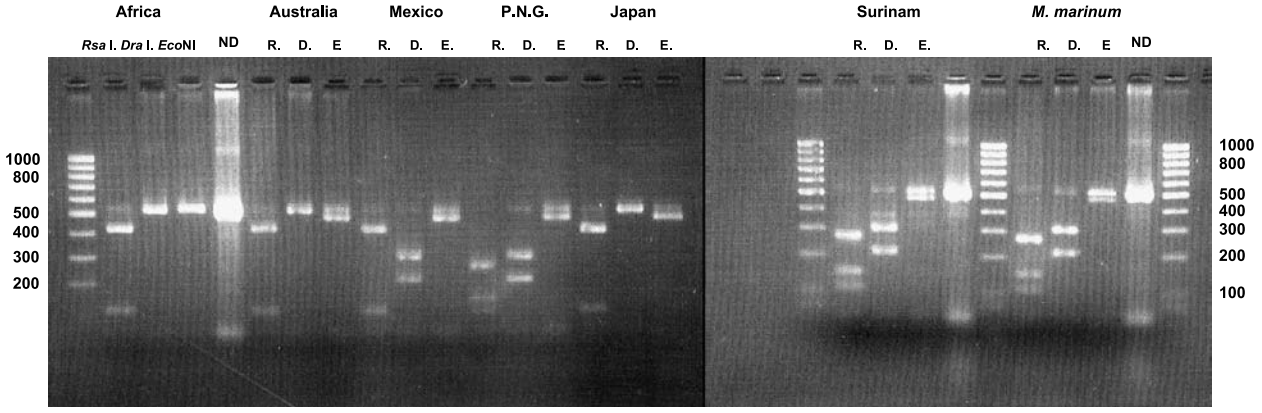

Fig. 3 Examples of PCR restriction profiles obtained from a representative set of *M. ulcerans* (from different geographic areas) and one *M. marinum* strain by using three restriction enzymes, *Rsa*I, *Dra*I, and *Eco*NI. The first and last lanes show the 100-bp ladder. ND, no digested PCR product; R, D, and E, *Rsa*I, *Dra*I, and *Eco*NI, respectively, P.N.G., Papua New Guinea.

Application for Mycobacteria (*M. tuberculosis*, *Mycobacterium ulcerans*, and *Mycobacterium marinum*)

In the field of *M. tuberculosis*, PCR-based RFLP is not so widely applied as the classical RFLP method. In a novel application of locus-specific RFLP, Cockerill et al.[18] have identified point mutations in the *katG* gene of *M. tuberculosis* that correspond to different levels of resistance to isoniazid by comparing the different RFLP banding pattern produced by the amplified gene. However, the discriminatory power is limited compared to other methods.

M. ulcerans and *M. marinum* are slow-growing mycobacterial species with optimal growth temperatures of 30°C to 33°C. These organisms are emerging necrotizing mycobacterial pathogens that reside in common reservoirs of infection and exhibit striking pathophysiological similarities. The interspecific taxonomic relationship between the two species is not clear as a result of the very high phylogenetic relatedness. To help understand the genotypic affiliation between these two closely related species, another approach of RFLP has been performed; namely, PCR restriction profile analysis (PRPA).

By targeting the 3′ end of 16S rRNA gene and by using three restriction enzymes, a set of geographically diverse *M. ulcerans* and *M. marinum* have been investigated.[19] The results (Fig. 3) showed that *M. ulcerans* can be typed at both intra- (three subtypes related to the geographical origin) and interspecific levels (differentiation between *M. marinum* and *M. ulcerans*). However, the major limitation of the technique is related to its discriminatory power as it cannot usually differentiate between these two species (Fig. 3); this may be related to the high degree of conservation of the mycobacterial 16SrRNA genes.

Application for Other Organisms

This new RFLP approach has been applied in a number of situations. Shortridge et al.[20] used the RFLP of the *ureC* gene to demonstrate the genetic diversity of *Helicobacter pylori* strains in the United States. The 16S, 23S, and 16S–23S spacer regions have also been used as targets for locus-specific RFLP.[21] In this variation of ribotyping, the ribosomal DNA is amplified and subjected to digestion with restriction enzyme, and the DNA fragments are visualized following separation by gel electrophoresis avoiding the need for Southern blotting.

Gene-specific probes have been used to subtype *Brucella* species,[22] *Legionella pneumophila*,[23] and *Pseudomonas aerugenosa*.[24] Furthermore, ribotyping has been applied successfully in many studies to differentiate bacterial strains.[25,26] Other applications of locus-specific RFLP found place in epidemiological studies of hepatitis C virus (HCV). By this technique, the virus can be subtyped into six major genetical groups.[27] The RFLP of the 5′ untranslated region has facilitated studies of the geographical distribution of viral genotypes and natural history of the disease.

CONCLUSION

Restriction fragment length polymorphism strategies are undergoing rapid technical improvements to circumvent

the different limitations (labor intensity, rapidity, and cost). Advances in the understanding of biological basis of microbial biodiversity at subspecies levels will improve the conceptual framework required for proper epidemiological interpretation of typing results. Wider application of these systems should shed more light on the epidemiology of hospital- and community-acquired infections, and therefore allow for more effective prevention and control strategies.

Retinoblastoma

Dietmar Lohmann
Universtiätsklinikum Essen, Essen, Germany

INTRODUCTION

Retinoblastoma is childhood cancer of the eye that originates from developing retina and affects one per 20,000 newborns. Familial aggregation of this retinoblastoma has been recognized in the early 19th century and, since then, this tumor has served as a model for familial cancer. For some time it was assumed all cases of retinoblastoma are hereditary and follow an autosomal dominant pattern of inheritance. Later it was recognized that most patients with tumors in one eye only, which account for about 60% of cases, have a nonhereditary form of this disease.[1] Knudson's seminal two-mutation model set the framework to explain the development of both hereditary and nonhereditary retinoblastoma.[2] His theory also guided the discovery of the causative gene, the RB1.[3] This tumor suppressor gene was the first of a now long list of genes that can cause hereditary predisposition to cancer.

CLINICAL ASPECTS

Diagnosis

Diagnosis of retinoblastoma is usually made in children under the age of 5 years. In most children, the first presenting sign is a white pupillary reflex (leukocoria) or strabismus. Diagnosis of retinoblastoma is usually established by examination of the fundus of the eye using indirect ophthalmoscopy. Most children have retinoblastoma in one eye only (unilateral retinoblastoma, 60% of cases).[1] Occasionally, multiple tumor foci are present in one eye (unilateral multifocal retinoblastoma). About 40% of children with retinoblastoma have tumors in both eyes (bilateral retinoblastoma). Most patients with bilateral retinoblastoma have more than one tumor focus per eye (bilateral multifocal retinoblastoma).

Family History

Patients with unilateral retinoblastoma most often have sporadic disease, i.e., no other case of retinoblastoma has been noted in their family. About 75% of patients with bilateral retinoblastoma are also sporadic; in the remainder (25%) there is a positive family history (familial retinoblastoma). Examination of the fundus of the eye in all first-degree relatives of children with retinoblastoma is required to identify retinal scars or quiescent tumors (retinomas).[4] The presence of such lesions in a relative indicates familial disease.

Therapy and Prognosis

Treatment of retinoblastoma depends on tumor stage, the number of tumor foci (unifocal, unilateral multifocal, or bilateral disease), localization and size of the tumor(s) within the eye, presence of vitreous seeding, and the age of the child. Treatment options include enucleation, external-beam radiation, systemic chemotherapy, cryotherapy, photocoagulation, brachytherapy with episcleral plaques. Following successful treatment, children require frequent follow-up examinations for early detection of new intraocular tumors. If the tumor(s) have not invaded extraocular tissues, treatment is favorable in most patients.

Second Tumors

Patients who are predisposed to retinoblastoma have an increased risk of specific neoplasms outside of the eye (second tumors). The spectrum of second tumors includes osteogenic sarcoma, soft-tissue sarcoma, and malignant melanoma.[5] Patients who have received external beam radiation for treatment of bilateral retinoblastoma have a higher risk of second tumors.

GENETICS OF RETINOBLASTOMA

Retinoblastoma Is Caused by Two Mutations

In 1971 Knudson hypothesized that two mutational events are sufficient for development of retinoblastoma (two-mutation model).[2] Later, molecular analysis showed that the two mutations alter both alleles of a single gene, the retinoblastoma gene (RB1).[6] This gene was cloned in

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020648

1986[3] and the finding of inactivating mutations confirmed Knudson's two-mutation hypothesis:[7,8]

- Familial retinoblastoma is caused by germ-line mutations in the RB1 gene. Family members that have inherited a mutant RB1 allele from a parent are at a high risk because only one mutation that alters the remaining normal allele is sufficient for complete functional loss of the retinoblastoma gene. Second mutations can occur in several retinal precursor cells and each of these cells may be the beginning of an independent tumor focus.
- Most patients with sporadic bilateral retinoblastoma are heterozygous for a mutant RB1 allele. This mutation has either occurred de novo in germ-line cells of one of the parents (most often in the germ line of the father) or is inherited from a parent who is a carrier of the mutation but has not developed retinoblastoma (incomplete penetrance). Tumors arise from retinal precursor cells that have acquired mutational loss of the second RB1 allele.
- Mutational inactivation of the RB1 gene is also a prerequisite for tumor development in patients with sporadic unilateral retinoblastoma. In most of these patients, both RB1 gene mutations occur in somatic cells and none of the two somatic mutations is detectable in DNA from peripheral blood.[9]

In recent years, molecular analysis in patients with retinoblastoma has shown that Knudson's original model needs to be extended:

- In some patients with sporadic bilateral or unilateral retinoblastoma the predisposing RB1 gene mutation is present in a mosaic state.[9,10] Mutational mosaicism occurs when the first mutation has occurred de novo during embryonic development of the child. It has to be assumed that in some children with mutational mosaicism the mutation is present in only a sector of retinal precursor cells. Tumor development can only occur in cells that are part of the mutant sector. This may account for the observation that patients with mosaicism for a given mutation develop fewer tumors than patients who are heterozygous for the same mutation.

The Retinoblastoma Gene and Protein

The RB1 gene consists of 27 exons and occupies over 183 kb of genomic sequence on chromosome 13q14. A CpG-island, which is normally unmethylated, is located at its 5′-end. In diverse tissues, the gene is transcribed into a 4.7-kb mRNA, which contains a 2.7-kb open reading frame. Orthologs with a high level of sequence similarity in translated regions of the human RB1 gene have been identified in several vertebrate organisms.

The protein encoded by the RB1 gene, pRb, is a 928-amino acid nuclear phosphoprotein that migrates at 110 kDa in SDS-PAGE when hypophosphorylated. It belongs to a small family of nuclear proteins that includes p107 and p130. These proteins are termed pocket proteins because of significant sequence similarity in two discontinuous regions (pockets A and B). Conditional on the phosphorylation status at multiple serine and threonine residues, this pocket can bind to members of the E2F family of transcription factors as well as to endogenous nuclear proteins that contain the LxCxE peptide motif. The C-terminal region of pRB contains a nuclear localization signal and a cyclin–cdk interaction motif that enables it to be recognized and phosphorylated by cyclin–cdk complexes. In addition, C-terminal region can bind to the nuclear c-Abl tyrosine kinase and to MDM2. One role of pRb is its function as a gatekeeper that negatively regulates progression through the G1 phase of the cell cycle. During the G1 phase of the cell cycle pRb is hypophosphorylated. This form can bind E2F and causes a repression of E2F-mediated transcription. Beginning in late G1 and continuing to the M phase, pRB is phosphorylated by G1 cyclin-dependent kinases. Upon phosphorylation of pRb, E2F is released and promotes transcription of genes that are required for cell division. Consequently, pRB controls cell-cycle phase transition by transcriptional repression. In addition to phosphorylation, cell cycle-dependent acetylation has been found to control pRb function. Acetylation hinders phosphorylation of pRb and enhances binding to the MDM2 oncoprotein. However, besides cell-cycle regulation, pRb has several other roles including control of apoptosis and stimulation of differentiation (for review of pRB functions, see Refs. [11–13]).

SPECTRUM OF RB1 GENE MUTATIONS

Spectrum Mutations That Cause Hereditary Predisposition to Retinoblastoma

Mutational analysis in DNA from peripheral blood identifies predisposing RB1 gene mutations in almost all patients with familial retinoblastoma (>95%) and in most patients with sporadic bilateral retinoblastoma (>85%) (Refs. [14,15] and unpublished results).

- *Large deletions*. About 5–10% of patients with bilateral and almost 5% of patients with sporadic unilateral retinoblastoma have interstitial cytogenetic deletions involving 13q14.

- *Gross deletions*. This class of mutations includes deletions of one or more exons up to the loss of the whole RB1 gene. Recent studies indicate that gross deletions account for 10–20% of predisposing RB1 gene mutations. The location and size of these mutations are heterogeneous.[15]
- *Point mutations*. More than 70% of mutations that predispose to retinoblastoma are single-base substitutions and small-length mutations (database of RB1 gene mutations: http://www.d-lohmann.de/Rb/mutations.html and Refs. [15,16]). Most of them are nonsense or frameshift alterations. Recurrent nonsense mutations are observed at 12 of the 15 CGA codons within the open reading frame. Missense mutations and small in-frame length alterations are infrequent (less than 10% of point mutations) and located in the regions that code for the pocket domains A and B of pRB.

Spectrum Somatic Mutations in Retinoblastomas and Other Tumors

It is possible that all retinoblastomas have mutations in both alleles of the RB1 gene. RB1 gene mutations have also been identified in several other tumor entities including osteogenic sarcoma and small cell lung cancer. The spectrum of somatic mutations comprises that of germ-line mutations with two important additions:

- More than 60% of retinoblastoma show loss of constitutional heterozygosity (LOH) at polymorphic loci located on chromosome 13. In these tumors, one RB1 allele is lost in consequence of deletions or one of several chromosomal mechanisms such as mitotic recombination and nondisjunction.[17]
- Another class of somatic mutation is hypermethylation of the CpG-rich island at the 5′-end of the RB1 gene. Hypermethylation is observed in about 10% of retinoblastomas and causes silencing of the transcription of this gene.[18]

GENOTYPE–PHENOTYPE ASSOCIATIONS

Tumor formation in carriers of predisposing RB1 gene mutations depends on the chance occurrence of second mutations. Because of the influence of stochastic events, a given predisposing RB1 gene mutation is associated with variable expressivity. Statistical analysis of phenotypical variation shows that the distribution of phenotypical expression within most families complies with a Poisson distribution (Böhringer und Lohmann, unpublished). However, there are a few notable exceptions.[19] In patients with sporadic retinoblastoma, the delineation of genotype–phenotype associations is further complicated by mosaicism. As noted above, phenotypical expression in patients who show mosaicism for a given mutation is usually milder compared to patients who are heterozygous for a mutation of the same kind. Analysis of families with retinoblastoma offers the best opportunity to determine differences in phenotypical expression between different classes of predisposing mutations. The number of tumor foci per mutation carriers varies between families. Some families show a high proportion of heterozygous carriers that stay free of retinoblastoma (incomplete penetrance). Moreover, affected members of these ''low-penetrance'' families develop fewer tumor foci when compared to mutation carriers in families with complete penetrance. Most of the variance of penetrance and expressivity between families is due to allelic heterogeneity.

Families with Complete Penetrance

Most families with retinoblastoma show complete penetrance, and, with few exceptions, mutation carriers have bilateral retinoblastoma. Almost invariably, predisposing RB1 gene mutations identified in these families cause premature termination codons.[14] Analysis of RNA from the blood of carriers of such mutations has shown that transcripts from alleles with premature termination codons are less abundant than transcripts from the normal allele. This indicates that these mutant mRNAs can be subject to nonsense-mediated decay. This may explain why oncogenic alleles with premature termination codons in any of exons 2 to 25 show a similar phenotypical expression.[14]

Families with Incomplete Penetrance and Milder Expressivity

In about 10% of families with retinoblastoma, penetrance is incomplete (''low-penetrance retinoblastoma''). In some of these families, less than one in five mutation carriers is affected. Usually, incomplete penetrance is accompanied by milder expressivity, i.e., affected mutation carriers have retinoblastoma in one eye only. The spectrum of mutations in families with incomplete penetrance and mild expressivity is distinct from that of families with complete penetrance and includes:

- *Promoter mutations*. Predisposing RB1 gene mutations have been identified in motifs that bind transcriptions factors. The most likely result of such mutations is a reduced level of structurally normal transcript.[20]

- *Missense and small in-frame mutations*. These mutations result in substitution, deletion, or insertion of one or few amino acids that are part of the A/B pocket of the pRB. Functional studies have shown that mutant pRB expressed from these alleles shows only a partial loss of normal function.[21]
- *Gross in-frame deletions*. Deletions of exon 4[22] and of exons 24–25[23] have been found in extended pedigrees. These mutations result in an in-frame loss of 40 and 58 amino acids that are not part of the A/B pocket.
- *Mutations that result in leaky splice defects*. Splice mutations that affect splice signals in exons or less conserved intronic splice signals can be associated with milder expressivity and incomplete penetrance. One reasonable explanation is that the effect of these mutations on splicing is ''leaky,'' and therefore a part of the mutant transcript is processed into a normally spliced mRNA.[24] This would result in higher levels of normal transcript compared to cells heterozygous for null mutations.

Second Tumors

Carriers of oncogenic RB1 gene mutations also show variable phenotypical expression with regard to the development of second tumors. A higher incidence of second tumors in patients who were exposed to external beam radiation for treatment of retinoblastoma indicates that environmental factors are important.[5] The finding of interfamilial variation of the occurrence of second tumors suggests risk modification by genetic factors.[25]

CONCLUSION

Retinoblastoma, a rare childhood tumor of the eye, has served as the prototype of hereditary cancer predisposition. As predicted from Knudson's two-mutation hypothesis, mutational change in both alleles of the RB1 gene is a prerequisite for tumor formation. Genetic analysis has shown that in most patients with sporadic unilateral retinoblastoma these two mutations have occurred in somatic cells. Most patients with sporadic bilateral retinoblastoma and patients with familial disease are heterozygous for a predisposing RB1 gene mutation that can be transmitted via the germ line. The spectrum of RB1 mutations that can cause retinoblastoma is heterogeneous and includes structural and epigenetic alterations. Mutations that leave intact some of the functions of the encoded protein can be associated with a milder phenotypical expression (''low penetrance retinoblastoma''). It is a challenge for future research to identify genetic factors that modify the risk of retinoblastoma and second cancers in individual mutation carriers.

INTRODUCTION

X-linked juvenile retinoschisis (RS, OMIM# 312700) is a vitreoretinal degeneration and is a common heritable early onset macular degeneration affecting males. A characteristic cystic spoke-wheel maculopathy is seen in virtually all affected males and results from foveal schisis or splitting within the inner retinal layers. Peripheral retinal schisis, predominantly in the inferotemporal quadrant of the fundus, is present in approximately 50% of cases. Most affected males are discovered with mild visual impairment early in their schooling, but some are identified in infancy with strabismus or nystagmus. The electroretinogram (ERG) is a key diagnostic test for RS. Typically, the ERG of affected males exhibits a selective reduction in the amplitude of the b-wave. The visual prognosis is good in most affected males as long as retinal detachment or vitreous hemorrhage does not occur. Carrier females remain asymptomatic and have no clinical signs.

OVERVIEW

RS is an inherited early onset macular degeneration affecting males.[1,2] *RS1*, the gene that is mutated in RS, encodes a 224-amino acid protein called retinoschisin. As a member of a family of cell adhesion proteins, retinoschisin may maintain cellular organization and synaptic structure of the retina. Retinoschisin contains a highly conserved carboxy-terminal discoidin domain in which mutations cluster, suggesting that the domain is essential for normal function. A number of missense and protein-truncating mutations of *RS1* have been identified; truncation or nonexpression of retinoschisin appears to have greater clinical severity.[3]

Molecular genetic analysis of *RS1* can complement fundus examination and clinical diagnostic testing of at-risk individuals. Mutation analysis may provide a definitive diagnosis where clinical tests and fundus examination are not sufficient to make a diagnosis. Carrier testing can be accomplished by either mutation analysis or linkage analysis with closely linked markers. This can be practically accomplished when sequence analysis has not yet identified a mutation in a particular family. Patients and families should be offered the opportunity of discussing these issues of testing with a genetic counselor.

CLINICAL FEATURES

Haas[4] provided the first clinical description of the disease in 1898. The phenotype of RS and its variability have been described by several authors.[5–8] The predominant phenotype includes foveal and peripheral retinoschisis and vitreous veils of partial retinal layers in the vitreous. Fundus examination may show the Mizuo phenomenon, an inner retinal sheen that occurs with the onset of light exposure after a period of dark adaptation.[9] An area of schisis may leave a retinal vessel unsupported in the vitreous cavity, called a ''congenital vascular veil.'' Affected males are identified between 5 and 10 years of age with poor visual acuity, typically 20/60–20/120.[10] A small number of patients present in infancy with bilateral bullous retinal detachment.[11] Visual impairment may be stable until age 50–60 when macular atrophy results in further central vision loss.[5,10] Acute sight threatening complications such as retinal detachment and vitreous hemorrhage occur in 10% and 5% of patients, respectively. Variation in disease presentation and disease progression is observed among affected members of the same family. Carrier females remain asymptomatic and generally have no signs of the condition.[10] Rarely, examination of the peripheral retina of a female carrier may show white flecks or areas of schisis.[12] The ERG is not able to detect carriers.

DOI: 10.1081/E-EDGP 120020649

PREVALENCE

The prevalence of RS ranges from 1:5000 to 1:25,000 depending on the population in which one ascertains cases. RS has a worldwide distribution across all races.

CLINICAL DIAGNOSTIC TESTING

The full field ERG of a male affected by RS shows a selective reduction of the amplitude of the dark-adapted b-wave and a normal amplitude and latency of the a-wave, leading to a reduction of the b/a ratio.[13,14] Recently, the multifocal ERG (mfERG) has been introduced as a clinical test of central retina function. The mfERG can be helpful as a diagnostic test for RS in patients where a significant reduction of the b-wave amplitude cannot be demonstrated with a full field ERG. In one such case, the waveforms of the mfERG showed a reduction in amplitudes of the central waveforms.[14–16] Optical coherence tomography (OCT) is a new technique that allows one to view a two-dimensional profile of the macula. Areas of retinal schisis can be identified in multiple retinal layers by OCT in eyes with RS.[14,15,17,18] These OCT findings are in contrast to the previous clinical understanding that the schisis separation occurred only in the innermost retinal layers.

MOLECULAR GENETICS OF RETINOSCHISIS

Retinoschisis was first mapped to Xp22 and then the *RS1* gene was identified by positional cloning.[19] *RS1* contains six exons and encodes a 224-amino acid protein called retinoschisin. Studies indicate that the protein is secreted by retinal cells as a disulfide-linked oligomeric protein complex, and that it is associated with the cell surface of all retinal neurons except adult horizontal cells.[20–22] Retinoschisin may function as a cell adhesion protein to maintain the integrity of the central and peripheral retina. The polypeptide consists of a leader sequence with a putative signal peptidase cleavage site and a highly conserved region in exons 4–6 known as a discoidin domain.[19] Discoidin domains are present in a family of extracellular or transmembrane proteins implicated in cell–cell adhesion or cell–matrix interactions—functions which correlate well with the observed splitting of the retina in RS.[23,24] Mutations cluster within the discoidin domain, exons 4–6, suggesting that this domain is essential for the normal function of retinoschisin.[25,26] Retinoschisin contains a high number of cysteine residues, 10 in total. Most mutations are missense mutations located in the discoidin domain of retinoschisin, with over 25% involving the loss or gain of a cysteine residue. Over 125 different missense, nonsense, insertions, deletions, and splice-site mutations in the RS1 gene have been associated with RS. An up-to-date listing of these mutations is maintained in RetinoschisisDB of The Retinoschisis Consortium (http://www.dmd.nl/rs/index).

MOLECULAR GENETIC TESTING

RS1 is the only gene known to be associated with RS. Molecular genetic analysis is an effective approach for the early detection of at-risk males, carrier detection, and prenatal diagnosis.[27] The phenotype of RS is sufficiently variable that Eksandh et al.[28] emphasized the importance of supplementary molecular genetic testing in boys with visual failure of unknown etiology. Three mutations within the *RS1* gene, E72K (214G>A), G74V (221G>T), and G109R (325G>C), are associated commonly with RS in individuals of Finnish descent. Approximately 95% of patients of Finnish heritage have one of these three founder mutations.[29] Mutation analysis for these mutations is available on a clinical basis. Sequence analysis of the six exons of the *RS1* gene identifies nearly 90% of males with a clinical diagnosis of RS, and mutational analyses are available at various clinical centers (http://www.geneclinics.org).[27]

HISTOPATHOLOGY

Historically, the histopathological findings in RS were considered to be primarily within the nerve fiber layer with degeneration of photoreceptors, thinning of the ganglion cell layer, and a focally absent or proliferative retinal pigment epithelium.[30–32] Newer clinical analysis based on noninvasive OCT shows lamellar dissections through retinal layers at multiple levels.[17]

MOLECULAR GENETIC PATHOGENESIS

For many years, RS was thought to be a result of a defect in the Muller cell that acted as a cellular scaffold within the retinal architecture. Recent studies on gene expression and immunolocalization of retinoschisin indicate that it is expressed in all major classes of adult retinal neural cells, with the possible exception of horizontal cells, and that there is no retinoschisin detected in Muller cells or processes,[22] although this is reported by others.[33,34] *RS1* is abundantly expressed in the inner segments of photoreceptors in human and mouse eye sections.[21,22,32] The exact cause of the retinal separation in RS is not known. To address this and understand the pathological basis of RS, Wang et al.[35] conducted in vitro experiments and

reported that the cause of RS is due to intracellular retention of the majority of mutant proteins. The phenotype may depend on the secretory capacity of the cells and the degree to which they may induce the unfolded protein response. Another study showed that misfolding of the discoidin domain, defective disulfide-linked subunit assembly, and inability of retinoschisin to insert into the endoplasmic reticulum membrane as part of the protein secretion process are all responsible for the loss in function of retinoschisin as a cell adhesion protein and lead to the development of RS.[36] Other investigators suggest that the mutant retinoschisin may be functionally defective leading to schisis formation.[32,37] A study of retinoschisin during development of the mouse retina showed that retinal ganglion cells are the first to express RS protein, by postnatal day P1; RS expression subsequently occurs in posterior retinal layers over a 14-day developmental period, indicating the presumptively important role of this protein in early eye development.[22]

MOUSE MODEL

To gain further insight into the function of the *RS1* gene and its role in the cellular pathology of RS, Weber et al.[38] generated knockout mice deficient in the mouse gene, *RS1h*. The $RS1h^{-/Y}$ male mouse has a retinal phenotype which closely resembles the human disease. These mice show generalized disruption of retinal cell layer architecture, splitting of the inner retinal layer with gaps between bipolar cells, and disruption of the synapses between photoreceptors and bipolar cells. These findings suggest that retinoschisin may be directly or indirectly involved in retinal cell layer architecture and structural properties of the retinal synapse.

CONCLUSION

Retinoschisin is a member of the discoidin domain family of cell adhesion proteins. Therapeutic intervention in RS may target restoring the function of retinoschisin in the retina or providing a substitute adhesive that prevents the separation of the retinal layers. Gene therapy is being attempted in the mouse model. Molecular genetic analysis of the *RS1* gene will be a necessary step before initiating clinical trials with or without gene therapy to treat RS patients.

INTRODUCTION

The goal of gene therapy is to treat disease by the introduction of new genetic material into affected or susceptible cells of the body. Gene therapy has been proposed as a treatment for a variety of disorders. Monogenic diseases may be treated simply by replacement of the defective gene with a functional copy. Alternatively, the new genetic material may selectively eliminate tumor cells, provide protection against viral infection, or stimulate the immune system against a specific antigen.

Initiated in 1990, the first gene therapy clinical trial aimed to introduce functional copies of the adenosine deaminase gene into deficient T cells using a retroviral vector.[1] Today, more than 600 clinical trials have been approved, a third of which employ retroviral vectors. The website for the *Journal of Gene Medicine* (http://www.wiley.co.uk/genetherapy/clinical/) provides helpful statistical summaries of approved gene therapy clinical trials to date. The majority of proposed gene therapy treatments are still being evaluated as phase I trials; only one phase III clinical trial has been conducted using retroviral vectors.[2] This trial involved injection of glioblastoma multiforme tumors with murine producer cells to yield in situ production of retroviral vectors expressing the thymidine kinase suicide gene. Unfortunately, therapeutic effectiveness was not improved over standard treatments of surgical resection and radiotherapy.

In general, despite major improvements in vectors since their first clinical use, the therapeutic effectiveness of retroviral vectors remains limited. Advantages and limitations of retroviral vectors, as well as current areas of research, will be discussed in the following review.

OVERVIEW

Retroviral Life Cycle

Retroviruses are RNA viruses containing two copies of a single-stranded RNA genome encapsidated by a protein core and outer lipid layer or envelope. The retroviral genome codes for three basic polyproteins. The *gag* gene codes for structural proteins of the viral core, whereas the *pol* gene generates viral protease, reverse transcriptase, and integrase. The third gene, *env*, codes for a glycoprotein which, following incorporation into the outer lipid layer, directs the retrovirus to bind to receptors on target cells, triggering fusion of the viral lipid envelope with the cell membrane. Following entry of the retroviral core into the cell, the viral RNA genome is copied into a double-stranded DNA provirus by reverse transcriptase. The proviral DNA is then inserted into the host genome by the integrase enzyme, and viral proteins are synthesized from the integrated provirus using cellular machinery (Fig. 1).

Retroviral Vectors

Stable integration of the viral genome into host chromosomes allows the possibility of long-term gene expression, making retrovirus-based vectors prime candidates for correction of a variety of deficiencies. The most common retroviral vectors used for gene therapy clinical trials are based on the murine leukemia virus (MLV). The most current vector system is composed of three components: a vector genome which contains only those viral sequences necessary for packaging, reverse transcription, and integration, and which can accept approximately 6–8 kb of exogenous DNA; a packaging construct which provides Gag and Pol proteins in trans but is not packaged due to a deletion in the packaging signal (ψ); and an envelope construct which codes for the Env protein (Fig. 2).[3] Removal of viral genes from the vector genome and their provision in trans generates replication-defective viral particles, capable of delivering genes to a cell but incapable of subsequent rounds of replication.

LIMITATIONS OF RETROVIRAL VECTORS

For retroviral vectors to be maximally effective, several limitations need to be addressed. First, there is a limited vector size which can be efficiently packaged within the viral core. Additionally, the presence of two copies of the

DOI: 10.1081/E-EDGP 120029807

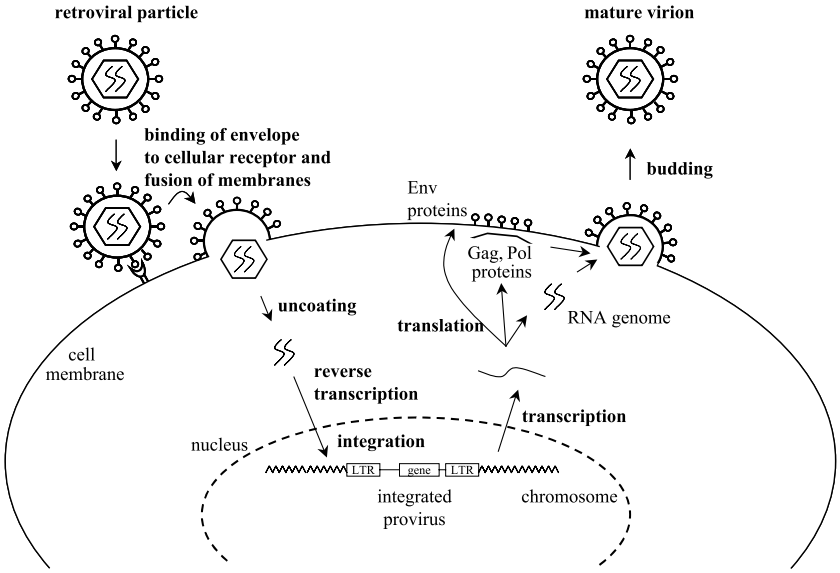

Fig. 1 The retroviral life cycle begins with interaction of the viral envelope with its host receptor, followed by fusion of viral and cellular membranes and entry of the viral core. The viral core disassembles (uncoating) and the viral genome is reverse transcribed into DNA, enters the nucleus, and is integrated into the host genome. The integrated provirus is transcribed by cellular transcriptional machinery, and Gag, Pol, and Env proteins are synthesized. Viral proteins and the newly transcribed viral genome colocalize at the cellular membrane to form viral particles which bud into the extracellular space.

vector genome and the nature of the inserted sequences themselves may contribute to vector instability and rearrangements during reverse transcription. Beyond these intrinsic limitations of viral structure, improvements are required in three major areas: transduction efficiency, gene expression, and safety.

IMPROVING TRANSDUCTION EFFICIENCIES

The number of cells transduced, or infected, by retroviral vectors is often insufficient to produce a therapeutic effect. Murine leukemia virus vectors require breakdown of the nuclear membrane during cell division for entry

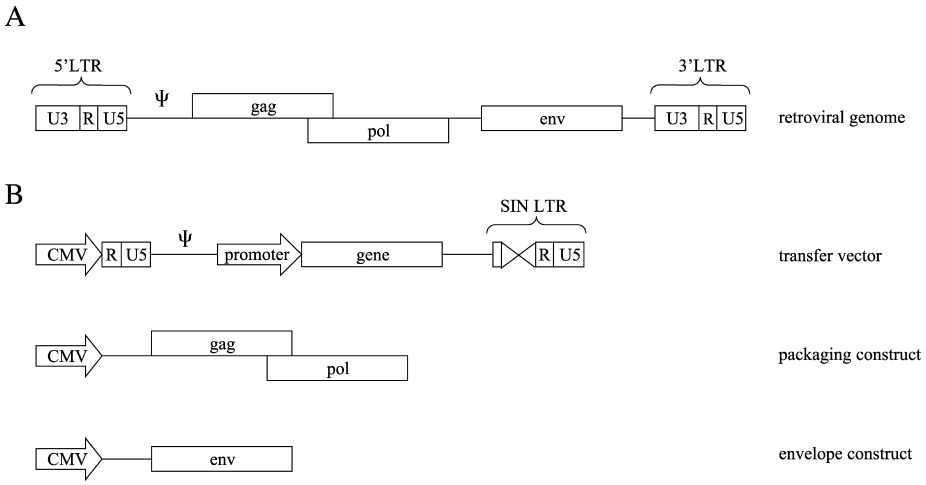

Fig. 2 A. The retroviral genome is composed of three genes, *gag*, *pol*, and *env*, flanked by long terminal repeats (LTR) which contain sequences necessary for initiation and termination of transcription as well as signals for integration into chromosomal DNA. The packing signal, ψ, is required for packing of the retroviral genome into virions. B. Production of retroviral vector particles is achieved by cotransfection of three plasmids and expression of the viral proteins in trans. The transfer vector is the only sequence packaged into the vector particle as the packaging signal has been removed from the other constructs. Safety of the transfer vector has been improved by deletion of viral enhancer and promoter sequences from the 3′LTR, creating a self-inactivating (SIN) vector with no active viral promoters.

into the nucleus and integration into the genome, thus limiting the number of cells that can be transduced. The traditional approach for enhancement of MLV vector transduction efficiencies has been stimulation of cell proliferation by the addition of various growth factors ex vivo.[4] Alternatively, lentiviruses, a subclass of retroviruses, possess nucleophilic signals which permit entry into the nuclei of nondividing cells. However, lentiviral-based vectors are not yet widely used in clinical trials.

The entry of a retrovirus into a cell is also largely determined by binding of the envelope glycoprotein to its cellular receptor, and the distribution of the receptor on various cell types will influence the vector's host range. Envelope proteins from heterologous retroviruses can be used to create pseudotyped vectors with broadened host ranges. For example, pseudotyping with the VSV-G rhabdovirus envelope protein is a common technique used to improve stability and extend the host range of retroviral vectors.[5]

Although pseudotyping and stimulation of cell proliferation have been successful in improving transduction efficiencies of particular cell types ex vivo, such expansion of viral host range may not provide the cell specificity required for gene delivery in vivo. To improve transduction efficiencies in vivo, several methods involving modification of natural retroviral envelopes have been explored to target vectors to a specific cell type (Fig. 3). The retroviral Env protein is composed of two subunits, the surface (SU) protein containing the receptor recognition domain and the transmembrane (TM) protein which anchors the complex within the viral lipid envelope. Binding of SU to its receptor is thought to trigger conformational changes which result in exposure of a fusion peptide on the TM subunit and subsequent fusion of viral and cellular membranes. Most attempts to reengineer the receptor binding site of the SU subunit have involved replacement of the natural receptor-binding domain with a ligand or single-chain antibody with tropism for an alternative cell surface molecule and have resulted in a lack of virus–cell fusion.[6] Some strategies have resulted in limited success, such as the replacement of the MLV Env receptor-binding surface of SU with the peptide ligand, SDF-1α, which resulted in transduction of human cells via the SDF-1α receptor, CXCR4.[7] However, transduction efficiencies were low.

A second approach to Env targeting, called tethering, concentrates vectors on the surface of specific cell types by the addition of a second binding moiety to the natural Env protein. The native receptor binding domain remains functional and mediates virus–cell fusion. The insertion of a von Willebrand factor-derived collagen-binding sequence at the N-terminus of the MLV envelope has resulted in improved gene delivery in vivo to sites of exposed extracellular matrix within tumor vasculature following systemic administration in mice.[8]

An alternate approach, the use of adaptor proteins which function as a bridge between the native MLV Env and cell surface receptors, has generally failed due to a lack of virus–cell fusion. However, greater success has been observed with the avian leukosis virus (ALV) Env protein. Use of an adaptor protein consisting of the single-chain antibody, MR1, which binds to a tumor-specific form of the EGF receptor, joined to the extracellular domain of the natural ALV receptor resulted in successful

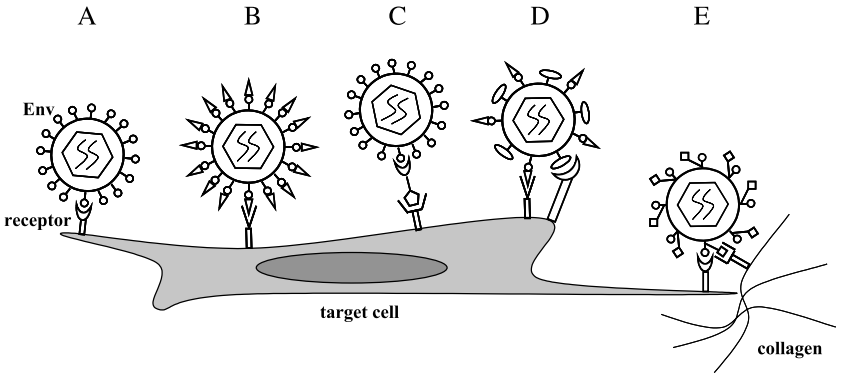

Fig. 3 Efforts to improve transduction of distinct cell populations have involved modification of viral envelope proteins. A. Retroviral infection begins with interaction of the native retroviral Env with a susceptible cellular receptor. B. Replacement of the native Env receptor binding domain with a peptide ligand may direct retroviral binding to a specific receptor. C. Adaptor proteins contain ligand binding sites from natural Env receptors linked to alternative ligands in an effort to direct retroviral binding to specific receptors. D. Trans-complementation of binding-defective influenza hemagglutinin proteins and fusion-defective retroviral Env proteins expands the retroviral host range while circumventing fusion defects often seen with retroviral envelopes possessing an alternative ligand at the receptor binding site. E. Attachment of a peptide ligand to the retroviral envelope protein outside of the receptor binding domain allows concentration of retroviral particles in the vicinity of target cells by interaction with receptors on nearby structures, e.g., collagen.

targeting of ALV-pseudotyped MLV vectors to cells expressing the tumor-specific EGF receptor.[9]

Finally, trans-complementation represents a strategy for circumventing the fusion defect. Orthomyxoviruses and paramyxoviruses possess two distinct envelope proteins which mediate binding and fusion functions separately, suggesting that segregation of the two functions may be possible for retroviral vectors as well. Lin et al. have demonstrated improved transduction efficiency into cells expressing Flt-3 by coexpression of a binding-defective influenza hemagglutinin protein and a fusion-defective MLV Env protein possessing the Flt-3 ligand at the receptor binding domain on an MLV vector.[10]

As an alternative method to improve transduction of tumors in vivo, the use of replication-competent retroviral (RCR) vectors has recently become of interest. As the majority of cells in the body are quiescent, transduction by MLV-based retroviral vectors should be selective for tumor cells. Following the initial transduction event, RCR vectors would replicate, essentially turning each transduced cell into a virus producer cell, and perpetuating gene delivery throughout the tumor. Importantly, RCR vectors typically contain a suicide gene which is toxic to the transduced cell following prodrug administration, thus eliminating tumor cells and minimizing the spread of virus to noncancerous cells. Injection of human glioma cell tumors in rats with MLV-based RCR vectors delivering the cytosine deaminase suicide gene showed 70–90% transduction rates, compared to 1% transduction with replication-defective vectors, and 100% survival of the rats for at least 60 days.[11] The RCR vectors were not detected in other tissues.

Improving Gene Expression

Variable levels of gene expression are observed following integration of current retroviral vectors into target cells. These can be attributed to chromosomal position effects at the site of integration, as well as limitations of vector function. Depending on the site of integration, vector genes may be silenced by a closed chromatin environment or subject to inappropriate regulation by host elements. Expression of retroviral vectors is restricted in several cell types, including embryonic stem cells and murine fibroblasts, as a result of the association of repressive factors with sequences in or near the 5′LTR and methylation of viral promoter elements. Additionally, host cells have a tendency to recognize foreign promoters, especially strong viral promoters such as SV40 and CMV typically used to drive expression of the gene of interest, and inactivate them by various mechanisms, including methylation. Even if gene expression remains active, transduced cells often lose viability over time because of an immune response elicited by the product of the delivered gene.

Replacement of repressive viral sequences with similar sequences from heterologous retroviruses and the minimization of CpG dinucleotides within viral promoters has lessened, but not eliminated, silencing of transgene expression.[12] Silencing of viral promoters has sparked an interest in the use of gene-specific regulatory sequences to direct transgene expression. Logg et al. have reported prostate-specific gene expression which persists over time by incorporation of the prostate-specific probasin promoter into RCR vectors, demonstrating the benefits of improved gene expression and tissue-specificity achieved with an authentic human promoter.[13] Incorporation of gene-specific locus control regions (LCR) into retroviral vectors confers integration site-independent and tissue-specific vector gene expression.[14] Additionally, the use of authentic genomic elements such as scaffold or matrix attachment regions and insulator elements has been reported to improve transgene expression when included in a retroviral vector.[15]

Improving Vector Safety

As retroviral transduction efficiencies and gene expression levels improve, so will the potential for serious adverse effects including retroviremia, generation of replication-competent revertants, germline transmission, and insertional mutagenesis. The recent demonstration that retroviral vectors favor integration sites within transcriptionally active loci has increased the probability of insertional mutagenesis caused by vector integration.[16] Additionally, the development of leukemia-like disease in two French SCID-X1 gene therapy patients as a result of retroviral vector integration in the vicinity of a known oncogene, LMO2, has underscored the necessity for improved safety mechanisms within gene therapy vectors.[17]

Many of the vector modifications described above to improve transduction efficiency and gene expression may also improve vector safety. Elimination of dispensable viral sequences from the vector, separation of necessary viral genes (*gag*, *pol*, *env*) onto individual packaging vectors, and replacement of viral sequences with heterologous retroviral components or exogenous *cis*-acting regulatory elements all combine to reduce the risk of homologous recombination between vectors and endogenous viruses and the development of chimeric replication-competent vectors. Additionally, transcriptional targeting, or the use of gene-specific regulatory elements to limit gene expression to desired cell types, will help prevent expression in inappropriate cell types. Targeting of vectors to specific cell types or tissues by reengineering

of envelope proteins will also limit gene expression to appropriate tissues. The use of insulator elements and matrix attachment regions within vectors may prevent inappropriate activation of cellular oncogenes by confining the action of vector regulatory elements to vector transgenes. Finally, attempts to target integration to specific genomic locations by modification of the integrase enzyme may eventually direct vector integration to benign sites within the genome. Tan et al. have shown that fusion of the synthetic polydactyl zinc finger protein, E2C, to the HIV-1 integrase results in preferential vector integration near the E2C binding site in vitro.[18] The E2C binding sequence is a unique site within the human genome; however, preferential integration has not yet been demonstrated in vivo.

RETROVIRAL VECTORS AS PHARMACEUTICALS

The development of gene therapy vectors for large-scale therapeutic use will also require improvements in several areas. As viral vectors can only be made by living cells, large-scale manufacturing of gene therapy vectors will require the establishment of producer cell lines which consistently yield stable, unrearranged viral vectors. Additionally, purification of vectors from producer cell supernatant is a cumbersome procedure and all processes must be carried out using Good Manufacturing Practices and the highest levels of quality control. Safety of viral vectors, namely, the potential to generate replication-competent vectors by recombination between vector components and endogenous retroviruses and insertional mutagenesis, is of significant concern in the development of vector therapy for use in humans. Finally, with in vivo vector therapy as a future goal, innovations are required which will minimize innate and humoral immune responses to systemically delivered vectors, especially inactivation of vectors by human complement and the possible development of antivector antibodies.

CONCLUSION

The therapeutic potential of retroviral vectors was first recognized over a decade ago. Due mainly to their ability to integrate into the host genome and the potential for long-term gene expression, retroviral vectors have now become one of the most widely used vehicles for gene therapy. However, despite many beneficial modifications, retroviral vectors are limited by the inability to transduce nondividing cells and inconsistent levels of gene expression. Additionally, with the recent development of leukemia-like disease due to insertional mutagenesis in two patients enrolled in a retroviral vector clinical trial, the safety of retroviral vectors is now a significant concern.

Reversed Line Blot Hybridization

R

Bert Gold
National Cancer Institute, Frederick, Maryland, U.S.A.

INTRODUCTION

Reversed line blot (RLB) hybridization is a specialized form of allele-specific oligonucleotide assay that provides a robust method for the molecular characterization of genes with numerous nonsynonymous variants. In most highly refined form, these assays rely upon highly multiplexed PCR reactions containing biotinylated primers to provide a substrate for nonradioactive detection systems. Reversed line blot technology involves mechanized covalent attachment of activated primary amine-conjugated oligonucleotides to carboxylated nylon membranes or BSA. Printed membranes are stored or sold dry in preparation for hybridization. Lines are visualized colorimetrically after hybridization using streptavidin horseradish peroxidase incubation then developed using a tetramethylbenzidine derivative and hydrogen peroxide. For rapid prenatal diagnosis of cystic fibrosis (CF), β-thalassemia, and other hemoglobinopathies, this technology is especially applicable. Commercial instruments are available to provide greater uniformity for the hybridization and color development.

TECHNICAL DESCRIPTION

Reversed line blot-polymerase chain reaction requires a moderate number of biotin tagged primers in robust multiplex PCR in order to provide a driver for solid support-bound probes. Optimal multiplex PCR reactions directed at a single locus rarely contain more than 20 separate amplicons. In single nucleotide polymorphism (SNP) typing, multiplex PCR can contain up to 100 amplicons; however, these experiments are not limited to a single genetic locus, thus the sequence optima are not subject to the same constraints as those used in genetic testing.

After denaturation and hybridization of tagged amplified sequences to probes attached to solid supports, filter-bound hybridization products are washed under conditions of increasing stringency in order to remove nonspecifically bound amplicon, followed by the use of a blocking buffer to further reduce background. Streptavidin conjugate is used to provide a chemical bridge between the solid support covered with a tagged, hybridized PCR product and an enzyme substrate complex susceptible to visualization using a colorimetric substrate. Detection of the labeled oligonucleotide probes is accomplished through incubation with substrate in a developing buffer. Peroxidase conjugate-mediated color development occurs during a 10-min incubation, in the dark, in a buffer containing low-concentration hydrogen peroxide. Filters are then washed in distilled water. Photography is best accomplished while the filters are still wet.

Molecular genetic tests have two different classes of validity: The first class is analytical validity, including analytical specificity and sensitivity, which provide a basis for judgment as to how a test performs in the laboratory. Another class of validation is clinical validity, which informs clinical decision making.

SPECIFICITY

Validation of RLB hybridization tests involves retrospective scoring of samples that have been reliably characterized by some other method, most often polymerase chain reaction–restriction fragment length polymorphism (PCR-RFLP). Polymerase chain reaction–restriction fragment length polymorphism takes advantage of base-pair changes that create or interrupt palindromic restriction-enzyme recognition sites. Although this is a simple approach, restriction-enzyme cleavage is limited to linkage analysis of polymorphic restriction sites and to situations in which the mutation serendipitously creates or disrupts a restriction site. It also requires that the amplification reaction produce a unique product fragment. For historical reasons, PCR-RFLP remains the gold standard for clinical diagnosis of point mutations. New technologies for mutation detection are often compared against it. In 1999, polymorphisms discovered in the binding site of PCR primers within the hemochromatosis locus changed clinical practice by exposing the myth that PCR-RFLP is the most reliable genotyping technique (see Ref. [1] for details).

A statistical rating of analytical specificity provides a measure of how often a test is negative when a mutation is not present. This amounts to measuring the number of false negatives, or mutations missed. This statistic is expressed as a percentage of mutations missed over all other classes of test outcome. The analytical specificity of

DOI: 10.1081/E-EDGP 120020725

RLBs is extremely high. Palomaki et al.[2] found the analytical specificity of cystic fibrosis tests conducted in the United States to be 99.4% (95% CI 98.7–99.9%) after removing challenges involving ΔI507. The few exceptions to the rule of high specificity are discussed in ''Limits and Clinical Applications'' below. Clinical specificity is the quotient of normals (or noncarriers) with negative results divided by all normals.

SENSITIVITY

Generically, analytical sensitivity is defined as the proportion of positive test results, when a detectable mutation is present. Analytical sensitivity is equivalent to the analytical detection rate. Between 1996 and 2001, when RLBs were widely used, Palomaki et al.[2] found an analytical sensitivity of 97.9%,[2] in U.S. CF molecular testing. They added that analytical sensitivity was consistent over the 6 years.

Two genetic tests, one for the hemoglobinopathies and β-thalassemia that would have broad (95% clinical sensitivity) worldwide coverage, and the other for a series of relatively common mutations in the human CFTR, were the first application of RDBs. The clinical sensitivity of the 25 mutation panels for CF carrier testing recommended by the ACMG in 2001 varies by ethnic group.

REPRODUCIBILITY (PRECISION)

Zhang and colleagues,[3] working at Cetus, reasoned that probes bound by UV or heat, were attached in random fashion to the filter and sometimes to each other, making it difficult to determine consistent or optimal hybridization conditions. Until then, Saiki and his collaborators[4–9] had been using nucleotidyl transferase-tailed polyT oligonucleotides under UV radiation to conjugate amino-derivatized membranes (Biodyne B); but Zhang et al. showed that oligonucleotides could be amino-functionalized by introducing these nucleophiles at 5′ oligomer ends during synthesis, and that these would be reactive with charged membranes. After attachment, reactivity of activated carboxyl groups on the membrane remains high; therefore blocking previously activated sites through charge neutralization is necessary before using the membrane in a hybridization reaction, as nucleic acids can otherwise attach to the sites at a low, but significant level, even without an amino-linker. Although charge neutralization and blocking were initially achieved by the Cetus group using hydroxylamine, the UCSF group later found NaOH just as effective.

A Belgian group[10] found that empirical adjustment of the hybridization conditions was a requirement in developing appropriate molecular interrogators for the common Belgian mutations, ΔF508, G542X, and N1303K. Cuppens et al. also showed that a multiplex PCR was a requirement for detecting the desired variety of mutations at the CF locus. Both of these important observations, the requirement for multiplex PCR and that for reproducible, empirically derived hybridization probes and conditions, have become understood as necessary prerequisites for a successful RDB.

Zhang et al.[3] also emphasized the importance of the physical relationship between the interrogated oligonucleotide and the solid support surface through the use of spacer linkers. In controlled experiments, they found that steric spacers aided hybridization and that oligonucleotides without linkers were up to fourfold less efficient in hybridization (see Ref. [1] for details).

Despite the development of covalent attachment by the predecessor Cetus group, the Roche Molecular Systems progeny group developed a proprietary process for the manufacture of BSA-conjugated oligonucleotides. The process involves the synthesis of 5′-amino link oligonucleotides followed by incubation with BSA and coating onto nylon membranes.[1,11] This proprietary process is used by Roche for the manufacture of their Linear Array Panel (LAp).

Commercialization of RLB hybridization strips required significant effort in ensuring their reproducibility and uniformity. During the period of scale-up at Roche Molecular Systems, it was found that dot blots themselves often gave equivocal results in the form of a halo around the dots. This had more to do with surface tension considerations when applying the amino-conjugated or BSA-conjugated oligos (''printing'') than it had to do with any other consideration. As a consequence, a decision was made to convert the dots to lines of uniform width. Roche developed its own in-house technology for printing line probes, although off-the-shelf commercial technology is available.[1] Extensive improvements in reproducibility and manufacture accompanied the commercialization process. Incubation temperature, temperature equilibration, and uniformity in conjugate and substrate distribution are known to be critical variables for color development. Optimum conditions for nucleotide hybridization and development of the RDB strips were devised and automated by Roche and Innogenetics, Inc., through the use of Tecan's Profiblot and Dynal's AutoReli. These shaking baths give uniformity to the strip development that is not easily achieved in any other fashion.

ROBUSTNESS

Because of speed, simplicity, high sensitivity and specificity, large numbers of individuals can be rapidly

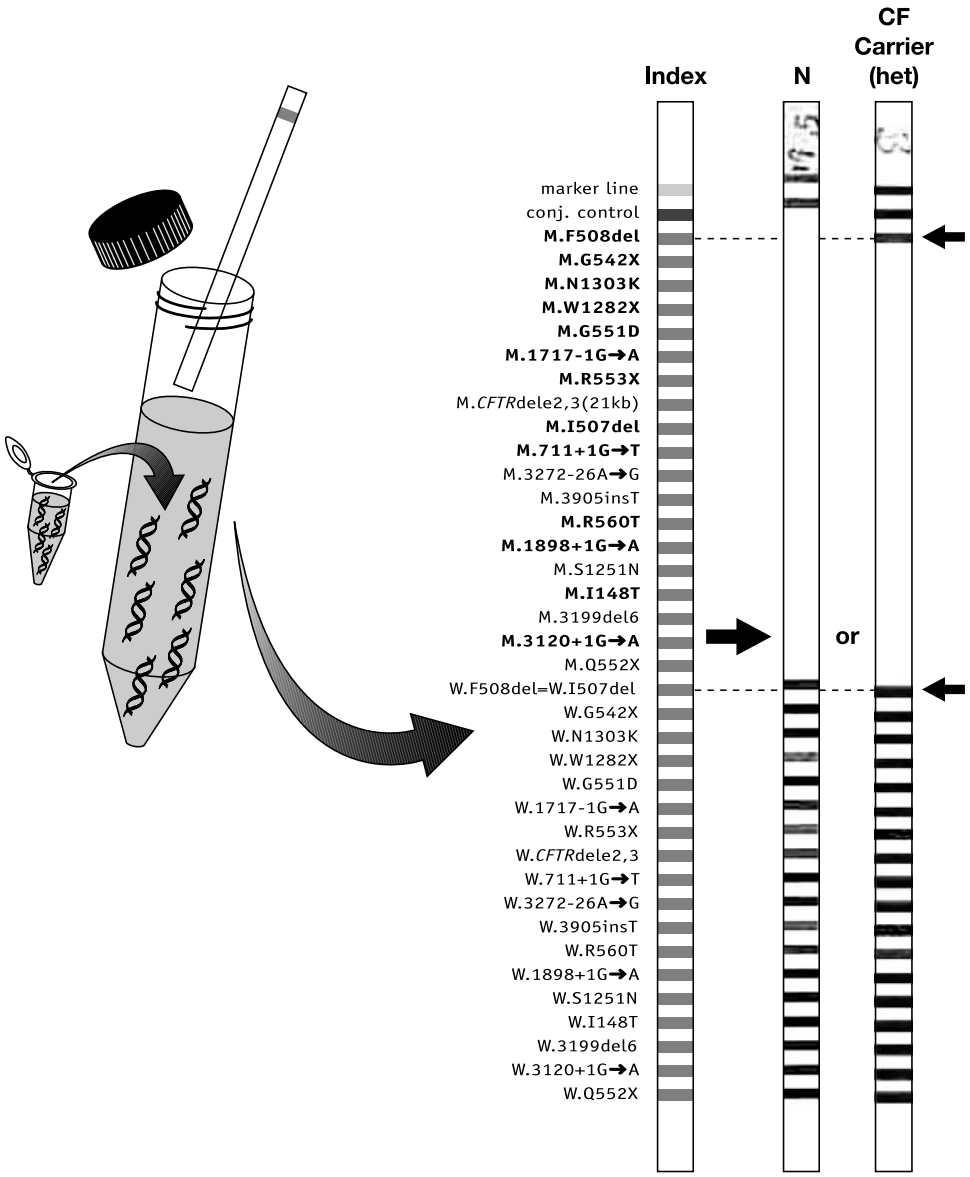

Fig. 1 Schematic of multiplexed reversed line blot assay for cystic fibrosis. In an RLB, primers for amplification are synthesized using a 5′-biotin. These are incorporated in a multiplex PCR for most CFTR exons. Amplified exons are represented by double helices in the smaller test tube on the left. These are hybridized against short variant and normal oligonucleotide probes arrayed on solid supports, represented by the larger screw cap tube. The index for the Innogenetics CFTR19 LiPA RLB provides a guide to printed oligonucleotide probes. Subsequent to hybridization, the filters are extensively washed, blocked, and incubated with a horseradish peroxidase-conjugated streptavidin. For visualization, a synthetic substrate is added and the reaction is permitted to proceed for a short time. The resultant arrays shown here and labeled as a normal strip (N) and CF Carrier (heterozygous individual) are photographed and subjected to interpretation. Note that the normal strip evidences colorimetric indicators corresponding only to normal oligonucleotide probes, whereas the carrier displays a colorimetric reaction when probed with the M.F508del oligonucleotide (upper arrow on right). (RLB photos courtesy Donna Adams of Innogenetics and Dr. Amy E. Krafft of the Armed Forces Institute of Pathology.)

tested using this technology, often in less than 1 day. One prerequisite is that binding of oligonucleotides must be sequence-specific under uniform hybridization conditions. In most cases, the destabilizing effect of a single base-pair mismatch is sufficient to disrupt the formation of stable probe–target duplex. This specificity requirement can often be met either by adjusting the length, position, and strand specificity of the probe, or by varying the amount of probe applied to the membrane. Most probes are as short as is required to achieve specific hybridization, usually 15–23 base pairs in length, with a destabilizing mismatch toward the middle, but at least 3 base pairs from

either end. The classic formula for predicting the dissociation temperature T_d of an oligonucleotide, 2°C for each A/T and 4°C for each G/C, is simple but not necessarily accurate. In recent years, many algorithms have been developed that appear to give much better estimates and can assist in the design of probes for particular hybridization conditions. Some mismatches are less destabilizing than others. G/T mismatches are less destabilizing than C/A and these can be avoided by using probe designs on the opposite strand. Increased length provides for efficient competition with the secondary structure of the amplicon. Destabilizing mismatches are favored in RLB probe design. Trimethylammonium chloride (TMAC) is a quaternary ammonium salt that is used as an adjunct in hybridization reactions. Trimethylammonium chloride eliminates the dependence of melting temperature on G–C content by reducing hydrogen bond energy between G–C base pairs. Additionally, TMAC binds specifically to A–T base pairs and increases their thermal stability. Thus the presence of TMAC at 3 M concentration in hybridization buffers reduces the melt temperature of an oligo with its complement to a function of length alone.[12]

Reversed line blots are often arrayed to permit rapid interpretation of heterozygotes where one normal and one variant allele are indicated (Fig. 1). However, where two mutations are close to each other and fall within the sequence of the oligonucleotide probe (a situation often observed with respect to HbA, HbS, and HbC), a different pattern is obtained. DNA from individuals with HbS/HbS (sickle cell disease) will not hybridize to the normal probe at either the S or the C position. Instead, such DNA hybridizes solely to the HbS probe.[13] This individual is distinguishable from HbS/HbC compound heterozygotes because the latter DNA will hybridize to both the mutant S and the mutant C probes. Similar RDB results are observed in the case of variants neighboring the ΔF508 CF mutation and those neighboring the IVS 1-1 and IVS 1-6 mutations, five nucleotides apart, that cause β-thalassemia.

In the past, RDBs have permitted the production of screening strips for aldolase B mutations (causing hereditary fructose intolerance),[14] nondeletion α-thalassemia,[15] or adult onset mitochondrial disorders such as Leber hereditary optic neuropathy[16] or hepatitis A contamination in food.[17] A recently published reverse dot blot assay for congenital adrenal hyperplasia has high clinical utility in identifying sexually ambiguous newborns.[18] These assays are flexible, inexpensive to implement, and use off-the-shelf commercially available hardware, reagents, and software. Both Tecan and Dynal manufacture specially engineered incubators and chemical dispenser devices that automate part of the RDB hybridization and developing process. While RDB assays are generally limited by an inability to detect large or quantitative deletions and an inability to characterize all but modestly expanded repeat sequences (ascertainment of the exact size of an expansion is often required for accurate molecular diagnosis), these strips can provide a means of accurate and reproducible genotype assignments. Automated spotting or line blotting of RLB strips allows the printing of large numbers of these with a minimum of operator intervention. Automation also permits higher density.

LIMITS AND CLINICAL APPLICATIONS

In molecular diagnosis there are two types of variant characterization: one for diseases with a major etiologic mutation, as in medium chain Acyl CoA dehydrogenase deficiency where almost 90% of affected pediatric patients have the same mutation (985A > G). Thus it is a simple matter to design a high-throughput test by either forward dot blot or PCR-RFLP. This, however, is not the case for the second type, CF or β-thalassemia. Hundreds of mutations are known that cause β-thalassemia or hemoglobinopathies, and nearly all are recessive, some causing milder and some more extreme phenotypes. And, even today, after a massive screening effort in the Mediterranean and Italy, where β-thalassemia is endemic, most patients are born into families with no history of the disease. Another example is CF in which one major mutation accounts for 70% of observed carriers and is present in homozygous form in less than 50% of affected individuals. Thus the clinical sensitivity, which is ethnicity specific, is much lower than most diagnostic tests found in a pathology laboratory. Like β-thalassemia, the vast majority of individuals who have CF are born into families with no history of the disease. Each of these diseases has a relatively wide mutation spectrum; that is, many different alleles are present that in combination can give rise to the disease. As a consequence, there is great motivation for carrier screening for each of these diseases, to provide early warning to at-risk families and to ascertain genetic carrier status far back in families presenting for screening. Chehab and his collaborators designed a series of very successful reverse dot blots aimed at these applications.[19–21] As the CF LAp offered by Roche Diagnostics and Innogenetics' Line Probe Assay (LiPA) have received the broad endorsement of U.S. molecular diagnostics laboratories, the RLB has come of age. In addition to these commercial offerings, there remains a large market of home-brew testing via reverse allele-specific oligonucleotides, for a variety of hereditary illness and infectious-disease typing. With the recent publication and evaluation of a 58-allele line probe assay by a Johns Hopkins and Roche Molecular Systems collaborative group,[11] the RLB has proved its analytical

utility in a variety of diagnostic situations. Limitations, such as the individuals who are compound heterozygote at closely spaced loci, occasionally fail to signal the presence of one or the other allele. This is because of interference. It is a characteristic of all sequence-specific assays that nucleotide variants within the probed region (usually $\sim$17 nucleotides) affect test accuracy. One example of this kind of interaction is detection of a S549N/R553X heterozygote in Wang et al.;[11] this failed to hybridize with the G551D wild-type probe which is encompassed by the probe for R553X. Another example is a ΔF508 mutation/I506V polymorphism heterozygote which failed to hybridize against the normal sequence in the region. These confounding results should notify the alert clinician of a test uncertainty that bears further investigation. This type of observation is one of the motives for the American College of Medical Genetics (ACMG) guideline of a two-tiered testing strategy for population-based CF screening.[22]

CONCLUSION

Polymerase chain reaction–restriction fragment length polymorphism has been the standard for molecular mutation screening; however, this method is not practical for high mutation spectrum disorders. Rapid reliable molecular diagnosis of these disorders requires a unique approach. Because the majority of these hereditary illnesses occur in families with no prior history, RLBs provide a high-sensitivity screening test to identify at-risk carriers. Direct DNA sequencing would be the most thorough mutation-detection approach, but it is arduous and capital intensive. Molecular carrier screening tests must be cost-effective to be practical. Commercialization of molecular diagnostics for high mutation spectrum disorders involves special considerations. Among these are low cost, high throughput, and rapid interpretation. Genotyping assay efficiency and throughput has considerably improved as a consequence of automation. Automation of many of the subtasks of nucleic acid hybridization including amplification, electrophoresis, and homogeneous signal detection has enabled the establishment of higher throughput molecular assays and diagnostics. Technical factors, such as methods of attachment of oligonucleotide probes to solid supports, the nature of the solid supports themselves, and PCR product visualization techniques, play an important role in formatting commercial diagnostics. Process automation has been inspired in part by the successful effort to map and sequence the human genome. Commercial tests have been developed for HLA class I and class II regions of human chromosome 6, mutations and polymorphisms in the cystic fibrosis transmembrane conductance regulator (*CFTR*) at 7q31, and for genotyping strains of human hepatitis B and C virus (HBV and HCV). Several diagnostics manufacturers have participated in the development of RLBs. There will undoubtedly be many improvements in automation and detection of DNA sequences using this technology in the short-term future.

Rh Genotyping—Clinical Aspects

R

Carlos M. Cotorruelo
Claudia Biondi
Amelia Racca
Universidad Nacional de Rosario, Rosario, Argentina

INTRODUCTION

The Rhesus blood group system is of clinical interest because it is involved in the pathogenesis of hemolytic disease of the newborn, hemolytic transfusion reactions, and some autoimmune hemolytic anemias. More than 48 different antigens have been serologically defined, making the Rh system the most polymorphic of all the erythrocyte blood group systems. There are five most frequently typed Rh antigens: C/c, E/e, and the D antigen, which is the most immunogenic, defining an individual as RhD-positive or RhD-negative. Classical hemagglutination used for Rh typing is still a powerful and practical technique, with specificity and sensitivity suitable for clinical applications, but has limitations. Molecular genotyping techniques such as polymerase chain reaction (PCR) can be used to overcome some of these limitations and, in addition, to improve the current level of resolution.

GENETIC BASIS OF THE Rh SYSTEM

The discovery of the Rh blood group system was made just over 60 years ago. A three-gene theory and a single-gene theory had been proposed to explain the inheritance of Rh antigens, but it was in 1991 when Colin et al.[1] demonstrated that the *RH* locus was composed of two genes and established the genetic basis for RhD-positive and RhD-negative polymorphism, as follows:

The *RH* locus is composed of two homologous genes denoted *RHD* and *RHCE*.
Caucasian RhD-positive individuals have either one or two *RHD* genes per cell, whereas the RhD-negative phenotype is caused by the absence of the entire—or at least part of the—*RHD* gene (Fig. 1).
The *RHD* gene encodes the RhD protein that expresses the epitopes of the D antigen.
The *RHCE* gene has four prevalent allelic forms: *RHCe*, *Rhce*, *RhcE*, and *RHCE*, and each allele determines the expression of two antigens in Ce, ce, cE, or CE combination carried by the RhCcEe protein (*RHCE* is the collective name of the four alleles).

Rh PROTEINS

The Rh proteins consist of 417 amino acids, have 12 transmembrane spans with six extracellular loops, and are involved in the export of ammonium from red blood cells (RBCs).[2,3]

D is the major Rh antigen detected on the surface of RBCs obtained from individuals with presumed genotypes *RHD*/*RHD* or *RHD*/−, commonly referred to as ''RhD-positive.'' It consists of a collection of at least 24 different epitopes expressed on the RhD polypeptide. Whether from RhD-positive or RhD-negative individuals, virtually all normal RBCs bear the antithetical antigens C and/or c (involving the second extracellular loop of the RhCcEe protein), in addition to E and/or e (involving the fourth extracellular loop on the same protein).[2,4,5]

Rh antigens may have a depressed, partial, or ablated expression on the RBC membrane because of allelic variants of the *RH* genes. A serological weakly reacting form of D was described as weak D because these red cells possess a relatively small number of D antigen sites. Another phenomenon related to D antigen expression is the partial D status associated with both qualitative (lack of one or more D epitopes) and quantitative polymorphism,[4] which can be identified because of anti-D production and/or lack of reactivity with some monoclonal anti-D. However, molecular analyses have shown that ''weak D'' possesses slightly modified D antigens,[6] suggesting that the terms ''weak D'' and ''partial D'' should be replaced by ''aberrant D'' because each case of altered D expression investigated to date demonstrates a unique D phenotype.[3,5]

RH LOCUS

The *RH* locus is localized on the short arm of chromosome 1p34–p36. Each *RHD* and *RHCE* gene encompasses approximately 57 kb of DNA and consists of 10 exons (Fig. 1). There is about 90% coding sequence homology between the *RHD* and *RHCE* genes. The 3′ untranslated region of *RHD* exon 10 covers more than 1500 bp, whereas a shorter stretch is known for *RHCE*. Deletions

DOI: 10.1081/E-EDGP 120024113

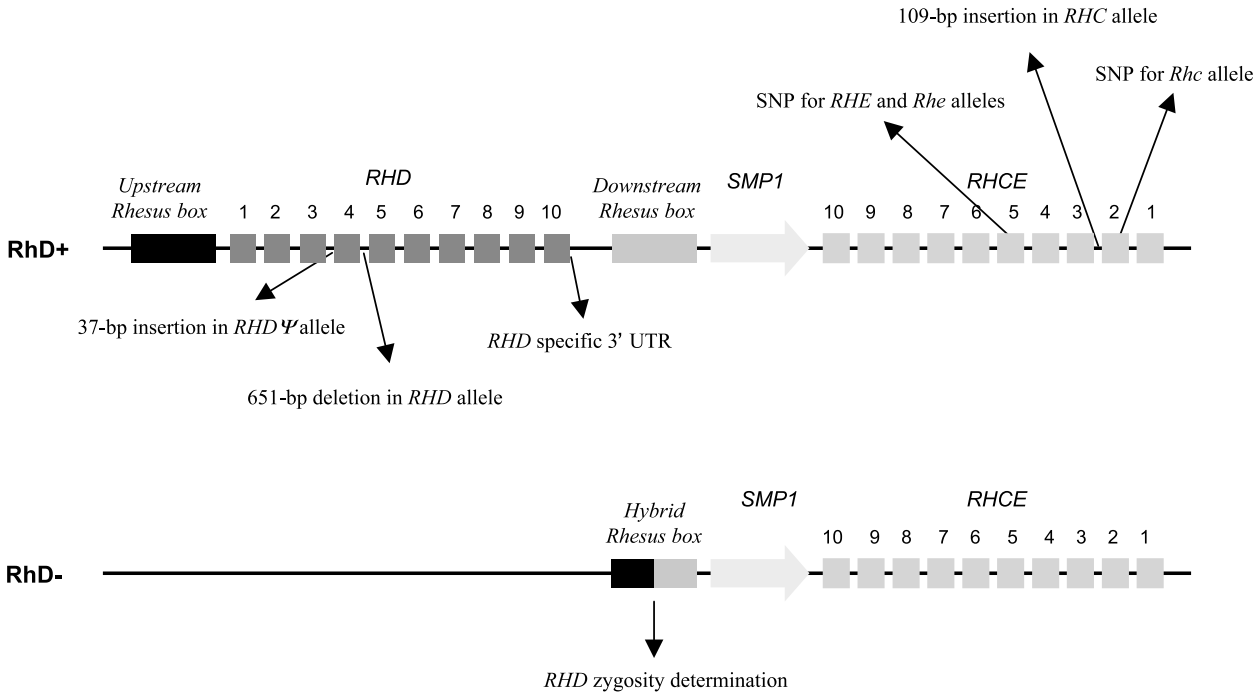

Fig. 1 Genomic organization of the *RH* locus in RhD-positive and RhD-negative chromosomes. Arrows indicate polymorphic sites used for *RH* genotyping. SNPs in *RHD* exons 1–7 and 9 are also detected in some *RHD* genotyping strategies.

of 109 bp in intron 2, 288 bp in intron 3, and 651 bp in the very short intron 4 have been reported.[2,3,5,7]

The physical distance between *RHD* and *RHCE* is approximately 30,000 bp, and it is filled with a *Rhesus box* and the *SMP1* gene. The two *RH* genes have opposite orientations and face each other with their 3′ ends. Considering this chromosomal organization, the lack of the *RHD* gene in most RhD-negative Caucasians was probable because of an unequal crossing-over event between two highly homologous DNA segments termed *Rhesus boxes*, which flank either side of the *RHD* gene, resulting in the formation of a hybrid *Rhesus box*. The analysis of the hybrid *Rhesus box* would be a predictor of *RHD* zygosity.[8] One copy of the hybrid *Rhesus box* predicts a heterozygous *RHD*-positive genome (Fig. 1).

Rh PHENOTYPE AND *RH* ALLELES

Besides the most common *RHD* DNA sequence, several allelic *RHD* variants are responsible for partial D phenotypes, weak D phenotypes, or unexpressed RhD proteins.[9,10]

Molecular alterations in partial D phenotypes generally affect at least one extrafacial amino acid. On the contrary, molecular studies of weak D phenotypes have shown that weak D alleles lead to aberrant RhD proteins with amino acid substitutions in transmembranous and intracellular segments that may disrupt the secondary or tertiary structure, or may alter the optimal membrane integration.[2,3,5,6]

It is important to note that there also exist unexpressed *RHD* alleles in RhD-negative phenotypes. These *RHD*-positive antigen D-negative alleles are most frequently found in non-Caucasian populations and are rare in whites. In Africans, the major *RHD*-negative allele is a *RHD* pseudogene designated *RHDΨ*.[11]

The *RHCE* gene also bears its own heterogeneity, which is responsible for C, c, E, and e polymorphisms. *RHC* and *RHc* alleles differ in one nucleotide in exon 1 and in five nucleotides in exon 2, whereas *RHE* and *RHe* have a difference of a single nucleotide in exon 5.[2,3,5,7] Different *RHCE* rare alleles are responsible for depressed, partial, or ablated expression of C/c and/or E/e antigens.[9,10]

RH GENOTYPING

Different PCR amplification protocols have been applied to determine the Rh phenotype in DNA obtained from normal donor peripheral blood, amniocytes, and trophoblastic cells.[12]

Analyses of *RHCE* single nucleotide polymorphism (SNP) of exons 5 and 2 have been used for E/e and c genotyping, respectively. A 109-bp insert in intron 2 of

the *RHCE* gene, found only in C-positive individuals, was the target for the *RHC* allele typing[3] (Fig. 1).

RHD genotyping was more complex because of the large number of different *RHD* alleles described. Developed strategies varied from *RHD* single-region PCR tests (involving exon 10, intron 4, or exon 7) to multiplex PCR tests for scanning all *RHD*-specific exons. However, *RHD* genotyping by probing the presence of *RHD*-specific polymorphisms was not suitable for certain population groups, such as Africans, where the presence of *RHDΨ* can reach 40%. Generally, checking two sufficiently distant regions of the *RHD* gene together with the *RHDΨ* has proven to be safe for determination of the RhD phenotype[3,12] (Fig. 1).

CLINICAL ASPECTS OF Rh GENOTYPING

Routinely, Rh typing is performed by agglutination with polyclonal and immunoglobulin (Ig) M monoclonal antibodies, or blends of IgM and IgG monoclonal antibodies. However, there are some clinical situations in which serological techniques cannot determine the RBC phenotype accurately:[13]

In fetuses at risk for hemolytic disease of the newborn because periumbilical blood sampling must be performed to obtain fetal erythrocytes.
In cases of autoimmune hemolytic anemia because autoantibody coating of RBCs may render serological typing impossible.
After a massive transfusion, when agglutination methods would detect antigens on both the patient's and the donor's RBCs.
In patients with altered expression of the D antigen and where serology is inconclusive for deciding transfusion therapy or anti-D prophylaxis.

RH genotyping with specificity and sensitivity comparable to serologic methods is of practical importance to overcome the limitations of classical hemagglutination and, in addition, to improve the currently possible resolution. Moreover, the application of molecular techniques to the identification of rare alleles is increasingly important, as many typing reagents on which serology is reliant are now either no longer available or in short supply.

