Other vectors, including herpesviruses, have been proposed as high-efficiency transducers of normal and malignant hematopoietic cells, and are entering clinical trials. However, although these viruses may become future substitutes for currently available vector systems, most investigators now accept that no naturally occurring virus and no simple physical vector will ever prove suitable for all gene therapy purposes. Ultimately, therefore, entirely new synthetic or semisynthetic vectors will have to be developed. Possibilities include the generation of hybrid viral vectors, which may combine, for example, the in vivo stability of adenoviruses and the integrating capacity of retroviruses.²⁷ Alternative, fully synthetic vectors will be developed by combining components from multiple different vectors, allowing safe, efficient, and specific gene transfer and regulation. In the meantime, however, gene therapy protocols for leukemia will require investigators to circumvent the limitations of current vectors and to choose their agents on the basis of the most important feature required.

Tumor cell modification

Correction or deletion of underlying defects

The strategy of introducing genetic material into a hematologic malignancy to correct the genetic defect causing the neoplastic phenotype or to directly kill the malignant cell is seductively elegant. This approach would be highly relevant to the leukemias and lymphomas, which harbor a number of oncogenes and fusion transcripts that are specific to the malignant clone and frequently form a critical component of the malignant process. For example, efforts are being made to neutralize fusion transcripts such as *BCR–ABL* or activated oncogenes such as *MYB* (in chronic myeloid leukemia, CML), using ribozymes, antisense RNA, or wild-type genes.^{28,29} Similarly, non-functional anti-oncogenes (tumor suppressor genes) such as *p53* may be replaced by wild-type genes in patients with acute myeloid leukemia (AML) or myelodysplasia (MDS).¹³ Interest is also increasing in targeting the gene pathways involved in regulating apoptosis. Experimental models suggest that even minor perturbations in these pathways can greatly modify the sensitivity of cancer cells to chemotherapy.

Numerous obstacles must be overcome before the corrective approach is successful. The first set deal with the genetic change itself. Unless correction of a single defect is subsequently lethal to the malignant cell, the transfer of an individual corrective gene to a patient with 10^{11} or 10^{12} leukemic or lymphomatous cells will leave many cells that are effectively premalignant, with a high risk of later transformation. Moreover, many relevant gene defects produce molecules with ‘transdominant’ effects that will continue to produce a malignant phenotype, even if a wild-type gene is introduced. Hence, most approaches to correction attempt to silence transdominant malignant genes.

This can be achieved with ribozymes, antisense oligonucleotides, or double-stranded RNA or RNA interference, or by homologous recombination with a wild-type gene.^{30,31} These ‘subtractive’ approaches to gene transfer are designed to destroy the function of an expressed gene rather than to add a new activity.

Ribozymes cleave specific sequences in targeted mRNA molecules. For clinical use, ribozymes that form hairpin or hammerhead structures are preferred because of their stability even in the absence of substrate and their activity under physiologic conditions. In viruses and other microorganisms, ribozymes function probably to autocatalyze their own cleavage into functional RNA, and perhaps also to destroy the RNA of invading organisms. For applications in gene transfer, ribozymes may be used to destroy transcripts originating from the unwanted host cell DNA sequence while leaving intact the mRNA originating from the transgene. Some ribozymes are currently under clinical investigation. The vascular endothelial growth factor (VEGF-F)-targeted ribozyme, for example, is currently being investigated for a possible role in breast, lung, and colon cancer.

Antisense oligonucleotides are short synthetic stretches of DNA that hybridize with specific mRNA and can prevent translation of the target gene by inducing RNaseH digestion of target mRNA. In every *in vivo* experiment, oligonucleotides were found to be susceptible to natural phosphodiester backbone degradation by cellular nucleases. Several sugar, base, and backbone modifications have been investigated to improve stability. Replacement of the phosphate moiety by phosphorothioates results in compounds with serum stability and high RNA-binding affinity. Toxic effects are apparent at higher dose levels, including complement activation, thrombocytopenia, and hepatotoxicity. Toxicity may be reduced by delivery in liposomes. Further modifications have concentrated on substitutions at the 2’ position with electronegative substituents, such as a 2-O-C-methylene bridge,³² which enhance RNA binding. The sequence has to be carefully chosen to avoid hybridization of full-length oligonucleotides to unrelated targets. Preclinical studies and initial clinical results, however, did not substantiate concerns that toxicity would reflect non-specific inhibition of RNA. Normal healthy cells tolerate the transient loss of function better than cancer cells, which carry the pro-apoptotic burden of multiple genetic alterations and genomic instability. Several clinical studies have been reported using antisense oligonucleotides to target the *c-MYB* or *p53* genes, either as marrow-purging agents for the chronic or accelerated phase of CML or intravenously for refractory AML or CML in blast crisis, without significant clinical responses or associated toxicities.^{33,34} An antisense *BCL2* oligonucleotide has also been administered to patients with refractory non-Hodgkin lymphoma (NHL), with objective clinical and biologic responses.³⁵ Several clinical studies of antisense oligonucleotide are underway.

RNA interference is an ancient mechanism of post-transcriptional gene silencing³⁶ in which short segments of double-stranded RNA direct RNases to digest specific sequences of mRNA. Initial attempts to harness this phenomenon for experimental manipulation of mammalian cells were foiled by non-specific antiviral defense mechanisms. The field advanced when synthetic duplexes of short RNAs were found to mediate specific and potent gene silencing.³⁷ Delivery of such molecules (e.g. in a lipid envelope) may facilitate application of this form of gene targeting to cancer therapy. Since RNA itself is fragile and costly, expression systems that allow the generation of siRNA inside the cell may be preferable alternatives,³⁸ and could be made part of a vector.

Introduction of a gene that directly kills tumor cells has frequently been used in gene therapy.³⁹ For example, a gene encoding an enzyme that metabolizes a drug to an active moiety, which then kills the tumor cell, can be expressed in cancer cells. The active molecule may also diffuse either through intercellular gap junctions or in the extracellular space and destroy adjacent tumor cells. In this way, transduction of even a small proportion of tumor cells can produce a large ‘bystander’ effect on adjacent tumor tissue. Unlike the corrective approach, the transgene is not specifically toxic to the tumor, and any normal cells that are transduced may be affected. For this reason, the main success has been in treating localized disease such as brain tumors. More recently, Hurwitz and colleagues^{40–42} have injected bilateral retinoblastomas with adenovirus type 5 encoding the thymidine kinase gene, followed by administration of ganciclovir. Several patients showed a complete response of vitreal tumor deposits.

Bystander effects notwithstanding, a high proportion of tumor cells must be transduced if tumor modification is to be useful. Since current vectors cannot be targeted to tumor tissue and are relatively inefficient, most of the gene therapeutic approaches described so far are limited to the treatment of accessible local disease—rarely an option in hematologic cancers. Several developments may ultimately overcome this obstacle. Extensive efforts have been made to alter the envelope proteins of vectors to ablate their natural cell tropisms and replace them with new tumor-associated binding specificities.^{43–47} It is also possible to make promoters that are active only in specific cell or tissue types. An example of this ‘transcriptional targeting’ is use of the carcinoembryonic antigen (*CEA*) promoter to drive a prodrug gene. This mediates selective gene expression in CEA-producing tumors. A combination of specific envelope (transductional targeting) and specific promoter (transcriptional targeting) may provide optimal specificity for tumor cells.

One can increase the efficiency of gene transfer to tumors by using conditionally replication-competent viruses. Viruses have been developed that will replicate in malignant but not in normal cells,⁴⁸ thereby providing multiple rounds of infection within tumor targets. Alternatively, normal cells could serve as vector carriers if they track to sites of tumor. The most obvious choice among cell carriers would be T cells or natural killer (NK) cells. Promoters that activate upon T-cell receptor (TCR) binding or after encounter with certain angiogenic factors could be used to trigger virus production and release. Systemic administration of vectors, particularly those derived from viruses, is also hampered by innate and adaptive immune responses. Inflammatory responses, specific antibodies, and cellular immune responses rapidly diminish the activity of even the largest doses of vector.⁴⁹ Efforts to induce selective and transient immunosuppression are only in their infancy.

Tumor vaccines

One of the most commonly used strategies of cancer gene therapy is to enhance the immunogenicity of weak tumor antigens by transducing tumor cells to express immune-activating molecules. In murine model systems, tumor cells expressing such molecules have augmented immunogenicity. Injection of neoplastic cells (including those derived from lymphoid and myeloid malignancies) in doses that would normally establish a tumor instead recruits immune system effector cells and eradicates injected tumor cells.^{50–53} Often, the animal is then resistant to challenges by further local injections of non-transduced parental tumor. The transduced tumor has therefore acted as a vaccine. In some models, established, non-transduced, parental malignant cells are also eradicated.⁵¹ A number of different molecules have been successfully exploited in animal models. These include chemokines, such as lymphotactin;⁵⁴ agents that enhance antigen presentation, such as granulocyte—macrophage colony-stimulating factor (GM-CSF);^{55–57} cytokines that enhance CD4⁺ cell activity, such as tumor necrosis factor α (TNF- α) and IL-7,^{58,59} or that increase expression of class I MHC antigens, such as interferon- γ (IFN- γ),⁶⁰ or that amplify T-cell responses, such as IL-2.⁶¹ Additionally, efforts have been made to express costimulatory molecules on tumor cells, including CD40 ligand (CD40L)^{62–66} and B7.1,⁶⁷ or intercellular adhesion molecules such as ICAM-1 and ICAM-3.⁶⁸

Translating this approach to human hematologic cancers is not straightforward. Although human leukemic cells are often readily available, they are difficult to grow in vitro (making murine retroviral transduction difficult), and they resist transduction with most currently available vectors. Leukemic cells may be heterogeneous, so that the population used to vaccinate may not express critical target antigens.⁶⁹ The use of an allogeneic cell line simplifies the logistics, but may result in the patient receiving a vaccine that does not express the appropriate target antigens. A phase I study of autologous AML cells engineered to secrete GM-CSF has recently commenced and is now extended to pediatric AML.⁵⁵ It has also proved feasible to express costimulator molecules such as CD40, CD40L, or B7.1 on primary tumor cells surfaces. We are using a combination of *CD40L* and *IL-2* gene transfer into pediatric ALL cells to generate an antitumor immune response in patients with high-risk disease who have entered remission. To date, this study has proved to be safe and has generated both cellular and humoral antileukemic immune responses in six out of eight patients treated.⁷⁰ Because these patients are treated in remission, it may be difficult to confirm whether there is any antileukemic activity. A similar study has begun for adults with chronic lymphocytic leukemia.⁷¹ As an alternative to inducing expression in tumor cells directly, and as a throwback to the vaccine adjuvant days, some groups are testing vaccines composed of autologous tumor cells mixed with GM-CSF-producing bystander cells.⁷²

In conclusion, genetic modification of tumor cells appears safe and is capable of generating specific humoral and cellular antitumor cytotoxic responses. There have been at least some reports of tumor regressions, and the approach is being evaluated in a wider range of tumors and in a larger number of patients, including those with leukemia.

DNA vaccines

Nucleic acid vaccines induce an immune response against a protein expressed in vivo from a naked encoding gene. Nucleotide-based vaccines have a number of appealing features. They provide prolonged antigen expression that can continuously stimulate the immune system, probably through an intracellular antigenic reservoir resistant to antibody-mediated clearance. This may favor induction of immune memory even in the absence of booster immunization.⁷³ Codelivery with plasmids encoding cytokines or costimulatory molecules can further enhance the immune response.⁷⁴ Moreover, nucleotide vaccination leads to antigen presentation to both specific cytotoxic T lymphocytes (CTL) and helper T cells. Preclinical experiments conducted in a mouse model of adult T-cell leukemia induced by the human T-cell leukemia virus I (HTLV-I) indicated a promising effect for a Tax-coding DNA vaccine against HTLV-I-induced tumors in vivo.⁷⁵ Immunization with DNA constructs encoding the idiotype (Id) of a murine B-cell lymphoma induced specific anti-Id antibody responses and protected mice against tumor challenge. Furthermore, use of DNA encoding an Id/GM-CSF fusion protein

improved vaccine efficacy.⁷⁶ By introducing unmethylated CpG motifs into the transferred genes, one can achieve further enhancement of the host immune response, as these motifs are one of the most immunogenic components of bacterial DNA recognized by the vertebrate immune system.⁷⁷ Clinical trials of DNA vaccines are ongoing in patients with cutaneous T-cell lymphoma and melanoma.

Host cell I modification

Immune system

In contrast to the meager clinical responses produced by tumor vaccines, the effects of adoptive transfer of T cells are quite dramatic. Recent studies of SV40 large T-antigen-dependent mouse tumor models of hepatocellular carcinoma and prostate cancer have shown that adoptive transfer of T cells from non-transgenic mice for which SV40 is non-self results in clear benefit.^{78,79} In humans, allogeneic donor leukocyte infusion can render remissions in relapsed CML after bone marrow transplantation by rejection of minor histocompatibility antigens that are foreign to the donor T cell.⁸⁰ Other human studies by Rooney et al⁸¹ have shown that adoptive therapy with virusspecific T cells is safe, feasible, and active as prophylaxis and treatment for post-transplant Epstein-Barr virus (EBV) lymphoproliferative disorder.

Human malignant cells harbor other potential targets for the immune system, including mutated oncogenes or fusion proteins generated by chromosomal translocations.^{82,83} Some lymphomas may express immunogenic virally encoded proteins.⁸⁴ Even normal proteins may be suitable targets if they are expressed in higher-than-usual quantities; tyrosinase and the MAGE series of proteins in melanoma cells are two good examples.⁸⁵ If tumor cells either express or are able to process and present these tumor-specific peptides, then malignancy-specific T cells administered in large enough doses should be effective treatment. However, generation of therapeutic doses of specific T cells is difficult, except in special cases where the tumors express viral proteins.

Artificial T-cell receptors

One way of circumventing the lack of tumor antigenspecific T cells is to transduce T cells with chimeric surface proteins that transmit TCR signals in response to target cells. Such proteins have an extracellular domain (ectodomain), usually derived from immunoglobulin variable chains, that recognizes and binds target antigen. This domain is attached via a spacer to an intracytoplasmic signaling domain (endodomain), usually the cytoplasmic segment of the TCR ζ chain, which transmits an activation signal to the T cell.⁸⁶ A wide variety of domains have been combined,⁸⁷ and the generation of these chimeras seems generally robust. This probably reflects the isolating effects of the lipid bilayer, which forces the extracellular and intracellular domains to remain structurally independent from each other. The structure of an artificial TCR is contrasted with that of a native TCR in Figure 28.2 (see Plate 7).