Hemolytic Disease of the Newborn

The RhD hemolytic disease of the newborn continues to affect at least 1:1000 live births despite the use of prophylactic anti-D Ig. Current management strategies for RhD alloimmunization include invasive procedures such as serial amniocentesis (to predict fetal anemia) and cordocentesis (to directly determine fetal blood type serologically), but both alternatives involve a high risk of fetal loss and may result in an important increase in anti-D titers.[4]

Since the molecular cloning of the Rh system, efforts have been directed toward the development of methods for DNA-based Rh typing particularly for the prenatal assessment of the fetal RhD status. The extreme sensitivity of assays based on PCR made it possible to determine the presence of the *RHD* gene and also *RHCE* alleles in fetuses using DNA derived from a single amniocentesis.[3,11,12,14] The high level of accuracy reached in *RHD* genotyping strategies allowed the incorporation of this prenatal diagnosis test into the management scheme applied to erythrocyte sensitization. If the fetus proves to be RhD-negative, the need for subsequent invasive procedures is obviated. If testing predicts that the unborn baby is RhD-positive, treatment can be planned with sufficient time.

However, to circumvent this risk associated with amniocentesis, several groups have investigated the possibility of determining the fetal RhD status through the use of fetal cells isolated from maternal blood.[15] The main problem is that the procedures needed to isolate sufficient numbers of fetal cells from maternal blood are time-consuming and technically demanding. Moreover, a cell subpopulation has been shown to persist for up to decades after delivery; thus it could interfere with fetal cell analysis in women who have had multiple pregnancies. An alternative approach based on the detection of *RHD* messenger RNA in fetal nucleated red cells has also been described, but the small number of subjects analyzed precludes any firm conclusion as to the reliability of this method.[16]

Recently, it has been found that during pregnancy, cell-free fetal DNA can be found in maternal plasma and may be utilized to determine fetal blood group status without invading the fetomaternal circulation. Lo[17] was able to demonstrate that fetal DNA is present at very high fractional concentrations in maternal plasma, constituting approximately 3% of total maternal plasma DNA during the second trimester of pregnancy and that fetal DNA is cleared very rapidly from the maternal plasma after delivery, with a half-life on the order of minutes. This high relative concentration suggests that fetal DNA could be robustly detected in maternal plasma using modern molecular technology and, unlike fetal cells in maternal blood, plasma DNA analysis is not complicated by the effect of persistence from prior pregnancies.

Both real-time PCR and conventional PCR technology have been applied to successfully determine the RhD status of unborn infants by analysis of plasma samples obtained from RhD-negative pregnant women. However,

it is very likely that for future large-scale clinical usage, protocols based on real-time PCR may be preferred because of the high sensitivity and homogenous nature of the assays. In addition, genotyping of fetal DNA extracted from maternal plasma can potentially be used for the diagnosis of many disorders involving single genes.[17]

One of the latest developments in hemolytic disease of the newborn is the discrimination of *RHD* heterozygosity from homozygosity in RhD-positive fathers by the specific detection of *RHD* deletion through PCR amplification of the hybrid *Rhesus box*.[8] This determination is of considerable value in the prenatal assessment of the fetal RhD status.

Autoimmune Hemolytic Anemia

Rh polypeptides are the most common targets for pathogenic anti-RBC autoantibodies in patients with autoimmune hemolytic anemia.[4] In patients whose RBCs are heavily coated with IgG, testing with antiglobulin-reactive sera is difficult, whereas tests with high-protein agglutinin reagents are impractical. For RhD phenotyping of these patients, it is necessary to dissociate antibodies from erythrocytes by elution, without damaging RBC membrane integrity or altering antigen expression. Yet, when the affinity of the antibody is high, the dissociation procedure may be incomplete and lead to wrong results.[13] In some cases, the removal of autoantibodies coating the erythrocyte membrane is reduced after the elution procedure, but the direct antiglobulin test remains positive. If the sample is serologically typed as RhD-negative with a direct agglutination technique, doubts may arise when performing the indirect antiglobulin test. In these cases, DNA analysis can confirm the RhD-negative phenotype and discard a probable weak expression of D. When serological typing is inconclusive and cannot be accomplished with its usual ease, DNA-based phenotype prediction is superior to serotyping.

Transfusion

Patients requiring blood transfusion who present with panreactive antibodies pose great difficulty to blood banks. Appropriate antisera in sufficient volume are necessary to screen for compatible antigen-negative blood donors. Moreover, in polytransfused patients, persisting transfused red cells hamper a definitive RBC antigen profile and hence antibody identification.[13] Genotyping is important in determining the true blood group of many polytransfused patients, can assist in the identification of suspected alloantibodies, and can help perform a more accurate selection of antigen-negative RBCs for transfusion.

Altered Expression of the D Antigen

Rh phenotyping may be inconclusive when erythrocytes possess a reduced expression of the D antigen. Limiting antibody sensitivity often hampers serological discrimination of such RhD phenotypes. Moreover, the use of monoclonal antibodies may fail to detect some weak D antigens.[13] In these cases with reduced antigen density, DNA-based analyses may be better than serological typing in inferring the true phenotype. Discrimination of *RHD* variants, such us partial D and weak D alleles, from the prevalent *RHD* allele would be advantageous to guide optimal RhD transfusion strategies or anti-D prophylaxis, considering the possibility of anti-D immunizations in these phenotypes that express aberrant RhD proteins.[6]

CONCLUSION

Molecular methods can be applied to overcome the limitations of classical hemagglutination for blood grouping. Both methodologies, in conjunction, are beneficial when attempting to identify antigen incompatibilities between a pregnant woman and the fetus. They are undoubtedly useful not only for diagnosing an Rh incompatibility but also for guiding therapeutic options to prevent Rh immunization. Molecular genotyping constitutes a supplemental technique to hemagglutination tests for the determination of the true blood group antigens in cases of warm-type autoimmune hemolytic anemia and polytransfused patients. It is also a useful tool for the selection of compatible blood units for alloimmunized patients. *RHD* genotyping in individuals with altered expression of the D antigen may be better than agglutination assays in inferring the appropriate phenotype when serology is inconclusive for deciding transfusion therapy or anti-D prophylaxis.

Ribotyping

Tim J. Inglis
PathCentre, Perth, Western Australia, Australia

INTRODUCTION

Ribotyping describes a series of methods used to characterize the ribosomal DNA operon in bacteria and other more complex organisms. In bacteria, rDNA is organized into the 16s, 23s, 5s, and spacer sequences. As ribosomal DNA is present in all bacteria and corresponds to genus and species, it has proved useful for identification and taxonomic and subtyping applications. The importance of rDNA to bacterial survival is reflected in the multiple copies present in most species.

TECHNICAL DESCRIPTION

Early ribotyping methods used digestion of extracted rDNA with restriction endonucleases, separation of rDNA fragments by electrophoresis, and hybridization with a cDNA probe in a Southern blotting process.[1,2] Unlike conventional restriction fragment length polymorphism (RFLP) analysis, which resolves the difference between bacterial isolates by comparison of ethidium bromide-stained DNA bands, ribotyping uses a cDNA probe to resolve differences between isolates by generating a smaller number of bands. The number of bands will depend on how many fragments the cDNA can hybridize to and therefore the number of cutting sites for the restriction endonuclease.[3,4] REs employed for ribotyping are frequent cutters such as *Eco*R1, *Bam*H1, and *Pvu*2, but some species require less commonly used restriction endonucleases such as *Pvu*2.[5] DNA probes hybridize to either 16s or 23s rDNA or both. Ribotyping probes include an *Escherichia coli* DNA and other sequences.[6,7] The membrane used for blotting can be either nitrocellulose or nylon, and the labeling system can be a fluorophore, digoxigenin, or a radioisotope.

Several variations have been introduced to adapt ribotyping for wider use. A version of ribotyping based on digestion with *Eco*R1, an *E. coli* cDNA probe, and a fluorescent tracer has been automated to simplify and speed up the procedure[8](Fig. 1). In PCR ribotyping, PCR primers to highly conserved regions of the 16S–23S intergenic spacer region are used to amplify the product for subsequent length polymorphism analysis.[9]

In outline, the manual ribotyping method is as follows:

1. Bacterial DNA extraction (phenol-chloroform, guanidium, etc.).
2. DNA check (concentration and mini-gel).
3. Digestion with restriction endonuclease.
4. Preparatory gel for blotting.
5. Southern blot.
6. rDNA digoxigenin labeling.
7. DNA marker ladder digenin labeling.
8. Prehybridization.
9. Hybridization.
10. Wash and development.
11. Ribotype pattern recording and analysis.

SPECIFICITY

As all bacteria have rDNA, ribotyping is theoretically practicable for all bacterial species. In the Enterobacteriaceae, the presence of 5–7 rDNA operons results in 10–15 bands, with potential for a good level of discrimination between strains of a given species.[10] On the other hand, Mycobacteria have only 1 or 2 rDNA operons and produce few bands on ribotyping with a correspondingly lower level of discrimination.[11] Southern blotting with alternative probes specific to mycobacteria (e.g., IS 6110 for *Mycobacterium tuberculosis*) has been much more productive for these bacteria.[12] The limited genetic diversity of some important gram-negative pathovars, such as *E. coli* O157, renders ribotyping less suitable for molecular epidemiology of these.[13] On the other hand, bacteria such as *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Listeria monocytogenes* can be effectively subtyped by ribotyping.[14–16] A large proprietary database of *Eco*R1 ribotypes obtained with the automated system exists for these bacteria. The automated method has been adapted for use with other restriction enzymes (e.g., *Pvu*2 and *Pst*1) but is not easily adapted to the other probes used in manual ribotyping protocols. Clearly, most ribotyping methods have been developed for highly specialized purposes, the details of the method being specific to the application. Each method requires validation against a representative collection of the

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120025608

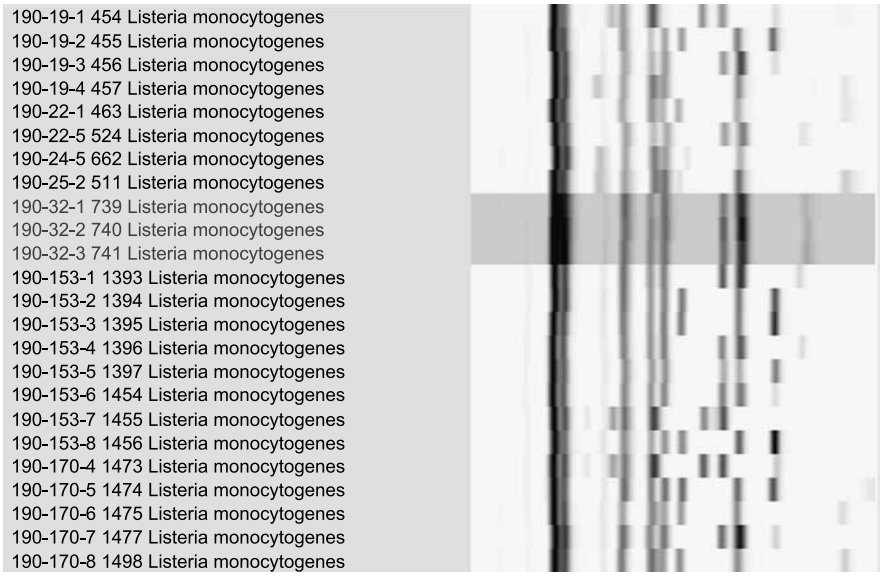

Fig. 1 *Eco*R1 ribotype patterns generated from *Listeria monocytogenes* analyses, showing highlighted cluster of indistinguishable isolates. (From L O'Reilly, PathCentre.)

species in question. The taxonomic value of the information generated by ribotyping therefore depends on the intraspecies variability of the rDNA operon, the number of copies present, the restriction endonuclease used, the cDNA probe, the range of strains already ribotyped, and the epidemiological setting from which the isolates were obtained. Ribosomal DNA has been used as an important arbiter of taxonomic status in determinative bacteriology.[17] Whereas this may be generally true down at species level, there have been reports of species that cannot be distinguished by 16s rRNA studies that have subsequently been resolved by DNA–DNA hybridization.[18] Ribotyping should thus be seen as less discriminating than DNA hybridization studies and therefore taxonomically subordinate. The automated ribotyping procedure is less suited to discriminating closely related fragments from some pathogens than traditional *Eco*R1 ribotyping, thus reducing its capacity to discriminate between strains.[19]

SENSITIVITY

Ribotyping requires only small amounts of high-quality bacterial DNA extract, particularly if the automated process is used. The use of a DNA hybridization probe reduces the sensitivity of band detection compared with conventional RFLP analysis, but, in doing so, improves the readability of the result.

REPRODUCIBILITY

Ribotyping is more reproducible than conventional RFLP analysis. As this is due in part to the specificity of the technique, the ribotype patterns obtained by a given method can give a higher reproducibility when a combination of several REs is used.[20] In the automated procedure, molecular markers and image optimization software are used to increase between-batch reproducibility so that band patterns can be compared with archived patterns using a computerized similarity index.

ROBUSTNESS

The various manual methods of ribotyping depend on a high level of technical skill, take a lot of dedicated laboratory time to complete, and are generally restricted to larger research laboratories.[21] Nevertheless, once established, the method is robust because a positive result depends on hybridization of digested bacterial rDNA with a specific probe. Automation of one of the more commonly used protocols has reduced the technical skill and dedicated time required without affecting the overall robustness of the method.

LIMITS

Ribotyping is limited mainly to analysis of bacterial species and has variable utility depending on the genera in

question. Ribotyping can be used to discriminate or identify as far as species level for most bacteria. Some species (e.g., Mycobacteria and some Enterobacteriaceae) cannot be reliably subtyped by this method without resorting to either multiple procedures (each with a different restriction endonuclease) or alternative probes (Southern blotting but not ribotyping,[12]). Ribotyping is not a satisfactory alternative to DNA hybridization studies as a final arbiter of taxonomic status[18] but can be used to gain an approximate assessment of taxonomic placing where the hybridization studies have already been performed.[17] At a practical level, the skills, time, and equipment required make manual ribotyping unsuitable for routine bacterial identification or molecular epidemiology service work.[21] Some of these shortcomings are met by the automated *Eco*R1 protocol.

CLINICAL APPLICATIONS

Ribotyping has seen wide application as a molecular epidemiology tool in clinical bacteriology.[3,8,10,13–16,19–21] It has often been used to complement other molecular typing methods such as DNA macrorestriction analysis when used in epidemiological investigations.[8,10,15,16,21,22] The most common of these applications are in hospital infection control and public health outbreak investigations where ribotyping is used to identify a cluster of isolates to confirm or refute preliminary epidemiological inferences.[23] In this setting, it has been argued that ribotyping is suitable for a wide range of typing applications.[22] More recently, the speed of automated ribotyping has made this version of the method more attractive to public health laboratories with a biosecurity role.[24] Larger reference laboratories have also found a use for ribotyping as one of a series of methods used to complete the identification and typing of species of uncertain status.

CONCLUSION

Ribotyping, or the characterization of the ribosomal DNA operon, has become an established analytical tool for bacteria and other more complex organisms. Automation of what was previously a lengthy experimental procedure now ensures that this technique can be used for a wide variety of molecular epidemiology tasks. The use of ribotyping, in connection with other genotyping procedures, is likely to play an increasing part in laboratory-based investigations of hospital- and community-acquired infections.

RNA Storage

Martin Hofmann
Institute of Virology and Immunoprophylaxis, Mittelhaeusern, Switzerland

INTRODUCTION

RNA can be isolated from many different types of cells from eukaryotic and prokaryotic origin, including animals, plants, and bacteria. Depending on the source and the type of sample (organ tissue, cultured cells), appropriate procedures must be applied for RNA extraction to 1) maintain the integrity of the RNA, 2) inhibit RNA degradation because of RNases, and 3) obtain clean RNA preparations by removing protein and DNA contaminations.

Because RNA extraction can be quite a lengthy procedure and, furthermore, in many cases, numerous samples have to be analyzed in parallel, it is necessary to store the isolated RNA. Again, storage conditions should be selected to preserve the RNA in such a way that storage does not modify the RNA in any way. However, the intended use of the stored RNA also determines the way how the RNA is to be stored.

In this article, an overview of currently used techniques to obtain RNA from various sources and a description of the factors to consider for RNA storage are presented.

HANDLING OF RNA: THE PROBLEM OF RIBONUCLEASE CONTAMINATION

The isolation of intact, clean RNA is crucial for downstream experiments such as reverse transcription of RNA for cDNA cloning, RNA fingerprinting and secondary structure analysis, as well as for functional studies involving RNA metabolism. RNA stabilization is an absolute prerequisite for reliable gene-expression analysis. Stabilization of RNA in biological materials immediately after harvesting the sample is necessary because changes in the gene-expression pattern occur because of specific and nonspecific RNA degradation as well as to transcriptional induction.

Even a single nick can render the RNA molecule nonfunctional. This has to be considered when gene expression is studied by performing in vitro transcription and translation experiments, or transfection of infectious, self-replicating viral RNA.[1]

Whereas double-stranded RNA is relatively resistant against most RNases,[2] particular care must be used when handling single-stranded RNA.

The most important factor determining the quality of the RNA to be studied is the ubiquitous presence of RNases. This is a group of RNA-degrading enzymes, each acting in a sequence-specific way on double- or single-stranded RNA. Furthermore, some RNases such as RNase A are extremely resistant to inactivation by heat. For this reason, a suitable method for RNA extraction must be chosen which allows instant inactivation of RNases. This is achieved by dissolving proteins in denaturing agents such as guanidinium thiocyanate, phenol, or beta-mercaptoethanol.

To avoid or minimize ribonuclease contamination problems, all materials used for working with RNA should be RNase-free. Water should be treated with diethylpyrocarbonate (DEPC) that inactivates nucleases or should be obtained by ultrafiltration through a high-efficiency organics removal system. Glassware must be baked at least for 4 hr at 180°C because autoclaving does not inactivate ribonucleases completely. Plasticware straight out of the package can generally be considered free from nuclease contamination and can be used without any pretreatment. However, reused plasticware such as electrophoresis tanks should be filled with 3% H_2O_2 solution for 10 min at room temperature, followed by thorough rinsing with RNase-free water. Because hands are a major source of RNase contamination, gloves must be worn and changed frequently. It is also a good idea to keep separate stocks of chemicals that are exclusively used for RNA work and are removed from the bottle only with RNase-free tools (e.g., baked spatula).

Several types of specific RNase inhibitors can be used. 1) Protein inhibitors of RNases, either isolated from human placenta or produced synthetically as a recombinant protein, can be added to the extracted RNA. Furthermore, because these RNase inhibitors generally do not interfere with reverse transcriptases and polymerases, they are frequently used to prevent RNA degradation during subsequent reactions such as reverse transcription. 2) Vanadyl–ribonucleoside complexes (VRC) bind to many RNases thereby inhibiting their activity. VRC can

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120022641

be added to the intact cells or tissue before lysis and remain in the RNA-containing fraction during all stages of RNA extraction and purification. However, VRC can only be used for certain in vitro enzymatic reactions (e.g., reverse transcription), whereas they interfere with others such as cell-free in vitro translation of mRNA.

Numerous commercial products for RNA extraction are available today. Most of them are either based on a combination of guanidinium isothiocyanate and phenol based on a single-step RNA isolation method originally described by Chomczynski and Sacchi[3] followed by RNA precipitation, or by binding of RNA in guanidinium-lysed samples to a silica-gel membrane from which the RNA is subsequently eluted after washing. These methods allow disruption of the cells and simultaneously inactivate ribonucleases.

PRINCIPLES OF RNA STORAGE

Basically, RNA can be stored in purified form after its extraction or synthesis, or unprocessed samples containing the RNA of interest are stored. However, even in the latter case, proper care must be taken to avoid (re) contamination of RNA with RNases once it is extracted from the stored sample.

Little information is available on the long-term stability of isolated and purified RNA during storage. Most studies have been carried out focusing on various storage conditions of unprocessed samples before RNA extraction, or the material was stored at the stage of lysed cells or tissue but before RNA was isolated.

Storage of Extracted RNA

Depending on the extraction method used, purified RNA is either being eluted directly from a filter or column after ion exchange chromatography, or it is obtained as a pellet after precipitation with ethanol or isopropanol. Irrespective of the storage conditions, it is of great importance that all materials (glassware and plasticware, chemicals, water, etc.) are free from RNase contamination.

The most common way to store RNA is by dissolving it in RNase-free water and freezing at $-70°C$. This bears the advantage that the RNA can be used virtually for any subsequent experiments without having to worry about interference of the storage medium with the reaction conditions in the experiments. However, RNA stored in water is prone to degradation because of unfavorable pH, as well as traces of RNases. For this reason, RNA should be dissolved in or eluted with a low salt buffer such as 1 mM sodium citrate or TE (10 mM Tris, 1 mM EDTA) at pH<7, thereby preventing base hydrolysis by chelating free cations present in the RNA preparation.

If the higher-order structural integrity of the RNA is crucial, it should be stored in a buffer with an increased salt concentration to maintain hybridization of double-stranded RNA as well as self-complementary sequence elements (stems, pseudoknots) in single-stranded RNA. This is particularly important if such RNA is to be analyzed for secondary structure elements by targeted chemical/enzymatic degradation.[4,5]

Stabilized formamide (FORMAzol®, Molecular Research Center, Inc., Cincinnati, OH) can be used to dissolve precipitated RNA. It allows to store the RNA for at least 2 years at $-20°C$, whereas RNA dissolved in aqueous solutions should always be kept at $-70°C$. However, formamide must be replaced by water if the RNA is to be used in any in vitro enzymatic reaction.

To avoid RNA degradation as a result of multiple freeze thawing, it is recommended to store the RNA in small aliquots rather than in one single volume.

As an alternative to storing in solution, RNA can also be kept frozen or even at room temperature as a precipitate that is often obtained anyway at the end of the extraction procedure. Aliquots are removed from the precipitate after vortexing, and the RNA is pelleted by centrifugation and redissolved under RNase-free conditions immediately before use.

Storage of Samples Before RNA Extraction Under RNA Stabilizing Conditions

Samples containing the RNA of interest can also be stored prior to RNA extraction. Tissue or cells are allowed to be perfused by chemicals that inhibit RNase activity by denaturing all proteins. A rapid inactivation of enzymatic activity in the sample is required, in particular, in gene expression studies where any induction or repression of mRNA transcription because of changed environmental conditions must be prevented immediately after specimen collection to reflect the expression profile of the intact tissue.

It has repeatedly been shown that Trizol®, a monophasic solution of phenol and guanidinium isothiocyanate (Invitrogen Life Technologies, Carlsbad, CA), can be used to store samples for extended periods of time even at ambient temperatures, without a significant decrease of the quantity or quality of RNA.[6,7] Therefore, storage of samples in Trizol should be considered whenever samples cannot be kept frozen immediately after collection.

Recently, another commercially available product, RNAlater® (Ambion, Austin, TX), has been introduced on the market. RNAlater® is a patented aqueous, nontoxic tissue and cell storage reagent that stabilizes and protects

cellular RNA in intact, unfrozen tissue and cell samples by quickly permeating the tissue.[8] It allows to store collected tissue specimens and cells at 4°C or even at ambient temperature, eliminating the need for 1) immediate snap-freezing of tissue in liquid nitrogen after collection and 2) instant RNA extraction. Most of the commonly used techniques can be used to extract RNA from RNAlater®-treated samples. RNAlater® has been shown to be suitable for RNA stabilization in animal and plant tissue and cells as well as in bacteria. Further information is available from Ambion's Web site at http://www.ambion.com.

Storage of Unprocessed Samples

Tissue, cell, and serum samples can also be stored in a native, unprocessed form. However, to block RNA degradation as soon and as efficiently as possible, specimens should be frozen immediately after collection, and thawing and refreezing before RNA extraction must be avoided. It has been shown repeatedly that handling and storing conditions of diagnostic samples have a significant impact on the RNA levels detected by RT-PCR.[9–11] Tissue samples collected for gene expression studies should be snap-frozen in liquid nitrogen. All samples should be stored at −70C at all times.

CONCLUSION

There is no universally applicable ''ideal'' method for storing RNA. The procedure to be chosen is dependent on the source, the kind, and the intended use of the RNA. The most important factor that determines the quality of the stored RNA is the ability to protect the RNA from degradation by RNases. Therefore, if purified RNA is stored, RNase-free tubes and solutions are crucial, and the RNA should be stored frozen at temperatures as low as possible. Thawing and refreezing should be avoided.

If storage or shipment in a frozen state is not possible, samples from which RNA is to be extracted should be kept in a protein-denaturing agent to prevent RNase activity. For gene expression studies, any ongoing mRNA transcription activity should be suppressed as soon as possible after sample collection by snap-freezing the samples or by storage in an excess volume of RNA-stabilizing agent.

Detailed protocols for RNA extraction and storage can be found in molecular biology laboratory manuals.[12,13]

Rolling-Circle Amplification (RCA)

R

Vadim V. Demidov
Boston University, Boston, Massachusetts, U.S.A.

INTRODUCTION

The rolling-circle amplification (RCA) reaction is an isothermal in vitro method for the hybridization-triggered enzymatic synthesis of hundreds to billions of linear copies of small, single-stranded, circular DNA probes. Thus, obtained long repeats of DNA sequences may serve as a signal amplifier for ultrasensitive detection of specific nucleic acids and other biologically important molecules in diagnostic genomics and proteomics. Depending on the goal and/or target molecule to be detected, RCA is performed using a variety of protocols and testing formats with either linear or exponentially branching kinetics. Because of their robustness and simplicity, the RCA-based assays hold a distinct position in the area of molecular diagnostics among other single-temperature amplification techniques.

RCA BASICS

RCA is based on the rolling replication of short, single-stranded DNA circles by certain DNA polymerases at constant temperature, the process discovered in the mid-1990s.[1,2] This reaction is initiated by the hybridization of a linear DNA single strand to a specific DNA minicircle, and it is widely used for diagnostic purposes in direct or indirect detection of different DNA/RNA, protein, and other biomarkers via a set of various biomolecular recognition events. A similar reaction was described for RNA polymerases as well,[3] but the RNA-generated process does not require any hybridization-dependent priming (or even promoter sequences). Therefore, the latter is only used to produce functional RNA sequences, such as RNA ladders and self-processing ribozymes.

Description of Method

Types and major features of RCA reactions

In its original formulation,[1,2] the RCA reaction involves numerous rounds of isothermal enzymatic synthesis in which DNA polymerase extends a circle-hybridized primer by continuously progressing around the circular DNA probe of several dozen nucleotides to replicate its sequence over and over again (Fig. 1A). This process is characterized by linear kinetics, easily yielding in one hour up to several thousands of sequence-complementary tandem repeats of an original DNA minicircle. These amplification products generally exhibit a wide, essentially continuous distribution over length and are normally seen in gel-electrophoretic images as a broad smear of high-molecular weight DNAs (Fig. 2, lane 2). The single-stranded nature of amplicons in case of linear RCA may be beneficial for subsequent manipulations with these DNAs towards their detection.[4]

A more complicated version, the double-primed RCA, called hyperbranched,[4] ramification[5] or cascade RCA,[6] operates with a pair of different primers. One primer is complementary, as in the linear RCA, to a DNA minicircle, whereas the other is targeted to the repeated, single-stranded DNA sequences of the primary RCA product.[4–6] Consequently, the double-primed RCA proceeds as a chain reaction with geometric kinetics featuring a ramifying cascade of multiple-hybridization, primer-extension, and strand-displacement events involving both primers (Fig. 1C). As a result, a discrete set of concatemeric double-stranded DNA (dsDNA) fragments is formed, yielding the distinct, ladder-type gel-electrophoretic bands (Fig. 2, lane 3).

Sometimes, this reaction produces amplicons so long that they cannot move through the gel during common gel electrophoresis (see lane 4 in Fig. 2). In terms of the degree of amplification, the geometric RCA is more potent, as compared with its linear alternative, yielding 10^9 or more copies of a circular sequence in about an hour.[4,6] Accordingly, it enables a bioanalyst to readily detect just a few probe molecules.[4–8] The double-primed RCA is usually performed at elevated temperatures by thermostable DNA polymerases, although in some cases it is performed by common polymerase enzymes at physiological or ambient temperatures.

Practical RCA formats

Generally, the RCA-based diagnostics can be classified into two groups: some of them operate with the preformed circular probes [Fig. 1D and E for the peptide nucleic acid (PNA)-assisted, nick-induced RCA and immuno-RCA,

DOI: 10.1081/E-EDGP 120020704

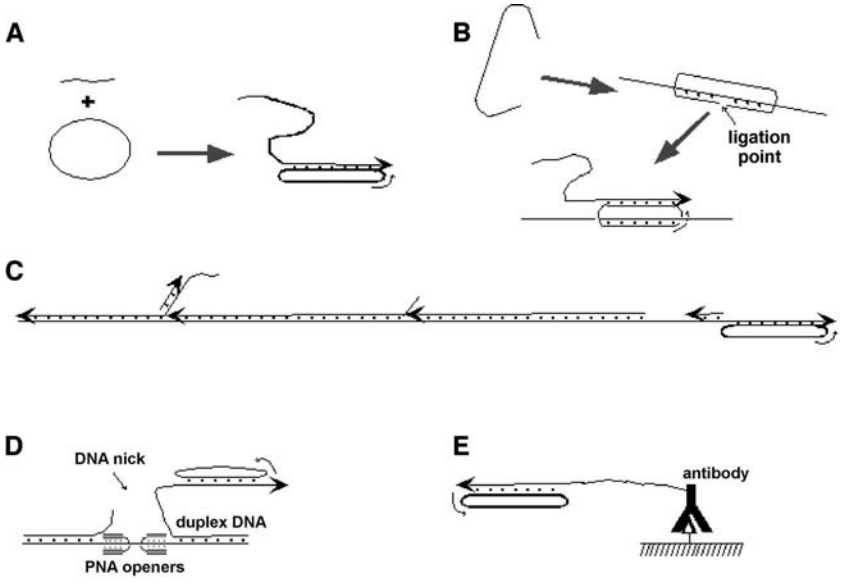

Fig. 1 Schematics of different RCA processes; the arrowhead symbolizes the DNA polymerase. Given a small, $\leq$100-nt size of DNA minicircles used in RCA and the strong rigidity of dsDNA fragments with these lengths, only part of the circular probe can be base-paired at any given time. Consequently, the geometry of RCA-generating complexes resembles a fiddlestick. (A) The RCA reaction carrying on a free DNA minicircle with the use of a single primer. If the DNA target is used to prime the RCA reaction, amplification products are fixedly linked to target molecules (see schematics D, for example). For surface-attached targets, these products will be immobilized on the solid phase. (B) RCA-based diagnostics of probe amplification with an in situ circularized linear oligonucleotide probe and a target-unrelated primer (ligation–RCA/L–RCA). In some cases, the topological linkages between a DNA minicircle and the marker/target DNA site may affect the rolling replication. A circular probe should then be released from the DNA target following the hybridization. (C) Initial stages of the double-primed RCA.[4–6] In these reactions, the second primer, which is complementary to the original RCA product, is used. Here, the DNA polymerases capable of strand-displacement synthesis are necessary. (D) The RCA reaction, which proceeds on dsDNA if assisted by PNA openers and DNA nicking.[14] (E) In immuno-RCA, the 5′ end of a primer is attached to a reporter antibody, which selectively binds to a test analyte immobilized on a solid surface.[7]

as examples], whereas others involve the circularization of hybridized linear probes by ligation followed by RCA (L-RCA; Fig. 1B). In the latter case, the in situ assembled DNA minicircles, called padlocks and earrings,[9–13] provide the corresponding DNA/RNA diagnostic assay with a higher sequence specificity, which is warranted by a multiple (at least dual) probe–target recognition and is also owing to the fact that mismatches close to the ligation point severely interfere with the ligation process. Importantly, padlocks and earrings ensure a higher stability of hybridization complex because of additional topological stabilization through the probe–target concatenation.[13] All this improves the hybridization stringency, allows one to more efficiently distinguish single-base sequence variants, and results in a highly localized hybridization/amplification signal retaining the positional information.

Further localization of the RCA-generated signal to essentially single visible points can be reached by condensation of amplication products after their hybridization to labeled oligonucleotides, known as RCA-CACHET.[4] In this way, the RCA amplicons are tagged with fluorescent labels at multiple sites in the tandem RCA-amplified DNA sequence. Thus ''decorated'' amplicons can be compacted into tiny objects by cross-linking with multivalent proteins, such as streptavidin and antibodies, which bind to amplicon-incorporated tags. If necessary, further increase of the RCA-generated signal to a superexponential level can be achieved by combining the RCA and PCR reactions.[5] Until recently, the RCA reactions have been run only on the single-stranded DNA and RNA targets, but, with the aid of PNA openers, these reactions can now be performed with dsDNA.[12,14] In immuno-RCA assays, the attachment of a reporter antibody to an RCA primer makes it possible to extend the RCA-based diagnostics on the non-nucleic-acid analytes, including proteins, which can be detected with superior sensitivities, compared to conventional enzyme immunoassays in ELISA and microparticle formats.[7]

The RCA-based analyses can be executed both as homogeneous assays in solution and as heterogeneous ''on surface'' assays, including the microtiter plate and microarray approaches for high-throughput genomics and

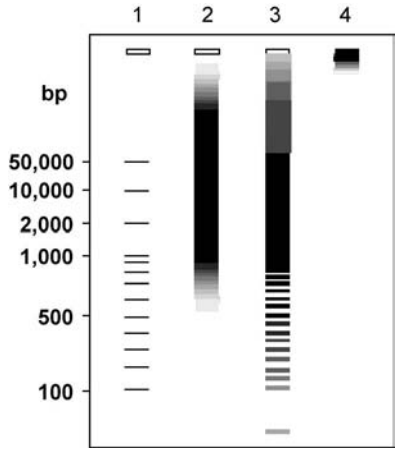

Fig. 2 Typical patterns of the RCA products generated with linear or geometric kinetics and resolved by gel electrophoresis (SYBR green or ethidium bromide staining). Usually, linear amplification is characterized by smearlike amplicons corresponding to essentially continuous distribution of single-stranded RCA products over length (lane 2). On the contrary, ladder-like amplicons are normally observed after geometric amplification representing linear concatemeric double-stranded copies of a circular template (lane 3). In some cases, most of the RCA products are so large that they cannot enter the gel (lane 4). Lane 1 corresponds to the size marker.

proteomics studies.[15,16] The RCA amplicons can be detected in several ways, such as fluorescence,[7] radiolabeling,[10] UV absorbance, and gel electrophoresis[4,12] by using either direct incorporation of various labels into the RCA products[10] or label-decorated amplicons.[4,7] Since it is not possible to even briefly describe this whole diverse range of RCA testing formats, the interested reader is referred to recent reviews[17,18] and corresponding original papers.

Specificity, sensitivity, and reproducibility

The RCA-based diagnostics exhibit an exceptional specificity for particular DNA/RNA sequences, as well as for marker molecules other than DNA/RNA, allowing the multiplex genotyping/detection of single-base mutations and specific antigens. Besides, RCA is an ultrasensitive method of detection: a variety of RCA formats permit essentially single-molecule counting of the DNA, RNA, or protein targets and some other analytes. Furthermore, RCA-based diagnostics are characterized by good reproducibility, with amplification errors being at a lower level compared to PCR. Consequently, such an exquisite sensitivity makes it possible to accurately and reliably quantify the gene copy number as well as to detect single-copy genes, discrete antigen–antibody complexes, and mRNA expression levels in individual cells.

Advantages and Limitations

RCA has several substantial advantages over other amplification techniques, which could be called ''the power of simplicity.''[17] Most importantly, RCA is an isothermal procedure and, therefore, has no need of special instrumentation to cycle the temperature, which is required with the widely used PCR-based diagnostics. This RCA feature significantly simplifies the automation and miniaturization of RCA-based diagnostics. In addition, RCA can be performed by a larger variety of DNA polymerases compared to PCR, which relies on only thermostable enzymes. Besides, RCA represents an inexpensive, more error-proof, and more sensitive (compared to PCR) analytical technology with a very wide dynamic range and higher multiplexity to serve as a potent alternative to the thermocycling diagnostic methods.

In comparison with other isothermal methods of signal, probe, or target amplification, such as transcription-based amplification, strand-displacement amplification, use of branched (or dendrimeric) probes, invasive signal amplification, or loop-mediated amplification, the RCA-based assays are less complicated and in many cases do not require any substantial preoptimization of an experimental protocol, thus being readily used by a beginner. RCA is the most flexible and adaptable amplification methodology featuring merely few drawbacks. The shortcoming of supersensitive RCA assays is that they require certain caution to avoid possible contamination/false positives. In some cases, release of probes from the hybridized targets and removal of the nontargeted DNA strands by additional treatment with endo- and exonucleases are also necessary to reach the requisite sensitivity of detection.[10,19]

CLINICALLY RELEVANT PILOT APPLICATIONS

The practical RCA potential to identify nucleic acid targets, antibodies, and antigens in clinical samples has recently been demonstrated in several feasibility studies. Specifically, the RCA-based protocol for an automated scoring of single nucleotide polymorphisms (SNPs) in a set of human genomic DNA samples with the nanogram sensitivity was developed.[15,20] Highly sensitive multiplex detection of hotspot somatic mutations present at very low abundance was also reported.[21] The RCA capability for pathogen diagnosis was convincingly proved by comparative study of RCA vs. PCR and ligase chain reaction (LCR) in detection of *Chlamydia trachomatis* in cervical specimens.[22] The workability of immuno-RCA for identification of allergen-specific immunoglobulins in samples from patients was shown in a microarray format.[23] In addition, RCA has been

adapted to immunohistochemistry, flow cytometry, and in situ hybridization to significantly improve their sensitivity without compromising cellular and tissue morphology.[24,25] RCA-mediated multiplex profiling of cytokines on microarrays with femtomolar sensitivity offers an advantageous approach for proteomic surveys.[16] All these pilot applications establish the firm basis for future clinical use of RCA methodology in a range of diagnostic applications, enabling the integration of genomic and proteomic information into cell- and tissue-based tests.

CONCLUSION

The RCA methodology represents a powerful and simple procedure for signal amplification that may serve as universal platform for in vitro diagnosis of a variety of biomarkers based on either nucleic acid sequence or antigenicity. Consequently, this technology should soon provide the laboratory researchers and clinical diagnosticians with highly sensitive and efficient customary diagnostic assays to expedite and to facilitate testing of miscellaneous analytes.

Rotavirus

C. Anthony Hart

INTRODUCTION

Diarrheal disease is the fourth commonest cause of death worldwide and most of the deaths are in children in developing countries. Rotavirus is the major cause of diarrheal disease in children and is increasingly recognized as a problem in adults. The virus is unenveloped and has a characteristic double-shelled capsid (80 nm) with a double-stranded RNA genome. The genome comprises 11 linear segments and each segment encodes one or more virus proteins. The polypeptides are highly variable and thus genetic and antigenic changes occur by mutation (antigenic drift), genome rearrangement, genome reassortment (antigenic shift), and cross-species transmission of animal rotaviruses. Infection can be diagnosed by antigen detection (ELISA) or detection of the genome by reverse transcriptase-PCR (RT-PCR) or polyacrylamide gel electrophoresis (PAGE) of RNA extracted from feces.

THE VIRUS

Rotavirus is a medium-sized (70–80 nm) unenveloped round virus (Fig. 1), with a characteristic wheel-shaped morphology (rota is Latin for a wheel). *Rotavirus* is a genus within the family Reoviridae.[1,2] Its genome consists of 11 segments of linear double-stranded (ds) RNA which range in size from 0.6 to 3.3 kbp.[3,4] Each segment encodes one or more polypeptides (Table 1). The polypeptides expressed are either nonstructural (NSP1–5) or structural (VP, virus proteins) proteins. The nonstructural proteins are involved in virus replication and are found only in the infected cell. The mature virion has a trilayered structure (Fig. 2). The inner layer is composed of 11 dsRNA segments surrounded by VP1, VP2, and VP3. The middle layer or inner capsid is composed of VP6 and the outer layer is made up of two proteins VP4 and VP7. VP4 is cleaved by proteolysis to produce VP5* and VP8* and if this does not occur the virus is not fully infective. There are 60 spikes or knobs that extend 120 Å from the virion surface.[3] The virion has icosahedral symmetry with 132 surface capsomers and a triangulation number T13. There are 132 large channels that traverse both the inner and outer capsid layers.

REPLICATION AND PATHOGENESIS

Rotavirus was not maintained in artificial culture until it was realized that proteolytic cleavage of VP4 was required for full infectivity. Thus culture in a variety of cells including MA104 is achieved by including trypsin in the culture medium. Some rotavirus strains attach to their cellular receptor (acetylated sialic acid) via VP5*. However, recent work has shown that sulfated sialyl lipid inhibits rotavirus attachment to MA104 cells in vitro and prevents rotavirus infection in mice. Following attachment, some rotaviruses enter host cells by receptor-mediated endocytosis, but others, particularly following trypsin pretreatment, enter directly by membrane permeabilization. Uncoating of rotavirus to release dsRNA is facilitated by low intracytoplasmic [Ca^{2+}]. Virus replication takes place entirely in the cytoplasm. The majority of VP and NSP are synthesized on cytoplasmic ribosomes but the glycoproteins, VP7 and NSP4, are synthesized on the rough endoplasmic reticulum. Subviral particles assemble in cytoplasmic viroplasms and then, facilitated by NSP4, bud through the endoplasmic reticulum transiently acquiring a membrane. The lipid is gradually replaced by a thin protein layer which becomes the outer capsid as the virion matures. The progeny virions are then released by cell lysis.

During the peak of rotavirus replication, infants excrete up to 10^{11} virus particles per milliliter of stool. The infective dose is of the order of 10^2 virus particles. Rotavirus infects the mature villous enterocytes of the small intestine. It cannot infect immature crypt cells or colonic enterocytes. In addition to acetylated sialic acid and sulfated sialyl lipids, some human rotaviruses bind to integrins. Four mechanisms have been suggested for rotavirus-induced diarrhea.[3,4] First, within 12–24 hr following infection small intestinal brush border disaccharidase enzyme levels fall to less than one-third of normal. This is a result of rotaviral inhibition of transport of disaccharidases to the microvillar membranes. Dietary

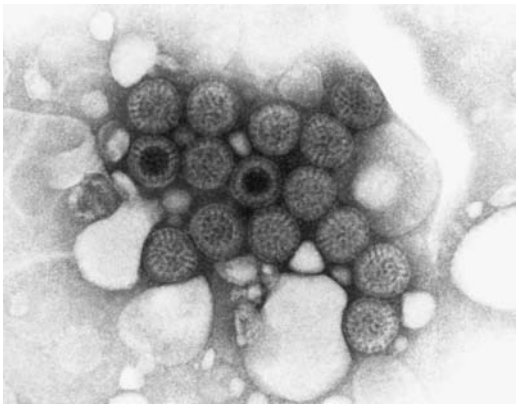

Fig. 1 Negative stain electron micrograph of rotavirus.

disaccharides must be broken down to monosaccharides as only monosaccharides can be absorbed. If they accumulate in the gut lumen then they hold water leading to an osmotic diarrhea. Recently, it has been found that NSP4 or even a 22-amino acid fragment from it can induce diarrhea in neonatal mice when administered orally or intraperitoneally.[5] It is thought that NSP4 acts as an exterotoxin causing diarrhea by opening a cellular cation channel which causes an increase in intracellular [Ca^{2+}], activation of adenyl cyclase, and cAMP-dependent Cl^- secretion. This causes a secretory diarrhea in a manner analogous to some bacterial enterotoxins.[6] Rotavirus is released from enterocytes by lysis and the increased cytoplasmic [Ca^{2+}] causes enterocyte death by oncosis. Thus the rate of dying of villous enterocytes exceeds the rate of production of new enterocytes in the crypts. This results in blunting of the villi and subsequent loss of surface area for absorption of fluid, electrolytes, and nutrients. Finally, there is some evidence that rotavirus affects the intestinal neuroendocrine axis which may also contribute to diarrhea. There are suggestions that NSP4 might be involved in each of the above mechanisms.[6]

IMMUNITY

Rotavirus diarrhea lasts on average 5–6 days and seems to resolve as the virus exhausts enterocytes to infect when it reaches the colon. In addition, it appears that T-cell-mediated immunity is important in resolution, at least in mice. Natural rotavirus infection protects against subsequent symptomatic infection but to a lesser extent against virological infection. It is likely that we will all experience a rotavirus infection, usually asymptomatic, every 2–3 years. However, immunity does appear to decrease with age and rotavirus outbreaks are increasingly reported in elderly patients. In a cohort study in Mexican infants the risks of rotavirus disease and rotavirus infection after one, two, or three prior episodes of infection were 0.23, 0.17, or 0.08, and 0.62, 0.40, or 0.34, respectively.[7] However, it is not clear which are the most important correlates of immunity. In several studies, serum IgG and IgA rotavirus antibodies correlate best with protection. Fecal antirotavirus IgA (which reflects duodenal IgA) also reflected protection against infection.

Table 1 Rotavirus genome and gene products

Genome segment	Molecular size (bp)	Gene product	Molecular weight (kDa)	Location in virion	Function
1	3,302	VP1	125	Core	RNA polymerase
2	2,690	VP2	94	Core	RNA binding
3	2,591	VP3	88	Core	Guanylytransferase
4	2,362	VP4 (VP5*+VP8*)	88	Outer capsid	Cell attachment, hemagglutinin, membrane permeabilization, neutralizing antigen (P-serotype)
5	1,581	NSP1	53	Nonstructural	RNA binding (zinc finger)
6	1,356	VP6	41	Inner capsid	Group and subgroup antigen, major capsid protein
7	1,104	NSP3	34	Nonstructural	RNA binding
8	1,059	NSP2	35	Nonstructural	RNA binding
9	1,062	VP7	38	Outer capsid	Glycoprotein, neutralizing antigen (G-serotype)
10	751	NSP4	28	Nonstructural	Glycoprotein, virus assembly, enterotoxin
11	667	NSP5	26	Nonstructural	RNA binding

TYPING, ANTIGENS AND ANTIGENIC VARIATION

Serogroups

Rotaviruses are subdivided into seven groups (Table 2). These serogroups are determined by epitopes on VP6 which forms the inner capsid. Of these, humans are infectable by groups A, B, and C, as are many other animal species. Most human infections are due to group A rotaviruses. Group B rotaviruses are associated with large epidemics of disease in adults and children alike.[8,9] Group C rotaviruses usually cause only mild disease and by adulthood 30% have antibodies. VP6 is the most abundant viral protein (780 molecules per virion) and the group-specific epitopes are localized between amino acids 48 and 75. Although antibodies to group epitopes are nonneutralizing in vitro they do give protection in mice.

Group A rotaviruses can be further divided into subgroups based on other, as yet undefined, epitopes on VP6. Four subgroups are possible: I, II, I and II, and neither.

Serotypes

There are two major serotype antigens: on VP4, the P (protease sensitive) type, and on VP7, the G (glycoproteins) type. These are expressed on the surface of the virus and antibodies to P and G epitopes are protective against infection.

VP4 forms the 60 knobs that protrude from the virion surface. It is nonglycosylated and makes up only 1.5% of the virion protein. Cleavage of VP4 (to VP5* and VP8*) stabilizes the knobs which become icosahedrally ordered. VP5* forms the body and base of the knob in β-pleated sheets and α-helices, respectively, VP8* forms the head in β-sheets, and both are involved in virus entry by permeabilization. Monoclonal anti-VP4 antibodies neutralize infectivity, and by use of such antibodies a number of different P-serotypes have been defined (Table 3).

Table 2 Reservoirs of different rotavirus groups

Group	Reservoirs in which infection has been detected
A	Man, primates, horse, sheep, pig, cattle, dog, cat, turkey, chicken, mice
B	Man, pigs, cattle, sheep, rats
C	Man, pigs, cattle, ferret
D	Chicken, turkey
E	Pigs
F	Chicken
G	Chicken

Table 3 Group A rotavirus P-serotypes and genotypes

[17]		–	Cattle, birds
[18]		–	Horses
[19]		–	Pigs
[20]		–	Mice

Table 4 Group A rotavirus G-types

Sero(geno)type	Host species
1 and 1*	Humans, pigs, cattle
2	Humans, pigs
3	Humans, monkeys, dogs, cats, horses, rabbits, mice, goats
4	Humans, pigs
5	Humans, pigs, horses
6	Humans, cattle
7	Birds, cattle
8	Humans, cattle
9	Humans, pigs
10	Humans, pigs, sheep
11	Pigs
12	Humans
13	Horses
14	Horses

Other P-types have been delineated by RT-PCR and sequencing (P-genotypes), and, unfortunately, P-genotypes do not correspond to serotype designations. VP8* carries the P-specific epitopes whereas VP5* epitopes are cross-reactive. There are 20 different P-genotypes and 12–15 P-serotypes (Table 3). Infection with one P-type does not necessarily protect against infection with the others. By convention P-genotypes are designated by a number in a squared bracket.

VP7 is the major neutralization antigen and comprises 30% of protein in the mature virion. It forms the smooth surface of the outer capsid through which the VP4 knobs protrude. It is a glycoprotein containing N-linked high-mannose oligosaccharides. It is encoded on the seventh, eight, or ninth segment depending upon the rotavirus strain. Its role in viral replication is unclear. Currently, 14 G-serotypes have been defined by use of neutralizing monoclonal antibodies and by RT-PCR. Fortunately, the G-serotypes and G-genotypes coincide (Table 4). Within a particular G-genotype the deduced amino acid sequences are 91–100% similar, but between genotypes the differences are significantly greater. Most of the divergence is represented in nine regions of VP7. Of the variable regions (VR), VR5 (αα 87–101), VR7 (αα 142–152), and VR8 (αα 208–221) are the major neutralization epitopes and escape mutants with point mutations in these regions occur easily.[10] Infection with one genotype does not necessarily impart protection against others.

Electropherotypes and Genogroups

Because there are so many virus particles excreted in the stool of an infected infant it is possible to extract rotavirus dsRNA in sufficient quantities for PAGE. The migration patterns of the 11 dsRNA segments allow rotaviruses to be typed. There are three major electropherotypes: long, short, and super-short. With the short electropherotype, the 11th genomic segment is larger than usual and thus migrates more slowly resolving between the 9th and 10th segments. With the super-short electropherotype, the 11th segment is even larger. By using radiolabeled, positive sense single-stranded RNA transcribed from viral cores in Northern blots at high stringency, it is possible to subdivide group A rotaviruses into two major genogroups. These are named for the prototype strains, namely, Wa (genogroup 1) and DS-1 (genogroup 2). The Wa genogroup viruses are generally long electropherotype, subgroup II with VP4 P[6] or P[8] and VP7 G1, G3, or G4 genotypes, whereas the DS-1 genogroup are usually subgroup I, short electropherotype, and P[4] and G2 genogroup. However, these broad subdivisions are being eroded by the tremendous variability of rotaviruses infecting man and other animals.[4]

Variability

Rotavirus populations can alter by point mutation (antigenic drift), genome rearrangement, genome reassortment (antigenic shift), and zoonotic introduction. The rotaviral genome is replicated by an error-prone RNA-dependent RNA polymerase and there is no proofreading capacity. This results in a mutation rate of one mutation per genome replication which is of the same order of magnitude as that of influenza A virus. Sequence variation has been most studied in the genes encoding VP7 and VP4, and there is more and more evidence of divergence from the original G-types.[4] Thus G1 and P[8], which globally represent some of the most common genotypes, have drifted sufficiently to require design of new primers for RT-PCR detection.[4] For example, P[8] rotaviruses can currently be divided into three lineages (Wa-like, F45-like, and OP354-like) on the basis of deduced amino acid substitutions at 11 sites on the VP4 protein. Similar variability in NSP4 even in the toxic peptide region is common.[4] Variability in non-group A rotaviruses is less well studied, but the nucleotide sequence of segment 8 (putative NSP2) of a group B adult diarrhea rotavirus from Calcutta showed only 77% homology to that of a murine strain and 93% similarity to other human isolates.[9]

Rotavirus genome rearrangements were detected during studies of chronic infection.[4] On PAGE of serial samples of feces from immunodeficient children, RNA segments were lost or diminished in concentration and new heavier bands emerged. Sequencing the new bands indicated that there were genome rearrangements but that these did not usually result in abnormal viral proteins.

Table 5 Primers used for VP4 (P) typing

Primer	Strain	Serotype ([GT])	NT	Sense	Sequence (5′ to 3′)	Primer type
Con3	Ku	1A[8]	11–32	+	TGG CTT CGC CAT TTT ATA GAC A	Consensus

5T-1	69M	4[10]	575–594	–	ATC ATA GTT AGT AGT CGG	Type specific

In contrast, genome reassortment is a major generator of diversity. This happens when two different rotaviruses infect the same cell at once. Mixed rotavirus infections have been detected in humans and a recent study of 3601 rotavirus strains from U.K. children with rotavirus diarrhea found approximately 2% to have novel [P]- and G-type combinations.[11]

Although it was considered that rotaviruses were species-specific it is becoming increasingly apparent that this is not so. The simian rotavirus SA11 can be used to infect mice, and some human rotavirus vaccines are reassortants of bovine or simian rotaviruses with human rotavirus VP7. How frequently this occurs naturally is unclear and most often it is inferred by detecting an animal-specific VP4 or VP7 in a human rotavirus strain. Examples of this include G5 (pigs), G6, and G8 (cattle) rotaviruses, and, for example, G8 rotavirus makes up over 50% of the G types in Malawi and Nigeria. Analysis of the Malawian rotavirus VP7 gene indicated that it is most closely related to bovine strains A5 (93.6% identical) and Cody (92.3%). In Nigeria a G8 cattle rotavirus isolate was found to be closely related to a human isolate in its VP7 (99.9%) and by Northern blot where all 11 segments cohybridized. Interspecies transmission combined with genomic reassortment appears to be a powerful generator of diversity.

THE DISEASE

Rotavirus diarrhea is as highly prevalent in developed as in developing countries, and all children have been infected by 2 years of age. It is responsible for from 20% to 60% of cases of infantile gastroenteritis that require hospitalization and for up to 40% in community-based studies.[2] In temperate countries it peaks in winter or early spring, whereas in sub-Saharan Africa peaks coincide with dry seasons.[1] Infection is transmitted feco-orally, and after a short incubation period (2–3 days) patients present with acute dehydrating watery diarrhea sometimes with vomiting. Illness lasts on average 5–6 days but prolonged rotavirus excretion can occur after severe disease occasionally with relapses of diarrhea. Extraintestinal disease including acute myositis, hemophagocytic lymphohistiocytosis, aseptic meningitis, and encephalitis has been described rarely.[1] Of particular interest has been the recent detection of rotavirus viremia which might be linked to such extraintestinal infection.[12]

Diagnosis

Laboratory diagnosis depends upon detection of the virus, its antigens, or genome in the feces of infected patients.

Table 6 Primers used for VP7 (G) typing

Where Y=thymine or cytosine.

Negative stain electron microscopy was the method first used to detect rotavirus. Its major advantages are that virus is detected by its distinctive morphology (Fig. 1), so the test is highly specific and the technology is ''catch-all'' in that other viral enteropathogens can also be detected. Its disadvantages are that it requires specialized expensive equipment with an experienced electron microscopist and that to be detectable there must be over 1 million viral particles per milliliter of sample.

A number of antigen detection formats have been designed including latex particle agglutination (LPA) and enzyme-linked immunosorbent assays (ELISA). In general, ELISA is more sensitive than LPA but with both there are problems of specificity. Latex particle agglutination has the advantage over ELISA of being in a format for single tests whereas ELISA is better for batch testing. Both are available as commercial kits.

Genome detection is either by PAGE of dsRNA extracted from stool or RT-PCR. Silver-stained PAGE gels are of equivalent sensitivity and specificity to electron microscopy. However, RT-PCR is the most sensitive technique but there are no commercial kits available. Using RT-PCR has the added benefit of allowing virus genotyping. Some of the PCR oligonucleotide primers available for detection and genotyping are shown in Tables 5 and 6.

TREATMENT AND PREVENTION

The mainstay of treatment is the assessment and degree of dehydration and appropriate rehydration as necessary. There are no antirotaviral drugs available but probiotics (*Lactobacillus* spp.) and oral pooled human immunoglobulin have been shown to decrease the frequency and duration of vomiting and diarrhea.[1] It is difficult to prevent transmission of rotavirus by simple hygienic measure, but in hospitals, children should be nursed in isolation or cohorted in rotavirus wards. Specific prevention by vaccine is possible as was demonstrated by the recently withdrawn live rhesus reassortant vaccine (containing G1–G4). It was one of the first rotavirus vaccines to be equally efficacious in infants in developing and developed countries. It was withdrawn from use because of concerns over its potential to cause intussusception. There are, however, a number of new candidate vaccines in production.

CONCLUSION

Rotavirus is the most important cause of infantile gastroenteritis both in terms of mortality and morbidity. It has a highly mutable genome changing by mutation, rearrangement, and reassortment, thus new strains are continually emerging. Continued vigilance is needed.

INTRODUCTION

Salmonella species have been isolated from humans and most animals, including domestic and wild mammals, reptiles, and birds. Many *Salmonella* serovars cause salmonellosis in humans and animals. *Salmonella* infection of humans and animals is one of the major public health problems in the world. *Salmonella* is also one of the major pathogens of foodborne disease throughout the developed and developing countries. *Salmonella* is transmitted to humans by contaminated food or poor hygiene. Most *Salmonella* infections result in self-limited gastroenteritis, and less commonly cause bacteremia with focal infection. The bacteremia caused by *Salmonella enterica* serovar Typhi and Paratyphi A are called typhoid fever and paratyphoid fever, respectively.

TAXONOMY

The genus name ''*Salmonella*'' is derived from Dr. D. E. Salmone, who first isolated *Salmonella choleraesuis* from porcine intestine. The nomenclature and classification of *Salmonella* have changed many times over the past century and still are not entirely stabilized. The classification has divided *Salmonella* into two species, *S. enterica* and *S. bongori*.[1] The *S. enterica* can be classified into six subspecies by its biochemical characteristics and host range (Table 1). Almost all serotypes pathogenic to humans belong to the subspecies *enterica*. The genus *Salmonella* is extremely polymorphic. Members of the seven *Salmonella* subgroups have been classified into over 2300 serovars according to somatic O, capsular Vi, and flagellar H antigens.[2] Differences within *Salmonella* serovars are based on those of the surface antigen such as O and H antigens. The O antigens are derived from polysaccharide domains of lipopolysaccharides (LPS) in the cell wall and the H antigens are derived from flagellin proteins in the flagella. O and H antigens are used for identification of *Salmonella* serovars by agglutination tests with O and H antigen specific antisera, and *Salmonella* serovars are determined by the combination of O and phase 1 and 2 H antigen type. Different *S. enterica* serovars produce different disease syndromes and show host specificities according to their antigenic profiles (Table 2). Therefore, it is necessary and important to differentiate *Salmonella* serovars from one another to ensure that each pathogen and its epidemiology are correctly recognized.

Major human pathogenic serovars include serovars Typhi, Paratyphi A, Shottmuelleri (Paratyphi B), Hirschfeldii (Paratyphi C), and Sendai. These serovars are almost always pathogens only of humans. The clinically important serovars, serovar Typhi and Paratyphi A, which are pathogens only of humans, cause enteric fever. The remaining serotypes of salmonellae are broadly spread into the animal kingdom. *Salmonella* has been isolated from all species, including mammals, poultry, birds, reptiles, amphibians, and insects. Human salmonella infections are generally caused by ingestion of contaminated food that is made from animal products, such as eggs and meat. *S.* Typhimurium and *S.* Enteritidis are the most frequently isolated serovars from foodborne outbreaks worldwide.

ORGANISM

The genus *Salmonella* belongs to the family Enterobacteriaceae. *Salmonella* is a gram-negative, motile, facultative anaerobic, non-spore-forming bacillus, 2–3 μm by 0.4–0.6 μm in size. It is differentiated from other Enterobacteriaceae by biochemical tests. *Salmonella* spp. ferment glucose, maltose, and mannitol but not lactose or sucrose. Most *Salmonella* strains produce acid and gas by fermentation. However, some *Salmonella* strains have variable biochemical tests. The following exceptional characteristics are helpful in identification; *S.* Typhi

S. bongori	

does not produce gas and is ornithine-negative, *S.* Choleraesuis is trehalose-negative, and *S.* Gallinarum–Pullorum is nonmotile.

IDENTIFICATION

Isolates with biochemical characteristics typical of *Salmonella* should be serogrouped by agglutination with polyvalent or monovalent antisera. Three kinds of surface antigens, namely, O and phase 1 and phase 2 H antigens are detected by agglutination by antigen-specific antisera in slide and tube agglutination tests. Although complete O-serotyping is used for identification, most laboratories examine only agglutination reactions to differentiate into groups O2(A), O4(B), O7(C), O9(D), O3,10(E_1), and several other groups. *S.* Enteritidis, which causes gastroenteritis, and *S.* Typhi, which causes typhoid fever, are both in the O9 group. Similarly, another cause of gastroenteritis, *S.* Typhimurium, and *S.* Paratyphi B, another cause of enteric fever, are both in the O4 group. Classical methods that rely on cultivation and biochemical tests for detecting *Salmonella* are time-consuming and often labor-intensive. In addition, for serotyping, antibodies must be produced for each serovar, which is extremely complex and time-consuming. Easier and more rapid methods are needed to identify *Salmonella* serovars and these are now available.

IDENTIFICATION OF MAJOR *SALMONELLA* SEROVARS BY PCR

Polymerase chain reaction (PCR) protocols have been developed to detect major *Salmonella* serovars, such as Typhi, Paratyphi A, Typhimurium, and Enteritidis. However, these methods are not yet widely used and are impractical in the areas where such salmonella infections are common. Detection of *Salmonella* species and major *Salmonella* serovars by PCR has been reported by many researchers, as shown in Table 3. *S.* Typhi and Paratyphi A are important in clinical laboratories, and their direct detection in blood or stool has been intensively studied.

Diagnosis of typhoid and paratyphoid fevers is performed on blood or stool by using culture methods and requires at least 4 or 5 working days. A rapid, alternative diagnostic method is required for the diagnosis of typhoid fever and paratyphoid fever. Targets for detection of *S.* Typhi by PCR include the *fliC-d* gene[3] Vi capsular antigen gene,[4] and 16S-23S rRNA spacer region gene.[5] If only one gene is targeted for the

identification of *S.* Typhi in these methods, other *Salmonella* serotypes can also be amplified. Multiplex PCR detecting two or more genes is now thought to be a more specific method for PCR identification. Recently, specific identification of *S.* Typhi by multiplex PCR, which targets the *rfbE*, *viaB* and *fliC-d* genes, has been reported, and this method correctly identified *S.* Typhi and differentiated *S.* Typhi from other *S. enterica* serovars with similar antigenic formulae.[6] This system enabled us to identify and differentiate *S.* Typhi from *S.* Paratyphi A, both clinically important serovars in human infections, by only a single PCR on bacteria isolated from blood or stool culture. A similar method for specific detection of *S.* Typhimurium has also been developed.[7] The antigenic formula of *S.* Typhimurium is O antigen (O4), phase 1 (H1) antigen (H:i), and phase 2 (H2) antigen (H:1,2). Three primer sets were designed for three genes—*rfbJ*, *fliC-i*, and *fljB-1,2*—encoding O:4, H:i, and H:1,2 antigens, respectively, and these were used in a multiplex PCR to identify *S.* Typhimurium. In another PCR, *sefA* and *fliC* genes were used as specific targets for *S.* Typhimurium.[8] PCRs for identification of *S.* Enteritidis, *S.* Dublin and *S.* Galinarum–Pullorum have also been developed.[8–11] Similarly, specific detection of *Salmonella* spp. has also been reported, and *Salmonella* spp. is detected by *invA*, *stn*, *phoQ*, *hin*, *fliC-i*, and *spaQ* genes with multiplex PCR or real-time PCR.[12–15]

The whole genome sequences of *S.* serovar Typhimurium LT2 and *S.* serovar Typhi CT18 have been determined and have been published in 2001. The whole genomic sequence data will make it possible to develop better diagnosis methods that are based on DNA.[16,17]

ANTIMICROBIAL RESISTANCE

Typhoid fever and paratyphoid fevers are still serious public health problems in many developing countries and are endemic in many countries, especially in Southeast Asia and Africa. Typhoid and paratyphoid fever are sometimes fatal infections of adults and children, with bacteremia and inflammatory destruction of the intestine and other organs. They require urgent treatment by the administration of appropriate antibiotics. Recently, fluoroquinolone-resistant and nalidixic acid-resistant strains of *S.* Typhi and *S.* Paratyphi A have emerged in the Indian subcontinent, becoming problematic in many other countries.[18,19] Fluoroquinolone resistance has been associated with mutations in *gyrA* and *parC*, which encode DNA gyrase and topoisomerase IV, respectively. Particularly in Enterobacteriaceae, *gyrA* mutations contribute greatly to fluoroquinolone resistance.[20] The product of the *gyrA* gene, DNA gyrase, is thought to be a target of fluoroquinolones. *gyrA* mutations lead to

conformational changes in DNA gyrase and cause fluoroquinolone resistance. Mutations at codon 83 and/or 87 of *gyrA* have been associated with fluoroquinolone resistance in *Salmonella* spp. Screening methods for antimicrobial resistance genes are also being developed by PCR. Screening methods for *gyrA* mutations giving fluoroquinolone resistance by PCR-restriction fragment length polymorphism (RFLP) have been developed and have been reported for *S.* Typhimurium,[21] *S.* Typhi, and *S.* Paratyphi A.[22] PCR-RFLP seems to be one of the best methods for the rapid detection of *gyrA* mutations.

CONCLUSION

Most of these PCR methods described here cannot be used for direct detection from clinical samples such as blood or stool. One has to isolate the causative agent by ordinary culture methods using SS agar or Maconkey agar plates, then apply several colonies on selective media to the PCR identification system. Thus, it takes 2 or 3 working days to get a final result.

The PCR methods described here may make it possible to detect and/or identify clinically important *Salmonella* serovars, such as *S.* Typhi, *S.* Paratyphi A, *S.* Enteritidis, and *S.* Typhimurium, within a few working days of arrival in the diagnostic microbiology laboratory. Furthermore, if specific primers to amplify other flagellar antigen genes and other O antigen synthesis genes are designed, it might be possible to identify other human pathogenic *Salmonella* serovars by a combination of PCR primers responsible for O and H antigen genes using multiplex PCR.

Serial Analysis of Gene Expression (SAGE) Technology

S

Farid E. Ahmed
East Carolina University, Greenville, North Carolina, U.S.A.

INTRODUCTION

Serial analysis of gene expression (SAGE) technology has provided rapid and comprehensive approaches for elucidating quantitative gene expression patterns that do not depend on a priori knowledge of gene sequence or transcript information. The SAGE method is based on the isolation of unique short sequence tags (9–21 bp long) from individual transcripts and their serial concatenation (linking) into long deoxyribonucleic acid (DNA) molecules, thereby overcoming the problem of transcript redundancy and allowing the method to be performed without subtraction or normalization. Sequencing of concatemer clones in parallel reveals individual tags and allows for the identification of up to $\sim$30 tag sequences in each reaction. Matching tags to genome sequences identifies the gene corresponding to each tag, and reveals novel internal exons and uncharacterized genes. Furthermore, the number of times a particular tag is observed provides a quantitative measure of transcript abundance in the ribonucleic acid (RNA) population.

The SAGE protocol can be used for studying any kind of biological phenomenon resulting from changes in cellular transcription. The technology not only provides a global gene expression profile of a particular type of cell or tissue in any organism, but also identifies a set of specific genes responsible for function by comparing the profiles obtained from a pair of cells kept at different circumstances.[2]

PRINCIPLES OF SAGE

SAGE is an ingenious method that allows for determining the expression patterns of thousands of unknown genes simultaneously in parallel (i.e., an open system) and quantitatively.[1] It was invented in the early 1990s, and was published in 1995 by distinguished investigators from the Johns Hopkins University Oncology Center (Baltimore, MD).[2] The original SAGE is based on two principles: 1) a unique 9- to 10-bp oligonucleotide fragment, or SAGE tag, can unambiguously identify a specific transcript [i.e., because a 9-bp fragment has 4^9 (or 262,144) potential combinations], and estimates suggest that the human genome encodes about 80,000 transcripts. Thus, statistically speaking, a 9-bp sequence tag obtained from a defined position in the cDNA can theoretically identify all human transcripts; and 2) concatenation (linking) of these tags, followed by their cloning into a plasmid vector, allows for serial analysis of transcripts by the sequencing of multiple tags within a single clone. Figure 1 depicts the SAGE method.

Double-stranded (ds) copy (c) DNA is synthesized from poly $(A)^+$ messenger (m) RNA using biotinylated oligo deoxythymine (dT) primer. The cDNA is then cleaved with an anchoring enzyme (AE)—a restriction endonuclease with a 4-bp recognition site, which cleaves most transcripts, on the average, every 256 bp (4^4). *Nla*III is the most frequently used AE. The most 3′ position of the cleaved cDNA is isolated by binding to streptavidin beads, providing a unique site on each transcript that corresponds to the restriction site located close to the polyadenylated tail. The cDNA is then divided in half and ligated via the anchoring restriction site to one of two linkers containing type IIS restriction sites (tagging enzyme, or TE) such as *Bsm*II, which cleaves at a defined distance up to 20 bp away from their asymmetrical recognition site. The linkers are designed so that when they are cleaved with TE, they are released with a short piece of the cDNA—a 9-bp tag. The two pairs of released blunt-ended tags are ligated to each other in a tail-to-tail formation by T4 polymerase, thus serving as a template for a polymerase chain reaction (PCR) with primers specific to each linker. Because amino groups block the 5′ ends of the linkers, only the mRNA-derived termini can be ligated. Thus the resulting amplification products contain two tags linked tail-to-tail (DITAGS), flanked by sites for the AE.

Analysis of DITAGS before amplification allows checking for any distortions as a result of the PCR amplification because the probability of any two tags being coupled in the same DITAG is small. Repeated DITAGS produced by biased PCR could then be excluded from analysis without affecting final results. Cleavage of the PCR product with an AE allows release of DITAGS that could then be concatenated by ligation, recovered by polyacrylamide gel (PAG) electrophoresis, cloned into a plasmid vector, and sequenced. Theoretically, inefficient enzymatic reactions that occur during the generation of a SAGE library can lead to inaccurate data. However,

Transcript-derived tag sequences are denoted by Ns. *Blunt-end ligation step. (From Ref. [11].)

rigorous testing of the reagents and the use of appropriate controls can avoid this problem. The analysis of SAGE data is performed by statistical methods, which extracts the tags from the sequence and determines their abundance and identity. Informatics is also available for data presentation.[3]

Several technical and conceptual difficulties intrinsic for the original SAGE method have been raised, including: 1) the need for a relatively high quantity of mRNA; 2) problems of constructing tag libraries; 3) short length of tags (9 or 10 bp); 4) inefficiency of blunt-end ligation; 5) possible loss of a fraction of mRNA species because of anchoring and tagging errors; 6) low cloning efficiency of concatemers; 7) reliance on PCR to amplify ligated DITAGS that may compromise the quantitative aspect of the method by altering the representation of mRNA; 8) tag sequencing errors; 9) incorrect matching of SAGE tag to sequences available in databases; and 10) options in case of unavailability of matches. Solutions to these problems are addressed below.

MODIFICATION TO THE ORIGINAL SAGE PROTOCOL

Since the inception of the original protocol, several modifications have been instituted to increase its efficiency. To reduce the amount of RNA needed, a modification named microSAGE was made, which required 500- to 5000-fold less starting input RNA. The new method utilized a single-tube format for all steps from RNA isolation to tag release in which the RNA—and later the cDNA—remained immobilized to the wall of the tube by means of streptavidin–biotin binding. Furthermore, total RNA was used instead of poly $(A)^+$ mRNA, resulting in reduction of the number of manipulations and accompanying loss of materials. In addition, a limited number of additional PCR cycles were performed on DITAGS.[4]

Other attempts to lower the quantity of input materials relied on the inherent poly (C) terminal transferase activity of reverse transcriptase to switch templates during

DNA polymerization (Clontech SMART system), which allowed the generation of PCR-amplified cDNA prior to the SAGE procedure. In PCR-SAGE, 900 pg of poly $(A)^+$ RNA generated a library validated by the presence of transcripts expressed in human oocytes.[5] In SAGE-Lite, starting with 50 ng of total RNA derived from cerebrospinal tissues or HT1080 cells, first-strand cDNA was PCR-amplified to generate large quantities of ds-cDNA, which was utilized as a substrate for SAGE analysis.[6] MiniSAGE[7] and SADE[8] employed procedures to diminish the loss of materials throughout the various steps, thereby allowing the use of only 1 μg of total RNA and 10^5 cells, respectively. Using an approach similar to microSAGE, a two-round PCR amplification of the DITAGS, and other minor modifications, a SAGE library was generated from a single PC-3 cell (scSAGE), but without adequate validation of results.[9] Although the above approaches suggest that amplified transcripts represent the original DNA mixture, a general concern about using PCR for tag amplification is the potential tag bias during PCR resulting in distortion of the true transcript level, which is especially important for template transcripts present at low abundance, leading to them being underrepresented in the final cDNA population.[1]

Another modification, dubbed small amplified RNA (SAR) SAGE, employed linear amplification of small mRNA fragments containing the SAGE tags, which allowed for preparation of libraries of over 100,000 tags from as few as 2500 cells (or ~50 ng of total RNA).[10] The procedure is similar to classical microSAGE, but employs a T7 RNA polymerase-dependent transcription of the mRNA segment between the tag and the poly $(A)^+$ tail, which allowed for synthesis of small mRNA molecules harboring the SAGE tags. For correctly identifying unknown tags, which contain ~10 bases, and ascertaining that they are not due to sequencing errors, methods employing reverse transcription (RT) PCR and other techniques to recover longer cDNA fragments were also reported.[10] A technical difficulty encountered in the original SAGE is that major products of PCR amplification are often linker dimers. By employing biotinylated PCR primers, biotinylated DITAGS were produced early on in the method, allowing removal of unwanted linkers by binding them to streptavidin beads at a later stage.[11]

To eliminate a small average size of cloned concatemers, which decreases the efficiency of tag collection, a heating step was carried out at 65°C for 15 min, followed by a quick chill on ice for 10 min of ligated concatemers. This step resulted in cloned concatemers with an average size of 67 tags, compared with 22 tags obtained by the original protocol.[12]

Modified SAGE protocols that generate longer TAGS have been attempted. One method employed *Rsa*I instead of the *Nla*III as the AE, which resulted in a tag length of 14 bases. In addition, this modification resulted in cohesive termini generated on cDNA tags for the ligation of both 5′ and 3′ linkers, allowing for higher efficiency in tag linker ligation and a lower possibility for linker dimer production.[11] Another modification for increasing the tag length by 2–3 bp, which employed *Sau*3A as the AE, has also increased the potential for transcript detection.[13] A technique dubbed as the generation of longer cDNA fragments from SAGE tags for gene identification (GLGI) extended the 10 tags to hundreds of bases long until they reached the 3′ end of the cDNA. This method employed a primer containing the 10-base SAGE tag as the sense primer, and another single-base anchored oligo (dT) as an antisense primer in a PCR reaction, together with a *pfu* DNA polymerase.[14] A procedure on that line, which also generated a 21-bp tag derived from the 3′ end of the transcriptase called LongSAGE, utilized a different type IIS tagging endonuclease (*Mme*I).[15] The longer cDNA fragment promises to permit a wider application of SAGE for quantitative analysis of global gene expression to complete the catalogue of expressed genes in humans and other species, to allow the identification of the 3′ cDNA sequence from any exon within the gene, and to delineate the 3′ boundary of expressed genes.

The use of different reverse transcriptases could play an important role in generating more representative cDNA. Although initial SAGE cDNA libraries have been constructed with the Moloney murine leukemia virus (MMLV), reverse transcriptase RNase H^- reverse transcriptase (Superscript II; Invitrogen) was reported to generate as much as four times more cDNA from a similar starting material. Furthermore, improved reverse transcriptases such as Sensiscript and Omniscript (Qiagen), used for generating high-quality cDNA from a limited amount of RNA that have been more recently introduced, promise to increase the efficiency of cDNA production.[1]

To overcome intrinsic PCR amplification problems resulting in transcript misrepresentation, a method that does not employ any PCR amplification at any stage of the process and identified as TALEST (or tandem arrayed ligation of expressed sequence tags) was used. The method utilized a series of restriction (*Eco*RI, *Bsg*I, and *Not*I) and punctuating (*Msp*I) endonucleases, which acted on ds-cDNA, resulting in the production of an *Eco*RI/*Not*I-tailed DNA fragment containing a 12-bp cDNA tag flanked at both ends by GC-clamped *Msp*I punctuation sequence. These sequences were resistant to thermal denaturation, permitting their concatemeration into long arrays and their subsequent recognition and analysis by high-throughput DNA sequencing.[16]

STATISTICAL AND BIOINFORMATICS CONSIDERATIONS

SAGE is a sampling method that determines the expression level of a gene (i.e., a resulting transcriptome) by measuring the frequency of unique short sequence tags derived from the corresponding mRNA transcript. Although the method is a very effective approach for determining the expression of mRNA populations, there can be significant biases in results caused by sampling errors, sequencing errors, nonuniqueness, and nonrandomness of tag sequences. Moreover, there are often transcripts that are present at a low copy number. To obtain a valid estimate of transcriptome size from SAGE libraries, one must sample a number of tags in a fashion inversely proportional to the lowest abundance level, which is not always known. Taking these mathematical considerations into account puts a strain on the design of a SAGE experiment.[17] Several statistical tests, all having their limitations, have been published for the pairwise comparison of SAGE libraries, and should be consulted before a SAGE experiment is designed. Computer programs, incorporating different statistical methods, are also available—free of charge—to facilitate data handling and analysis.[18]

To enhance the utility of SAGE data, the NCI's Cancer Genome Anatomy Project (CGAP) has created an informatics tool ''SAGE Genie,'' a web site for the analysis and presentation of SAGE data (http://cgap.nci.nih.gov/SAGE). SAGE Genie provides an automatic link between gene names and SAGE transcript levels, accounting for alternative transcription and many potential errors, and allowing for an invaluable means to archive and analyze the expression profiles for any given gene under any biological context.[19]

APPLICATIONS OF SAGE

More than 6.8 million SAGE transcript tags have been generated from 171 libraries and stored in CGAP database (http://cgap.nci.nih.gov/SAGE). Table 1 shows various SAGE databases available on the Internet. Many SAGE tags may have no match to known expressed sequences, and the majority of these unmatched novel SAGE tends to be low copies. Use of these novel tags and probes was proposed to allow identification of novel genes in human genomes that are difficult to identify by conventional methods.[20]

SAGE technology has been applied to the fields of cancer research, immunological research, cardiovascular research, brain research, pharmacological and drug discovery research, taxonomy, and transcriptome discovery in all phyla.[1–3,15,20,21]

CONCLUSION

Gene expression profiling is a powerful tool for discovering genes and their products, and for generating new mechanistic hypotheses at the core of understanding the function of the genome. Approaches using SAGE share a number of strengths and limitations. Considering SAGE limitations, first, a small number of transcripts would be expected to lack an AE site and should be missed in the analysis. Although it is possible to utilize a second AE to overcome this problem, this has rarely been attempted in practice because of the effort and expense involved. Second, the approach relies on DNA sequencing, with its inherent cost and throughput limitations. Third, it is a statistical sampling method, which depends on the appropriate understanding and design of the study before the rigorous experimental part is even attempted.

A notable strength of the SAGE method, like no other gene expression profiling, is that results from any experiment are directly comparable to existing SAGE gene expression databases. Significant differences among these comparisons can be spotted by using a variety of statistical methods and bioinformatics to identify new transcriptomes.[21] Contrary to the static genome, an approach represented by the transcriptome is an interactive module that allows the study of the influence of external and internal factors, thereby serving as a dynamic link between an organism's genome and its physical characteristics.

Single Cell Gel Electrophoresis Assay (Comet Assay)

Lisa Giovannelli
Vanessa Pitozzi
University of Florence, Florence, Italy

INTRODUCTION

Single cell gel electrophoresis allows detection of DNA breaks based on the electrophoretic migration of DNA from single nuclei embedded in agarose. The assay is commonly known as the ''comet'' assay because of the typical shape of the DNA fragments migrated out of the nucleus, resembling the tail of a comet when they are viewed through a microscope. The idea of electrophoresing single nuclei by embedding cell suspensions in thin agarose layers on microscope slides was originally developed for detection of radiation-induced DNA damage. A few years later, a modification of the original version of the method was introduced, consisting in conducting the electrophoresis after a DNA unwinding step in alkaline conditions, which greatly improved detection of single-strand breaks (SSBs) and also allowed detection of alkali-labile sites (ALS). Since then, the comet assay has gained increasing popularity, and today it is one of the most widely used methods in genetic toxicology, particularly in the alkaline version, which encompasses detection of a broader spectrum of DNA lesions. In addition to strand breaks, the comet assay can also be used for cross-link detection. The reasons for its popularity are also the small amount of cells/tissue required, high sensitivity, low cost, relative rapidity, and simplicity.

PRINCIPLES OF DETECTION

The principle underlying the comet assay is the increased electrophoretic migration of DNA upon formation of strand breaks or nicks.[1,2] To allow DNA migration, the agarose-embedded cells undergo a lysis process that eliminates cytoplasm, cellular membranes, and DNA-associated proteins such as histones. The naked DNA left in the gel retains its original nuclear shape and supercoiled arrangement, and is referred to as ''nucleoid.'' The undamaged nucleoid cannot migrate in an electric field because of its high molecular weight and compact structure. However, if breaks are present in the DNA molecule, the supercoil relaxes to some extent, and loops or free ends can be pulled out of the nucleus. It has been proposed that in the neutral version mainly loop migration takes place, unless the frequency of double-strand breaks (DSBs) is high enough to generate fragments that can move out of the nucleus.[3] In the alkaline comet assay, both relaxed loops and fragment migration take place, with the fragments being completely or partially single stranded, depending on breakage frequency.[3,4]

OUTLINE OF THE METHOD

The comet assay can be conducted on virtually any nucleated cell that can be brought into suspension. Thus, both cultured or freshly isolated cells from any organ can be used. Isolating cells from solid tissues usually involves time-consuming procedures, often implying the use of extracellular matrix-digesting enzymes, which can damage DNA. Instead, for the study of endogenous levels of DNA damage, it is necessary to use rapid isolation techniques to reduce the onset of artefacts, and, for some purposes, intact nuclei isolation by simple homogenization is advisable.[5] International expert guidelines have been provided for using the assay in in vivo genotoxicity testing.[6] Care should also be taken to prevent DNA damage induction during the procedure. For this purpose, it is convenient to work in dim light to avoid UV-induced DNA damage, and all solutions used should contain EDTA to inhibit endonuclease activity.

However, prepared, isolated cells or nuclei have to be obtained in a small volume of medium (10–20 μL) or in a pellet, to be either mixed or resuspended in low-melting point (LMP) agarose (0.5–1% in phosphate-buffered saline) at 37°C. A drop of mixture is transferred onto a fully frosted or agarose-precoated slide, covered with a coverslip, and allowed to solidify at 4°C. To obtain a suitable cell density, an 18×18-mm gel can be made with 70 μL LMP containing 20–50,000 cells. Smaller gels can be prepared if needed, and two or more gels can be accommodated on one slide.

The slides with the gel-embedded cells are immersed in a lysis solution containing detergents and having a high salt content to eliminate cellular membranes, cytoplasm, and organelles. The composition of one commonly used lysis solution is as follows: 1% *N*-lauroyl-sarcosine, 2.5 M

DOI: 10.1081/E-EDGP 120022642

NaCl, 100 mM Na_2EDTA, 1% Triton X-100, and 10% dimethylsulfoxide. Proteinase K can be added to improve deproteinization of DNA. The pH of the lysis solution can be neutral or alkaline, depending on the type of assay. The incubation is usually conducted at 4°C for 1 h, although longer times have been used.

In the neutral assay, the detectable lesions are mainly DSBs. In the alkaline assay, additional lesions can be visualized owing to the alkaline unwinding step preceding electrophoresis. The slides are submerged in a solution containing NaOH (0.3 or 0.03 mM) and EDTA (1–2 mM). The pH of the unwinding solution can vary, depending on the types of lesion to be detected: 12.1 for SSB (including those produced by the excision repair systems), and >13 for additional detection of ALS, i.e., modified sites that are converted in breaks at high pH, such as DNA base adducts. Cross-links can also be detected by measuring the prevention of DNA migration induced by X-ray.[7] The unwinding time chosen by many laboratories is 20 min; however, longer times can be used to increase the amount of single-stranded DNA and thus the extent of migration.

Electrophoresis is conducted with the slides placed side by side on a platform in a standard electrophoresis tank. The electrophoresis solution is usually the same as the unwinding solution for the alkaline assay, whereas in the neutral assay tris–borate–EDTA (TBE) or tris–acetate–EDTA (TAE) buffer is used. The applied voltage varies, depending on the desired extent of migration, from 0.55 to 1.0 V/cm for the alkaline (with 0.8 V/cm being the most widely used) and from 0.55 to 9.0 V/cm for the neutral assay. The associated amperage is generally rather high and it is advisable to conduct the run at 4°C.

Neutralization is required in the alkaline assay before staining. In this case, the slides are washed with a Tris buffer solution at neutral pH for a few minutes.

DNA staining can be brought about with ethidium bromide, 4,6-diamidino-2-phenylindole (DAPI), propidium iodide, or other fluorescent dyes by applying about 20 μL of a diluted staining solution (1–20 μg/mL) onto each gel and sealing with a coverslip. The slides can be stored in a dark, moist chamber at 4°C until they are viewed (usually overnight). For long-term storage, gels can be dried by placing the slides in a warm oven for a few hours, and then stored indefinitely at room temperature. For reexamination, the gels can be rehydrated[8] and stained as above.

DATA ANALYSIS

Comets can be analyzed visually in a quantitative way. A scheme has been described[4] for visual scoring based on five recognizable classes of comet, from undamaged, having no discernible tail, to highly damaged, with almost all DNA in the tail. Examples of comets in different classes of damage are given in Fig. 1. Fifty to 100 comets are selected randomly from each slide, and each comet is given a value according to the class it is assigned to, so that an overall score can be derived for each gel from the sum of all the comets' values. The advantage of visual scoring is that it is very quick.

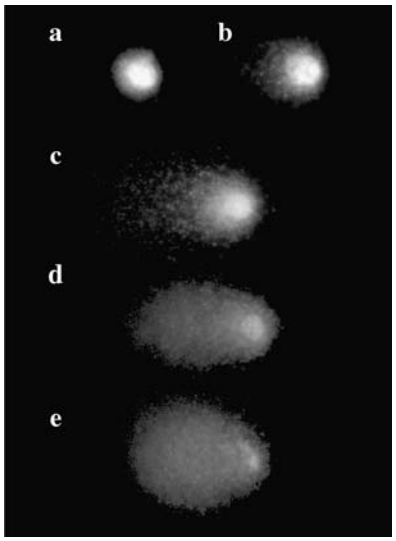

Fig. 1 Examples of comets in different classes of damage. Images of ethidium bromide-stained nuclei, showing increasing degrees of DNA damage (from image a to e) after electrophoretic migration.

Several software programs are also commercially available that automatically analyze individual comet images acquired in digital form with a CCD camera mounted on a microscope. These programs are designed to provide fluorescence profiles of comet head and tail and to measure various parameters such as percentage of total fluorescence in head and tail, tail length, and ''tail moment'' (conceptually the product of tail length and DNA fluorescence in tail).[6] The percent of DNA in the tail is a widely used parameter and is linearly related to DNA break frequency, up to about 80% in the tail.

MODIFICATIONS FOR SPECIFIC PURPOSES

Enzymatic Detection of Specific Classes of DNA Damage

An enzymatic modification of the alkaline comet assay to allow detection of oxidized bases was first described by Collins et al.[9] These authors suggested the use of lesion-specific DNA glycosylases/endonucleases involved in bacterial DNA repair to convert specific DNA base

modifications to strand breaks. The embedded nucleoids are incubated in the presence of the enzyme after the lysis step, so that additional breaks can be introduced at sites of damaged bases. The amount of enzyme-specific lesions can then be calculated by the difference between the breaks found in enzyme-treated and those in buffer-treated slides. Any base modification can be detected with this procedure, as long as the proper repair enzyme is available. Among the DNA repair enzymes used in the comet assay, formamidopyrimidine-DNA glycosylase (FPG) and endonuclease III (ENDO III) have been used for the detection of oxidized purines (8-OH-guanine, 7-methylguanine, 5-OH-cytosine, and 5-OH-uracil) and pyrimidines (thymine glycol, dihydrothymine, dihydroxydihydrothymine, and uracil glycol), respectively.

UV endonuclease for recognition of UV-damaged bases (6-4 photoproducts, pyrimidine dimers)[4] and uracil glycosylase (UDG) for detection of misincorporated uracil[10] have also been used.

Comet Assay—Fluorescence In Situ Hybridization

This procedure allows detection of DNA breaks within specific DNA sequences. It involves DNA unwinding of the embedded nucleoids followed by hybridization with a fluorescence in situ hybridization (FISH) DNA probe, based on the principle that DNA will be available for hybridization at single-stranded sites produced by alkaline unwinding in the presence of strand breaks.[11]

Treatment of Embedded Cells

The cells embedded in agarose can be kept viable and treated by incubating the slides in an appropriate medium containing the chemical to be tested for genotoxicity at the desired concentration. The radiation effect on DNA breakage and DNA repair can also be studied in embedded cells by irradiating the slides.[12] The advantage of this procedure is that the cells can be lysed immediately after treatment and run through the comet assay, avoiding further manipulation (trypsinization, centrifugation).

Measurement of DNA Content

When comet assay data are analyzed by means of a computer-assisted system, it is possible to evaluate the total DNA content from the value of the total fluorescence for each nucleoid. In this way, simultaneous measurement of the level of DNA breakage and content can be obtained in the same nucleus. This approach was first developed by Olive and Banath,[13] who showed dependence of the extent of induced DNA damage on the cell cycle point.

Identification of Subpopulations in the Sample

The comet assay can be used to differentially analyze cell subpopulations within a sample. A modification of the procedure can be used to label specific cell types that can be recognized along with the comets.[14] In some cases, one can take advantage of the fact that the nucleoids retain the morphological features of the original nucleus, so that, e.g., smaller or larger nuclei can be differentiated in a heterogeneous population of cultured cells, or polymorphonuclear blood cells can be separated from mononuclear cells.[15]

CALIBRATION AND STANDARDIZATION

Calibration of the comet assay is based on the fact that ionizing radiation produces strand breaks in DNA with known efficiency.[16] By using the comet assay to measure the breaks introduced into cells irradiated with different doses of X-rays, a standard curve can be obtained (Fig. 2), allowing conversion of the comet assay parameters (percent DNA in tail or tail moment) in break frequency. With this approach, the sensitivity of the method has been evaluated as less than 0.5 breaks/10^9 Da of DNA,[17] similar to other established methods for DNA damage measurement.[16] However, the comet assay saturates at lower levels of damage. A comparison between different methods for oxidative DNA damage detection was recently conducted by a European group to validate current protocols for the measurement of DNA oxidation.[18] This concerted effort showed that the values of

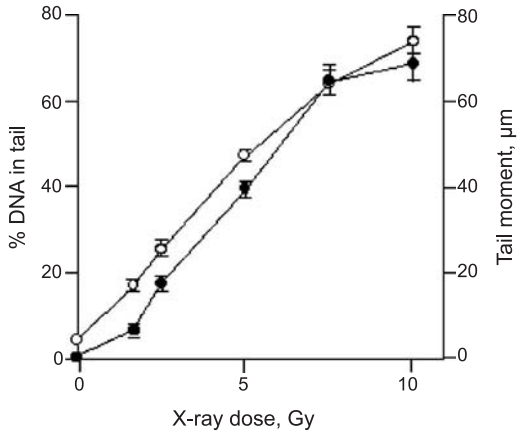

Fig. 2 Example of a calibration curve obtained by X-ray. Lymphocytes were embedded in agarose and irradiated with a range of doses before lysis and electrophoresis. The percent of DNA in the tail (open circles) and the tail moment (solid circles) are plotted. (From Ref. [17].)

DNA oxidation measured with the comet assay are significantly lower than those obtained in the same samples with chromatographic methods.

Protocol validation is an important issue, in view of the numerous variations of the method used in different laboratories, and guidelines have been provided by experts to improve intra- and interlaboratory comparisons.[19] To minimize variations due to visual scoring, each operator should undergo training involving ''calibration'' against a computer image-analysis system. Another potential source of variability is represented by reagents, gel preparation, lysis conditions, alkaline unwinding, and electrophoresis. To control these variations, standard samples should be included in every experiment. These should ideally be cells of the same type as those analyzed, prepared in aliquots to be frozen to $-80°C$ and stored until needed. Critical to the standardization is making sure that the storage process does not affect DNA integrity over time.[20]

CONCLUSION

Because of its unique design, the comet assay has proved useful in many fields. As a test for genetic toxicity, it has been widely used in human studies for biomonitoring environmental DNA-damaging substances.[21] A number of clinical applications have also been described, such as monitoring DNA damage in patients undergoing cancer chemo- or radiotherapy.[22] These studies, conducted in peripheral blood cells or in cancer biopsies, can provide information on both the sensitivity of tumor cells to the treatment and the toxic responses of normal tissues. Furthermore, measurement of the basal levels of DNA damage in cancer cells might have potential as a diagnostic and prognostic tool.[23] Other clinical conditions investigated with the comet assay include male infertility and oxidative stress-related pathologies such as diabetes.[22] Another important application is the measurement of oxidative damage in nutritional studies in humans.[24] Finally, in vivo and in vitro experimental studies with the comet assay have provided mechanistic information on the genotoxic effects of chemicals and radiation and on fundamental cellular processes such as DNA repair and apoptosis. Future developments and modifications will probably further enlarge the already wide scope of application of this assay.

Single Nucleotide Polymorphism (SNP) Genotyping Techniques—An Overview

Richard M. Twyman
University of York, York, U.K.

INTRODUCTION

Single nucleotide polymorphisms (SNPs) are individual base positions in the genome that show natural variation in a population. They represent the most abundant form of genetic variation in humans, accounting for more than 90% of all differences between unrelated individuals. SNP patterns are likely to influence many human phenotypes; therefore large-scale association studies based on SNP genotyping are expected to help identify genes affecting complex diseases and responses to drugs or environmental chemicals. SNPs play a major role in all stages of the drug development process—from target identification to clinical trials. The analysis of SNPs may also help to tailor drugs and drug regimes to particular genotypes—the underlying principle of pharmacogenomics. Given the potential impact of SNPs on healthcare, the biotechnology industry has focused urgently on the development of high-throughput methods for SNP genotyping. All genotyping methods are a combination of distinct methods for allele discrimination and signal detection, and these methods are the subject of this article.

SNP GENOTYPING

High-throughput SNP genotyping methods have been developed in order to exploit the many healthcare benefits which will arise from a detailed knowledge of genetic variation.[1–3] SNP genotyping technologies have two components—a method for determining the type of base present at a given SNP locus (allele discrimination), and a method for reporting the presence of the allele(s) (signal detection).[4–6] There are three general allele discrimination methods: hybridization/annealing (with or without a subsequent enzymatic discrimination step), primer extension, and enzyme cleavage. In each case, the technology platform may be homogeneous (in solution) or heterogeneous (involving both a liquid and a solid phase, such as a microarray). Some of the assays require prior amplification of the genomic target, whereas others are sensitive enough to work directly on genomic DNA or cDNA. There are many signal detection platforms, and most of these follow the fate of a label either in real time or at the assay end point. Uniquely, mass spectrometry can be used to detect the allele-specific product of a discrimination assay without the need for a label, by distinguishing the masses of DNA molecules containing alternative bases.

ALLELE DISCRIMINATION METHODS

Allele-Specific Hybridization

The simplest method for discriminating between alleles at an SNP locus is hybridization using allele-specific oligonucleotide (ASO) probes. Two probes are required—one specific for each allele—and stringency conditions are employed such that a single-base mismatch is sufficient to prevent hybridization of the nonmatching probe (Fig. 1a). The ASO probes can be used as labeled/unlabeled pairs, in which case two separate assays are required to genotype each SNP, one in which probe 1 is labeled and probe 2 is unlabeled, and one in which these roles are reversed. Alternatively and preferably for high-throughput assays, distinct labels can be used for each probe (e.g., different fluorophores or mass tags), so that each SNP can be genotyped in a single reaction. More sophisticated assays, such as TaqMan, use allele-specific hybridization as the primary discriminating reaction, but additional enzymatic steps are required to detect the signal.

Allele-specific polymerase chain reaction (PCR) is a modification of allele-specific hybridization in which discrimination is achieved by allele-specific primer annealing (followed by PCR amplification) rather than the direct detection of a hybridized people (Fig. 1b). Although it is possible to use a strategy in which the variable base position is in the middle of one of the primers, which is directly analogous to the ASO technique, this allows the extension of a mismatched primer/template if stringency conditions are not optimized. A more sensitive approach is to place the 3′ end of one of the primers at the variable base position because extension is dependent on perfect complementarity at the 3′ end of the primer.[7]

(d) Allele-specific invasive cleavage. In each case, the SNP position and the variable base position in the probe are shown. (*View this art in color at www.dekker.com.*)

Another modification of allele-specific hybridization is allele-specific ligation, in which two oligonucleotides are annealed at adjacent sites and DNA ligase is used to join them together. One of the oligonucleotides has two allele-specific variants, and the discriminatory base is at the most 3′ position. If there is perfect complementarity between the ASO and the template, it will be successfully ligated to the common oligonucleotide. If not, ligation will fail and the two oligonucleotides will remain separate. The assay in itself is not very sensitive, but sensitivity can be increased using additional steps such as the ligase chain reaction (in which the ligation reaction is reiterated with further oligonucleotides complementary to the first ligation product) or rolling circle amplification technology (RCAT; in which two ASOs about 80 nucleotides in length are designed to form a circle on the template, generating a closed loop or padlock probe when ligated). Primers annealing to this circle can be extended with a strand-displacing DNA polymerase, so that when the nascent strand completes the circle and encounters itself, it is continually displaced, generating a long concatemer that is easy to detect using fluorescence methods.[8]

Allele-Specific Single-Base Primer Extension

In allele-specific single-base extension (also called mini-sequencing), primers that anneal one nucleotide upstream of the polymorphic site are designed, and allele discrimination depends on the ability of this perfectly annealed primer to be extended (Fig. 1c).[9] This is distinct to allele-specific PCR where the discriminatory position lies within one of the primers and extension depends on the ability of the primer to anneal to its template. Allele-specific primer extension methods are more adaptable than hybridization/annealing assays because a much greater diversity of labeling strategies can be used. For example, the free nucleotides in solution can be labeled with four different

fluorescent tags, mass tags, or haptens, allowing the same mix to be used in the detection of multiple SNPs in parallel (e.g., on a microarray). Primer extension methods for genotyping have been extensively patented as Genetic Bit Analysis™ (GBA) technology (Orchid Biosciences, Inc.) and form the basis of many popular commercial genotyping systems (e.g., SnaPshot; Applied Biosystems).

Allele-Specific Enzymatic Cleavage

One of the earliest and most widely used genotyping methods, restriction fragment length polymorphism (RFLP) analysis, works on the principle of allele-specific enzymatic cleavage. An RFLP is generated when an SNP occurs at a restriction endonuclease recognition sequence, and one allele preserves the sequence while the other destroys it. If we consider any DNA fragment with three adjacent restriction sites, with the middle one containing an SNP, then digestion of amplified genomic DNA with the appropriate restriction endonuclease will produce either a single large fragment (if the central restriction site is absent) or two smaller fragments (if the central restriction site is present and cleavage occurs).

RFLP analysis is difficult to adapt for high-throughput genotyping, but this has been achieved for another cleavage-based assay known as Invader.[10] The Invader assay employs a unique method of allelic discrimination involving overlapping probes and an enzyme that specifically recognizes the resulting ''flap'' (Fig. 1d). An advantage of the Invader assay is that it requires no PCR amplification. Two signal probes are used, one recognizing each allele, plus a third invader probe. The signal and invader probes hybridize in tandem, and the signal probe overlaps the invader probe, generating a flap that is recognized by an enzyme called Cleavase, a modified form of the thermostable FEN-1 enzyme (flap endonuclease). A flap with the appropriate structure is generated only if the signal probe completely matches the template and there is a one-base invasion. The cleaved flap can then be used in a second round invader assay to generate a fluorescent signal, or the cleaved flap can be detected by mass spectrometry.

DETECTION OF ALLELE-SPECIFIC PRODUCTS

Methods Utilizing Fluorescent Labels

Direct fluorescence detection

The most straightforward way to detect an allele-specific product is to label it by incorporating one or more nucleotides conjugated to a fluorescent dye. Direct fluorescence detection is generally used with solid-phase assay formats (microarrays and bead arrays) and where allele-specific products are separated by gel electrophoresis or capillary electrophoresis.

A variation on this approach is to use an intercalating fluorescent dye such as ethidium bromide and to study the melting profile of DNA duplexes. This method for typing SNPs is known as dynamic allele-specific hybridization (DASH).[11] One (unlabeled) ASO is added to a PCR product and allowed to anneal in the presence of an intercalating dye, which fluoresces specifically in the presence of double-stranded DNA. The reaction is then heated, and fluorescence is measured in real time as the temperature rises. As the duplex denatures, fluorescence steadily decreases. When the melting temperature of the probe is reached, denaturation is completed and the fluorescent signal falls to background levels. The thermal melting profile of each allele is different because one is perfectly complementary to the probe and the other contains a mismatch.

Fluorescence resonance energy transfer

Fluorescence resonance energy transfer (FRET) occurs where two fluorophores are in close proximity, and one of the fluorophores (the donor) has an emission spectrum that overlaps the excitation spectrum of the other fluorophore (the acceptor). When a lone donor fluorophore is excited, light is produced with a characteristic emission spectrum. However, when the donor fluorophore is excited in close proximity to the acceptor fluorophore, energy is transferred to the acceptor fluorophore with the result that the intensity of emission from the donor is reduced (quenched), whereas that of the acceptor is increased (enhanced).

Although FRET enhancement can be used for SNP genotyping, two of the most popular homogenous assays in current use employ FRET quenching. The TaqMan assay, mentioned earlier, uses the intrinsic 5′ nuclease activity of *Taq* DNA polymerase to generate a fluorescent signal from a short ASO probe.[12] Two ASO probes are required—one specific for each allele. Each probe contains a unique donor fluorophore and a common acceptor fluorophore, and is short enough for the donor to be quenched when the probe is intact (either hybridized or in solution). However, when the probe hybridizes to the PCR template, the 5′ exonuclease activity of *Taq* DNA polymerase digests it, thus releasing the two fluorophores into solution and eliminating the quenching effect (Fig. 2a). The Molecular Beacon assay[13] involves the use of longer probes that have self-complementary ends labeled with the donor and acceptor fluorophores. Non-hybridized probes will self-anneal, bringing the donor and

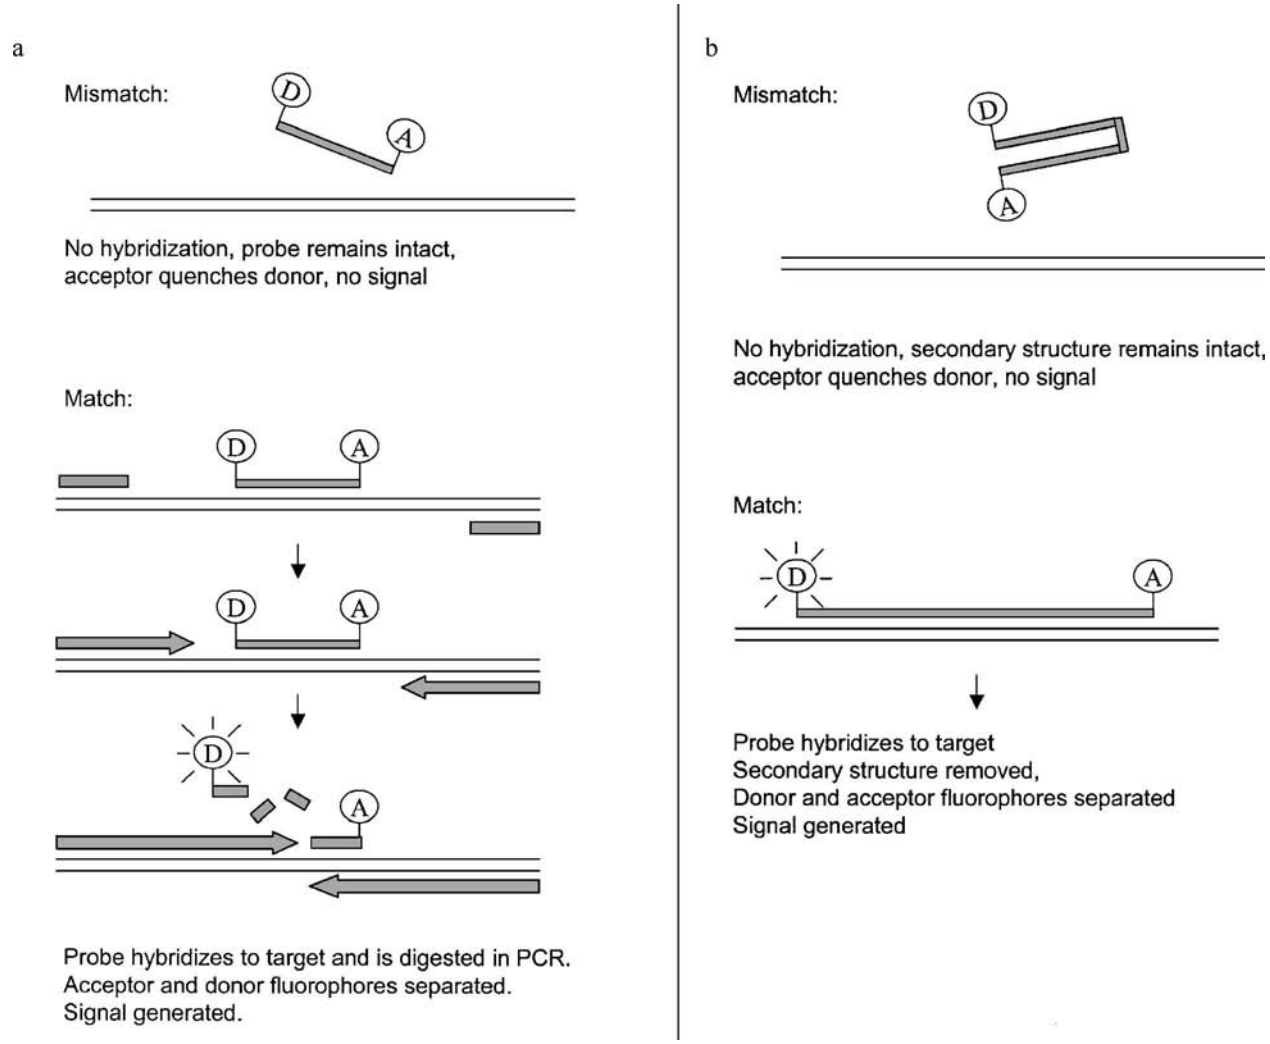

Fig. 2 Principles of the two most popular fluorescence-based homogenous genotyping methods: (a) TaqMan assay; (b) Molecular Beacon assay. (*View this art in color at www.dekker.com.*)

acceptor fluorophores together, resulting in quenching. Where hybridization occurs, the donor and acceptor fluorophores are separated such that the quenching effect is eliminated and a fluorescent signal is produced. As with the TaqMan assay, two probes labeled with different donor fluorophores are required—one specific for each allele (Fig. 2b).

Fluorescence polarization

When a fluorophore is excited by plane-polarized light, the fluorescence emitted by the dye is also polarized. This phenomenon is termed fluorescence polarization (FP). Complete FP occurs only when the dye molecule is stationary. Therefore the degree of observed FP is dependent on how fast a molecule tumbles in solution, and this is in turn dependent on the volume of the molecule, which is related to its molecular mass. Therefore changes in molecular mass (e.g., caused by primer extension, probe hydrolysis, or invasive cleavage) can be detected by changes in FP as long as all other conditions (temperature, viscosity, etc.) remain constant. FP is used as the detection method in the SnaPshot (Applied Biosciences) and Acycloprime (Perkin Elmer) commercial genotyping systems.

Mass Spectrometry

Genotyping assays involving mass spectrometry are distinct from those discussed above in that signal

detection is direct, based on differing molecular weights of small DNA fragments rather than the behavior of a label.[14] The analysis of DNA by mass spectrometry requires soft ionization (i.e., without fragmentation) and is usually achieved by matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) analysis. The MALDI procedure involves mixing the allele-specific products of the discrimination assay with a matrix compound on a metal plate. The mixture is then heated with a short laser pulse, causing it to expand into the gas phase where ionization is achieved by applying a strong potential difference. Ions are accelerated toward the detector and the time of flight (the time taken to reach the detector) is measured, allowing the mass/charge ratio to be calculated.

High-resolution mass spectrophotometers can accurately discriminate between alternative alleles in DNA fragments of 3–20 nucleotides in length. The smallest difference in mass between alternative allelic products is about 9 Da, representing an adenosine/thymidine polymorphism. Advantages of MS-based methods include its accuracy (as long as the sample is very pure) and the fact that each genotyping reaction takes a fraction of a second, allowing thousands of reactions to be carried out serially in a single day.

The majority of current MS genotyping platforms involve the use of DNA chips because the chip can be used directly as a MALDI plate. Thus far, the technique has been used to determine the masses of allele-specific hybridization probes, allele-specific primer extension products, and the products of invasive cleavage reactions. Commercial systems utilizing mass spectrometry include MassArray (Sequenom, Inc.) and PinPoint (PerSeptive Biosystems, Inc.).

Another promising MS genotyping technology involve the use of cleavable mass tags (chemical moieties of known molecular mass) as labels to replace fluorophores.[15] The advantage of mass tags is that, due to the accuracy of MS-based mass determination, the range of labels that can be used is virtually limitless, so ultra-high throughput genotyping is possible. The MassCode system (Qiagen Genomics) uses this technology.

Pyrosequencing

Pyrosequencing is a novel method for sequencing short stretches of DNA based on the detection of pyrophosphate, a normal by-product of DNA synthesis.[16] Although similar in principle to primer extension allele discrimination methods, pyrosequencing is suitable not only for typing SNPs but also for scoring entire haplotypes (groups of linked SNPs). Pyrosequencing works on the basis that pyrophosphate can be used to generate adenosine triphosphate (ATP), which then stimulates luciferase activity, causing the emission of a chemiluminescent signal. To achieve this, the primer extension reaction must include adenosine 5′ phosphosulfate (APS) and the enzyme ATP sulfurylase, which converts APS into ATP in the presence of pyrophosphate. Also present is luciferin (the substrate of luciferase) and the enzyme apyrase, which continuously degrades unincorporated dNTPs and excess ATP. The dNTPs are added to the reaction one by one. Only if the incoming dNTP is complementary to the template will it extend the primer and release pyrophosphate, resulting in the production of an equimolar amount of ATP. Visible light is generated in proportion to the amount of ATP and is detected as a peak on a pyrogram. When the degradation of the present dNTP is completed by apyrase, the next is added. A thioderivative of dATP must be used to avoid constant stimulation of luciferase activity.

CONCLUSION

Association studies aim to find patterns among 0.1% variation in the human genome (mostly represented by SNPs) corresponding to differences in complex phenotypes such as disease susceptibility and response to drugs. The success of such studies relies on accuracy, sensitivity, and high throughput in SNP genotyping. Many of the technologies described in this article are geared toward highly parallel analysis, although MS stands out as a platform where increased throughput is realized by ultra-rapid serial processing.

The sensitivity of most genotyping techniques reflects some form of amplification step either before, during, or after the actual allele discrimination assay. In the majority of cases, this amplification step relies on the PCR, but novel formats such as the Invader assay and RCAT are also becoming popular. Although homogenous assay formats are versatile, array-based technology platforms have the advantage of higher throughput. Recent developments[4] include the use of electrostringent hybridization arrays, where electric currents are used to increase the speed and sensitivity of hybridization, and the detection of allele-specific products based on their electrochemical properties when hybridized to oligonucleotide probes attached to minute electrodes. Another emerging technology, bead arrays, combines the flexibility of the homogenous assay format with the convenience and throughput of chip-based detection systems. Bead array systems that employ fluorescence-based detection and sorting are commercially available from Lynx Therapeutics and Illumina, Inc.

Single-Tube Two-Round Real-Time PCR

Jörg Berg
General Hospital Linz, Linz, Austria

INTRODUCTION

The introduction of real-time PCR in routine diagnostic laboratories has markedly increased the convenience and speed of PCR-based diagnostic assays. As product detection and identification in real-time PCR is performed within closed PCR vessels, the necessity for cumbersome post-PCR analysis steps is omitted. When real-time PCR is carried out in glass capillaries, e.g., on the LightCycler instrument, the PCR cycling speed is markedly increased to approximately 30 sec per cycle only. This rapid-cycle real-time PCR permits product detection by the utilization of various formats of fluorescence dye technologies such as fluorescence resonance energy transfer (FRET) hybridization probes, TaqMan probes, molecular beacons, or SYBR Green I. With this technique numerous protocols have been developed for diagnostic purposes. The sensitivity of rapid-cycle real-time PCR has been demonstrated to the extent of detecting a single copy of DNA per reaction vessel. In order to achieve this high technical sensitivity, the amplification reaction is required to run highly efficiently. However, this may not always be obtained in diagnostic applications. Sequence constraints may prevent ideal primer and probe design, and the complexity of nucleic acids from a clinical sample may preclude ideal amplification conditions.

OVERVIEW

In many diagnostic applications the analytical sensitivity of PCR has been markedly increased, when two rounds of PCR were performed, one PCR after another. In the first round of PCR sample DNA is amplified below the detection limits. Thereafter, the products of the first round of PCR are further amplified to detectable levels in the second round of PCR. For the second round of PCR usually a second set of primers are used which anneal within the DNA sequence of the first-round products. This second set of primers is then termed nested primers or second-round primers. Thus the application of two-round PCR to diagnostic PCR assays has resulted in improved assay sensitivities. In addition, the use of second-round primers increased the specificity of the PCR analysis, because the second-round primers amplify only if the first-round PCR yielded a specific product.[1] So in virus diagnostic applications consensus or indiscriminate primers have been used in a first-round PCR to amplify target DNA, which in a second-round PCR was further amplified with primers that more specifically annealed to the selected viral target DNA. This has increased the sensitivity of PCR analysis to the extent that, for example, in the diagnosis of HIV infection a single copy of HIV-1 cDNA could be detected.[2,3] Furthermore, the two-round PCR technique has successfully been utilized with the simultaneous amplification of various viral genomes such as from herpes simplex virus-1, herpes simplex virus-2, and human cytomegalovirus. Furthermore, two-round PCR has been applied to the genotyping and subtyping of viral strains.[4] For PCR diagnosis and monitoring of hematological malignancies such as the chronic myelogenous leukemia, two-round PCR has successfully been employed for the assessment of the chromosomal translocation t(9;22). This has yielded in high sensitivity of detecting up to one malignant cell within 10^6 normal leukocytes.[5]

As a disadvantage, two-round PCR has suffered from the necessity to recover the products from the first PCR, in order to introduce them into the second-round PCR. During the recovery of first-round products carryover contaminations into samples assayed in parallel may sometimes occur and thus may cause false positive test results to occur. To avoid this, various techniques have been developed to perform two-round PCR in single closed reaction tubes for the conventional PCR technique.[6–8]

In real-time PCR using LightCycler capillaries, the disadvantage of two-round PCR also relates the necessity to recover first-round PCR products. As LightCycler capillaries are rather inaccessible for pipetting, PCR products are usually retrieved by a brief centrifugation step, which releases the capillaries' contents into small tubes. But this procedure is thought to be particularly prone to product carryover. In order to avoid the centrifugation procedure, a two-round real-time PCR technique has been developed for LightCycler capillaries that remain closed during both rounds of PCR.

DOI: 10.1081/E-EDGP 120020686

SINGLE-TUBE TWO-ROUND REAL-TIME PCR

Single-tube two-round real-time PCR was achieved in LightCycler capillaries by separating the first-round PCR mixture from the second-round PCR mixture by a layer of silicone oil placed in between for the duration of the first round of PCR.[9] Thus the first round of PCR was exclusively performed with the first-round primers and reagents. Then, after the completion of the first-round PCR a brief centrifugation step forced the second-round reagents including the second-round primers to move underneath the silicone oil. Thus second-round reagents were united with first-round products and the second-round PCR was performed (Fig. 1). As the capillaries remained closed during the entire procedure, product carryover into samples analyzed in parallel was avoided between both rounds of PCR.[9]

The feasibility of this method was initially demonstrated by using nested pairs of primers for the PCR-mediated detection of the MBR/JH chromosomal translocation t(14; 18) (q32;q21) in cells of the human B-lymphoma cell line DoHH2.[10] As those cells carry this translocation, they were used as source for MBR/JH-specific DNA. The first-round and second-round PCR mixtures were prepared with equal volumes of 15 μL that were separated in the LightCycler capillary by 5 μL of silicone oil. Both PCR mixtures contained SYBR Green I as detecting fluorochrome. First-round PCR primers were used at about half the concentrations more than were used for the second-round primers. The second-round mixture was void of Taq polymerase and contained only primers and buffer. Capillaries were loaded with the first-round PCR mixture followed by the silicone oil. A brief centrifugation ($735 \times g$ for 5 sec) established the two separate phases with the silicone oil on top, onto which the second-round PCR mixture was layered (Fig. 1). The capillaries were closed, and the first and second PCR cycling programs were performed interrupted only by the centrifugation step after the first round of PCR. Product generation was recorded during both rounds of PCR, and after the completion of the second round of PCR melting curve analysis was performed to discriminate MBR/JH-derived products from primer dimers (Fig. 2). The single-tube two-round PCR detected the MBR/JH fusion gene from as low as 50 pg DoHH2 cell-derived DNA (Fig. 2A–D). This detection limit corresponded to about two to three cells per PCR. For comparison, one-round PCR using the first-round primers only detected the MBR/JH fusion gene from 500 pg DoHH2 DNA. This corresponded to a detection limit of about 20 to 30 cells per PCR only. Thus, the two-round PCR was found to exhibit an approximately 10-fold increased sensitivity than the one-round PCR with this application.[9]

As mentioned above, the described principle of single-tube two-round real-time PCR relates to the physical separation of the first-round PCR mixture from the second-round reagents during the first round of PCR. To test whether the 5 μL of silicone oil sufficed for the effective separation of both reaction mixtures, mock single-tube two-round real-time PCRs were performed with first-round mixtures, prepared without primers. Instead, the primers were placed on top of the oil layer. After completion of the mock first round of temperature cycling, centrifugation was performed and the second round of temperature cycling was carried out. Thus, in repeated experiments amplification products were obtained only in the second round of temperature cycling, and not during the first round[11] (Fig. 3).

Furthermore, when first- and second-round reaction mixtures are unified after the completion of first-round PCR, both mixtures should mix up to homogeneity. In order to accomplish this, both mixtures were prepared to equal volumes. However, mixing experiments with bromphenol blue as indicator dye in the second-round mixture revealed that homogeneity of both mixtures was not obtained immediately after centrifugation. Instead, the centrifugation forced the upper liquid phase to move underneath the first-round mixture. When the temperature

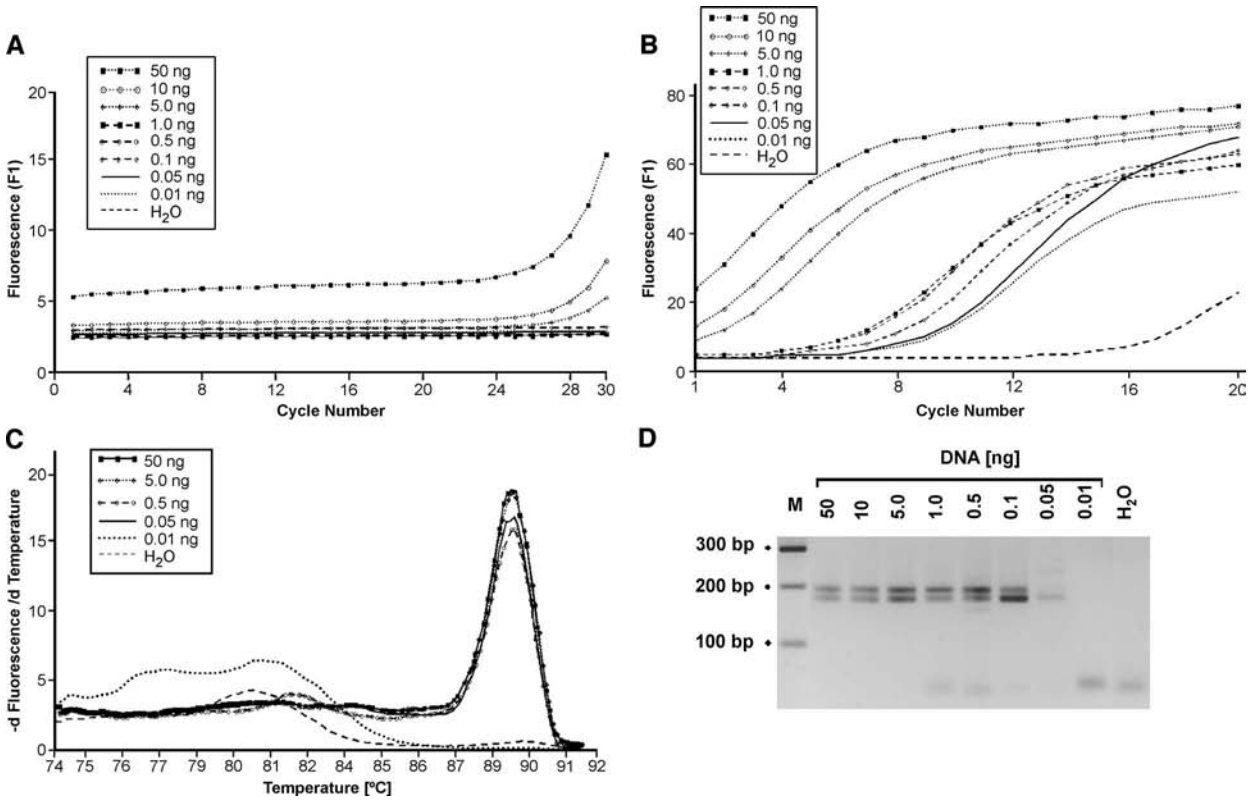

Fig. 2 Example of single-tube two-round real-time PCR for the detection of MBR/JH translocation. Real-time PCR on the LightCycler instrument was performed with graded amounts of genomic DNA (50 to 0.01 ng). Product generation was recorded in real-time fashion during the first round (A) and the second round (B) of PCR. Note that baseline normalization was switched off to show the increase of fluorescence during both rounds of the two-round PCR in comparable fashion. (C) After the amplification melting curve analysis was performed. The products specific for the MBR/JH fusion gene generated peaks corresponding to a melting temperature of about 89.5°C. As the melting peaks superimposed upon each other, only parts of the results are presented for clarity of the figure. (D) The amplification products after both rounds of PCR were resolved by standard agarose gel electrophoresis (3% agarose, 100 V for 1 hr, visualization by ethidium bromide staining and UV illumination). The first-round primers generated a 199-bp product whereas the second-round primers generated a 178-bp product. The nucleic acid molecular weight marker was resolved in lane M. (From Ref. [9].)

cycling was initiated, both mixtures were found mixed to homogeneity after about four to five temperature cycles. When much smaller volumes such as 2 or 5 μL for the second-round mixtures were used compared with the first-round mixtures, homogeneous mixing of both phases was not observed in experiments with bromphenol blue, and nested primer PCR did not occur either.[9]

In a further development of single-tube two-round real-time PCR reverse transcription (RT) was tried to perform within the same closed reaction tube used for the two-round PCR. As detection format, FRET hybridization probes were used instead of SYBR Green I. In this application a two-tube nested RT real-time PCR on the LightCycler instrument was merged into one capillary.[12] The first-round reaction mixture contained the reagents for the RT and for the first round of PCR. The primers for the first and second round of PCR were chosen to exhibit marked differences in their annealing temperatures (8–10°C). So the selected high annealing temperature of the first-round primers resulted in high specificity in the first round of PCR. As a lower annealing temperature was applied to the second-round PCR, potential spurious products of the first-round PCR were further amplified to arrive at a high sensitivity for the assay. In order to further increase sensitivity, the second-round PCR mixture was complemented with a hot start Taq polymerase. This enzyme needs extensive heating (about 7–10 min at 95°C) to be rendered active. As this was not reached with the temperature profile applied to the first round of PCR, the formation of primer dimers did not occur in the second-round mixture during the first round of PCR. As a result the developed HCV-specific assay exhibited an about 20-fold increased detection limit compared to a single-round HCV-specific real-time RT-PCR assay. With the

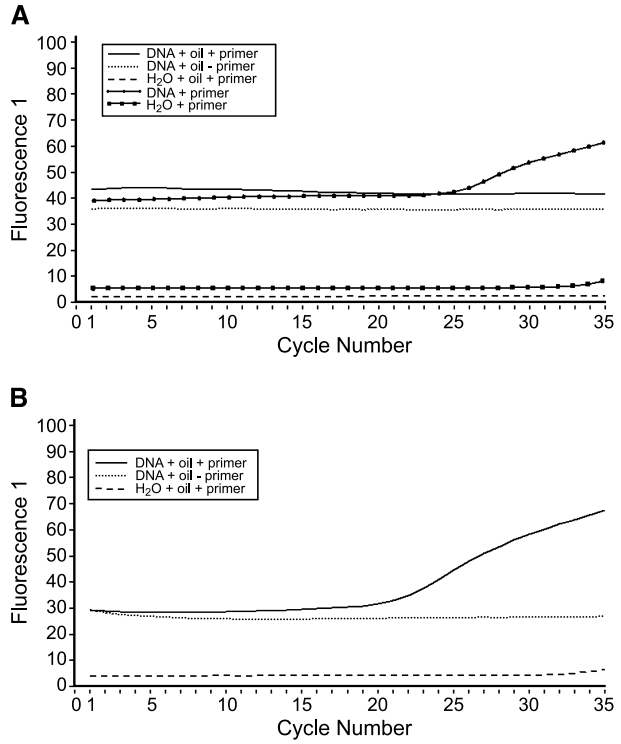

Fig. 3 Effectiveness of the oil layer for single tube two-round real-time PCR. (A) First-round PCRs in the presence of SYBR Green I were performed with primers (DNA+primer), with primers layered on top of the oil phase (DNA+oil+primer), and without primers (DNA+oil−primer) and with H_2O instead of DNA, with primers (H_2O+primers) and with primers layered on top of the oil phase (H_2O+oil+primers). Fluorescence intensities were recorded in real-time fashion. After the first-round PCR the capillaries were spun down and second-round PCR was performed with real-time recording of the fluorescence intensities. (From Ref. [11].)

detection limit of 100 IU/mL this single-tube two-round RT-PCR assay was found suitable for the routine testing of patient samples and for the routine screening of donor samples for the preparation of blood-derived products.[12]

The following limitations were, however, observed with this HCV-specific single-tube two-round real-time RT-PCR approach. The first-round PCR was performed in the absence of the FRET hybridization probes. When they were already added to the first round of PCR, the detection limit was found lower than without hybridization probes. As the probes were omitted in the first-round reaction mixture, quantification was not possible during the first round of PCR, only during the second round of PCR to which they were applied. Therefore this procedure caused a limited range of quantification from about 2500 IU/mL to about 100 IU/mL only. This is in marked contrast to the ranges of quantification with one-round real-time PCR, which usually covers several orders of magnitude.[13] Furthermore, real-time PCR assays have been demonstrated to exhibit very high precision with coefficients of variance usually in the range of a few percents. When this HCV-specific single-tube two-round real-time RT-PCR assay was analyzed for its precision, coefficients of variance of about 10% were obtained.[12] Nevertheless, the developed assay sufficed for the purpose of sensitive detection of HCV RNA in clinical samples, which was not achieved with one-round real-time RT-PCR.[14] As the reaction tubes remained closed during the whole procedure including RT, first- and second-round PCR, and product detection by melting curve analysis, carry-over contaminations into samples analyzed in parallel were precluded.

CONCLUSION

Various approaches have been applied to improve the sensitivity of diagnostic PCR assays. Greater amounts of sample have been used to extract nucleic acids from, in order to permit greater concentrations of sample nucleic acids applied to assays. Also, greater volumes of sample nucleic acids themselves have been applied to PCR assays. These approaches have usually resulted in about two- to fourfold increased sensitivities of PCR analysis. Markedly increased sensitivities have been observed when two rounds of PCR amplification, i.e., two-round PCR, were performed either with nested or with seminested primers. When two-round PCR was performed in single closed tubes with real-time PCR technology, an increase in sensitivity of about 10- to 20-fold was obtained compared to single-round real-time PCR. In various diagnostic applications real-time PCR per se has been shown to exhibit sensitivities comparable to those performed in two-round PCR by conventional thermocycler PCR.[15] However, when this sensitivity was not obtained, nested PCR has been developed with real-time PCR techniques and has yielded in improved sensitivity.[16–19]

In order to set up single-tube two-round real-time PCR for routine use in diagnostic laboratories, various parameters need to be considered and optimized. These include the volumes of the reaction mixtures for the first- and second-round PCR, the use of nested or seminested primers, the primer annealing temperatures, and primer concentrations for first- and second-round PCR. Furthermore, the choice of the detection format may influence the sensitivity and/or the quantification range of those assays, as described above. So the development of a single-tube two-round real-time PCR assay may be easy or laborious in some cases. However, assay development is facilitated by the opportunity to monitor amplifications during PCR in real-time fashion. The reward for the efforts will be a

robust single-tube two-round real-time PCR assay with improved sensitivities that also avoids carryover contamination of first-round amplification products into samples assayed in parallel.

SNP Genotyping Using Single Molecule Fluorescence

Rudolf Franz Zirwes
Stephanie Bousart
Evotec Technologies GmbH, Düsseldorf, Germany

INTRODUCTION

The differential susceptibility or resistance to many human diseases as well as the individual response to medications and environmental, nutritional, or pathogenic stimuli are based on the genetic diversity of the human population. Single nucleotide polymorphisms (SNPs) are single nucleotide positions in genomic DNA that show natural variation, occur on average once at every 500–1000 nucleotides in the human genome, and account for more than 90% of all human sequence variability. Although they have the potential to be tetra-allelic, almost all SNPs are bi-allelic. SNPs revolutionize human molecular genetics because they represent a dense panel of genetic markers distributed across the entire genome. Currently, SNP genotyping is employed in a variety of application areas including population dynamics and evolution, identification of disease-related genes, for the optimization of new drug development, as well as for forensic and diagnostic genetic testing. In addition, SNP genotyping holds great promise for the individualization of clinical diagnostics and therapeutics (i.e., the tailoring of drugs and dose regimens to individual patients) in the future.

This report gives an introduction into the GALIOS™ Genotyping System, a novel technology which provides homogeneous, rapid, and cost-efficient analysis of SNPs and mutations in genomic DNA. The accuracy, specificity, sensitivity, robustness, and reproducibility of GALIOS™ for diagnostic genotyping are illustrated and its potential for miniaturized high-throughput genotyping is discussed.

CHALLENGES AND CURRENT TECHNOLOGIES FOR SINGLE NUCLEOTIDE POLYMORPHISM GENOTYPING

The specific requirements for SNP genotyping technologies vary strongly with the application area. For example, large-scale genetic association studies performed for the identification of disease susceptibility genes and for the optimization of drug developments require the analysis of many thousands of identified SNP positions in hundreds to thousands of individuals to obtain statistically significant association data. Hence, they demand high-throughput SNP genotyping capable of providing up to 500,000 SNP scores (and more) per day. In addition to the evident need for very low running costs, such high-throughput SNP genotyping technologies must be highly automated and must feature economical, fast, and flexible assay development. In contrast, clinical SNP genotyping in forensic, diagnostic, or therapeutic applications usually does not require such high throughput but strongly demands the highest possible sensitivity, specificity, and reliability of the genotyping results. Moreover, prevention of cross-contamination and sample interchange is pivotal for the use of SNP genotyping results in clinical environments.

Currently applied methods for SNP genotyping are based on four general mechanisms for allele discrimination: primer (or probe) extension, allele-specific PCR, allele-specific hybridization, or structure-specific endonuclease cleavage. Although some current methods have considerable potential for high-throughput or clinical genotyping or both, they all have specific restrictions. Methods using primer extension (e.g., pyrosequencing[1] and template-directed dye-terminator incorporation[2]) and most chip-based methods require prior target amplification and purification. This causes many individual steps which complicate automation, rise costs, and provide uncontrolled error sources. Despite the fact that many assays based on allele-specific PCR [e.g., ''amplification refractory mutation system'' (ARMS) assay[3] or allele-specific hybridization (e.g., 5′-nuclease assays[4] and molecular beacon assays[5]) are homogeneous, they usually require expensive specialty probes. Moreover, most high-density chip-based methods do not allow for flexible, rapid, and inexpensive implementation of newly identified SNPs. Whereas the Invader assay[6] based on structure-specific enzymatic cleavage overcomes many of the described restrictions, it requires huge amounts of genomic DNA because its sensitivity is about 1 order of magnitude below PCR-based methods. Finally, all methods which employ traditional macroscopic fluorescence techniques—encompassing conventional fluorescence intensity, fluorescence polarization, and fluorescence resonance energy transfer—have only limited potential for

DOI: 10.1081/E-EDGP 120020762

miniaturization, an essential step toward cost-efficient high-throughput genotyping.

GALIOS™—HOMOGENEOUS HIGH-CONTENT SINGLE NUCLEOTIDE POLYMORPHISM GENOTYPING

A new technology has been developed for homogeneous, sensitive, rapid, and cost-efficient analysis of SNPs and mutations in genomic DNA. The GALIOS™ Genotyping System (Evotec Technologies GmbH, Düsseldorf, Germany) combines the high specificities of seminested PCR and allele-specific amplification, concurrently performs amplification and allele-specific labeling, and simultaneously interrogates both alleles of a given bi-allelic SNP in a ''one-tube'' reaction. Moreover, the GALIOS™ Genotyping System is fully generic and does not require the expensive and time-consuming synthesis of specialty primers or probes. Figure 1 illustrates the GALIOS™ principle of bi-allelic SNP scoring in a one-tube reaction. The reaction mix contains four target-specific and two universal primers; one pair of gene-specific amplification primers, two types of seminested, allele-specific diagnostic primers containing different universal sequence tails at their 5′-ends, and two types of fluorescent universal detection primers tagged with fluorescence dyes excitable at 543 nm (TAMRA) or 633 nm (EVOblue™), respectively. The tailed diagnostic primers have identical sequences, except for the 5′-tail portion and at least one internal nucleotide, which is complementary to the corresponding nucleotide of the respective allele. During a GALIOS™ reaction, the high-concentrated amplification primers dominate the early PCR cycles and amplify the genomic region of interest independent of the allele. In contrast, the low-concentrated diagnostic primers are extended predominantly in later PCR stages and lead to allele-specific generation of universally tailed PCR products. Upon progress of the

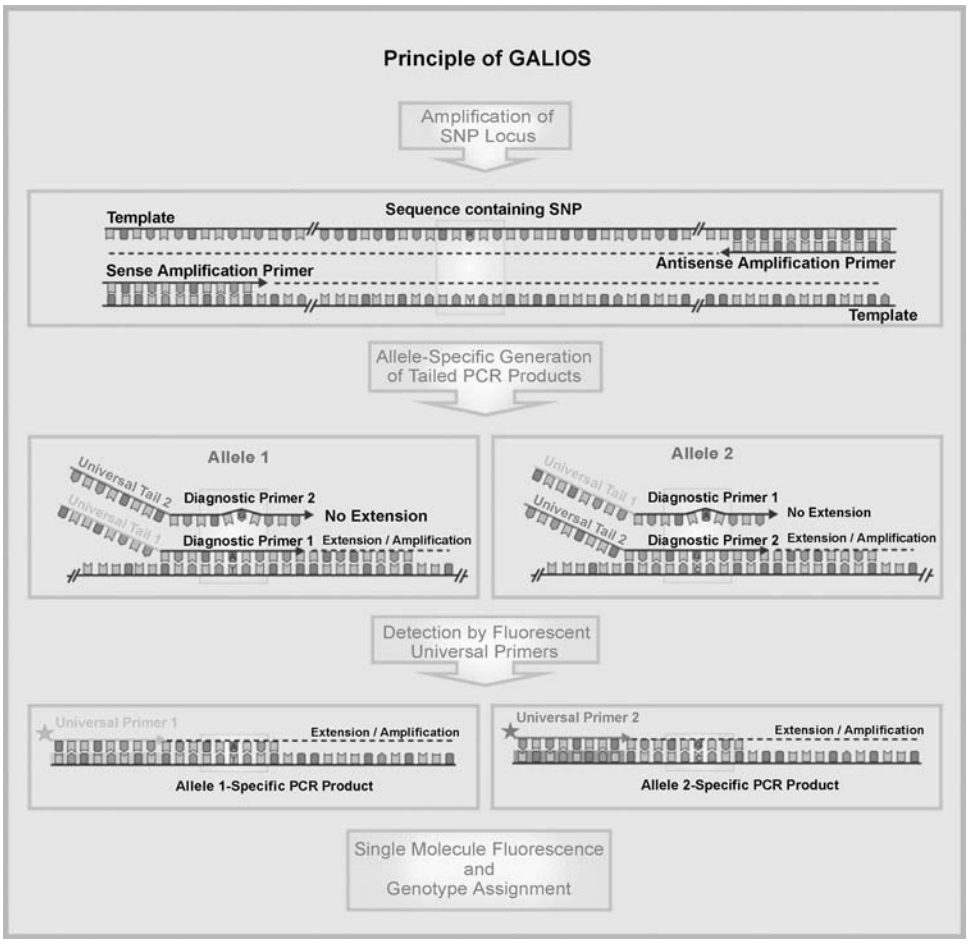

Fig. 1 The principle of biallelic SNP scoring with GALIOS™. (*View this art in color at www.dekker.com.*)

GALIOS™ reaction, these tailed PCR products serve as a template for the universal labeling primers, finally resulting in allele-specific accumulation of fluorescent amplification products.

After the GALIOS™ amplification, reaction mixes are analyzed directly, without any post-PCR processing or physical separation steps, by single molecule fluorescence (i.e., fluorescence correlation spectroscopy or FCS).[7–10]

Whereas traditional macroscopic fluorescence techniques monitor the average fluorescence output from the entire ensemble of emitting fluorophores in a given reaction, single molecule fluorescence employs confocal optics with a very tiny illumination volume of approximately 1 fL (10^{-15} L). Only fluorescence emitted within this confocal volume is observed and traced in a time-resolved manner. The resulting fluorescence raw data are amenable to different types of fluctuation analysis including FCS, which statistically samples the fluorescence fluctuations emitted from single molecules in discrete time intervals, with a temporal resolution down to microseconds and below. This process is termed autocorrelation and provides information on multiple fluorescence parameters including the average number, the molecular brightness, the triplet fraction, and the translational diffusion time of fluorescent molecules within the confocal volume. By fitting the autocorrelated fluorescence signal to a two-component model, the relative amounts of two species of fluorescent molecules differing in their translational diffusion time (e.g., the amounts of free universal primer and fluorescent PCR product in GALIOS™ reactions) are determined.

By combining confocal optics and autocorrelation, FCS virtually eliminates problems associated with conventional macroscopic fluorescence techniques, such as probe adsorption, inner filter effects, photobleaching of fluorophores, and particularly the decrease of signal with decreasing reaction volumes (i.e., with miniaturization). Thus, FCS provides a high signal-to-noise ratio (SNR) and a maximum sensitivity that is essentially independent of the assay volume. This allows ultimate assay miniaturization down to 1 μL or below sustaining a consistent signal quality—a favorable feature for economical high-throughput SNP genotyping. In addition, the obtained multiple fluorescence parameters serve as intrinsic quality controls within each reaction.

AUTOMATED GENOTYPING WITH FLUORESCENCE CORRELATION SPECTROSCOPY

Both the MF10S microplate reader [developed jointly by Olympus Optical Co., LTD (Tokyo, Japan) and Evotec Technologies GmbH] and the Analyzer ΔA2.0 (Evotec Technologies GmbH) are bench-top instruments for automated FCS analysis and perform automated adjustment, FCS measurements, autocorrelation, data fitting, and SNP genotype assignment. Reaction mixes are excited at 543 and 633 nm, and the quantities of allele-specific fluorescent amplification products (% amplimer) at each wavelength are determined. Genotypes are assigned by calculation of a normalized fluorescence signal (NFS), i.e., the difference of the quantities of fluorescent amplification products normalized by the sum of all amplimer-derived signal $[(543-633)/(543+633)]$. The software employs user-defined or default limit values for multiple fluorescence parameters and the quantities of fluorescent amplification products from negative and positive control reactions, thus providing multiple intrinsic quality controls for successful amplification and single molecule detection in each reaction. Additionally, user-defined limits for discrimination of the three possible genotypes allow for automated SNP genotype assignment.

ACCURACY, REPRODUCIBILITY, AND PRECISION OF GALIOS™ GENOTYPING

The performance of GALIOS™ is demonstrated by genotyping the SNP at position 655 ($A_{655}G$) within the human MLH1 (mutL homolog 1) gene.[11] The hMLH1 protein functions as a mismatch repair protein and helps to maintain the fidelity of DNA during replication. The $A_{655}G$ transition within the *hMLH1* gene replaces isoleucine at position 219 by valine ($I_{219}V$) in the hMLH1 protein and is associated with the inherited familial cancer syndrome of hereditary nonpolyposis colorectal cancer (HNPCC).[12]

To compare the accuracy of the GALIOS™ genotyping technology to a conventional genotyping method, 60 genomic DNAs (gDNAs) were analyzed in parallel by 1) PCR amplification and subsequent restriction fragment length polymorphism analysis (PCR-RFLP) and by 2) GALIOS™.

For PCR-RFLP, a 191-bp PCR product encompassing the $A_{655}G$ polymorphism of the *hMLH1* gene was amplified from each gDNA. The antisense primer was designed such that a *Cla*I restriction site (AT/CGAT) was introduced into the 191-bp PCR product upon amplification from allele A but not from allele G. Consequently, restriction digests of the amplimers with *Cla*I analyzed by agarose gel electrophoresis revealed distinct restriction fragment patterns for the three hMLH1 genotypes (Fig. 2A and B).

For GALIOS™ genotyping, all 60 gDNAs were amplified in duplicate reactions, each at 20 μL final

volume containing 5 ng gDNA. GALIOS™ reactions consisted of $1\times EVO_{AMP}$ buffer (Evotec Technologies GmbH), 2.5 mM $MgCl_2$, 0.2 mM of each dNTP, and 1 U Q-BioTaq (Q•BIOgene, Heidelberg, Germany). Amplification, diagnostic, and universal labeling primers were 300, 10, and 5 nM, respectively. Thermal cycling included an initial 2-min denaturation at 94°C, followed by 45 cycles of 94°C for 20 sec, 55°C for 40 sec, and 72°C for 45 sec. Samples were maintained at 72°C for 5 min before holding at 4°C prior to analysis. FCS measurements were performed for 3×3 sec in each reaction both at 543 and 633 nm. Mean values of the fractions of fluorescent PCR product (amplimer) from triplicate measurements were used for further genotype calculations. In all samples, amplimer values indicating allele-specific amplification signal were at least 8-fold higher than the corresponding background ''noise'' from no-DNA control reactions at the respective wavelength (SNR>8) (Fig. 2C). Bi-allelic SNP scores were made when the SNR was ≥ 8 and the ratio of the higher to the lower allele signal was ≥ 6 for homozygous and ≤ 2 for heterozygous scores. Calculation of the NFS revealed distinct values for each hMLH1 genotype (A/A, A/G, and G/G), and the resulting bi-allelic SNP scores were 100% identical for both GALIOS™ and PCR-RFLP, demonstrating the accuracy of GALIOS™ genotyping. The high confidence of the GALIOS™ genotyping results was also confirmed by the narrow intragenotype distribution of NFS values (Fig. 2D).

Reproducibility and precision of GALIOS™ genotyping were assessed by repetitive hMLH1 genotyping of subsets of gDNAs and evaluation of the distribution of the NFSs (Fig. 2E).

For intrasample precision, a single gDNA sample per hMLH1 genotype was amplified and measured by FCS for 10×3 sec at both 543 and 633 nm. All combinations of individual amplimer values from both wavelengths were used to calculate 100 individual NFSs per genotype. For interwell precision, a single gDNA per hMLH1 genotype was amplified in 10 individual GALIOS™ reactions. Each reaction was measured by FCS, each for 3×3 sec at both

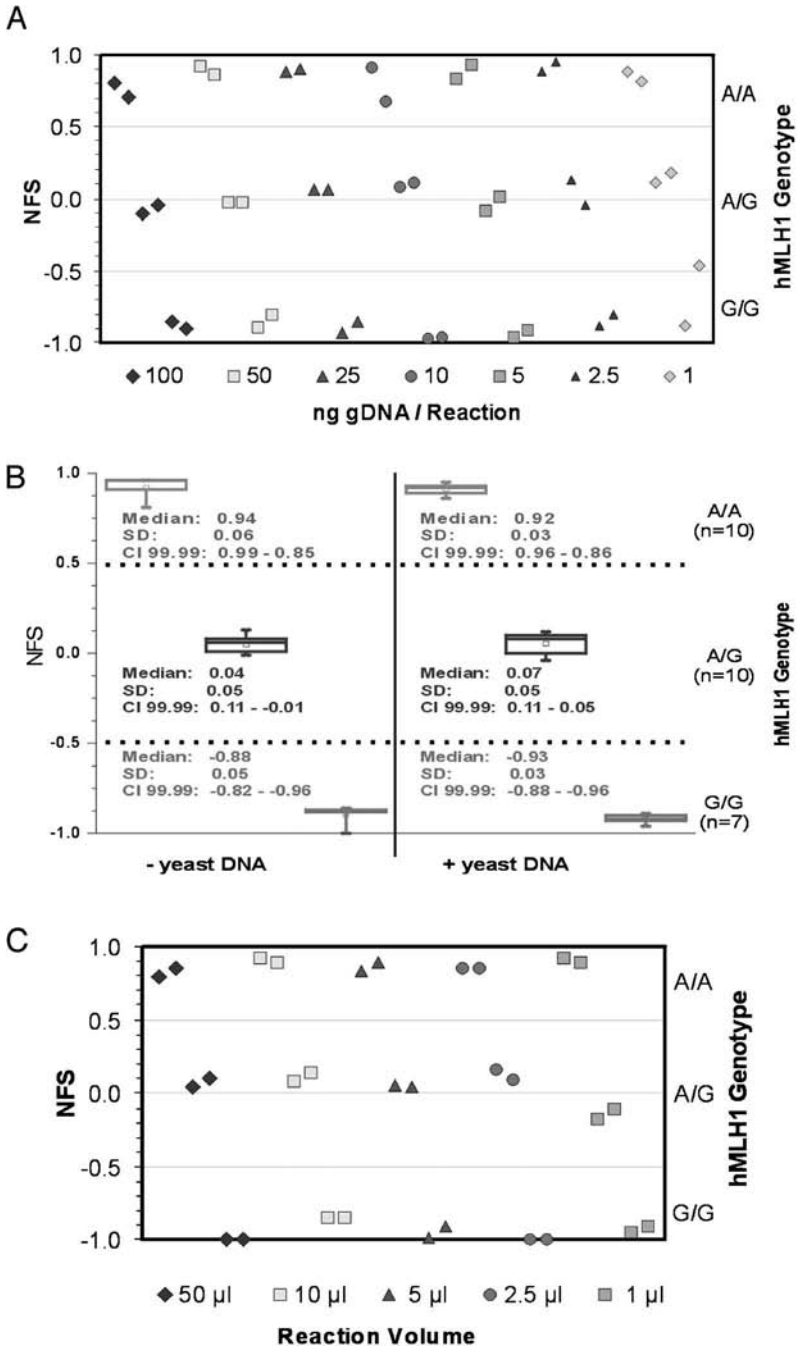

Fig. 3 Robustness, specificity, and miniaturization of GALIOS™ genotyping. (A) Plot of the NFS values obtained for hMLH1 $A_{655}G$ genotypes (A/A, A/G, and G/G) using 100–1 ng of gDNA per reaction. (B) Box plot illustrating the highly precise distribution of NFS values obtained for each hMLH1 $A_{655}G$ genotype from several ($n = 7$–10) gDNAs both in the absence (−yeast DNA) or presence (+ yeast DNA) of unspecific template. Median, S.D., and CI 99.99% values are denoted at the respective boxes. (C) Plot of the NFS values obtained for each hMLH1 $A_{655}G$ genotype obtained from standard and miniaturized reaction volumes (50–1 µL) containing a gDNA concentration of 1 ng/µL. (*View this art in color at www.dekker.com.*)

543 and 633 nm. Mean amplimer values from triplicate measurements were used to calculate 10 individual NFSs per genotype. For intersample precision, 10, 10, and 7 individual gDNAs for hMLH1 genotypes A/A, A/G, and G/G, respectively, were amplified and measured by FCS for 3×3 sec each at both 543 and 633 nm. Mean amplimer values from triplicate measurements were used to calculate individual NFSs.

All precision experiments yielded fully reproducible results and the NFS values showed a narrow distribution for each hMLH1 genotype (Fig. 2E), thus indicating the high reproducibility and precision of GALIOS™ genotyping.

Accuracy, reproducibility, and precision of GALIOS™ genotyping were highly identical when FCS measurement time was reduced to 1×2 sec at both 543 and 633 nm (data not shown).

ROBUSTNESS AND SPECIFICITY OF GALIOS™ GENOTYPING

Upon variation of the amount of genomic DNA from 100 to 1 ng per 20 μL reaction, unambiguous genotype discrimination was obtained (Fig. 3A), illustrating the robustness of GALIOS™ against variations in template concentration.

The specificity of GALIOS™ genotyping was examined by parallel analysis of 27 gDNAs (10, 10, and 7 for hMLH1 genotypes A/A, A/G, and G/G, respectively) with and without addition of 10 ng yeast gDNA representing a 500-fold molar excess of ''contaminating'' template. The results of the FCS analysis show that accuracy and precision of genotyping results are not affected by the presence of excess unspecific DNA (Fig. 3B), thus proving the very high specificity of the system.

MINIATURIZED SINGLE NUCLEOTIDE POLYMORPHISM GENOTYPING WITH GALIOS™

Duplicate GALIOS™ reactions of each hMLH1 genotype were performed in final reaction volumes ranging from 1 to 50 μL and a final gDNA concentration of 1 ng/μL (Fig. 3C). The three genotypes were clearly distinguished irrespective of the assay volume. Even 1 μL reactions containing 1 ng of genomic DNA perform genotype discrimination with the same confidence as 50 μL reactions containing 50 ng of genomic DNA.

CONCLUSION

The GALIOS™ SNP genotyping technology is ideally suited for diagnostic SNP genotyping and has potential for high-throughput genotyping as well. The homogeneous assay principle and direct detection by single molecule fluorescence facilitate automation and minimize cross-contamination risks. Universal labeling primers provide a generic system for flexible, fast, and cost-efficient assay development without a need for the synthesis of labeled primers or specialty probes, and small reaction volumes reduce costs per bi-allelic SNP score effectively. The system is robust to variations in template concentration and provides highly sensitive and confident genotyping with as little as 1 ng of gDNA. High-content data from single molecule fluorescence provide intrinsic quality controls for highly reliable SNP scoring without additional control reactions.

Currently, by using FCS measurements, about 15,000 bi-allelic SNP scores per day can be analyzed on a single MF10 S instrument. Using Evotec Technologies' readers for ultra-high throughput screening (μHTS),[13] this number can be increased to at least 10-fold to allow for high throughput genotyping.

Spinal Muscular Atrophy

Shuji Ogino
Brigham and Women's Hospital, Dana-Farber Cancer Institute, and Harvard Medical School, Boston, Massachusetts, U.S.A.

INTRODUCTION

Spinal muscular atrophy (SMA) is the second most common severe autosomal recessive disease after cystic fibrosis. SMA is caused by degeneration of the anterior horn cells of the spinal cord. Despite the complexity of SMA genetics, considerable progress has been made in the diagnostics for patients and carriers since the identification of the disease gene, *SMN1*.