Immunoglobulin T-cell receptors (also called as IgTCR or T bodies) are the most commonly described constructs. They are created by joining the variable domain of an immunoglobulin with an intracytoplasmic signaling molecule. They unite the specificities of antibodies with the potency of cellular killing by transposing antibody recognition to T cells. T cells expressing these chimeric TCR are redirected to kill tumor cells that express antigen on their surface. The generation of T lymphocytes with an antibody-dictated specificity allows targeting toward any tumor-associated antigen for which a monoclonal antibody exists. In contrast to the lengthy process of selection and expansion of lymphocytes with native specificity for target antigens, large populations of antigen-redirected T lymphocytes can be obtained by simple retroviral transduction. Since chimeric TCR based on immunoglobulin provide T-cell activation in an MHC-unrestricted manner, mechanisms of tumor escape from T-cell recognition, such as downregulation of HLA class I molecules and defects in antigen processing, are bypassed. T-cell-mediated effector functions are much more likely to result in tumor cell lysis than humoral immune responses alone. Cytokine secretion upon T-cell activation by tumor antigen will result in the recruitment of additional components of the immune system, amplifying the antitumor immune response. Furthermore, unlike many intact antibodies, T cells can migrate through microvascular walls, extravasate, and penetrate the cores of solid tumors to exert their cytolytic activity.

These predictions have been tested *in vivo*. In a mouse model of ErbB2-expressing ovarian carcinoma, for example, autologous lymphocytes expressing scFv- ζ TCR directed against ErbB2 were infused into tumor-xenografted mice, resulting in total regression of the tumors.⁸⁸ Similarly, lymphocytes expressing scFv against CEA fused with Fc ϵ Ig were effective at rejecting colon carcinomas in a mouse model of this tumor.⁸⁹ Chimeric receptors can also activate homing—ErbB2-targeted T cells labeled with fluorescent dye were specifically detected in the tumor tissue of SCID mice bearing ErbB2⁺ tumors.⁹⁰

The first clinical trials of a chimeric TCR was performed with an HIV-Env-specific CD4 ζ construct expressed in either autologous or syngeneic T cells.⁹¹ No specific effect on HIV viral load could be demonstrated, and transduced T cells persisted only at very low levels. The outcome of this study is representa-

Figure 28.2 Artificial TCR (dimer) and native TCR. Artificial receptor components can be divided into two groups. External section is involved with antigen recognition. This is usually composed of a Single Chain Variable Fragment (ScFv) derived from a monoclonal antibody. This is connected to the internal section of the receptor via a flexible spacer which allows the receptor multiple orientations. The internal section transmits signal. In this figure we show a signaling domain composed of a fusion of signaling portions of CD28 and CD3 ζ . This receptor is capable of transmitting a CD3 ζ signal and CD28 co-stimulatory signal upon antigen recognition. Simplicity of artificial receptor is contrasted to the complexity of the native TCR which requires an aggregate of multiple proteins to transmit a similar signal. See Plate 7.

tive of many others, and demonstrates the limitation of chimeric TCR. The signaling function of engineered chimeric proteins is much less effective than that of the native TCR, during which CD4 or CD8 coreceptors are recruited to the signaling complex via their interaction with class I and II MHC molecules. These coreceptors bring Src kinases to the TCR, promoting phosphorylation of TCR immunoreceptor tyrosine-based activation motifs (ITAM) and enhancing signaling severalfold.⁹² Furthermore, the engagement of just the TCR is not sufficient to achieve full T-cell activation. A costimulatory signal from CD28 is required to cause clonal expansion and full activation of T cells. Chimeric receptors with just a TCR ζ -chain intracellular sequence do not fully activate naive T cells in transgenic mice.⁹³ In essence, chimeric TCR act as crude triggers of cell killing but lack the signaling components to fully activate and induce proliferation of T cells.

Deficient signaling may be overcome in a number of ways. The endodomains can be modified to transmit a more complete signal. For example, constructs containing endodomains composed of the intracellular segment of CD28 joined to that of CD3 ζ were able to activate T cells and trigger killing of targets and proliferation.^{94,95} More complex endodomains involving portions of different costimulatory molecules have also been described.⁹⁶ Alternatively, investigators have generated 'bi-specific' T cells. Autologous T cells that recognize a powerful antigen unrelated to the tumor (e.g. allo or viral antigens) are expanded by repeated stimulation and subsequently transduced with a chimeric receptor before being returned to the patient. Activation via their native TCR leads to their persistence and activation. Recognition of tumor by their chimeric TCR triggers killing of targets. In other words, tumor killing is 'piggy-backed' onto a more potent antigen response.^{97,98}

T-cell modification to improve survival or overcome tumor evasion mechanisms

Adoptively transferred T cells must still face tumor evasion strategies, and hence frequently persist and function poorly in vivo.^{99,100} Genetic modification may circumvent this obstacle. For example, IL-2 administration improves the survival of infused lymphocytes but is toxic at the required doses.¹⁰¹ Genetically modified lymphocytes producing IL-2 should result in high local concentration and could

improve their persistence without systemic toxicity. Liu and Rosenberg¹⁰² transduced melanoma-reactive human T cells to secrete IL-2, and after stimulation these cells proliferated without addition of exogenous IL-2. Furthermore, transduction did not alter their specificity or ability to recognize tumor cells. An alternative strategy to promote survival is to transduce T cells with an anti-apoptotic gene. Transduction of T cells with a *BCLX*-expressing retroviral vector results in partial resistance to Fas anti-body-induced apoptosis.¹⁰³ Unfortunately, concerns over oncogenesis (see below on gene therapy as a cause of leukemia) render these types of growth-promoting activities unlikely to be evaluated clinically in the near future.

The immunosuppressive cytokine transforming growth factor β (TGF- β) is secreted by many tumors. In murine models of both thymoma and malignant melanoma, transgenic mice genetically engineered so that all of their T cells are insensitive to TGF- β signaling were able to eradicate tumors.¹⁰⁴ In a preclinical human study, EBV-specific CTL were transduced with a retroviral vector expressing a mutant dominantnegative TGF- β type II receptor (DNR) that prevents the formation of the functional tetrameric receptor. Cytotoxicity, proliferation, and cytokine release assays showed that levels of exogenous TGF- β inhibitory to wild-type CTL had minimal inhibitory effects on DNR-transduced CTL.¹⁰⁵ If long-term murine toxicity studies continue to confirm that DNR-transduced CTL are not tumorigenic, this approach may be useful not only for Hodgkin lymphoma but also for other lymphomas and solid tumors that secrete TGF- β .

Suicide genes

Suicide genes make transduced cells susceptible to an agent that is not ordinarily toxic. More than a dozen examples of these systems exist, but the most widely used clinically is the thymidine kinase gene from herpes simplex virus 1 (*HSV-tk*). This enzyme phosphorylates the prodrug ganciclovir, which results in the death of dividing cells when subsequently incorporated into DNA.

These genes have been used to treat relapsed leukemia after allogeneic stem cell transplantation. After this procedure, donor T cells contribute to a graft-versus-leukemia effect to reduce relapse, facilitate engraftment, and reduce opportunistic infections. Nevertheless, in a subset of patients, donor T cells can cause potentially lethal graft-versus-host disease (GVHD). The introduction of a 'suicide gene' in donor T cells that can be activated *in vivo* allows for their positive effects to be manifest, with the option of their possible subsequent deletion should GVHD ensue. Donor T lymphocytes transduced with *HSV-tk* have been administered to patients after T-cell depletion.^{106,107} In these studies, administration of ganciclovir alone resulted in resolution of GVHD in five out of seven patients. Although these studies demonstrated proof of principle, *HSV-tk* therapy has several limitations. Ganciclovir must often be administered to treat cytomegalovirus (CMV) infection or reactivation after bone marrow transplantation, resulting in deletion of the needed donor T cells. HSV-tk is a virus-derived protein and is strongly immunogenic. Hence, cells expressing the protein are likely to survive only in immunosuppressed patients. Even then, an immune response may be detected.¹⁰⁶ In more immunocompetent patient groups, *HSV-tk*-transduced cells are rapidly deleted.¹⁰⁸

More useful suicide genes encoding for non-immunogenic proteins with low basal toxicity but high efficacy after triggering are under development. For example, a suicide system has been developed that is based on endogenous pro-apoptotic molecules linked to modified FK506-binding proteins (FKBP). These molecules contain a binding site for a lipid-permeable chemical inducer of dimerization.¹⁰⁹ Administration of this dimerizing drug results in the aggregation of two or more chimeric pro-apoptotic molecules, leading to their activation and thus apoptosis. Similarly, inducible Fas is based on a self-protein and should be non-immunogenic.¹¹⁰ Its inducer, AP1903, seems to lack toxicity.¹¹¹ Another possibility is to use inducible caspase molecules. These constructs may improve function, since caspases are downstream of Fas in the apoptosis-signaling cascade, distal to many antiapoptotic molecules, such as c-FLIP and BCL2. Human *CD20* has also been proposed as a non-immunogenic suicide gene. Exposure to a monoclonal chimeric anti-CD20 antibody (rituximab), in the presence of complement, results in rapid killing of transduced cells.¹¹² This strategy precludes the need for coexpression of a surface marker for sorting. However, rituximab will result in the unwanted loss of B cells as well as donor T cells. Since transduction can never be 100% efficient in any of these systems, coexpression of a non-immunogenic selectable marker together with the suicide gene is required to allow for selection of suicide gene-expressing cells. An internal ribosomal entry site (IRES) or a linker sequence containing a cleavage site that will be cut by endogenous proteases post protein translation (e.g. FMDV 2 A peptide) may be useful in obtaining reliable coexpression of both genes.¹¹³

Sensitivity of host cells to cytotoxic drugs

If HSC could be rendered resistant to one or more cytotoxic drugs, they might be able to resist the myelosuppressive effects of cytotoxic drugs during leukemia therapy, allowing longer or more intensive therapy that could cure additional patients.¹¹⁴⁻¹¹⁶

The *MDR1* gene has been the most widely considered for human therapy. Its product, P-glycoprotein, func-

tions as a drug efflux pump and confers resistance to many chemotherapeutic agents.¹¹⁷ The feasibility of using *MDR1* to protect hemopoietic cells has been demonstrated by transgenic mouse experiments,^{118,119} and retroviral transfer of *MDR1* to murine clonogenic progenitors conferred drug resistance both in vitro and in vivo.¹¹⁹ These experiments with *MDR1* containing vectors prove the principle that drug-resistance genes can be used to attenuate drug induced myelosuppression. It is likely that other drug resistance genes could function analogously. DNA methylguanine methyltransferases (MGMT) are enzymes that repair DNA damage induced by the nitrosoureas, a class of alkylating agents used widely in cancer chemotherapy. Preliminary data suggest that retrovirally mediated gene transfer of the human *MGMT* gene to mouse bone marrow cells results in protection of murine progenitors from toxicity produced by carmustine (BCNU).¹²⁰ Other drug resistance genes, including those for dihydrofolate reductase and topoisomerase II, are also under consideration for clinical testing. In a human breast cancer study, a significant proportion of hematopoietic cells were protected when expression levels of drug-resistance genes were adequate to reduce the sensitivity of stem cells to chemotherapeutic agents.¹²¹

The clinical application of drug-resistance gene transfer has several potential pitfalls. The low efficiency of stem cell transduction observed with current clinical protocols predicts that drug-induced myelosuppression cannot be ameliorated unless there is dramatic progress in vector targeting. There is also the risk of transferring the genes to neoplastic cells that contaminate the hematopoietic stem cell graft and produce drug-resistant relapse. Finally, toxicity to non-protected organs—including gut, heart, and lungs—may rapidly supervene when marrow resistance allows intensification of cytotoxic drug dosages.

Gene marking

The underlying principle of gene marking is that the transfer of a unique DNA sequence into a host cell will allow its easy subsequent detection, thereby serving as a marker of these labeled cells. Gene marking is not intended for any direct therapeutic benefit, but rather to obtain information regarding the biology and function of adoptively transferred cells.

In autologous stem cell transplantation

Autologous HSC rescue has shown promise as effective treatment for leukemias and lymphomas,^{122–125} although disease recurrence continues to be the major cause of failure. Whether recurrence originates from stem cell harvest or residual disease is unclear.^{122–127} Concern that the HSC may contain residual malignant cells has led to extensive evaluation of purging techniques.^{128–131} However, no method has been unequivocally shown to reduce the risk of relapse in naturally occurring disease,^{127–132} and purging techniques usually slow engraftment due to damage to normal progenitor cells.

By marking stem cells prior to their infusion, we can determine if contaminating malignant cells in the stem cell harvest contribute to relapse following autologous stem cell transplantation.¹³³ The HSC product is marked at the time of harvest with retroviral vectors encoding the neomycin resistance gene (*neo*). Then, at relapse, it is possible to detect whether the marker gene is present in the malignant cells. Since 1991, this strategy had been studied in a variety of malignancies treated by autologous HSC transplantation,^{133–137} including AML, CML, ALL, neuroblastoma, and lymphoma. In pediatric patients receiving autologous bone marrow transplantation as part of therapy for AML, 4 of 12 patients who received marked marrow relapsed. In 3 of the patients, detection of both the transferred marker and of a tumor-specific marker in the same cells at the time of relapse provided unequivocal evidence that the residual malignant cells in the marrow were a source of leukemic recurrence.

More difficult questions can be answered by simultaneously marking cells with different vectors. For instance, what are the effects of purging on relapse and engraftment? Comparison of two purging methods, 4-hydroperoxycyclophosphamide (4-HC) and culture with IL-2, by differential marking revealed greater contribution to hematopoietic reconstitution by 4-HC-purged marrow.¹³⁸ Notably, in these studies, marker gene levels were lower than in studies using unpurged marrow.

No in vitro assay can yet assess the capacity to repopulate the hematopoietic compartment. Differential marking in single patients allows comparison of these properties between different sources of stem cells (e.g. peripheral blood versus marrow), the function of different subpopulations, and the consequences of ex vivo manipulation, such as stromal support or cytokines. For instance, it is possible to use growth factors such as IL-1, IL-3, and stem cell factor to increase by 10- to 50-fold the numbers of hematopoietic progenitor cells.¹³⁹ It is not certain that such ex vivo data will be reflected by results in vivo. In primate and human studies, transplantation of marrow treated ex vivo with growth factor combinations that greatly augment both progenitor numbers and gene transfer rates yielded disconcertingly low levels of long-term gene expression in vivo.¹³⁹ The likeliest explanation for this seeming paradox is that many of the growth factors intended only to induce cycling in marrow stem cells also induce their differentiation and the loss of their self-renewal capacity. Another useful comparison is the repopulating capabilities of autologous bone marrow CD34⁺ cells and peripheral

blood stream cells.¹⁴⁰ Judging by differential marking, the latter cells contributed to hematopoietic earlier and for longer times.