CLINICAL DESCRIPTION

SMA is characterized by symmetric proximal muscle weakness. Sensory neurons may have also been affected in SMA type I (see below) patients.[1] SMA is classically subdivided into three types according to age of onset and clinical severity, based on the diagnostic criteria.[2] Type I SMA (Werdnig–Hoffmann disease; OMIM#253300) is characterized by the onset of severe muscle weakness and hypotonia in the first few months of life, and the inability to sit or walk. Fatal respiratory failure usually occurs before the age of 2 years. Type II SMA (intermediate type; OMIM#253550) is characterized by the onset of proximal muscle weakness before 18 months of age, the ability to sit but not to walk unaided, and survival beyond 4 years of age. Type III SMA (Kugelberg–Welander disease; OMIM#253400) is characterized by the onset of proximal muscle weakness after the age of 2 years, the ability to walk independently until the disease progresses, and survival into adulthood.

INCIDENCE AND PREVALENCE

SMA affects $\sim$1/10,000 live births and with a disease allele frequency of $\sim$1/100 and a carrier frequency of $\sim$1/50.[3] Approximately 60% of SMA patients have type I, and the remaining 40% have type II or III.[3] Type II is more common than type III SMA.

MOLECULAR GENETICS

SMN1, the Disease Gene, and *SMN2*, the Disease Modifier Gene

SMN1 (OMIM#600354) and its homologue, *SMN2* (OMIM#601627), lie within the telomeric and centromeric halves, respectively, of a large inverted repeat in 5q13.[4] *SMN* consists of nine exons (exons 1, 2a, 2b, 3 through 8), with the stop codon present near the end of exon 7. The coding sequence of *SMN2* differs from that of *SMN1* by a single nucleotide (840C>T) in exon 7. In contrast to *SMN1*, at least one copy of which is indispensable for the survival of motor neurons, $\sim$5–10% of normal individuals lack both copies of *SMN2*. The failure of *SMN2* to compensate fully for the loss of *SMN1* is due to the sequence difference in exon 7. Although translationally silent, the 840C>T in *SMN2* decreases the activity of an exonic splicing enhancer so that less full-length transcript is generated. A recent study also suggests the presence of exonic splicing silencer around the position 840 that is active in *SMN2*, but not in *SMN1*.[5] *SMN* gene duplication occurred more than 5 million years ago, before the separation of human and chimpanzee lineages, but that the *SMN2* gene sequence per se appeared for the first time only in *Homo sapiens*.[6]

SMN1 Deletion Mutations and Conversion Mutations

Approximately 94% of individuals with clinically typical SMA lack both copies of *SMN1* exon 7.[7] Loss of *SMN1* exon 7 can occur by a large deletion, typically including the whole gene, or by conversion to *SMN2* exon 7. Absence of the *SMN1* exon 7 sequence indicates a functional or a de facto absence of the *SMN1* gene.

Most converted genes from *SMN1* to *SMN2* had *SMN2* sequences in all of the polymorphic nucleotides except for the *SMN1* sequence in exon 8.[8] A half of the hybrid *SMN1*/*SMN2* genes had a single Ag1-CA/C212 haplotype,

Databases: *SMN1*—OMIM: 600354, 253300 (SMA type I), 253550 (SMA type II), 253400 (SMA type III); Genbank: XM_017078; GDB: 120378. *SMN2*—OMIM: 601627.

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120021948

suggesting that these hybrid *SMN* alleles had a common origin.[8] Other variants of hybrid *SMN* genes are rarely present. Considering increased number of *SMN2* copies in mild SMA patients in the absence of *SMN1* exon 7, gene conversion from *SMN1* to *SMN2* is a more likely hypothesis than unequal recombination and intrachromosomal deletion.[8] There is also evidence of gene conversion from *SMN2* to *SMN1*.[9]

SMN1 Small Intragenic Mutations

In a subset of the SMA patients who do not lack both copies of *SMN1*, ~30 small intragenic mutations (''subtle'' or ''nondeletion'' mutations) in *SMN1* have been identified (reviewed in Ref. [10,11]), for which we proposed the use of standard nomenclature.[10] These intragenic mutations provide solid evidence that *SMN1* is indeed the SMA gene, because intragenic *SMN1* mutations are associated with the SMA phenotype regardless of the status of other candidate genes. The three most frequently reported small intragenic mutations are the Y272C missense mutation (815A>G), the 768_778dupTGCTGATGCTT frameshift mutation, and the 399_402delAGAG frameshift mutation.

SMN1 De Novo Mutations

SMN1 has a high rate of de novo deletion mutations. There is a high frequency of recombination and crossover events at 5q13, presumably secondary to the presence of the large inverted repeat as well as smaller repeats around the *SMN1* and *SMN2* loci. The high rate of de novo mutations in *SMN1* likely underlies the high carrier frequency for SMA in the general population despite the high genetic lethality of the disease. De novo mutations of paternal origin are much more frequent (with a mutation rate of $\sim 1.6 \times 10^{-4}$)[3] than those of maternal origin.[12]

GENOTYPE–PHENOTYPE CORRELATION

At least one of the factors underlying the variable phenotype of SMA is the *SMN2* copy number. Individuals with type III SMA have, on average, more copies of *SMN2* than individuals with type II or type I SMA,[13–16] and likely express more full-length SMN protein from *SMN2*. The number of *SMN2* copies correlates with longer survival.[15] Mouse models of SMA also show dosage effects of *SMN2* in rescuing SMA symptoms.[17] However, other modifying factors must exist as *SMN2* copy numbers of the three SMA types overlap.

Various small intragenic mutations have also different effects on SMA phenotype. In in vitro experiments, G279V (836G>T) and Y272C (815A>G) caused a severe impairment of oligomerization, whereas S262I (785G>T) and T274I (821C>T) caused a mild impairment, and the degree of impairment correlated with the severity of SMA associated with the mutations in vivo.[18]

Other candidate modifier genes include *NAIP*, *H4F5* (*SERF1*), and *Htra2-β1*. It remains a possibility that SMA phenotypes are modified by genes responsible for neuromuscular disorders other than *SMN1*-linked SMA, including *IGHMBP2*, *HEXA*, *SCO2*, and others (reviewed in Ref. [10]).

POTENTIAL THERAPEUTICS

Currently, there is no therapy that cures SMA. However, active investigations are underway, and new therapeutic approaches will likely emerge in the near future. Potential therapeutic approaches (reviewed in Refs. [11,19]) are: 1) to increase full-length mRNA from *SMN2* by an in vivo alteration in the splicing pattern of *SMN2* exon 7 through activation of *trans*-acting factors, or antisense RNA molecules; 2) to increase the overall transcription level of SMN mRNA by activating the *SMN* promoter; 3) to stabilize the SMN protein; 4) to repair degenerated motor neurons; 5) to replace degenerated motor neurons by stem cell therapy; and 6) to target modifying factors other than *SMN2*. A high throughput drug screening for the identification of compounds that up-regulate full-length SMN protein is underway.

MOLECULAR GENETIC TESTING

Linkage Analysis

Localization of the SMA critical region allowed linkage analysis as the first genetic test. Informative linkage markers have been listed.[20] Linkage analysis remains an important tool in certain clinical settings.[3,21]

PCR-Restriction Fragment Length Polymorphism (RFLP)

The most commonly used method to confirm genetically the diagnosis of SMA is a qualitative PCR-RFLP assay to detect the homozygous absence of *SMN1*.[22] The PCR-RFLP assay takes advantage of the base differences in exons 7 and 8 to distinguish *SMN1* from *SMN2*. The restriction endonuclease *Dra*I digests only the *SMN2* exon 7 PCR products because of a restriction site generated by a mismatched reverse primer.[22] Another method introduces *Hin*fI control restriction sites in both the *SMN1* and the *SMN2* exon 7 PCR products to ensure complete digestion, in addition to the *SMN1* unique restriction site.[16]

PCR-Denaturing High-Performance Liquid Chromatography (DHPLC)

A rapid PCR-DHPLC method to detect homozygous absence of *SMN1* exon 7 has been described.[23]

Prenatal and Preimplantation Genetic Testing

Prenatal testing to detect the homozygous absence of *SMN1* can be performed on chorionic villous sampling (CVS) specimens, amniotic fluids, or maternal peripheral blood.[24] Preimplantation genetic testing to detect the homozygous absence of *SMN1* exon 7 has been described (reviewed in Ref. [10]).

Quantitative *SMN* Gene Dosage Analysis

To identify SMA carriers necessitates a quantitative approach, i.e., *SMN* gene dosage analysis. The first highly precise assay to determine copy numbers of *SMN1* and *SMN2* utilizes quantitative competitive PCR-RFLP, with *CFTR* exon 4 as a two-copy genomic reference.[13] To correct for variation in amplification efficiency, *SMN* and *CFTR* internal standards are used. Each standard has the same primer binding sites as its genomic counterpart, and a small internal deletion, which allows the internal-standard PCR products and the genomic PCR products to be separated and quantified independently.[13] The rationale for this quantification method has been described.[25] Various dosage analysis methods have since been described,[14,16,26,27] including real-time quantitative PCR.[15,28] *SMN* gene dosage analysis can be used for the detection of heterozygous absence of *SMN1* in SMA patients who do not lack both copies of *SMN1*.[16]

Heteroduplex formation between *SMN1* and *SMN2* PCR products may affect quantitative PCR-RFLP.[25] In addition to heteroduplex formation, reproducible PCR bias between *SMN1* and *SMN2* sequences may be present in *SMN* gene dosage analysis.[29]

SMN1 Small Intragenic Mutation Analysis

Analysis for the detection of small intragenic mutations is typically performed by DNA sequencing. Although labor-intensive and not routinely offered, it can be performed.[20] A multiplex, allele-specific PCR assay to detect the seven relatively common small intragenic mutations has been described.[30]

Monosomal Analysis

A monosomal-analysis method utilizes the separation of single human chromosomes of homologous pairs by fusing human cells with mouse cells and culturing with selection. A monosomal-analysis method to identify an *SMN1* deletion/conversion carrier who had two copies of *SMN1* on the normal chromosome 5 (the ''2+0'' genotype) has been developed.[31] This promising technology obviates the need to perform extensive linkage and dosage analyses to distinguish carriers with two copies of *SMN1* from noncarriers (the ''1+1'' genotype) who passed a de novo deletion mutation to an affected child.[3]

GENETIC COUNSELING

SMA Genetic Risk Assessment

Methods of SMA genetic risk assessment for various clinical settings have been described in great depth.[3,10] Risk assessment is an integral part of genetic testing. The purpose of genetic risk assessment is to provide family members with risk estimates as accurately as possible for their decision making. Risk assessment for SMA is particularly important, because of the complexity of SMA genetics. The disease allele frequency is relatively high; small intragenic mutations are undetectable by the standard assays; the paternal de novo mutation rate is high; and the presence of two copies of *SMN1* on one chromosome 5 can mask a deletion/conversion mutation on the other chromosome 5 in *SMN* gene dosage analyses.

It should be noted that genetic risk assessments are estimates based on published data from a finite number of cases in specific populations. It should also be noted that additional family information, especially additional genetic information, often dramatically improves the accuracy of genetic risk assessments. Thus genetic risk assessment is often an ongoing process, and genetic testing on additional family members should be performed whenever indicated by the initial results.[10]

SMN1 Allele and Genotype Frequencies

For SMA risk assessment, normal and disease allele frequencies have been estimated.[10] Most disease alleles in SMA are deletions (or conversions) of at least exon 7 of *SMN1* (''0-copy'' alleles). A normal chromosome 5 usually has one copy of *SMN1* (''1-copy'' allele). However, two copies of *SMN1* are often present on the same chromosome 5, for which we use the term ''2-copy allele.'' We refer to disease alleles with small, intragenic mutations in *SMN1* as ''1^{D}'' (''1-copy-disease'') alleles. Updated frequency of each *SMN1* allele or genotype is listed in Table 1 (modified from Ref. [11]).

Table 1 Updated *SMN1* allele and genotype frequencies

Allele			Designation	Frequency
''0-copy''			**a**	9.88×10^{-3}
''1-copy''			**b**	9.50×10^{-1}
''2-copy''			**c**	4.04×10^{-2}
''1^{D}-copy''			**d**	1.81×10^{-4}
Status	**Genotype**[a]	**Gene dosage**	**Designation**	**Frequency**
Noncarrier	''2+2''	4	$\mathbf{c}^2$	1.63×10^{-3}
	''2+1''	3	2**bc**	7.67×10^{-2}
	''1+1''	2	$\mathbf{b}^2$	9.02×10^{-1}
Carrier	''2+1^{D}''	3	2**cd**	1.46×10^{-5}
	''2+0''	2	2**ac**	7.98×10^{-4}
	''1+1^{D}''	2	2**bd**	3.43×10^{-4}
	''1+0''	1	2**ab**	1.88×10^{-2}
Affected	''1^{D}+1^{D}''	2	$\mathbf{d}^2$	3.27×10^{-8}
	''1^{D}+0''	1	2**ad**	3.57×10^{-6}
	''0+0''	0	$\mathbf{a}^2$	9.77×10^{-5}

[a]Genotype is indicated by ''(*SMN1* allele on one chromosome 5)+(*SMN1* allele on the other chromosome 5).''
Source: Modified from Ref. [11].

CONCLUSION

Since the discovery of the disease gene, *SMN1*, there has been considerable progress in the understanding of molecular genetics of SMA. Comprehensive SMA genetic testing, comprising qualitative PCR-RFLP, *SMN* gene dosage analysis, and linkage analysis, in combination with appropriate genetic counseling and risk assessment, currently offers the most complete evaluation of SMA patients and their families. In addition, new technologies, such as monosomal analysis techniques, may be widely available in the near future. Understanding of molecular genetics will also facilitate the development of new therapy that may cure SMA in the future.

Staphylococcus aureus—Detection of MRSA

Sameer Elsayed
University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

Antimicrobial resistance is becoming an increasingly recognized global health problem. One particularly important worldwide threat is that of methicillin-resistant *Staphylococcus aureus* (MRSA), which, by virtue of its highly virulent nature similar to its methicillin-sensitive counterpart, is capable of causing a wide array of serious illnesses, although with limited options for therapy. Recent advances in molecular science have resulted in an improved understanding of the genetics of methicillin resistance in *S. aureus* and have fostered the development of new molecular techniques for the laboratory detection of this emerging pathogen. This article will provide the reader with a comprehensive overview of MRSA, focusing on the epidemiology, microbiology, clinical features, genetics, and molecular detection of this microorganism.

BACKGROUND

S. aureus is a major human pathogen, causing a wide spectrum of hospital-acquired and community-acquired infections worldwide.[1,2] The use of potent antimicrobials, such as the β-lactam class of antibiotics, for the treatment of severe *S. aureus* disease has contributed significantly to reduced morbidity and mortality rates.[3] However, of great global concern is the rapid emergence and spread of MRSA strains. Since their first description in 1961 in the UK shortly after the introduction of methicillin into clinical use,[4] MRSA strains have spread to all parts of the world.[1,5–7] Rates of methicillin resistance in *S. aureus* vary markedly by geographical region, ranging from $\leq 2\%$ in Switzerland and The Netherlands to over 70% in Hong Kong and Japan.[1] Although methicillin is no longer used clinically or for laboratory susceptibility testing (having been replaced by cloxacillin and oxacillin, respectively), strains classified as methicillin-resistant harbor the *mecA* gene, which, when expressed, renders isolates resistant to all β-lactam agents, including penicillinase-resistant penicillins (e.g., methicillin, oxacillin), cephalosporins, and carbapenems.[8,9] These strains also have a tendency to carry other antibiotic-resistant genes, resulting in multiple drug resistance.[1,10,11] Although glycopeptides, such as vancomycin, and newer antimicrobials with purported activity against multidrug-resistant MRSA are available for clinical use, patient outcomes have been less than favorable with these agents.[12] Furthermore, the increasing use of vancomycin has contributed to the emergence of vancomycin-resistant enterococci[13] and, more recently, vancomycin-resistant staphylococci.[14] The MRSA epidemic has, until lately, been largely confined to the hospital setting. However, the epidemiology has now expanded into the community, with a number of community-acquired infections caused by newly emerging virulent clones of MRSA being recently described.[7] Nevertheless, MRSA remains a serious hospital infection control problem, whereby strict measures and surveillance activities are required to prevent the intrainstitutional and interinstitutional spread of these strains from colonized or infected patients.[15] To facilitate the institution of appropriate antimicrobial chemotherapy and/or infection control measures for MRSA, rapid and accurate laboratory diagnostic methods are critical. Laboratories have traditionally relied on phenotypic methods, particularly the standard oxacillin salt agar screen recommended by the National Committee for Clinical Laboratory Standards (NCCLS)[8] and also *mecA* gene product latex agglutination tests,[9,16] for the detection of methicillin resistance in *S. aureus*. However, *mecA* expression—and hence methicillin resistance—is variable, being influenced by a complex interplay between *mecA* and a number of other genes as well as various environmental and in vitro factors.[10,16,17] Phenotypic detection may also be confounded by the common occurrence of heterogeneous MRSA strains composed of susceptible and resistant subclones.[10,18] Additionally, strains of *S. aureus* lacking the *mecA* gene may occasionally demonstrate low-level, nonclinically significant, phenotypic resistance to methicillin because of other mechanisms, but are not considered to be true MRSA.[9,10,16] Furthermore, some of these phenotypic tests may be labor-intensive and slow (turnaround time >24 hr). Hence an increasing number of laboratories are resorting to the use of more widely available molecular methods, either alone or in combination with these phenotypic assays, for detecting MRSA.

DOI: 10.810/E-EDGP 120020910

Molecular detection of *mecA* is now considered the gold standard method for MRSA diagnosis,[16] and a number of genotypic assays based on polymerase chain reaction (PCR) and real-time PCR platforms have been recently described, which allow for easy, rapid (2–5 hr), and precise detection of the *mecA* gene in clinical isolates of *S. aureus*.[19–22]

MICROBIOLOGICAL DESCRIPTION

S. aureus and other members of the genus *Staphylococcus* are gram-positive, catalase-positive, predominantly facultatively anaerobic, nonmotile, nonspore-forming, spherical-shaped bacteria, approximately 0.5–1.0 μm in diameter, which typically form irregular ''grapelike'' clusters and/or occasional configurations of single cells, pairs, tetrads, and short chains, and are differentiated from other closely related genera by their cell wall teichoic acids, susceptibility to lysostaphin, intrinsic bacitracin resistance, lack of cytochrome *c* (as determined by the modified oxidase test), and relatively low guanine plus cytosine DNA base composition.[23] Approximately 35 species of staphylococci have been described to date. Based on the production of the enzyme and virulence factor coagulase (encoded by the *coa* gene), the staphylococci are classified as either coagulase-positive (*S. aureus*, and the veterinary pathogens *Staphylococcus schleiferi* subspecies *coagulans*, *Staphylococcus lutrae*, *Staphylococcus delphini*, *Staphylococcus intermedius*, and *Staphylococcus hyicus*) or coagulase-negative.[23] A positive tube (free) coagulase test serves as the basis for presumptive identification of *S. aureus* because the other coagulase-positive staphylococcal species are almost never encountered in human infections. However, rare strains of *S. aureus* may lack the *coa* gene and/or fail to produce coagulase.[23] Heat-stable nuclease (encoded by the *nuc* gene) is another virulence factor produced almost exclusively by the coagulase-positive staphylococci and serves as the basis for the DNase test.[23] The organism is also characterized by the presence of protein A on its cell surface, allowing for rapid, species-specific identification through the use of IgG-coated latex bead-based agglutination kits. *S. aureus* is a very hardy organism that grows well on most microbiological media and under a variety of incubation conditions. The morphology of *S. aureus* on solid agar media is somewhat distinctive; after 24 hr of growth, colonies are approximately 3–5 mm in diameter, creamy yellow to orange in color, smooth, and slightly raised. Strains frequently demonstrate beta-hemolysis on blood-containing agar media. Sequencing of the 16S rRNA gene can be used for definitive speciation of *S. aureus*. However, colonial features, biochemical tests, and 16S rRNA profiles do not differentiate MRSA from methicillin-sensitive *S. aureus* (MSSA).

CLINICAL SIGNIFICANCE

Natural Habitat and Reservoir

S. aureus is widely distributed in the environment, although it may also be found as part of the normal bacterial flora of humans or other mammals. Strains may colonize various anatomic sites including the skin, mucous membranes, and the upper respiratory, gastrointestinal, and genitourinary tracts.[24] Nevertheless, *S. aureus* has a particular predilection for colonizing the anterior nares of humans.[15,24] A constellation of host factors is believed to play a role in the ability of an individual to asymptomatically carry this organism. It is estimated that 20% of humans are persistent *S. aureus* carriers, 60% are intermittent carriers, whereas the remaining 20% are noncarriers.[24] Carriage of MRSA has similar anatomic predilections but occurs less commonly, being more prominent in hospitalized patients and health-care workers.[15,24] Some patients who become colonized with MRSA eventually develop an MRSA infection. MRSA are easily spread from a colonized patient or health-care worker to other hospitalized individuals, usually via unwashed hands.[15,24] Airborne transmission may be important in the development of nasal carriage.[24]

Spectrum of Infection

S. aureus is characterized by an ability to harbor and express an impressive armamentarium of virulence factors, leading to a wide spectrum of infectious and toxin-mediated illnesses. Diseases caused by MSSA and MRSA have ranged from relatively mild skin and soft-tissue infections (cellulitis, folliculitis, furunculosis, and impetigo) and urinary tract infections to more severe conditions such as pneumonia, empyema, intra-abdominal infection, deep tissue infection, osteomyelitis, septic arthritis, device-related infections, septicemia, endocarditis, meningitis, brain abscess, and toxigenic states such as toxic shock syndrome, scalded skin syndrome, and food poisoning, leading to significant morbidity and/or mortality.[2] However, most individuals with MSSA/MRSA are colonized asymptomatically.

Therapy of Infections

Vancomycin is the first-line antibiotic used for the treatment of infections caused by MRSA. Newer agents with in vitro and in vivo efficacy against MRSA include

linezolid (an oxazolidinone), quinupristin-dalfopristin (a streptogramin A/B combination), daptomycin (a lipopeptide), and the topical antibiotics mupirocin and fusidic acid.[4,22] Some strains, particularly those acquired in the community, commonly demonstrate sensitivity to several other non-β-lactam antistaphylococcal agents, including clindamycin, trimethoprim–sulfamethoxazole, fluoroquinolones, macrolides, and aminoglycosides.[1,2,6,18]

MOLECULAR CHARACTERIZATION

Methicillin resistance in *S. aureus* and other staphylococci is caused by the production of penicillin-binding protein 2a (PBP2a, also known as PBP2′), a novel 78-kilo Dalton penicillin-binding protein encoded by the *mecA* gene.[10] PBP2a, along with PBPs normally produced by *S. aureus*, are enzymes that catalyze peptidoglycan cross-linking reactions in the bacterial cell wall, resulting in a rigid structure that protects the bacterium against osmotic cell lysis and death.[10] However, PBP2a is distinct from putative *S. aureus* PBPs in that it has a low binding affinity for β-lactam antibiotics, resulting in continued cell wall synthesis, albeit not as efficiently, at β-lactam concentrations that would otherwise be lethal.[10] Nevertheless, *mecA* expression—and hence PBP2a production—is variable, being regulated by at least 20 additional genes of known or unknown function.[10,17,18] Two particularly important regulatory genes are located adjacent to the *mecA* locus, namely, *mecR1* (encoding a membrane-bound signal transducer/inducer protein triggered by the presence of β-lactam antibiotic) and *mecI* (encoding a *mecA* transcription repressor protein), which make up the *mec* regulatory gene system, and, together with *mecA*, form the *mec* gene complex (of which there are two configurations in MRSA, designated type A or B).[18] These complexes, in turn, are located on a recently described large (21–67 kb) mobile genetic element, termed the staphylococcal cassette chromosome *mec* (SCC*mec*), which, via its cassette chromosome recombinase A and B (*ccrA* and *ccrB*) genes, integrates into the *S. aureus* chromosome at a specific location near the origin of replication.[7,18] These two *ccr* genes form part of a *ccr* gene complex, of which there are three types.[7,18] There are five types of SCC*mec* element, based on their overall genetic composition, including the type of *mec* and *ccr* gene complex they carry.[7,18] These elements function as antibiotic resistance islands and are responsible for the horizontal transmission of resistance to methicillin and other non-β-lactam anti-

biotics.[7] Types IV and V SCC*mec* elements are the smallest and most transmissible types, being prominent in community-acquired infections and typified by the lack of resistance factors to non-β-lactam antibiotics.[18] Because SCC*mec* elements are also found in methicillin-resistant coagulase-negative staphylococci, molecular assays for the detection of *mecA* or SCC*mec* alone are not diagnostic for MRSA unless a *S. aureus*-specific gene marker is included. A number of published protocols for the molecular detection of MRSA have been based on PCR and, more recently, real-time PCR platforms involving the detection of *mecA* and a *S. aureus*-specific gene marker such as *femA*, *femB*, or *nuc*.[19–22] The *fem* factors are normal chromosomal genes found in all *S. aureus*, mediating critical steps in peptidoglycan synthesis and being necessary for the expression of *mecA* in MRSA.

MOLECULAR TESTING

Conventional or real-time multiplex PCR methods may be used to detect MRSA. In the case of real-time PCR, a number of fluorescent-based technologies such as FRET,[20] TaqMan®,[21] and molecular beacon[22] probes have been used in this regard. This section will briefly outline methods for conventional and molecular beacon probe-based real-time PCR assays for MRSA detection.

Template DNA Preparation

Laboratory cultures

Isolates should be pure and phenotypically identified as *S. aureus* prior to testing. Control strains of MRSA (ATCC 33591), MSSA (ATCC 25923), and *mecA*-negative *Staphylococcus epidermidis* (ATCC 14990), in addition to a no-template (water) control, should be included with each run. Prepare a 1.0 McFarland standard suspension of the organism in 0.85% NaCl. Extract DNA using either commercial nucleic acid extraction kits or Chelex-100 resin. For the latter, Chelex-100 is added to 800 μL of bacterial suspension to a 1.5-mL final volume, followed by vortexing, heating to 80°C for 10 min, and centrifugation for 15 min at $16{,}000 \times g$, resulting in a supernatant containing template DNA.

Clinical specimens

Preferred specimens include nasal swabs or blood from positive blood cultures. For the latter, a single morphotype of gram-positive cocci in clusters resembling staphylococci should be confirmed prior to testing. Obtain a 0.5-mL aliquot of blood and centrifuge for 2 min at $900 \times g$ to remove particulate matter (e.g., charcoal). Resuspend the pellet in 0.85% NaCl and repeat centrifugation. Perform another centrifugation step at $12{,}000 \times g$ for 15 min to pellet down the bacteria. Resuspend the pellet in 0.85% NaCl to make a 1.0 McFarland standard suspension, then follow the subsequent directions for template extraction as outlined in ''Laboratory Cultures'' above. For nasal swabs, the use of commercial DNA extraction kits is recommended. Control strains should be included as for laboratory cultures.

PCR Primers and Probes

Tables 1 and 2 outline sets of primers and probes that may be used for conventional and real-time multiplex PCR assays, respectively.

Preparation of PCR Mixture

Conventional PCR: Prepare 25-μL reactions similar to that described previously,[26] but use 2 μL of supernatant containing template DNA and include the *femA* primer set.

Real-time PCR: Prepare 50-μL reactions as per the method of Elsayed et al.[22]

Amplification and Detection of Target DNA

Conventional PCR: PCR products may be separated by electrophoresis on a 1.5% agarose gel containing ethidium bromide and visualized under ultraviolet (UV) light.

Real-time PCR: The protocol of Elsayed et al.[22] may be used. Collect fluorescence data during the annealing stage of amplification. The presence of a specific amplicon is indicated by a probe-generated fluorescence signal exceeding the instrument-calculated threshold level.

CONCLUSION

Molecular detection of MRSA has greatly improved our understanding of the epidemiology of this resistant microbe. Further developments in molecular methods, heralded by the recent sequencing of the entire genome of a strain of MRSA, in addition to the emergence of DNA microarray technology out of the research setting, may lead to new and exciting diagnostic and therapeutic advances.

Staphylococcus aureus—Toxin Detection

Karsten Becker
Westfälische Wilhelms-Universität Münster, Münster, Germany

INTRODUCTION

Staphylococcus aureus is an extraordinarily versatile pathogen, colonizing distinct ecological niches and causing a wide spectrum of mild to severe, life-threatening infections in humans as well as economically important infections in animals. In addition to superficial lesions and systemic infections, *S. aureus* is responsible for toxin-mediated diseases, such as toxic shock syndrome (TSS), staphylococcal food poisoning (SFP), and staphylococcal scalded-skin syndrome (SSSS). The virulence factors causing toxicosis are members of the family of bacterial pyrogenic toxin superantigens (PTSAgs) comprising the TSS-causing toxic shock syndrome toxins (TSST) and the staphylococcal enterotoxins (SEs) producing the food-borne illness. In addition, PTSAgs have been strongly implicated in other acute (e.g., Kawasaki syndrome) and chronic diseases, such as atopic dermatitis. Furthermore, the exfoliative toxins (ETs)—also known as epidermolytic toxins—cause SSSS (also known as pemphigus neonatorum and ''Ritter's disease'').

THE ''SUPERFAMILY'' OF PYROGENIC TOXIN SUPERANTIGENS AND THE EXFOLIATIVE TOXINS

The PTSAgs of *S. aureus* belong to a ''superfamily'' of true exotoxins sharing common phylogenetic relationships, sequence homology, structure, and function.[5] Because they are bivalent molecules that bind two distinct molecules, they are able to stimulate T-lymphocyte proliferation in a non-antigen-specific manner by recognizing T-cell antigen receptor (TCR) Vβ and interacting with invariant regions on class II major histocompatibility complex (MHC) products on the surface of antigen-presenting cells (Fig. 1). Thus, by bypassing intracellular processing, they are the most potent activators of T lymphocytes stimulating, at nano- to picogram concentrations, up to 30% of T cells (only 1 in 10^5–10^6 T cells is activated upon conventional antigenic peptide presentation to the TCR); hence they are termed ''superantigens.'' This excessive polyclonal activation results in a massive release of proinflammatory cytokines (Fig. 1).[1,2] In addition, staphylococcal PTSAgs have several other important properties contributing to their role in disease. They have mitogenic activity and are able to induce high fevers, stimulate neutrophil recruitment to a site of infection resulting in local inflammation, and enhance host susceptibility to endotoxin shock 100,000- to 1 million-fold.

In contrast to the TSST-1 and SEs, the superantigenic activity of ETs has been debated for years. Whereas the mass of the ETs is similar to that of the staphylococcal PTSAgs, the degree of primary sequence and structural homology is poor.

Staphylococcal Enterotoxins

In addition to their nature as superantigens, SEs function as potent gastrointestinal toxins causing SFP, which has a major public health impact.[1,3–5] Superantigenicity and emesis activities of SEs have been shown to result from distinct regions of the toxin protein. SEs comprise a family of homologous but antigenically different exotoxins, which are heat stable and resistant to inactivation by gastrointestinal proteases. SEs have also been implicated in several allergic and autoimmune diseases. The repertoire of SEs includes the five classical enterotoxins SEA through SEE and the more recently identified enterotoxins starting with SEG (Table 1). To date, the ''alphabet'' of SEs and their coding genes has reached the letter ''Q.'' However, some of the recently described SEs were shown to be nonemetic, thus actually lacking the defining property of SEs. Nevertheless, the standard convention hitherto has been to refer to proteins exhibiting sequence similarity to SEs as enterotoxins.

For some SEs, slightly divergent sequences and minor epitope differences are known, resulting in their further subdivision.[5] SEC comprises several unique molecular variants named SEC_1, SEC_2, and SEC_3 as well as variants produced by animal-adapted strains of *S. aureus* and *S. intermedius*, such as ovine (SEC_{ovine}), bovine (SEC_{bovine}), and canine (SEC_{canine}) types. In addition, variants of SEG are known.

Different *S. aureus* strains harbor different combinations of PTSAgs.[6] The majority of the SE-encoding genes are located on mobile genetic elements [plasmids,

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020909

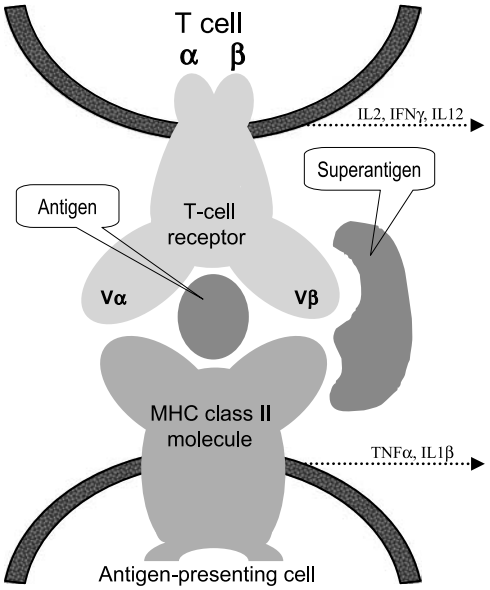

Fig. 1 Schematic representation of the different interactions of antigens and superantigens with the MHC class II molecule and the T-cell receptor.

prophages, and pathogenicity islands, e.g., SaPI1 (prototype), SaPI3, SaPI4, SaPIbov] except for the genes that encode SEG, SEH, and SEI, which are chromosomal. Analyzing the *seg–sei* intergenic and flanking regions, Jarraud et al.[7] found a highly prevalent operon encoding—in addition to SEG and SEI—further enterotoxins, designated SEK, SEL, and SEM. SEK and SEL were renamed subsequently as SEN and SEO, respectively. Phylogenetic analysis of all hitherto known SE genes indicates that they all potentially derived from this operon (named the enterotoxin gene cluster, *egc*), inferring that *egc* is in an SE gene nursery. Constructing phylogenetic trees from nucleic acid and amino acid sequences, respectively, three monophyletic groups were identified by Jarraud et al.: one composed of *sea*, *sed*, *see*, *seh*, *sej*, *sen*, and *seo*; another including *seb*, *sec*, and *seg*; and a third comprising *sei* and *sem*.[7]

Toxic Shock Syndrome Toxins

In 1981, Bergdoll et al. identified enterotoxin F, an exotoxin that caused TSS.[8] However, it was renamed toxic shock syndrome toxin-1 (TSST-1) because of its lack of emetic activity (Table 1). Despite its similar biological activities and three-dimensional structure, TSST-1 is generally considered to be different from other PTSAgs, forming its own group comprising—in addition to the classical TSST-1—a minor variant, $TSST_{ovine}$. Compared to other staphylococcal PTSAgs, TSST-1 is shorter and has no cysteines. Unlike the SEs, TSST-1 is able to cross the mucosa.

Exfoliative Toxins

Two classical, immunologically different ETs of *S. aureus* are recognized, ETA, which is chromosomally encoded and heat stable, and ETB, which is carried on a β-lactamase plasmid and is heat inactivated.[9] A serologically different heat-labile ET isolated from a horse strain of *S. aureus* was termed ETC. Recently, ETD, a novel ET integrated on a pathogenicity island, has been published.[10] Other SEs causing exfoliation in piglets were named SHETA and SHETB and have been purified from culture supernatants of *Staphylococcus hyicus* (Table 1).

Superantigenicity of ETs has been a subject of debate for many years. X-ray crystallographic structures of ETs suggest that they are members of the trypsinlike serine protease family. Although protease activity has not been demonstrated in vitro, ETA and ETB have intrinsic esterase activity, which is associated with serine proteases. Recently, desmoglein 1 has been identified as putative target protein for ETA.[11] Whereas some earlier studies describe ETs as mitogens (e.g., because of contamination of the toxin preparation with hitherto unknown superantigens), others fail to demonstrate superantigenic activity. A recent study with recombinant ETA and ETB demonstrates that these recombinant toxins do not act as superantigens.[12]

LABORATORY DETECTION OF EXOTOXINS

Phenotypic Detection Methods

Conventional methods for the detection of PTSAg-producing *S. aureus* strains are based on biological or immunological procedures detecting or measuring the toxin in culture supernatants of suspected *S. aureus* strains in contaminated food extracts or in patient specimens.

Biological methods using animals and human volunteers were the first approaches to determine the production of SEs. Monkeys have been considered to be the primary animal model to study the emetic activity of SEs. Investigating the emetic activity in biological assays is the most important basis to characterize a candidate exotoxin as yet unknown SE.

Since antigen–antibody reactions became available, the adaptation of immunodiffusion assays (e.g., Ouchterlony technique) for detection of toxin proteins have radically changed the diagnostics of PTSAgs. Further increase of sensitivity by about 100-fold because of the introduction of reversed passive latex agglutination, radioimmunoassay (RIA), and enzyme immunoassay (EIA) methods made it possible to detect as little as 1 ng/mL of toxin. Because biological assays are less specific and sensitive and restricted by high costs, availability of the experimental animals, and ethical considerations, immunological

methods, which are commercially available as diagnostic kits, are the basis for phenotypic detection of the classical PTSAgs.

However, conventional methods are relatively time- and labor-consuming. Nonspecific reactions due to cross-reactivity between PTSAgs and contaminations by nonstaphylococcal bacteria do occur. Furthermore, phenotypic assays depend on the concentration of PTSAgs expressed and thus can be negatively influenced by various factors (e.g., catabolite concentration, temperature, pH). Also, differences in the toxin production levels by strains grown on natural substrates and laboratory media have been described.

Regarding generalized SSSS, the superficial blisters are only very rarely culture-positive, but ET-positive strains are usually grown from specimens obtained from the suspected site of infection (e.g., umbilicus, breast, surgical wound). A number of different immunological

techniques have been developed to determine ET production by *S. aureus* recovered from patients with suspected SSSS. Although these methods have been reported to be specific and sensitive for detection of ETs, they rely on isolating putative toxinogenic *S. aureus* strains from the patient. A recently developed EIA based on $F(ab')_2$ fragments was able to detect ETA directly from serum with high sensitivity.[13]

Nucleic Acid-Based Detection Methods for PTSAgs

Hybridization methods

Since 1986, protein sequences have been established for PTSAgs and ETs as well as nucleotide sequences for the corresponding genes (Table 1). Early molecular approaches for the detection of these toxin genes have been developed that use DNA–DNA hybridization techniques based on gene fragments or oligonucleotide probes (enzyme-, hapten-, radiolabeled). For detection of toxigenic staphylococci, e.g., colony hybridization and single-phase liquid hybridization assays were used. The hybridization techniques have never gained much use for direct detection of PTSAg-bearing staphylococci in patient specimens or in food, because their sensitivity and specificity was too low.

Nucleic acid amplification methods

The advent of DNA amplification-based methods, in particular the development of the polymerase chain reaction (PCR), provides a new, highly specific and sensitive tool for the detection of the PTSAg-encoding genes.[14–16] In addition, the PCR technique allows the detection of toxin genes with little sample preparation in a relatively short period, most recently further shortened by the application of real-time PCR methods. The detection of SE- and TSST-encoding sequences by molecular methods has been reported by several investigators, mainly in DNA extracts derived from bacterial cultures and, to a lesser extent, directly in foods or patient specimens (Table 2). The development of multiplex PCR

systems allows the simultaneous detection of PTSAg genes for diagnostic and epidemiological purposes.

Nucleic acid-based methods are hampered by their inability to distinguish nonviable cells from viable ones because DNA from dead cells would also be amplified and detected. This may be of special importance for testing food samples, where enterotoxigenic staphylococci that have been killed by heat or other processing would yield a positive response. However, positive PCR results only indicate the presence of PTSAg genes in extracted DNA. They do not prove that production of toxin proteins occurs by a given isolate or indicate the presence of such proteins in samples. On the other hand, contamination of food products restricted on preformed SE proteins is not detectable by PCR but causative for SFP. In addition, false negative PCR results have been reported because of the presence of inhibitors of the DNA polymerases, which have been found to exist in food matrices.

Oligonucleotide arrays

Although oligonucleotide arrays (the so-called ''DNA chips'') have increasingly been used over the last few years to analyze DNA sequences as well as gene expression based on cDNA of mRNA for a number of microorganisms, applications to detect specifically staphylococcal toxins in medical specimens or food are still unavailable. Nevertheless, the potential is great because in contrast to traditional DNA detection methods restricted to target only a single or a few genes at a time at best, microarrays are able to integrate thousands of probes into the same chip-based hybridization procedure. This enables not only the detection of all staphylococcal toxins simultaneously, but also of other genes of specific interest, e.g., taxonomic marker genes, antibiotic resistance genes, and target structures for staphylococcal subtyping. However, this technique faces some of the same problems that have met traditional DNA hybridization, especially to get enough sensitivity to detect the target genes in specimens.

CONCLUSION

Detection of the genes involved in staphylococcal toxin-mediated diseases constitutes a challenge because the toxin-bearing bacteria are often present in low numbers and masked by other components of the specimen. Traditional phenotypic immunological and biological methods are time- and labor-consuming and often hampered by low sensitivity and specificity. DNA-based methods, especially amplification techniques, provide highly specific and sensitive techniques that allow the detection of staphylococcal target genes in a short period with little sample preparation. The ''all-in-one'' tool as offered by the microarray technology may further enhance our diagnostic options.

Streptococcus pneumoniae

David R. Murdoch
Christchurch School of Medicine & Health Sciences, Christchurch, New Zealand

INTRODUCTION

Streptococcus pneumoniae is a gram-positive bacterium that typically grows as lancet-shaped pairs of diplococci. All pathogenic strains are surrounded by a polysaccharide capsule that allows the bacterium to evade phagocytosis, thereby delaying clearance.

There are more than 90 capsular serotypes of *S. pneumoniae* and the distribution of each serotype varies with age and geography. Nasopharyngeal carriage of *S. pneumoniae* is common, especially in young children where rates of 40–50% are frequently observed. Carriage occurs in approximately 10–30% of adults at any one time.

S. pneumoniae is the most common cause of community-acquired pneumonia, otitis media, and sinusitis. It is also an important cause of primary bacteremia and meningitis. Less common infections with *S. pneumoniae* include endocarditis, peritonitis, and osteomyelitis.

OVERVIEW

Laboratory diagnosis of *S. pneumoniae* infection relies on culture of the bacterium from relevant clinical samples.[1] Typically, *S. pneumoniae* colonies have an umbilicated appearance surrounded by a zone of α-hemolysis when grown on blood agar. Identification of *S. pneumoniae* isolates is usually based on the demonstration of capsule formation, bile solubility, and/or susceptibility to optochin. Blood and other samples from normally sterile sites are the samples of choice for culture. Sputum culture is complicated by contamination with nasopharyngeal colonizing bacteria. Recent developments in pneumococcal infection diagnostics include a new immunochromatographic urinary antigen test that is sensitive for diagnosing pneumococcal pneumonia in adults.[2]

β-Lactams are the antibiotics of choice for treating *S. pneumoniae* infections. However, the global emergence of penicillin-resistant strains over the past 20 years has restricted therapeutic options. Extended spectrum cephalosporins (e.g., ceftriaxone) have been successfully used to treat serious infections with penicillin-resistant pneumococci, but resistance to this class of antibiotic is also increasing. Resistance to other classes of antibiotics (macrolides, tetracycline, cotrimoxazole, fluoroquinolones, and chloramphenicol) has also emerged to significant levels, and many *S. pneumoniae* strains are now exhibiting resistance to multiple antibiotic classes.

BODY OF TEXT

There are several clinical applications of genomics-based technologies to *S. pneumoniae*. Genotypic tests may assist with the identification and typing of *S. pneumoniae* isolates cultured from clinical samples. Gene amplification methods have been developed to rapidly detect *S. pneumoniae* directly from clinical samples, thereby obviating the need to rely on culturing the organism. Detection of antimicrobial resistance genes can provide valuable clinical and epidemiological information. Recent publication of the complete genome sequence of *S. pneumoniae* has facilitated the use of genomics-based technology to identify important genes of this bacterium, including the identification of potential new targets for antimicrobial drugs. The clinical applications of proteomic technologies in medical microbiology are still being realized, although proteomics is likely to have a future role in the investigation of the epidemiology, taxonomy, and antimicrobial resistance of human pathogens.

Use of Genotypic Tests to Identify and Type *S. pneumoniae* Isolates

Optochin susceptibility, bile solubility, and encapsulation are the phenotypic characteristics most widely used to identify *S. pneumoniae* isolates. While most clinical isolates of *S. pneumoniae* are readily identified with these phenotypic tests, the occurrence of isolates with atypical characteristics has increasingly caused problems in diagnostic laboratories.

For these reasons, there has been increased interest in genotypic techniques, such as gene amplification and DNA hybridization, for identifying *S. pneumoniae* isolates, especially those strains exhibiting atypical characteristics. The most widely studied targets for DNA amplification are the genes encoding pneumolysin (*ply*), autolysin (*lytA*), and pneumococcal surface antigen A (*psaA*). Although once thought to be specific to

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020914

S. pneumoniae, use of these targets has been complicated by the discovery that all three genes can occasionally be found in strains of other streptococci, especially *Streptococcus mitis*.[3,4] Modification of the polymerase chain reaction (PCR) primers used to amplify the *psaA* gene has enabled more specific identification of *S. pneumoniae*,[5] and positive results by this *psaA*-specific PCR are generally in agreement with the detection of capsule formation.[6] Initial reports of the results from partial sequence analysis of the gene encoding the manganese-dependent superoxide dismutase (*sodA*) indicate that this is a reliable method for species-level identification of streptococci from the mitis group (including *S. pneumoniae*).[7]

A commercial test using DNA probe complementary to the 16S rRNA of *S. pneumoniae* (AccuProbe®, GenProbe®, San Diego, CA) is being used by an increasing number of diagnostic laboratories. Evaluations of the AccuProbe® system have recorded positive results from streptococcal isolates with discordant combinations of phenotypic characteristics.[3,8] Without an absolute gold standard, it is difficult to be certain whether these atypical isolates are *S. pneumoniae* or not, although many of these isolates appear to be organisms that are genetically divergent from typical *S. pneumoniae* strains. Restriction digestion by *Rsa*I of the amplified 16S rRNA gene of *S. pneumoniae* produced identical results to the AccuProbe® system,[6] and may be a useful alternative to the AccuProbe® for identification of atypical strains of *S. pneumoniae*.

At present, the main role for genotypic tests is to aid the identification of atypical streptococcal isolates resembling *S. pneumoniae*, as optochin-sensitive, bile-soluble α-hemolytic streptococci are almost always *S. pneumoniae*. To date, no genotypic method, alone or in combination with phenotypic tests, has been shown to reliably identify all atypical *S. pneumoniae* isolates, although the *psaA*-specific PCR and partial sequence analysis of *sodA* are probably the most discriminatory of evaluated methods.

Typing of *S. pneumoniae* Isolates

Beyond the identification of *S. pneumoniae* strains, genotypic methods are increasingly being used for epidemiological typing purposes. Capsular serotyping by immunological means has been the standard typing method for *S. pneumoniae*, but requires technical expertise and is time-consuming; furthermore, not all strains are typeable. However, serotype data will continue to be required for historical comparisons and as part of pneumococcal vaccine studies. Serotype-specific multiplex PCR assays have been developed to provide a rapid and cost-effective method of providing serotype data,[9,10] obviating the need to perform immunological testing. When serotype data is unnecessary, the most commonly used genetic fingerprinting method for *S. pneumoniae* is restriction fragment-length polymorphism combined with pulsed-field gel electrophoresis.

Use of DNA Amplification Methods to Detect *S. pneumoniae* in Clinical Samples

PCR is the DNA amplification method almost exclusively evaluated in published studies for the detection of *S. pneumoniae*. A variety of PCR assays has been used, the most common targets being *ply* and *lytA*, although none has been sufficiently standardized for introduction into routine use.

Pneumonia

The use of PCR as a tool for diagnosing pneumococcal pneumonia has been evaluated in both adults and children. Most studies of *S. pneumoniae* PCR have focused on testing blood samples (whole blood, serum, or plasma) for the purpose of detecting occult pneumococcal bacteremia. Using positive blood culture as the comparison standard, the reported sensitivities for detecting *S. pneumoniae* in blood samples have ranged from 29% to 100% in adults, and from 57% to 100% in children.[11] When the definition of pneumococcal pneumonia also includes patients with positive sputum cultures, the reported sensitivities range from 26% to 88%.[11] The reason for this variation is unclear, as similar PCR protocols were used in most studies. Positive PCR results were also recorded from control subjects in many of these studies, and these findings are not readily explained.

For the few studies that have evaluated PCR for detecting *S. pneumoniae* in respiratory samples, sputum PCR positivity rates have been high (82–100%).[11,12] However, specificity of PCR testing of sputum samples is low because of its inability to distinguish colonization from infection.[12,13] It is possible that quantitative PCR may be useful in this setting, and that infection can be distinguished from colonization by a higher bacterial burden in the former,[14] but this is yet to be systematically evaluated. PCR has also been used successfully to detect *S. pneumoniae* in invasive respiratory samples.[15]

Meningitis

The diagnosis of pneumococcal meningitis traditionally relies on the appearance of gram-positive diplococci in cerebrospinal fluid (CSF) and/or the isolation of

S. pneumoniae from CSF. Both tests can be negative if antibiotics were given before CSF was obtained. A new immunochromatographic antigen detection test is a promising rapid method.[16] Several studies using a variety of assays have evaluated PCR as an alternative method for rapidly diagnosing pneumococcal meningitis,[17–22] including as part of assays designed to detect multiple bacterial pathogens.[17,20,21] These preliminary studies show that PCR is at least as sensitive as culture, and PCR may be particularly useful in Gram stain- and culture-negative cases. As yet, a standardized PCR assay has yet to be developed. Furthermore, no direct comparisons have been made between PCR and the immunochromatographic antigen detection assay for rapidly diagnosing pneumococcal meningitis.

One advantage PCR has over other rapid diagnostic techniques for meningitis is the potential to detect antimicrobial resistance as well as the pathogen itself. The rapid detection of penicillin resistance in *S. pneumoniae* is especially important for pneumococcal meningitis, as active antibiotics need to be commenced as soon as possible. Preliminary studies of seminested and real-time PCR systems targeting the pneumococcal penicillin-binding protein (PBP) 2B gene (*pbp2B*) enabled the rapid detection in the same assay of penicillin-resistant and penicillin-susceptible strains of *S. pneumoniae* in CSF.[18,22]

Otitis Media

PCR has been used to improve the sensitivity of detection of pneumococcal middle ear infections.[23] When testing middle ear fluid from patients with otitis media with effusion, almost all culture-positive samples are PCR-positive, and many other samples are culture-negative and PCR-positive. This almost certainly reflects the greater sensitivity of PCR over culture.

Detection of Antimicrobial Resistance Genes in *S. pneumoniae*

The genetic basis of resistance in *S. pneumoniae* to major antibiotics has been well documented. Resistance to β-lactams occurs when PBPs are altered through the acquisition of chromosomal DNA from other pneumococci or from other streptococcal species (especially *S. mitis*). Pneumococcal resistance to macrolides occurs by either target site modification through methylation or by active drug efflux. Tetracycline resistance is mainly attributable to the production of cytoplasmic proteins capable of interacting with the ribosome and making it insensitive to tetracycline inhibition. Resistance to fluoroquinolones is primarily mediated by point mutations in the genes encoding DNA gyrase (*gyrA* and *gyrB*) and topoisomerase IV (*parC* and *parE*), and less commonly by a drug efflux mechanism.

Diagnostic laboratories rely on phenotypic tests to determine the antimicrobial susceptibility profile of bacteria isolated from clinical samples. Increasingly, genetic tests are being used to complement phenotypic tests in the identification of antimicrobial resistance genes or mutations associated with antimicrobial resistance. The main reasons for detecting these genes are for epidemiological purposes and for the rapid identification of resistant strains directly in clinical samples; the former is usually a function of regional reference laboratories, while the latter remains restricted mainly to research laboratories. The detection and monitoring of penicillin resistance in *S. pneumoniae* has been the principal focus, as this resistance phenotype is of the greatest clinical importance. Detection of alterations in the genes encoding PBPs by PCR can provide information on penicillin resistance at least one day earlier than conventional phenotypic antimicrobial susceptibility testing.[24–27] In addition, the pattern of changes can predict whether penicillin resistance is low-level or high-level as determined by minimal inhibitory concentrations (MICs).[26] As already noted, rapid PCR assays have also been applied to the detection of penicillin-resistant *S. pneumoniae* directly in CSF samples from a small number of patients with suspected meningitis.[18] A major problem with the development of these PCR assays is the relatively divergent nature of the alterations in the genes encoding PBPs that confer penicillin resistance, particularly in the transpeptidase-encoding region. However, within this divergent region, there are alterations that are common in many penicillin-resistant pneumococcal strains,[25] and these changes are seen in pneumococcal strains from different geographic locations. Further work is needed to determine the best targets for PCR-based diagnostic assays.

CONCLUSION

S. pneumoniae remains an important human pathogen throughout the world. The emergence of antibiotic resistance (especially to β-lactams) has fuelled efforts to develop improved diagnostic tests to identify *S. pneumoniae* in clinical samples and to rapidly detect antibiotic resistance. Genetic, particularly PCR-based, tests have many attributes that make them ideally suited for this purpose. To date, there are no standardized PCR protocols for routine use in diagnostic laboratories and there are few genomics-based commercial diagnostic kits.

Future research needs to determine ideal PCR targets and sample types to overcome specificity problems when diagnosing pneumococcal infection and to accurately and rapidly detect antibiotic resistance. Quantitative PCR assays may assist in distinguishing colonization from infection with *S. pneumoniae*, and may provide prognostic information. Efforts to create robust standardized protocols will greatly assist with the introduction of these assays into routine diagnostic laboratories.

Streptococcus, Group A

Joseph E. Alouf
Heide Müller-Alouf
Institut Pasteur, Paris, France

INTRODUCTION

Streptococcus pyogenes (group A Streptococcus in the Lancefield classification scheme of serological typing) is a bacterial pathogen strictly associated with the human species (no animal reservoir known). This Gram-positive microorganism colonizes the throat or skin and is responsible for a wide spectrum of suppurative infections and nonsuppurative sequelae. The diseases caused by *S. pyogenes* range from simple skin infections (impetigo, erysipelas) and uncomplicated tonsillopharyngitis to more severe diseases such as scarlet fever, invasive deep tissue infections (cellulitis, myositis, necrotizing fasciitis), bacteremia, puerperal sepsis, streptococcal toxic shock syndrome (STSS), and very likely Kawasaki disease. Furthermore, group A streptococci (GAS) play a major role in the development of poststreptococcal infection sequelae including acute rheumatic fever (ARF), acute glomerulonephritis, reactive arthritis, Sydenham's chorea, and the recently investigated obsessive-compulsive disorders and Tourette's syndrome.

VIRULENCE AND PATHOGENICITY FACTORS

Great progress has been achieved over the past decade in our knowledge of these factors which comprise a great number of both cell surface (somatic)-associated molecules and extracellular products, among them the family of the streptococcal superantigens.[1,2] The interaction of these factors with host's tissues contributes to the virulence and pathogenicity of GAS and thereby initiates the pathophysiological processes leading to illness.[1–6] Moreover, the immunogenetics of the host influences the outcome of the streptococcal infection.[7]

SOMATIC VIRULENCE EFFECTORS

These factors expressed at the surface of the bacteria comprise the M proteins (124 serotypes), the hyaluronic acid capsule, and fibronectin-binding proteins, and other factors (lipoteichoic acid, various proteins) which allow *S. pyogenes* to bind to, colonize, and invade human mucus tissues and skin.[1,2] M proteins are the major virulence factors of the microorganism and act as antiphagocytic effectors by interfering with opsonization and phagocytosis by polymophonuclear leucocytes via the alternate complement pathway.[1] Strains of certain GAS M-protein types are more often associated with particular severe clinical syndromes. For example, during the past two decades, strains of M1 and M3 types have been frequently isolated from patients with severe invasive diseases associated with increased mortality in North America and Europe.[1,4,8] The resurgence of ARF in the 1980s in the United States was strongly associated with type M18 strains.[1]

THE STREPTOCOCCAL GENOME

The advent of recombinant DNA technology and recent deciphering of the genomes of *S. pyogenes* serotypes M1,[9] M3,[10] and M18[11] have taught much about the organism's virulence and pathogenicity mediated by both cell-associated and extracellular products. They have also allowed the discovery of a number of streptococcal superantigens.

The sizes of these three genomes are ca. 1.85, 1.90, 1.89 bp, respectively, and open reading frames (ORF) range between 1752 and 1895. Approximately, 1500 ORF are conserved between the three serotypes. Four to six bacteriophage genomes were identified per bacterial chromosome confirming that many cell-associated and extracellular factors are encoded by phage genome.

EXTRACELLULAR PRODUCTS

Group A streptococci release more than 25 extracellular proteins (not all of which have been well characterized) in culture media and in the infected host as reflected by immunoelectrophoretic analysis of concentrated culture supernates against concentrated human γ-globulins[12] and by assay of specific antibodies against streptococcal proteins in human sera.[4,8,10,16] The secreted proteins comprise the membrane-damaging (cytolytic) toxins

DOI: 10.1081/E-EDGP 120020912

streptolysin O and streptolysin S, NAD-glycohydrolase, cysteine proteinase, DNAses, other hydrolytic enzymes, and 11 exotoxins of the family of the bacterial superantigens (SAgs). The molecular and immunological aspects of these SAgs and their implications in the pathogenesis of severe streptococcal diseases, particularly toxic shock syndrome (STSS), are thereafter described.

WHAT ARE SUPERANTIGENS?

Superantigens include a class of certain bacterial and viral proteins exhibiting highly potent lymphocyte-transforming (mitogenic) activity toward human and or other mammalian T lymphocytes.[13,14] Unlike conventional antigens, SAgs bind to certain regions of major histocompatibility complex (MHC) class II molecules of antigen-presenting cells (APCs) outside the classical antigen-binding groove. They simultaneously bind under their native form to T lymphocytes bearing certain specific motifs in the variable region of the β chain (Vβ) of the T-cell receptor (TcR). The human T-cell repertoire comprises about 24 major types of Vβ elements.[15] Each SAg interacts specifically with a characteristic set of Vβ motifs. As a consequence, SAgs stimulate at nano- to picogram concentrations up to 30% of T cells, whereas only 1 in 10^5–10^6 T cells are activated upon conventional antigenic peptide presentation to TcR in the immune response.

REPERTOIRE AND BIOCHEMISTRY OF *S. PYOGENES* SUPERANTIGENS

The repertoire of *S. pyogenes* SAgs includes 11 structurally and functionally related, single-chain proteins with molecular weights ranging from ca. 23 to 27 kDa.[14] Most of these proteins have been purified to homogeneity. The repertoire comprises: 1) the classical erythrogenic (scarlatinal) toxins A and C (due to their likely association with scarlet fever), also designated streptococcal pyrogenic exotoxins A and C (SPE A, SPE C); 2) a series of recently discovered mitogenic exoproteins, called streptococcal superantigen (SSA), streptococcal mitogenic exotoxin (SMEZ), and the pyrogenic toxins SPE G, SPE H, SPE I, SPE J, SPE K, SPE L, and SPE M, respectively.[4,9–11,14,16] The occurrence of these exotoxins discovered over the past 12 years was inferred for some of them from genome mapping of serotypes M1, M3, and M18 GAS. The respective genes were further transcribed, and the superantigenicity and lethality of corresponding SAg proteins established.[16] Serological studies showed the presence of antibodies against these SAgs.[4]

GENETIC DETERMINANTS OF THE SUPERANTIGENS

All known streptococcal SAgs with the exception of SMEZ, SPE G, and SPE J are encoded by bacteriophage genes integrated in the bacterial chromosome.[4,9,14] Four naturally occurring *speA* alleles have been found in strains recovered from patients with severe invasive diseases. Three of these *speA*1, *speA*2, and *speA*3 encode toxins differing by a single amino acid. The toxin encoded by *speA*4 was 9% divergent from the other three ones with 26 amino acid changes. Strains expressing *speA*2 and *speA*3 have caused the majority of STSS episodes in the past 12 years, suggesting that the gene products, SPE A2 and SPE A3, may be the more bioactive toxic forms of the toxin. This may be due to higher affinity to HLA-DQ molecule. Four alleles of *speC* have been described and 24 for *smez* gene.[17] Detailed studies on SMEZ-2[19] and SMEZ-16[20] proteins showed that they are the most potent SAgs (in terms of mitogenic activity) discovered thus far.

Molecular Relatedness

The determination of the nucleotide sequences of the 11 streptococcal SAgs listed above allowed the establishment of their amino acid sequences which revealed various degrees of molecular and structural relatedness at both amino acid sequences and three-dimensional (3-D) levels. These SAgs were found to share important structural homologies or similarities with *S. aureus* enterotoxin SAgs. Interestingly, certain streptococcal SAgs are more similar to some staphylococcal SAgs than to other streptococcal SAgs.[14] The genomic and structural relatedness suggests that these SAgs share a common ancestor.[17,18]

Crystal Structure of the Superantigens

High-resolution X-ray crystallographic techniques have led to the elucidation of the 3-D structure of five *S. pyogenes* SAgs, namely, SPE C, SPE A, SSA, SPE H, and SMEZ-2.[17] All of these toxins as well as *S. aureus* SAgs investigated to date appear as compacted ellipsoidal proteins sharing a common characteristic two-domain folding pattern comprising a NH_2-terminal β barrel globular domain, a long α helix that diagonally spans the center of the molecule, and a COOH-terminal globular domain based on grasp motif.[18] Valuable information on the molecular architecture of MHC–SAg–TcR complexes was obtained by X-ray crystallography of the SAgs bound to human MHC class II molecules and (or) TcR.[14,18,19]

These studies revealed the essential role of Zn in this process for certain SAgs.

BIOLOGICAL AND MOLECULAR TEST METHODS FOR DETECTION OF SAGS AND SAG CARRYING *S. PYOGENES*

The detection and assay of SAgs in bacterial supernatants, purified preparations, or biological fluids (e.g., patient plasma) are based on the classical mitogen-induced lymphocyte proliferation test. Human peripheral blood lymphocytes, purified (Ficoll gradient) from the blood of healthy donors, are incubated in multiwell microtiter plates at 10^{-5} cells per well. After 48 hr, 0.1 μCi of tritiated thymidine is added for another 24 hr. The cells are harvested and thymidine incorporation is measured in a radioactivity scintillation counter.[4] This procedure is also used by testing the inhibition of SAg-induced lymphocyte proliferation by specific antibodies against the relevant SAg.[4]

The determination of SAg-specific TCR Vβ pattern is investigated by Vβ enrichment analysis using anchored multiprimer amplification.[15]

The identification of SAg genes in *S. pyogenes* isolates is undertaken by polymerase chain reaction (PCR). Bacterial isolates are grown overnight in brain–heart infusion medium. The bacterial cells are spun down and washed. Their DNA is purified and used for PCR with specific primers for the various *spe* genes. A primer pair specific to a DNA region encoding the 23S rRNA is used as a positive control.[4]

BIOLOGICAL AND PATHOPHYSIOLOGICAL PROPERTIES

Streptococcal as well as staphylococcal SAgs exhibits a remarkable spectrum of biological and pharmacological activities. These activities comprise among others 1) the pyrogenic effects resulting from the release of interleukin-1 and tumor necrosis factor-α;[20] 2) immunosuppression of humoral and cell-mediated responses, deletion of T-cell repertoire, anergy, and apoptosis of lymphocytes.[14]

Consequences of Immune System Cells Stimulation by Superantigens

The excessive activation of an unusual high proportion of T lymphocytes and APCs in vivo and in vitro upon binding the SAg molecules triggers massive production of a wide array of inflammatory and other Th1/Th2 and APC-derived cytokines, by the stimulated cells. This process takes place through a complex of upregulated and downregulated immunological networks, activation signals, and the cooperation of adhesion molecules on target cells leading to a cascade of events including further release (besides cytokines and chemokines) of other pharmacologically active products, particularly those of the arachidonic acid/lipid pathways.[4,14,21,22] This SAg-mediated hyperstimulation of the immune system of the host can overwhelm the host regulatory network and thereby assist pathogen evasion of the adaptive immune response.[18] Moreover, the excessive and aberrant activation of T cells causes damage to tissues and organs and cell apoptosis which may result in disease and even death.[13,22] Superantigen activity, particularly SPE A, has been found in acute-phase serum samples from streptococcal disease patients.[4]

CLINICAL ASPECTS OF SUPERANTIGEN-MEDIATED DISEASES

S. pyogenes represent a potent threat to both healthy and immunocompromised individuals. These bacteria release, besides the SAgs described here, a wide array of potentially harmful cytolytic toxins and exoenzymes.[1,2,4,12] As mentioned above, the production of these effectors during host infection by GAS contributes to a broad spectrum of diseases ranging from mild to severe cutaneous and other tissue infections, to life-threatening septicemia and toxic shock syndrome. A detailed description is beyond the scope of this review. We will summarize here the major aspects of STSS (reported death rate of 30% to 70%) mainly mediated by SAgs.[1,2,4,22] This illness is a significant portion of invasive *S. pyogenes* cases such as painful cellulitis, soft-tissue infections (necrotizing fasciitis, myonecrosis), bacteremia, deep-seated infections preceded by blunt trauma, muscle strain, hematoma, or joint effusion at the infection site. The early symptoms of STSS are often flu-like including myalgia, chills, and fever. Severe localized pain is a hallmark of the illness. These symptoms are followed by persistent fever, systolic hypotension, and shock. Multiorgan failure and tachycardia may occur as well fasciitis and myositis. Disseminated intravascular coagulation may lead to impaired circulation and subsequent gangrene of the limbs and ultimately death.[4,22]

Host Implication in Superantigen-Mediated Invasive Diseases

Several lines of evidence support the contention that certain individuals may be genetically more susceptible to the effects of individual SAgs in the pathogenesis of STSS and other severe streptococcal diseases in relation with the

excessive release of inflammatory cytokines triggered by the superantigens in host's organism.[7,13,23,24] Indeed, specific human leukocyte antigen class II haplotypes conferred strong protection from systemic diseases. Patients with the DRB1*1501/DQB1*0602 haplotype mounted significantly reduced responses and were less likely to develop severe systemic diseases.[7] This finding is supported by recent report showing that erythrogenic toxin SPE A binding to class II HLA is dependent on DQ α-chain polymorphisms such that HLA-DQA1*01 α-chains show greater binding than DQA1*03/05 α-chains.[24]

CONCLUSION

Streptococcal SAgs are very original and highly mitogenic bacterial protein toxins exhibiting particular mechanisms of molecular and functional action on immune system cells and indirectly on other cellular and tissue targets in the host. They play a major role in severe invasive streptococcal diseases, particularly in the pathogenesis of streptococcal toxic-shock syndrome. The in vivo SAg-mediated release of inflammatory cytokines has a pivotal role in these diseases. The immunogenetics of the host influences the outcome of invasive streptococcal infection.

Subtelomeric Rearrangements in Unexplained Mental Retardation

Samantha J. L. Knight
University of Oxford, Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Headington, U.K.

INTRODUCTION

Mental retardation (MR), also referred to as learning disability, learning difficulty, intellectual disability, developmental delay, impaired cognition, or mental handicap, is an extremely common condition, affecting about 3% of the population. Virtually all of those individuals with moderate to severe MR [intelligence quotient (IQ) under 50] need lifelong support and about half of those with mild MR (IQ 50–70) are significantly impaired throughout life. Although MR carries with it immense clinical, social, and psychological burdens, the origins remain poorly understood. Its causes tend to be thought of broadly, such as prenatal insult, social disadvantage, and inheritance. As a consequence, it has been impossible to provide effective therapeutic or preventive strategies.

One avenue that has been better pursued in recent years is the exploration of genetic causes. It has long been suspected that small chromosomal rearrangements, undetectable by conventional cytogenetic diagnostic methodologies, might be involved in the etiology of MR. However, it is only within the past decade that advances in molecular methodologies and technology have allowed this hypothesis to be tested. Initial studies focused on the ends of chromosomes (the telomeres and adjacent subtelomeric regions) and showed that small, previously undetected rearrangements are a significant cause of unexplained moderate to severe MR, occurring in 7.4% cases. These findings have been corroborated since through a vast number of independent patient studies, and the importance of subtelomeric anomalies in unexplained MR is now well recognized in clinical genetics.

This entry discusses the background to the subtelomeric studies, the methodologies available for testing subtelomeric regions, the MR subtelomeric studies to date, and how subtelomeric testing has become a widely used tool in clinical diagnostic laboratories, particularly in the diagnosis of unexplained MR. The conclusion addresses the overall impact that subtelomeric testing has had on the diagnosis of MR, the implications for patients and their families, and also future research avenues for exploring the genetic causes of MR and improving our overall understanding of neurocognitive development.

SUBTELOMERIC REARRANGEMENTS IN UNEXPLAINED MENTAL RETARDATION

Background

The standard test for suspected chromosomal rearrangements is cytogenetic analysis at a 400–550 band resolution. This has been available for many years, but cannot routinely detect rearrangements smaller than 5 megabases (Mb) and much larger abnormalities may be missed if they occur in regions where the banding pattern is not distinctive. The suggestion that a substantial proportion of MR might be a result of smaller chromosomal anomalies, undetectable using conventional cytogenetic analysis, gave the impetus to develop new molecular diagnostic assays which have a higher level of resolution and reliability.

A major advance came with the discovery that the very end portions of human chromosomes (the telomeres and adjacent subtelomeric regions) can be cloned by functional complementation in yeast. This paved the way for the identification of telomere-specific microsatellite markers and for generating telomere-specific cosmids, bacteriophage P1 artificial chromosomes (PACs), and bacterial artificial chromosomes (BACs).

Wilkie,[1] in 1993, first suggested that subtelomeric rearrangements might be responsible for MR. Screening telomeres for rearrangements held a number of attractions. First, the majority of translocations involve chromosome ends and therefore an assay that targeted telomeres would detect these with 100% sensitivity regardless of size. Second, the regions adjacent to telomeres are gene-rich so rearrangements involving these would be more likely to have phenotypic consequences than rearrangements in many other parts of the genome. Finally, rearrangements involving telomeres were emerging as an important cause of human genetic diseases. For example, Wolf–Hirschhorn, Cri du Chat, and Miller-Dieker syndromes and alpha-thalassemia with mental retardation of chromosome 16 were all known to be a result of the unbalanced products of subtelomeric translocations. In 1995, the results of a pilot study that used polymorphic loci to study the subtelomeric regions of 28 chromosomes in 99 mentally retarded individuals were reported by Flint

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020621

et al.[2] The findings suggested that at least 6% of idiopathic MR might be explained by submicroscopic rearrangements involving telomeres. The first extended study was reported by Knight et al.[3] who used a novel multitelomere fluorescence in situ hybridization (FISH) approach.[4] The results confirmed those of the pilot study and found that subtelomeric rearrangements contributed to the MR in 7.4% cases with moderate to severe MR with dysmorphic features, in about half of those with a family history, and also in 0.5% cases with mild MR.[3]

Subtelomeric Testing Methods

The complex structure of subtelomeric regions and the practical difficulties of testing 41 telomeres in a single procedure proved particularly challenging when it came to developing a robust, cost-effective diagnostic technique with a high degree of sensitivity and specificity.[5] However, subtelomeric rearrangements have now been detected using at least nine different approaches: 1) multitelomere FISH;[3] 2) multiplex or multicolor FISH, including M-TEL[6,7] and combined binary ratio labeling fluorescence in situ hybridization (S-COBRA FISH);[8] 3) telomere spectral karyotyping (telomere SKY);[9,10] 4) primed in situ labeling (PRINS);[11] 5) high-resolution chromosome analysis;[12] 6) comparative genome hybridization (CGH) to chromosomes;[13,14] 7) scanning short tandem repeat polymorphisms;[15–18] 8) locus copy number measurement by hybridization with amplifiable probes (MAPH)[19–21] and multiplex ligation-dependent probe amplification (MLPA);[22] and 9) telomere array CGH.[23,24] Of all the available methods, the FISH-based approaches still provide the gold standard for the detection of copy number changes and for balanced rearrangements (Fig. 1). However, neither these nor any of the alternative methods can be singled out as ideal; concerns over cost or sensitivity and specificity or both are constantly recurring issues. The advantages and drawbacks of each method are summarized briefly in Table 1.

Subtelomeric Anomalies and Unexplained Mental Retardation

Since the initial findings, the results of testing subtelomeric regions of almost 3300 individuals with MR have been reported. These can be divided broadly into three categories: 1) case reports; 2) studies of few, although highly selected patient sets; and 3) studies of smaller or larger sample sets referred because the patients have unexplained MR (includes mild or moderate to severe MR, with or without dysmorphic features and normal karyotypes at a 550-band level). The latter allow an estimate of the overall frequency of subtelomeric anomalies associated with MR. Of the 2690 unselected unexplained MR cases reported, 136 have subtelomeric rearrangements, giving a frequency of $\sim$5% in this group. The results can be further subdivided, at least for some studies, according to the degree of MR. Combining these, subtelomeric anomalies are found in 0.3% of those with mild MR and 7.9% with moderate to severe MR. Overall, the results show that small, subtelomeric anomalies are more likely to be present in those with moderate to severe MR, those with dysmorphic features, and those with a positive family history, but as addressed in the following section, these features are present in a substantial number of MR referrals.

Who Should Be Tested?

Patients with unexplained MR account for approximately 15% of all referrals passing through genetics and

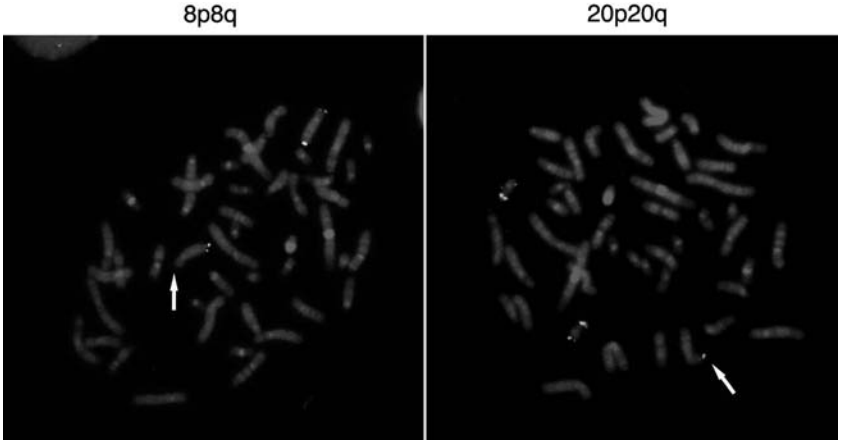

Fig. 1 Example of telomeric FISH result. The arrows highlight the unbalanced subtelomeric rearrangements in a patient monosomic for 8p (left metaphase) and trisomic for 20p (right metaphase). (*View this art in color at www.dekker.com.*)

Table 1 Subtelomeric testing methods

Method	Advantages and drawbacks
	Advantages
Multitelomere FISH	Interpretation is straightforward
	Tolerates poor chromosome resolution
SKY and M-FISH:	Tolerate chromosome preparations with low mitotic index
Telomere SKY, M-TEL, S-COBRA	Useful for samples where chromosomal material is limited
PRINS	Uses only a single probe for all telomeres
High-resolution chromosome banding	Extension of standard karyotypic analysis
	No additional expensive equipment required
CGH to chromosomes	Uses DNA sample
	Interrogates the whole genome as well as telomeres
Microsatellite genotyping	Uses DNA sample
	Can detect uniparental isodisomy as well as copy number changes
	Can be automated
MAPH and MLPA	Uses DNA sample
	FISH workload significantly reduced
Telomere array CGH	Uses patient's DNA sample
	Drawbacks
Multitelomere FISH	Labor-intensive
	Commercial kits expensive, but probes can be produced ''in house''
	Knowledge of polymorphisms and cross-hybridizations required
SKY and M-FISH:	Often labor-intensive
Telomere SKY, M-TEL, S-COBRA	Requires specialized, expensive imaging equipment and software
	Knowledge of polymorphisms and cross-hybridizations required
PRINS	Only detects monosomy
High-resolution chromosome banding	Labor-intensive. Requires highly experienced and diligent analyst
	Fully dependent on high-quality, high-resolution banding[a]
CGH to chromosomes	Resolution at telomeres only $\sim$4 Mb so smaller anomalies will be missed
	Efficacy yet to be proven for all telomeric regions
Microsatellite genotyping	Requires parental samples as well as probands
	Labor-intensive (can be many false positives to follow up)
	Requires highly informative markers (even with >85% heterozygosity, only 72% monosomies, 75% uniparental isodisomy, and 50% trisomies are detected)
MAPH and MLPA	False positive rate of $\sim$4%
	False negative rate of $\sim$2% (depending on the frequency of genuine copy number changes expected)
Telomere array CGH	Experimentally expensive and requires access to specialized arraying and scanning equipment
	False positive rate high and some probes give false negatives
	Rigorous evaluation and optimization pending

[a]In the United Kingdom, the recommended quality for microdeletion detection is quality score 7, as laid out by the National External Quality Assessment Scheme (NEQAS) (for information, see http://www.well.ox.ac.uk/~sknight/NEQAS/NEQASBandingCriteria.htm and http://www.ukneqas.org.uk/Directory/GENET/clincyto.htm). In practice, few laboratories achieve this standard routinely, although would endeavor to do so for selected cases, on request. According to the UK NEQAS for Clinical Cytogenetics 2000, sample slides submitted by the United Kingdom's 40 Clinical Cytogenetics laboratories ranged in quality from quality score 4 to quality score 8.