These marking studies also provided information on the transfer of marker genes to normal hematopoietic cells and showed that marrow autografts contribute to long-term hematopoietic reconstitution after transplantation.¹⁴¹ Long-term transfer for more than 10 years has been seen in the mature progeny of marrow precursor cells, including peripheral blood T and B cells and neutrophils.¹³⁸

T-cell marking

Several studies have also shown the feasibility of gene-marking CTL to track their expansion, persistence and homing to sites of disease.^{81,142,143} For example, gene marking of EBV-specific CTL for the prophylaxis and treatment of lymphoproliferative disorders post HSC transplantation has demonstrated the persistence of gene-marked CTL for 78 months post infusion. In addition, gene-marked EBV-CTL given as treatment for relapsed Hodgkin lymphoma have been shown to traffic to tumor sites.¹⁴³

New methodologies

Two new techniques will allow even more informative marking trials. Quantitative real-time polymerase chain reaction (PCR) enables simple, highly accurate quantification of integrant copy number that can easily be standardized against an internal control. This is a significant improvement over the semiquantitative PCR techniques used previously. In addition, every retroviral integration event results in a unique integration site in genomic DNA. The progeny of a transduced cell will bear the same integration site, and cutting of PCR-amplified flanking DNA with a restriction endonuclease yields multiple fragments whose lengths are unique to the integration site. The number of fragments from a given sample indicates 'clonality'. Individual fragments can be sequenced and the precise location of integration elucidated.¹⁴⁴ Detection systems specific to a particular provirus-flanking region can be developed and will allow precise tracking of an individual clone. This approach allows the evolution of clones and the true pluripotency of transduced cells to follow over time. We can even begin to hypothesize about such things as the number of true stem cells in harvested marrow or blood. Importantly, a reduction in the number of clones with a rise in marker levels may herald the emergence of integration-induced leukemogenesis, as described below.

Gene therapy as a cause of leukemia

Any vector that randomly inserts its genetic information into the genome of target cells is, by definition, causing insertional mutagenesis. Hence, the risk of insertional mutagenesis disrupting normal gene function, inactivating tumor suppressor genes, or activating oncogenes should be directly proportional to the number of insertion/integration events. However, the activation of a single proto-oncogene by itself should not be sufficient to convert a normal cell into a tumor cell—rather multiple gene disruptions would be required. Since current integrating vectors are inefficient, transducing a small proportion of cells with a low retroviral copy number, the risk of inducing a malignant change has always been considered to be small. Until recently, the only description of retroviral vector-related tumorigenesis in humans or non-human primates was in a monkey who developed T-cell lymphoma following transduction with a replication-competent retroviral vector. Analysis of the tumor revealed multiple integration sites caused by chronic productive retroviral infections,¹⁴⁵ further supporting the belief that the replication-incompetent retroviruses used clinically would not share this predisposition.

Unfortunately, this confidence was shattered by reports of two cases of T-ALL in 11 patients with common γ -chain deficiency (*X-SCID*) who received retrovirally corrected autologous stem cells.¹⁴⁶ Subsequent integration analysis revealed single integrations in each T-ALL line, both of which were proximate to *LMO2*, a locus known to be involved in T-cell growth and differentiation. Why was this single integration event sufficient to trigger leukemia? The common γ chain is involved in transmitting potent proliferative signals. In the construct used, expression was controlled by the retroviral long terminal repeat (LTR) rather than by the gene's native promoter system. Overexpression of the common γ chain together with activation of *LMO2* at some stage of T-cell development may be sufficient for leukemogenesis. A similar observation was made when mice transplanted with stem cells transduced with truncated nerve growth factor receptor (dLNGFR) developed AML with a single integration involving the *Evi1* gene.¹⁴⁷ Like *LMO2*, disruption of *Evi1* was not felt to be sufficient on its own to cause AML. In other words, the transgene itself represents the 'second hit'. If this hypothesis is correct, the approaches that we have outlined for the gene therapy of leukemia are unlikely to prove problematic, since few involve the introduction of unregulated T-cell growth factors. While continued caution is essential, it is also important to remember that many hundreds of cancer patients have received retrovirally transduced cells without developing leukemia.

Summing up

Figure 28.3 shows the distribution of attempts at cancer gene therapy thus far, and Table 28.2 lists some current studies of interest. Many obstacles must be

Figure 28.3 Distribution of cancer-gene therapy protocols in North America to date.

Table 28.2 Some examples of current cancer gene-therapy protocols

Study	Title, institution, and comments
9803–242	A phase I study of CD40L gene-transduced leukemia cells in patients with chronic lymphocytic leukemia University of California, San Diego Investigators here modified autologous CLL cells by transducing them with an adenovirus containing a coding sequence for CD40L. These CD40L-expressing autologous CLL cells are then administered to the patient as a tumor vaccine. This phase I study has now closed and demonstrated some clinical benefit. This approach is being pursued in a phase II study
9705–188	Autologous transplantation for chronic myelogenous leukemia with stem cells transduced with a methotrexate resistant DHFR and Anti-BCR/ABL containing vector and post transplant methotrexate administration University of Minnesota, Minneapolis This is an example of a study where the retroviral vector provides antisense sequences that directly target the genetic cause of the malignancy—in this case <i>bcr/abl</i> . Transduced marrow is also rendered resistant to methotrexate
0310–608	Administration of LMP2a specific cytotoxic T lymphocytes to patients with relapsed EBV-positive Hodgkin’s disease Baylor College of Medicine, Houston, Texas In this study, gene-transfer technology is used to facilitate ex vivo selection and expansion of tumor-specific T cells. Dendritic cells are transduced with an adenovirus coding for a tumor antigen, LMP2. These transduced dendritic cells are used to selectively stimulate LMP2-specific T cells from peripheral blood mononuclear cells. Neither transduced cells nor vector are directly administered to the patient
0005–400	Transfer of the multidrug resistance gene, <i>MDR-1</i> , to hematopoietic progenitors from patients with high-risk lymphoma University of Massachusetts Medical School Cancer Center, Worcester This is an example of a chemoprotection study. Transduced, read ministered marrow should be resistant to subsequent chemotherapy
9907–330	Autologous CD8 ⁺ T-lymphocyte clones transfected to express CD20-specific scFvFc-ζ as therapy for recurrent/refractory CD20 ⁺ lymphoma City of Hope National Medical Center, Duarte, California Investigators retarget T cells to recognize CD20 with an artificial T-cell receptor. This study will have the potential side-effect of depleting normal B cells as well as tumor cells
0205–535	Phase I study to evaluate the safety of cellular immunotherapy for high-risk CD19+ acute lymphoblastic leukemia after autologous hematopoietic stem cell transplantation using genetically modified CD19-redirectioned autologous cytolytic T-cell clones City of Hope National Medical Center, Duarte, California This study is similar to 9907–330, except here CD19 is targeted by an artificial receptor instead of CD20. As well as an artificial receptor, cells are engineered to express a suicide gene, <i>HSV-tk</i> . This renders T cells susceptible to ganciclovir. If unacceptable side-effects occur, the investigators have the option of administering ganciclovir, which will delete transduced T cells
0301–564	Autologous T cells retrovirally transduced to express anti-CEA-scFv-CD28ζ as therapy for adenocarcinoma Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts The first proposed clinical study of second-generation artificial TCR that incorporate a CD28 signal as well as a ζ signal

removed before the extraordinary potential of gene transfer can be fully exploited in therapy for hematologic malignancies. However, most advances in medicine proceed incrementally. Gene transfer is already being used successfully to complement conventional therapies for malignant hematologic disorders, it is facilitating the development of cytotoxic T-cell therapies for leukemia and lymphoma, and it is being explored as a means of generating leukemia vaccines. The benefits of this new technology can only increase as current limitations are progressively—albeit slowly—surmounted.

Allogeneic stem cell transplantation

Richard J O'Reilly, Esperanza B Papadopoulos, Trudy N Small, and Stephen Mackinnon

Introduction

Bone marrow transplantation (BMT) from a human leukocyte antigen (HLA)-matched sibling is considered the treatment of choice for patients with acute myeloid leukemia (AML)¹ or acute lymphoblastic leukemia (ALL)² at high risk for relapse in first remission and for all patients with acute leukemia in second or greater remission, aplastic anemia,³ myelodysplastic syndromes (MDS; reviewed in reference 4), and several lethal forms of immunodeficiency, such as Wiskott-Aldrich syndrome and severe combined immunodeficiency (SCID; reviewed in reference 5). For selected patients with chronic myeloid leukemia (CML),⁶ non-Hodgkin lymphoma (NHL),⁷ or Hodgkin's disease,⁸ as well as those with hemoglobinopathies, particularly β -thalassemia (reviewed in reference 9), allogeneic BMT may offer a considerable advantage over other forms of treatment.

Over the last 20 years, tremendous progress has been made in our understanding of the human histocompatibility gene complex and the cellular mechanisms giving rise to graft rejection and graft-versus-host (GVH) disease (GVHD). This has resulted in more precise HLA typing that has improved selection of potential unrelated donors, and has led to the emergence of more effective strategies to ensure engraftment and to prevent or ameliorate GVHD. Marked progress has also been made in supportive care measures and in the treatment and prevention of opportunistic infections following BMT. In this chapter, we shall describe the clinical features of allogeneic marrow grafts, focusing on the biologic and therapeutic determinants of a successful transplant at each of the different stages of its development. We shall also delineate the genetic and cellular characteristics of the graft and host that affect outcome. We shall then review recent advances in transplantation medicine and their impact on the results of allogeneic hematopoietic stem cell transplants applied to the treatment of hematopoietic malignancies.

Clinical and biological characteristics of allogeneic BMT applied to the treatment of hematological neoplasia

Identification of donors suitable for allogeneic BMT—the HLA gene complex: the major determinant of histocompatibility in human BMT

Experimental murine models demonstrating the relevance of matching for the major histocompatibility complex (MHC) to the prevention of lethal GVHD¹⁰ paved the way for the initial successful applications of HLA-matched marrow grafts in humans.^{11,12} The major histocompatibility region in humans, located on the short arm of chromosome 6, encodes a series of genes, each exhibiting an extensive degree of allelic polymorphism (Figure 29.1).¹³ This complex is divided into:^{13,14}

- class I genes (HLA-A, -B, and -C), encoding proteins expressed on the surface of all nucleated cells;
- class II genes (HLA-DR, -DQ, and -DP), encoding surface proteins on a more limited number of cell types, such as early hematopoietic cells, tissue macrophages, circulating monocytes, dendritic cells, endothelial cells, B cells, and activated T cells;
- class III genes, encoding other functional proteins, such as the complement proteins C2 and C4.

The HLA genes are codominantly expressed. Within a family, identification of parental haplotypes inherited by each sibling can usually be ascertained by serologic typing of HLA-A, -B, -C, and -DR determinants of a patient, siblings, and parents. Classically, histocompatibility within the HLA-D region can be defined by mutual unresponsiveness in mixed lymphocyte culture (MLC).¹⁵ Parental HLA haplotypes are usually inherited en bloc, giving rise to a 1-in-4 likelihood

Figure 29.1 Map of expressed genes of the HLA region on the short arm of chromosome 6.

that any two siblings will be genotypically HLA-matched. Because there are often more than two children in a sibship, HLA-identical siblings can usually be identified for 35–40% of individuals. For an additional 5% of patients, a phenotypic match or a partially HLA-mismatched family donor can be found.

An HLA-compatible unrelated donor can also be identified for a proportion of patients by searching among HLA-typed volunteer marrow donors participating in large registries. The combined pool of these registries now includes over 8 million volunteer donors. Currently, these registries can identify HLA-compatible unrelated donors for the majority of patients of European Caucasian ancestry, particularly patients inheriting common HLA-A, -B, and -DR haplotypes.^{16,17} Unfortunately, because the number of volunteers derived from ethnic minorities is still limited, the proportion of successful searches for patients in these minority groups is much lower.

Despite serologic matching for HLA-A, -B, and -DR, the incidence of graft rejection and severe GVHD following a serologically matched unrelated BMT is significantly higher than that observed following an HLA-matched sibling BMT.^{17,18} Based on these findings, several groups have been examining whether and to what degree unrelated serologically HLA-matched donor-recipient pairs are actually matched at the molecular level. More recently, molecular tissue typing of donor and recipient DNA by PCR-based techniques has generally been adopted. These sequence-based typing methods include singlestrand conformational polymorphisms (SSCP) and sequence-specific oligonucleotide probes (SSOP).¹⁹ These methodologies have allowed us to distinguish multiple molecular variants of many serologically defined alleles within of both HLA class I and class II. Reference strand-mediated conformation analysis (RSCA) is a novel conformational method that offers high resolution and high sample throughput for typing the HLA class I and class II genes. This technique differs from conventional sequence-based typing methodologies in that the HLA type is assigned on the basis of accurate measurement of conformation-dependent DNA mobility in polyacrylamide gel electrophoresis (PAGE). RSCA has been successfully applied in blind studies of HLA typing, demonstrating that it is reproducible, able to identify new alleles, and able to resolve ambiguous heterozygous combinations.²⁰ Several of these micro variants can also be distinguished *in vitro* by cloned alloreactive T cells. T cells reactive against certain micro variants, such as microvariants of HLA-B44, have been implicated as effectors of marrow allograft rejection²¹ and GVHD.²² One or more microvariant disparities between patients and potential unrelated donors serologically matched for HLA class I alleles have been detected in 30–48% of cases in different series.^{23,24} Studies of the clinical relevance of these disparities to graft rejection and GVHD are now being conducted,^{16,21} and will be discussed later in this chapter.