Source: Dr. Ros Hastings, organizer of UK NEQAS for Clinical Cytogenetics, personal communication.

pediatrics clinics, and so who then, among these vast numbers, should be investigated for subtle subtelomeric aberrations? Detection rates are higher among those with moderate to severe mental retardation, but screening all individuals in this group is usually considered impractical because of the cost. One argument is that the high rate of familial occurrence does justify blanket screening of all individuals with unexplained MR on the grounds that in familial cases, all results are informative.[3] However, a more cost-effective strategy would be to identify clinically a subgroup in whom small deletions occur at a much higher frequency. But is this possible? One approach that has been taken has been to investigate the clinical phenotypes of all of those MR individuals diagnosed

with a subtelomeric rearrangement and to identify features that occur more frequently in this group.[25] The results indicate that prenatal onset of growth retardation and a positive family history for developmental delay are good indicators for subtelomeric anomalies. These criteria, plus features suggestive of a chromosomal phenotype, have been included in a five-item clinical checklist, predicted to improve the diagnostic pickup rate of subtelomeric rearrangements among the developmentally delayed.[25] However, this checklist is not routinely adopted in clinical practice, presumably because diagnoses might be missed.

A more clinically useful approach is to determine whether anomalies of particular subtelomeric regions result in an identifiable and specific phenotype, thereby directing the clinician toward the diagnosis. This strategy is simplest when there is a de novo deletion or duplication affecting only a single subtelomeric region. The most striking example is the ''1p36 deletion syndrome.'' As shown in Fig. 2(a), cases of 1p monosomy account for

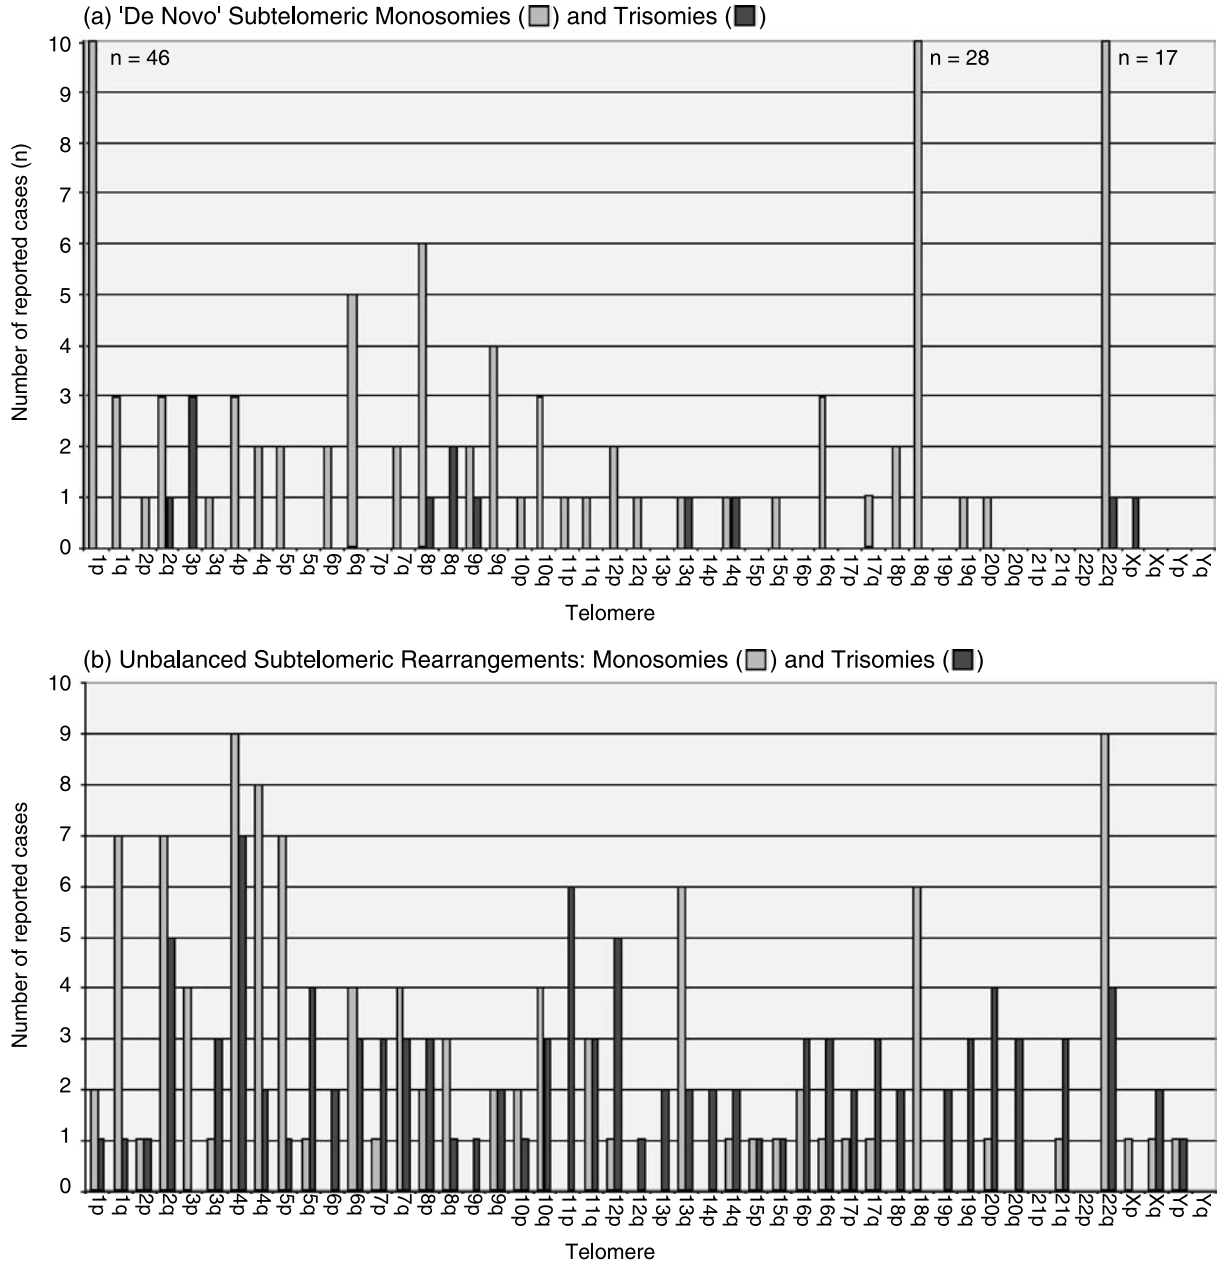

Fig. 2 Spectrum of telomeric involvement in reported MR studies (identical rearrangements within a family have been included only once). (*View this art in color at www.dekker.com.*)

one-third of all reported 'de novo' monosomies and trisomies, over twice that for any other telomere. From these cases, a specific 1p36 deletion phenotype has been defined and is already aiding clinicians. Monosomies for 18q and 22q also occur frequently [Fig. 2(a)]. Cytogenetically visible deletions both of the long arm of 18q and 22q13.3 are known to be associated with MR, although the overlapping phenotypes of patients with smaller subtelomeric deletions are likely to help refine and further delineate the chromosomal regions contributing to the phenotypes.

Figure 2(b) shows a summary of the anomalies reported in MR individuals with unbalanced subtelomeric translocations. The vast majority are familial originating from a phenotypically neutral, balanced translocation in one of the parents. Although some telomeres are more frequently involved than others, to date, there is no indication that specific translocation events between any two subtelomeric regions are favored over others. This makes it difficult to use unbalanced translocations to dissect out exactly which parts of a patient's phenotype are associated with the monosomy or trisomy because there may always be uncertainty regarding the phenotypic consequences of having both. For example, patients with unbalanced rearrangements involving monosomy 4p may have phenotypes atypical of Wolf–Hirschhorn Syndrome because the associated trisomy masks the features.[3] Furthermore, the actual combination of subtelomeric regions involved in an unbalanced rearrangement may determine the overall severity or even lethality of a phenotype. Nonetheless, some unbalanced translocations may prove informative, and studies have been undertaken to compare the anomalies found with their clinical phenotype.[26,27]

Spectrum of Telomeres Involved in Unexplained Mental Retardation

Of all of the subtelomeric anomalies noted in unexplained MR, there are only seven telomeres (including four acrocentric p-arms) for which no deletions have been reported and four telomeres (including two acrocentric p-arms) for which no duplications have been reported. For the acrocentric telomeres, this is most likely because chromosome-specific probes do not exist and, in most cases, available probes have not been tested. For the other telomeres, it may be because such anomalies are comparatively rare in MR. Alternatively, the subtelomeric deletions or duplications might be lethal, although this is unlikely to be the case for 18p, 19p, and Yq monosomies or for Yq and 18q trisomies because microscopically visible cases do exist. Another possibility is that some anomalies are being missed because they occur more distal to the current probe sets. Finally, some subtelomeric anomalies simply might not occur or might be phenotypically neutral or rare polymorphisms that will take more time to come to light. The latter do exist because a number of apparently normal individuals with subtelomeric anomalies have already been noted.[28]

CONCLUSION

The discovery that subtelomeric rearrangements are a significant cause of unexplained MR has led to a vast number of studies aimed at providing diagnoses in this group. Results from over 3000 patients show that rearrangements involving the ends of chromosomes can be detected in about 5% of unselected cases, that the prevalence of subtelomeric anomalies is higher in patients with moderate to severe MR (about 7%), and that in about half of those with subtelomeric anomalies, the rearrangements appear to have arisen de novo whereas in half they are familial, unbalanced rearrangements arising from balanced translocations in a parent. Efforts are in progress to refine our current knowledge and to identify more specific subsets of MR individuals by defining those phenotypes more likely to be associated with subtelomeric rearrangements. Some progress has been made based on reported cases, but many more cases need to be categorized before the phenotypes of particular deletions or duplications become clear.

Although originally developed for the study of idiopathic MR, subtelomeric testing is also proving useful for other clinical applications, including the full characterization of partially defined chromosomal abnormalities, the study of spontaneous recurrent miscarriages, infertility, and hematological malignancies, and for preimplantation diagnosis (in selected cases). Whatever the application, one diagnostically important issue will be to resolve how much monosomy or trisomy at each of the telomeric regions can be tolerated without phenotypic effect. This is being addressed by establishing a set of markers and clones to measure the size of monosomic/trisomic regions, thereby providing the foundations for future studies designed to determine whether a given subtelomeric rearrangement would be expected to be benign or pathogenic.[29]

The identification of subtelomeric rearrangements represents an important step toward understanding the genetic causes of unexplained MR. The findings thus far have been particularly relevant for providing clinical diagnoses and more accurate genetic counseling, but ultimately will be important for understanding cognitive development as a whole and for developing new therapeutic avenues. In this respect, subtelomeric studies have already opened important avenues for future research. For example, one crucial question is whether

small rearrangements occurring elsewhere in the genome might also be responsible for a significant proportion of unexplained MR cases. Indeed, there are already indications that whole-genome screening for copy number changes would be worthwhile.[15,30] One emerging technology that might prove suitable for this is CGH to microarrays as a single array-CGH experiment has the potential to identify copy number changes anywhere in the test genome at a resolution of 1 Mb or less. Using such approaches will undoubtedly lead to further advanced diagnostic, counseling, and therapeutic capabilities together with a greater scientific understanding of unexplained MR and will also find application in a wide range of other human conditions with genetic origins.

TaqMan Oligoprobes

Dino A. De Angelis

INTRODUCTION

The parallel development of fluorescent probes and of high-throughput thermal cyclers capable of continuously measuring fluorescence has fueled the emergence of real-time polymerase chain reaction (RT-PCR) as the diagnostic method of choice to accurately detect and quantify the occurrence of a specific DNA sequence in a given sample (see chapters on Real-Time PCR, Quantitative Real-Time PCR, Real-Time PCR platforms). The uses of RT-PCR range from gene copy number determination to RNA expression profiling to allelic discrimination, to name a few. Regardless of the chemistry used in RT-PCR, specific hybridization of the probe to the target DNA sequence ultimately results in the production of a specific fluorescent signal that can be measured in the reaction vessel directly, without any post-PCR processing of the samples (such as performing agarose gel electrophoresis of the reaction, or indeed even opening the reaction vessel). The major fluorescence detection technologies used in RT-PCR are described elsewhere in this encyclopedia, including DNA binding fluorophores, linear oligoprobes, hairpin oligoprobes (such as molecular beacons), scorpion probes, and hybeacons. The TaqMan assay has the privilege of being the most widely used fluorescence detection methodology for RT-PCR, and also one of the first ones to be developed. The purpose of this chapter is to introduce the principle behind the TaqMan assay, and to discuss different parameters in the design of TaqMan oligoprobes (also referred to as 5′ nuclease oligoprobes).

PRINCIPLE OF THE TAQMAN ASSAY

Like several eubacterial DNA polymerases, *Thermus aquaticus* (Taq) polymerase is a bifunctional enzyme consisting of a polymerization domain and a nuclease domain, and it is the latter that is crucial for the TaqMan assay.[1] In essence, the TaqMan assay is identical to a standard PCR reaction powered by Taq polymerase, except for the addition of the TaqMan probe, a nonextendable fluorescently labeled oligonucleotide hybridizing on the target DNA between the forward and reverse primers[2–3] (Fig. 1A). The TaqMan probe is modified with a fluorescent reporter dye (R) at its 5′ end and a fluorescence quencher dye (Q) at its 3′ end. Because of the proximity of the two dyes in the intact TaqMan probe, fluorescence resonance energy transfer (FRET) takes place from the reporter dye (FRET donor) to quencher dye (FRET acceptor) (De Angelis, FRET chapter, EDGP, and Ref. [4]). This proximity results in low fluorescence emission from the reporter dye because most of its excited state energy is transferred to the quencher dye. During extension from the forward primer, Taq polymerase encounters the TaqMan probe hybridized to the sequence being amplified. Taq then displaces the first few bases of the TaqMan probe off the template (Fig. 1B), and subsequently cleaves the TaqMan probe with its 5′ nuclease activity. While this was initially thought to be a 5′–3′ exonuclease, subsequent work showed that it is an endonuclease that cleaves at the juncture between the unhybridized and hybridized portions of the probe.[1,5] This cleavage results in an increased separation of the reporter dye on the 5′ end of the TaqMan probe from the acceptor (or quencher) on the 3′ end, yielding increased donor fluorescence emission (Fig. 1C). Therefore, when the TaqMan probe hybridizes perfectly to a DNA sample in the PCR reaction, an increase in fluorescence proportional to accumulation of the cleaved TaqMan probe follows every amplification cycle, and this signal is monitored in real time. On the other hand, in the absence of a perfect match, the probe remains intact and there is no increase of fluorescence above background.

The first use of the 5′ nuclease activity of Taq specifically designed to cleave a nonextendable, radioactively labeled oligonucleotide probe positioned between forward and reverse primers in a PCR reaction, was described in 1991.[6] The introduction of dual-labeled fluorescent probes[7] was a quantum leap that made the technology easier to use and safer; however, the analysis of fluorescence from accumulated cleaved probe in the sample still required some post-PCR reaction processing. The advent of the ABI PRISM™ 7700 system allowed continuous monitoring of fluorescence in real time.[8–10]

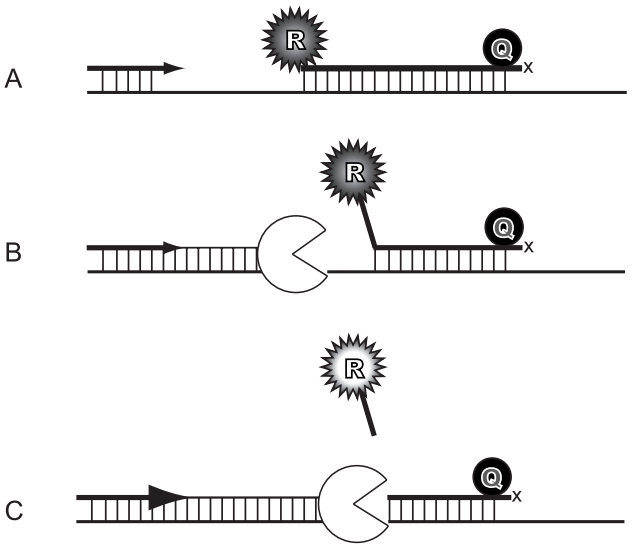

Fig. 1 Schematic depicting three stages of the TaqMan assay. (A) Hybridization: The forward primer (indicated by the arrow) and the TaqMan probe, labeled at the 5′ end with the reporter dye (R) and at the 3′ end with the quencher dye (Q) are shown annealing to the template DNA. The x on the TaqMan indicates that the probe is nonextendable. Proximity of R and Q yields low fluorescence from R through FRET. (B) Extension: Taq polymerase extends the forward primer and encounters the TaqMan probe. C) Cleavage: Taq polymerase cleaves the TaqMan probe, thus releasing the reporter from the quencher and causing an increase in the fluorescence of the reporter, which is monitored by the RT-PCR instrumentation.

PHYSICOCHEMICAL PROPERTIES OF TaqMan PROBE

TaqMan probes are covalently modified at the 5′ end with a reporter dye; commonly used dyes for this purpose are listed in Table 1. When excited by incident light, these dyes emit light at wavelengths ranging from 515 nm (FAM) to 565 nm (HEX, VIC). The first nucleotide of a TaqMan probe—the one covalently labeled with the reporter dye—can only be A, C, or T; a G residue is not allowed because this base partially quenches reporter fluorescence, whether the probe is cleaved or not.

The quencher dye can be positioned in the middle of the probe, but the 3′ end is preferred because the dyes can interact more effectively due to the greater flexibility of the probe, thereby increasing FRET efficiency and lowering reporter fluorescence before cleavage. Positioning the quencher at the 3′ end also ensures that the endonuclease activity of Taq can be activated at any point along the length of the probe, and still result in separation of the dyes. Tetramethyl rhodamine (TAMRA) is a commonly chosen dye because through FRET it can effectively quench the excited state energy of all the reporter dyes cited above (absorption range 500–570 nm) (Table 1). However, as it quenches the reporter, TAMRA also emits light of a different wavelength (~580 nm), which contributes to increasing the total fluorescence in the sample. Nonfluorescent quencher dyes such as DABCYL [4-(4′-dimethylaminophenylazo) benzoic acid] have been introduced. With an absorption range of 450 to 550 nm, DABCYL can effectively quench the fluorescence of the shorter wavelength emitting dyes (such as FAM, JOE, and TET) in the intact probe without contributing any fluorescent signal (compare the emission maxima of the reporter dyes in Table 1 with the absorption properties of the quencher dyes in Table 2). Proprietary dark quenchers with wider absorption ranges and evocative names are constantly being developed, such as Black Hole Quencher™ 1 and 2 (Biosearch Technologies), and Eclipse™ dark quencher (Epoch Biosciences). Nonfluorescent quenchers are particularly useful for multiplexing (chapter on Multiplexing, EDGP), where two (or more) TaqMan probes labeled with reporters with distinct emission maxima (such as FAM and HEX) are present in the same PCR reaction to simultaneously monitor the levels of different targets in the sample.[11]

In addition to being dual fluorescent labeled at the 5′ and 3′ end, TaqMan probes are also modified with a phosphate group at their 3′ end. This modification renders them nonextendable, preventing priming of DNA synthesis from the probe itself by Taq polymerase.

Table 1 Commonly used reporters for TaqMan probes

5′ Reporter	Full name	Absorbance (nm)	Emission (nm)
FAM	6-Carboxyfluorescein	492	515
TET	Tetrachloro-6-carboxyfluorescein	521	536
JOE	2,7-Dimethoxy-4,5-dichloro-6-carboxyfluorescein	520	548
HEX	Hexachloro-6-carboxyfluorescein	535	565
VIC™	A proprietary fluorescent dye (Applied biosystems)	535	565

Table 2 Commonly used quenchers for TaqMan probes

Quencher	Full name	Absorbance range (nm)	Emission
TAMRA	Tetramethyl rhodamine	500–575	580 nm
DABCYL	4-(4′-Dimethylaminophenylazo) benzoic acid	400–550	Dark
ECLIPSE™	A proprietary dark quencher (Epoch Biosciences)	390–625	Dark
BHQ-1™	A proprietary dark quencher (Biosearch Technologies)	480–580	Dark
BHQ-2™	A proprietary dark quencher (Biosearch Technologies)	550–650	Dark

SEQUENCE AND POSITIONING OF TaqMan PROBE

Many of the rules that apply to PCR primer design also apply to TaqMan probe design (see Primer/Probe Design chapter in EDGP). The sequence of the TaqMan probe should have GC contents within 40–60% preferably. Long sequences of identical nucleotides should be avoided in the probe. The sequence should be devoid of self-complementarity, or complementarity with the forward and reverse primers. The TaqMan probe should anneal as close as possible to the forward primer without overlapping. The size of the amplicon (dictated by the forward and reverse primers) should be quite short, never exceeding 300 bp.

The TaqMan probe should be 20–30 nucleotides in length, with a high melting temperature (65°C to 67°C). This is ~10°C higher than the forward and reverse primers of the PCR reaction, and ensures that the probe is bound more stably than the primers when there is a perfect match with the target DNA sequence (Fig. 1A). This is important, because hybridization of the probe with the template DNA activates the Taq 5′ nuclease activity, which in turn generates the fluorescence increase because of cleavage. In the case of a TaqMan probe designed to distinguish between two alleles of a specific marker gene, the polymorphic site should be positioned near the middle of the probe to cause as much destabilization as possible of the mismatched duplex (Fig. 2).

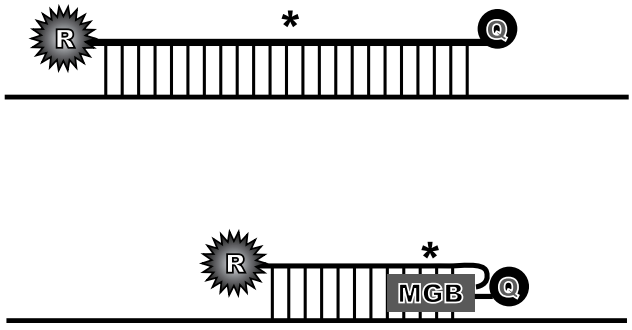

Fig. 2 Comparison of the classical TaqMan probe and the minor groove binder (MGB) TaqMan probe. Classical TaqMan probes (top) are longer than the MGB counterparts. Allelic discrimination is best achieved by positioning the polymorphic site (indicated by the asterisk) toward the center of the probe. The MGB probes (bottom) are shorter because of the additional duplex stabilization afforded by the MGB group over the span of approximately 5 base pairs. Allelic discrimination is best achieved by positioning the polymorphic site in the MGB portion of the TaqMan probe.

MINOR GROOVE BINDER PROBES

A recent improvement on classical TaqMan probes is the development of minor groove binders (MGB) chemistry.[12] Modification of an oligonucleotide with an MGB such as dihydroclyclopyrroloindole tripeptide (DPI_3) results in a substantial increase in the interaction of the oligonucleotide with a complementary DNA strand. The MGB effectively acts as a clamp that secures the base-pairing interaction between the oligonucleotide and the target DNA sequence (Fig. 2). The MGB interacts with the minor groove of the double-stranded DNA mainly through van der Waals forces, stretched over approximately 5 base pairs. The increase in stability is such that the binding energy of a 12-mer probe modified with an MGB group at either end is similar to the binding energy of a perfectly matching 27-mer, nonmodified oligonucleotide. For TaqMan probes, the MGB is added at the 3′end, which de facto makes the oligonucleotide nonextensible. The quencher dye can be conjugated directly to the MGB.

Unlike the TaqMan probe, where optimal discrimination of polymorphic sites is achieved by positioning the mismatch near the center of the probe, MGB-modified TaqMan probes discriminate between alleles better when the mismatch is in the 3′ end of the sequence (see asterisks in Fig. 2). Base mismatches in the MGB binding region of the TaqMan probe greatly affect the ability of the MGB to bind and stabilize the base-pairing interaction, resulting in destabilization of the DNA duplex. Whereas a mismatch in the non-MGB binding region results in a decrease of 3–9°C in the melting temperature of the duplex, a mismatch in the MGB portion of the probe can result in

decreases as much as 16°C.[12] Combined with the fact that MGB probes are much shorter than regular TaqMan probes (12–16 vs. 20–30 bp), this results in a superior mismatch discrimination overall when using MGB-modified probes.

CONCLUSION

Established more than a decade ago, the TaqMan assay is one of the most widely used several fluorescence-based detection methodologies for real-time PCR. Continuing improvements in the chemistry of reporter and quencher dyes have resulted in 1) lower background fluorescence and 2) higher discrimination potential of the probes for multiplexing purposes. These developments, along with the ease of designing the probes, ensure the TaqMan assay will remain very much in use for several years to come.

INTRODUCTION

Methodologies for the detection of nucleotide substitutions as well as small insertions and deletions in clinical molecular diagnosis of human genetic diseases have been recently reviewed.[1] For unknown mutations, although the gold standard is direct DNA sequencing, it is usually not practical to routinely sequence the entire coding regions of candidate gene or genes in patients suspected of having the genetic disease. Very often, a high-throughput, low-cost mutation screening method is used to quickly scan the coding exons and intron/exon junctions for the presence of mutations, followed by sequencing of suspected regions prior to sequencing of the regions containing the mutations. Commonly used screening methods for unknown mutations include denaturing gradient gel electrophoresis (DGGE),[2] temperature gradient gel electrophoresis (TGGE),[3] single-strand conformation polymorphism (SSCP),[4] heteroduplex analysis (HA),[5,6] chemical mismatch cleavage (CMC),[7] enzyme mismatch cleavage (EMC),[8,9] protein truncation test (PTT),[10] mismatch binding protein (MutS),[11] and cleavase fragment length polymorphism (CFLP).[12] The drawbacks of these methods include low sensitivity (SSCP, HA), difficulty in casting denaturing gradient gel (DGGE), synthesis of long GC clamped primers (DGGE, TGGE), the inability to detect homozygous mutations (HA, CMC, EMC), high background (CMC, EMC), lack of documented reports (CFLP, EMC, MutS), and preferential elimination of unstable mutant transcripts (PTT).[1] Furthermore, most of these methods are used for the detection of mutations in nuclear genes. Application of these methods to the detection of mitochondrial DNA (mtDNA) mutations is limited because of the heteroplasmic feature of pathogenic mtDNA mutations and numerous benign, homoplasmic single nucleotide polymorphisms. Thus a unique requirement for the molecular analysis of mtDNA mutations is the ability to detect heteroplasmic mtDNA mutations and to distinguish them from homoplasmic sequence variations. In search of an effective and sensitive mutation detection method, we recently developed the temporal temperature gradient gel electrophoresis (TTGE) that not only resolves the wild-type and mutant homoduplexes and the wild-type/mutant heteroduplexes into four distinct bands, but also detects a heteroplasmic or heterozygous change in the background of homoplasmic or homozygous polymorphism. Here we describe the utility of TTGE in the detection of mutations in both nuclear and mitochondrial genomes.

PRINCIPLES OF TTGE

Temporal temperature gradient gel electrophoresis (TTGE) was first introduced by Yoshino et al.[13] in 1991. It is based on the difference in the sequence-specific melting behavior of the normal and mutant DNA in a temporal temperature gradient that gradually increases in a linear fashion over the duration of the electrophoresis (Fig. 1). In TTGE, the denaturing environment is formed by a constant concentration of urea in the polyacrylamide gel and a temporal temperature gradient (0.5–3°C/hr). During the course of electrophoresis, the gradual temperature increase causes the double-stranded DNA to become partially denatured, and the electrophoretic mobility of the partially denatured DNA decreases. As a result of the different melting behavior, mutant and wild-type molecules are separated on the gel as they begin to denature at different temperatures (Fig. 1). A homozygous mutation shows band shift and a heterozygous mutation shows multiple bands because of the presence of two homoduplexes and two heteroduplexes at optimal separation conditions. Usually, an AT base pair to GC base pair change results in band shift-down and the GC pair to AT pair change results in band shift-up. This is because three hydrogen bonds in GC pairs hold the double-stranded structure tighter than the two hydrogen bonds in AT pairs. TTGE differs from TGGE in that TGGE has a fixed

DOI: 10.1081/E-EDGP 120020753

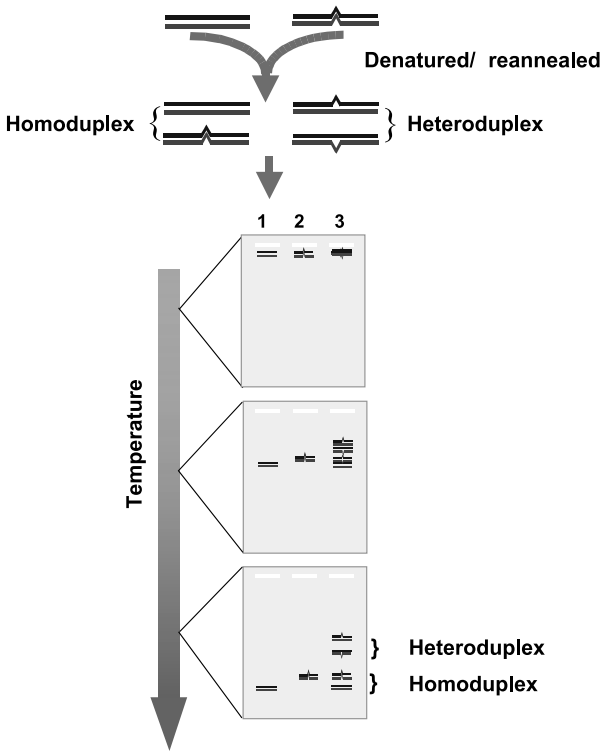

Fig. 1 Principles of TTGE. The PCR products are denatured and reannealed gradually to form homoduplexes, and heteroduplexes if there are mutations. During electrophoresis, the duplexes become partially denatured due to the temperature gradient. Based on the melting behavior of the duplexes, the partially denatured duplexes become separated while the temperature rises. (*View this art in color at www.dekker.com.*)

temperature gradient from top to bottom of the gel.[14] In TTGE, the temperature at any location of the entire gel is the same at any given time, but changes with respect to time (temporal temperature). Thus it is easier to modulate the temperature during electrophoresis and provide a broader separation range that leads to a much higher sensitivity of detection. Because the denaturant in TTGE is the temperature, there is no difficulty in the preparation of a chemical denaturant gradient gel. The size of the DNA fragments to be analyzed on TTGE can be as large as 1 kb. A GC clamped primer is not a requirement.

RUNNING CONDITIONS OF TTGE

DNA fragments of interest are amplified by polymerase chain reaction (PCR). The primers are usually about 18–22 nucleotides with T_m of 54–60°C, and the size of the PCR product is about 300–1000 bp. Prior to TTGE analysis, the PCR products are denatured at 95°C for 30 sec and slowly cooled to 45°C for a period of 45 min at a rate of 1°C/min. The samples containing reannealed homoduplexes and heteroduplexes are maintained at 4°C until loading onto the gel. TTGE is performed on a Bio-Rad D-Code apparatus. Two back-to-back 20 cm × 20 cm × 1 mm 4.5–6% polyacrylamide (acrylamide/Bis=37.5:1) gels are prepared in 1.25× TAE buffer containing 6 mol/L urea. The percentage of the gel depends on the size of the PCR product. Five microliters of denatured and reannealed PCR products are mixed with equal volume of 2× loading buffer (70% glycerol, 0.05% bromophenol blue, and 0.05% xylene cyanol) and loaded onto the gel. The electrophoresis is carried out at 110–145 V for 4–7 hr at a constant temperature increment of 1–2°C/hr. The temperature range for the electrophoresis depends on the melt curve of the DNA fragment determined by computer simulation using MacMelt (or WinMelt) software (Bio-Rad Laboratories). In addition, the melting temperature decreases by approximately 2°C for each molar of urea used. The gels are stained in 2 mg/L ethidium bromide for 5 min and imaged with a digital charge-coupled device (CCD) gel documentation system. DNA fragments showing alterations in banding patterns are sequenced to determine the nucleotide change. To confirm if a mtDNA mutation is homoplasmic or heteroplasmic, usually a second method, such as PCR/allele-specific oligonucleotide (ASO), dot blot, or PCR/restriction fragment length polymorphism (RFLP) analysis is used.[15,16]

APPLICATION OF TTGE ANALYSIS TO THE DETECTION OF NOVEL *CFTR* MUTATIONS

Cystic fibrosis (CF) is one of the most common and life-shortening autosomal recessive disorders, with an incidence of 1 in every 2000–3000 Caucasians. It occurs less frequently among African-Americans (1 in 15,300)[17] and Hispanics. The disease is caused by mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene.[18] Although it appears that the majority of CF mutant alleles carry the ΔF508 mutation, more than 900 *CFTR* mutations have been identified (Cystic Fibrosis Genetic Analysis Consortium, 2003, http://www.genet.sickkids.on.ca). The overall mutation spectrum and the common mutations found in specific geographic or ethnic background varied significantly among different populations. Current molecular diagnoses are designed to detect 80–97% of CF chromosomes in Caucasians and Ashkenazi Jews. However, by using the pan-ethnic mutation panel, the detection rate for Hispanic CF patients is only about 58%.[19] To improve the mutation detection rate and to provide a more accurate risk assessment for

Hispanic CF patients, TTGE was developed for comprehensive mutational analysis.

Primers were designed for all 27 exons, including at least 20 bp into the flanking intron regions.[20] The sizes of the PCR products range from 260 bp for exon 23 to 862 bp for exon 13. The PCR and TTGE conditions have been described above and also in a previous publication.[20] Figure 2 shows the detection of homozygous and/or heterozygous mutations and/or polymorphisms in *CFTR* gene. Panel A is a heterozygous G386A (G85E) mutation in exon 3 showing four bands. The two upper bands are heteroduplexes, and the lower two bands are homoduplexes, with the mutant homoduplex shift-up. Panel B is a heterozygous 875+40A>G polymorphism in intron 6A, showing similar four bands with the mutant homoduplex shift-down. Panel C is a heterozygous 124–146 del23 mutation showing two bands with the homoduplex deletion mutant shift-down. The mismatched heteroduplex bands are not formed, probably as a result of the large deletion. Panel D is a homozygous C2800T (Q890X) nonsense mutation in exon 5, showing single-band shift-up. Panel E shows a homozygous (lane 2) and a heterozygous (lane 3) 1285insTA mutation. The two homoduplex and the two heteroduplex bands are clearly separated.

These results indicate that TTGE banding patterns of homozygous and/or heterozygous mutations can be easily recognized. Using TTGE analysis, we have identified at least 22 novel mutations and 2 novel polymorphisms.[20,21] Sequencing of the 350 TTGE negative DNA fragments detected eight additional distinct mutations. These mutations are either located in the GC-rich region or close to the end of the DNA fragment, or nucleotide substitutions without the change in the number of hydrogen bondings. However, as soon as the TTGE condition is optimized for the melting domain in which the mutation located, the mutations were detected.

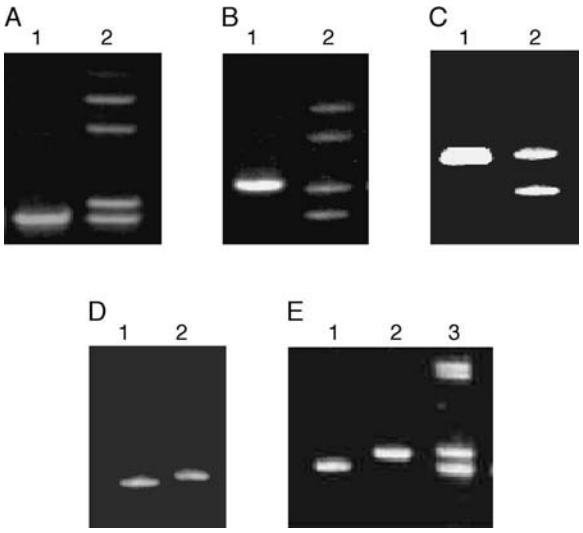

Fig. 2 Detection of mutations in *CFTR* gene by TTGE analysis. Lanes 1 are wild-type DNA and lanes 2 and 3 are mutant DNAs. A) Heterozygous G386A (G85E) mutation in exon 3. B) Heterozygous 875+40A>G polymorphism in intron 6a. C) heterozygous 124–146del23 mutation in exon 1. D) homozygous mutation C2800T (Q890X) in exon 15. E) Homozygous (lane 2) and heterozygous (lane 3) 1285insTA in exon 8.

DETECTION OF HOMOPLASMIC AND HETEROPLASMIC MUTATIONS IN MITOCHONDRIAL GENOME

Energy metabolism disorders caused by mutations in mtDNA represents a group of heterogeneous diseases. The most frequently found mtDNA point mutations are A3243G for mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS), A8344G for myoclonus epilepsy, ragged red fibers (MERRF), T8993G/C for neuropathy, ataxia, retinitis pigmentosa (NARP), and Leigh syndrome, and G11778A for Leber's hereditary optic neuropathy (LHON).[16,22] Molecular analysis of the known mtDNA mutations is usually carried out by polymerase chain reaction/restriction fragment length polymorphism (PCR/RFLP) or multiplex PCR/ASO (allele-specific oligonucleotides) dot blot (cross reference) method. Recently, a capillary-based technique was also used for A3243G mutation analysis.[23] Using multiplex PCR/ASO method to screen 44 known point mutations in 2000 patients with mtDNA disorders, we have demonstrated that only about 6% of the patients had identifiable, disease-causing mutations.[16,22] These data suggest that the majority of the pathogenic mutations have yet to be identified.

One of the unique characteristics of mitochondrial genetics is heteroplasmy. Because there are hundreds to thousands of mitochondria per animal cell, the percentage of mutant mitochondria can vary from 0% to 100%, unlike the nuclear gene mutation that is 100% for homozygous and 50% for heterozygous. In addition, there are numerous homoplasmic mtDNA variations. Thus the requirement for an effective mutation detection method is the ability to distinguish between the heteroplasmic and homoplasmic mtDNA mutations.

Both psoralen clamp and GC clamp have been used for broad-range (0–80% denaturant) denaturing gradient gel electrophoresis (DGGE).[24,25] Michikawa et al.[25] developed the DGGE conditions for 18 psoralen-clamped DNA segments to analyze 20 different known mtDNA point mutations in tRNA genes. Sternberg et al.[24] used the traditional DGGE method with a GC clamp to investigate 35 unrelated patients with mitochondrial

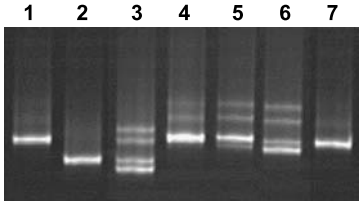

Fig. 3 Detection of heteroplasmic A3243G mutation in mitochondrial DNA. PCR products of 643 bp (nt3116 to nt3758) containing the $tRNA^{Leu(UUR)}$ and part of 16S rRNA and ND1 regions were analyzed with TTGE. Lanes 1 and 7: wild type; lane 2: homoplasmic T3197C polymorphism with band shift-down; lane 3: 47% heteroplasmic A3243G mutation in a homoplasmic T3197C polymorphism background; lanes 4–6: A3243G mutations with 7%, 24%, and 62% of mutant heteroplasmy.

encephalomyopathy. These studies were restricted to tRNA genes only. Recently, we have developed the temporal temperature gradient gel electrophoresis (TTGE) for the fast screening of the entire mitochondrial genome for mtDNA mutations.[26,27]

Thirty-two pairs of overlapping primers were designed to amplify the entire 16.6 kb of mitochondrial genome.[26,27] The primer sequences and detailed PCR and TTGE conditions have been previously described.[26,27] The sizes of the PCR products vary from 306 to 805 bp.[26] Figure 3 shows the ability of TTGE to detect various percentages of mutant A3243G heteroplasmy. The homoplasmic T3197C polymorphism shows a band shift down (lane 2) as a result of the TA pair to CG pair change. Under optimal conditions, a single heteroplasmic mutation produces four bands representing the wild-type and mutant homoduplex bands (lower two bands in lanes 3–6) and two wild-type/mutant heteroduplex bands (upper two bands in lanes 3–6). As can be seen in this figure, the intensities of the two heteroduplex and the mutant homoduplex bands increase as the percentage of the mutant A3243G mtDNA increases from 7% to 62% (lanes 4–6 of Fig. 3). The detection of the heteroplasmic A3243G mutation in the presence of a homoplasmic T3197C background is also illustrated, where the wild-type homoduplex and all other bands are down-shifted (Fig. 3, lane 3) because of the presence of T3197C polymorphism. These results clearly demonstrate the power of TTGE to detect and distinguish homoplasmic and heteroplasmic mutations, as well as to identify heteroplasmy in the presence of a homoplasmic polymorphism. If there is more than one heteroplasmic mutation within the same DNA fragment, TTGE will show more than four bands.[26,27]

TTGE analysis was performed on DNA specimens obtained from patients with mitochondrial respiratory disorders without identifiable common point mutations. DNA fragments showing abnormal banding patterns were sequenced to identify the exact mutations.[26] One of the difficulties is that direct DNA sequencing sometimes cannot unequivocally detect low levels of heteroplasmic mutations. Very often, TTGE detects heteroplasmic banding patterns, but sequencing does not detect the mutations although the reduced peak height of the wild-type nucleotide may suggest the presence of mutation. In this case, a second mutation detection method, such as ASO, should be designed to confirm the putative heteroplasmic mutation.[26]

SENSITIVITY, SPECIFICITY, FALSE POSITIVE, AND FALSE NEGATIVE RATE OF TTGE

From our experience in the study of *CFTR* nuclear gene mutations, the TTGE method has a sensitivity of detecting approximately 92% of all mutations. Its specificity is estimated to be about 99%, with a false negative rate of about 1%, without any false positives.

For mitochondrial genes, 109 samples with 15 different previously identified mutations in 6 different genes were analyzed. All the mutations and status of heteroplasmy/homoplasmy were correctly identified.[17] In the screening of unknown mtDNA mutations, some TTGE-positive DNA fragments did not show mutations upon direct DNA sequencing. This is probably a result of the limited sensitivity of DNA sequencing.

CONCLUSION

TTGE is a powerful method for mutation detection. It is simple, sensitive, high-throughput, and cost-effective. For nuclear gene mutations, the distinction between homozygous and heterozygous mutations is obvious. The identification of unknown heteroplasmic mtDNA mutations is more difficult. This is attributable to the limited sensitivity of direct DNA sequencing in the detection of low percentage of heteroplasmy. Very often, the TTGE showed the presence of heteroplasmic mutations but sequencing failed to score the mutation.

ABBREVIATIONS

ASO	allele-specific oligonucleotide
CFLP	cleavase fragment length polymorphism
CMC	chemical mismatch cleavage
DGGE	denaturing gradient gel electrophoresis
EMC	enzyme mismatch cleavage
HA	heteroduplex analysis

MutS	mismatch binding protein S mutation analysis
PTT	protein truncation test
SSCP	single-strand conformation polymorphism
TGGE	temperature gradient gel electrophoresis
TTGE	temporal temperature gradient gel electrophoresis

Tetracycline Resistance

Marilyn C. Roberts
University of Washington, Seattle, Washington, U.S.A.

INTRODUCTION

Tetracyclines were discovered in the 1940s and consist of a group of antibiotics that inhibit protein synthesis by preventing the attachment of aminoacyl-tRNA to the ribosomal acceptor (A) site. Tetracyclines are ''broad-spectrum'' agents with activity against a wide range of gram-positive and gram-negative bacteria, anthrax, chlamydiae, Lyme disease, traveler's diarrhea, brucellosis, *Helicobacter pylori* disease, *Francisella tularensis*, mycoplasmas and rickettsiae, and protozoan parasites.[1] These antibiotics are also used prophylactically for the prevention of malaria by mefloquine-resistant *Plasmodium falciparum*. Tetracyclines are also listed as alternative therapy for *Vibrio cholerae*, some atypical *Mycobacterium* diseases, *Burkholderia*, and *Donovana granulomatis*, and have potential use in the treatment of filarial nematodes and rheumatoid arthritis. In addition, a number of noninfectious conditions such as acne, blistering skin diseases, and rosacea use tetracyclines. Tetracycline was first available commercially in 1953, whereas the semisynthetic second-generation compound doxycycline became available in 1967. The favorable antimicrobial properties of these agents and the absence of major adverse side effects have led to their extensive use in the therapy of human and animal infections, and as food growth promoters in food animals.[1] In a span of 30 years, tetracyclines have accounted for almost one third of all antibiotics approved for human use. Although tetracyclines retain important roles in both human and veterinary medicine, the emergence of microbial resistance has limited their effectiveness. The increasing incidence of bacterial resistance to tetracyclines has in turn resulted in efforts to establish the mechanisms by which genetic determinants of resistance are transferred between bacteria and the molecular basis of the resistance mechanisms themselves.[1]

MECHANISMS OF TETRACYCLINE RESISTANCE

Resistance to tetracycline can be caused by mutations to host efflux pumps, their 16S rRNA sequences, or the altering permeability of the cell. This usually provides low-level stepwise resistance, which until recently has rarely been clinically important. The more common method is the acquisition of new genes conferring tetracycline resistance. It is believed that this second method occurred in the last hundred years, as illustrated by a study of Enterobacteriaceae collected between 1917 and 1954 where only 2% was resistant to tetracycline.[1,2]

Numerous studies have characterized acquired resistance genes. Presently, two genes are considered related and given the same gene designation if they share $\geq 80\%$ of amino acid sequences in common with each other. Two genes are considered different and given different designations if they share $\leq 79\%$ amino acid sequence identity.[3] This comparison can now be performed using GenBank sequence information. The number of *tet* genes has reached the end of the Roman alphabet and to accommodate new *tet* genes numbers are being assigned.[3] Levy et al.[3] have agreed to be the contact persons to confirm proposed new numbers for a new tetracycline resistance gene to prevent two distinct *tet* genes from being assigned the same numbers, or two related genes being assigned different numbers. There have been 33 different tetracycline-resistant *tet* genes characterized and three oxytetracycline-resistant (*otr*) genes characterized (Table 1).[4] This includes the *otr*(C) gene, which was recently sequenced in the laboratory and is another efflux protein. Nineteen of the *tet* genes and two of the *otr* genes code for efflux pumps, 11 tet genes and one *otr* gene, [*otr*(A)], code for ribosomal protection proteins, and three genes code for enzymatic alterations of the tetracycline molecules [*tet*(X), *tet*(36) and *tet*(37)]. (Table 1).[4] The *tet*(U) sequence is known but seems to be unrelated to other types of resistance genes (Table 1).[1]

In general, clinically important Tc^r pathogens rarely owe their resistance to mutations.[1] Some exceptions have been described including Tc^r cutaneous propionibacteria with mutations in the 16S rRNA.[1] Previously, little work has been performed specifically on the detection of tetracycline mutations, although more work is now being done.

DOI: 10.1081/E-EDGP 120025612

Table 1 Mechanism of resistance for characterized *tet* and *otr* genes

Efflux (21)	Ribosomal protection (11)	Enzymatic (3)	Unknown[a]
tet(A), *tet*(B), *tet*(C), *tet* (D), *tet*(E)	*tet*(M), *tet*(O), *tet*(S), *tet*(W), *tet*(32),	*tet*(X)	*tet*(U)
tet(G), *tet*(H), *tet*(J), *tet*(V), *tet*(Y),	*tet*(Q), *tet*(T), *tet* (36)	*tet*(37)	
tet(Z), *tet*(30), *tet*(31), *tet*(33)	*tet*(A), *tetB*(P),[b] *tet*	*tet*(34)	
tet(35)			
tet(K), *tet*(L)			
tetA(P)			
otr(B), *otr*(C)			
tcr3			

[a]*tet* (U) has been sequenced but does not appear to be related to either efflux or ribosomal protection proteins.
[b]*tetB*(P) is not found alone and the *tetA*(P) and *tetB*(P) genes are counted as one operon.

DETECTION OF ACQUIRED TETRACYCLINE RESISTANCE GENES

DNA–DNA Hybridization

The use of molecular tests to determine the carriage of specific antibiotic resistance genes began over 20 years ago.[5] Initially, the entire plasmid, or a relatively large fragment ($\geq$600 bp) carrying the gene of interest, was radiolabeled and used as a DNA probe in DNA–DNA hybridization assays to distinguish different *tet* genes from each other.[6] Then smaller ($\leq$500 bp) intragenic fragments, representing internal segments of the structural gene, were used. These were made by cutting the desired band out of a plasmid after it had been cleaved with restriction enzyme(s) and then by separating the fragments on an agarose gel. Currently, small 20- to 30-bp probes are used for hybridization. The sequences are determined by the gene or genes of interest and are prepared de novo. The advantage is that cross-hybridization is minimized, hybridization time is short, and they are now cheap to purchase.

All the various probes need to be labeled (radiolabel or nonradiolabel) before use. A number of nonradiolabeled systems are currently available commercially, but we have found that using these systems requires that the test be purified DNA to reduce possible interactions with the antibody used for detection and the protein left in the test DNA. In contrast with ^{32}P-labeled probes, whole bacterial dot blots cannot be screened using nonradiolabeling systems because they give too many false-positive reactions. Hybridization conditions depend on the base composition (G+C content) of the probe and should be set so that different *tet* genes do not cross-hybridize with each other.[7] The hybridization conditions will vary depending on the type of probe used, the type of label, and the kit used for the detection. Positive and negative controls should be run with each set of experiments.

To prepare dot blots from whole bacteria, turbid bacterial suspension (3 McFarland standard) are spotted onto a support such as nylon and then lysed in situ. For gram-negative bacteria, the isolates are taken from grown plates or in broth, whereas for gram-positive isolates, they must grow in broth with reagents that weaken the cell wall (D-threonine and glucose). To increase the sensitivity of the dot blot assay, we have used purified DNA instead of lysed bacteria.

Each method (radiolabel vs. nonradiolabel) for labeling probes has advantages and disadvantages. In the author's laboratory, both nonradiolabeled and radiolabeled probes were used. The radiolabeled probes can be reused for at least five to seven times. A disadvantage of the nonradiolabeled method is that it is unsatisfactory when using anything other than purified DNA because of the high level of false positives generated. Thus, nonradiolabeled probes are not used in the author's laboratory for whole bacterial dot blots because of the high background and the nonspecificity of binding with this type of target sample. In contrast, ^{32}P-labeled probes have few false positives and are very specific when using whole bacteria dot blots. For verification of novel finding, a second method such as polymerase chain reaction (PCR) with hybridization of the PCR product should always be performed.

PCR Assay

Numerous PCR assays have now been developed in a variety of resistance genes discussed in this review.[6–10] Each PCR assay uses a pair of primers, which can be the same as those used for DNA–DNA hybridization. The template may be purified DNA, proteinase-K lysates of whole bacteria, and/or direct patient materials. The PCR assay can use direct patient material, if from a normally sterile site, as the source of the template to determine whether a particular antibiotic resistance gene is present in the sample without growing the bacteria. Using nonsterile sites as source of material is not desirable because most of

the genes discussed in this review are commonly found in commensal species[8] and will be positive.

Initially, the PCR assays detected single genes. We then modified our two primers to look for *tet*(M)/*tet*(O)/*tet*(S) and the *tet*(K)/*tet*(L) PCR assays.[6,11] Which gene was amplified was determined by hybridization with an internal probe specific for only one of the three genes. More recently, multiplex PCR has been developed where each *tet* gene has it own set of primers and four to six different genes are detected in one reaction.[9,10] Each gene could be determined by the size of the PCR fragment. In all PCR assays, it is important to verify that the fragment visualized carries the correct sequences. Using one of these two methods is the only way to verify that the PCR fragment is correct. The multiplex PCR could be performed using a real-time PCR system, or even an automated system if available. Manual PCR assays are not well suited for quickly screening a large number (>100) of isolates per run. Both PCR and DNA–DNA hybridization methods can give false-negative results. To reduce the false-positive PCR assay, the author's laboratory uses an internally labeled oligonucleotide probe that is hybridized to the PCR products. This allows one to verify that the PCR product visualized is the correct one. Positive and negative controls are run with each assay. Reduction in PCR conditions may be used to identify related unknown genes. This is how the *tet*(37) gene was identified.[12]

Microarray

Microarrays offer a new method for screening for the presence of *tet* genes. In this format, the specific gene probes are placed onto a solid substrate in a lattice pattern. The test DNA is then labeled and hybridized to the array, and specific target–probe duplexes are detected using a reporter molecule. Recently, we developed and tested a glass-based microarray using 17 *tet* genes.[13] We initially tried to use the short probes we had developed for PCR and DNA–DNA hybridization (see above), but these were too insensitive to low copy number genes, which are usually found in natural isolates. They were able to detect cloned genes where there are high copy numbers of the target *tet* gene. We found that 550-bp PCR products used with purified DNA that was biotinylated were able to detect low copy numbers of *tet* genes.[13] Each probe was printed as four replicated spots within each array. The target DNA was grown and DNA was extracted with a DNeasy Kit (Qiagen). Other DNA extraction methods were not adequate. One microgram of target DNA was biotinylated using nick translation and then used. Detection used a Tyramide Signal Amplification, Alexa fluor 546, and microarray scanner. The detection threshold of three times the standard deviation above the standard negative signal intensity was set so that any signal over this threshold limit was called positive. Positive detection was confirmed either by PCR or DNA–DNA hybridization.

The prototype assay demonstrates the feasibility of developing a high-throughput planar microarray for the detection of *tet* genes. However, the current process needs to be automated before microarrays can be widely adopted. One advantage is that a variety of different probes ($\leq$10,000) can be incorporated on a single slide.

Mutation

Mutations that upregulate innate efflux pumps can alter the host's susceptibility. The mutation in the *marR* region of the chromosome enhances intrinsic resistance to a large group of antibiotics including tetracycline.[15] The level of tetracycline resistance increases as the cells are grown continually in the presence of tetracycline. Another example is *Neisseria gonorrhoeae*, which have an *mtrCDE*-encoded efflux pump. When there is a 1-bp deletion of an A within the 13-bp inverted repeat sequence of the *mtrR* promoter region, the host cell shows a fourfold increased resistance to tetracycline, penicillin, and erythromycin.[16] In *N. gonorrhoeae*, the chromosomally mediated resistance is often more common than plasmid-mediated acquired antibiotic resistance. Mutations in efflux pumps have been documented in a variety of pathogens and opportunistic species including *Burkholderia cepacia*, *Campylobacter jejuni*, *Escherichia coli*, *Enterobacter* spp., *Haemophilus influenzae*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Serratia marcescens*, and *Stenotrophomonas maltophilia*.[1,18] Recently, 15 Tc^r clinical isolates [minimum inhibitory concentrations (MICs): 2–64 μg/mL tetracycline and 1–32 μg/mL doxycycline] of cutaneous propionibacteria were found to have a cytosine instead of guanine at position 1058 in the 16S rRNA.[17] This change was associated with increased tetracycline resistance. Mutations, which alter the permeability of outer membrane porins and/or lipopolysaccharides, can also affect bacterial susceptibility to tetracycline and other agents.[18] How often these mutations occur and whether they are of clinical importance have not been established. At this time, mutations occur by sequencing the region thought to contain the base pair change(s).

CONCLUSION

The emergence of bacterial resistance to tetracyclines mirrors the situation with most antimicrobials currently in use. These drugs are relatively inexpensive, have a broad-spectrum of activity, and have been extensively used in the prophylaxis and therapy of human and animal

infections and as animal growth promoters. The selection pressures exerted by the use of tetracyclines in these various environments have resulted in the emergence of resistant organisms. The first tetracycline resistance *R* factors were identified over 40 years ago in Japan.[1] Since then, tetracycline resistance genes have spread in both gram-negative and gram-positive genera, primarily by conjugal transfer of plasmids and/or transposons. The dramatic increase in the number of species and genera that have acquired tetracycline resistance since the 1950s has led to a reduction in the efficacy and use of current tetracycline therapy for many diseases.

As PCR and microarray technology become less expensive and more automated, it will be easier for more laboratories to look at the genotypes of antibiotic-resistant bacteria. However, this information will need to be shown to be clinically relevant and cost-effective. This scenario assumes that clinical laboratories will continue to culture bacterial samples, although there are some suggestions that nonculture techniques such as PCR could replace standardized culture methods in the coming years because these methods can be less costly. Regardless of where culture methods go at this time, it is inadvisable to look for specific tetracycline resistance genes in direct samples other then those taken from normally sterile sites because many commensal bacteria carry the same resistance genes as do the pathogens.[1]

Thyroid Cancer—Detection of Tumor Cells by Molecular Methods

Jörg Bojunga
Stefan Zeuzem
Saarland University Hospital, Homburg/Saar, Germany

INTRODUCTION

Over the last years, new PCR-based techniques have improved the sensitivity and specificity of detection of primary and recurrent cancer in different types of neoplasms. In the field of endocrinology, thyroid cancer makes up more than 90% of all endocrine cancers and accounts for 63% of deaths from endocrine cancer, although thyroid neoplasms are rare, constituting only 1% of all cancer in the United States. Because most of initial diseases as well as recurrences can successfully be managed with surgical and/or radioiodine treatment, effective methods for early detection of thyroid cancer and disease recurrence are crucial.

RATIONALE FOR MOLECULAR DIAGNOSTIC TESTING IN PATIENTS WITH SUSPECTED THYROID CANCER

The initial workup of a thyroid nodule consists of ultrasonography and—if indicated—a fine-needle aspiration biopsy (FNAB). Despite the fact that cytological examination of FNAB by an experienced pathologist provides the most accurate and cost-effective means of diagnosing thyroid neoplasms, in some situations, cytological examination may not provide a conclusive diagnosis. For example, biopsy samples are cytologically found to be ''intermediate'' or ''suspicious,'' but most of these lesions are benign. In addition, preoperative diagnosis of lesions with follicular histology is difficult, and a consistent number of not otherwise specified ''follicular nodules'' are surgically resected more for diagnosis than therapeutic purposes. Because operation could be recommended only to those patients with a high risk of malignancy, the use of a molecular-based approach with detection of tissue- or tumor-specific mRNA transcripts may provide a more objective method to assure reliable diagnosis. As a consequence, molecular techniques for the diagnosis of cancer in thyroid nodules are most needed for patients in whom conventional FNAB cytology yields an indeterminate ''follicular neoplasm,'' patients who have either adenomas or low-grade carcinomas.

Besides the restrictions of preoperative FNAB mentioned above, postoperative surveillance of patients with thyroid cancer includes several limitations as well. Since the 1970s, serum thyroglobulin, especially when performed with TSH stimulation, is an established tumor marker of residual and recurrent differentiated thyroid carcinoma. However, serum thyroglobulin immunoassay results may be unreliable or uninterpretable in patients with antithyroglobulin antibodies, which can be detected in up to 20% of patients. Therefore a molecular-based, sensitive, and convenient screening test to diagnose recurrent thyroid cancer, not requiring TSH stimulation or the absence of thyroglobulin antibodies, would be useful.

PAPILLARY AND FOLLICULAR THYROID CARCINOMA

Galectin-3

Galectin-3 (GAL-3) is a β-galactosil-binding protein, which is involved in regulating cell–cell and cell–matrix interactions. In addition, galectins have been implicated in the initiation and regulation of cell growth and malignant transformation. Galectin-3 has been widely used as a marker of thyroid cancer in immunohistochemistry. Hereby normal thyroid tissue and benign nodules have been considered not to express GAL-3, while its expression has been demonstrated in malignant transformation of follicular cells. Using GAL-3 as an additional marker, most studies evaluating it as a marker in immunohistochemistry reported high sensitivity and specificity in differentiating malignant from benign thyroid disease for both FNAB-derived cytology and conventional histology.[1] However, there is some concern about the specificity of GAL-3 expression, because GAL-3 expression has been found in Hashimoto's thyreoiditis (HT) using immunohistochemistry, and even a ubiquitous expression of galectin-3 mRNA in benign and malignant thyroid tumors using RT-PCR has been

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120021942

described. Taken together, recent data indicate that a search for GAL-3 protein overexpression by immunohistochemical methods, but not by RT-PCR, may yield an additional marker of malignant potential of thyroid nodular lesions, and may be a useful adjunct to the currently available diagnostic tools for the preoperative diagnosis of malignant thyroid tumors.

CD44v6

CD44 is a polymorphic family of immunologically related integral membrane glycoproteins associated with cell–matrix adhesion, lymphocyte activation and targeting, and tumor growth and metastasis. Some variant isoforms, especially those containing sequences encoded by v6–v10, are overexpressed in several human neoplasms, including thyroid cancer, particularly in the papillary variant. Reports of successful differentiation of thyroid papillary carcinoma from other lesions by CD44 immunostaining of thyroid fine-needle aspirates were followed by studies using RT-PCR to detect CD44 mRNA in leftover cells inside the needle used for FNAB.[2] These studies suggested that thyroid tumors may be more accurately diagnosed by a combination of cytological examination and detection of CD44 variants in RNA obtained by FNAB, in particular when coexpression of CD44v6 and galectin-3 was detectable. However, CD44 exons were also present in transcripts in a high proportion of benign samples. Taken together, in thyroid cancer the clinical applicability of CD44v detected by RT-PCR still has to be determined, in particular in the light of the excellent specificity and sensitivity of FNAB conventional cytology in papillary thyroid carcinoma (PTC).

Oncofetal Fibronectin

Oncofetal fibronectin has been proposed as a possible tool for the preoperative diagnosis of thyroid carcinomas, based on the finding that the expression of oncofetal fibronectin mRNA was significantly increased in papillary and anaplastic carcinomas, compared to normal thyroid tissues and follicular adenomas. Several reports using oncofetal fibronectin as a marker of malignancy showed that combined examination using both RT-PCR-based and cytological approaches may contribute to a more precise preoperative diagnosis of papillary and anaplastic carcinomas.[3] However, other groups found that oncofetal fibronectin overexpression detected by immunohistology, but not RT-PCR, may yield an additional marker of papillary and anaplastic carcinomas.[4] Taken together, this particular marker is unlikely to benefit patients with ''follicular neoplasms'' and most of papillary lesion, although it may be helpful in diagnosing patients with papillary lesion and limited cellularity.

RET/PTC Rearrangements

RET activation has only been found in PTC tumors and is therefore called RET/PTC. Activated forms of the RET proto-oncogene are the consequence of oncogenic rearrangements fusing the tyrosine kinase domain of the RET gene with the 5′ domain of different genes. Therefore several variants of RET/PTC have been observed, the three main types designated as RET/PTC1, 2, and 3. Two other types of RET rearrangements (RET/PTC4 and 5) have also been described recently. In most populations, generation of the fusion transcripts is identified in almost half of PTC lesions.

One study examined thyroid aspirates for the presence of RET/PTC gene rearrangements by RT-PCR for the three most common ret/PTC gene rearrangements (RET/PTC1, 2, and 3). In this study, no false-positive results were obtained. In addition, the identification of RET/PTC gene rearrangements refined the diagnosis that would otherwise have been considered indeterminate or insufficient for cytological diagnosis in several cases.[5] Another study reported RET/PTC activation, in particular the RET/PTC1 isoform, in a significant number of cases of Hurthle cell adenomas and carcinomas, but not in hyperplastic nodules.[6] However, RET/PTC rearrangements have been found in benign nodules as well. In addition, on the basis of a growing number of RET/PTC oncoproteins, evaluation of only one, two, or three isoforms appears to be incomplete in most cases.

MEDULLARY THYROID CARCINOMA

In medullary thyroid carcinoma (MTC), laboratory tests for preoperative diagnosis and postoperative follow-up are performed using basal as well as pentagastrin-stimulated serum calcitonin (CT), which is supplemented by estimation of serum levels of carcinoembryonic antigen (CEA).

In contrast to papillary and follicular thyroid carcinoma, to date only a few studies have been published concerning the preoperative diagnosis of MTC using PCR-based methods. The reason for that discrepancy may be that patients with MTC are usually readily diagnosed by conventional cytology and serum calcitonin measurements. One study reported the preoperative diagnosis of MTC by RT-PCR using RNA extracted from leftover cells of FNAB.[7] As transcripts specific for MTC, calcitonin, carcinoembryonic antigen, and RET proto-oncogene mRNA, respectively, were used. In another study using identical primer sequences, calcitonin mRNA was found in all samples of FNAB derived from patients with MTC, but not in samples from patients with follicular adenoma and follicular/papillary carcinoma, respectively.[8] On the other hand, all MTC patients in these studies presented

with ''high levels'' of serum calcitonin, whereas all of the non-MTC patients but one had serum calcitonin levels below the threshold. Therefore, RT-PCR-based assays did not add any additional information to the measurement of serum calcitonin alone.

MOLECULAR ANALYSES OF PERIPHERAL BLOOD AND POSTOPERATIVE SURVEILLANCE OF THYROID CARCINOMAS

Papillary and Follicular Thyroid Carcinoma

The application of RT-PCR to detect circulating thyroid-specific mRNA in recurrent thyroid cancer was first reported in a study in which all patients with thyroid carcinoma and metastases were tested positive for circulating thyroglobulin (TG) mRNA, whereas patients without metastases were tested negative.[9] In a subsequent study,[10] circulating mRNA transcripts of TG, thyroid peroxidase (TPO), and RET/PTC1 were used as tumor markers in patients with thyroid disease. Although there was a correlation between existence of these transcripts in peripheral blood and diagnosis of thyroid carcinoma, TG and TPO mRNA transcripts could be detected in the peripheral blood of all control subjects as well as in several human cell lines when PCR assay sensitivity was increased. Finally, an optimistic study was published,[11] which reported an RT-PCR assay to detect blood-borne TG mRNA that was more sensitive than the conventional TG serum assay. However, in the study of the authors,[12] only a weak correlation between the detection of circulating TG mRNA and the diagnosis of thyroid cancer was found with low assay sensitivities, whereas at high RT-PCR sensitivity, TG-mRNA expression was found not to be specific for thyroid tissue and was not correlated with a diagnosis of thyroid cancer in patients. The conclusion was that TG mRNA is not a tissue-specific marker, which could be confirmed by testing different human tissues for TG mRNA expression. At low assay sensitivities, thyroglobulin mRNA expression was exclusively found in thyroid tissue, whereas at high sensitivities, thyroglobulin mRNA expression was not only limited to thyroid tissue but was also found in lymphocytes as well as in several other tissues.

Our finding of missing tissue specificity of TG mRNA has been reproduced by many other groups (see below), and now there is a bright spot of evidence that detection of TG mRNA in peripheral blood might reflect detection of illegitimate transcription in cell types of nonthyroid origin—e.g., lymphocytes—as it has been described earlier, and circulating TG mRNA is not a reliable tumor marker for the follow-up of patients with thyroid cancer.[13–15]

Medullary Thyroid Carcinoma

Searching for local relapse or distant metastases in medullary thyroid carcinoma is often very difficult and includes laboratory tests as mentioned above as well as selective venous catheterization, ultrasound, octreotide scan, computer tomography, and magnetic resonance imaging. Therefore molecular detection of circulating tumor cells may again represent a new approach in order to improve early diagnosis of metastasized MTC.

One study has been published which has explored blood-borne cytokeratin 20 mRNA as a potential tumor marker in thyroid cancer, especially MTC.[16] However, the limitation of this study was that the tissue specificity of the transcripts was not evaluated, and, as others have shown, the detection of micrometastasis by cytokeratin 20 RT-PCR is limited because of stable background transcription in granulocytes. Another study[17] investigated whether circulating tumor cells can be detected in the peripheral blood of patients with MTC by RT-PCR targeted to CT mRNA and whether the results of this method are correlated with disease manifestation and metastatic potential. Although the authors concluded that the results of the RT-PCR-based procedure seem to reflect tumor spread and aggressiveness and thus may help with early identification of patients with disseminated and rapidly progressive disease, these results have not been confirmed yet. In the study of the authors,[18] RT-PCR on blood samples from patients diagnosed with MTC disease was performed using primers specific for CT and CEA, respectively. Because there was no significant correlation between CT/CEA mRNA status and clinical staging, and, furthermore, comparable limitations as mentioned in the chapter above have to be expected, we could not recommend circulating CT/CEA mRNA as a tumor marker in MTC.

FUTURE PERSPECTIVES

In the preoperative diagnosis of thyroid cancer, several tissue- and/or tumor-specific mRNAs have been described. Molecular techniques for the diagnosis of cancer in thyroid nodules are most needed for lesions with follicular histology on FNAB, lesions which are either adenomas or low-grade carcinomas. To prove significant clinical utility for new molecular diagnostic techniques, the sensitivity and positive predictive value of these methods must be demonstrated. In several cases published, a higher sensitivity and specificity could be achieved using molecular techniques compared to ''conventional''

methods. However, new immunohistochemical markers have markedly enhanced the differential diagnostic accuracy between benign and malignant thyroid neoplasms, in particular galectin-3, which has been shown to be an important preoperative marker of thyroid malignancy and, in addition, seems to be a reliable presurgical marker to differentiate between follicular adenomas and follicular carcinomas as well. Especially in medullary carcinoma, the existing serum protein markers—calcitonin and CEA—and conventional cytology are quite sensitive for establishing the diagnosis. Reverse transcription-polymerase chain reaction-based methods have to be significantly more sensitive and specific to rationalize their considerably higher costs and expenditure of energy and time compared to established methods. To date, this has not been proven.

In the postoperative follow-up of patients with thyroid cancer, conflicting data have been published and the use of PCR techniques revealed several problems of the molecular approach. These problems are based on some technical as well as biological limitations.

First, most of the technical problems of the initial studies derived from the nonquantitative, but only qualitative, approach. Using ''low'' assay sensitivities, a correlation between PCR result and metastases of thyroid cancer could be observed, whereas at ''high'' assay sensitivities, nonspecific results were obtained and illegitimate transcription in blood cells was suspected as a cause. Additional studies using quantitative assay format initially seemed to circumvent this problem of qualitative RT-PCR assays and optimistic reports were published. However, recent studies using a quantitative assay provide evidence for the existence of thyroid-specific mRNA in peripheral blood of all patients, irrespective of their thyroidal status. These results give rise to a question regarding the clinical applications of not only qualitative RT-PCR detection but also quantitative measurement of tumor-specific mRNA in peripheral blood. Furthermore, many TG mRNA RT-PCR assays had a poor specificity and low positive predictive value. To date, no standardized RT-PCR assay exists and many different results between the groups may therefore simply reflect technical differences between the assays. For medullary carcinoma, the existing serum protein markers are quite sensitive and the rationale for the use of RT-PCR-based methods is questionable. Now before considering the clinical application of these methods, an intensive and complete reevaluation is obligatory.

Second, biological limitations of molecular assays have to be considered. A prerequisition for a reliable assay detecting circulating tumor cells is that these cells indeed circulate continuously in peripheral blood. However, there is experimental evidence of intermittent release of tumor cells in the bloodstream, and analyses of different blood samples taken at different times indicate that tumor cells persist only transiently in peripheral blood. An additional limitation of the molecular approach is that the presence of circulating tumor cells does not necessarily lead to the development of clinically significant metastatic disease. Several studies have shown that the metastatic process in humans is inefficient on both a temporal and numeric basis, and this phenomenon has been termed ''metastatic inefficiency.'' The vast majority of tumor cells that enter the bloodstream are killed by immunological, mechanical, and unknown mechanisms, and the lungs as well as the liver are the major sites responsible for this ''metastatic inefficiency.'' As a consequence, the amount of tumor cells circulating in the peripheral blood is considerably altered by these mechanisms.

CONCLUSION

Polymerase chain reaction-based techniques may improve the preoperative diagnosis and staging of patients with thyroid malignancies and therefore help to avoid unnecessary radical procedures. However, there is a growing number of literature on the use of immunostaining markers for the preoperative diagnosis of thyroid cancer. To date, the studies published do not give good reasons for the use of technically more demanding and probably less specific RT-PCR assays. In the follow-up of patients with thyroid cancer, a reliable PCR-based assay that predicts relapse or metastases is to date—in view of the many conflicting data that have been published—not available. Nevertheless, molecular detection of tumor cells is likely to have an impact on the practice of thyroid malignancies in the future.[19]

Tissue Microarrays in Pathology

Guido Sauter
Ronald Simon
Martina Mirlacher
University of Basel, Basel, Switzerland

INTRODUCTION

Advances in molecular medicine and biology have fundamentally changed biomedical research strategies. For example, the development of the DNA microarray technology, in conjunction with the completion of the human genome sequencing project, now enables researchers to analyze many human genes, in a highly parallel manner, on both the DNA and RNA levels. As a consequence, the rate of discovery of new genes involved in cancer and other diseases has increased significantly. However, a major drawback of the DNA array technology is the need for unfixed tissues and its enormous expense, which hampers comprehensive studies including statistically relevant sample sizes. In addition, such kinds of analyses require disintegrated tissues, obliterating information on the tissue distribution of marker molecules. Therefore, evaluation of the clinical importance of promising candidate genes is optimally performed using histological sections of diseased and nondiseased patient tissues. However, hundreds to thousands of tissue samples, optimally with attached follow-up data, must be analyzed to yield statistically sound results. This leads to a massive workload in involved pathology laboratories. Moreover, the analysis of multiple genes results in a critical loss of precious tissue material because the number of conventional tissue sections that can be taken from a tumor block usually does not exceed 200–300. To overcome the limitations of conventional tissue analysis, we developed the tissue microarray (TMA) technology, which significantly facilitates and accelerates in situ analyses. In this method, minute tissue cylinders (diameter: 0.6 mm) are removed from hundreds of different primary tumor blocks and subsequently brought into one empty ''recipient'' paraffin block. Sections from such array blocks can then be used for simultaneous in situ analysis of hundreds to thousands of primary tumors on DNA, RNA, and protein levels.

TECHNICAL DESCRIPTION

Preparatory Work

It is important to realize that most of the work (approximately 95%) devoted to TMA manufacturing is traditional pathology work that cannot be accelerated by machinery. This preparatory work is similar to what is needed for traditional studies involving ''large'' tissue sections, apart from the number of tissues involved, which can be an order-of-magnitude higher in TMA studies than in traditional projects. The preparatory work includes:

1. Identification of potentially suited tissues.
2. Review of all sections from all candidate specimens to select the optimal slide.
3. Definition of the structure (outline) of the TMA, including generation of a file that contains the identification numbers of the tissues together with their locations and real coordinates (Fig. 1 and Table 1).

Recipient Block Preparation

In contrast to normal paraffin blocks, tissue microarray blocks are cut at room temperature. Therefore a special type of paraffin is needed with a melting temperature between 55 and 58°C (''Peel-A-Way'' paraffin, Polysciences Inc., Pennsylvania, USA). The paraffin is melted at 60°C, filtered, and poured in a stainless steel mold (e.g., $30 \times 45 \times 10$ mm). A slotted plastic embedding cassette (as used in every histology laboratory) is then placed on the top of the warm paraffin.

TMA Manufacturing

TMA manufacturing is a simple three-step procedure that is repeated for each sample placed on the TMA:

1. Making a hole in an empty (recipient) paraffin block.

DOI: 10.1081/E-EDGP 120020800

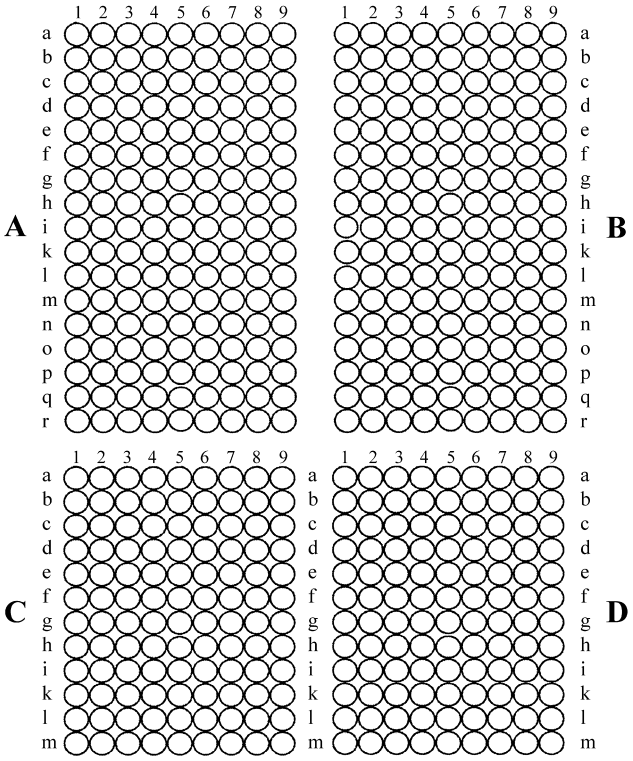

Fig. 1 TMA outline example. The TMA has been divided into four subsections to facilitate navigation during microscopy.