Minor alloantigen systems contributing to graft rejection and GVHD following BMT in humans

Although the proteins encoded by the HLA gene complex are the major determinants of histocompatibility in humans, other alloantigens affect the engraftment of a hematopoietic stem cell graft in non-syngeneic hosts and the reactivity of donor lymphoid cells against the transplant recipient. Despite the use of aggressive pretransplant immunosuppression and post-transplant GVHD prophylaxis, marrow transplants from HLA genotypically identical siblings are still associated with a significant risk of graft rejection and GVHD (see below). These clinical manifestations of alloreactivity have been ascribed to the ability of host or donor T cells to react against minor alloantigens unique to the hematopoietic cells of the donor graft or host tissues, respectively. Several polymorphic minor alloantigenic systems, such as the MLS, H-Y, and QA-1 alloantigens, have been identified as potential targets of allointeractions in murine models.^{25,26}

Although there have been reports linking the emergence of host-type minor alloantigen-reactive,

HLA-restricted T cells capable of inhibiting clonogenic donor hematopoietic cell growth with graft rejection and GVHD,^{27,28} the minor alloantigens actually targeted during human marrow allograft rejections or GVHD remain poorly defined. One minor alloantigen, H-Y, which is encoded by the human Y chromosome, is expressed on male hematopoietic cells, and can be a target for cytotoxic T cells.²⁹⁻³¹ The increased risk of graft rejection in women transplanted with marrow from male donors and the increased likelihood of GVHD following transplantation of males with bone marrow derived from females have been hypothesized to be due to in vivo responses to the H-Y alloantigen.³²⁻³⁵ An H-Y peptide epitope presented by HLA-A2, -A1, -B7, and -B60 has been isolated and sequenced. This nonameric peptide, FIDSYICQV, is encoded by a gene that maps to the centromeric portion of the Y chromosome.^{36,37} HLA-A2-restricted H-Y-specific T cells have been implicated in the pathogenesis of marrow graft rejection.³⁸ Intriguingly, however, one large series has failed to implicate H-Y-specific responses in GVHD developing in HLA-matched male recipients of female sibling marrow bearing the appropriate HLA-restricting elements HLA-A2 or HLA-A1.³⁹

Other human minor alloantigens encoded by autosomal genes have also been identified. Goulmy and co-workers^{29,40} have generated T-cell clones from marrow allograft recipients that are HLA-restricted and recognize at least five antigens on hematopoietic cells (HA-1 to HA-5). These antigens appear to be the products of non-allelic genes that segregate in a Mendelian mode of inheritance. HA-1, HA-2, and HA-5 are expressed only by cells derived from the hematopoietic system, while HA-3 and HA-4 are expressed on a wider array of cell types.^{40,41} Differences within HA-1 have been implicated in GVHD.³⁹

The nature of the minor HA alloantigens targeted was completely unknown until 1995, when den Haan et al⁴² succeeded in acid-eluting and isolating the HA-2 peptide antigen from its HLA-restricting element by reverse-phase high-performance liquid chromatography (HPLC). To distinguish the relevant peptide antigen, target cells with the same HLA-restricting element were pulsed with isolated peptides and exposed to HA-2 minor alloantigen-specific cytolytic T cells. Thereafter, the peptide was sequenced. The amino acid sequence of HA-2 revealed that this antigen belongs to the non-filamentous class I myosin family of proteins, which contribute to cell locomotion. Studies are currently underway to determine whether this protein displays allelic polymorphisms. More recently, the HA-1 minor alloantigen has also been isolated and sequenced. Interestingly, this antigen appears to have two different alleles that can be distinguished by HLA-restricted T cells.⁴³ Ultimately, typing for these alleles may improve the selection of donors comparably matched for their HLA determinants.

Biologic and therapeutic determinants of engraftment

Pretransplant immunosuppression and myeloablation

Allogeneic hematopoietic and lymphoid cell grafts are more susceptible to growth inhibition or rejection by host resistance systems than grafts of solid organs such as the kidney. As a consequence, durable engraftment and expansion of allogeneic marrow cells can only be achieved if the host's immune system is ablated. Only patients with SCID are sufficiently immunocompromised to permit consistent engraftment of unmanipulated HLA-matched marrow grafts without preparative treatment with immunosuppressive drugs. Although the preparative regimens utilized for patients with leukemia are largely designed to eliminate leukemic clones, they must also be sufficiently immunosuppressive and myeloablative to ensure engraftment of transplanted allogeneic hematopoietic cells. Initially, total-body irradiation (TBI) administered in a single dose of 10 Gy combined with cyclophosphamide was used for this purpose.⁴⁴ However, in the last 15 years, other cytoreduction regimens have been introduced that incorporate larger doses of fractionated TBI⁴⁵ and other chemotherapeutic agents such as etoposide,^{46,47} cytarabine,^{48,49} melphalan,⁵⁰ thiotepa^{1,51-53} and fludarabine.⁵⁴ High-dose busulfan combined with cyclophosphamide has also been utilized to avoid the use of TBI.⁵⁵

The concept that engraftment of hematopoietic cells can only be achieved if ablative doses of drugs are administered prior to transplant has been effectively challenged by durable engraftment with persistent mixed or full donor chimerism after less intensive, non-myelablative chemotherapeutic regimens. Such sublethal, non-ablative regimens may ultimately significantly extend the application of allogeneic stem cell transplants, permitting the transplantation of older patients, patients with more chronically debilitating hematopoietic malignancies such as myeloma, and patients with genetic disorders such as Fanconi anemia,⁵⁶ who tolerate current high-dose alkylating agent-based preparative regimens poorly. However, clinical trials with longer follow-up are still needed to adequately assess the potential of these promising approaches to induce durable engraftment and longterm eradications of the patient's underlying malignancy.

Sources of allogeneic hematopoietic cells for transplantation

Until relatively recently, allogeneic transplants have almost exclusively used the donor's marrow as the source of hematopoietic stem cells. In the last 5-10 years, granulocyte colony-stimulating factor (G-CSF)-mobilized peripheral blood stem cells

(PBSC), which have been shown to be enriched for CD34⁺ primitive progenitors,^{57–59} and umbilical cord blood cells derived from normal HLA-matched related or unrelated donors have been increasingly used as sources of hematopoietic progenitors for transplantation. Experience with allogeneic cord blood transplants will be summarized in a later section of this chapter. However, since many centers are now beginning to use donor PBSC instead of bone marrow, current estimates of the advantages and potential disadvantages of PBSC transplants (PBSCT) in comparison with BMT need to be briefly summarized. The potential advantages of G-CSF-stimulated PBSC are several. First, they can provide doses of CD34⁺ progenitors that are four- to fivefold higher than those contained in a marrow allograft.^{58,59} This increased dose of progenitor cells facilitates engraftment. Furthermore, as noted above, PBSCT may contain tenfold more T cells than a marrow graft. These additional donor T cells may be associated with potentially good and harmful effects, namely enhanced antileukemic effect and an increased incidence of GVHD. Lastly, at any given dose of progenitor cells, G-CSF-stimulated PBSC induce a somewhat more rapid reconstitution of platelet counts, and a comparably rapid recovery of neutrophil counts in the post-transplant period.^{58–61}

The results of several randomized trials addressing the issues of acute and chronic GVHD, relapse, and survival have now been reported.^{62–68} With the exception of the European Group for Blood and Marrow Transplantation (EBMT) trial,⁶³ among the studies listed, the cumulative incidence of acute GVHD was found to be statistically no different whether using PBSC or bone marrow stem cells. Interestingly, the EBMT study (the largest prospective trial) is also the only study using three doses of post-transplant methotrexate as opposed to the customary four doses given for acute GVHD prophylaxis. The probability of chronic GVHD developing has varied by report; four studies showed a significantly higher probability of chronic GVHD after allogeneic PBSCT than after allogeneic BMT. This includes a retrospective registry analysis of 824 patients who underwent allotransplantation.⁶⁹ In contrast, the other studies do not show a statistically significant difference. These studies showed, with one exception,⁶⁶ no obvious difference in the relapse rates between allogeneic PBSCT and BMT. Patients with low-risk disease had similar rates of disease-free survival irrespective of the stem cell source. On the other hand, two of the larger randomized trials^{64,67} show a significant difference in overall survival favoring PBSCT, largely because of lower transplant-related mortality in patients with advanced-stage disease. There are also data indicating that recipients of allogeneic PBSCT have faster immune reconstitution than recipients of BMT.⁷⁰

In summary, PBSC grafts may improve disease free survival in patients with advanced disease but may only lead to more chronic GVHD in patients with standard-risk disease without improving survival.

The pre-engraftment period

Following infusion of the stem cell allograft, the hematopoietic progenitor cells migrate to the bone marrow and spleen. Marrow cellularity begins to recover 10–14 days following a transplant, and, by 10–21 days post grafting, neutrophils of donor origin can be detected in the circulation. Prior to this time, patients are profoundly pancytopenic and require intensive support with platelet and red cell transfusions as well as broad-spectrum antimicrobial therapy for presumed or documented infections. All blood products, including fresh frozen plasma (FFP), infused to support transplant recipients must be irradiated, since they contain allogeneic lymphocytes capable of inducing lethal third-party GVHD.⁷¹

Prior to neutrophil engraftment, patients are susceptible to both bacterial and fungal infections. The risk of neutropenic sepsis is increased by the toxicity of the conditioning regimen, which may be further exacerbated by methotrexate given to prevent GVHD. This can cause breakdown of the normal epithelial barriers to infection in the mouth and gut. Additionally, the use of tunneled central intravenous lines often leads to infections with gram-positive bacteria from the skin. Viral infections common during this period of neutropenia and lymphopenia principally include recurrences of herpes simplex virus (HSV) types 1 and 2.⁷² These infections may cause significant morbidity. Herpes zoster infections may occur at any time in the post-transplant period, resulting in a cumulative risk of reactivation of herpes zoster in the first 2–3 years post transplant that can be as high as 50%.⁷³ Human herpes virus 6 (HHV6) may also be activated in this period, and has been implicated as a cause of marrow suppression, graft failure, pneumonitis and encephalitis.^{74–76} The BK papovavirus is another virus that commonly reactivates during the post-transplant period. It has been implicated in the pathogenesis of encephalitis/encephalopathy, hepatitis, and, more commonly, hemorrhagic cystitis.^{77–79} Severe enteritis in the early transplant period may be caused by rotavirus and adenovirus.^{80,81} Adenovirus may also cause severe pneumonia, hepatitis, and hemorrhagic cystitis.^{82,83}

Multiple strategies have been developed to decrease the incidence, morbidity, and mortality of these post-transplant infections. Prophylaxis with fluconazole or itraconazole has also been associated with reduced systemic fungal infections.^{84–86} Lipid-based formulations of amphotericin have been used in the treatment of systemic fungal infections, with less renal toxicity.^{87,88} Acyclovir prophylaxis reduces the incidence

of genital and labial herpes simplex infections as well as herpes zoster infections.^{89,90}

Some patients may develop clinical signs and symptoms of hepatic veno-occlusive disease (VOD). These include hepatomegaly, massive ascites, and jaundice.^{91–93} This disorder is caused by damage to the endothelial lining of the hepatic sinusoids, which induces edema and obstruction to the flow of blood through hepatic capillaries and venules. This process may be mild, moderate, or severe.

Certain chemotherapeutic agents also have unique early side-effects requiring careful monitoring and prophylaxis. Cyclophosphamide can cause a cardiomyopathy resulting in decreased cardiac output, particularly in patients who have previously received high doses of anthracyclines or other cardiotoxic agents.^{94,95} Cyclophosphamide can also induce mild to severe hemorrhagic cystitis, a complication that may be prevented by hydration sufficient to sustain a brisk diuresis or continuous direct bladder irrigation for patients who cannot tolerate high doses of parenteral fluids. Mesna may also be used to prevent this complication.^{96–99} High-dose busulfan has been associated with neurotoxicity, including seizures, which can generally be prevented with phenytoin. Busulfan, melphalan, thiotepa, and TBI can cause injury to the pulmonary microvasculature, resulting in interstitial infiltrates and/or diffuse hemorrhages.¹⁰⁰ High-dose cytarabine can cause severe conjunctivitis, which is generally preventable with topical steroids.¹⁰¹ Less frequently, this agent can cause cerebellar toxicity.

Factors affecting engraftment and reconstitution of hematopoietic function

Engraftment post transplant is heralded by the development of donor-derived myeloid and erythroid progenitors in the marrow and the emergence of neutrophils in the blood, generally 10–21 days post transplant. Engraftment of donor hematopoietic and lymphoid cells can be ascertained by several techniques, including conventional cytogenetics,¹⁰² detection of donor-specific restriction fragment length polymorphisms (RFLP),¹⁰³ or minisatellite allelic polymorphisms or, in sex-mismatched pairs, detection of X and Y probes using fluorescence in situ hybridization (FISH) techniques.¹⁰⁴ Persistent thrombocytopenia and leukopenia often complicate intercurrent infections due to viruses, such as cytomegalovirus (CMV)¹⁰⁵ and HHV6, as well as GVHD.¹⁰⁶

Graft failure following allogeneic BMT is empirically defined either as a failure to develop donor marrow function or as marrow aplasia that occurs following initial hematologic reconstitution. Graft failure associated with immune rejection is also documented by the loss of donor lymphoid and hematopoietic cells in the bone marrow and circulation. Most graft failures occur within the first 2 months post transplant, but graft failures as late as 4–5 months post transplant have been reported.

The pre-BMT cytoreductive regimen utilized, the type of transplant administered, and the degree of HLA disparity between donor and host each contribute to the incidence of graft failure. For example, the incidence of graft failure following a transplant of unmodified marrow for aplastic anemia varies from 5% to 30%, depending on the patient's prior transfusion history, if conditioning with Cyclophosphamide alone is utilized.^{34,107,108} If, however, antithymocyte globulin (ATG) or total lymphoid irradiation are added to the conditioning regimen, consistent engraftment is observed.^{3,109,110} Similarly, while unmodified marrow grafts from HLA-matched siblings administered to patients with leukemia cytoreduced with TBI and Cyclophosphamide^{17,111} are rarely associated with graft failure, unmodified grafts from HLA-disparate donors may fail as a result of graft rejection in a significant proportion of cases. Rates of 6–28% have been reported in similarly treated patients when HLA-disparate donors have been used. The risk of graft failure is increased in proportion to the number and type of HLA allodisparities unique to the donor.^{112,113} Depletion of T cells from a marrow allograft renders the graft more susceptible to graft failure and rejection, even if the donor is an HLA-matched sibling.^{40,148,149} Graft failure rates as high as 10–30% and 40–50% have been reported in leukemic recipients of T-cell-depleted HLA-matched^{33,114–116} or two- to three-antigen-mismatched grafts¹⁷¹, respectively.