2. Taking a cylindrical sample from the tissue sample (donor) paraffin block.
3. Placing the cylindrical tissue sample in the premade hole in the recipient block.

Commercially available or various kinds of homemade tissue-arraying systems are used for TMA manufacturing. Exact positioning of the tip of the tissue cylinder at the level of the recipient block surface is crucial for the quality and the yield of the TMA block. Placing the tissue too deeply into the recipient block results in empty spots in the first sections taken from the TMA block. When the tissue cylinder is not positioned deep enough, empty spots are created in the last sections taken from this TMA. If tissue cylinders protrude, they may be gently pressed deeper into the prewarmed TMA block (40°C for 10 min) by using a glass slide.

Array Sectioning

TMAs can be sectioned like standard paraffin blocks by using regular microtomes. A special tape sectioning kit (Instrumedics Inc., NJ, USA) may be utilized to facilitate cutting, especially for large TMAs. The tape system leads to highly regular nondistorted sections (which are ideal for automated analysis) and helps to prevent arrayed samples from floating off the slide during incubation and washing steps.

TMAs from Frozen Tissues

TMAs may also be manufactured from frozen tissues.[1] Here recipient blocks are made from OCT compound (Sakura Finetek, the Netherlands) that is frozen down in a Tissue-Tek standard cryomold. The resulting OCT block is mounted on top of a plastic biopsy cassette. During the

arraying process, it is important to keep the tissue in the needle frozen. This can be carried out by cooling the needle with a piece of dry ice before punching, and while dispensing the tissue core into the recipient block, 4- to 10-μm sections of the whole block are cut from the array block, using a cryostat microtome with or without a Tape Transfer System and slides.

REPRESENTATIVITY OF TMAs

An important concern connected to the TMA technology is the question whether or not ''tiny'' tissue cores measuring less than 0.6 mm in diameter are representative of an entire tumor.[2–6] To date, at least 20 studies have addressed this question, comparing immunohistochemistry (IHC) findings on TMAs with the corresponding traditional ''large'' sections (e.g., Refs. [2–5,7]). Most of these studies reported a high level of concordance of results, and concluded that the inclusion of more than one tissue core per donor block further increases the concordance. For example, Camp et al. studied the expression of ER, PR, and Her2 in 2–10 tissue cores obtained from the same donor blocks in a set of 38 invasive breast carcinomas. They found that analysis of two cores was sufficient to obtain identical results, compared to the corresponding whole tissue sections in 95% of cases. A concordance of 99% is reached if four cores were analyzed, and analysis of additional cores did not result in a significant further increase of concordance.[2]

However, it is important to note that both large sections and TMA tissue cores represent only a very small fraction of the tumor bulk from which they derive. Perhaps, even more important than comparing individual results obtained on large sections and on TMA sections, is the question of whether or not the whole tumor can be represented by any type of size-limited histological samples such as TMAs or large sections.

APPLICATIONS OF TMA TECHNOLOGY

In principle, all types of research requiring in situ tissue analysis can be performed in a TMA format. For example, TMA sections have been used for IHC, fluorescence in situ hybridization (FISH), or RNA in situ hybridization (Fig. 2).[8,9] To date, TMAs have mostly been used for cancer research, but there are also many applications in other research fields. Depending on the aim of a particular analysis, oncology TMAs may be divided into four groups: prevalence TMAs, progression TMAs, prognostic TMAs, and TMAs composed of experimental tissues.

1. **Prevalence TMAs** are assembled from tumor samples of one or several types without attached clinicopathological information. These TMAs are useful to determine the prevalence of a given alteration in tumor entities of interest. A typical example of a prevalence TMA has been reported by Schraml et al.[10] The TMA containing 4788 different samples from 130 different tumor types has been used for the analysis of multiple different markers on the DNA and protein level, including FISH and IHC analysis of cyclin E amplification and overexpression. Cyclin E amplification was detected in 15 different tumor types and Cyclin E protein accumulation in 48 tumor types.
2. **Progression TMAs** contain samples of different stages of one particular tumor type. They are instrumental in uncovering associations between tumor genotype and phenotype. For example, an ideal breast cancer progression TMA would contain samples of normal breast from patients with and without breast cancer history, several different nonneoplastic breast diseases, ductal and lobular carcinoma in situ, invasive cancers of all stages, grades and histologic subtypes, as well as metastases and recurrences after an initially successful treatment.
3. **Prognosis TMAs** contain samples from tumors with available clinical follow-up data. They represent a fast-and-reliable platform for the evaluation of the clinical importance of newly detected disease-related genes. Validation studies using prognosis TMAs readily reproduced all established associations between molecular findings and clinical outcome. For example, significant associations were found between estrogen or progesteron expression[11] or HER-2 alterations[12] and survival in breast cancer patients, between vimentin expression and prognosis in kidney cancer,[13] and between Ki67 labeling index and prognosis in urinary bladder cancer,[5] soft tissue sarcoma,[14] and in Hurthle cell carcinoma.[15]
4. **Experimental TMAs** may be constructed from tissues such as cell lines[16,17] or xenografts.[18] Cell line TMAs are optimally suited for screening purposes, e.g., the rapid identification of cell lines with a specific genotype. Selected cell lines can then be grown and, e.g., utilized for testing potentially inhibiting drug candidates.

AUTOMATION

TMAs are optimally suited for large-scale expression profiling projects. Automation of the interpretation is the absolute key issue for such projects. In principle, TMAs

are highly suited for automated analysis. The greatest difficulty for automated tissue analysis, the selection of an appropriate tissue area, has been solved to a large extent during TMA manufacturing. Several systems enabling automated TMA analysis have recently been introduced. Some of them utilize fluorescent dyes for immunostaining because of the better dynamic range compared to peroxidase-based systems and the potential for multicolor analyses. However, fluorescence-based immunostaining is limited by the complex staining protocols for multicolor applications and the difficult manual reevaluation of questionable staining results. Most commercial products for automated TMA analysis, therefore, concentrate on conventionally immunostained TMA sections. These are generally based on an automated microscope with a charge-coupled device (CCD) camera. An overview image is used to identify the localization of each tissue spot in the TMA for subsequent high-resolution scanning. Studies have shown, that such ''low-tech'' solutions quantifying the total signal intensity per TMA spot are easy to establish and surprisingly efficient for identification of clinico-pathological associations.

CONCLUSION

The TMA methodology is now an established and frequently used tool for tissue analysis. The equipment is affordable and easy to use in areas where basic skills in histology are available. Basically, all kinds of in situ analyses, such as IHC, in situ hybridization, and in situ PCR assays, may be adapted to TMAs with only slight (if any) modifications of the respective large section protocols.

Treponema pallidum, T. pertenue, T. endemicum, and *T. carateum*

Hsi Liu
Centers for Disease Control and Prevention, Atlanta, Georgia, U.S.A.

INTRODUCTION

The genus *Treponema* includes pathogenic and saprophytic spirochetes. Four of the treponemes are human pathogens, and three of these are *Treponema pallidum* subspecies: subspecies *pallidum* (*T. pallidum*) causes venereal syphilis; subspecies *pertenue* (*Treponema pertenue*) causes yaws; and subspecies *endemicum* (*Treponema endemicum*) causes endemic syphilis, or bejel. The three subspecies of *T. pallidum*, with identical morphologies and similar antigenic properties and genomic structures, cannot be distinguished based on current serologic or genetic methods. The diseases are categorized according to their clinical presentations and the geographic distributions. *Treponema carateum*, the causative agent of pinta, remains classified as a separate species because of insufficient genetic information to determine whether it too is a subspecies of *T. pallidum*. Current efforts to control these diseases are focused on combining molecular and serologic methods with epidemiological surveillance and treatment.

T. PALLIDUM

T. pallidum causes venereal syphilis, also called ''the great imitator'' because the clinical features are similar to those of many other diseases. Untreated, syphilis progresses through several distinct stages. Following exposure and an incubation of 9 to 90 days, the primary stage becomes apparent and is characterized by a painless skin lesion called a chancre, and sometimes by regional lymphadenopathy. It is believed that *T. pallidum* is disseminated through the bloodstream within hours after initial contact with an infected person.[1–3] Chancres, which contain millions of organisms, usually heal spontaneously.[3] The secondary stage of the disease is characterized by generalized mucocutaneous lesions and lymphadenopathy. This stage is followed by a latent period, during which the infection can be detected only by serological tests. If the infection is left untreated, approximately one third of infected individuals will develop tertiary syphilis, characterized by gummatous lesions of any organ of the body including the cardiovascular or the nervous systems. Infants born to mothers infected with *T. pallidum* may contract congenital syphilis as a result of transplacental transmission. Congenital syphilis can be classified into distinct stages similar to those of acquired syphilis.

Epidemiology

In many industrialized countries, the number of syphilis infections has declined significantly. In the United States, the rate of infection so far in 2003 is fewer than four cases per 100,000 population; however, the number of cases is expected to fluctuate, and syphilis remains a significant health problem in many major U.S. cities. Meanwhile, the disease remains endemic in many other parts of the world. The World Health Organization in 1999 reported 12 million new cases worldwide, with some regions showing a significant increase in prevalence.[4] For example, the Russian Federation experienced a 26-fold increase of congenital syphilis from 1991 to 1999.[5] With current high rates of international travel, STD infections in one endemic region may easily become a significant problem in other parts of the world.[6] Concurrent HIV infection also alters the natural history of syphilis. Rapid progression from primary syphilis to neurosyphilis has been observed in many coinfected individuals. While no penicillin-resistant strains of *T. pallidum* have been reported, erythromycin-resistant *T. pallidum* has been described and results from a single base pair mutation in both copies of the 23S rRNA gene.[7]

Structure, Biochemistry, and Genomics

Treponemes are spiral in shape, 6 to 15 μm in length and 0.1 to 0.2 μm in diameter. They contain two membranes: the inner cytoplasmic membrane and an outer membrane, which is unique in its lack of membrane proteins and lipopolysaccharides. An endoflagella is located in the periplasmic space between the two membranes.

Use of trade names is for identification only and does not constitute endorsement by the U.S. Department of Health and Human Services, the Public health Services, and the Centers for Disease Control and Prevention.

DOI: 10.1081/E-EDGP 120020917

T. pallidum cannot be continuously grown in culture; however, up to a 2000-fold expansion has been achieved when treponemes are inoculated into eukaryotic cell cultures in the presence of serum, 1.5–5% O_2 and N_2.[8,9] The optimal temperature for in vitro growth is 33–35°C; this limited temperature range may result from the presence of heat-labile enzymes such as 3-phosphoglycerate mutase and may be regulated by minerals such as manganese.[10]

The complete genome of *T. pallidum* has 1.138 million base pairs, encoding an estimated 1041 open reading frames, and is relatively small compared to the genome of *Escherichia coli*.[9,11] The genome lacks almost all the pathways for fatty acid, amino acid, and nucleotide biosynthesis, but the genome sequence also reveals 18 ABC transporters, which may be important for acquiring these nutrients from the host environment. The genome lacks respiratory components or obvious pathogenic factors or plasmids and contains five possible hemolysins and many flagellar genes.

Analysis of the genome indicates a strong codon usage bias toward G and in the leading strand. Proteins made from the lagging strand are high in arginine but low in lysine content.[12] In addition, the DNA metabolism-related proteins contain twice the amount of cysteine as cell envelope proteins.[13]

Genetic Polymorphism and Molecular Typing

Despite the fact that pathogenic treponemes are closely related, a recent molecular system, based on two genes, *arp* (AF 411124) and the *T. pallidum* repeat gene (*tpr*; 8), has been used to type clinical isolates of *T. pallidum*.[14–16] The *arp* gene varies in the number of repeats of a 60-bp sequence, with clinical isolates demonstrating variations from 4 to 22 repeats. The *tpr* gene family consists of 12 genes (A to L). The typing system uses primers that amplify the *tpr* E, G, and J genes followed by *Mse I* endonuclease digestion and the RFLP patterns of the *tpr* genes. The system has been successfully used in several endemic regions and in outbreak situations in industrialized countries. However, this molecular typing method cannot distinguish between subspecies of *T. pallidum*. Other members of the *tpr* gene family (*tpr D* and *K*) have shown genetic polymorphism and multiple alleles, but may not be suitable for development into a typing system.[17,18]

Paster et al.[19] differentiated *T. pallidum* from oral and other spirochetes using a dendrogram generated from the 16S rRNA sequence, relying on a single base pair change. Several genes have been reported to have single base pair mutational differences when comparing *T. pallidum* with other nonvenereal treponemes.[20,21] However, unless the functions of the genes are known, a single base pair mutation alone may not be sufficient for typing purposes.

Recent Progress in Laboratory Tests for *T. pallidum*

An experienced clinician and a suitable laboratory test are essential for the diagnosis of syphilis. Two types of serologic tests are available: the nontreponemal tests, such as the VDRL and RPR tests, are used for screening, and the treponemal tests, such as TP-PA and FTA-ABS tests, are used as confirmation. Unfortunately, serological tests cannot distinguish active from previously treated or past infection. However, they remain the only means available to diagnose latent disease. One of the current goals is to develop treponemal tests utilizing cloned protein antigens.

Alternative diagnostic methods include direct detection of treponemes or specific nucleic acid sequences. The gold standard of direct detection of *T. pallidum* is the rabbit infectivity test (RIT). The RIT has a sensitivity of a single organism but is cumbersome, expensive, and time-consuming, requiring access to an animal facility, and takes 1 to 2 months to complete the test. Thus, it is not recommended for use as a routine laboratory test. Alternatively, treponemes can be visualized in lesion preparations by dark-field microscopy or direct fluorescent antibody tests (DFA-TP). Dark-field microscopy and DFA-TP tests have a sensitivity of approximately 10^5 organisms/mL in the lesion preparation.

Nucleic acid amplification tests (NAAT) such as the polymerase chain reaction (PCR), which amplifies and detects the presence of the nucleic acids of the organisms (dead or alive), are the newest laboratory tests developed in the past 15 years. Any segment of the genome of *T. pallidum* can be used to design primers for PCR. The primers, however, must be tested for specificity and sensitivity and validated using clinical specimens. Currently, six gene targets (*tpf*-1, *bmp*, *tmpA*, *tmpB*, 47-kDa protein gene, and *pol A*) and one RNA target (16s rRNA) have been reported as potential clinical tests. The analytic sensitivity of the targets varies from 10^{-3} of the 16S rRNA, because of multiple copies,[22] to one copy per reaction in the *pol A* PCR using the ABI 310 genetic analyzer.[23] The PCR primers designed from the 16S rRNA have the highest sensitivity; however, the method is complex, and it is difficult to control the specificity because primers' sequences resemble other species' 16S rRNA sequences. The primers for the 47-kDa protein gene (TP574) have been extensively tested. The *pol A* (TP105) PCR has been used in multiple samples, is relatively robust, and is sensitive to a single organism.[23] A combination of 47-kDa protein gene and *pol A* PCRs is recommended for use together as a diagnostic PCR test.

A newer generation of thermocyclers permit real-time PCR testing combined with microfluidic techniques, simplifying sample preparation to a single injection and making results available within 30 min. It is likely that a real-time PCR test will become the standard screening test for syphilis in the near future.

Nonvenereal Treponematoses

The three nonvenereal treponematoses have distinct clinical courses and can be separated into early and late stages similar to those of syphilis. Some excellent reviews on the characteristics of the diseases are available.[24–26]

T. PERTENUE

T. pertenue causes yaws (also known as frambesia, bouba, pian, parangi, or paru). The disease is transmitted nonsexually, by direct skin contact, with most patients infected in childhood. Yaws is characterized by skin ulceration and sometimes bone involvement. Yaws affects populations in humid tropical parts of West and Central Africa, in Southeast Asia, and in some Pacific Islands (Table 1). Sporadic infections are found in South America, primarily in Colombia, Venezuela, Haiti, and Brazil. However, the effects of intervention can be dramatic. For example, a 1988 survey performed in northern Ecuador found that 16.5% of the population had clinical symptoms of yaws and that 96.3% of the population was seropositive. As of 1998, after 10 years of community intervention, the TP-PA seropositivity rate had fallen to 3.5% in the same region, with no clinical yaws cases reported recently.[27] Although sporadic cases in rural areas or in the tropical rain forests still occur, this report illustrates that an intensive prevention and treatment program can eliminate yaws.

Table 1 Characteristics of treponemes and geographic distribution

Disease	***T. pallidum*** **syphilis**	***T. pertenue*** **yaws**	***T. endemicum*** **bejel**	***T. carateum*** **pinta**
Natural infection in host

Primates	+	+	+	+

T. ENDEMICUM

T. endemicum causes endemic syphilis, or bejel [also known as Skrljevo disease, Rijeka (Fiume), or Grobnik disease]. Bejel is characterized by mucous, skin, or osseous lesions, and is found mainly in dry and arid or temperate areas of Africa and the Middle East (Table 1). However, it has been eradicated in many locations. Bejel is transmitted by direct contact or contaminated fomites, and it mainly affects children 5 to 12 years old. Like yaws and pinta, bejel affects rural populations with poor sanitation and hygiene.

T. CARATEUM

T. carateum causes pinta (also known as mal de pinto, azul, or carate). Pinta is characterized by primary skin lesions, which may last for years; a latent period may follow, or secondary, disseminated lesions, called pintides, may appear and may persist for the patient's life. Serologic tests do not become positive until after secondary lesions have appeared. Pinta was once endemic in much of Central and South America, and remains prevalent in remote rural populations (Table 1). *T. carateum* can be propagated only in primates; thus, no organisms are currently available for genetic studies.

CONCLUSION

Despite the fact that treponemal infections can be easily cured by penicillin treatment, the diseases caused by pathogenic treponemes remain a global problem. Prevention efforts must be focused on finding and treating active cases. A better understanding of the biology of these organisms and improved diagnostic methods are also important. By combining inexpensive diagnostic methods, including extensive screening and effective treatment, global elimination of treponemal infections is possible.

ACKNOWLEDGMENTS

The author would like to thank the National Center for Infectious Diseases, CDC, for support of some studies presented in this review. I would also like to thank Drs. Bret Steiner, David Cox, and Ron Ballard for critical appraisal of the manuscript. I would like to apologize to my colleagues for not citing many important works because of space limitations.

Trichinella spp.

Edoardo Pozio
Istituto Superiore di Sanità, Rome, Italy

INTRODUCTION

Nematodes belonging to the genus *Trichinella* are the etiological agents of trichinellosis in humans, who acquire the infection by ingesting raw or undercooked meat and meat products from various types of animals. In animals, these parasites have a cosmopolitan distribution on all continents but Antarctica. According to the World Health Organization, the global prevalence of trichinellosis is around 10 million.

BIOLOGY

The adults of *Trichinella* parasites are small worms (1–2.5 mm in length and 0.025–0.038 mm in width), which live in the mucosa of the small intestine for 15–20 days and then in the striated muscles at the larval stage for years. The infecting stage is the larva (0.6–1.2 mm in length) present in muscles, which, after the ingestion by another host, develops to the adult stage in the small intestine in about 48 hr; male and female worms mate and females produce newborn larvae starting 5–6 days after infection. Newborn larvae, released in the lymphatic vessels by the female, migrate to the blood vessels and reach all body sites of the host. Only newborn larvae, which reach striated muscles, are able to develop to infective larvae. They penetrate the muscle cells and induce the host cell to change into a nurse cell, in which larvae can survive for years, waiting for a new host to ingest the infected muscles.[1] Some *Trichinella* species induce the formation of a collagen capsule around the larva in the nurse cell (encapsulated species), whereas other species do not induce capsule formation (nonencapsulated species).[2]

EPIDEMIOLOGY

The *Trichinella* genus includes eight species and three genotypes (Table 1),[2,3] which can only be distinguished through biochemical or molecular analysis.[4]

Both a sylvatic and a domestic cycle of *Trichinella* have been documented.[2,5,6] The sylvatic cycle has been observed for all *Trichinella* species, and it is maintained in nature by animals with cannibalistic and scavenger behavior (Table 1), although omnivores (e.g., wild boar) can also act as a reservoir. Human infections related to the sylvatic cycle are mainly caused by the consumption of game meat (e.g., bear, walrus, fox, cougar, wild boar, and warthog).[5] The domestic cycle is only established as a result of improper practices in animal rearing, mainly pig rearing[2] (e.g., the use of raw or uncontrolled pig scraps or the carcasses of sylvatic carnivores as food for pigs). In nearly all cases, the domestic cycle has involved *Trichinella spiralis*, although in particular epidemiological situations, *Trichinella britovi* and *Trichinella pseudospiralis* have also been transmitted between pigs and from pigs to humans.[2,6] A high prevalence of *Trichinella* infection in pigs has also been shown to be associated with the transmission to unusual hosts, such as herbivores. For example, in France and Italy, about 3500 human infections were caused by the consumption of raw horse meat imported from countries with a high prevalence of *T. spiralis* infection in pigs.[2] In China, where the prevalence of *Trichinella* infection in pigs is very high, hundreds of human infections were attributed to the consumption of mutton.[2] Whether or not rodents constitute a reservoir of *T. spiralis* in the domestic cycle has been a topic of debate, especially with regard to rats, although it is more likely that these animals act as a vector of *Trichinella* infection, as opposed to a reservoir.[2,6]

The countries reported to have the highest prevalence of trichinellosis in humans are Argentina, Byelorussia, Bulgaria, Chile, China, Croatia, Georgia, Latvia, Lithuania, Malaysia, Mexico, Moldova, Myanmar, Romania, Russia, Serbia, Thailand, and Ukraine. In the European Union, in the past 25 years, more than 6800 human infections, 5 of which resulted in death, have been documented, with the cause of infection reported to be the consumption of horse meat, pork, and game meat.[5] In the United States, in the past 10 years, about 40 human infections per year have been reported, including some deaths.[5] In Canada, about 20 persons per year acquire infection for the consumption of game meat, prevalently walrus meat consumed by Inuit populations in the Arctic.[5] A few human infections have also been documented in Africa (i.e., Ethiopia, Kenya, Senegal, and Tanzania) and in the Australian Region (New Zealand and Papua New Guinea).[2]

Table 1 Geographical distribution, hosts, and main biological and clinical features of *Trichinella* species and genotypes

Species	Geographical distribution	Cycle	Hosts	Biological features	Clinical features
T. spiralis	Cosmopolitan	Domestic and sylvatic	Pig, wild boar, horse, bear, fox	Encapsulated; no resistance to freezing; high number of larvae per female	Highly pathogenic; short incubation period; lethality <0.2%
Trichinella nativa	Arctic and subarctic regions of Asia, Europe, and North America	Sylvatic	Bear, fox, wolf, walrus, raccoon, cougar, dog	Encapsulated; high resistance to freezing; low number of larvae per female	Moderately pathogenic; long incubation period; severe enteric symptoms; deaths have been reported
Trichinella T6	Rocky Mountains (USA) from Montana to Alaska	Sylvatic	Bear, fox, wolf, cougar	Encapsulated; high resistance to freezing; low number of larvae per female	Moderately pathogenic; long incubation period
T. britovi	Temperate areas of Europe and Asia, Northern and Western Africa	Sylvatic; seldom domestic	Fox, wolf, raccoon dog, wild boar, pig, horse, dog	Encapsulated; moderate resistance to freezing; low number of larvae per female	Moderately pathogenic; long incubation period; mild or no enteric symptoms; no deaths reported
Trichinella T8	Namibia, South Africa	Sylvatic	Lion, hyena	Encapsulated; low number of larvae per female	Unknown
Trichinella T9	Japan	Sylvatic	Fox	Encapsulated; low number of larvae per female	Unknown
T. pseudospiralis	Cosmopolitan in Asia, Europe, North America, and Tasmania	Sylvatic; seldom domestic	Pig, wild boar, fox, marsupials, carnivorous and omnivorous birds	Nonencapsulated; no resistance to freezing;	Highly pathogenic; short incubation period; deaths have been reported
Trichinella murrelli	United States	Sylvatic	Fox, bear, raccoon, horse, lynx	Encapsulated; no resistance to freezing	Moderately to highly pathogenic; long incubation period; mild or no enteric symptoms; deaths have been reported
Trichinella nelsoni	Kenya, Tanzania, South Africa	Sylvatic	Hyena, lion, warthog	Encapsulated; no resistance to freezing	Moderately to highly pathogenic; long incubation period; mild or no enteric symptoms; deaths have been reported
Trichinella papuae	Papua New Guinea	Sylvatic	Wild pig, crocodile	Nonencapsulated; no resistance to freezing;	Slightly to moderately pathogenic
Trichinella zimbabwensis	Zimbabwe	Sylvatic	Crocodile, varan	Nonencapsulated; no resistance to freezing;	Unknown, but pathogenic in experimentally infected monkeys

CLINICAL ASPECTS

The incubation period for trichinellosis lasts from 2 to 50 days, depending on the number of infective larvae ingested (a greater number of larvae correspond to a shorter incubation period).[7] The acute stage of trichinellosis corresponds to the phase in which the newborn larvae migrate from the lymphatic vessels and invade the muscle cells. The acute stage can be preceded by loose stools or diarrhea, with flatulence, moderately intense abdominal pain, loss of appetite, and vomiting.[7]

The principal manifestations of the acute stage are fever, eyelid and periocular edema, and muscle pain. The onset of the acute stage is sudden, beginning with general weakness, chills, headache, fever (up to 40°C), excessive sweating, and tachycardia. In nearly all cases, these symptoms are followed by symmetrical eyelid and periocular edema, and edema frequently affects the entire face.[7] In some persons, petechiae, intraconjunctival hemorrhages, and hemorrhages of nail beds occur. These symptoms are accompanied by eosinophilia (up to 19,000 cells/μL) and leukocytosis (up to 15,000–50,000 cells/μL). Although eosinophilia appears early (i.e., before the development of clinical signs and symptoms), it increases between 2 and 5 weeks after infection. Leukocytosis, although not as common as eosinophilia, is characteristic of the acute stage of trichinellosis, and it indicates the presence of inflammation. This symptomatology is followed by pain in various muscle groups, which may restrict motility. Both creatinophosphokinase and lactate dehydrogenase activities have been observed in 75–90% of infected persons, and they peak earlier with respect to anti-*Trichinella* antibodies.[7] The principal electrolyte disturbance is hypokalemia, which results in reduced muscle strength and cardiac disturbances, as revealed by ECG. Decreased levels of proteins and albumin result in a hydrostatic edema.[7] Trichinellosis can also cause miscarriage or premature delivery, although infected women have delivered healthy babies. When infection is severe, complications such as cardiovascular, neurological, respiratory, and digestive disturbances can occur and hospitalization is compulsory.[7] Twenty deaths have been documented worldwide out of a total of 10,030 cases.[8]

It has not been possible to determine whether or not individual *Trichinella* species have specific clinical or biological patterns; this is because the number of infective larvae ingested has remained unknown in most cases, making it impossible to establish whether the clinical patterns observed were related to the species or to the infective dose. Nonetheless, *T. spiralis* infection, which is the cause of most human infections,[2] is believed to be more severe than *T. britovi* infection, possibly because *T. britovi* females are less prolific. In fact, in *T. britovi*-infected persons, only asymptomatic, mild, and moderate infections have been reported. In *Trichinella nativa* infections, there is a greater involvement of the intestine, with severe diarrhea. *T. murrelli* seems to be more likely to provoke skin reactions and less likely to cause facial edema. *T. pseudospiralis* seems to cause signs and symptoms that last longer.

DIAGNOSIS

The diagnosis of trichinellosis should be based on three main criteria:

1. Anamnesis based on epidemiological data: the source of infection, the amount of infected meat ingested, the number of larvae present in the infected meat, and the number of cases involved in the epidemic focus.
2. Clinical evaluation, i.e., recognition of the signs and symptoms of trichinellosis and definition of the clinical manifestations, which significantly affect the choice of treatment.
3. Laboratory tests: immunodiagnosis and/or detection of larvae in a muscle biopsy. The most reliable test is an ELISA that uses an excretory/secretory antigen. Antibodies are detectable in serum samples from 2 to 8 weeks postinfection, depending on the infecting dose, the *Trichinella* species, and the host response.[7,9]

TREATMENT

The effectiveness of the most commonly used antihelminthics (i.e., albendazole and mebendazole) is strictly related to the amount of time that has elapsed since the individual acquired the infection: they are completely effective only when used in the early stages of infection. As a general rule, the later the treatment is prescribed, the higher the probability that the infected person will harbor viable larvae in their muscles for years, with possible persistent myalgia. Thus, as the time elapsed since infection increases, the doses of antihelminthics should be higher and they should be administered for longer periods of time.[7]

Mebendazole should be administered at a daily dose of 25 mg/kg/day, in 3–4 doses/day for 2 weeks. Albendazole should be administered at a daily dose of 20 mg/kg/day, in 3–4 doses/day for 2 weeks. For severe infections, treatment can be repeated after 5 days.[7]

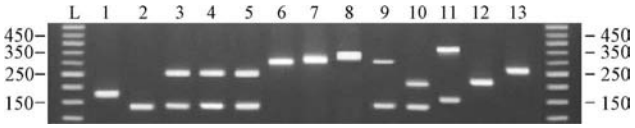

Fig. 1 Multiplex PCR amplification of single larvae of *Trichinella*. Photograph of an ethidium bromide-stained 2.5% agarose gel under ultraviolet light illumination. The samples are as follows: L (ladder 50), sizes are in base pairs; lane 1, *T. spiralis*; lane 2, *T. nativa*; lane 3, *T. britovi*; lane 4, *Trichinella* T8; lane 5, *Trichinella* T9; lane 6, *T. pseudospiralis* (Palearctic isolate); lane 7, *T. pseudospiralis* (Nearctic isolate); lane 8, *T. pseudospiralis* (Tasmanian isolate); lane 9, *T. murrelli*; lane 10, *Trichinella* T6; lane 11, *T. nelsoni*; lane 12, *T. papuae*; lane 13, *T. zimbabwensis*.

Glucocorticosteroids (e.g., prednisolone 30–60 mg/day in multiple doses) should be administered together with the benzimidazole and never alone because they could increase the larval burden by delaying the expulsion of adult worms from the intestine.

Pregnant women should only be treated if the infection is severe and under the strict supervision of a physician. Only antihelminthics (e.g., pyrantel) that are poorly absorbed by the intestinal lumen should be used. These antihelminthics are affective only against intestinal worms and not against migrating larvae or larvae in the muscles.[7] Prednisolone can be administered at a dose of 20–30 mg/day, tapering the dose, particularly for women in the third trimester.

MOLECULAR CHARACTERIZATION OF INDIVIDUAL LARVAE

The lack of morphological markers and the fact that the biological and biochemical markers do not allow the species to be easily or rapidly identified stress the importance of methods based on polymerase chain reaction (PCR) in identifying *Trichinella* parasites at the species level.[4] The use of PCR-derived methods also allows the species to be identified based on a single larva, which is important because, frequently, only one larva is detected in human biopsies and in muscle samples of animal hosts. Furthermore, the identification of single larva allows more than one species of *Trichinella* to be detected in the same host, i.e., mixed infections.

Although a variety of molecular methods have been developed in recent years,[4,10–13] the most reliable and simple-to-perform method for the molecular identification of single *Trichinella* larva is a multiplex-PCR analysis,[11,14] which is capable of identifying all species, one genotype, and three populations of *T. pseudospiralis* (Fig. 1).

PREVENTION AND CONTROL

Trichinellosis can be prevented through suitable food preparation. Meat and meat products should be cooked to an internal temperature of 70°C for at least 3 min. Meat and meat products can also be rendered innocuous by freezing them solid at −15°C for at least 3 weeks (for cuts up to 15 cm in thickness) or for at least 4 weeks (for cuts up to 60 cm in thickness),[15] although freezing-resistant *Trichinella* species do exist, and, in areas where these species are endemic, consumers should be informed that freezing is not recommended, especially for game meat. Those meat-preparation methods that are not considered as effective include microwave cooking, curing, drying, and smoking.[15] The consumption of raw meat products should be discouraged under all circumstances. An important means of preventing infection in humans is by performing veterinary controls (i.e., the artificial digestion of muscle samples for the detection of muscle larvae) at slaughterhouses for potentially infected animals, such as pigs, horses, and game animals.[15]

To prevent domestic animals from becoming infected, good animal-rearing practices are essential: avoiding the use of untested food, adopting microbiological barriers for preventing the entrance of rodents and other synanthropic animals into the pigsty and food storage areas, and the proper disposal of dead animals.[15] Although the infection cannot be feasibly controlled in wildlife, hunters should be discouraged from leaving animal carcasses in the field after skinning, a practice which favors the spread of the infection among sylvatic animals.

CONCLUSION

The risk of acquiring *Trichinella* infection through the consumption of raw or undercooked meat has, in recent years, increased as a result of the increased globalization of both the food industry and eating habits. Identifying the etiological agents of these infections at the species level is quite important in aiding physicians in diagnosis and treatment, in tracing the source of the infection, in determining the area of origin of the infected meat, and in developing the most appropriate measures for controlling infection at all phases of food production. With regard to diagnosis, although only molecular methods can be used to identify the parasites at the species or genotype level, they cannot replace the currently

available diagnostic techniques, such as ELISA for diagnosis in humans[9] and the digestion of muscle samples for diagnosis in animals,[15] given their high cost, lower sensitivity, and the need to perform a muscle biopsy.

Trichomonas spp.

Holgar Mayta
Robert H. Gilman
Johns Hopkins School of Public Health, Baltimore, Maryland, U.S.A.

INTRODUCTION

Four species of the family Trichomonadidae are found in humans, *Trichomonas vaginalis* (Donne, 1836), *Trichomonas tenax* (O.F. Muller, 1773), *Pentatrichomonas hominis* (Davaine, 1860), and *Trichomitus fecalis* (Cleveland, 1928). Although there have been many nomenclature problems with *Pentatrichomonas hominis* (Davaine, 1860), it is clear that this parasite represents another genera of the family Trichomonadidae.[1,2]

The most widely and best studied parasite is *T. vaginalis*, the urogenital trichomonad, which occurs almost exclusively in the lower genital tract. *Trichomonas vaginalis* is considered the only typical trichomonad with definite pathogenicity for humans.

Trichomonas tenax is considered a normal commensal of the human oral cavity. It is found especially in the tartar around the teeth or in the defects of carious teeth; although there is no evidence of direct pathogenesis, it is frequently associated with phylogenic organisms in pus pockets or at the base of teeth and its incidence is higher among patients with periodontal disease.[3]

OVERVIEW

The present paper is a review on the current state in the diagnosis of parasites of the genera trichomonas; most information has been obtained from studies on *T. vaginalis*.

BIOLOGY AND LIFE CYCLE

Trichomonas are flagellated protozoan, which vary in size and shape. In axenic culture they are usually pear-shaped ranging in size from 4 to 30 μm, but when attached to epithelial cells the amoeboid forms are predominant.[4] Organisms of the genera Trichomonas are characterized by possessing a single nucleus and five flagella, four of which are free and located at the anterior portion, and the fifth is a recurrent anterior flagellum, which is attached to the body as an undulating membrane. The cell body is longitudinally bisected by a thin hyaline structure, the axostyle, which starts at the nucleus and protrudes from the posterior end of the parasite.[5] The nucleus located in the anterior portion has a porous double membrane characteristic of a eukaryotic cell; the Golgi complex is also highly developed. The cytoplasm is rich in glycogen granules and ribosomes, but lacks mitochondria, peroxisomes, or glycosomes.[4]

Trichomonas exist only as trophozoites; they lack a cystic stage and reproduce generally by longitudinal binary fission without disappearance of the nuclear envelope.[4] Mitosis in *T. vaginalis* has been well characterized and includes the four mitotic phases: prophase, metaphase, anaphase, and telophase;[6] the chromatin condenses to six chromosomes;[7] no recent data on the mitotic division exist for *T. tenax*.

The genome of *T. vaginalis* has been estimated to be approximately 2.5×10^7 bp with only 33% of unique sequences.[8] The overall content of G+C was estimated to be about 36%. *Trichomonas vaginalis* has six monocentric chromosomes, which seem to be haploid.[7,9] However, 0.1% of the population displays diploid metaphases with some cells exhibiting four nuclei suggesting a possible occurrence of meiotic division.[7]

No extra nuclear DNA is present in Trichomonas; detection of extra chromosomal DNA in the hydrogenosome was looked for but not found.[8,10]

EPIDEMIOLOGY AND TRANSMISSION

Although trichomoniasis (*T. vaginalis*) is the most common nonviral sexually transmitted disease, epidemiological data are limited because official reporting is not required. According to the World Health Organization 174 million new infections occurred in 1999[11] with 8 million occurring in North America. Prevalence varies in different populations; the prevalence of trichomoniasis among black American population is higher than any other population in the United States.[12]

Transmission of Trichomonas parasites is direct, person-to-person. *T. vaginalis* is almost exclusively transmitted directly by sexual intercourse. However, infection in newborns and infants is commonly a consequence of mother-to-child transmission during

DOI: 10.1081/E-EDGP 120020919

delivery.[13] Newborn girls can acquire infection from their infected mothers during passage through the birth canal and remain asymptomatic until puberty. Transmission of *T. vaginalis* in children before and after puberty may be indirect especially in an environment with infected family members.[13]

T. tenax is spread by direct as well as indirect mouth-to-mouth contact, sharing of oral hygiene utensils such as a toothbrush may be an important source of transmission.[1] A zoonotic transmission may also be possible, as a PCR-based molecular analysis of isolates obtained from dogs and cats confirmed the presence of *T. tenax* in these animals.[14]

CLINICAL MANIFESTATIONS

Clinical trichomoniasis in women varies from asymptomatic state in 10% to 50% of infected women to an obvious vaginitis,[15] which may be either acute or chronic in nature. Women with asymptomatic infection have a normal vaginal pH and flora[16] but during the following 6 months up to 50% of these patients will develop symptoms. Acute infection is characterized by diffuse vulvitis due to a copious leucorrhea; the discharge is usually frothy, yellow or green, and mucopurulent.[17] Small hemorrhagic spots may be seen in the vaginal and cervical mucosa, which is commonly referred as a ''strawberry appearance'' and is observed only in 2% of the patients. These signs and symptoms are cyclic and worsen around the time of menses.[4,17] In chronic infection symptoms are mild with pruritus and dyspareunia; vaginal secretion may be scanty and mixed with mucus.[15,20]

Although vaginitis is the most common manifestation of *T. vaginalis* infection the disease may also be associated with infertility, premature rupture of membranes, premature delivery, low birth weight, still birth, and neonatal death.[18] Other complications include an increased risk of pelvic inflammatory disease,[19] HIV infection,[20] and possibly cervical cancer.[21]

Trichomoniasis in men is largely asymptomatic; men are considered asymptomatic carriers of *T. vaginalis*. Disease in men may be categorized into three groups: an asymptomatic carrier who is identified by investigation of sexual contacts of infected women; acute trichomoniasis, characterized by profuse purulent urethritis; and mild symptomatic trichomoniasis, which is clinically indistinguishable from other causes of nongonococcal urethritis.[4] Complications in men include nongonococcal urethritis, prostatitis epydidymitis, urethral disease, and infertility.[22]

DIAGNOSIS

Diagnostic techniques have been developed primarily for the detection of *T. vaginalis* but are equally applicable to the detection of *T. tenax*. Diagnosis of Trichomonas traditionally depends on the microscopic observation of motile protozoa. Although this technique is rapid, specific, and cost effective, it has a low sensitivity detecting only half of the culture positive samples.[23] The low sensitivity is probably due to the loss of the distinctive motility after the parasite has been removed from body temperatures for any length of time. Sensitivity is increased if specimens are examined immediately after being taken.

The culture method is the gold standard for the detection of Trichomonas; however, culture requires an inoculum of 300 to 500 trichomonads/mL[24] and up to 7 days before a sample could be reported as negative. During this period positive patients may continue transmitting the disease. Moreover, inadequate transport or storage of samples may result in a negative culture. The InPouch TV system (BioMed Diagnostics, San Jose, CA) is considered the most advantageous culture systems. It consists of a two-chambered bag that allows performing an immediate wet-mount microscopic examination through the bag as well as a culture,[25] but as with other culture techniques sensitivity may vary especially according to rapid access to incubators.

Cell culture is more sensitive than broth culture and wet-mount preparation; however, cell culture is not routinely performed and is neither convenient nor used at present for rapid diagnosis.[24]

Papanicolaou (Pap) smear and other staining techniques have also been performed as a detection tool for trichomonas.[26,27] Papanicolaou smear is preferred as it is routinely performed in gynecological screening for cytological abnormalities. Staining techniques are not reliable, however, as Trichomonas does not always appear in its typical pear-shape form.

Detection of *T. vaginalis* based on antibody detection is not reliable because of serotype differences among different strains and because host response to the parasite is widely variable. In addition, infection of *T. vaginalis* by a double-stranded RNA virus (the *T. vaginalis* virus, TVV) may influence expression of antigenic proteins.[28]

Detection of the parasite in clinical samples using labeled monoclonal antibodies has shown similar sensitivity and specificity results to those obtained by culture.[29]

Techniques based on DNA analysis have been increasingly used in clinical laboratories to improve the specificity and sensitivity of *T. vaginalis* diagnosis. Hybridization techniques such as the Affirm VP system

(MicroProbe Corp., Bothwell, WA) or the dot blot and in situ hybridization demonstrated a better performance than the wet-mount preparation. However, the number of false-negative results was high when the Affirm VP system was tested.[30] The requirement for radioactive material for the dot blot and in situ hybridization is the main drawback of these techniques.

Polymerase chain reaction-based techniques have been widely explored for the detection of both *T. vaginalis* and *T. tenax*. Repetitive DNA sequences of *T. vaginalis* have been cloned, sequenced, and characterized for PCR amplification;[31,32] however, low sensitivity is observed because of the high variability of these sequences and the presence of insertion elements, causing more than a single product or absence of amplification. The beta tubulin gene has also been used as a target for PCR amplification, but this PCR shows a cross-reaction with some *T. tenax* isolates and fails to amplify some axenically cultivated *T. vaginalis* isolates.[33] Techniques based on the amplification of ribosomal coding DNA sequences have been described both for *T. tenax*[34] and *T. vaginalis*.[35] Ribosomal genes (rDNA) have been demonstrated to be highly conserved among different Trichomonas strains;[2] also, ribosomal genes are generally multicopy genes. The nature of the rDNA genes made them the most advantageous target for PCR-based detection. Both human Trichomonas are capable of invading organs and tissue that are not their natural environment making them difficult to identify using current techniques; rDNA-based PCR is especially useful when those cases occur.

Random amplified polymorphic DNA (RAPD) amplification may be useful to characterize *T. vaginalis* strains according to resistance to metronidazole, and infection with TVV or mycoplasmas; however, virulence of strains or geographic distribution has not been genotypically correlated.[36]

Antigenic differences between *T. tenax* isolates from respiratory passages and isolates from the oral cavity have suggested that the isolates from the respiratory passages may belong to a separate species.[3] However, no further studies have been conducted in this regard. The use of molecular biology techniques should be able to provide a definitive answer to whether there is a difference in the oral and respiratory *T. tenax* isolates.

TREATMENT

Metronidazole and other nitroimidazoles are effective against Trichomonas. The standard treatment for vaginal trichomoniasis is 250 mg of metronidazole, given orally, either three times a day for 7 days, or in a single 2-g dose.[37,38] Both the infected patient and sexual partner, whether symptomatic or asymptomatic, should be treated to prevent reinfection. Both regimens are equally effective.[37]

Although treatment is highly effective, resistance of *T. vaginalis* to metronidazole is now on the rise, and according to the Centers for Disease Control 5% of all *T. vaginalis* patient isolates have some level of resistance to metronidazole.[38]

The mechanism of metronidazole resistance may be a consequence of a reduced transcription of the ferredoxin gene and/or a consequence of abolished or decreased activities of the pyruvate–ferredoxin oxidoreductase and hydrogenase enzymes.[39]

CONCLUSION

Human parasitism by Trichomonas species has been demonstrated to cause serious health problems especially due to potential complications and increased susceptibility to other more serious transmitted disease agents. Although much research is still needed to determine the pathogenicity and virulence of Trichomonas it is clear that at least *T. vaginalis* infection causes several complications in pregnancy and increases the risk of transmission of other sexually transmitted diseases.

Although culture for Trichomonas has many drawbacks, it remains the gold standard for the identification and diagnosis of Trichomonas. Polymerase chain reaction-based amplification of DNA sequences is now both useful and accessible for the detection of these parasites and can be used both for patient diagnosis and epidemiological studies. Cost effectiveness does not constitute a barrier to the use of DNA amplification. Equipment and reagents are more accessible nowadays; prices are now comparable to those required for implementing an ELISA technique. Caution should be taken, however, when PCR techniques are applied in different settings. A great variety of Taq polymerases are now commercially available, most of them are genetically modified and perform differently. Standardization of the PCR condition under local settings should be performed before field application. We have seen a sensitive rDNA assay become insensitive because protocols were not followed and the type of Taq used was changed.[40]

INTRODUCTION

Whipple's disease (WD) is a good example of progress resulting from the introduction and development of molecular genetic techniques. In 2003 Bentley et al. and Raoult et al. sequenced and published the full genome of the causative bacterium *Tropheryma whipplei* which allowed to ascertain specific targets for the detection of the bacterium in the host and the environment.

The first case report of a patient suffering from diarrhea, polyarthritis, and bronchitis was by G.H. Whipple in 1907. He described the disease as a new entity and it was known since as ''intestinal lipodystrophy,'' later on as Whipple's disease.[1] Although a systemic disease was considered, the underlying agent was unknown for many years. For a long time the diagnosis was based on clinical symptoms and later on histological investigations: periodic acid-Schiff (PAS) positivity in the affected tissue has been considered as a pathognomonic sign. In 1960, a bacterium was identified in the affected tissue using electron microscopy.[2] The start of genetic techniques in the disease was the sequencing of 16S rRNA in 1991, which allowed to determine the phylogenetic position as an actinomycete,[3] and the bacterium was named after its culture *T. whipplei*.[4]

TYPE OF PATHOGEN

T. whipplei is a short rod-shaped bacterium, approximately 0.3 μm in diameter and 1.5 μm long. Morphologically, the bacterium has a characteristically trilamellar ultrastructure including a plasmic membrane surrounded with a thin wall, itself surrounded with a structure like a plasmic membrane.[5] This morphology is not typical of Gram-positive or Gram-negative bacteria. However, the bacterium appears Gram negative at the Gram staining, even if the phylogenic analysis classified it among the Gram-positive bacterium. *T. whipplei* is also well stained by PAS staining.[6] The culture of *T. whipplei* has been an elusive goal for many generations of microbiologists. For the first time, in 1997, two strains of *T. whipplei* have been isolated from cardiac valves on a macrophage system in which microbicide functions have been inhibited.[7] Unfortunately, no isolate has been subcultured.[7] Two years later, the bacterium has not only been isolated but also established from a cardiac valve of a patient with WD endocarditis. More precisely, the bacterium has been propagated in human fibroblasts in minimum essential medium with 10% fetal calf serum and 2 mM glutamine.[6] Since this work has been reproduced, four other strains have been isolated and established. Two strains were obtained in the same laboratory where the first strain of *T. whipplei* was established. One strain was isolated from a blood culture of a patient with WD endocarditis, and another strain was isolated from a duodenal biopsy from a patient with digestive WD.[8] Two other strains obtained in another laboratory were from cerebro-spinal fluid samples.[9] Finally, the availability of the sequenced genome of *T. whipplei* has allowed the successful design of a cell-free culture medium for *T. whipplei*.[10] This medium provided missing amino acids (DMEM/F12 medium) and was supplemented with 10% fetal calf serum, 1% L-glutamine, and 1% nonessential amino acids. The culture flask was incubated vertically at 37°C in a 5% carbon dioxide atmosphere. The doubling time of *T. whipplei* was 28 hr and was unchanged from passage three up to now.

CLINICAL FEATURES AND SPECTRUM

The clinical picture is often multifaceted. In the past, WD was often considered to be a gastrointestinal disease, but it is now established that nearly every organ system can be involved. The course varies in the same extent, so it was suggested that different clinical courses may result from *T. whipplei* subtypes, identified according to its 16S–23S rDNA.[11] Mostly affected are Caucasian middle-aged

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP-120020921

men (male/female ratio 8:1), but no valid estimates of the incidence are available.

The initial complaints are mostly arthralgia and swelling of the joints. This seronegative, nondestructive arthropathy in an approximate frequency of up to 85% can occur years before diagnosis and is often associated with HLA-B27. Affected joints are predominantly peripheral. Arthropathy in knees, wrists, and ankles occur in about 45% each.[12]

Diarrhea is the other major symptom. It is followed by a general malabsorption resulting in weight loss and anorexia. Weight loss can be found in about 90% of the patients. Gastrointestinal symptoms, which lead to the diagnosis, consist of episodic and watery diarrhea and steatorrhea accompanied by colicky abdominal pain and, in one-third, by occult blood in stool.[13] Endoscopic investigation reveals a pale yellow mucosa alternating with erythematous, erosive parts in the duodenum or jejunum, and duodenal biopsies are positive in the PAS stain.

A less frequent but severe course is the infection of the central nervous system (CNS). Dementia, personality changes, or memory disorders can become apparent as well as myoclonia, nystagmus, or ophtalmoplegia. In some cases CNS involvement is found without other affections.

PREVALENCE

The distribution of the bacterium in the environment seems to be ubiquitous. The DNA of the bacterium has been detected in excretions (feces) of patients suffering from WD and in sewage water.[14,15] The bacterial DNA was also found in saliva, gastric fluid of healthy humans, so that it seems possible that it can survive outside cells and body fluids are the way of distribution.[16,17] Normally, the bacterium can be found within membrane-bound vesicles in the cytoplasm of macrophages as well as in many other cell types such as plasma cells, granulocytes, epithel cells, endothelial cells, smooth muscle cells, and lymphocytes.

MANAGEMENT

Untreated disease may be fatal, but adequate and consequent antibiotic therapy often leads to complete remission. The systemic infection requires the use of antibiotic agents. However, treatment is based on empirical observations. A common antibiotic therapy starts with cephalosporine or meropenem (2 weeks intravenous), followed by cotrimoxazole orally for 1 year minimum. In the majority of cases this treatment results in a quick improvement of complaints. However, the disease may have a chronic relapsing course. In these cases changes in antibiotic treatment have to be considered. Second-line antibiotics include tetracycline, minocycline, or oral penicillin.[18] In therapy refractory cases the positive effects of immunosupportive treatment with interferon gamma have been described.[19] Additionally, general replacement therapy is necessary in many cases with malabsorption syndrome.

In patients responding to antibiotic treatment, control endoscopies and duodenal biopsies are recommended 6 and 12 months after diagnosis.[20] Treatment can be stopped after 1 year if the patients have no clinical signs and duodenal biopsy is no longer PAS positive.

MOLECULAR CHARACTERIZATION

In 1991, Wilson sequenced a fragment of 16S rRNA from a patient with WD.[3] This sequence was original and showed that, phylogenically, the bacterium was included to the *Actynomyces* clade. One year later, the sequencing of 1321 bp of the 16S rRNA from the biopsy of a patient confirmed these data;[21] the bacterium was named then *Tropheryma whippelii*. After the culture and the description of the bacterium, the bacterium was officially named *Tropheryma whipplei*.[4] At the time the genome sequencing of *T. whipplei* was initiated, only five genes were identified: 16S rRNA, 5S rRNA, 23S rRNA, *rpoB*, and *hsp65*.[22] Phylogenetic analysis classified *T. whipplei* within the high G+C content Gram-positive bacteria class (Actinobacteria, relatively near to two known species in human pathology, *Actinomyces pyogenes* and *Rothia dentocariosa*, and to bacteria principally found in the environment). The 16S–23S interregion of *T. whipplei* had been studied by PCR and sequencing from clinical samples from patients with WD.[11] The sequence analysis has revealed the existence of six different types of spacer.[11] The more frequent spacer types were types 1 and 2.[23]

Recently, the genome of two different strains of *T. whipplei* has been entirely sequenced.[22] Sequencing of *T. whipplei* Twist, propagated from the cardiac valve of a patient, revealed a 927,303-bp genome which encodes 808 predicted protein-coding genes and presents a GC% of 47%.[22] Sequencing of *T. whipplei* TW08/27, propagated from the cerebrospinal fluid of a patient, revealed a 925,938-bp genome which encodes 784 predicted protein-coding genes and presents a GC% of 46.3%.[24] *T. whipplei* presents a unique circular chromosome and is the only known reduced genome species (<1 Mb) within the Actinobacteria.[22,24] The two genomic sequences of the two strains are mostly (>99%) identical at the nucleotide sequence level and encode quasi-identical

gene complements. One of the specific genome features includes deficiencies in amino acid metabolisms. This observation points to a host-restricted lifestyle for *T. whipplei*. To compensate for the defective biosynthetic pathways, the missing amino acids must be obtained from the environment or the host. This information has allowed the design of a comprehensive medium, supplemented with amino acids, in which *T. whipplei* grows axenically.[10] Another specific characteristic of *T. whipplei* is the lack of clear thioredoxin and thioredoxin reductase genes. Thioredoxin reductase is a ubiquitous enzyme that reduces thioredoxin, which in turn acts as electron donor in various essential redox reactions in the cell.[22] A functional thioredoxin system has systematically been retrieved in all bacterial genomes sequenced so far. Thus *T. whipplei* might be the first example of a bacterium without the usually essential thioredoxin pathway, but this observation must be confirmed by further experiments. A mutation in DNA gyrase, which predicts a resistance to quinolone antibiotics, is also present. These data are consistent with the high minimal inhibitory concentration of ciprofloxacine observed in vitro for *T. whipplei*.[25] The genome of *T. whipplei* contains also a gene cluster that seems to direct the biosynthesis and export of extracellular polysaccharide. This observation could explain the fact that the *T.whipplei* cell wall includes, in addition to peptidoglycan, an unusual inner layer composed mainly of polysaccharides which accounts for the positive PAS staining reaction. The alignment of the two genome sequences revealed a large chromosomal inversion, the extremities of which are located within two paralogous genes.[24] These genes belong to a large cell-surface protein family defined by the presence of a common repeat highly conserved at the nucleotide level. The repeats appear to trigger fragment genome rearrangements in *T.whipplei*, potentially resulting in the expression of different subsets of cell-surface protein.[24] This phenomenon might represent a new mechanism developed to evade the host's immune response during the course of this chronic disease. It is also remarkable to note a high frequency of repeats in *T. whipplei* because usually repeated sequences are considered to be less frequent in the reduced genomes.[24] Besides, new primers were designed according to the sequence of this highly conserved domain, allowing the improvement of the current molecular diagnosis of WD.[26] The isolated lifestyle of parasitic bacteria has been proposed to induce ''ongoing genome degradation.'' However, *T. whipplei* genome exhibits a coding content (86%) comparable to the free-living bacteria and shows a few pseudogenes and a small sign of ''ongoing degradation.'' Finally, the important finding derived from *T. whipplei* genome sequences is the frequent genomic instability mediated by protein-coding repeats within genes of membrane proteins.

MOLECULAR TESTING

The histology analysis of biopsies using the PAS staining, which has been considered for a long time, as pathognomonic of WD, is not completely specific. Polymerase chain reaction assays could be performed on various biopsies (duodenum, adenopathy, cardiac valve, kidney, brain, synovial biopsy), liquid samples (cerebrospinal fluid, joint fluid, aqueous humor, blood), saliva, or stools.[27] The DNA extraction is a clue step and different protocols have been proposed.[27] These protocols could be applied in fresh sample or included in paraffin. Before the genome sequencing, all the five identified genes were used as targets for the molecular diagnosis of the WD.[28–31] For each PCR assay, it is necessary to include positive (DNA extracted from a suspension of *T. whipplei*) and negative controls. Indeed, samples must be separated every five samples by a negative control, including water and DNA extracted from control tissues (intestinal or other biopsies). The positive and negative controls must be correct to validate and interpret the results of each PCR assay. Recently, a PCR assay targeting the *rpoB* gene and using a real-time PCR apparatus has been successfully applied for the diagnosis of WD.[32] This technique offers the advantages of reducing PCR time and risk of contamination. The availability of the genome has offered the possibility to rationally choose DNA targets. Indeed, a real-time PCR assay targeting repeated sequences of *T. whipplei* performed in samples from patients with WD and in a control group has allowed the significant enhancing of PCR sensitivity without altering its specificity, when compared to regular PCR.[26] All the sequence primers available and published for the specific diagnosis of WD (except those targeting the 16S rDNA sequence), the target gene, and the molecular size expected of the amplified product are summarized in Table 1. When an amplification product is obtained by PCR, the identification of *T. whipplei* should be confirmed by sequencing or hybridization. Indeed, the main problem with PCR is the specificity, due notably to problems of contamination depending on the technique used and the studied samples. Besides, some divergences have been observed between laboratories. Positive results have been reported in saliva, gastric liquids, and duodenal biopsies in patients without WD.[33] However, these data have not been confirmed by other teams.[32,34] Presently, we recommend for the definite molecular diagnosis of WD, notably for atypical cases, to use at least two pairs of primers targeting two different sequences to avoid false-positive results.

CONCLUSION

Molecular techniques now play an important role in the diagnosis of Whipple's disease. The genome analysis allows new insights into the etiopathogenesis of the disease and potentially in therapeutic options. Improved assays for the detection of *Tropheryma whipplei* have increased the reliability in diagnosis and may offer the possibility to identify the natural reservoir of the bacterium.

Trypanosoma cruzi

John M. Kelly
Martin C. Taylor
Shane R. Wilkinson
London School of Hygiene and Tropical Medicine, London, U.K.

INTRODUCTION

The insect-transmitted protozoan parasite *Trypanosoma cruzi* is the causative agent of Chagas' disease, a debilitating condition that has a considerable impact on public health in Latin America. Despite the importance of the infection, the mechanisms underlying the severe pathology associated with the disease are still poorly understood. In addition, the drugs in current use have limited efficacy and there is no immediate prospect of a vaccine. However, research on Chagas' disease is now receiving fresh impetus with the completion of the human and *T. cruzi* genome projects. Together with the application of postgenome technologies, this is providing new insights into the genetic and biochemical nature of the parasite and the mechanisms and consequences of host–parasite interactions. Rapid progress in these areas should facilitate the development of new chemotherapeutic approaches and provide the tools and reagents necessary to address the complex epidemiology of the disease.

THE NATURE OF CHAGAS' DISEASE

In Latin America, 18–20 million people are infected with *T. cruzi* resulting in up to 50,000 fatalities per year.[1] Chagas' disease is endemic in more than 20 counties with 100 million people at risk. It is by far the most serious parasitic infection in the region with an estimated economic burden of $8 billion per year. There is a close association between poverty and the disease because the reduviid bug that transmits the parasite is usually restricted to poor-quality housing. Most individuals are infected while sleeping, when parasites are deposited on their skin as the bug defecates during a bloodmeal. The parasites then penetrate the skin, typically via the bite wound or other lesion (Fig. 1). Transmission can also occur congenitally (5–10% of children born to infected mothers are themselves infected) or by blood transfusion. This latter route is increasingly recognized as a potential problem in the United States where there are estimated to be 100,000 infected individuals that have migrated from endemic areas.

In humans, Chagas' disease has three stages. The initial acute stage is characterized by a high parasitemia and a range of symptoms that can last for 4–8 weeks. Although the symptoms are usually mild, there can be a 5% fatality rate in children, often because of acute myocarditis or meningoencephalitis. The disease then subsides and most individuals are asymptomatic for the rest of their lives. However, they remain infectious and can serve as a reservoir. In approximately 30% of cases the disease develops into the chronic form, often many years after the initial infection. Premature and progressive heart disease is the most common clinical manifestation, and prognosis for these individuals is poor. Other serious symptoms that can be associated with chronic disease include swelling of the esophagus and colon (the so-called megasyndromes) and abnormalities of the central nervous system. Reactivation of *T. cruzi* infection in HIV carriers has also been recognized as an increasing problem. Most patients identified with dual infections have been found to display neurological dysfunction and/or heart lesions.

Pathology in Chagas' disease is mainly a consequence of interactions between the parasite and the host immune system. *T. cruzi* elicits polyclonal lymphocyte activation, a type of response common in many viral, bacterial, and parasitic diseases and which is thought to constitute a nonspecific immune evasion strategy. This has also been linked with the immunosuppression and pathology associated with the chronic form of Chagas' disease. Geographical variations in the percentage of infected people who go on to develop chronic disease has hinted that the spectrum of symptoms may reflect the genotypic diversity of the parasite (below) rather than differences in host genetic background, although this remains controversial.

There has been a major debate within the Chagas' disease research community about the factors responsible for triggering the development of the chronic pathology.[2] Some have argued that the continued presence of the parasite is required, whereas others consider that the disease is an autoimmune condition. There is now strong evidence, at least in a mouse model, that the continued presence of the parasite is both sufficient and necessary to promote chronic disease pathology.[3] This has important

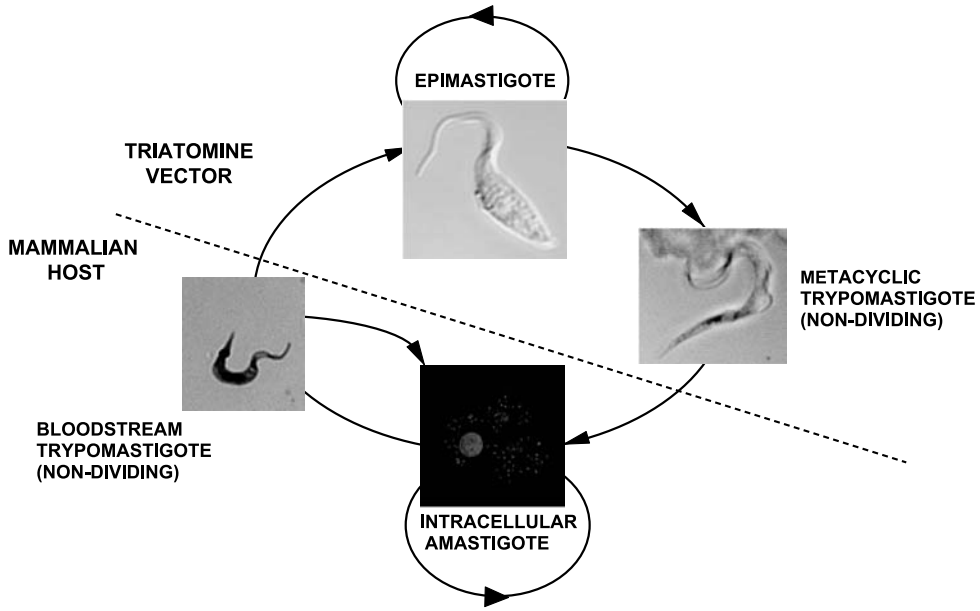

Fig. 1 Life cycle of *T. cruzi* showing the four major forms of the parasite. Epimasigotes and amastigotes divide by binary fission, whereas both of the trypomastigote forms are nonreplicative. The small rounded nonflagellated amastigotes can grow in almost any mammalian cell type. In the image shown intracellular amastigotes can be identified as small red dots following DNA staining. The large red dot is the host cell nucleus. Amastigotes differentiate into bloodstream trypomastigotes, which are released after host cell lysis. These can reinvade other cells or be taken by an insect vector during a bloodmeal. (*View this art in color at www.dekker.com.*)

implications because it provides a theoretical basis for the use of drugs targeted directly at *T. cruzi* as a means of reducing chronic disease severity and/or progression.

A wide range of techniques have been developed for the diagnosis of *T. cruzi* infection. Unfortunately, these can lack sensitivity and/or specificity and it is often necessary to use more than one approach. For example, the success of microscopic diagnosis is limited by the low level of parasitemia out with the acute phase and serological tests can suffer from cross-reactivity with antigens of *Leishmania* or the nonpathogenic trypanosome *Trypanosoma rangeli*. More recently, encouraging results have been achieved with PCR-based approaches that exploit the species specificity of high-copy-number satellite repeat sequences.[4] Only two drugs are currently available for the treatment of Chagas' disease, nifurtimox and benznidazole. They are partially effective against the acute stage but have several drawbacks. Both can produce toxic side effects, require long-term administration under medical supervision, and remain unproven as a treatment for chronic disease. Improved public health measures such as the ''Southern Cone Initiative'' have been successful in reducing infection rates in some countries where transmission is predominantly domestic.[5] However, even if all the routes of parasite transmission could be blocked throughout its entire geographic range, such is the nature of the infection, some individuals will still be suffering from chronic Chagas' disease in 40 years time.

CHARACTERISTICS OF *T. CRUZI*

T. cruzi is a member of the family Trypanosomatidae (order: Kinetoplastida), which also includes *Trypanosoma brucei*, the etiological agent of African sleeping sickness, and *Leishmania* species, which cause cutaneous/visceral leishmaniasis. Chagas' disease is a zoonosis and the parasite has been detected in more than 150 species of mammals. The opposum *Didelphis*, which is found throughout South America, plays a central role in the transmission between sylvatic (forest) and domestic habitats, where animals such as dogs, cats, and rodents serve as important reservoirs. *T. cruzi* is transmitted by blood-feeding reduviid bugs of the subfamily Triatominae. In the insect vector, *T. cruzi* undergoes differentiation from the noninfectious epimastigote form into the metacyclic trypomastigotes that are capable of initiating an infection in the host (Fig. 1). Trypomastigotes can invade a large number of mammalian cell types including macrophages, muscle cells, and nerve cells. Epimastigotes (Fig. 2) are the stage that is most easily cultured in the laboratory.

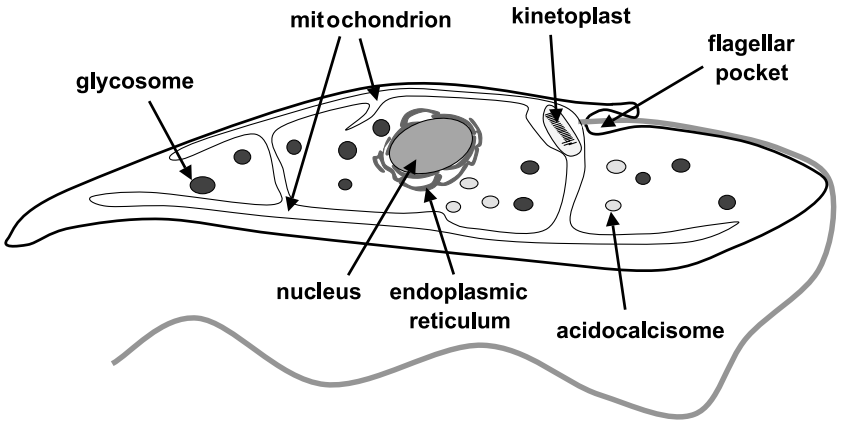

Fig. 2 Schematic representation of a *T. cruzi* epimastigotes. *T. cruzi* contains a large, single mitochondrion that is dispersed through much of the cell. The mitochondrial genome is organized as a defined structure, the kinetoplast (light blue), which is adjacent to the flagellar pocket and base of the flagellum. The parasite contains other subcellular structures typical of eukaryotes including the endoplasmic reticulum (red) and the nucleus (purple). It also possesses a number of unusual organelles[6] such as glycosomes (dark blue) and the acidic calcium storage compartments acidocalcisomes (yellow). (*View this art in color at www.dekker.com.*)

T. cruzi has a complex population structure that reflects at least 60 million years of divergence. On the basis of a large number of genotypic and phenotypic studies the species has now been divided into two major groups, *T. cruzi* I and II.[7] Group II parasites also display marked heterogeneity and have been separated further into five subdivisions (II a–e). It has been proposed, and there is some experimental evidence,[8] that *T. cruzi* II is more frequently associated with the development of chronic pathology, whereas *T. cruzi* I gives rise to more benign disease. Given the considerable genetic diversity of the parasite this is probably an oversimplification. Until recently, reproduction in *T. cruzi* was thought to be exclusively asexual with the parasite having a clonal population structure. However, new data from phylogenetic[9] and laboratory[10] studies have demonstrated that genetic exchange can occur and that it is initiated by parasite cell fusion within infected host cells. Although probably a rare event, the potential for genetic exchange could have major epidemiological consequences including the spread of undesirable phenotypes such as virulence and drug resistance.

Trypanosomatids diverged early from the main eukaryotic lineage and their study has led to the discovery of many novel genetic and biochemical phenomena. These include mitochondrial RNA editing, unusual secondary modifications to cell surface proteins, sequestration of glycolytic and fatty acid biosynthetic enzymes in organelles called glycosomes (Fig. 2), and an oxidative defense system based on the unique low-molecular weight thiol trypanothione. Parasite-specific features such as these have attracted considerable interest in the context of drug design.[11]

THE UNUSUAL NUCLEAR AND MITOCHONDRIAL GENOMES OF *T. CRUZI*

As with the other trypanosomatids, the chromosomes of *T. cruzi* do not condense during mitosis, and karyotype studies have had to rely on pulse field gel electrophoresis and related techniques. These indicate that the nuclear genome is organized into about 40 chromosomes ranging from 0.4 to 4.5 megabases. The genome size (haploid content) is 45 megabases and the total number of genes has been estimated to fall within the range of 8–10,000. There is significant variation in the size of chromosomes between different parasite strains and, although the genome is generally diploid, the sizes of homologous chromosomes within the same cell can often differ considerably. The genome contains an extensive range of repetitive DNA elements and several large surface glycoprotein gene families, some with over 500 members. *T. cruzi* has an extremely complex cell surface, and this large and diverse repertoire of genes, many of which are expressed in a stage-specific manner, is critical to several aspects of the parasite life cycle (Fig. 1). These include host cell invasion, protection from complement and disruption of the host immune response.[12] In the parasite genome there are no recognizable RNA polymerase II-specific promoters for protein-coding genes; transcription is polycistronic and each mRNA is modified posttranscriptionally by addition of spliced leader RNA to its 5′ end. In the case of surface antigen genes, evidence is now accumulating that their stage-specific expression is regulated predominantly at the level of RNA stability.[13]

T. cruzi contains a single mitochondrion that forms a complex structure that extends throughout much of the

cell (Fig. 2). The mitochondrial genome, which contains 20–25% of the total cellular DNA, is sublocalized at a specific site organized as a tight compact disc called the kinetoplast[14] (Fig. 2). It contains two classes of circular DNA, maxicircles and minicircles, which form a concatenated network. The maxicircle DNAs are between 20 and 30 kb and are present in 25–50 copies per cell. The minicircle DNAs, of which there are 5–10,000 copies per cell, have a size range from 0.5 to 2.5 kb. Maxicircle DNA is analogous to the mitochondrial genomes of other organisms and contains genes encoding ribosomal RNA and components of the mitochondrial respiratory system. Most unusually, many of the primary transcripts of the protein coding genes do not contain a complete open reading frame and need to undergo RNA editing to produce functional mRNA.[15] This requires posttranscriptional insertion or deletion of uridine residues, a process mediated by small transcripts called guide RNAs that are encoded by the minicircle DNAs. Minicircles have a conserved region, which encompasses the postulated origin of replication and a region of high variability that reflects the repertoire of expressed guide RNAs.

THE *T. CRUZI* GENOME PROJECT

The *T. cruzi* genome project is expected to be completed in 2004.[16] At the time of writing the ''shotgun-sequencing'' phase of the project has been finished to a 14× coverage. However, the recent finding that the genome sequencing strain CL Brener is a hybrid of two distantly related class II lineages[9] will make the final production of a contiguous and fully annotated sequence a complex procedure. The consequences of this hybridization event are that allelic copies of genes in CL Brener can vary in sequence by more than 2%, and that recombination has produced chromosomes that are mosaics of the parental genotypes. Despite this, the genome project is already having a major impact on research strategies with the focus changing from the characterization of individual genes to a more comprehensive high-throughput functional analysis. This is being further driven by improvements in the tools that are available for genetic modification of the parasite[17] and by the new microarray and proteomic techniques, which can provide a snapshot of the relative expression of thousands of genes simultaneously. Because the genome sequence is only now approaching completion, these types of techniques have yet to be applied to *T. cruzi* in a systematic manner. However, developmental regulation, responses to environmental stimuli and drug treatment, dissection of signal transduction pathways, and the identification of virulence factors are examples of questions that will soon be amenable to analysis on a genome-wide basis.

CONCLUSIONS

In terms of understanding why Chagas' disease is such a debilitating condition, the two most important questions are ''Does the development of chronic disease pathology require the continued presence of the parasite?'' and ''Do all *T. cruzi* parasites have the potential to induce chronic disease?'' Because of the long-term nature of the disease, the low level of parasitemia in chronic patients, and the possibility of mixed infections these are not trivial problems to address.

Results achieved with PCR-based diagnosis increasingly support the premise that all untreated (and many treated) patients remain infected with the parasite for life. In addition, most clinical trials have demonstrated a positive correlation between chemotherapy (despite its limitations) and some degree of prevention/alleviation of chronic disease pathology. These findings therefore argue strongly that the development of more effective and less toxic drugs should be a major goal of postgenome research. In this context it may ultimately be feasible to identify individuals in the indeterminate stage of the disease who are infected with parasites that predispose them to develop chronic pathology and who should be prioritized for chemotherapy. This will require exploitation of the new postgenome technologies to define genotypic or phenotypic markers diagnostic of parasites capable of inducing chronic disease.

Tuberous Sclerosis

David J. Kwiatkowski
Brigham and Women's Hospital, Boston, Massachusetts, U.S.A.

INTRODUCTION

Tuberous sclerosis (TSC) is an autosomal dominant genetic disorder characterized by development of distinctive nonmalignant tumors termed hamartomas and hamartias, in several organ systems. Tuberous sclerosis hamartomas involve the skin, brain, and kidneys in most TSC patients. Tuberous sclerosis is due to inactivating mutations in either the *TSC1* gene, which encodes the protein hamartin, or the *TSC2* gene, which encodes the protein tuberin. Most TSC lesions follow the first germline hit-second somatic hit tumor suppressor gene paradigm, such that complete loss of either hamartin or tuberin leads to tumor development.

CLINICAL AND MOLECULAR GENETICS OF TSC

About two-thirds of TSC cases are sporadic, representing new mutations. Tuberous sclerosis occurs in up to 1 in 6000 live births without apparent ethnic clustering. Large families with the condition are rare due to reduced reproduction among those affected.[1–3]

The *TSC1* gene consists of 23 exons with an 8.6-kb mRNA encoding the 130-kDa hamartin, and occupies 53 kb on 9q34 (Fig. 1).[3] The *TSC2* gene consists of 42 exons with a 5.4-kb mRNA encoding the 200-kDa tuberin and resides in 40 kb on 16p13 (Fig. 1).[3]

More than 600 mutations in *TSC1* and *TSC2* have been identified.[3] Comprehensive mutational analyses indicate that about 85% of TSC patients will have a mutation found in either *TSC1* or *TSC2*.[4,5] *TSC2* mutations are about 4.2 times as common as *TSC1* mutations, reflecting a higher germline mutation rate.

In *TSC1*, about half of the mutations are single base substitutions, of which most are nonsense mutations (Fig. 1). Just over half of the nonsense mutations are recurrent C to T transitions at six of the seven CGA codons within the *TSC1* coding region. Missense mutations are rare in *TSC1*, but have been confirmed as disease causing in a few cases. In *TSC2* as well, about half of the mutations are single-base substitutions (Fig. 1).[3] Nonsense mutations comprise about a third of these and commonly occur at five of the seven CpG sites which can transition to nonsense codons in *TSC2*. In contrast to *TSC1*, missense mutations are relatively common in *TSC2* (Fig. 1). *TSC2* has two CpG sites that are mutational hotspots which lead to missense mutations—1831-2 (611R>W and 611R>Q) and 5024-5 (1675P>L). These two CpG sites account for nearly half of the missense mutations in *TSC2*. Another relatively common mutation in *TSC2* is an 18-bp in-frame deletion mutation near the C-terminus (Fig. 1). However, no mutation in either gene is seen in more than 2% of all TSC patients.