Identification of the processes contributing to graft rejection and failure has spawned the development of increasingly effective strategies for their reversal or prevention. Principal among these has been the development of tolerable yet more immunosuppressive preparative regimens to eliminate residual host T cells. Examples are intensifications of standard preparative protocols to include additional immunosuppressive drugs such as cytarabine,¹¹⁸ thiotepa,⁴⁹ and fludarabine,⁵⁶ and treatment of the host (either prior to or following the transplant) with T-celldepleting monoclonal or hetero antibodies such as OKT3, Campath-1, and ATG.³³

Acute and chronic GVHD

GVHD is a pathologic process induced by engrafted immunocompetent donor T cells reacting against alloantigens expressed on host cells. The main targets of this reaction are cells originating from the host's lymphohematopoietic system.¹¹⁹ Host dendritic cells appear to be the most potent stimulants of this reaction.¹²⁰ Indeed, recent studies in murine models suggest that functional host dendritic cells are essential for the stimulation and initiation of GVHD by

alloreactive donor T cells in vivo.¹²¹ In response to host alloantigens, donor T cells divide and mature into cytotoxic and helper T cells, which can either directly injure targeted host cells or recruit other cells, such as natural killer (NK) cells and monocytes, to kill host cells.^{122–123} Indeed, such donor T cells specifically reactive against host unique HLA microvariant alleles or against host minor alloantigens have been isolated from the blood and affected tissues of patients suffering from acute GVHD.^{22,39} These activated donor T cells also produce cytokines such as tumor necrosis factor α (TNF- α), which may further contribute to the observed pathology.^{124,125}

Over the past 15 years, the specific types of T cells capable of initiating potentially lethal acute GVH reactions have been extensively characterized. In lethally irradiated mice transplanted with marrow and spleen cells from MHC-disparate donors, either CD8⁺ or CD4⁺ T cells may induce lethal GVHD, depending on whether the MHC disparity unique to the host is an MHC class I or class II determinant.^{126,127} In mice bearing multiple MHC disparities and in outbred species, such as humans, however, depletion of all T-cell subsets is required to prevent GVHD. Selective depletion of CD4⁺ or CD8⁺ T cells alone is ineffective.^{127,128} On the other hand, in murine models, when donor and recipient are H-2-matched but differ for one or more minor alloantigens, depletion of CD8⁺ T cells from the marrow and spleen cell graft may prevent GVHD.¹²⁹ In clinical trials, the incidence and severity of GVHD have also been reduced, but not eliminated, in HLA-matched sibling recipients of CD8⁺ T-cell-depleted marrow grafts administered with cyclosporine and methotrexate prophylaxis post transplant.¹³⁰

The main manifestations of acute GVHD are an erythematous maculopapular skin rash, which may be focal or diffuse, hepatitis, enteritis, and delayed hematopoietic and lymphoid reconstitution.^{131–133} The incidence and severity of acute GVHD are principally related to the type and the degree of allospecificity existing between donor and host.⁵ GVHD is also strongly influenced by host factors such as patient age and sex, intensity of the preparative cytoreduction, presence or absence of concurrent infection, and type of resident microflora, as well as donor features such as gender, previous sensitization to host minor alloantigens by pregnancy, and the number of T cells contained in the marrow allograft.^{32,134,135}

Chronic GVHD is a complex disorder, pathologically distinct from acute GVHD. Although chronic GVHD often develops in patients with antecedent acute GVHD, it may occur de novo late (conventionally defined as later than 100 days) after transplantation, particularly in association with tapering or discontinuation of immunosuppressive drug therapy. Chronic GVHD presents with localized or diffuse sclerotic changes of the skin, with hypo- and hyperpigmentation, focal lichen planus lesions, and, in severe cases, recurrent, superficial skin ulcerations, debilitating scars, and joint contractures. Systemic manifestations may include xerostomia, xerophthalmia, biliary cirrhosis, malabsorption, and failure to gain weight.¹³⁶ A minority of patients with chronic GVHD develop an obliterative bronchiolitis, which may result in chronic obstructive pulmonary disease and death due to respiratory failure or intercurrent pneumonia.¹³⁷

Chronic GVHD also results in impaired hematopoiesis and delayed immune reconstitution. Persistent thrombocytopenia in patients with GVHD is associated with a very poor prognosis.¹³⁸ Prolonged humoral immunodeficiencies, including IgA, IgG2, and IgG4 subtype deficiencies, render these patients highly susceptible to recurrent pyogenic infections caused by *Streptococcus pneumoniae*, *Haemophilus influenzae* and other encapsulated organisms, similar to those observed in individuals with congenital agammaglobulinemia.^{139,140}

Experimental findings suggest that chronic GVHD may be due to ineffectively controlled immunosuppressive and potentially autoreactive T-cell clones, potentially generated in response to populations of host-reactive donor T cells participating in acute GVHD reactions.

As will be discussed subsequently, multiple strategies have been utilized to prevent acute GVHD. However, even when drug prophylaxis with low-dose methotrexate and cyclosporine has been used, 30–50% of patients transplanted with unmodified HLA-identical sibling BMT have developed grade II–IV acute GVHD, requiring systemic immune suppression with high doses of glucocorticoids.^{141,142} Responses to steroid treatment, including stabilization and improvement of the skin rash and the hepatic and gastrointestinal abnormalities, are usually detected within 5–7 days of starting treatment. However, for patients with severe (grade III–IV) GVHD or moderate (grade II) GVHD that is refractory to steroid treatment,¹⁴² prognosis is poor. Additional treatment with ATG, CD3-specific immunotoxins, or other T-cell-specific monoclonal antibodies can often result in complete or partial resolution of the skin manifestations of GVHD, but these agents are less effective in abrogating GVH-induced hepatic and gastrointestinal dysfunction.^{143–145} These secondary therapies for steroid-refractory GVHD may also be relatively toxic, and commonly intensify the host's susceptibility to secondary infection.^{143,144} Unfortunately, the majority of patients with steroidrefractory GVHD, unresponsive to these second-line therapies, will ultimately succumb to sequelae of GVHD or associated infections, particularly CMV-induced interstitial pneumonia, aspergillosis, and bacterial sepsis.^{142,146,147}

Although chronic GVHD is reversible in a significant proportion of patients, responses must be measured over months to years. Without systemic immunosuppression, less than 25% of patients have survived over 18 months.^{146,147} Prolonged treatment with prednisone coupled with azathioprine or cyclosporine can induce slow reversal in up to 76% of cases.^{146,147} In addition, treatment with methoxypsoralen and ultraviolet irradiation may reverse the skin changes associated with chronic GVHD.¹⁴⁸ In steroid-refractory cases, treatments with other immunosuppressive agents, including clofazimine,¹⁴⁹ low-dose total lymphoid irradiation,¹⁵⁰ mycophenolic acid,¹⁵¹ and thalidomide,¹⁵² have been proposed, based on promising results in small reported series. Rates of responses described for these agents range from 10% to 55%. Other strategies, including the use of extracorporeal photopheresis, are also being explored.¹⁵³ The ultimate effectiveness of any or all of these second-line therapies is still in question. Indeed, in one prospective randomized trial, patients with acute GVHD treated with thalidomide to prevent chronic GVHD actually fared less well than those treated with a placebo.¹⁵⁴

Prevention of GVHD by prophylactic use of drugs or antibodies post transplantation

The excessive morbidity and mortality associated with severe GVHD, particularly in recipients of unrelated or HLA-non-identical related marrow transplants, as well as older adults even after HLA-matched sibling transplants, continuously underscore the need for more effective methods for preventing GVHD or abrogating its severity. In view of the essential role of donor T cells in the initiation of GVHD,¹¹⁹ prevention and treatment have focused on two principal approaches:

- administration of combinations of immunosuppressive drugs immediately prior to and following unmodified BMT, in an effort to prevent or inhibit the proliferation and function of donor T cells that are host-reactive;
 - manipulation of the marrow graft to remove alloreactive donor T cells capable of inducing GVHD.

Early studies in a dog model first demonstrated that low-dose methotrexate could significantly decrease the incidence and severity of acute GVHD following DLA-identical marrow grafts. Based on these studies, methotrexate prophylaxis was introduced in clinical trials in the 1970s. Unfortunately, despite such prophylaxis, 50–70% of individuals receiving HLA-identical sibling grafts still developed acute GVHD and 30% developed chronic GVHD. In subsequent randomized trials, cyclosporine alone was found to be equivalent to methotrexate in preventing GVHD.¹⁵⁵ However, the combination of cyclosporine and methotrexate reduced the incidence of acute grade II-IV GVHD following HLA-matched related BMT to 33%, compared with 54% with methotrexate alone ($p=0.014$), resulting in a significantly improved survival in prospective trials.^{156,157} Unfortunately, this combination has had little effect on the incidence or severity of chronic GVHD.

Randomized phase III trials in both the related and unrelated setting comparing tacrolimus (FK506) with cyclosporine in combination with methotrexate for the prevention of GVHD following HLA-matched sibling transplants have demonstrated a significant reduction in the incidence of acute grade II-IV GVHD in those given tacrolimus versus cyclosporine.^{158,159} In the sibling trial,¹⁵⁹ the incidence of grade III-IV acute GVHD was similar in both arms. There was no difference in the incidence of chronic GVHD between the tacrolimus and the cyclosporine. The relapse rates of the two groups were similar. The patients in the cyclosporine arm had a significantly better 2-year disease-free and overall survival than patients in the tacrolimus arm. There was a higher frequency of deaths from regimen-related toxicity in patients with advanced disease who received tacrolimus. There was no difference in the disease-free and overall survival in patients with non-advanced disease. The survival disadvantage in advanced-disease patients receiving tacrolimus warrants further investigation. In the unrelated donor trial,¹⁵⁸ there was a significant trend toward decreased severity of acute GVHD across all grades. The probability of grade II-IV acute GVHD in the tacrolimus group (56%) was significantly lower than in the cyclosporine group (74%; $p=0.0002$). Overall and relapse-free survival rates for the tacrolimus and cyclosporine arms at 2 years were 54% versus 50% ($p=0.46$) and 47% versus 42% ($p=0.58$), respectively.

In summary, both these trials showed a significant reduction in grade II-IV acute GVHD in the patients receiving tacrolimus and methotrexate. However, this reduction in acute GVHD did not result in improved survival or relapse-free survival, and was (at least in siblings) associated with an unexplained survival disadvantage in patients with advanced disease.

Other immunosuppressive agents, such as rapamycin,¹⁶⁰ mycophenolic acid,¹⁶¹ and thalidomide,¹⁶² are currently under investigation in BMT.

T-cell-depleted marrow transplants for prevention of GVHD

GVHD can be effectively prevented in both HLA-matched and HLA-disparate recipients through the use of marrow grafts rigorously depleted of T lymphocytes prior to infusion. The most extensively evaluated techniques for T-cell depletion include:

- agglutination with soybean lectin followed by resetting with sheep red blood cells (SBA-E-) as described by Reisner and co-workers;^{163,164}

- depletion with Campath-1, a monoclonal anti-body against CDw52 that binds human complement derived from the donor's own plasma;¹⁶⁵
- T-cell depletion with one or more T-cell-specific mouse monoclonal antibodies and rabbit complement;^{166–168}
- treatment with T-cell-specific immunotoxins;¹⁶⁹
- immunoadsorption of T cells via monoclonal antibodies bound to immunomagnetic beads or polystyrene membranes;^{170,171}
- positive selection of CD34+ stem cells by immunoadsorption.¹⁷²

Less-selective techniques capable of reducing T cells by 1–1.5 log₁₀, such as elutriation, are also being explored.¹⁷³ These techniques may differ by 1–2 log₁₀-fold in the degree of T-cell depletion achieved.¹⁷⁴ The threshold dose of clonable T cells administered in a marrow allograft associated with a significant risk of GVHD following HLA-matched sibling BMT¹⁷⁵ has been established at 10⁵ clonable T cells/kg recipient weight. For this reason, grade II-IV acute GVHD and chronic GVHD are still reported from large series using techniques achieving less than a 2.5–3.0 log₁₀ depletion of T cells, even when cyclosporine is given as additional prophylaxis against GVHD. This trend is even more evident following transplantation of HLA-disparate marrow grafts. For such patients, only methods that can reduce the dose of clonable T cells to less than 0.5×10⁵/kg can prevent the development of severe acute GVHD in all but a small proportion (<15%) of cases.⁵

Although several series have shown that T-cell depletion of a marrow allograft may reduce the incidence and severity of acute GVHD and, with certain methods, chronic GVHD, a clear advantage of T-cell-depleted transplants over unmodified marrow grafts reflected in long-term disease-free survival has thus far been clearly documented only in patients with SCID transplanted from HLA-non-identical donors.⁵ In such cases, T-cell-depleted BMT from HLA-A, -B, -D haplotype-disparate parental donors has been associated with rates of long-term disease-free survival with immunologic reconstitution comparable to those achieved with T-cell-replete HLA-identical sibling marrow grafts. However, for patients with leukemia and aplastic anemia, reductions in GVHD and GVH-associated mortality accrued by the use of T-cell-depleted BMT have, until recently, been largely counterbalanced by an increased incidence of graft failure or rejection. This situation has been changing rapidly. The use of tolerable, more effective immunosuppressive preparatory regimens has dramatically reduced the risk of graft failure following T-cell-depleted BMT,¹⁷⁶ resulting in a significant improvement in long-term and disease-free survival rates, particularly among older recipients of matched sibling grafts and recipients of marrow derived from unrelated donors. As T-cell-depleted marrow grafts have become more widely utilized, it has also become clear that the increased risk of leukemic relapse ascribed to T-cell-depleted transplants is not observed in all leukemic groups. Although patients transplanted for CML are clearly at increased risk,^{177–178} those transplanted for AML are not.^{163,179–182} These observations, coupled with the finding that leukocyte infusions administered to patients relapsing post transplant induce durable remissions in a high proportion of patients relapsing with CML, but are usually ineffective when used to treat relapses of ALL or AML, have led to a re-examination of the basis of the enhanced resistance to leukemia conferred by a marrow graft—the so-called ‘graft-versus-leukemia’ (GVL) effect.

GVL: enhanced resistance to leukemia conferred by marrow allograft and augmentation by posttransplant adoptive cell transfer

An enhanced resistance to leukemia conferred by a marrow allograft was first suggested by comparisons of unmodified marrow grafts derived from identical twins versus HLA-matched siblings applied to the treatment of AML in first remission.¹⁸³ Weiden et al¹⁸⁴ subsequently analyzed a large series of patients with leukemia, transplanted with marrow from HLA-matched siblings, and found that leukemic relapse was lower among patients developing moderate to severe acute GVHD and/or chronic GVHD. These data led investigators to speculate that the antileukemic effect of a marrow allograft is largely based on the activity of alloreactive T cells responsible for GVHD.

Early results of T-cell-depleted marrow grafts for the treatment of leukemia tended to support this general hypothesis, since the incidence of relapse following T-cell-depleted BMT was higher than that reported for unmodified grafts.¹⁸⁵ However, subsequent analyses demonstrated that the risk of relapse for patients transplanted for leukemias^{44,186,187} is consistently increased only for patients transplanted for CML,^{163,186,187} and is not significantly increased among patients transplanted for acute leukemias. Nevertheless, these findings have suggested that T cells exert a crucial role in transplants for CML—not only in facilitating engraftment of donor marrow but also in eradicating residual leukemic cells resistant to the myeloablative cytoreduction administered prior to transplant.

Strong evidence that donor lymphoid cells contribute directly to resistance against CML was first provided by Kolb et al,¹⁸⁸ who reported that infusions of donor-derived peripheral blood mononuclear cells could induce durable remissions in patients with CML who relapsed following an allogeneic BMT. This finding has since been confirmed by many centers.^{188–198} Overall, approximately 75% of patients who relapse with CML post transplant can be induced into durable

molecular remissions by this approach (Figure 29.2). The doses of T cells administered in the mononuclear cell fractions have generally been in the range (1–10) $\times 10^8$ /kg. Infusions of such large T-cell numbers, have, as expected, been associated with a significant incidence of acute GVHD, although approximately one-quarter of the patients treated have achieved remission without exhibiting signs of GVHD.^{195,196} Stepwise T-cell dose-escalation studies administered to patients relapsing with CML in chronic phase more than 9 months post T-cell-depleted BMT have also shown that remissions can be regularly achieved with T-cell doses as low as 10^7 /kg,^{195,196} without concomitant GVHD. Such T-cell doses, if given at the time of BMT, would be expected to induce GVHD in 60–70% of cases. However, when these doses are given later than 12 months post BMT, they have induced mild GVHD in less than 10% of HLA-matched recipients.^{175,196}

The specific donor-derived effector cells that selectively induce regressions of CML post transplant are currently unknown. However, CD4⁺ T cells probably play a significant role in that the emergency of CD4⁺ donor T cells capable of differentially inhibiting the growth of host clonogenic CD34⁺ Philadelphia-chromosome (Ph)-positive CML progenitors has been a consistent correlate of remission induction.¹⁹⁹ Furthermore, adoptive transfer of CD8⁺ T-cell-depleted mononuclear cells from the original HLA-matched marrow donor has been reported to induce remissions of CML without inducing GVHD.²⁰⁰ The observation that when Ph⁺ host cells are eliminated following donor leukocyte infusions, residual Ph⁻ presumably non-leukemic host T cells are also eradicated^{196,197} gives additional support to the hypothesis that the effectors are not leukemia-specific but are reacting against minor alloantigens expressed

Figure 29.2 Results of donor leukocyte infusions for treatment of relapsed chronic myeloid leukemia post bone marrow transplantation. White bars represent the results of Collins et al.²⁰³ and shaded bars those of Kolb et al.¹⁹⁴ Cyt, cytogenetic; Hem, hematologic; Acc, accelerated; n, number of patients in each study.

both on leukemic cells and on normal cells of the lymphohematopoietic system.

The role of alloreactive T cells as effectors of resistance against acute leukemias is less clear. In several series, including an analysis of the International Bone Marrow Transplant Registry (IBMTR) transplant compendium, recipients of T-cell-depleted marrow for the treatment of AML in early remission have not shown any increase in the risk of relapse post transplant.^{193,194} In ALL, the GVL effect associated with a marrow allograft remains controversial. On the one hand, in the IBMTR compendium of transplant results, recipients of a T-cell-depleted HLA-matched transplant for the treatment of ALL have been found to experience a modest but significant increase in the rate of relapse over that observed in recipients of unmodified transplants. This finding has suggested that, in the majority of patients transplanted for ALL, GVL effects could not be distinguished from GVHD.²⁰¹ On the other hand, the use of donor leukocytes to promote GVHD in patients with ALL in relapse or secondary or greater remission at the time of transplant have not reduced the risk-of-relapse rate, although the donor leukocyte infusions did induce an increased incidence and severity of GVHD.²⁰² Similarly, donor leukocyte infusions have been largely ineffective in eradicating relapse of ALL occurring post transplant. Indeed, in recent compendia of the European and American experiences with donor leukocyte infusions to treat disease recurrence following allogeneic BMT, Kolb et al.¹⁹⁴ and Collins et al.²⁰³ found respectively that whereas donor leukocyte infusions induced remissions in the majority of patients treated for cytogenetic (80–100%) or hematologic (70–80%) relapse of CML, only a small fraction of patients with relapsed AML or ALL achieved durable remissions. These latter findings suggest that the enhanced leukemia resistance conferred by a marrow allograft for AML or ALL may not be as dependent upon alloreactive T cells for its expression as for CML, or, conversely, that clonogenic AML and ALL cells may be less sensitive to the cytolytic and/or cytotoxic activity of alloreactive T cells than clonogenic CML progenitors—either because they are too numerous and are so rapidly replicating as to outstrip alloreactive T-cell populations emerging from the donor leukocyte infusions or because these leukemic cells do not express target or accessory structures needed for recognition and killing by such alloreactive T cells.²⁰⁴ To address the former possibility, several groups are now evaluating the activity of donor leukocyte infusions administered after a course of induction chemotherapy designed to reduce leukemic populations as treatment for patients relapsing with AML or ALL post transplant.²⁰⁵

The facts that T-cell-depleted marrow grafts that effectively prevent GVHD are not associated with an increased rate of relapse when applied to patients

with AML and that alloreactive T cells may be only marginally active against ALL have fostered consideration of alternative cellular bases for the enhanced resistance to these leukemias conquered by a marrow allograft. Investigators exploring such mechanisms have focused on the detection, identification, and characterization of donor-derived cell populations developing after an unmodified or T-cell-depleted marrow allograft that are capable of discriminating between leukemic and non-leukemic host hematopoietic cells as measured by cytotoxicity or colony inhibition in vitro.

To date, three types of effector cells exhibiting this characteristic have been distinguished:

- donor-type NK cells;²⁰⁶
- donor T cells exhibiting broad, HLA-non-restricted NK-like leukemocidal activity;²⁰⁷
- at low frequency, HLA-restricted donor T cells that can differentially inhibit the growth of clonogenic host leukemic cell populations.^{199,208,209}

Of the non-T-cell populations that might contribute to an antileukemic effect, NK cells may be of particular importance. Two recently published studies have highlighted the GVL effect of HLA-C mismatching. The Japan Marrow Donor Program reported that in unrelated donor transplantation, matching at HLA-C was associated with a significantly higher relapse rate.²¹⁰ The Perugia group have reported that in the haploidentical setting, mismatching at HLA-C, as determined by killer inhibitory receptor (KIR) group-ings, significantly reduced the incidence of relapse in patients with AML.²¹¹

Another strategy being evaluated in an effort to detect or generate leukemia-reactive T cells has been to establish mixed leukocyte cultures between HLA-matched or partially matched normal donor T lymphocytes and isolated host leukemic cells. T-cell lines and clones derived from such cultures have been assessed for their capacity to distinguish between leukemic and non-leukemic targets such as phytohemagglutinin (PHA)-stimulated T lymphoblasts and Epstein—Barr virus (EBV)-transformed normal B cells obtained from the host during remission. Using this approach, Sossman et al^{208,209} generated CD3⁺CD4⁺ T cell lines and HLA-DR, -DP-restricted CD4⁺ T-cell clones exhibiting selective, proliferative and cytotoxic responses against ALL cells derived from an HLA-A, -B, -D-mismatched patient. Faber et al²¹² similarly generated HLA-restricted CD8⁺ leukemia-specific cytotoxic T cells from the peripheral blood lymphocytes of an HLA-matched sibling of a patient with AML. Although the frequency of such clones has been low when compared with the frequency of clones exhibiting reactivity against both normal and leukemic cells of the host, this latter study indicates the possibility of generating leukemia-selective cytotoxic T cells potentially lacking the potential to induce GVHD, even from HLA-matched normal donors.

Taken together, the studies cited above have clearly shown that several effector systems may contribute to the antileukemic effect of an allogeneic BMT, including alloreactive potentially GVH-inducing T cells reactive against major and minor alloantigens expressed on both normal and leukemic cells, T cells reactive against differentiation antigens preferentially expressed on leukemic cells, and NK cells.

Infections in the early stages of immune reconstitution

Interstitial pneumonias (IP) still constitute the major cause of death in the first 3 months post transplant. Between 25% and 35% of patients transplanted for leukemia develop this complication. Historically, over 50% of these cases were caused by CMV.²¹³ Other viruses, such as adenovirus,⁸³ respiratory syncytial virus (RSV),²¹⁴ influenza, and parainfluenza,²¹⁵ have gained prominence as methodologies to detect these viruses have improved, and more widespread use of prophylactic or pre-emptive therapy of CMV infections has reduced the incidence of CMV IP.^{216–219} *Pneumocystis carinii* IP is much less common owing to the widespread use of cotrimoxazole²²⁰ or pentamidine prophylaxis before and after marrow transplantation. However, the more intensive and prolonged administration of steroids, used either to prevent or to treat GVHD, has led to a significant increase in the incidence of *Aspergillus* pneumonia.^{221–223}

CMV remains the most common cause of life-threatening infections in the post-transplant period. Approximately 70–90% of transplant recipients who are CMV-seropositive, or who receive grafts from seropositive donors, will become viremic post transplant during the first 3–6 months following engraftment.^{224,225} In the absence of pre-emptive or prophylactic antiviral therapy, 30–40% of CMV-viremic patients will develop IP. In contrast, this complication is low among seronegative patients with seronegative donors who receive blood-product support from CMV-negative donors.²²⁴ This finding, coupled with molecular analyses of CMV isolates from CMV-positive individuals, suggests that CMV disease post BMT usually results from reactivation of latent virus from the host or the graft.²²⁶ Alloreactions between donor and host augment the risk of CMV disease. Thus recipients of HLA-matched related marrow grafts who develop moderate to severe GVHD have a higher incidence of CMV IP^{227–229} when compared with allograft recipients without GVHD. Furthermore, CMV IP is a rare complication in recipients of syngeneic or autologous BMT.²³⁰ More intensive cytoreductive regimens are also associated with an increased incidence of CMV disease.^{229,231}

Over the last 15 years, a number of effective strategies have been developed to reduce the incidence of CMV IP and improve treatment outcome. The risk of developing CMV disease may be reduced to less than 2% by the exclusive use of either CMV-negative or filtered leukocyte-reduced blood products in CMV-negative donor—recipient pairs.^{232,233}

In the late 1980s, several studies demonstrated that CMV IP could be effectively treated in 50–70% of affected marrow allograft recipients using combined therapy with ganciclovir and intravenous gammaglobulin.^{234–237} Neither agent alone had a significant effect on the course of CMV IP. For patients unable to tolerate ganciclovir, primarily because of myelosuppression, foscarnet used in combination with gammaglobulin has also been reported as being effective.²³⁸ Unfortunately, these antiviral combinations have often been ineffective in reversing overt CMV disease in recipients of unrelated BMT, prompting the evaluation of these agents in prophylactic strategies. Several groups have reported their experience either with preemptive antiviral therapy, i.e. therapy initiated at the time of CMV viremia, or with prophylactic therapy, initiated in all seropositive patients or recipients of marrow allografts from seropositive donors at the time of engraftment. Two randomized trials have demonstrated that early treatment of patients with detectable virus in body fluids (blood or bronchoalveolar lavage) significantly reduced the frequency of CMV IP, thereby reducing transplant-associated mortality.^{216,217} Two other prospective randomized trials have demonstrated the effectiveness of prophylactic ganciclovir in reducing early CMV disease.^{218,219} However, effective prophylaxis has ultimately not led to a reduction in transplant-associated mortality. The most recent study by Boeckh et al²¹⁹ revealed that although prophylactic ganciclovir was more effective than pre-emptive treatment in preventing early (<100 days) CMV disease, recipients of prophylactic ganciclovir had a higher incidence of late (>100 days) CMV disease, which was generally fatal. Furthermore, this prophylactic use of ganciclovir has been associated with neutropenia, which was severe enough in up to 30% of patients to warrant discontinuation of treatment. In such patients, the incidence of other infections was increased.^{219,238} Given these results, the pre-emptive treatment of CMV viremia appears to be the better approach. However, this strategy depends critically on access to viral detection methods that detect virus before the onset of overt disease. Although rapid viral detection methods, such as shell vial cultures, polymerase chain reaction (PCR) analysis and assays for the CMV pp65 early antigen, have markedly improved the ability to detect clinically occult viremia,^{238–241} the impact of these tests depends on the type and vigilance of the surveillance schedules employed.