About a third of *TSC1* mutations are small deletions (<29 bp), while half that number are small insertions (<34 bp). Nearly all small insertions and most deletions arise as duplications/deletions of a tandem repeat of single or multiple bases. Similar observations apply to small deletions and insertions found in *TSC2*. Large deletions and rearrangements are relatively common in *TSC2*, accounting for 16% of all mutations, whereas they are rare in *TSC1*, accounting for only 2%. In *TSC2*, deletions show no consistency in either size or junction fragments involved, ranging in size from 1 kb to over 100 kb.[3]

Patients with *TSC1* mutations have symptoms and clinical features that are milder on average than patients with *TSC2* mutations, although there is considerable overlap in severity.[4] Linkage studies provide evidence against a third TSC gene. Patients in whom mutations cannot be found are likely partially explained by mosaicism, which is well documented in TSC, and hinders efforts at mutation detection.[3]

Tuberous sclerosis molecular genetic testing is available commercially in the United States through Athena Diagnostics, and through several academic laboratories in Europe. In most laboratories the overall mutation detection rate is less than 80%, and findings of sequence variation of uncertain significance are often made, including possible missense and splice site mutations. Mutation identification has benefit for genetic counseling and prenatal diagnosis, particularly for individuals who have TSC. For parents of sporadic cases of TSC, the benefit is less clear, as such parents have a very low recurrence risk (~2%) if they are thoroughly screened clinically (exam by an experienced clinician and imaging studies of brain and kidney) and have no evidence of TSC.

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120025767

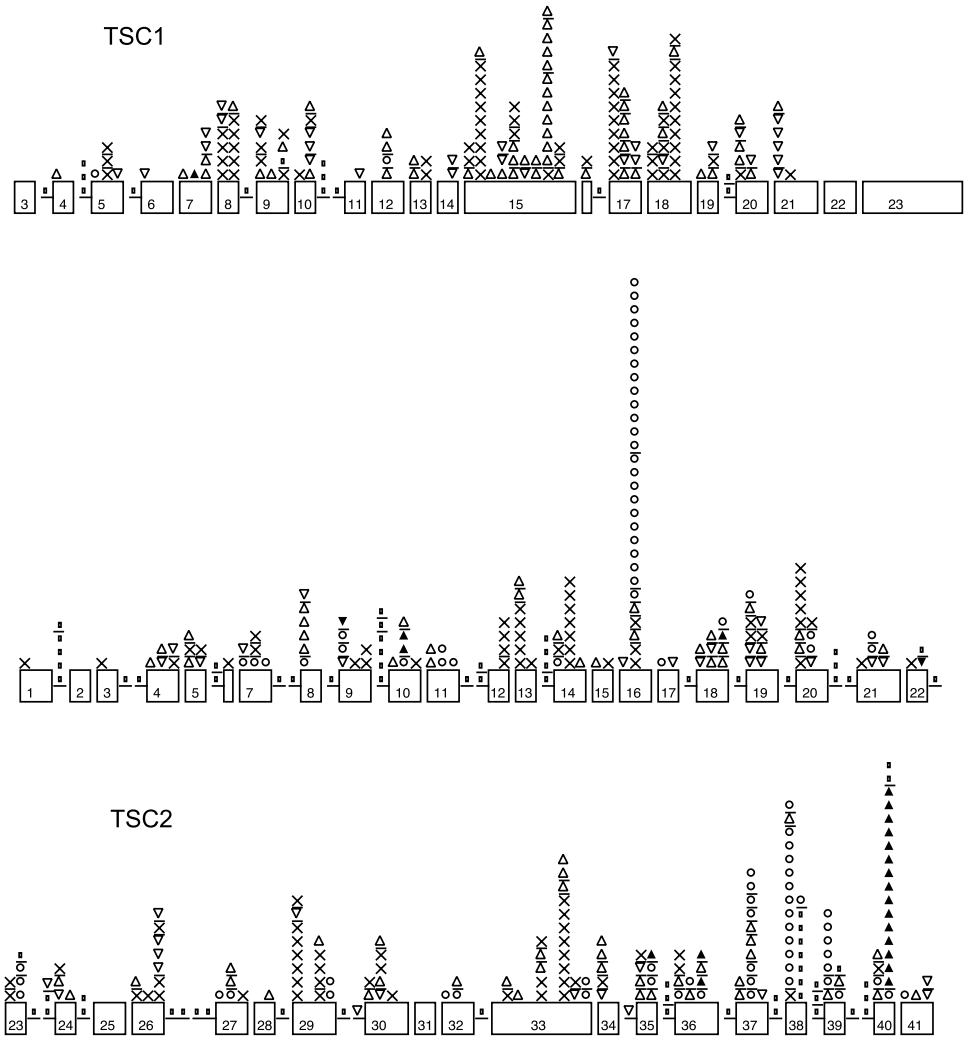

Fig. 1 Map of the sites of several hundred small mutations in TSC1 and TSC2. Proportional drawings (boxes) of all of the exons of TSC1 and TSC2 are shown. Intron regions are not drawn to scale and are expanded only when a mutation is present. Mutation symbols are: ×, nonsense; ■, splice site; △, deletion; ▽, insertion; ○, missense; □, in-frame deletion. A line separates mutations occurring at nearby but not identical nucleotide positions.

CLINICAL FEATURES OF TSC

Although hamartomas typically occur in several organ systems in TSC, the vast majority display limited growth potential and do not require intervention. A small fraction display persistent growth, necessitating surgical control. However, progression to malignancy is very rare in TSC and has been seen only in TSC renal hamartomas, termed angiomyolipoma (AML), at a frequency of about 2% of all TSC patients.[1,2] Another remarkable feature of TSC hamartomas is that they first appear at different ages during the patient's life and at times spontaneously resolve. For example, cardiac rhabdomyomas are often present at birth, but then usually disappear during childhood. The diversity and variability of clinical presentations and hamartomas in TSC have led to formal diagnostic criteria (Table 1).[6]

The cardinal feature of TSC is the cortical tuber, which is a distinctive form of brain hamartia.[1,2,7] Grossly, tubers are firm, smooth, somewhat raised, pale lesions of the cerebral cortex, and can number up to 40 in one brain, ranging in size from a few millimeters to several centimeters. The second common brain lesion seen in TSC is the subependymal nodule (SEN), typically found in the lateral ventricle. They occur as smooth nodules projecting into the ventricle and typically calcify in patients past the age of 10.

Histologically, cortical tubers are characterized by architectural disarray with disruption of cortical lamination.[1,2,7] Tubers contain a mixture of cells, including normal and dysplastic neurons, astrocytes, and the hallmark giant cell. Giant cells extend short aberrant processes and express both glial and neuronal proteins. Subependymal nodules consist of large cells

Table 1 Diagnostic criteria for TSC

Major features
1. Facial angiofibromas or forehead plaque
2. Nontraumatic ungual or periungual fibroma
3. Hypomelanotic macules (three or more)
4. Shagreen patch (connective tissue nevus)
5. Multiple retinal nodular hamartomas
6. Cortical tuber[a]
7. Subependymal nodule
8. Subependymal giant cell astrocytoma
9. Cardiac rhabdomyoma, single or multiple
10. Lymphangiomyomatosis[b]
11. Renal angiomyolipoma[b]

Minor features
1. Multiple, randomly distributed pits in dental enamel
2. Hamartomatous rectal polyps
3. Bone cysts
4. Cerebral white matter radial migration lines[a]
5. Gingival fibromas
6. Nonrenal hamartoma
7. Retinal achromic patch
8. ''Confetti'' skin lesions
9. Multiple renal cysts

Definite tuberous sclerosis complex: either two major features or one major feature plus two minor features.
Probable tuberous sclerosis complex: one major plus one minor feature.
Possible tuberous sclerosis complex: either one major feature or two or more minor features.
[a]When cerebral cortical dysplasia and cerebral white matter migration tracts occur together, they should be counted as one rather than two features of tuberous sclerosis.
[b]When both lymphangiomyomatosis and renal angiomyolipomas are present, other features of tuberous sclerosis should be present before a definite diagnosis is assigned.

in a vascular stroma, with occasional cells that attain giant cell proportions with aberrant and/or multiple nuclei. Subependymal giant cell astrocytomas (SEGA) develop from a SEN in 5–10% of TSC patients. Although there is growth to a size >1 cm, there is no histological progression. These lesions must be treated by surgical resection to prevent hydrocephalus and other adverse effects.

The major presenting symptoms and signs of cerebral TSC are a variety of epileptic seizures.[1,2,7] These seizures have their origin in the cortical tubers or in nearby transitional cortex. About two-thirds of TSC patients first present with infantile spasms usually between the ages of 3 and 9 months. There is a correlation between the number of cortical tubers in a TSC patient and both a younger age at onset and severity of seizures.

Mental retardation and developmental problems are serious consequences of brain involvement by cortical tubers.[1,2,7] Mental retardation is variable but can be profound, and rarely occurs in the absence of a generalized seizure disorder. Developmental problems are very common in TSC and include autistic behavior, hyperactivity, sleep disorders, and aggressive behavior.

Angiomyolipomas (AMLs) are the most common lesion in the TSC kidney, being seen in about 75% of children by adolescence using ultrasound imaging.[1,2] These lesions consist of a variable mixture of aberrant vessels, smooth muscle, and fat. Angiomyolipomas are typically bilateral and of variable size. Lesions >5 cm diameter are not rare, and large lesions are associated with a significant risk of bleeding as well as loss of nephrons due to compression.

Cutaneous findings are present in the great majority of TSC patients and are the most easily identified sign of the disease.[1,2] Most lesions are of minor clinical significance, but facial angiofibromas can be a significant cosmetic issue. Hypomelanotic macules or white spots typically have a lance-ovate shape (Ash-leaf) and are most common over the trunk and buttocks. Three or more of these lesions are very unusual in the general population and thus are considered a major diagnostic criterion (Table 1). The lesions are present at birth and do not change, although they are more easily observed following suntanning.

Facial angiofibromas are red to pink papules or nodules with a smooth surface that are found in a malar distribution and extending down to the chin.[1,2] They typically first appear between the ages of 2 and 6, and progress to a variable extent during puberty. Histological findings are dermal fibrosis and angiogenesis with occasional large glial appearing cells. Forehead fibrous plaque is a larger lesion related to facial angiofibroma, and Shagreen patch is also a related lesion found typically on the upper buttock. Ungual fibromas are another common cutaneous manifestation of TSC, being seen in most adults over the age of 30 years, but rarely prior to adolescence. These lesions are red- or flesh-colored papules or nodules occurring in the finger or toe nail regions.

Lymphangiomyomatosis (LAM) is a disorder seen almost exclusively in females which is characterized by smooth muscle cell proliferation and cystic changes in the lung parenchyma. Most LAM patients also have AMLs in the kidney or elsewhere in the abdomen. Lymphangiomyomatosis presents clinically as progressive dyspnea, or acute dyspnea due to pneumothorax, and can be progressive and fatal. However, 40% of adult TSC women have CT-scan evidence of LAM, and most of those are asymptomatic.

The retina is involved by hamartomas in about 50% of TSC patients. Cardiac rhabdomyomas are also found in most TSC infants when echocardiographic screening is done. These lesions can be up to several centimeters in diameter and consist of glycogen-filled myocytes. In most cases, there are no symptoms and the lesions spontaneously decrease in size or disappear over time. Less often, rhabdomyomas cause heart failure due to obstruction, affect myocardial function by replacement, or cause rhythm disturbances, and surgical resection is considered.

PATHOGENESIS OF TSC

Tuberous sclerosis hamartomas, particularly renal AMLs, usually display loss of heterozygosity (LOH) for the wild-type allele of either *TSC1* or *TSC2*, consistent with a two-hit mechanism for complete inactivation of either *TSC1* or *TSC2*.[3] This has not been seen as consistently for other types of TSC lesions, but microdissection has been effective in some cases (e.g., LAM) to demonstrate LOH events. Cortical tubers do not show evidence of LOH either, and cell admixture likely explains this finding.

Consistent with a relative lack of malignancy in TSC patients, limited surveys of human cancer specimens have failed to show evidence of either *TSC1* or *TSC2* mutation, with the possible exception of bladder carcinoma.

Seminal studies in Drosophila led to major insights into the cellular functions of TSC1 and TSC2.[8] Translation and extension of these studies in mammalian cells have led to a model of P13 K–Akt–TSC1/TSC2–Rheb-mTOR signaling that is shown in Fig. 2. In normal quiescent cells, P13 K and Akt are inactive, the TSC1/TSC2 complex is active as a GTPase activating protein (GAP) for Rheb, there are low levels of Rheb-GTP, and mTOR is inactive. In response to growth factor stimulation, P13 K and Akt become activated, TSC2 is phophorylated by Akt, and the TSC1/TSC2 complex becomes inactive as a GAP, so that Rheb-GTP levels rise, stimulating mTOR. In cells lacking TSC1 or TSC2, the residual TSC2 or TSC1 does not function as a GAP for Rheb, and Rheb-GTP levels are high, leading to constitutive activation of mTOR and phosphorylation of S6K1 and 4E-BP1. The model shown captures the main pathway involving TSC1 and TSC2, but omits many details and interconnections in the complex biochemical pathway that regulates cell growth. One

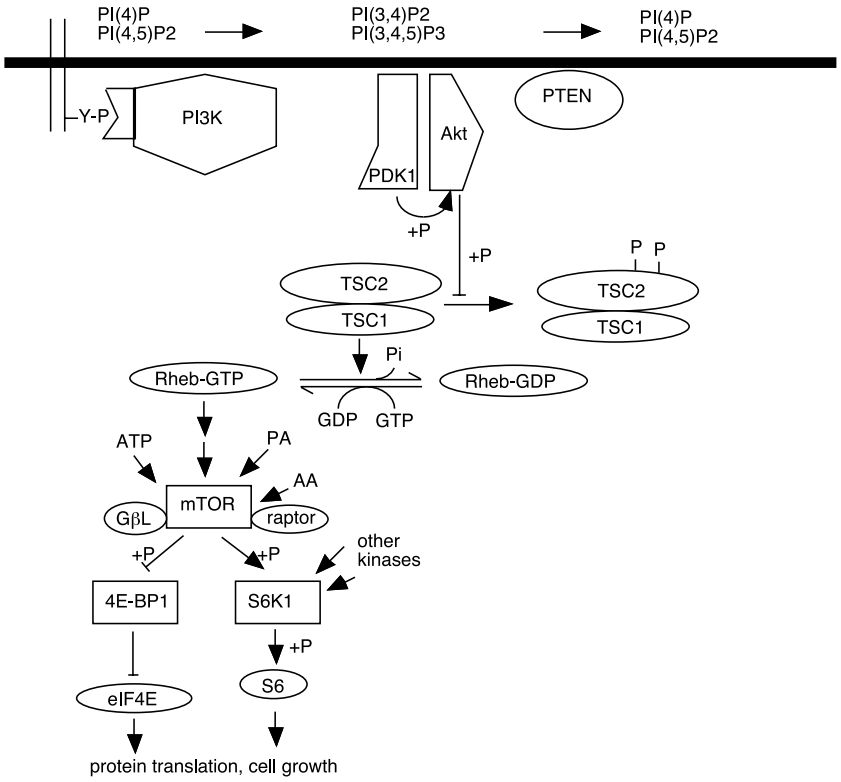

Fig. 2 Signaling pathway model for the function of TSC1 and TSC2 in mammalian cells. A phosphorylated growth factor receptor is shown at the upper left, to which a PI3 K molecule is binding. This leads to conversion of the indicated phosphoinositides to 3′-phosphoinositides, which leads to recruitment of Akt to the membrane in a position where it can be phosphorylated and activated by PDK1 and a second kinase. PTEN functions to terminate this signaling pathway by acting as a 3′ phosphatase on these phosphoinositides. Activated pAkt phosphorylates TSC2 which inactivates its GAP activity. When active, TSC1/TSC2 complex serves as a GAP for Rheb, reducing levels of Rheb-GTP. Rheb-GTP activates mTOR by an uncertain mechanism (thus two arrows). ATP, phosphatidic acid (PA), and amino acids (AA) all influence mTOR activity, although the sensing mechanisms are unknown and likely indirect. Active mTOR phosphorylates 4E-BP1 and S6K1. p4E-BP1 releases from eIF4E, permitting formation of the eIF4F translation complex. pS6K1 phosphorylates S6, and together they activate the translational machinery. For simplicity only the main pathway involving TSC1, TSC2, and mTOR is shown. Arrows indicate positive actions and bars represent negative actions. TSC1 and TSC2 are used here and in the text to denote the corresponding proteins hamartin and tuberin.

clinical correlate of this model is that hamartomas that occur in TSC both in patients and animal models typically express phospho-S6 and phospho-S6K1, signposts of activation of mTOR. Two consequences of activation of this pathway are the secretion of VEGF by cells in many TSC lesions and abnormal STAT phosphorylation.

The molecular basis of epileptogenesis induced by cortical tubers is uncertain, although disorganization of the cortex in these lesions likely contributes. There is increased transcription of genes encoding glutamatergic receptors by dysplastic neurons and giant cells in tubers, with reduced expression of gamma-aminobutyric acid (GABA)-ergic receptors.[7] These expression changes may contribute to epileptogenesis in TSC. Tuber giant cells and SEN cells also express pS6 and pS6K1, like other TSC lesions, consistent with complete inactivation of TSC1 or TSC2 with activation of mTOR as in other TSC hamartomas.

The TSC1/TSC2 complex has size 330 kDa, and the GAP domain of TSC2 comprises about 10 kDa of this complex. This alone suggests that there are other functions of the complex. TSC1 has been reported to bind to ezrin and other ERM family proteins, and appears to be involved in adhesion events and rho signaling to the actin cytoskeleton.[9] TSC2 has been reported to have a role in the membrane localization of polycystin-1 in renal epithelial cells.[10] A role for the TSC1/TSC2 complex in beta-catenin signaling has also been described. Whether any of these observations are independent of or relate to the role of TSC1/TSC2 in the P13 K signaling pathway is unknown.

CONCLUSION

Tuberous sclerosis is a disorder that affects approximately 40,000 people in the United States. It is remarkable in several respects: the frequency and severity of associated epileptogenesis, the unique predisposition to autism and other behavioral syndromes, and the unusual spectrum of associated tumors including LAM. The placement of the TSC genes in the PI3 K–Akt–TSC1/TSC2–Rheb-mTOR signaling pathway explains the hallmark giant cells seen in cortical tubers and provides the possibility of several pharmacological approaches that may be helpful in TSC. This includes drugs already in use in the clinic, including rapamycin and analogues (inhibit mTOR), farnesyl transferase inhibitors (inhibit Rheb), angiogenesis inhibitors, and interferon-γ. Current ongoing and planned trials of these agents in both preclinical models and TSC patients are of considerable clinical and basic interest.

Vibrio cholerae

Durg V. Singh
Institute of Life Sciences, Bhubaneswar, India

INTRODUCTION

Vibrio cholerae is a natural inhabitant of aquatic environments.[1] *V. cholerae*, which belongs to the O1 and O139 serogroups, is the only serogroup reported to be responsible for epidemic and pandemic forms of cholera,[2,3] whereas the *V. cholerae* non-O1 and non-O139 strains are associated with cases of sporadic cholera and extraintestinal infections.[4] Genetic and phenotypic analyses of *V. cholerae* revealed that, in addition to the genes encoding cholera toxin (CT), they require the colonization toxin-coregulated pilus (TCP) and a central regulatory protein, ToxR, which coregulates the expression of CT and TCP.[3] Polymerase chain reaction (PCR), multiplex PCR, and hexaplex PCR have been used to detect *V. cholerae* belonging to O1, O139 , non-O1, and non-O139 serogroups and virulence-associated genes, including CT (*ct*), zonula occludens toxin (*zot*), accessory cholera enterotoxin (*ace*), TCP (*tcp*), and outer membrane protein (*ompU*), and a central regulatory protein, ToxR.[5] Molecular techniques have been used to detect genetic changes in *V. cholerae* associated with displacement of existing serogroups by newly emerging serogroups or by other serogroups, which may provide new insights into the epidemiology of cholera. This work will focus on the current status of knowledge of epidemiology, antibiotic resistance, and virulence-associated factors of *V. cholerae*, which cause diarrhea in humans.

EPIDEMIOLOGY OF CHOLERA

V. cholerae is the causative agent of cholera, an acute dehydrating diarrhea that occurs in epidemic and pandemic forms.[2,3] Cholera has been recognized as one of the ''emerging and reemerging infections, threatening many developing countries.'' Several recent events that mark the epidemiological importance of the disease include the reemergence of cholera in Latin America in 1991, the explosive outbreak of cholera in Rwandan refugees in Goma and Zaire,[3] and the emergence of *V. cholerae* in the Indian subcontinent during 1992.[6,7] All pandemics, except for the seventh pandemic, which originated in Indonesia, arose from the Indian subcontinent, usually from the Ganges Delta region, and reached other continents.

Molecular Epidemiology

Molecular typing methods have been used to study the epidemiology of *V. cholerae*. While analyzing the nucleotide sequence of *asd* gene in *V. cholerae*, Karaolis et al.[8] demonstrated that the sixth and seventh pandemic strains and the U.S. Gulf coast *V. cholerae* O1 isolates may have derived from nontoxigenic strains, and postulated that horizontal gene transfer occurred in *V. cholerae*, resulting in the emergence of a new pathogenic strain. The use of gene probes to study restriction fragment length polymorphism (RFLP) in the *ctxAB* genes and their flanking DNA sequences, which are part of a larger genetic element (CTX element), indicated that the U.S. Gulf coast isolates of toxigenic *V. cholerae* O1 are clonal and different from other seventh pandemic isolates.[2] The diversity of CTX genotypes in *V. cholerae* O139 was reported, which may have resulted from the duplication of CTX prophage.[3] However, the toxigenic O139 strains prevalent in two endemic areas in India, including Calcutta and Alleppey, Southern India, and Bangladesh, are not clonal, and the Alleppey O139 strains are different from the Calcutta and Bangladesh strains, which contain the unique arrangement of the CTX prophage.[7]

Ribotyping and multilocus enzyme electrophoresis (MEE) analysis of the toxigenic *V. cholerae* O1 El Tor strains indicated clonal diversity, and the clones reflected broad geographical and epidemiological areas.[5,9,10] Comparative analysis of the El Tor strains of *V. cholerae* O1 and the epidemic O139 strains suggests that the O139 strains are related to El Tor strains and are derived from them by possible genetic changes in serotype-specific gene cluster.[3,9] Numerical analysis of ribotype patterns also revealed that *V. cholerae* strains belonging to the non-O1 and non-O139 serogroups are widely diverse from the O1 and O139 *V. cholerae* strains.[3,5,11] Further studies demonstrated the transient appearance and disappearance of more than six ribotypes of classical vibrios and three different ribotypes of *V. cholerae* O139. Different ribotypes often showed different CTX genotypes resulting from difference in the copy number of the CTX element and the variation in the integration site of the CTX

Restriction pattern corresponding to ribotypes derived from strains is shown in lanes 1 and 2 (B-I), lanes 3 and 4 (B-II), and lane 5 (B-IV), and a new ribotype (B-VI) derived from *V. cholerae* O139 strain ALO95 isolated from a diarrheal patient is shown in lane 5. (From Ref. [12]. Courtesy of ASM Press, New York.)

element in the chromosome, giving rise to new clones possibly by natural selection involving unidentified environmental factors and immunity of the host.

Ribotype analysis of O139 strains isolated until 2001 showed diverse ribotype patterns[7] and, since then, one more ribotype has been detected[12] (Fig. 1). Results of pulsed-field gel electrophoresis (PFGE) analysis of clonal diversity in O139 strains showed that PFGE patterns were highly similar but nonidentical with minor differences in banding patterns of *Not*I restriction patterns. This study suggested that although O139 had a cloned origin, this serogroup is undergoing changes in a manner analogous to that seen among the El Tor strains.[13] Studies on clonality of clinical and environmental *V. cholerae* O1, O139, non-O1, and non-O139 groups by using enterobacterial repetitive intergenic consensus sequence (ERIC) PCR, box element PCR, amplified fragment length polymorphism (AFLP), and PFGE collectively indicated that *V. cholerae* O1 and O139 had a clonal origin, whereas the non-O1 and non-O139 strains belonged to different clones. The clinical isolates resembled environmental isolates in their genomic patterns, suggesting that aquatic environments are reservoirs for *V. cholerae*.[5] It was also shown that the multiple clones of *V. cholerae* O139, identical to those of O139 that caused an epidemic in 1992, were present in the aquatic environment.[14]

Antibiotic Resistance

Antibiotic susceptibility tests of O1 strains isolated from the 1979 outbreak in Bangladesh showed resistance to tetracycline, in addition to other antibiotics ampicillin, kanamycin, streptomycin, and cotrimoxazole (trimethoprim-sulfamethoxazole). The subsequent follow-up study of the epidemiological assessment of the outbreak indicated that the O1 isolates were not resistant to tetracycline, including streptomycin, chloramphenicol, amoxicillin, or nalidixic acid. All the classical *V. cholerae* strains isolated in Bangladesh during 1988 and 1989 were resistant to tetracycline, whereas strains belonging to the El Tor biotype were sensitive to the drug. Almost after a decade, tetracycline-resistant El Tor strains reemerged in Bangladesh in 1991 and in Tehran in 1998.[3,15] In October 1995, the emergence of nalidixic acid-resistant O1 *V. cholerae* El Tor strains was reported in Southern India.[16] Moreover, 80–100% of *V. cholerae* O1 isolated in Kenya, South Sudan, Peru, and Guinea-Bissau, and 65–90% of isolates from Somalia isolated between March 1994 and December 1996, were not resistant to tetracycline, whereas all the O1 isolates from Tanzania and Rwanda were resistant to this drug.[3] A number of *V. cholerae* O1 strains isolated during 1992–1997 in Calcutta showed resistance to tetracycline (in addition to ampicillin, chloramphenicol, cotrimoxazole, neomycin, and streptomycin) and emerging resistance to nalidixic acid.[17] Analyses of the antibiotic susceptibility of *V. cholerae* O1 strains isolated from Kottayam, Alleppey, and Trivandrum, Southern India, in 2000 showed that these strains are resistant to nalidixic acid, and/or neomycin, and/or streptomycin, respectively, in addition to other drugs tested, and are sensitive to tetracycline, suggesting the existence of different R-types of *V. cholerae* strains in different locations.[18] Continuous surveillance of outbreaks of cholera in Kerala, Southern India showed the emergence of nalidixic acid-resistant strains of *V. cholerae* O1 in 2002 (unpublished).

In the analysis of the O139 strains isolated during the past 9 years, Faruque et al.[7] showed that O139 strains remained largely susceptible to ciprofloxacin, tetracycline, and gentamicin, and resistant to ampicillin; susceptibility to cotrimoxazole, chloramphenicol, and streptomycin varied during this period. Recent studies have shown that O139 strains isolated from different parts of India were, by and large, resistant to ampicillin, furazolidone, streptomycin, and nalidixic acid, except for Calcutta strains that were sensitive to nalidixic acid. Recently, emergence of nalidixic acid-resistant strains of *V. cholerae* O139, which are sensitive to sulfamethoxazole, trimethoprim, and streptomycin, was observed from the outbreak of cholera in Alleppey and Trivandrum, Southern India in 2002 (unpublished). Waldor et al.[19] reported the presence of a 62-kb self-transmissible transposon-like (SXT) element encoding resistance to sulfamethoxazole, trimethoprim, and streptomycin in *V. cholerae* O139 isolated during this period. The SXT

element could be conjugally transferred from *V. cholerae* O139 to *V. cholerae* O1 and *Escherichia coli* strains, where it integrated into recipient chromosomes in a site-specific *rec-A*-independent manner. Considering the rapidly changing patterns of antibiotics observed among *V. cholerae* strains, it appears that there is substantial mobility in genetic elements encoding antibiotic resistance in *V. cholerae*.

VIRULENCE-ASSOCIATED GENES

Cholera is characterized by a severe watery diarrhea caused by toxigenic *V. cholerae*, which colonizes the small intestines and produces an enterotoxin, CT.[3] Although production of CT encoded by the *ctxAB* genes is directly responsible for the manifestation of diarrhea, cholera pathogenesis relies on the synergistic action of a number of other genes, such as colonization TCP and outer membrane protein (*ompU*), and a regulatory protein, ToxR, which coregulates the expression of CT and TCP,[3] and part of the CTX-genetic element comprising zonula occludens toxin (*zot*) and accessory cholera enterotoxin (*ace*), which are virulence factors and also play a role in the morphogenesis of the filamentous phage CTXΦ.[19]

PCR

Multiplex PCR was successfully used to detect the CT and associated virulence gene fragments and, simultaneously, to identify the O1 and O139 serogroups of *V. cholerae*.[20] From the diagnostic point of view, toxigenic–pathogenic and nontoxigenic–nonpathogenic strains of *V. cholerae* can be differentiated by the presence of *ctx* and *tcp* genes. It was difficult to know whether the CT gene-negative strain possesses other toxin genes, such as, *zot*, *ace*, part of the CTX genetic element, and *ompU*. None of these methods can be used to individually identify toxin and virulence genes. Hence, a one-step hexaplex PCR was developed for rapid detection of an array of six specific virulence genes comprising CT subunit A (*ctxA*), zonula occludens toxin (*zot*), accessory cholera enterotoxin (*ace*), adherence outer membrane protein (*ompU*), TCP (*tcpA*), and the regulatory protein (ToxR).[20] Results of representative strains of *V. cholerae* are shown in Fig. 2. Employing the hexaplex PCR, 97 strains of *V. cholerae* and *Vibrio mimicus* were screened for the presence of virulence genes. It was found that hexaplex PCR can rapidly detect, in a single tube, the six commonly known virulence genes in *V. cholerae*, and was specific and sensitive.

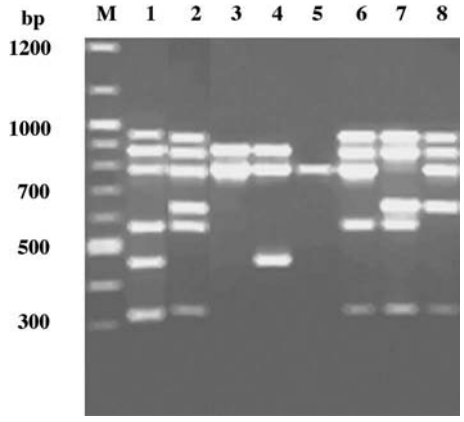

Fig. 2 Agarose gel electrophoresis of hexaplex PCR products obtained with *V. cholerae* strains. Lane M, 100-bp DNA ladder (NEB); lanes 1 and 2, toxigenic *V. cholerae* O1 El Tor strain 20 and classical strain 569B; lanes 3–5, nontoxigenic *V. cholerae* O1 El Tor strains X392, 2740-80, and 1074-78; lane 6, *tcpA*$^-$ *V. cholerae* O1 classical strain O395 RT 110-12; lane 7, *toxR*$^-$ *V. cholerae* O1 classical strain O395-12; lane 8, *ctxA*$^-$ *V. cholerae* O1 classical strain CVD 103-HgR.

DIAGNOSIS

Laboratory diagnosis of acute untreated cholera is fairly simple and straightforward as a large number of cholera vibrios are present in the stool of such cases. The stool samples or rectal swabs transported either in Cary–Blair transport medium, alkaline peptone water, or tellurite–taurocholate peptone broth in the laboratory are plated on commonly used thiosulfate–citrate–bile salts–sucrose (TCBS) medium for isolation of *V. cholerae*.[21] The sucrose-fermenting *V. cholerae* isolates are readily detected on this medium as large, yellow, smooth colonies. Suspected colonies from TCBS are inoculated into Kligler iron agar (KIA) medium. Cultures yielding an alkaline slant over acid butt with no gas or H_2S are then tested for oxidase activity and reactivity with polyvalent O1 or O139, and monospecific Ogawa or Inaba antisera using growth from the KIA slant. In case of doubtful agglutination or nonagglutination with O1 or O139 antisera, it is imperative to perform some tests such as oxidase and string test, mannitol and sucrose fermentation, lysine and ornithine decarboxylation, and arginine dihydrolation.

CLINICS AND THERAPY OF CHOLERA

Cholera is a clinical–epidemiological syndrome caused by *V. cholerae* belonging to serogroups O1 and O139. It is characterized by the passage of voluminous stools of rice water character and vomiting, which leads to

dehydration resulting from underlying deficit due to loss of large quantities of extracellular fluids. Hypovolemic shock, acidosis, and death can ensue in adults, as well as in children, if prompt and appropriate treatment is not initiated.

The key to therapy is provision of adequate rehydration until the disease has run its course in the absence of antimicrobial therapy. Rehydration can be accomplished by intravenous infusion of fluid in severe cases, or by oral rehydration with an oral rehydration solution (ORS).[2,22,23] Antimicrobial agents play a secondary but valuable role in therapy by decreasing the severity of illness and the duration of excretion of the organism. The drugs of choice are tetracycline, erythromycin, furazolidone, cotrimoxazole, norfloxacin, and ciprofloxacin. The hypoglycemia that is sometimes seen in pediatric patients should be treated with 25% or 50% glucose given intravenously.

CONCLUSION

Because *V. cholerae* is a water-borne organism, regular monitoring of this water-borne pathogen is required to protect public health particularly in developing countries where hygienic condition is poor. DNA-based molecular techniques have provided evidence to detect genetic changes in *V. cholerae* and for emergence of new clones or other serogroups. Screening of antibiotic susceptibility will possibly help to find the rapidly changing pattern of antibiotic resistance among *V. cholerae* strains and to trace the mobility of a genetic element(s), if any, encoding antibiotic resistance.

Hexaplex PCR may be used for the rapid detection of virulence genes in O1, O139, non-O1, and non-O139 serogroups from pure bacterial culture and directly from a variety of specimens, including clinical specimens, after removing inhibitors of PCR present in human feces by centrifugation and activity of remaining inhibitors by 10-fold dilution, foods by quantitative PCR, and environmental samples by extracting DNA from water samples. However, there is a need to develop a multiplex PCR for a rapid and accurate detection of *V. cholerae* belonging to O1, O139, non-O1, and non-O139 serogroups, in addition to virulence genes from a variety of samples.

V

Vibrio vulnificus

Olivier A. E. Sparagano
University of Newcastle, Newcastle, U.K.

Brian Austin
Heriot-Watt University, Edinburgh, U.K.

INTRODUCTION

Vibrio vulnificus is a motile marine (and estuarine) gram-negative bacterium that contaminates filter-feeding shellfish, fish, and humans involved in lethal septicemia and wound infections. Outbreaks in United States, Europe, Asia, and Australia are mainly related to oyster consumption followed by clams and mussels. In addition, there have been cases of human disease in Europe (e.g., The Netherlands) associated with the handling of eels.

TAXONOMY

It was first described as *Vibrio parahaemolyticus* by the CDC in 1964 and separated in 1970.[1] The closest neighbor was thought to be *Vibrio anguillarum* type B (*Vibrio anguillarum forma anguillicida*), according to the description of Nybelin.[2] Former biotypes 1 and 2 were considered no longer appropriate,[3] and it was subsequently deemed preferable to refer to the organisms as a serovar (=serotype=serogroup) rather than biotype.[4] With serovar E being similar to biotype 2, serovar B is close to human clinical strains[5] and a new serovar A was recently described in Spain.[6]

ECOLOGY

V. vulnificus has been isolated from waters[7] with temperatures ranging from 9°C to 31°C, but proliferation was observed when the temperature exceeded 18°C[8] and will revert to a viable but nonculturable (VNBC) state if water temperatures go below 10°C and, therefore, could become undetectable by culturing.[1] Interestingly, studies on temperature resistance showed better results when *V. vulnificus* is subjected to starvation.[9] It also appears that for waters with salinity above 20 ppt, *V. vulnificus* levels decline and should not be considered as a risk for humans.[10]

PATHOLOGY

Two main pathologies have been associated with *V. vulnificus*: wound infections and primary septicemia.[1,11–15] Recently, an alarming number of human cases were reported in Japan,[16] Taiwan,[17] Singapore,[18] Chile,[19] United States,[20] New Zealand,[21] and Spain.[22] Infection occurs also in immunocompromised patients. Furthermore, snakebites were complicated when *V. vulnificus* was also present in the wound.[23]

The proliferative and degenerative symptoms could be indicated by the observation that *V. vulnificus* induces apoptosis in macrophages[24] bypassing the first defense mechanisms of the host. Proinflammatory cytokines are known to be of major importance in septicemia because of this bacterium.[25] For details of other virulence factors, see the review by Strom and Paranjpye.[1]

However, metalloproteases have been well studied in connection with virulence.[26] In addition, the expression of a capsular polysaccharide (CPS) was shown to be virulence-related.[27] Molecular studies have been carried out (to be developed further in another article in this volume) on a 68-kbp plasmid, which was found in virulent strains from fish.[28]

DETECTION

Molecular Detection

Studies on the 16S rDNA gene have already given some interesting results either by differentiating *V. vulnificus* against other representatives of the *Vibrio* or by differentiating type B from type A strains, thus allowing an understanding of mixed infections and seasonal variation between strains.[29] Indirect study with PCR-DGGE showed sensitivity based on a pure culture of *Escherichia coli* of between 10^4 and 10^5 cfu/mL.[30] A study of the 16S–23S rDNA spacers highlighted the possibility of detecting NCBV strains in oysters,[31] demonstrating the value of such molecular methods to

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120021698

identify pathogens that will not grow on artificial media whatever species they are.

DNA probing the *cth* and *tlh* genes (hemolysin-related genes) allowed authors to differentiate *V. vulnificus* and *V. parahaemolyticus*, respectively.[32] However, polymorphism is still a major problem to find strain-specific or species-specific probes not cross-reacting with other vibrios.[33]

However, other authors tried to elucidate the gene regulations of *V. vulnificus* to develop new control methods. The haem uptake receptor R (hupR) was shown to share homologies with the LysR family and could be a positive regulator of *hupA* gene to satisfy *V. vulnificus* iron requirements.[34]

Several regions such as cytolysin, *vvhA* (*V. vulnificus* hemolysin gene), pR72H (a 0.76-kb *Hin*dIII DNA fragment cloned from *V. parahaemolyticus*), and 16S–23S rRNA were simultaneously used to specifically identify this bacterium.[40] The *vvhA* gene responsible for the production of the cytolytic hemolysin of *V. vulnificus* and its activation by the cAMP receptor protein (CRP) has also been extensively studied.[35] Mutagenesis study of a virulent *V. vulnificus* strain identified four essential capsular polysaccharides (CPS) for virulence expression.[36] A seminested PCR on the *vvhA* gene showed its transcription in NCBV populations and may be very useful for assessment of water quality.[37]

Nonmolecular Detection

Pathogenic *Vibrio* spp. are usually isolated by preenrichment, for example, in alkaline peptone water (APW) with 1% NaCl. Some media have been developed specifically for *V. vulnificus* and include semiquantitative approaches[38] and selective agars.[39]

An immunofluorescence method was used successfully to detect *V. vulnificus* serovar E, showing the possibility of developing immunological tests.[40]

CONCLUSION

V. vulnificus has a bad reputation because of the tremendous debilitating impact on animals and humans. However, there is some progress toward the identification and the prevention of the diseases. For the latter, some workers have successfully protected eels against *V. vulnificus* attacks by immunization showing that capsular antigens are better for protection and should be administered by intraperitoneal injections with vaccines enriched with toxoids.[41] However, vaccination strategies gave different results according to the route of administration and the antigen preparation.[42] Nevertheless, there is optimism for controlling this bacterium, with preliminary studies already highlighting bacteriophage activities[43] and the effect of bacteriocins on *V. vulnificus*.[44] After observing that around 85% of male patients developed endotoxic shock, some studies have examined the role of estrogens for protection.[45] However, further studies of the genome could allow the identification of key factors needed to eradicate this pathogen. In addition, it would then be possible to develop new microarray techniques to identify culturable versus nonculturable or pathogenic versus nonpathogenic strains or differentiating several pathogens at the same time.[46]

Viral Encephalitis—Japanese Encephalitis, Tick–Born Encephalitis, and St. Louis Encephalitis

Matthias Niedrig
Jens Mehlhose
Robert Koch Institut, Berlin, Germany

INTRODUCTION

Japanese encephalitis (JE), St. Louis encephalitis (SLE), and Tick–Born encephalitis (TBE) are important representatives in the group of *Flavivirus* diseases. The viruses of these diseases are transmitted by mosquitoes or ticks. Symptoms of diseases are very different; they could reach from mild over severe encephalitis to death.

The following geographical distributions are typical for each disease:

- Japanese encephalitis: Asia, Australia;
- St. Louis encephalitis: North, Central, and South America;
- Tick–Born encephalitis: Europe, Asia.

The typical diagnostic for these diseases includes virus detection by polymerase chain reaction (PCR) or isolation and detection of antiviral antibodies. Treatment is in general symptomatic. For TBE specific immunoglobulin is available.

TRANSMISSION

All three diseases are caused by flaviviruses which are RNA-viruses of the family of Toga viruses.

A majority of flaviviruses can cause encephalitis in humans, e.g., JE, TBE, SLE, Murray–Valley encephalitis, etc.

Tick–Born encephalitis virus is transmitted by infected ticks. Ticks live mainly in forests with much grass, bushes, and dry leaves. The virus enters the body by a tick bite. Direct transmission from person to person is not known. Small rodents, birds, roes, and deer are primary virus reservoirs. Transmission via unpasteurized milk or cheese is a common problem in high endemic areas.

Japanese encephalitis virus is transmitted by mosquitoes. They live in humid areas with much water, in East Asia and Southeast Asia. Direct transmission is not known. Domestic animals, rodents, pigs, equines, and birds are primary virus reservoirs.

St. Louis encephalitis virus is also transmitted by mosquitoes, but in America direct transmission has not been described.[1–12]

GEOGRAPHICAL DISTRIBUTIONS

The virus of TBE occurs in definite areas in Europe: Albania, Austria, Croatia, Czech Republic, Estonia, Finland, Germany, Hungary, Latvia, Lithuania, Poland, Romania, Russia, Slovenia, Slovakia, Sweden (Fig. 1).

In Germany TBE virus occurs in certain areas in Bavaria, Baden-Württemberg, Hess, Thuringia, and in the Rhineland-Palatinate.

There is an increase of the disease in spring, summer, and early autumn.[6,13,14]

Japanese encephalitis mainly occurs in Japan, China, Eastern Siberia, India, North Thailand, Australia; especially in areas with much water and swamps (Fig. 2). There is a periodic increase in summer.[1–4,15–22]

St. Louis encephalitis occurs in Canada (Ontario), United States (especially in western states and in the southeast), Trinidad, Jamaica, Panama, Brazil, and Argentina (Fig. 3).

An accumulation of disease is regionally limited and increases in summer and early autumn, especially in years with warm and wet weather and great population of mosquitoes.[4,5,9,10,23–30]

INCUBATION PERIOD

The incubation period of all three diseases is generally between 5 and 15 days. Single cases of 21 days (SLE) and 28 days (TBE) were described.[3,5,6]

SYMPTOMS

The symptoms are very variable. There are very mild and nearly asymptomatic but also severe and deadly cases. They are often more severe in elderly people.

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120021409

Fig. 1 Geographical distribution of tick–born encephalitis. (Courtesy of M. Bröker and D. Gniel, Chiron Vaccines, Chriron Behring GmbH.) (*View this art in color at www.dekker.com.*)

A biphasic course of disease is typical for TBE. The disease starts with symptoms, which are similar to flu: mild temperature, headache, pain in the limbs.

A typical meningo encephalitis may occur in 10% of infected people after a short interval (5–10 days) without symptoms. These are the following symptoms: high temperature; heavy headache; nausea and vomiting; meningeal irritations; occasional numbness or stupor, especially in patients older than 50 years; neurological signs (paralysis, convulsions).

Typical for TBE is persistent symptomatic over months, especially in elderly people, although there is a complete recovery in most cases. Persistent headache, weakness of concentration, and mild paralysis are very seldom after disease recovery.

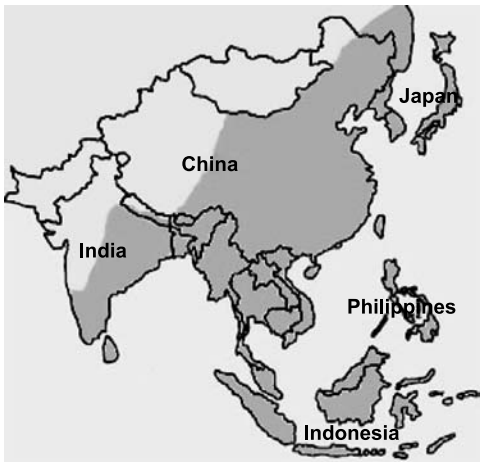

Fig. 2 Geographical distribution of Japanese encephalitis. (*View this art in color at www.dekker.com.*)

The symptoms of JE are also very variable. Most infections are asymptomatic. There are severe cases especially in small children and elderly people with the following symptoms: high temperature, headache, stiffness of the neck and other meningeal signs, vomiting,

Fig. 3 Geographical distribution of St. Louis encephalitis. (*View this art in color at www.dekker.com.*)

stupor, disorientation, paralysis, disturbance of reflexes. Temperature drops in most cases after the 10th day of disease, but the infection very often leads to persistent neurological and psychical damages (tremor, convulsions, paralysis, mental, and behavior weakness). The mortality is nearly 10%.

The following symptoms are typical for SLE: high temperature, headache, stiffness of the neck, vomiting, shunning the light, confusion, tremor, increase of unconsciousness until coma, changes in liquor (pleocytosis, increase of protein). Complications are pneumonia or gastrointestinal hemorrhages. The mortality rate is nearly 10–20%, especially in patients older than 50 years. Causes of death are failure of the kidneys or coma. Encephalitis can lead to persistent damages after enduring the disease, e.g., mild paralysis, defects of speech, memory weakness.[1,3–6,9,13,14,22,27,28,31–33]

COMPLICATIONS

Complications by TBE are very seldom and mainly found in elderly patients; typical is a cure with defects. Damage of the cardiac excitations system is reported. Tick–Born encephalitis infections could be more severe if *Borrrelia burgdorferi* causing Lyme disease infection is present in parallel with an infected tick.

Japanese encephalitis is more severe; the rate of complications is higher. Neurological and psychical damages are relatively frequent, e.g., convulsions, paralysis, mental weakness.

St. Louis encephalitis also has a higher rate of complications, typically in elderly people. There are mild and subjective consequences (tiredness, forgetfulness, weakness of concentration, defects of speech), but also dangerous complications such as convulsions, paralysis, pneumonia, hemorrhages.[1,3–6,9,11,22,27,28,30,31]

PROGNOSIS

Tick–Born encephalitis has a relatively good prognosis. Their mortality rate amounts to 1–2%, especially in elderly patients who suffer complications in the central nervous system.

The mortality rate of JE is higher; it amounts to nearly 10%, especially in patients older than 50 years.

St. Louis encephalitis has a similar mortality rate to JE (less than 5% in patients younger than 50 years; 10–20% in patients older than 50 years).[3–6,9,10,14,34,35]

DIAGNOSTICS

PCR and RT-PCR Diagnostics of Viral Encephalitis

Molecular detection of pathogenic viruses by PCR has become a very important tool in diagnostics. Although PCR provides the most sensitive and fastest method for virus genome detection, there are some very important issues that must be considered when using this method. Because of the high sensitivity, contaminations by traces of positive amplification products could cause false-positive results. These problems are partially overcome by the new real-time PCR technology which avoids contamination of the amplified viral genome sequences. The other aspect that must be considered is that the virus load could be very different in the course of the different diseases, within different organs, or different specimens (blood, liquor, sputum, etc.), which could cause problems regarding the interpretation of the results. Therefore, a negative result cannot be interpreted as an exclusion of the respective viral infection. For Flavivirus infection such as JE, SLE, and TBE the majority of patients show a very mild course of disease and very often only a low viremia. Only in severe cases with encephalitis symptomatic is it likely to get positive results by PCR in the acute phase of the disease. The introduction of PCR in the diagnosis of this kind of diseases will lead to more information on the pathogenesis and course of disease in these patients. Presently, most of the JE, SLE, and TBE infections are still diagnosed by conventional detection of IgM and IgG antibodies in serology assays such as immunofluorescence, ELISA, and/or neutralization tests.

Typical for the diagnosis of TBE are the following methods:

- Detection of virus antibody by ELISA in serum or liquor (IgM in acute phase serum; IgG);
- Virus isolation and detection of nucleic acid in blood or liquor in the first phase of the disease (PCR, cell culture);
- Western blot in special laboratories.[6,13,14]

Typical for the diagnosis of JE are the following methods:

- Virus isolation from tissues;
- Detection of viral nucleic acid from liquor by RT-PCR and confirmation of the sequenced RT-PCR product;
- Detection of virus antibody (IgM, IgG) by indirect immunofluorescence (from blood or other body fluid);
- Detection of virus antibody by ELISA (specific IgM in acute phase serum or IgG);

- Virus antibody by neutralization test;
- Immunohistochemistry and laboratory findings (mild leukocytosis).[7,36–39]

Typical for the diagnosis of SLE are the following methods:

- Virus isolation from the brain and detection of viral nucleic acid by RT-PCR and confirmation of the sequenced RT-PCR product;
- Virus antibody (IgM, IgG) by indirect immunofluorescence, by ELISA or by neutralization test;
- Immunohistochemistry findings from the brain;
- Laboratory diagnosis (mild leukocytosis).[40–42]

DIFFERENTIAL DIAGNOSIS

Tick–Born encephalitis, Japanese encephalitis, and St. Louis encephalitis have to be distinguished from other diseases of the central nervous system, especially from inflammatory diseases of the brain (other viral encephalitis, viral or bacterial meningitis, poliomyelitis, tuberculosis, Lyme disease). Because of the unspecific symptoms of these diseases, other Flavivirus infections should also be considered for differential diagnosis. In parts of the Far East where TBE is endemic the Omsk hemorrhagic fever is also endemic; in most areas where JE is also endemic dengue infections are occurring regularly as well; and since 1999, the West Nile virus is distributed in North America also in the same areas where SLE is present.

The following criteria indicate TBE:

Clinical image is compatible with TBE (biphasic disease course after a tick bite in a high-risk area; first phase with symptoms similar to flu, short interval without symptoms, neurological symptoms after 4–10 days); and

Diagnostic detection of viral nucleic acid by PCR or virus by isolation or detection of specific viral antibodies of IgM or IgG type. Differentiation of TBE-specific antibodies from other anti-Flavivirus (yellow fever, dengue, West Nile, JEV, SLE)-directed antibodies could create difficulties in serology. A fourfold rise in the antibody titre in two follow-up serum samples is a strong indicator of an infection.

The following criteria indicate JE:

Clinical image is compatible with the disease (headache, high temperature, neurological symptoms within the last 3 weeks before onset of disease, being in Eastern Asia or in India or in Southeast Asia or in Australia); and

A JE case is confirmed with one of the following laboratory diagnoses: isolation of the virus from tissues or detection of the virus nucleic acid in a sequenced RT-PCR from liquor;

Diagnostic detection of viral nucleic acid by PCR or virus by isolation from liquor and/or blood. Detection of specific viral antibodies of IgM or IgG type. Differentiation of JEV-specific antibodies from other anti-Flavivirus (yellow fever, dengue, West Nile, TBE, SLE)-directed antibodies could create difficulties in serology. A fourfold rise in the antibody titre in two follow-up serum samples is a strong indicator of an infection.

The following criteria indicate SLE:

Clinical image is compatible with the disease [headache, high temperature, neurological symptoms within the last 3 weeks before onset of disease, having been in the United States, Canada (Ontario), Trinidad, Jamaica, Panama, or Brazil]; and

A SLE case is confirmed with one of the following laboratory diagnoses: diagnostic detection of viral nucleic acid by PCR or virus by isolation from liquor and/or blood.[1,2,5,6,13,28] Detection of specific viral antibodies of IgM or IgG type. Differentiation of SLE virus-specific antibodies from other anti-Flavivirus (yellow fever, dengue, West Nile, TBE, SLE)-directed antibodies could create difficulties in serology. A fourfold rise in the antibody titre in two follow-up serum samples is a strong indicator of an infection.

TREATMENT

Treatment is symptomatic for all three diseases. For TBE, immediate vaccination and/or administration of specific hyper immunoglobulin antisera could be considered for treatment. For SLE and JE antiviral treatment is not available. The treatment is limited by symptomatic and supportive measures.

The following measures are sensible: drugs against temperature, aches, and other symptoms; intensive medical measures against complications such as stupor, unconsciousness, coma, convulsions, etc.[3–5,8,13,18,19,30,43–47]

PROPHYLAXIS

Avoidance of tick bites is an important principle of prophylaxis against TBE.

It is recommended to wear bright, long clothes on trips to forests in high-risk areas and to use repellants. Immediately after some outdoor activities in endemic areas search the body carefully for ticks, remove the ticks carefully, disinfect the wound carefully after removing the ticks, and use ticks prevention for domestic animals.

There is an indication for vaccination against TBE. The vaccination is active (consists of inactive virus) and recommended for travelers in high-risk areas and for people with outdoor activities in their profession or those on holiday (ranger, gardening, veterinary surgeon, hiking, etc.).

Complete protection against TBE is achieved after three vaccinations (one basic vaccination and two boosters). A new vaccination is recommended after 3 years. A passive immunization with globulin is possible in the first 2 days after the exposition.[7,13,14]

Prophylaxis against JE requires protection against mosquitoes (e.g. saving clothes, mosquito nets, fly screens, repellants) in high-risk areas (e.g., Eastern Asia, Southeast Asia, India, especially in summer). Vaccination is possible for people traveling to high-risk areas (e.g., trekking tours) or staying in high-risk areas for a longer time, especially in rural regions. This vaccination is active. Protection is effective 4 weeks after the vaccination for about 4 years. There is a lifelong immunity after an infection (also asymptomatic).[8,22,31,43–46,48]

Measures of protections against mosquitoes are important for prophylaxis against SLE. It is recommended to stay away from water or in wet regions especially at night in high-risk areas (United States, Canada, Trinidad, Jamaica, Brazil), wear long clothes or saving clothes, use mosquito nets, fly screens, repellants, etc. Vaccination is not available.[4,5,9,28]

CONCLUSION

Tick–Born encephalitis, Japanese encephalitis, and St. Louis encephalitis are three species of encephalitis caused by Flaviviruses (Flavivirus diseases) transmitted by arthropod vectors such as mosquitoes or ticks.

Typical for these diseases are:

- Occurrence in regions with specific geographical distributions;
- Symptomatic, very different course of diseases, more severe in elderly people;
- Treatment is typically symptomatic; specific antiviral treatment with immunoglobulin only for TBE;
- Specific diagnosis mainly based on serological assays.[1,3,5,6,13,14,31,48–50]

Viral Hemorrhagic Fevers—Arenaviridae, Filoviridae, Bunyaviridae, and Flaviviridae

Christian Drosten
Bernhard-Nocht-Institute of Tropical Medicine, Hamburg, Germany

INTRODUCTION

With increasing international traveling activity, the importation of severe exotic viral diseases into non-endemic countries is becoming more and more likely. Terrorist attacks with highly pathogenic viruses are another scenario making diagnostic tools for these viruses more relevant than ever.

VIRAL HEMORRHAGIC FEVERS

The term ''viral hemorrhagic fever'' (VHF) describes a variety of viral diseases which are characterized by fever and bleeding in humans. This syndrome is caused by RNA viruses belonging to the families Filoviridae (Ebola virus and Marburg virus), Arenaviridae (Lassa virus, Junin virus, Machupo virus, Guanarito virus, and Sabia virus), Bunyaviridae [CCHF virus, Rift Valley fever (RVF) virus, and Hantaviruses], and Flaviviridae (yellow fever virus and dengue virus). After transmission from their reservoir host or vector to humans, these viruses cause an acute infection and there is no evidence of chronic courses.

The clinical symptoms in the early phase of a VHF are very similar irrespective of the causative virus and resemble a flu-like illness or a common enteritis. Headache, myalgia, gastrointestinal symptoms, and symptoms of the upper respiratory tract dominate the clinical picture. Hepatitis is also common. Therefore, especially in the early phase, virological testing is of utmost importance in diagnosis. The late phase of a VHF is more specific and characterized by organ manifestations and organ failure. Hemorrhage, the hallmark of a VHF, is present only in a fraction of patients depending on the virus species or even virus strain. Mild and subclinical courses seem to occur in all hemorrhagic fevers. However, if the disease is symptomatic, the case fatality ranges between 5% and 30%, but may be as high as 80% in Ebola fever.

With a few exceptions, currently, there exists no specific and effective therapy for VHF. The drug ribavirin is effective against Lassa virus and probably against CCHF virus. Vaccines have been developed against yellow fever virus,[1] Junin virus,[2] and RVF virus.[3]

Isolation of the virus in cell culture or laboratory animals, PCR, virus antigen detection, electron microscopy, and detection of specific antibodies in the serum of the patient are common methods for laboratory diagnosis of a VHF. According to the focus of this volume, this article addresses molecular diagnostic methods only. However, diagnosing a VHF always requires combined testing with more than one method.

This article reviews published VHF RT-PCR methods. Reported analytical sensitivities are compared against virus concentrations found in patients, and primers are reevaluated based on the latest GenBank entries by multiple sequence alignment (refer to table legends).

MOLECULAR DIAGNOSIS OF VIRAL HEMORRHAGIC FEVER—REVIEW OF PUBLISHED METHODS

Filoviruses

Ebola and Marburg viruses can be detected by Filoviridae-specific primers binding to the polymerase gene. These primers target sites that are highly conserved among the virus family[4] and were applied in PCRs of conventional and real-time format (Table 1, PCR 1–3). The glycoprotein gene of Ebola virus is used as a target to detect all four subtypes of Ebola virus (Zaire, Sudan, Ivory Coast, and Reston), but not Marburg virus (Table 1, PCR 4).[4] Furthermore, real-time PCRs in the glycoprotein gene for differentiating Zaire and Sudan strains, as well as for detecting Marburg virus, are available (Table 1, PCR 7 and 8).[7,8] PCR tests targeting the nucleoprotein gene detect and differentiate Ebola subtypes Zaire and Reston (Table 1, PCR 5 and 6). However, differentiation between filovirus species or subtypes is not required in the clinical situation.

Sensitivity studies have been mainly carried out using the polymerase gene-specific PCR. The clinical sensitivity of this PCR was 100% in two studies and thus higher than virus isolation or antigen capture assay.[4,5] Furthermore, even in patients with silent seroconversion, Ebola virus RNA can be detected in PBMC by a nested format of the

polymerase gene PCR.[9] The viral RNA concentration in a serum of a convalescent and an acute patient was 3×10^3-fold and 3×10^5-fold, respectively, above the detection limit of the real-time format of the polymerase gene PCR.[6] Taken the data on clinical and analytical sensitivity together, the polymerase gene PCR is a reliable tool to diagnose filovirus infections.

Bunyaviruses

CCHF virus is generally detected by RT-PCR targeting the S RNA segment which is best characterized among the three genomic segments (Table 2, PCR 1–3). However, the virus could be detected by PCR in only 2/3 of retrospectively (serologically) confirmed cases.[11] RNA concentration in serum was tested in one case of CCHF virus infection and found to be 7.7×10^5 copies/mL of plasma by real-time PCR,[6,16] which is about 3×10^2 times above the detection limit of that assay. According to the current data, PCR is a useful tool in diagnosing CCHF, but must be complemented by virus isolation and serology.

For detection of Rift Valley fever virus, assays targeting the M and S segment are available (Table 2, PCR 4–7). Quantitative real-time PCR has also been developed[6,15] but has not yet been applied to clinical samples. Only one clinical evaluation study has been conducted[13] showing a sensitivity of 70.6% (Table 2, PCR 5). All samples negative by PCR but positive by virus culture had detectable IgM, suggesting that a

Abbreviations: g/ag, genomic/antigenomic primer; p, probe; SB, Southern blot; FAM, 6-carboxyfluorescein; TX, 6-carboxytetramethylrodamine.

combination of IgM and PCR testing seems to be at least equivalent to virus isolation.[13]

Hantavirus infections causing renal syndrome are usually diagnosed serologically because the virus is rapidly cleared. Therefore, hantavirus PCR assays are not discussed here in detail.

Arenaviruses

All current diagnostic PCRs target the S RNA segment (Table 3). For some Lassa virus PCRs, clinical evaluation data are available showing 85% and 100% sensitivity (Table 3, PCR 1 and 3). These studies also demonstrate that virus is detectable beginning at least from day 3 of fever. Quantitative real-time PCR was established (Table 3, PCR 2) and used to monitor virus RNA concentrations during the course of disease in two cases of Lassa fever.[6,23] The RNA concentrations in serum of these patients were 5×10^2–2×10^6-fold above the detection limit of the assay. Extensive sequence information for the S RNA segment of Lassa virus has recently become available and reveals considerable genetic variability of the virus.[22,24,25] In light of these new sequences, some PCR primers, which had been designed mainly on the basis of isolates from Guinea, Sierra Leone, or Liberia, require revision (Table 3, PCR 3–6).

PCR assays are published for the New World arenavirus Junin (Table 3, PCR 7 and 8). Clinical sensitivity of the combination of the two different Junin PCRs was 98%.

A PCR predictably amplifying any member of the Arenaviridae has been developed by targeting the highly conserved termini of the S RNA segment.[22] Although this PCR amplifies the whole 3.4-kb S RNA, it was able to detect Lassa virus RNA in clinical samples. The L RNA segment of arenaviruses contains highly conserved

regions which are now being used to develop a PCR assay that is able to detect various Old World arenaviruses such as Lassa virus and lymphocytic choriomeningitis virus. In conclusion, suspected Lassa virus infections will be identified by PCR with high probability after day 3 of illness, but primers may fail because of the variability of the virus.

Flaviviruses

Yellow fever is usually detected using a universal flavivirus PCR (Table 4, PCR 1–8). Most of these universal assays target the NS5 which is highly conserved among the *Flavivirus* genus. Data on clinical sensitivity of these assays for yellow fever are largely lacking. Only few yellow fever virus-specific PCR tests have been published (Table 4, PCR 9–11). A quantitative real-time PCR specific for yellow fever virus exists, and in two cases, the viral RNA concentration in serum has been determined by this assay.[6,35] It was 2×10^2-fold and 1×10^3-fold above the PCR detection limit. Therefore, yellow fever may be reliably diagnosed by PCR, but virus isolation and serology must be performed in parallel.

Dengue hemorrhagic fever (DHF) is rare compared with dengue fever (DF) and is almost exclusively seen in endemic areas. The molecular diagnosis of dengue infection has been extensively reviewed elsewhere.[36,37] Noteworthy are recently developed real-time PCR assays, which either detect all dengue virus subtypes[6] or differentiate between the four subtypes.[38–40] Because dengue virus is rapidly cleared during infection, DF and DHF are usually diagnosed by detection of specific IgM (μ-capture EIA), which may be complemented by PCR and virus isolation. In a few imported cases of dengue

fever, the diagnosis was established by PCR before the development of specific IgM.

Apart from yellow fever and dengue virus, rare flaviviruses such as Kyasanur Forest virus or Alkhurma virus can cause a hemorrhagic fever.[41,42] Use of universal flavivirus PCRs is appropriate when these infections are suspected and typical VHF agents have been ruled out.

CONCLUSION

Improved amplification and detection technologies are beginning to improve the diagnostics of even very exotic viral infections. The sensitivity of many available methods can be assumed sufficient for the clinical setting, but more sequencing of virus strains is necessary to increase the reliability of molecular tests in the detection of rare variants. For the time being, molecular diagnostics can only complement classical methods such as virus culture, antigen testing, and antibody serology. The sensitive issue of diagnosing hemorrhagic fevers must be restricted to experienced laboratories equipped with biosafety level 4 facilities that allow handling of life virus.

von Hippel–Lindau Disease

V

Deborah J. Marsh
Diana E. Benn
Kolling Institute of Medical Research, University of Sydney, Sydney, Australia

INTRODUCTION

Von Hippel–Lindau disease (VHL; OMIM#193300) is one of the endocrine neoplasia syndromes characterized by loss of function germline *VHL* mutations that predispose specific hormone-secreting cell types to become neoplastic. The live birth incidence of this disease is in the range of 1 in 36,000 to 1 in 39,000.[1] Individuals affected with VHL develop both benign and malignant tumors, as well as cysts, in many organ systems. Given the multisystem nature of this disorder, a multidisciplinary treatment approach is required.

VHL (chromosomal location 3p26–p25) was identified in 1993 using positional cloning strategies,[2] and, subsequently, loss of the corresponding wild-type allele in affected tissue was reported, consistent with this gene having a tumor suppressor function.[3] Up to 50% of patients with germline *VHL* mutation develop only one feature of this disease; however, penetrance is believed to be approaching complete by 65 years of age (reviewed in Ref. [4]). Given its small size, consisting of only three exons encoding a 213-amino acid protein product, *VHL* is readily amenable for genetic scanning in at-risk or symptomatic individuals.

CLINICAL DESCRIPTION

Presentation

Patients with VHL are predisposed to develop tumors, predominantly retinal and central nervous system (brain and spinal cord) hemangioblastomas (HABs), clear cell renal cell carcinomas (CCRCCs), pheochromocytoma (PHEO), and, occasionally, extraadrenal paragangliomas (PGLs) (reviewed in Ref. [4]). Clear cell renal cell carcinomas are the major cause of morbidity. In addition, VHL patients may develop endolymphatic sac tumors, pancreatic islet cell tumors, papillary cystadenomas of the epididymus (males), or, occasionally, broad ligament (females) and visceral cysts of the kidneys and pancreas.

Phenotypic Expression—The Subtypes of VHL

Based on clinical expression, VHL disease has been divided into four subtypes. The majority of VHL kindreds are classified as VHL Type 1 families and manifest HABs (retinal and central nervous system), CCRCC, and other characteristic lesions but by definition, not PHEO. The presence of PHEO in association with Type 1 lesions indicates VHL Type 2 families (7–20% of all families), with a further subclassification of families as low (Type 2A) or high (Type 2B) risk for CCRCC, and Type 2C having PHEO only.[5]

Clinical Diagnostic Criteria for VHL

For patients with a family history, the occurrence of a central nervous system HAB, PHEO, or CCRCC or even multiple pancreatic cysts is indicative of VHL disease. For sporadic presentation, a diagnosis of VHL would be indicated by the presence of two or more retinal or central nervous system HABs and a characteristic visceral tumor. As epididymal or renal cysts occur frequently in the general population, they are not included as part of the diagnostic criteria. Sporadic presentation of retinal or central nervous system HAB, especially in a young patient, may also be an indication of VHL (reviewed in Ref. [1]).

Clinical Management of VHL

Clinical management of a patient with VHL requires comprehensive serial screening with regular follow-up as well as surgical intervention. Von Hippel–Lindau patients have a greater than 70% lifetime risk of CRCCs, which cause death of 15–50% of patients. Annual imaging [computed tomography (CT) and/or ultrasonography] is suggested, in addition to renal surgery. Once symptomatic, CCRCCs have already undergone metastasis and respond poorly to chemotherapy or radiotherapy. Surgical resection is also recommended for central nervous system HABs (located in the cerebellum, spine, and brain stem)

DOI: 10.1081/E-EDGP 120027617

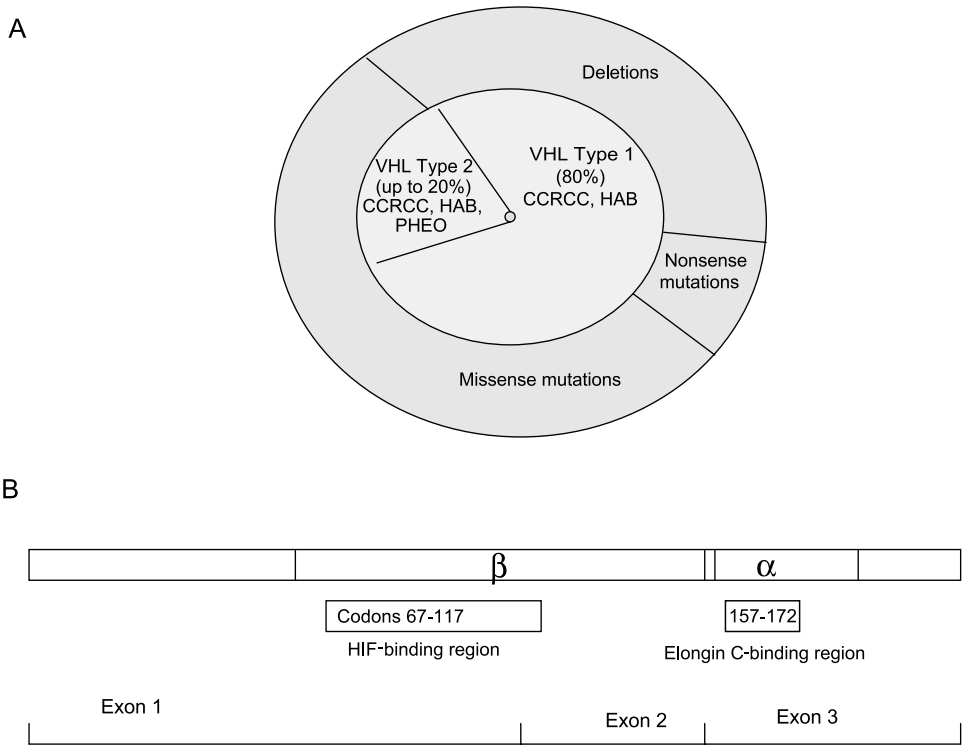

Fig. 1 A. Distribution of germline mutations in VHL Types 1 and 2. VHL Type 1 disease exhibits germline deletions (46%), nonsense mutations (10%), and missense mutations (40%), the latter frequently found in the β region of *VHL*. VHL Type 2 disease shows missense mutations (96%) and rarely deletions (4%). (Reviewed in Ref. [18].) B. Regions of VHL showing exon regions encoding the α and β domains, HIF-binding region (codons 67–117), and elongin C-binding domain (codons 157–172).

and PHEO. Unrecognized PHEO may cause hypertension at times such as surgery or pregnancy, due to sudden elevation in circulating catecholamines, leading to a life-threatening situation. Regular screening for PHEO, including urinary catecholamines, and imaging studies [ultrasonography, CT, or magnetic resonance imaging (MRI)] should be conducted. Given the early onset nature of PHEO in VHL, it has been recommended that screening begins at 5 years of age.[6]

Retinal angiomas are present in greater than half of patients with VHL. Regular opthalmological examinations from a young age are suggested as a preventative measure in VHL patients with the aim of avoiding retinal detachment and hemorrhage that may lead to blindness. Imaging techniques, such as CT or MRI, are suggested to assess for pancreatic cysts (if pancreatic islet tumors are identified, surgery is recommended) and endolymphatic sac tumors of the internal auditory canal that may lead to hearing loss.

Lifelong, regular surveillance is required to best manage the multiple and often recurrent tumors in VHL. Detailed review articles focusing on appropriate clinical management for VHL patients have been published.[1,7]

MOLECULAR DESCRIPTION

VHL—The Gene and Protein

The VHL gene is made up of 639 nucleotides, consisting of three exons that generate two mRNA species. The larger one of 4.6 kb corresponds to all three exons and generates a full-length 213-amino acid protein which is expressed in most tissues and has been implicated in a variety of functions including fibronectin matrix assembly, angiogenesis, and regulation of hypoxia-inducible genes.[8] The VHL gene product (pVHL) is a component of a ubiquitin ligase which targets the transcription factor hypoxia-inducible factor (HIF) subunits HIF-1α and HIF-2α for ubiquitination and proteolytic degradation in the presence of oxygen, by forming a ubiquitin–ligase complex with elongin B and C, as well as Cullin-2 and Rbx1 (reviewed in Ref. [9]).

There are two main domains of pVHL, the α helical domain interacting with elongin C, and the β domain where binding to HIF takes place. Generally, cells defective for pVHL (resulting from VHL inactivation) cannot degrade HIF-α subunits leading to the transcriptional activation of HIF target genes such as vascular

endothelial growth factor.[10] This is consistent with the angiogenic nature of VHL-associated tumors.

The role of pVHL in oxygen-sensing pathways and the highly vascularized nature of the tumors seen in VHL may, in the future, extend the clinical management options discussed above to include molecular drugs designed to inhibit HIF and/or its downstream targets. Early studies have suggested that these inhibitory drugs may work best in concert with other molecular drugs targeting cellular growth and survival pathways with the aim of achieving tumor regression and/or disease stabilization (reviewed in Ref. [11]).

Identified *VHL* Mutations

Over 160 different germline *VHL* mutations have been identified in over 500 kindreds worldwide and are recorded in the Human Gene Mutation Database (http://archive.uwcm.ac.uk/uwcm/mg/hgmd0.html). Mutations include missense and nonsense point mutations, microdeletions, microinsertions, splice site, complex rearrangements (including inversions), whole gene, and gross deletion.[12] Intragenic germline point mutations are spread across the coding sequence and exhibit two clusters, one at the 3′ end of exon 1 and the other at the 5′ end of exon 3, but no mutations have been identified in the first 53 codons.[13] Mutation ''hot spots'' are apparent at hypermutable sequences such as CpG dinucleotides.[14] Founder mutations have also been reported,[15] as well as germline mosaicism which is a factor to take into consideration when analyzing for apparently sporadic presentations of VHL.[16] Some index cases may in fact present de novo, with no known family history.

Genotype/Phenotype Correlations in VHL

The phenotypic expression of VHL disease can vary widely between families, and specific correlations of genotype and phenotype are now recognized. Von Hippel–Lindau Type 1 families typically have deletions (46%), missense (44%), and nonsense (10%) mutations (reviewed in Ref. [17]) (Fig. 1A). These missense mutations are frequently observed in the β-domain of pVHL and are predicted to lead to loss of function of pVHL by disrupting the protein's hydrophobic core (Fig. 1B). In particular, mutations in exon 2 cause loss of the ability of pVHL to shuttle between the nucleus and the cytoplasm, leading to loss of regulation of hypoxia-inducible genes.[18]

In general, the majority of kindreds with VHL Type 2B disease and virtually all Type 2A and 2C patients have missense mutations.[5] In Types 2A and 2B, either binding to elongin C (α domain of VHL) or the HIF-α binding site (VHL β domain) is affected by mutations, thus interrupting the degradation of the target proteins such as HIF-α in the proteosome (Fig. 1B). For Type 2C families with PHEO as the only expression of VHL disease, the missense mutations are generally clustered in the VHL α domain. It has been demonstrated that mutants such as L188V with an increased likelihood of PHEO-only phenotype can downregulate HIF but cannot promote fibronectin matrix assembly. This suggests that after pVHL inactivation abnormal fibronectin assembly may contribute to PHEO pathogenesis in VHL disease.[19]

Genetic Screening

Who should undergo genetic screening for VHL?

Presymptomatic, predictive mutation analysis is recommended for all at-risk members of a family with VHL, increasing the diagnostic power of the clinician. Given the direct benefit of early, appropriate clinical screening in this condition, knowledge of young mutation carriers and immediate instigation of a clinical management program may be integral to the prevention of malignant tumor development, loss of sight and hearing. As VHL is an autosomal dominant condition, the offspring of an affected parent have a 50% chance of inheriting a *VHL* mutation. If after predictive testing the at-risk family member is shown not to carry the *VHL* mutation present in the family, no additional genetic or clinical screening is required. A recent study of VHL patients' attitudes toward presymptomatic genetic diagnosis in children as well as prenatal genetic diagnosis reports a wide range of opinions, indicating that these areas remain controversial.[20]

It should be noted that approximately 50% of PHEO-only families with no other evidence of VHL disease may have germline *VHL* mutations. Other familial syndromes where PHEO may present as the sole phenotype include multiple endocrine neoplasia Type 2 (mutations in the *RET* protooncogene) and pheochromocytoma–paraganglioma syndrome [mutations in the succinate dehydrogenase (*SDH*) genes *SDHB*, *SDHC*, and *SDHD*, encoding three of the four subunits of mitochondrial complex II] (reviewed in Ref. [21]). In addition, *VHL* germline mutations in 3–11% of patients with apparently sporadic PHEO have been reported.[22]

Standard molecular techniques used for *VHL* mutation scanning

The heterogeneity of mutation type seen in VHL means that multiple molecular techniques are required to enable a complete mutation scan. Mutations have been identified in nearly 100% of VHL families using a combination of fluorescence in situ hybridization (FISH), Southern

blotting, and sequencing of the coding and flanking regions of *VHL*.[12]

dHPLC—Suitable for detecting a subset of *VHL* mutations

More recently, denaturing high-performance liquid chromatography (dHPLC) has been used as an alternative to sequence analysis for rapid scanning for mutations in *VHL*.[23,24] This technique makes use of mismatched heteroduplex formation due to the presence of a mutant and wild-type allele. Mismatched heteroduplexes, and mutant and wild-type homoduplexes, can be distinguished after elution from a chromatographic column at a predetermined temperature based on sequence-specific thermostabilities. Given that gross germline deletion of *VHL* and its flanking intervals have been reported in VHL (predominantly those with Type 1), it is important to recognize that standard dHPLC would not be a suitable screening tool for this subset as the presence of only one allele would preclude the formation of heteroduplexes.

CONCLUSION

Von Hippel–Lindau disease is a multisystem disorder requiring a multidisciplinary approach, with regular imaging and biochemical analyses required to monitor affected patients and identify disease in its early stages. Genetic screening to identify germline *VHL* mutations, enabling targeting of affected individuals for vigilant clinical surveillance, is an important component of the clinical management of at-risk members in VHL families. As our knowledge of pVHL and the molecular pathways in which it functions increases, future treatment options in the form of molecular target drugs may provide an alternative, or an adjunct, to the surgical intervention offered today for tumors such as PHEOs and CCRCC, the latter of which is the greatest cause of mortality in VHL.

Online information specifically for the VHL patient is available at: http://www.vhl.org. Detailed reviews recommended for further reading on this subject include Maher and Eng,[13] Lonser and colleagues,[7] and Bryant and colleagues.[9]

von Willebrand Disease

M. Said Enayat
The Birmingham Children's Hospital NHS Trust, Birmingham, U.K.

INTRODUCTION

In 1926, Eric von Willebrand described a bleeding diathesis in a series of families from Äland Islands in Finland, that although resembling hemophilia bleedings the patients have also shown platelet function abnormalities. Referred to this condition as ''pseudohemophilia,'' he clearly identified a different pattern of autosomal inheritance with varying degree of the penetrance. The pathophysiology of this disorder has been clarified during the past 40 years when it was noted the difference in bleeding tendencies between factor VIII deficiency hemophilia and von Willebrand disease (VWD) which is caused by deficiency of another clotting protein, namely, the ''von Willebrand Factor or VWF.'' In 1985, VWF cDNA was cloned, allowing major advances in the molecular genetics of VWD, and, subsequently, its structure was deduced from the cDNA and confirmed by direct amino acid sequence analysis. Von Willebrand disease is a common autosomally inherited bleeding disorder with variable clinical presentation. Von Willebrand disease is due to quantitative or qualitative abnormalities of VWF and its gene is encoded on chromosome 12.[1]

von Willebrand factor is a large, multimeric glycoprotein ($10–20 \times 10^6$ kDa) circulating in blood plasma, platelet α-granules, and subendothelial connective tissue, and secreted by the vascular endothelial cells and bone marrow megakaryocytes.[2] von Willebrand factor has two essential hemostatic functions: mediating platelet adhesion to subendothelial connective tissue and carrying FVIII in blood circulation, essential for normal FVIII survival.[3]

von Willebrand factor gene is located at the short arm of the human chromosome 12 (12p13.2), contains 52 exons, and spans about 180 kb. The structure of VWF gene, pseudogene, the protein, and its specific functional domains are summarized in Fig. 1. Exon 28 is the largest exon with 1379 bases, encoding for A1 and A2 domains. A VWF pseudogene has been localized on chromosome 22q11–13, spanning 21–29 kb and corresponds to exons 23–34 of VWF gene. The VWF cDNA encodes a primary translocation product of 2813 amino acid residues. Von Willebrand factor precursor contains 22 amino acids signal peptide, a large propeptide of 741 amino acids and a mature subunit of 2050 amino acids.[4] Amino acid residues of VWF are numbered from the signal peptide, which would be from 1 to 2813. The VWF subunit is extensively glycosylated with 12 N-linked and 10 O-linked oligosaccharides. The N-linked oligosaccharides of VWF have the unusual property of having ABO blood group determinants and this has implication in the level of VWF concentration. Following translation of a $\sim$9-kb mRNA, removal of the signal peptide, and initial glycosylation, the monomeric subunits of VWF with a molecular weight of approximately 250 kDa form dimers in the endoplasmic reticulum. In the endothelial cells, after further posttransitional modification in the Golgi apparatus, large VWF multimers are either constitutively secreted in the circulation or stored in Weible–Palade bodies[5] which release their stored VWF molecules after stimulation by a variety of stimuli, including vasopressin analog (DDAVP) treatment. Various binding functions of VWF are localized to different domains of this molecules including binding to platelet glycoprotein Ib (GP1b), ristocetin, botrocetin, heparin, sulfatides, and minor binding sites for collagen types I and III.[6]

MOLECULAR DIVERSITY OF VWD

von Willebrand disease is an extremely heterogeneous disorder, and results from phenotypic and genotypic tests form the basis of the diagnosis and classification of different types of VWD. The numerous variants of VWD generally fit in the original classification of either type I (partial) and III (total) reduction or type II with qualitative defect of VWF. Multimeric analysis of von Willebrand antigen (VWF:Ag) by SDS-gel agarose gel electrophoresis[7] results in identification of many different type II variants that have minor structural differences. The latest classification of VWD, however, reduced the total number of type 2 to four variants of 2A, 2B, 2M, and 2N on the basis of their structure/function (Table 1).[8] As type 1 VWD is now considered to be purely quantitative disorders, some previously designated variants have now been reclassified as type 2, e.g., type 2M (Table 1). The molecular basis of these six new subtypes with clear pathophysiological mechanisms has now been further defined with identification mutations in some of these

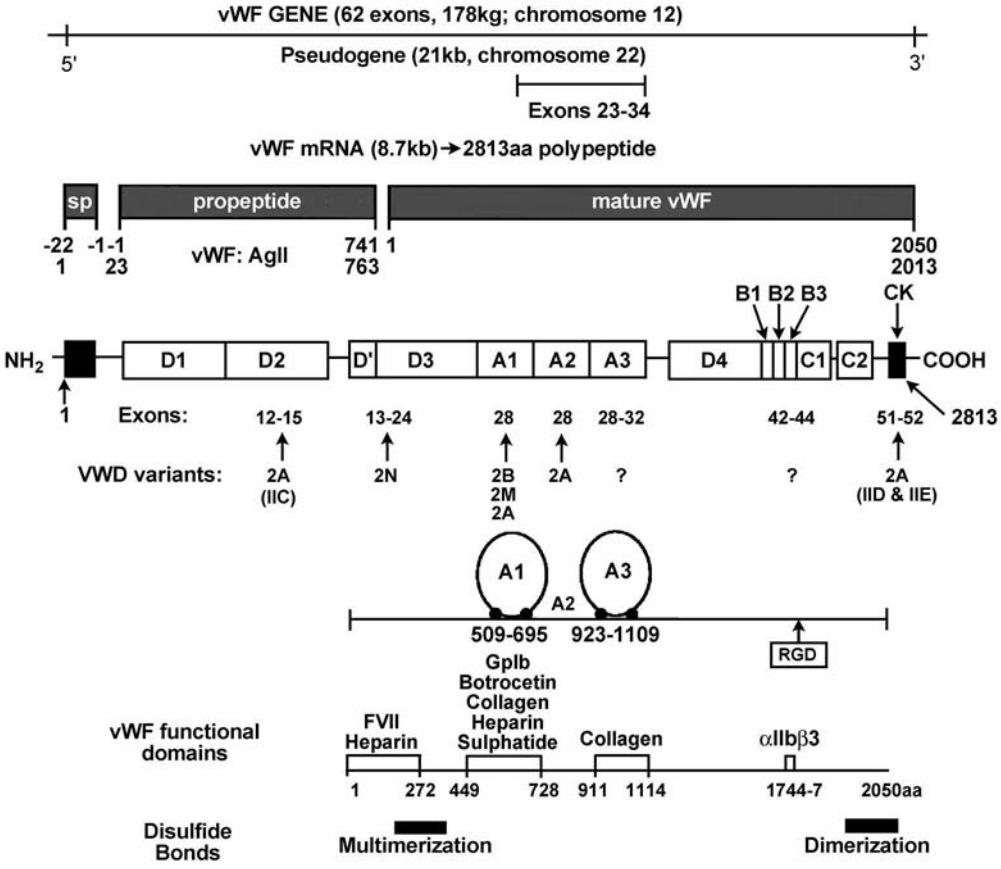

Fig. 1 Schematic presentation of the human VWF gene, pseudogene, mRNA, and protein. Numbers below the boxes representing signal peptide (sp), propeptide, and mature VWF in the upper row (in red) are that of mature VWF amino acid numbers and below them are the amino acid numbers from the ATG initiation codon (residue 1) to the carboxy-terminal lysine (residue 2813) of the pre-pro-VWF (in blue). The lettered boxes denote the series of the repeated homologous segments. The approximate localization for known VWF functional domains within the mature VWF sequence is indicated below. The general location of mutations associated with the most common type 2 variants of VWD is depicted below the domain structure of VWD together with the associated exons. (*View this art in color at www.dekker.com.*)

defects. A database of VWD lists all the point mutations, insertions, and deletions identified in this type. This site (http://www.shef.ac.uk/vwf), which has been created on behalf of the ISTH VWF Scientific and Standardization Committee, is maintained by Sheffield University and contains up-to-date information on the latest mutations and polymorphisms in *VWF* gene. In the recent 2003 XIX Congress of the International Society on Thrombosis and Hemostasis in Birmingham, United Kingdom, several presentations emphasized the need for a new classification of VWD based on molecular diagnosis and improved multimeric analysis of VWF. With so many unclassifiable patients with type 1 VWD group, it has now been suggested that such an improved multimeric method would help in future classification of these patients.

Type 1 VWD patients have reduced VWF:Ag level with normal multimer composition (Fig. 2). This is the commonest VWD type, accounting for about 70% of the clinical cases, with patients having mild to moderate bleeding. It has dominant mode of transmission with incomplete penetrance of approximately 60%. While lowering of VWF:Ag could be the result of a mutation in VWF gene, additional variations such as ABO blood group, race, and age complicate the diagnosis of this type of VWD. A broad range of VWF levels suggests several distinct molecular mechanisms could be responsible for this type of VWD, and in many affected families possession of a single mutant allele does not consistently cause symptoms, with some patients being asymptomatic and only transmitter of the disease. In some other families, exceptionally lowered VWF levels and with dominant inheritance trait and very high penetrance may be caused by dominant-negative missense mutations that impair the intracellular transport and secretion of normal VWF

Table 1 Previous and revised classification of VWD

Revised classification of VWD	Previous classification
Type 1 VWD Partial quantitative deficiency of VWF	Type I, I ''platelet normal,'' I ''platelet low'' IA, I-1, I-2, I-3
Type 3 VWD Virtually complete deficiency of VWF	Type III
Type 2 VWD Qualitative abnormalities of VWF	
Type 2A Qualitative variants with decreased platelet-dependent function that is associated with absence of high molecular weight multimers	Type IIA, B, C, D, E, F, G, H, I and I ''platelet discordant''
Type 2B Qualitative variants with increased affinity for platelet GP1b	Type IIB, I New York, I Malmö, I Sydney
Type 2M Qualitative variants with decreased platelet-dependent function not caused by the absence of high molecular weight multimers	Type B, IC, ID, Vincenza
Type 2N Qualitative variants with markedly decreased affinity for factor VIII	Normandy

subunits. Presently, a European study into molecular and clinical markers for diagnosis and management of type 1 VWD has been reporting large number of mutations associated with this type of VWD.[9]

Severe type 3 VWD has autosomal recessive inheritance with a prevalence of about one per million. Molecular analysis of this type has been more difficult, with no possibility of targeting for mutation detection. Reported

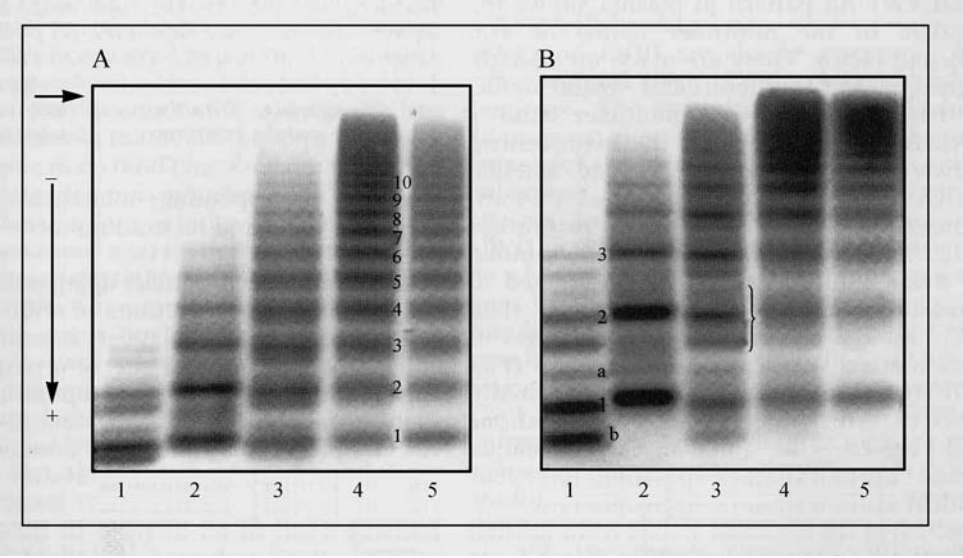

Fig. 2 VWF:Ag multimer patterns in normal and different types of VWD plasma. The plasma samples were electrophoresed in 1.2% (panel A) and 1.8% (panel B) agarose gel with sodium dodecyl sulphate, and the bands were visualized by 125I-labeled anti-VWF monoclonal antibody followed by autoradiography. Lane 1 is a type IIA phenotype; lane 2, IID phenotype; lane 3, type 2B; lane 4, normal; and lane 5, type 1 VWD plasma. The triplet structure of multimer band is demonstrated in lane 3 (panel B). The minor satellite bands ''a'' and ''b'' can be best seen in the band 1 of plasma from phenotype IIA VWD in lane 1. Arrow at the top of the gel points to the line between the stacking and separating gels. Direction of electrophoresis is from top to the bottom.

mutations for type 3 VWD are either homozygous or compound heterozygous, and although total or partial VWF deletions have been reported, this is uncommon. A large number of nonsense, frame shift, or missense mutations that predict the loss of VWF protein expression, or a markedly truncated or disrupted protein, have been identified.[10,11] Multiple substitutions in the VWF gene that mimic the pseudogene sequences have also been reported to cause type 1 and 3 VWD.[12] Haplotyping with a large battery of RFLPs including a highly polymorphic tetranucleotide repeat in intron 40 in families with type 1 and 3 VWD can have an important role in determining the inheritance of disease in these families.[13] Gene tracking of the affected allele can be used to identify the transmitters or the asymptomatic carriers of VWD, and this methodology has been found to be an essential initial step in studying such families prior to more comprehensive investigations and mutation detection.[14]

In the latest classification of the VWD, type 2 variants with qualitative abnormalities of VWF are divided into four groups of 2A, 2B, 2M, and 2N (Table 1). They are classified on the bases of phenotypic data and functional assays. These categories have distinct pathophysiological mechanisms, and their reported mutations are located in specific functional regions of the VWF gene. Each group has distinct clinical features and with specific therapeutic need. FVIII:C and VWF:Ag concentration, together with multimer distribution, ristocetin-induced platelet aggregation, and FVIII binding assay are the minimum phenotypic assays, which are needed for these classifications. Type 2A VWD patients have decreased platelet-dependent function with selective absence of high and intermediate molecular weight multimers (Fig. 2). Both recessive and dominant mode of inheritance have been reported; however, dominant inheritance accounts for the majority of cases. The reported mutations are all single-base substitutions with five in the A1 domain, and the rest in the A2 domain. However, mutations for some of the type 2A phenotypes that are now classified in this group (formally designated as type IIC, IID, and IIE VWD; Table 1) are located in other regions of VWF gene. Most of the point mutations for type 2A VWD were identified in exon 28 where VWF pseudogene is also located. Using allele-specific PCR strategies for amplification of this exon circumvents this problem.[15] Arg1597Try mutation accounts for about 1/3 of type 2A VWD patients. The mechanisms for these mutations can be divided into two categories.[16] Group 1 mutation is the result of improper folding of the VWF multimers, resulting in impairment of the assembly, storage, and retention in the endoplasmic reticulum, both in the plasma and in the platelet compartments. In group 2, the mutations do not interfere with VWF assembly or secretion, but they do render normal VWF multimers more susceptible to a specific VWF cleaving metalloproteinase or ADAMST13 present in the plasma.[17] ADAMST13 cleaves normal VWF multimer between the proteolytic site Tyr1605 and Met1606, and generates a 176-kDa fragment localized to the C-terminus, and a 140-kDa to the N-terminus of the mature VWF.[18]

In the very rare recessive IIC, IID, and IIE phenotypes, several missense, small insertions, or deletion mutations have been reported in the D2 domain. The common pathophysiological mechanism involved in all of these VWD type 2 A mutations is the absence of high molecular weight multimers and, consequently, the reduction in in vivo VWF-dependent platelet adhesion.

Type 2B VWD is characterized by increased affinity of the mutant VWF for platelet and reduction in high molecular weight multimers (Fig. 2). The remaining VWF multimers are not hemostatically effective and cause bleeding and thrombocytopenia in the patients that can be exacerbated during physical exercise, stress, and pregnancy. This defect is identified in the laboratory by enhanced ristocetin-induced platelet aggregation. Type 2B is inherited as an autosomal dominant and accounts for less than 20% of all type 2 VWD. Aside from a single amino acid insertion, the genetic defect is generally found to be a point mutation in the A1 domain of VWF gene that contains the glycoprotein Ib (GpIb) binding domain and results in a gain of function. The most frequent mutations are Arg1306Trp, Arg1308Trp, Val1316Met, and Arg1314Gln accounting for $\sim$90% of the subtype.

Type 2M variants are characterized by decreased platelet-dependent function not caused and associated with loss of high molecular weight multimers, and their phenotype can be caused by mutations that inactivate specific binding sites for the ligands in connective tissue or on the platelet surface, without affecting multimer assembly or stability. Most of these variants were previously grouped with type I VWD, including type B with absent ristocetin—but normal botrocetin-cofactor activity and normal multimers and ''Vincenza'' variant where unusually ultrahigh molecular weight multimers are present.[19] In the past few years, mutations have been identified and are now listed in the database. Some of these mutations, including Ala1374Cys and Ala1374His, have been confirmed by mutation recombinant VWF studies. A type 2M ''Vincenza'' mutation, heterozygous Arg1205His, is the latest to be reported for type 2M VWD identified in all of the affected members of seven Italian families and in one German patient.[20]

Type 2N VWD or ''Normandy VWD'' results from defective binding ability of VWF with FVIII, and these patients show disproportionately reduced levels of FVIII and normal VWF multimers.[21] As a result of description of this type of VWD, FVIII binding assay should be the differential diagnosis test for patients with mild to

moderate hemophilia A. In fact, it is possible that some previously reported apparent female hemophilia cases with unusual inheritance pattern may have been due to this type of VWD. These ambiguities can now be clarified by FVIII binding assay. Type 2N VWD mutations are all clustered in the N-terminal region (D′ and D3 domains, from exon 13 to 24) of the VWF gene, which contains the FVIII binding site (Fig. 1). Apart from one deletion, all of them are single-base substitutions. Type 2N VWD patients are generally homozygous or compound heterozygous for one or more of these mutations. The most frequently reported mutation is Arg854Gln and, along with most of the others, does not result in complete disruption of FVIII binding to VWF. Even in homozygous patients, a residual level of binding can be demonstrated and is only slightly reduced in the heterozygous state. Combination of a type 2N Cys788Arg mutation, together with another (Cys1225Gly in pre-pro VWF), can also cause a mixed phenotype associated with both mutations. This type has been classified as combined type 1 and type 2N VWD.[22] Other combinations of type 2N mutation on one allele and a frame shift mutation on the other VWF allele have also been reported.[23]

CONCLUSION

Since the initial description of VWD in 1926, we now have a better understanding of molecular biology, genetic abnormalities, and pathophysiology of this disorder. Treatment for the severely affected patients and carrier detection in these families has also been achieved. But with clarification of the molecular genetics and identifications of the mutational basis of this disease, together with insight into structure–function relationship of VWF molecule, future efforts should now be directed toward more definitive diagnostic methods, classification, and novel treatments of this common human bleeding disorder.

Wilson Disease

Juliane Halangk
Hartmut Schmidt
Heiko Witt
Charité, Berlin, Germany

HISTORICAL INTRODUCTION

Wilson disease, also referred to as hepatolenticular degeneration, was first described in 1912 by Samuel A. Kinnier Wilson as a familial progressive disorder of the central nervous system accompanied by liver cirrhosis, and by Bruno Fleischer as a ''pseudosclerosis'' with tremor, liver cirrhosis, and corneal deposits.[1,2] One year later, Rumpel demonstrated an excessive hepatic copper accumulation in Wilson disease.[3] This finding was confirmed by Lüthy, who also detected an elevated copper concentration in the basal ganglia.[4] An autosomal recessive inheritance pattern was shown by Bearn,[5] and in 1993 the disease-causing gene was identified as a metal-transporting P-type ATPase designated *ATP7B*.[6–8]

CLINICAL PRESENTATION

Wilson disease is a protean disorder with a broad clinical spectrum owing to the toxic effect of copper on the various organ systems. The disorder occurs worldwide with an estimated prevalence in Caucasians of approximately 1 per 30,000 to 1 per 100,000 live births and a carrier frequency of about 1 per 90 to 1 per 150.

Most patients with Wilson disease present between 5 and 35 years of age. However, Wilson disease should be included in the differential diagnosis in individuals with liver disease of uncertain cause even if they are younger or older. Clinical presentation of liver disease varies from acute fulminant liver failure requiring transplantation to chronic liver disease with cirrhosis and its complications, such as portal hypertension, esophageal varices, and hypersplenism, but also solely steatosis may occur.

Neurological manifestations of Wilson disease typically develop later in life, most often in the third decade, but may also occur in children. The spectrum of symptoms range widely from discrete tremor, dysarthria, and lack of motor coordination to severe pseudobulbar palsy. Because of affection of the basal ganglia clinical signs of Parkinson disease such as micrographia, hypersalivation, hypomimia, and rigid dystonia may occur. Psychiatric manifestations include behavioral changes and deterioration of performance at school or at work. Major depression, anxiety, or frank psychosis are further presentations. Many of those patients with neurological or psychiatric symptoms have liver disease, but not all of them display hepatic symptoms.

Kayser–Fleischer rings are characteristic although not mandatory findings in Wilson disease, representing deposits of copper in the Descemet's membrane of the peripheral cornea. They appear as a band of golden-brownish pigment when visible by direct inspection. However, in most cases, slit-lamp examination by a skilled examiner is required. Other ophthalmological changes such as sunflower cataracts representing copper deposition in the lens might be revealed. These clinical observations are of diagnostic value, but do not obstruct vision. Nonetheless, Kayser–Fleischer rings are not entirely specific for Wilson disease and are also observed in patients with chronic cholestatic diseases.[9] Kayser–Fleischer rings typically develop later in the course of the disease, are rare in childhood, and are mostly although not necessarily detectable in patients with neurological manifestations, but in only about 55% of patients presenting initially with liver disease.[10]

In some patients, Coombs-negative hemolytic anemia is the first clinical disease manifestation. Other rare extrahepatic manifestations of Wilson disease may include renal tubular abnormalities, arthralgias, cardiomyopathies and arrhythmia, amenorrhea, or repeated miscarriages (reviewed in Ref. [11]).

MOLECULAR GENETICS

Copper is absorbed in the small intestine and enters the liver via the portal vein. In the liver, copper is incorporated into ceruloplasmin or copper-containing enzymes and excess copper is secreted into the bile. The precise intracellular target for the toxic action of copper is unknown. Copper is potentially toxic because of its ability to promote free radical formation. Lipid peroxidation of membranes and organelles as well as modification of mitochondrial DNA and alterations of protein synthesis are described in patients with Wilson disease.

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020662

The Wilson disease gene, ATP7B, encodes a P-type ATPase that acts as a membrane copper-transport protein. In hepatocytes, ATP7B is located in the trans-Golgi apparatus where it functions to incorporate copper into ceruloplasmin and to excrete copper into the bile.[12,13] Although the genetic defect in Wilson disease resides primarily in the liver, ATP7B is also expressed in a variety of other tissues including kidneys, brain, heart, muscle, and pancreas.

Human *ATP7B* is approximately 50 kb, has 21 exons, and is located on the long arm of chromosome 13 (13q14.3–q21.1). The gene product consists of 1465 amino acids. It forms eight transmembrane domains with most of the protein residing on the cytoplasmic side. In addition to the characteristics of all P-type ATPases such as the ATP-binding site, the phosphatase domain, and the motif containing aspartyl phosphate, ATP7B contains six N-terminal copper-binding motifs.

DIAGNOSING WILSON DISEASE: A HIGH INDEX OF SUSPICION

Diagnosis of Wilson disease is particularly challenging: no single laboratory test or clinical finding exists to establish or rule out definitive diagnosis. Early diagnosis, however, is crucial, as timely therapy may maintain normal life expectancy. If Wilson disease is suspected, the complete diagnostic battery of physical examinations and laboratory tests including liver biopsy with measurement of hepatic copper content has to be performed. Neither normal serum ceruloplasmin, urinary copper levels, nor absent Kayser–Fleischer rings exclude the disease.

Ceruloplasmin serum levels less than 20 mg/dL are suspect for Wilson disease, although normal concentrations are seen in 5–25% of patients; moreover, 10–30% of heterozygous carriers display lowered ceruloplasmin levels. Decreased ceruloplasmin is also observed in patients with chronic liver disease of other etiology[14] and can be absent in cases of aceruloplasminemia.

Reduced serum copper concentrations below 60 μg/dL may be found in Wilson disease. However, most patients show normal copper levels and up to one third of heterozygous carriers exhibit decreased serum copper.[10] In contrast, the determination of serum free copper reveals increased concentrations in Wilson disease.

Measurement of 24-hr urinary copper excretion represents a valuable diagnostic test. Individuals who excrete >100 μg (>1.6 μmol) in 24 hr are suspect for Wilson disease. Various chronic liver diseases and especially cholestatic diseases, however, might also increase urinary copper.[15] In addition, urinary copper excretion after D-penicillamine challenge should be measured in suspected Wilson disease. Urinary copper excretion is a useful marker in monitoring pharmacotherapy and compliance.

Liver biopsy with determination of hepatic copper content is the most valuable single diagnostic procedure. Liver copper >250 μg/g dry weight is highly suggestive for Wilson disease, but may be also found in cholestatic diseases and in idiopathic copper toxicosis. The major shortcoming of a single liver biopsy specimen is underestimation of hepatic copper because of inhomogeneous copper deposition in the liver. Detection of copper in histological specimens by special staining methods such as rhodamine or orcein staining depends on its intracellular localization and is therefore insensitive and rarely helpful in establishing diagnosis. The histological findings in Wilson disease may resemble the features of various other liver disorders such as autoimmune hepatitis or nonalcoholic steatohepatitis.

Neuropsychiatric examination is required in every patient with Wilson disease and magnetic resonance imaging (MRI) should be performed in patients presenting with neurological manifestations.

MANAGEMENT

In all patients with Wilson disease, whether symptomatic or not, consequently implemented treatment is obligatory for maintaining normal life expectancy. The aim of therapy is the elimination of excess body copper and prevention of copper reaccumulation. Treatment should be initiated as soon as the diagnosis is established, and the mainstay remains lifelong pharmacotherapy.[11] Cessation of therapy leads to progression of disease and can even cause acute fulminant liver failure. Thus, the patient's compliance is essential and should be monitored as well as potential side effects of medication.

Chelating agents such as D-penicillamine promote urinary excretion of excess copper. In the initial phase of therapy, penicillamine is usually administered in doses of 1000–1500 mg/day in two divided dosages. Maintenance therapy can be started when 24-hr urinary copper excretion is less than 500 μg. Maintenance dose is usually 750–1000 mg/day administered in two divided dosages. In pediatric patients, 15–25 mg D-penicillamine per kilogram body weight should be administered in two divided dosages. Food inhibits absorption of penicillamine; thus the drug should be taken 1 hr before or 2 hr after meals. D-Penicillamine antagonizes the effect of pyridoxine and daily supplementation with 25 mg is recommended. D-Penicillamine therapy has to be discontinued in 20–30% because of severe side effects including fever, rash, lymphadenopathy, neutropenia, thrombocytopenia, lupuslike symptoms, nephrotoxicity, Goodpasture syndrome, myasthenia gravis, and polymyositis. It is

crucial to realize that these side effects can occur even years after starting initial therapy. Worsening of neurological symptoms has been reported in some patients treated with D-penicillamine.

Trientine (triethylene tetramine dihydrochloride) is an alternative, rather expensive chelator with fewer side effects. Trientine is given at an average daily dose of 750–1500 mg as two to three divided dosages (in children, 15–20 mg/kg body weight). Side effects include iron deficiency anemia because of its chelating action requiring iron supplementation.

Zinc salts have few side effects, and three daily dosages of 100 mg ingested before meals are effective in maintenance therapy (in children, 3–4 mg/kg body weight). Zinc interferes with copper absorption in the gastrointestinal tract and induces intestinal metallothioneins, which act as endogenous chelators. Zinc salts can be combined with D-penicillamine or trientine. Because of interactions, chelating agents should be administered with some hours delay and not simultaneously with zinc.

Ancillary to pharmacological treatment dietary copper restriction is recommended, but its therapeutic value remains to be determined.

In patients with fulminant hepatic failure or decompensation of chronic liver disease liver transplantation is required. The molecular defect in Wilson disease is cured by a liver graft and no specific therapy in respect to Wilson disease is necessary after transplantation. The neurological course of disease after transplantation is currently under investigation.

GENETIC TESTING

The discovery of the underlying genetic defect in Wilson disease raised the hope of overcoming the obstacles in diagnosing the disease. Genetic testing in Wilson disease, however, is complicated by the fact that most patients are compound heterozygous with different mutations on each allele. More than 300 *ATP7B* mutations spread over the entire coding sequence have been described and are listed in a database that can be downloaded at http://www.uofa-medical-genetics.org. The most frequent *ATP7B* mutation found in Caucasians is a histidine by glutamine exchange at codon 1069 (H1069Q) in exon 14, which is found in 10% to 70% of Wilson's disease chromosomes.[16] It is proposed that the H1069Q mutation results in an increased degradation of mutated protein within the endoplasmic reticulum.[17] Another frequent mutation in Caucasians represent 3402delC, whereas the most frequent mutation in Asia is R778L.[18]

The large number of mutations and the high prevalence of compound heterozygotes hamper genotype–phenotype correlation analysis. In a homogeneous population from Saxonia, Germany, H1069Q was found in 87% of patients. Homozygosity for H1069Q was shown to be associated with later onset of disease, predominance of neurological symptoms, and milder hepatic disease compared to compound heterozygotes or carriers of other mutations.[16] This correlation has also been established in several other populations.[19,20] However, conflicting results have been obtained by others.[21] Genotype–phenotype correlation of other mutations is rendered difficult by their low frequency and the different ethnic backgrounds of the populations studied. The phenotypic appearance of a certain genotype is most probably influenced by a variety of genetic, epigenetic, and environmental factors that remain to be elucidated.

Genetic testing in Wilson disease is possible in affected index patients and indicated in patients in which the clinical presentation and the laboratory tests do not allow a definite diagnosis. Genetic testing is also indicated to identify asymptomatic relatives. It has to be pointed out that a negative genetic test result does not exclude Wilson disease in a suspected case.

Several methods have been described for mutation detection in Wilson disease. In areas where a specific mutation is common, such as H1069Q in Central Europe, genotyping using restriction fragment length polymorphism (RFLP) analysis or melting curve analysis with fluorescence resonance energy transfer (FRET) probes is feasible.[22]

For screening further mutations, single-strand conformation polymorphism (SSCP) analysis represents an alternative approach. However, sensitivity of SSCP is low with a detection rate of only 50–60%, and homozygous individuals may be missed by this method because of absent heteroduplex generation. Moreover, *ATP7B* contains numerous harmless polymorphisms that cannot be discriminated from disease-causing mutations by an altered SSCP mobility pattern.

Direct DNA sequencing with a sensitivity of 65–85% is available in specialized laboratories, but is time-consuming and cost-intensive.

Predictive genetic testing of family members is possible and can be generally recommended. Screening of sibs is especially mandatory, as each sib possesses a one in four chance of being affected. If the underlying mutations are unknown, haplotype analysis using microsatellite markers (*D13S314*, *D13S301*, *D13S316*) or intragenic SNPs is alternatively feasible to detect asymptomatic sibs. The risk for offspring of an affected patient is approximately 1 per 180, assuming a carrier frequency

of 1 per 90. This risk, however, is markedly higher in consanguineous families.

Although prenatal testing is principally feasible, Wilson disease is in our opinion no indication for prenatal diagnosis and induced abortion because treatment started in asymptomatic individuals after birth allows a normal life span.

CONCLUSION

Wilson disease should be considered in patients with uncertain signs of hepatic, neurological, or psychiatric disease. Ocular slit-lamp examination as well as measurement of serum ceruloplasmin, urinary copper excretion before and after D-penicillamine challenge, and liver biopsy with determination of the hepatic copper content are required. It has to be pointed out that Wilson disease is a diagnostic challenge because of the variety of clinical presentations and laboratory findings. Genetic analysis is rendered difficult by a high number of different mutations in distinct regions of the *ATP7B* gene and the high prevalence of compound heterozygotes. Genetic testing is indicated in patients in which the clinical presentation and the laboratory tests do not allow a definite diagnosis. A negative genetic test result does not rule out Wilson disease. Family screening of first-grade relatives should be done to detect asymptomatic cases. Early therapy with chelators or zinc is lifesaving and has to be continued lifelong. Special attention has to be directed to therapy compliance and occurring side effects. Liver transplantation is necessary in decompensated liver disease, but its utility in neurological disease is controversial.

Wolff–Parkinson–White Syndrome, Familial

W

Robert Roberts
Baylor College of Medicine, Houston, Texas, U.S.A.

INTRODUCTION

Wolff–Parkinson–White (WPW) syndrome was described as a clinical entity in 1930 by the individuals whose name it bears.[1] It had been postulated the genesis of the WPW syndrome was due to an accessory pathway bypassing the AV node from the atria to the ventricle. This was subsequently confirmed by electrical cardiac mapping and this technique is now used routinely to identify and ablate the accessory pathway.[2] Wolff–Parkinson–White syndrome is the second most common cause of paroxysmal supraventricular tachycardia in the western world, and in Asian countries such as China it is the number one cause.[3] It became a model for reentry tachycardia. Thus WPW has become the intrigue of the electrophysiologist both as a mechanism for tachycardias as well as a disease that has a specific treatment.

CLINICAL DESCRIPTION

The most common presenting complaint is palpitations and/or a sense of a rapid heart rate followed by presyncope, syncope, or sudden cardiac death (SCD). Sometimes, the only feature is sudden death, which can occur without warning, usually in the setting of atrial fibrillation with a rapid ventricular response. It is also very common for WPW to be discovered as an incidental finding without symptoms on the electrocardiogram due to a routine medical checkup. The incidence of the disease increases with age. It is claimed that about 50% will be symptomatic due to associated supraventricular tachycardia. However, it should be emphasized that WPW may occur in infancy as a cause of SCD more commonly than is generally recognized. At this age electrocardiograms are frequently not performed and it would be rare at postmortem to examine the conduction system. In a recent study of SCD in the young in which pathology studies were performed and electrocardiograms were obtained, WPW exceeded that of familial hypertrophic cardiomyopathy as a cause of SCD. There is also the concern that WPW may play a role in the so-called sudden infant death although this is more commonly associated with Brugada syndrome or long QT syndrome.

It is reasonable to expect that all WPW is genetic in origin. The percentage of cases due to familial vs. sporadic remains unknown. Only one gene has yet been identified and based on our studies[4] in other families with WPW it is evident there are several other genes responsible for this syndrome. The familial form of WPW caused by the gene PRKAG2 has other clinical features, which distinguish it from the more common form of WPW. In addition to having the WPW syndrome and supraventricular tachycardias, it is often associated with hypertrophic cardiomyopathy and conduction defects. In routine WPW syndrome, atrial fibrillation is said to occur in about 20–30% of cases, whereas in the syndrome due to PRKAG2 it is more frequently occurring in up to 50% of cases.

GENETICS

It should be emphasized that all forms of WPW syndrome are likely due to genetic defects. Most cases with the WPW syndrome have an accessory pathway without conduction defects or hypertrophy. The form of WPW due to the PRKAG2 gene is inherited in an autosomal dominant pattern. The PRKAG2 gene located on chromosome 7q36 encodes the gamma 2 subunit of AMP-activated protein kinase (AMPK). AMP-activated protein kinase consists of three subunits, alpha, beta, and gamma, with each subunit encoded by a distinct gene.[5] The alpha subunit is the catalytic component, and the beta and gamma are regulatory units. The gamma subunit has the binding site for AMP which is essential for enzymatic activity. AMP-activated protein kinase is present in all tissues although there may be tissue specificity on the basis of isoforms present within the heterotrimeric enzyme. There are three isoforms of the beta and three isoforms of the gamma which are derived from alternate transcripts of the same gene. The genetic defect consists of mutations in the PRKAG2 gene which encodes for the gamma subunit. The initial mutation was a substitution of glutamine for arginine at residue 302. The PRKAG2 gene consists of 16 exons and is more than 280 kb. The AMPK subunit protein is 63 kDa.[6] Six mutations[7] have been described as listed in Table 1, all of which are missense

mutation, except for the leucine insertion. Expression of two of these mutations, the R302Q[8] and N488 I,[9] as a transgenic in the mouse is associated with the WPW syndrome, cardiac hypertrophy, and abnormalities in the conduction system. The penetrance based on the few families so far studied is in the range of 70% to 80%.

GENOTYPE TO PHENOTYPE CORRELATIONS

In 1930, Wolff, Parkinson, and White[1] described patients with electrocardiograms showing a short PR interval, a delta wave, and a wide QRS complex. It was postulated an accessory atrial ventricular pathway would explain the particular ECG and the recurrent tachycardias. Electrophysiological investigations, cardiac electrical mapping, surgical findings, anatomic studies, and results of ablation treatment have confirmed the presence of accessory conduction pathways (Fig. 1). The normal cardiac conduction is from the atrium to the ventricles through the AV node. In WPW syndrome, there is an accessory pathway between the atrium and the ventricle which bypasses the AV node and this prematurely depolarizes a portion of the ventricle to give you the short PR interval and the slurred upstroke of the QRS. However, the overall activation of the ventricle is slightly later due to the normal electrical impulse which passes through the AV node. A property of the AV node is to decrease the rate of transmission to the ventricle. Under certain conditions, conduction through the AV node to the ventricle can give rise to retrograde conduction from the ventricle to the atrium through the accessory pathway. Upon arrival in the atrium, the AV nodal conduction system has recovered resulting in reentry of the impulse into the AV node. Arrival of this impulse in the ventricle can now again be transmitted retrograde back through the accessory pathway generating a circus movement leading to reentry tachycardia. Wolff–Parkinson–White syndrome has long been regarded as intriguing to cardiologist and particularly to the electrophysiologist as it is the sine quo non of reentry tachycardia. The most common form of supraventricular tachycardia observed with WPW is that of antegrade conduction through the AV node with retrograde conduction through the accessory pathway. The usual result is a regular supraventricular tachycardia with a rate of about 120 to 160 beats per minute. The overall configuration is a narrow QRS. The vectors of the QRS, however, may vary depending on the anatomical location of the accessory bundle. The most common anatomical bundle is that which goes from the left atrium to the left ventricle and occurs in about 50%; a posteroseptal, right ventricular, or anteroseptal insertion of the AV pathway is found in approximately 30%, 13%, and 7% of patients, respectively. It is claimed that about 80% of the supraventricular arrhythmias associated with WPW have a regular supraventricular tachycardia with a narrow QRS. In the remaining 20% the arrhythmia is generally atrial fibrillation. The incidence of tachyarrhythmias in WPW syndrome is unknown. Reports from a variety of studies indicate 10–80%. Atrial fibrillation is very dangerous because it predisposes to failure and sudden death. This is because the rapid rate is transferred to the ventricle due to lack of the damping effect of the AV node. This rapid rate of the ventricle prevents proper relaxation during diastolic for adequate blood to return to the heart resulting in

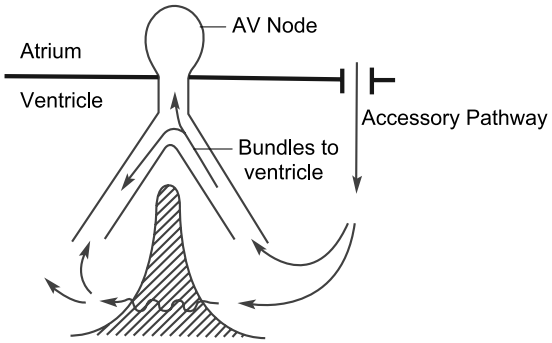

Fig. 1 Cardiac electrical conduction is normally from the SA node through the atrium and subsequently transmitted to the ventricles by the AV node and right and left bundles. In WPW, there is an accessory pathway as indicated in the figure connecting the atrium to the ventricle without going through the AV node. Thus, an impulse arising in the atrium may get conducted to a portion of the ventricle through the accessory pathway and subsequently be retrograde conducted through the normal conduction system including the AV node. Arrival of this retrograde conduction impulse is delayed in the AV node permitting adequate recovery time for the accessory pathway so that it may be conducted again through the accessory pathway giving you reentry tachycardia. Other times conduction through the accessory pathway will simply give preexcitation of only a portion of the ventricle indicated by the short PR interval and the slurred upstroke of the QRS. The remainder of the QRS is generated by conduction through the AV node and bundle branch system.

decreased cardiac output, cardiac failure, and may deteriorate into ventricular tachycardia or fibrillation and sudden death. Atrial fibrillation is particularly dangerous if there is a short antegrade refractory period as ventricular fibrillation is more likely to occur.

The genetic defect is in the PRKAG2 gene which encodes for the gamma subunit of the kinase AMPK. AMP-activated protein kinase is a sensor of the body's ATP level. AMP-activated protein kinase is activated by an increase in the ratio of AMP to ATP. AMP-activated protein kinase increases the availability of ATP by increasing glucose absorption, inhibiting glycogen synthesis, increasing fatty acid oxidation, and decreasing fatty acid synthesis. The phenotype consistently observed in addition to WPW syndrome is excess glycogen in the myocytes of the heart.[10] Hypertrophy of the heart is also observed in a percentage of the patients. Several genetic animal models expressing either the R302Q mutation[8] or the mutation N488I[9] as a transgene have been generated. All of them have the preexcitation syndrome and excessive myocardial glycogen phenotype. The model expressing the R302Q mutation has the preexcitation syndrome, increased cardiac glycogen, and inducible supraventricular reentry tachycardia as observed in the human phenotype. In this model,[8] we have shown there is loss of function of AMPK leading to loss of inhibition of glycogen synthase resulting in increased formation of glycogen in the heart. The hypertrophy is probably a compensatory feature due to less ATP available for contractility inducing formation of more sarcomeres. The mechanism whereby AMPK leads to accessory pathways or alters conduction remains to be determined. AMP-activated protein kinase with the R302Q mutation has been shown to inhibit the cardiac sodium inward current in in vitro studies.[11] This is an exciting area of research as AMPK is also one of the pivotal enzymes in obesity, insulin resistance, and the metabolic syndrome.

INCIDENCE

The true incidence of preexcitation is unknown but varies from one to three per thousand populations. As preexcitation on the ECG is often concealed it is felt the true incidence of preexcitation is grossly underestimated.

DIAGNOSIS

Patients presenting with supraventricular tachycardia or the symptoms of syncope or presyncope due to an arrhythmia should have a regular 12-lead electrocardiogram to detect preexcitation, namely, short PR interval with slurred upstroke of the QRS. If an accessory pathway is anticipated as the accessory pathway is often concealed, it may be necessary to do an intracardiac electrophysiological study. Premature atrial stimulation is performed to induce supraventricular tachycardia which would indicate the presence of an accessory pathway. Termination of the supraventricular tachycardia by single premature impulse is further evidence of an accessory pathway. The other procedure that helps to make the diagnosis is the administration of procainamide, which inhibits the accessory pathway inducing conduction through the normal AV nodal system resulting in normalization of the electrocardiogram. The presence of a family history is highly suggestive and the disease can be confirmed by myocardial biopsy showing the characteristic phenotype of excessive glycogen deposition if mutations in the AMPK gene are responsible for the disease.

TREATMENT

Incidental identification of WPW on electrocardiogram requires assessment of possible symptoms. If the patient is asymptomatic having never had palpitations or syncope, no further specific treatment is required. It is important, however, to remind the patient that they should not take digoxin or verapamil. If the individual is a pilot or makes his living by driving a vehicle, one may be concerned with the possibility of development of atrial fibrillation. It is suggested in these asymptomatic individuals that electrophysiological studies be performed to determine whether there is a short accessory pathway, which is more likely to predispose to atrial fibrillation. If that were the case, then the recommended treatment would be radiofrequency ablation of the accessory pathway. Individuals with documented preexcitation and symptoms should be considered for curative therapy, namely, ablation. If ablation is not considered, then drug therapy such as beta-blockers, amiodarone, or flecainide should be considered. In the familial form of WPW, there is also a conduction defect in the regular normal AV node system and a pacemaker is frequently required for complete heart block. Patients presenting with supraventricular tachycardia should be converted with i.v. adenosine, as seldom it is necessary to perform electrocardioversion.

GENETIC COUNSELING

The familial form of WPW is inherited as an autosomal disorder. This means 50% of the offspring will inherit the mutant gene and thus be at risk of developing the disease. As it is autosomal dominant, there is vertical transmission of the gene with each generation expected to have individuals affected with the disease. The mutant gene

will affect males and females equally, and based on experience with families so far, one can expect the penetrance to be in the 70–80% range. Onset of the disease is age dependent and increases with age, but onset can occur very early or very late. Once a proband has been identified in a family, it is important to screen all family members with at least a 12-lead electrocardiogram. Individuals in a family with segregation of the disease who are symptomatic with a normal electrocardiogram should have EP studies with provocation to exclude an accessory pathway.

GENETIC TESTING

In North America, genetic testing is not yet approved as the procedure is still research. Therefore any attempt to screen must be done on a research protocol. In some European countries, genetic screening is already a routine procedure. The gene responsible for this syndrome is the gamma 2 subunit of the AMPK protein. The official designation for the gene is PRKAG2. As there are already multiple mutations present in the PRKAG2 gene, it is preferable to sequence the complete cDNA.

CONCLUSION

Wolff–Parkinson–White syndrome is the second most common cause of supraventricular tachyarrhythmias in the western world and the most common cause in Asian countries such as China. The first gene responsible for this disorder was identified to be a mutation in the gamma 2 subunit of AMPK, which is encoded by the gene PRKAG2. This has now been confirmed in several families throughout North American and Europe. Six mutations all except one are missense mutations present in the gamma 2 subunit. The syndrome consistently exhibits preexcitation (short PV interval on the ECG), delayed upstroke of the QRS, and often is associated with impaired atrioventricular conduction as well as ventricular hypertrophy. Genetic animal models have been developed and are being explored to improve the diagnosis, prognosis, and treatment of this syndrome. Genetic testing is available through DNA sequencing but is performed at present only as a research tool.

INTRODUCTION

Lymphatic filariasis is a significant health problem in many developing countries. Globally, 1.1 billion people live in known endemic areas and about one-fourth of them may be infected. Lymphatic filariasis is the second leading cause of permanent and long-term disability and undermines the social and economic welfare of the affected people and communities. The World Health Organization launched a global program to eliminate lymphatic filariasis as a public health problem by the year 2020. Human lymphatic filariasis is mainly caused by *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*. Bancroftian filariasis, *W. bancrofti*, is responsible for 90% of lymphatic filariasis and widely distributed throughout the tropics and subtropics. *B. malayi* infection is endemic in Asia such as China, Korea, India, Indonesia, Malaysia, Philippines, and Sri Lanka. *B. timori* infection occurs in Indonesia (islands of Alor, Flores, and Timor).[1]

The microfilariae of *W. bancrofti* were first described by Demarquay in 1863 and the adult worms were first described in 1877 by Cobbold in Australia and by Lewis in India. In 1878, Manson completed the description of the life cycle by showing that mosquitoes acted as intermediate hosts for the parasite.[2] It has been speculated that *W. bancrofti* originated from Southeast Asia, where its closest known relative, *Wuchereria kalimantani*, parasitizes the Indonesian leaf monkey. From there, it was presumably carried by the earliest migrants to the islands of the South Pacific, perhaps as early as 2000 BC. Another migration from the same area of Southeast Asia, known to have settled in Madagascar sometime before 500 AD, may have brought filariasis to that island and subsequently to the mainland of Africa. Filariasis is known to have spread throughout Central Africa and into Arabia by the 14th or 15th century (with no evidence of its presence in Egypt in pharaonic times) and to have been imported to the New World via the slave trade in the 17th and 18th centuries. It was introduced into north-eastern Australia during the 19th century, but has since been eradicated.[3]

BODY OF TEXT

Diagnosis of Filariasis

Diagnosis of filariasis infection is frequently made on strict clinical grounds, particularly in endemic areas, but demonstration of microfilariae in the circulating blood is the only means by which one may make a certain diagnosis. The advantage and disadvantage of the detection techniques were discussed in Table 1.

Microscopic Examination

In the past, surveys for lymphatic filariasis depended on the examination of blood films, which, in most areas, had to be collected around midnight. The thick blood smear technique normally employed to detect microfilaria is intensive especially when the parasite is nocturnally periodic and a nocturnal specimen is required to increase the chance of detecting the infection. The need for a nocturnal blood sample has been obviated by the administration of 50 and 100 mg of DEC before blood examination. Furthermore, conventional microscopy is not suitable for large-scale microfilariae screening of populations in endemic areas because it is very time-consuming and labor-intensive.

Various concentration methods have been developed to increase the sensitivity for the direct demonstration of

DOI: 10.1081/E-EDGP 120021498

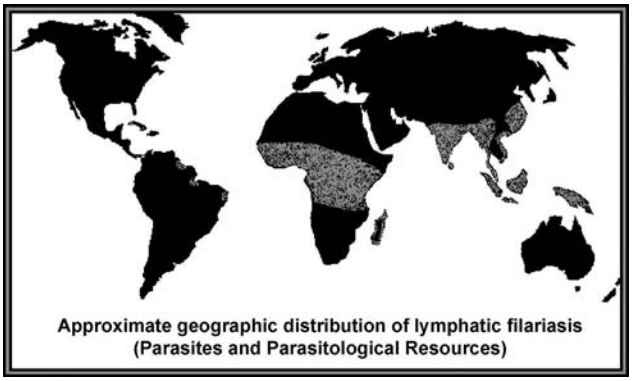

Fig. 1 Distribution of lymphatic filariasis. (From Ref. [1].) (*View this art in color at www.dekker.com.*)

microfilaria, and these include the Knott's concentration and membrane filtration techniques in which 1 mL or more heparinized blood can be processed and the microfilaria can be concentrated for easy detection.

The Knott's concentration technique, although simple and economical to perform, is rather tedious. The membrane filtration technique, which effectively concentrates microfilariae onto a membrane that can be stained with Giemsa and examined under a light microscope, is a rapid, sensitive, and easy technique to carry out. However, the membrane filter technique requires the large volume of blood collected when the carrier cases are investigated. These two techniques should nevertheless be used to detect low microfilaremic states and to monitor the effectiveness of chemotherapy where microfilaria counts may become very low.

A recent technique developed for the detection and identification of microfilaria in blood samples is the

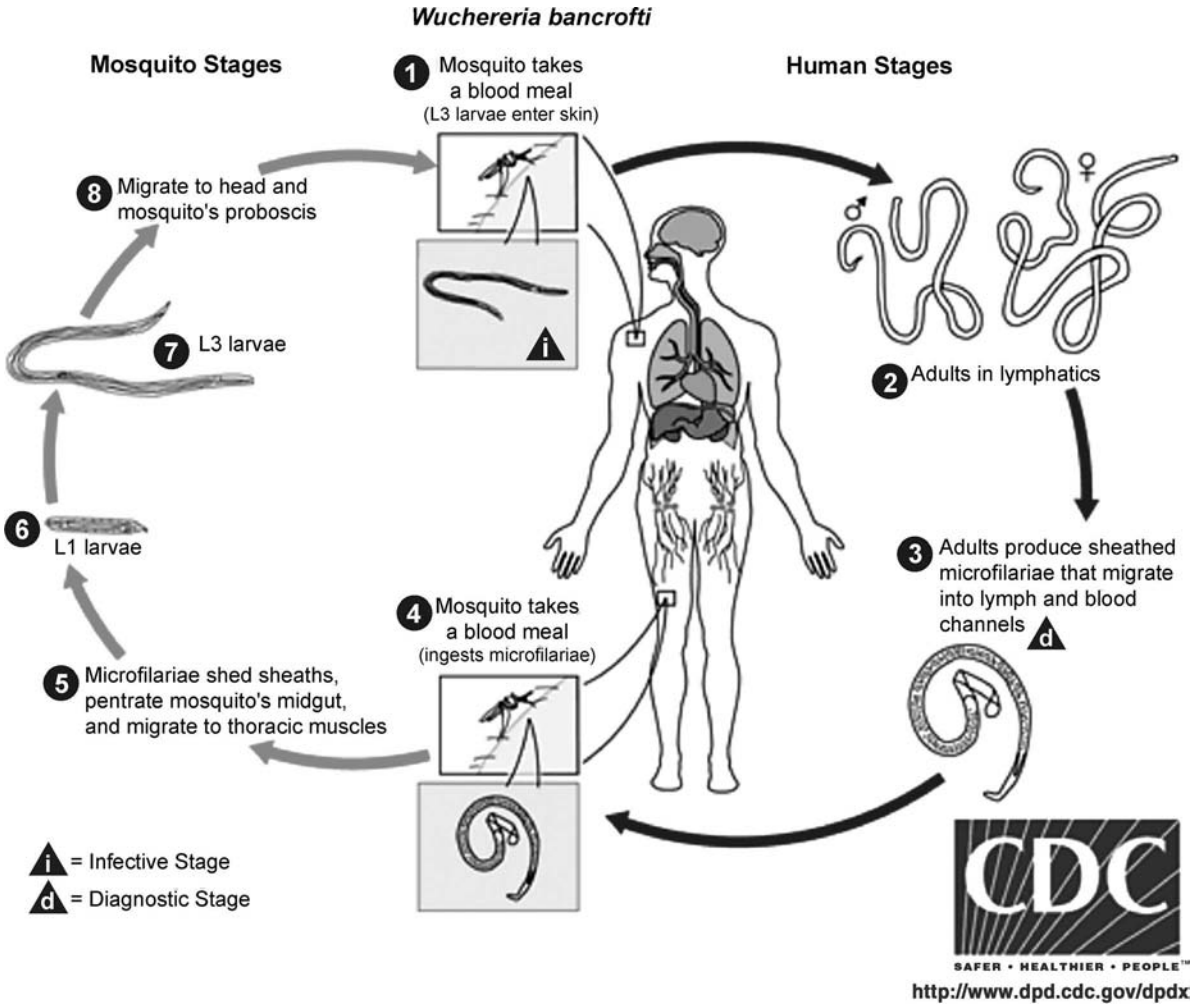

Fig. 2 Life cycle of *W. bancrofti*. (From Ref. [2].) (*View this art in color at www.dekker.com.*)

Table 1 Comparison of the methods used for detection of *W. bancrofti*

Methods	Advantage	Disadvantage
Giemsa stain of thick blood films	• Low cost • Easy	• Underestimate • Cannot detect low density of microfilariae • Blood collection at night time
Filtration test	• Easy • Sensitive	• Time-consuming • Blood collection at night time
Immunological test	• Blood can be taken at anytime • Sensitive	• Cross-reaction among closely nematode • Costly
DNA probes	• Sensitive • Specific • Can be used for detection of the parasite in mosquitoes	• Costly • Blood collection at night time
PCR-based methods	• Very sensitive • Specific • Reproducible • Can be used for detection of the parasite in mosquitoes	• Costly • Blood collection at night time

quantitative buffy coat (QBC) technique, which involves centrifugation of the blood sample collected in a micro-hematocrit tube containing heparin, EDTA, and acridine orange. Microfilariae, if present, are concentrated in the area of the buffy coat after centrifugation and can be viewed by fluorescent microscopy as acridine orange stains the DNA of the parasite.[4]

Immunological Diagnosis

Intradermal tests

Intradermal tests performed by several investigators have produced equivocal results. Early studies with purified antigenic extracts of adult *Dirofilaria immitis* (Sawada antigen) showed high positive rates in *W. bancrofti* microfilaremic and clinically positive patients.[5] However, it was found that this antigen could not discriminate between patients with and without clinical manifestations. In addition, the Sawada antigen was reported to have cross-reactivity with other filarial infection.[6] Subsequently, other investigators compared the Sawada antigen with *W. bancrofti* microfilarial and larval extracts and *B. malayi* infective larval antigen.[7] From these studies, it appears that antigen prepared from human parasites has greater diagnostic utility in intradermal tests.

Antibody detection

A number of serological assays have been developed for the immunodiagnosis of lymphatic filariasis. These include the indirect fluorescent antibody test (IFAT), indirect hemagglutination test (IHA), precipitin techniques, and the enzyme-linked immunosorbent assay (ELISA). Various stages of antigens have been employed in the IFAT. These include frozen sections of adult worm and larvae,[8] papainized microfilaria,[9] and sonicated fragment microfilaria.[10] From these studies, homologous antigens were found to be better than heterologous antigens for antibody detection. The IHA test and precipitin techniques have not been widely used for the diagnosis of filariasis in recent years as previous studies have shown their lack of sensitivity.[11] However, the ELISA is very popular in the diagnostic laboratory because its sensitivity is reported to be equal to that of radioimmunoassay (RIA).

Nevertheless, the methods that have focused on the detection of filarial antibodies in the host generally lacked sufficient sensitivity and specificity to discriminate effectively between past and present filarial infections in humans. The detection of circulating filarial antigens in the peripheral blood would thus provide a more accurate indication of active filarial infection in man than the detection of antibody.

Antigen detection

Antigen detection assays would be especially useful for diagnosing a microfilaremic prepatent and occult infection where classical parasitological tests are not useful. *W. bancrofti* represents a success to the detection of circulating antigen, in that an ELISA is commercially available for detection of this parasite (Trop-Ag

W. bancrofti ELISA kit, JCU Tropical Biotechnology Pty Ltd, Queensland, Australia). The assay is dependent on a monoclonal antibody, Og4C3, which, curiously, despite being raised against antigens of the bovine parasite *Onchocerca gibsoni*, detects circulating antigen in serum samples from individuals infected with *W. bancrofti*, but not *Onchocerca volvulus*. Negative results were obtained with sera from individuals harboring *B. malayi*. A second specific assay, which is currently undergoing commercial development, is based on the mAb AD12.1 which recognizes a 200-kDa antigen in the circulation of individuals infected with *W. bancrofti* which again is of adult worm origin. Both assays have been evaluated as diagnostic tools in a number of studies and can detect circulating antigen in virtually all (94–100%) microfilaria carriers, as antigen levels remain constant throughout the day.

However, antigen detection methods are now recognized to have advantages over other diagnostic methods for *W. bancrofti* infection. The ELISA format of assays such as the Og4C3-dependent test is not ideal for use in the field. A new rapid assay has therefore been developed (the filariasis card test produced by ICT Diagnostics using mAb AD12.1). This assay takes only 5–15 min to complete, requires no specialized equipment, and gives comparable results to ELISA. Such assays are likely to prove valuable in the global effort to eradicate lymphatic filariasis as a public health issue. The immunochromatographic test (ICT) kit has been validated and used worldwide as an effective tool in detecting infections, especially in low-level microfilariae carriers, which are not usually detectable by conventional night blood examination. The ICT filariasis card test was recently recommended as a rapid screening tool to define the prevalence and distribution of filariasis as part of the global program to eliminate lymphatic filariasis. It was found that adult filarial antigen levels persist in microfilariae-negative persons for up to 3 years after treatment.[12]

Monoclonal antibody-based enzyme immunoassays for detecting parasite antigens would therefore be more suitable for field application. Several groups of researchers have successfully used such assay in the diagnosis of lymphatic filariasis. Weil et al.[13] used two monoclonal antibodies to detect *D. immitis* in a direct sandwich ELISA and to detect *W. bancrofti* antigens in human sera.

DNA probes

During the 1980s, a substantial effort to isolate and characterize filarial species-specific DNA probes was undertaken. The main objective was the development of a diagnostic system that would allow assessment of the impact of filarial nematode control programs. Later, the adaptation of polymerase chain reaction (PCR) technology and the development of a procedure involving ELISA detection of PCR products permitted the adoption of DNA probe-based methodology from the bench to the field. It is also of interest to note that effective diagnosis, the initial objective of the DNA probe-based research, was not only achieved, but also surpassed in that a deeper knowledge of the epidemiology of filarial disease, as well as filarial phylogenetic relationships, was achieved from this work.[14] PCR development has had a major impact on filarial diagnosis. The species-specific DNA probe sequences referred to above were used to design PCR primers that allowed both specific and sensitive parasite detection. The specificity of amplified DNA was confirmed by hybridization with species-specific oligonucleotides or the full DNA probes. The use of filarial DNA probe-based research has, in addition to benefiting diagnosis, contributed greatly to our knowledge of the epidemiology and pathology of the corresponding human diseases, as well as to genomic structure and evolutionary connections between related species. *W. bancrofti* PCR detection systems were developed to identify the parasite in mosquitoes.[15]

Polymerase chain reaction assays

Polymerase chain reaction is an in vitro method for amplifying selected nucleic acid (DNA or RNA) sequences by a pair of oligonucleotide primers. The method consists of repetitive cycles of DNA denaturation, primer annealing (hybridized to their complementary sequences), and extension by DNA polymerase. The product of each PCR cycle is complementary to and capable of binding primers, and so the amount of DNA synthesized is doubled in each successive cycle.

The development of PCR-based assays for the diagnosis of many parasitic and nonparasitic infections offers the possibility of improved sensitivity and specificity. These assays were recently developed for diagnosis of infection with the filarial parasite *O. volvulus* and *B. malayi* and are more sensitive than parasitologic diagnosis. The recent identification of a *W. bancrofti* repeated DNA sequence has enabled the development of a PCR-based assay capable of detecting *W. bancrofti* genomic DNA in human blood, urine, hydrocele fluid, and mosquito vectors such as *Aedes polynesiensis* and *Culex quinquifasciatus*.[16]

Recently, a nested PCR is introduced for improvement of specificity and sensitivity of detection, involving two steps of amplification. In the first step, initial pair

of primers is used to generate a long sequence that contains the target DNA sequence. Subsequently, a small amount of this product is used in a second step of amplification, which employs primers to the final target DNA. The efficiency of the second round of amplification is enhanced because of the more rapid and more complete denaturation of the first reaction product as compared with total genome. The application of nested PCR has been used for many infectious diseases including parasite, bacteria, and virus. The seminested PCR is the use of two rounds of PCR and by the replacement of one of the two primers from the first round of PCR with a different primer in the second round. This technique was applied for various kinds of detection such as monoclonal B-cell population in plastic-embedded bone marrow biopsies,[17] bacterial diseases,[18] and viral diseases.[19]

The polymerase chain reaction assay was developed for species-specific detection of filarial parasites in the blood samples from infected individuals (*B. malayi*, *W. bancrofti*, and *Loa loa*) and even in the mosquito vectors.[20,21] The 969 nucleotides of the moderately repetitive *W. bancrofti* sequence have been described as being species-specific. This sequence has a moderate copy number (450–700) and appears to be interspersed within the parasite genome. The use of this region in PCR to detect *W. bancrofti* has been documented.[3]

CONCLUSION

Sensitivity and specificity of the detection tools for *W. bancrofti* are crucial. At present, the PCR protocol has been introduced for diagnosis of parasitic infection in human blood because it is rapid, reproducible, and has a high specificity and sensitivity. It can diminish the time consumed in detection of parasites and requires relatively few amounts of blood, and thus it is not only suitable for the screening of parasitic infection in a large blood sample numbers, but also will be beneficial for elucidation of the possible vectors of the multiple infection. However, the cost of PCR is still high and it requires sophisticated equipment that may be not suitable for manipulation in the fieldwork.

Yersinia spp.

Luther E. Lindler
Walter Reed Army Institute of Research (WRAIR), Silver Spring, Maryland, U.S.A.

INTRODUCTION

The genus *Yersinia* includes a group of organisms with a wide range in pathogenic potential. On one end of the spectrum are saprophytic organisms that do not cause animal disease, while on the other end is the organism that causes plague. Recently, we have compared the genomic sequences of the agent that causes plague on an intraspecies level. This article will present a brief description of the pathogenic *Yersinia* in terms of disease and properties including virulence factors. The currently available genomic information will also be discussed with an emphasis on the emergence of plague as a unique bacterial disease.

PATHOGENESIS

There are three species of *Yersinia* that are pathogenic for humans. *Yersinia pestis* causes plague whereas *Yersinia pseudotuberculosis* and *Yersinia enterocolitica* cause gastroenteritis. The principal features that differentiate these organisms are listed in Table 1. A good source for differential identification of these species can be found at http://vm.cfsan.fda.gov/~ebam/bam-8.html.

Plague

The characteristic that separates *Y. pestis* infection from disease by the other pathogenic *Yersinia* spp. is the former's ability to cause serious infection of healthy animals. The disease caused by *Y. pestis*, plague, can take three forms. Bubonic plague occurs following the bite of an infected flea. The inflammation is caused by the uncontrolled growth of the organism. The organism gains access to the circulatory system from the lymphatic system such that the liver becomes infected. *Y. pestis* reaches high numbers in the liver and spleen. The organism can be recovered from the blood shortly before death. Septicemic plague occurs when the organism can be recovered from blood in the absence of a bubo. Death occurs because of multiple organ failure as a consequence of lipopolysaccharide (LPS) toxicity. Discoloration of the individual, hence the name Black Death, occurs because of hemorrhage and cyanosis as a result of disseminated intravascular coagulation precipitated by LPS intoxication. The last form of the disease, pneumonic plague, is spread by aerosol. This infection results in a fulminate pneumonia followed by spread to deeper organs. Death can occur within 24 hr.

Gastrointestinal *Yersinia*

Both *Y. pseudotuberculosis* and *Y. enterocolitica* can cause foodborne illness, although infections caused by the latter organism are more common. A thorough description of the disease and causative bacteria can be found at http://vm.cfsan.fda.gov/~mow/chap5.html. Briefly, these organisms enter the host by the oral route where they gain access to the mesenteric lymph nodes. Generally, the infection does not progress beyond this point except in immunocompromised individuals. In rare cases, the organism can infect deeper tissues and cause bacteremia. More typically, infection results in fever, diarrhea, and abdominal pain. Finally, some strains of *Y. enterocolitica* produce a heat-stable enterotoxin (Yst) as indicated in Table 1. However, the role this toxin plays in virulence is unclear because stains lacking it are virulent.

PHYSIOLOGICAL DIFFERENCES

Major physiological differences between the pathogenic *Yersinia* are listed in Table 1. One of the most striking features is the inability of *Y. pestis* to produce typical gram-negative O-side chains on LPS at any growth temperature.[1] Both of the enteropathogenic *Yersinia* are also rough when grown at mammalian body temperature but produce O-side chains on their LPS when grown at room temperature. All of these organisms are serum-resistant in the absence of O-polysaccharide.

Another notable physiological difference between *Y. pestis* and the enteropathogenic *Yersinia* is motility. *Y. enterocolitica* and *Y. pseudotuberculosis* are motile

Table 1 Comparison of *Y. pestis* properties with *Y. pseudotuberculosis* and *Y. enterocolitica*

Characteristic	Yps[a]	Yptb[a]	Ye[a]	Function
pYV	+	+	+	YOP production and antiphagocytosis
pPst	+	−	−	Plasminogen activator production
pFra	+	−	−	Murine toxin and capsule synthesis
HPI	+	+/−[b]	+	Yersiniabactin siderophore production
pgm loci	+	+[c]	−	Pigmentation on Congo red agar
pH 6 Antigen (*psa*)	+	+	+	Putative adhesin; designated *myf* in Ye
yst	−	−	+	Heat-stable enterotoxin
YadA	−	+	+	Adhesin
LPS O antigen	−	+	+	Cell structure/envelope
Invasin (Inv)	−	+	+	M cell translocation
Ail	+/−[d]	+	+	Host cell attachment and serum resistance
IS*1541* and IS*100*	++[e]	+	+[f]	Insertion sequence elements
Low calcium response (LCR)	++[g]	+	+	Regulation of YOPs and reduced growth at 37°C in the absence of added Ca^{2+}
Motility at 26°C	−	+	+	Chemotaxis
Rhamnose fermentation	−[g]	+	−	Sugar metabolism
Melibiose fermentation	−[g]	+	−	Sugar metabolism
Urease	−[g]	+	+	Nitrogen assimilation

[a]Yps: *Y. pestis*; Yptb: *Y. pseudotuberculosis*; Ye: *Y. enterocolitica*.
[b]Nonpathogenic strains are negative.
[c]The 68-kb *pgm* locus is present in *Y. pseudotuberculosis* but is usually silent.
[d]In some strains of *Y. pestis*, *ail* is interrupted by a copy of IS*285*, but in others, this locus is intact.[2]
[e]The ++ and + refers to the higher number of these insertion sequence elements or relative intensity of the LCR seen in *Y. pestis* vs. *Y. pseudotuberculosis* and *Y. enterocolitica*, respectively.
[f]*Y. enterocolitica* does not harbor copies of IS*100*.
[g]Metabolic capability known to undergo reversion.

when grown at room temperature but nonmotile when grown at 37°C.[1] In contrast, *Y. pestis* is nonmotile at all tested growth conditions. Strain CO92 appears to have an intact set of flagella genes,[2] whereas KIM encodes a mutant *flhD* flagella regulatory element.[3] It remains to be determined if there are environmental conditions that *Y. pestis* might become motile.

Generally, the growth of *Y. pestis* is more fastidious at 37°C than is growth of the enteropathogenic species. The growth rate of *Y. pestis* is not enhanced when cultivated at 37°C compared with 26°C, whereas the rate of cell division is enhanced for the enteropathogenic *Yersinia*. This fact is partially a result of a larger number of nutritional requirements by *Y. pestis* at the higher growth temperature as well as a more pronounced low calcium response (requirement for millimolar amounts of calcium for growth at 37°C) by this species.[4]

Subclassification

Y. pestis is generally classified into biotypes according to the ability to ferment glycerol and to produce nitrate.[5] The three biotypes are Antiqua (nitrate +, glycerol +), Mediaevalis (nitrate −, glycerol +), and Orientalis (nitrate +, glycerol −). Strains of *Y. pseudotuberculosis* and *Y. enterocolitica* are generally classified according to serotypes (http://vm.cfsan.fda.gov/~ebam/bam-8.html).

THE GENOME

Early studies analyzed the relationship between *Y. pestis*, *Y. pseudotuberculosis*, and *Y. enterocolitica* as well as other enteric gram-negative organisms at the whole-cell DNA hybridization level.[6] More recent experiments using multilocus sequence typing and IS*100*-based fingerprinting have clearly shown that *Y. pestis* is a recently emerged clone of *Y. pseudotuberculosis* with remarkably little sequence variability.[7] *Y. pestis* itself is extremely monomorphic at the DNA sequence level.

Two complete genomes from two biotypes of *Y. pestis* have been completed. The first was the modern biotype Orientalis strain CO92[2] and the second was the Medievalis strain KIM.[3] CO92 is a recent pneumonic plague isolate that is highly virulent, while KIM is a

Table 2 Interesting characteristics of complete sequences *Y. pestis* strains CO92 and KIM[a]

Characteristic	Strain		Comments
	CO92	KIM	
Size (bp)	4,653,728	4,600,755	Larger size of CO92 mostly because of more copies of IS elements as well as one 11 kb and other numerous smaller insertions
rRNA operons	6	7	Loss of one operon possibly due to intragenomic recombination
Number of ORFs	4,012	4,198	Numbers include identified pseudogenes
Pseudogenes	149	54	KIM (Mediaevalis) is thought to be an older biotype[5]
IS*1541*	66	58	Includes complete and partial copies
IS*100*	44	35	Used in genotyping[7]
IS*285*	21	19	
IS*1661*	9	10	Includes complete and partial copies
Chromosomal type III secretion	Intact	Mutant	*sseJ* of KIM encodes a frameshift mutation in this *Salmonella* pathogenicity island 2-like system
Phage and large islands	21	15	These are regions with significantly different G+C ratios than the 47.6% found on the majority of the chromosome
Selenocysteine-associated genes	*selB* frameshift	Intact	Suppression of opal mutations in genes with frameshifts
Secretin near *tad* loci	Absent	Split	Involved in biofilm formation; mutated in KIM, and deleted in CO92
yapB	Intact	Truncated	Encodes autotransporter apparently nonfunctional in KIM
rscA	Intact	Truncated	Locus known to be involved in systemic dissemination in *Y. enterocolitica*[18]
Single-stranded prophage	Present	Absent	Phage element near *tca* and *tcc* insecticidal toxin genes

[a]Taken from Refs. [2,3]. Complete plasmid sequences can be found in Refs. [8–13].

laboratory strain isolated from a human pneumonic case over 4 years ago. Interesting characteristics to emerge from the genomic sequencing projects of these two *Y. pestis* strains are noted in Table 2.

MOLECULAR DIAGNOSTICS

Several molecular assays have been developed based on DNA sequences specific to the various pathogenic *Yersinia*. A few of these assays are listed in Table 3.

Y. pestis Assays

Classically, the identification of *Y. pestis* has been based on Gram's stain, biochemical reactions, and reactivity of the organism with anticapsular antibody. The first and most common molecular target for the identification of *Y. pestis* is the *pla* locus (Table 3). Although not reported in the literature, false positive reactions have been seen from environmental samples (Dr. Joan Gebhardt, Naval Medical Research Center, Silver Spring, MD, personal communication). In addition, atypical strains of *Y. pestis* that lack *pla* have been found to be virulent in animal models.[14] The second locus used for specific identification of *Y. pestis* is the capsular gene *caf1*. However, *caf1*-negative strains have been reported to be virulent.[15]

Y. pseudotuberculosis and *Y. enterocolitica* Assays

The high degree of homology between *Y. pestis* and *Y. pseudotuberculosis* at the DNA level makes development of molecular assays specific for the latter organism difficult. The 16S rRNA sequence is identical for these bacterial species. A 1 base pair difference was noted in the 23S rRNA gene, and an assay has been developed based on this polymorphism.[16]

Y. enterocolitica is a more important foodborne pathogen than is *Y. pseudotuberculosis*, and therefore more assays have been developed to detect this species (Table 3). The 16S rRNA sequence is significantly different from the other pathogenic *Yersinia* so that this makes a convenient higher copy number target. One

Table 3 Partial list of published molecular diagnostic tests for *Yersinia*

Organism	Target	Method	Sensitivity	Comments	Reference
Y. pestis	*pla*	Standard PCR	10 CFU/reaction	Early molecular diagnostic developed based on *Y. pestis* specific gene	[19]
Y. pestis	*pla*	Fluorogenic PCR	~850 copies/reaction	Detection limit based on purified DNA; specific detection obtained in fleas, blood, tracheal fluid, serum, and swabs	[20]
Y. pestis and *Y. pseudotuberculosis*	*pla*, *caf1*, *inv*, and *yopM*	Standard PCR	~80 CFU/reaction	Useful assays for differentiation of closely related species of this genus	[21]
Y. pestis	*pla* and *caf1*	Standard PCR	~10–50 CFU/reaction	PCR assays developed for two species-specific genes	[22]
Pathogenic *Yersinia*	rRNA	Fluorogenic probes, PCR and in situ hybridization	~100 CFU/mL	Suitable for identification of infected tissues	[16]
Y. enterocolitica	rRNA	Fluorogenic PCR	10 CFU/mL	Sensitive method suitable for detection in blood samples	[23]
Y. enterocolitica	rRNA and *ail*	Standard PCR	~1 CFU/reaction	Duplex PCR using two specific targets	[17]
Y. enterocolitica	*yst*	Fluorogenic PCR	100 CFU/reaction	Good for identification of some pathogenic strains of the organism	[24]

group has combined this target with the *ail* gene that is specific for only pathogenic strains of *Y. enterocolitica*.[17]

CONCLUSION

The genus *Yersinia* includes completely avirulent or low virulence strains of enteropathogenic species to probably the most deadly pathogen known to humankind (*Y. pestis*). Genomic examination of *Y. pestis* has revealed interesting characteristics of this highly virulent organism and shed some light on the emergence of this pathogen. Expansion of our available information pertaining to different strains of *Y. pestis* (including atypical strains) and comparison to highly related strains of *Y. pseudotuberculosis* will undoubtedly open other doors for our understanding of the emergence of deadly pathogens as well as lead to new understanding of host specificity.

ACKNOWLEDGMENTS

The author was supported by the United States Army Medical Research and Materiel Command Biological Defense Research Program. He would like to thank the members of his laboratory who have worked on *Y. pestis* pathogenesis, genotyping, and diagnostics.