Currently, adoptive immunotherapy with donor-derived, in vitro selected and expanded, CMV-specific T-cell clones is being evaluated for the prevention of CMV disease. The preliminary results in clinical trials have been highly promising.²⁴² The adoptive transfer of $(3-10) \times 10^7$ CMV-specific T cells/ml has induced significant levels of circulating CD8⁺ cells exhibiting CMV-specific cytotoxicity, which have been sustained for at least 8 weeks post infusion. Repeated doses have been infused without toxicity or GVHD. None of the first five patients who received these cloned cells developed CMV disease.²⁴² Larger trials of this approach have confirmed these results,²⁴³ and have demonstrated the potential of adoptive cell transfer to restore specific antiviral immunity, thereby reducing post-transplant morbidity and mortality. In addition, the successful use of donor-derived interleukin-2 (IL-2)-activated T cells into which a suicide vector has been inserted to allow for elimination of infused cells in the event of GVHD has been reported.²⁴⁴

Infections in the later stages of immune reconstitution

Immune reconstitution following a marrow allograft can be a protracted process, and is adversely affected by advanced patient age, post-transplant prophylaxis and treatment of GVHD, and transplants of HLA non-identical related or 'matched' unrelated donors.²⁴⁵ Although T-cell populations (primarily CD8⁺ T cells) begin to redevelop within the first 2 months post transplant, CD4⁺ cell recovery may not occur for 6–18 months post BMT, and responses to mitogens and specific antigens may be severely depressed for 6–24 months.^{133,245,246}

During the periods of profound T-cell deficiency between engraftment and 6–8 months post transplant, BMT patients are also at risk for polyclonal or oligoclonal B-cell lymphoproliferative disorders (LPD) and monoclonal lymphomas induced by EBV.^{247,248} The risk of EBV-LPD following lectin-separated T-cell-depleted grafts has been reported to be as high as 6% for HLA-matched related and 12% for unrelated transplants when equine antithymocyte has been administered to the patients to prevent immune rejection.²⁴⁸ Rates of EBV-LPD of approximately 6% have been recorded following HLA-matched transplants depleted with T-cell-specific mouse monoclonals,²⁴⁹ and as high as 8–24% in recipients of HLA-non-identical grafts depleted of T cells with T-cell-specific monoclonal antibodies.^{249,250} Similarly, Martin et al²⁵¹ have reported a 16% incidence of EBV-LPD in patients given infusions of certain T-cell-specific monoclonal antibodies for treatment of GVHD following unmodified marrow transplants. The EBV-LPD that arise post transplant are usually of donor rather than host origin.^{249,251} The basis for these B-cell transformations remains unclear, but may in part reflect an inability of patients early post transplant to generate T cells capable of suppressing donor B-cell expansions.²⁵²

Prior to the 1990s, the majority of patients who developed an EBV-LPD died from these disorders. Specifically, monoclonal proliferations were refractory to classical chemotherapy, radiation and/or antiviral therapy. In 1993, Papadopoulos et al²⁵³ first demonstrated that adoptive transfer of EBV-specific immunity by infusion of small doses of peripheral mononuclear cells derived from a patient's EBV-seropositive donor could induce complete and durable remissions of EBV-LPD in the majority of patients, including those with monoclonal EBV-associated lymphomas. These infusions were calculated to deliver in the range of $(0.5-1.0) \times 10^6$ CD3⁺ T cells/kg. This finding has now been confirmed by several other groups.^{254,255} The efficacy of this approach probably reflects the expansion of circulating EBV-specific cytotoxic T-cell precursors found in high frequency in the leukocytes of normal seropositive marrow donors.²⁵⁶ Indeed, within 2 weeks following infusions of as few as 10^3 EBV cytotoxic T-lymphocyte (CTL) precursors, frequencies of EBV-reactive CTL regularly increase from undetectable levels to frequencies as high as $1/10^4$ T cells in the blood.²⁵² Further substantiation of this hypothesis comes from the studies by Rooney et al,²⁵⁵ which demonstrated sustained remissions following infusions of small numbers of genetically marked EBV-specific T cells derived from T-cell lines generated in vitro. Not all patients, especially children, have EBV-cytotoxic T cells available or even an EBV-seropositive donor. Recent reports have shown that rituximab, a humanized anti-CD20 monoclonal antibody, has been effective as both treatment and prophylaxis of EBV lymphoma.^{257,258}

Late complications of marrow transplants

The late sequelae of the TBI and chemotherapy used for cytoreduction prior to transplant may be mild to severe, depending on the type of agents used and their dose intensity. The toxicity of the transplant cytoreduction is also affected by the patient's age at transplant, as well as by the regimens used prior to referral for transplant to induce, consolidate, and maintain remissions of the primary disease. For example, toxicity induced by regimens incorporating myeloablative doses of TBI tends to be more profound and enduring than those induced by regimens that include myeloablative combinations of chemotherapeutic agents alone, and is more damaging when the radiation is given in a single large dose rather than in multiple fractions.^{259,260}

One of the most devastating late complications resulting from damage induced by TBI and chemotherapy is leukoencephalopathy.²⁶¹ This complication occurs almost exclusively in patients transplanted for leukemia who have received cranial radiation and/or extended courses of intrathecal methotrexate as treatment or prophylaxis for central nervous system (CNS) leukemia prior to referral for transplantation. In such patients, the risk of leukoencephalopathy has been reported to be as high as 7%.²⁶¹ This complication usually induces severe symptoms, including slurred speech, confusion, ataxia, seizures, and spasticity, which may progress to coma and death. Less severe CNS toxicities may also be observed, in the form of neuropsychological dysfunctions and varying degrees of retardation.²⁶² However, the incidence of the latter complications has not been established. Transient neurologic toxicities, including tremors, seizures, and paresis, may also complicate the use of cyclosporine and tacrolimus for prophylaxis of GVHD.²⁶³⁻²⁶⁵

Endocrine abnormalities involving the thyroid, pituitary gland, and gonads are common late sequelae of BMT. Hypothyroidism, requiring hormone replacement, has been reported in 10%^{266,267} and compensated hypothyroidism in an additional 34-36% of patients transplanted for leukemia. Analysis of gonadal function post BMT has revealed that the age and the type and intensity of the cytoreductive regimen utilized are important factors in determining whether ovarian function will recover in females. In one study, women younger than 27 years cytoreduced with cyclophosphamide alone regularly recovered ovarian function within the first year post transplant (median 6 months); however, more than 35% women older than 27 years had sustained ovarian failure.²⁶⁸ Young women who received TBI and cyclophosphamide in preparation for BMT for leukemia have experienced a 55% incidence of permanent ovarian failure, compared with a 74% incidence in older women.²⁶⁸ In a single-institution study of prepubescent females undergoing BMT following cytoreduction with hyperfractionated TBI and chemotherapy, at least 50% were able to enter puberty and sustain menarche.

A proportion of women who recover ovarian function post transplant may achieve successful pregnancies. Thus, in a long-term study by Sanders et al,²⁶⁹ 110 of 708 women (15%) who were postpubescent at the time of BMT recovered normal ovarian function. Of these, 32 became pregnant. The proportion of pregnancies resulting in live births was 79%. There was a statistically higher incidence of spontaneous abortions ($p=0.02$) and preterm births ($p=0.01$) complicating the pregnancies of women who received TBI as part of their conditioning regimen as compared with those prepared with cyclophosphamide alone. Despite these complications, the children born were normal and had no higher an incidence of birth defects than that associated with pregnancies in the general population.

Deficiencies of Leydig cell function are rare in boys and men transplanted after preparation with

cyclophosphamide with or without TBI.²⁷⁰ Indeed, we have found that most prepubertal boys undergoing BMT following cytoreduction with hyperfractionated TBI and chemotherapy undergo a normal transition to puberty.²⁷¹ However, despite normal testosterone levels, many will have compensatory elevations of follicle-stimulating hormone (FSH). Unfortunately, spermatogenesis is eliminated or severely impaired, resulting in infertility in the majority of patients with leukemia who received TBI and up to one-third of patients given cyclophosphamide alone.²⁷¹ Of 618 postpubertal men evaluated by Sanders et al,²⁶⁹ 157 had some level of spermatogenesis, including 66% of those treated with TBI. The partners of 35 of these men had one or more pregnancies, which were not associated with increased rates of spontaneous abortion, preterm delivery, or congenital abnormalities.²⁶⁹

The degree of growth retardation following transplantation is influenced by age at transplant, radiation schema (single dose versus fractionated or hyperfractionated), as well as prior CNS radiation. The effects of radiation on linear growth are complex and multifactorial, involving not only hypothalamic production of growth hormone-releasing factor (GHRF) but also the intrinsic growth potential of long bones. The use of hyperfractionated regimens of TBI has been associated with less impaired growth potential than standard-dose regimens.²⁷² Whether and to what degree treatment with growth hormone or GHRF can partially correct short stature in these cases is now under study.

TBI may induce cataracts in the late post-transplant period. Recipients of single-fraction high-dose TBI have the highest incidence—reported to be as high as 50%. For patients given fractionated TBI, the incidence is approximately 10–20%.²⁷³

Cytoreduction with alkylating agents has been associated with secondary malignancies post BMT—although, to date, the incidence of such neoplasms have been relatively limited^{274,275} and lower than the incidence of secondary tumors recorded in patients given comparable or lower localized doses of radiation and chemotherapy for other neoplasms such as Hodgkin's disease. In a large study of 19 229 recipients of an allogeneic BMT at 235 centers,²⁷⁵ the overall risk of solid tumors was 2.7 times that expected in the general population (8.3 times if the patient survived for more than 10 years post allogeneic BMT). The cumulative risk of a solid tumor developing post BMT was 2.2% at 10 years, increasing to 6.7% at 15 years. The most common solid tumors arising post BMT included malignant melanoma, squamous cell carcinomas of the buccal mucosa (particularly in patients with prior chronic GVHD), and cancers of the liver, CNS, thyroid, bone, and connective tissue. More prolonged follow-up is still needed before a full assessment of the risk of secondary neoplasms can be made.

HLA-matched marrow transplants for leukemia

In the 1970s, BMT was utilized predominantly in patients with end-stage disease, whose leukemias were probably refractory to chemotherapy. In this poor-risk group of patients, a 13–18% disease-free survival (DFS) was observed, which increased to 25% in a subgroup of patients transplanted in good physical condition.²⁷⁶ These results paved the way for exploration of the use of marrow transplantation in patients in better clinical condition, earlier in the course of their disease, when the leukemic cell burden was low and residual leukemic cells were still likely to be sensitive to the cytoreduction employed.²⁷⁷ In 1979, the Seattle group²⁷⁷ reported a series of patients with AML transplanted in first complete remission (CR) who achieved a 63% long-term DFS associated with only a 12% incidence of relapse. Subsequently, similar results were achieved in several other transplant centers, heralding the widespread use of HLA-matched marrow grafts to treat patients with acute leukemias in first or second remission and CML in first chronic phase. Approximately 25 years of this experience can now be evaluated. Furthermore, the results of allogeneic BMT can be compared with those achieved with chemotherapy as well as autologous transplants at different stages in the course of these leukemias.

Acute myeloid leukemia

For patients with AML in second or later remission or relapse, an allogeneic HLA-matched marrow graft is generally regarded as the treatment of choice, since few of these patients have survived disease-free if treated with chemotherapy alone²⁷⁸ (see Chapters 37 and 38). Marrow transplants from HLA-matched siblings following cytoreduction with cyclophosphamide coupled with TBI or busulfan have provided extended DFS for 20–40% in adults and 30–50% in children grafted in second CR.^{279–282} Alternatively, some centers have proceeded directly to allogeneic transplant in first relapse, and report a 23% DFS.²⁸³ The use of similar cytoreduction followed by an autologous, purged marrow graft obtained during second remission may also lead to long-term (5-year) DFS in up to one-third of cases.^{284,285} Although autologous transplants are associated with a higher risk of relapse than HLA-matched marrow grafts (>50% versus 20–25%) and a lower probability of long-term DFS, in some centers they are considered the treatment of choice for patients in second remission who lack an HLA-matched donor, being somewhat superior to chemotherapy alone. A retrospective analysis performed by Busca et al²⁸⁶ reported a similar DFS in 24 patients with AML in second or third CR given an

unrelated (30%, $n=9$) or autologous (25%, $n=12$) BMT.

In the 1980s, four prospective randomized trials tried to address whether allogeneic BMT from an HLA-matched sibling or chemotherapy was the best postremission therapy for adults (<45 years) with AML in first CR.^{279,287–289} In all four trials, relapse was significantly lower among transplanted patients (for BMT, the relapse rate was 9–40%; for chemotherapy, it was 71–88%). However, the lower relapse rate following transplant was counterbalanced by a higher rate of non-relapse mortality. Despite this, the 3- to 5-year DFS rates were superior in the transplant arms of each study, although these differences were statistically significant in only two.^{279,288} Concerns regarding the results of these studies included the possibility of patient selection bias as well as the adequacy of treatment and supportive care administered to the chemotherapy control arms.²⁹⁰ Although the postinduction therapy varied in each of the four chemotherapy arms, the drugs administered were representative of ‘standard’ consolidation or intensification regimens at the time.

To address concerns raised by the earlier trials, two large multicenter randomized studies were subsequently undertaken. These trials compared outcomes in recipients of chemotherapy alone with those of allogeneic or autologous marrow transplantation. In the first study, the UK Medical Research Council (MRC) AML-10 trial,²⁹¹ patients received two identical induction and consolidation courses, followed by allocations to the allogeneic transplantation arm if an HLA-matched donor was available or, if not, randomization to either the autologous transplantation or the observation-alone arm. Data were analyzed on an intention-to-treat basis. The 1063 patients under 55 years who entered complete remission were tissue-typed. Of these patients, 419 had a matched sibling donor and 644 had no match. When compared on a donor versus no donor basis, the risk of relapse was reduced in the donor arm (36% versus 52%; $p=0.001$) and the DFS rate improved (50% versus 42%; $p=0.01$), but the overall survival (OS) rate was not different (55% versus 50%; $p=0.1$). However, only 61% of patients with a donor underwent transplantation. When patients were subdivided into risk groups based on cytogenetics alone or with the addition of blast response to the first course, a reduction in relapse risk was seen in all risk groups and in three age cohorts (0–14, 15–34, and 35+ years). Significant benefit in DFS was only seen in the intermediate-risk cytogenetic group (50% versus 39%; $p=0.004$). The OS benefit was only seen in intermediate-risk patients (55% versus 44%; $p=0.02$). The reduction in risk of relapse in good-risk patients was attributable to patients with $t(15;17)$ but not to patients with $t(8;21)$ or $inv(16)$. Allogeneic transplantation given after intensive chemotherapy was able to reduce relapse in all risk and age groups. However, owing to the competing effects of procedural mortality and an inferior response to chemotherapy if relapse does occur, there was a survival advantage only in patients at intermediate risk. This trial found no survival advantage in children, patients over 35 years, or good-risk disease. Criticisms of this trial have included the fact that almost 40% of those allocated to the allogeneic transplantation arm did not receive a transplant and that the allograft was performed only after four intensive courses of chemotherapy, which potentially could have adversely affected transplant-related mortality.

In a second trial, Zittoun and colleagues²⁹² compared patient outcome following intensive chemotherapy versus allogeneic or autologous transplantation. In this study, patients who achieved a complete remission after standard induction therapy (daunorubicin and cytarabine) and one course of intensive consolidation therapy (intermediate-dose cytarabine, 500–1000 mg/m² every 12 hours×12 doses, and amsacrine, 120 mg/m²/day×3 doses) were allocated to an allogeneic transplant if an HLA-matched sibling was available or were randomized to an autologous transplant versus a second course of intensive chemotherapy with high-dose cytarabine (2 g/m² every 12 hours×8 doses) and daunorubicin (45 mg/m²/day×3 doses) if the patient lacked a sibling donor. Patients over 45 years of age were excluded from the allogeneic transplant arm. The projected DFS rate at 4 years was 55% for the allogeneic arm, 48% for the autologous arm, and 30% for the intensive chemotherapy arm. The difference in outcome between the autologous transplant arm and intensive chemotherapy was statistically significant ($p=0.05$). The difference between the allogeneic arm and the chemotherapy arm was also statistically significant ($p=0.04$). Relapse in the allogeneic arm was 25%, versus 41% and 57% in the autologous and chemotherapy arms, respectively. In an intention-to-treat analysis, no significant differences in outcome were revealed between the two transplant groups.

In earlier trials comparing transplantation and chemotherapy, benefits from lower relapse rates in the allogeneic arm were offset by higher non-relapse mortality rates. In addition, questions have been raised as to whether the chemotherapy control arm in the study by Zittoun et al²⁹² contained ‘optimal’ therapy.²⁹³ Thus, when the Cancer and Leukemia Group B (CALGB) examined the efficacy of sequential low-, intermediate-, or high-dose cytarabine as postremission intensification therapy in patients with AML under the age of 60, patients receiving the high-dose cytarabine regimen (3 g/m² every 12 hours×6 doses) had a 44% probability of remaining in continuous remission at 4 years.²⁹⁴ These results are similar to

those achieved in the autologous arm of the Zittoun study. A follow-up study from the CALGB demonstrated that certain 'good'-risk cytogenetic abnormalities, such as t(8;21)(q22;q22) and inv(16)(p13q22), predict responsiveness to intensive chemotherapy with high-dose cytarabine. Patients in this study who had these 'good-risk' cytogenetic abnormalities achieved a 51% DFS rate when given high-dose cytarabine as postremission consolidation.²⁹⁴ This result has prompted questions as to whether or not such good-risk patients should be considered candidates for any transplant approach.

To address these concerns, several multicenter analyses reanalyzed the results of transplantation to assess the impact of cytogenetic abnormalities on outcome following allogeneic or autologous BMT in patients with AML in first CR.^{295,296} In a retrospective analysis of the IBMTR data, Gale et al²⁹⁵ found that the DFS rate for patients with cytogenetic abnormalities associated with 'good-risk' AML was 56% (46–66%). A subsequent analysis of outcome following allogeneic BMT for AML in first CR conducted by the EBMT²⁹⁶ demonstrated 5-year leukemia-free survival rates of 67%, 57%, and 29% for patients with favorable (abn(16) and t(8;21)), standard intermediate (t(15;17), pseudodiploid, hyperdiploid, and diploid) and poor prognosis (abn(5) and/or (7), abn(11q) and hypodiploid) cytogenetic abnormalities, respectively. For patients with favorable or standard cytogenetic abnormalities, allogeneic BMT achieved remission duration and DFS rates that were significantly better than those recorded for autologous marrow grafts. However, for those with unfavorable karyotype, there was no difference in outcome following allogeneic or autologous BMT. Multivariate analysis of these data demonstrated that cytogenetics at diagnosis was the most important prognostic indicator of DFS and relapse.

While the results of more intensive chemotherapeutic regimens over the last 15 years have improved the outcomes for patients with AML, novel approaches to allogeneic transplantation using T-cell-depleted techniques have also been developed that result in a lower non-relapse mortality and diminish the incidence and severity of GVHD.^{53,297,298} For example, a report from the Memorial Sloan-Kettering group¹⁸² demonstrated a 77% DFS rate at 2 years in adult patients with AML transplanted in first CR ($n=31$), following cyto-reduction with TBI, thiopeta, and cyclophosphamide. Bone marrows were T-cell-depleted with soybean lectin agglutination followed by resetting with sheep red blood cells, resulting in a 2.5–3.0 log₁₀ depletion of T cells. No patient experienced graft failure or grade II-IV acute GVHD. In this report, the relapse rate was 3.4% and the rate of non-leukemic mortality was 19.4%. Transplant teams from the Dana-Farber Cancer Center¹⁸¹ and Ulm University Hospital²⁹⁸ reported similar findings, with 63% and 80% DFS rates, respectively, for patients with AML transplanted in first remission. In these studies, the bone marrow grafts were T-cell-depleted utilizing the anti-CD6 monoclonal antibody or Campath-1G/1M, respectively. These studies demonstrate that advances in allogeneic transplantation techniques have led to a reduction in regimen-related mortality and to improved DFS rates. However, the long-term DFS rates recorded in these studies have so far only been reported for intensive chemotherapy or autologous BMT in adults. Given these developments, the selection of an 'optimal approach' for the treatment of adults with AML—particularly those older than 45 years—must await the results of planned or active protocols comparing these second-generation chemotherapy and transplantation regimens.

While current chemotherapy regimens for the treatment of AML in children have resulted in 3- to 5-year DFS rates ranging from 40% to 55%,^{299–301} HLA-matched marrow grafts administered to children with AML in first remission have also achieved impressive results, with 49–80% of such patients surviving disease-free at 3–5 years post transplant.^{280,302,303} For patients treated with allogeneic BMT for AML in first CR, pretransplant cyto-reduction with cyclophosphamide coupled with TBI has yielded better results than preparative regimens combining busulfan and cyclophosphamide.^{209,303,304} In an initial prospective trial conducted by the Children's Cancer Study Group (CCSG),³⁰⁴ the DFS rate was superior for children who received an allogeneic HLA-matched BMT when compared with those randomized to non-ablative chemotherapy ($p<0.05$). A subsequent CCSG study³⁰¹ has compared chemotherapy versus an autologous transplant purged with 4-hydroperoxycyclophosphamide (4HC) versus an allogeneic HLA-matched transplant administered after a standard or more intensively timed intensive course of DCTER induction chemotherapy. This study demonstrated an overall improvement in DFS in each post-remission treatment group when the more intensive DCTER regimen was used to induce remission. Again, however, the DFS rates for patients treated with allogeneic marrow grafts were significantly superior to those recorded for the postremission groups treated with either chemotherapy or a purged autologous marrow graft, irrespective of the induction treatment administered. Indeed, for those patients induced into remission with the more dose-intensive DCTER regimen, the DFS rate at 5 years for the allogeneic arm was 72%, which is significantly better than the 52% and 55% DFS rates achieved respectively with an autologous marrow graft or chemotherapy alone.³⁰⁵

In summary, HLA-identical sibling allogeneic stem cell transplantation is generally accepted as the therapy of choice for patients with AML in first remission who do not have favorable cytogenetics.

Acute lymphoblastic leukemia

Transplantation for ALL in first remission

Current treatment of ALL in childhood will result in long-term survival in more than 70% of patients^{306–310} (see Chapter 31). For those children considered at an increased risk of relapse, more-intensive regimens have resulted in sustained DFS rates of 60–70%.^{309,310} Because of these excellent results, it has been difficult to identify children with ALL who will clearly benefit from an allogeneic transplant in first remission. Indeed, allogeneic BMT in pediatric patients with high-risk ALL has led to long-term DFS rates of 56–84%, which are no superior to those that can currently be achieved with chemotherapy alone.^{311–315}

The place of allogeneic marrow grafts in the treatment of adults with ALL who have achieved an initial remission is only slightly less controversial.³¹⁶ Current chemotherapeutic regimens induce remissions in 70–85% of adults, but only 20–51% of these patients will achieve long-term DFS, depending upon the characteristics of the ALL under treatment^{317–319} (see also Chapter 32). In particular, for patients who, at initial diagnosis, present with disease features associated with a high risk of relapse, such as white cell count above 20 000/mm³, age over 60 years, CNS involvement, chromosomal translocations t(4;11), t(8;14), or t(9;22), null or B-cell phenotype, or failure to achieve remission within 5 weeks of induction therapy, the proportion who will survive in sustained remission is small. In contrast, in several series, HLA-matched marrow transplants have resulted in 3- to 5-year DFS rates of 30–71% in high-risk young adults (younger than 40 years) with ALL in first remission, with relapse rates post transplant of 9–35%. While DFS rates vary significantly, depending upon the type of cytoreduction^{317–326} and the method of GVHD prophylaxis utilized,³¹¹ the promising results achieved have suggested that allogeneic BMT may offer a significant advantage to adults with ALL with high-risk features in first CR.

Three prospective randomized trials have attempted to further define the optimal postremission therapy in adult patients with ALL. In the first of these, patients under the age of 40 years were allocated to an allogeneic BMT arm if they had an HLA-identical sibling. Patients younger than 40 years without a donor and those aged between 40 and 50 years were randomized to chemotherapy versus autologous BMT.³²⁷ In this trial, which used an intention-to-treat analysis, the 5-year survival rates were similar in patients randomized to the allogeneic BMT arm and those randomized to the autologous BMT or chemotherapy arms. However, although there was no benefit from allogeneic BMT in adults with 'standard-risk' ALL, for those with high-risk features, there was a significant difference in overall and disease-free survival, favoring the allogeneic BMT arm: 44% versus 20%, respectively. In the second prospective study, patients younger than 55 years who achieved a complete remission following induction were allocated to receive an allogeneic BMT if an HLA-identical sibling was available or were randomized to an autologous BMT with or without interleukin-2 (IL-2).³²⁸ In this study, the 3-year probability of DFS was significantly higher in recipients of an HLA-identical sibling transplant than in the autologous transplant groups: 68% versus 26%. Post-transplant IL-2 had no effect on the DFS of patients in the autologous transplant group, whose main cause of failure was relapse. The third trial is the MRC UKALL XII/Eastern Cooperative Oncology Group (ECOG) E2993 to prospectively define the benefit of allogeneic and autologous BMT in adult Philadelphia chromosome-negative (Ph⁻) ALL in first CR.³²⁹ All patients received two phases of standard induction and, if in CR, were assigned to allogeneic BMT if they had an HLA-matched sibling donor. Other patients were randomized to either standard consolidation/maintenance therapy or autologous BMT. The data were analyzed on an intent-to-treat basis. Standard risk was defined as Ph⁻, age 35 years or less, time to CR 4 weeks or less, and white cell count less than 30 000/mm³ for B-lineage and less than 100 000/mm³ for T-lineage. The actuarial 5-year event-free survival (EFS) rates for these 434 Ph⁻ patients, who had intended to undergo an allogeneic BMT (*n*=170) or were randomized (*n*=264), were 54% and 34%, respectively (*p*<0.04). The study showed that allogeneic BMT conferred the most potent antileukemic effect for all adult patients with ALL in first CR and, despite increased early toxicity, appears to provide favorable long-term results.

In summary, these studies demonstrate that allogeneic BMT may be a preferred option for certain subsets of patients with adult ALL in first remission.

Transplantation for ALL in second or greater remission or relapse

The results reported for HLA-matched sibling BMT applied to the treatment of children with ALL in second CR vary considerably both in DFS rates and in the incidence of relapse. Regimens utilizing single-dose TBI and cyclophosphamide have been associated with relapse rates ranging from 30% to 57% at 2 years, and DFS rates of 33–50%.^{330,331} In contrast, regimens incorporating higher doses of hyperfractionated TBI followed by cyclophosphamide²⁸⁰ or fractionated TBI administered with high-dose cytarabine,³³² etoposide,³²² or altered doses of cyclophosphamide³²⁵ have resulted in long-term DFS rates of 59–64% at 5 years and relapse rates of 9–16%.

Meaningful comparisons between transplant results and those achieved with chemotherapy alone must take into consideration the characteristics of the

patients treated—particularly the duration of first remission and the chemotherapy that they have previously received. Although children with ALL who relapse early in the course of their initial chemotherapy (e.g. in the first 18 months) may be induced into a second remission, they are unlikely to survive disease-free for more than 6–12 months. This contrasts with the results of chemotherapy alone in patients with ALL who relapse after completing 18–24 months of chemotherapy,³³³ 40–81% of whom may survive disease-free. Given these results, it has been argued that a transplant is indicated for children who relapse early in the course of their disease, but not necessarily in those relapsing after a prolonged initial remission.

To address this issue, we and others have conducted retrospective analyses of single-center and multicenter experiences from this point of view.³³⁴ In these studies, children with ALL in second remission whose initial relapse occurred while still on chemotherapy fared significantly better if they received an allogeneic BMT than if they were treated with chemotherapy alone. The five-year DFS rates for children transplanted ranged from 30% to 56%. For those patients treated with chemotherapy alone, the 5-year DFS rates reported since 1986 varied from 17% to 31%. These results indicate that allogeneic BMT is superior to chemotherapy for children with ALL who relapse within 1–2 years of achieving first remission. In our own series reported by Boulad et al,³³⁴ and in those reported by Chessels et al³³⁵ and Barrett et al,³³⁶ transplants may also be superior to chemotherapy in children with ALL who relapse later in first remission. In our own single-center series, for those patients whose first remissions were later than 24 months, the 10-year DFS rate is 81% following allogeneic BMT, compared with 31% with chemotherapy alone.³³⁴ In the multicenter analysis conducted by Chessels et al³³⁵ and the large matched-pair study of children reported to the IBMTR and the Pediatric Oncology Group by Barrett et al,³³⁶ the 5-year leukemia-free survival rates for children who received transplants were 55% and 53%, respectively, versus 18% and 32% for children treated with chemotherapy. Because of continuing concerns regarding treatment-allocation biases, however, prospective trials comparing allogeneic BMT versus aggressive chemotherapy are still needed to resolve this issue.

For adults with ALL who have failed to sustain an initial remission, an HLA-matched marrow graft is the treatment of choice. For adults transplanted in second remission, the reported extended DFS rates for transplant recipients range from 22% to 43%, with relapse, post transplant, representing the cause of failure in 26–56% of cases.^{45,308,323,335} For children and adults transplanted in later remissions or relapse, the extended DFS is only 8–25% at 3–5 years post grafting.^{45,311,337}

Chronic myeloid leukemia

Until recently, allogeneic BMT was the treatment of choice for patients under the age of 60 with CML who have an HLA-compatible donor,³³⁸ cure being achieved in 50–90% of patients transplanted in first chronic phase in reported series.^{6,338–340} In the past, single-agent chemotherapy for CML has been found to be only palliative; it does not significantly prolong survival³⁴¹ (see also Chapter 41). Although certain multidrug chemotherapy regimens can transiently eradicate the Ph⁺ clone, re-emergence of Ph⁺ cells has ultimately occurred in almost all cases. As a result, these regimens have not resulted in a significant improvement in median survival.³⁴² Interferon- α (IFN- α), used as first-line therapy in CML, has induced hematologic remissions in as many as 70% of patients. However, complete cytogenetic remissions have been less common, occurring in fewer than 20% of patients.³⁴³ Nevertheless, several randomized trials have shown a survival advantage in patients who receive IFN- α for the treatment of CML, compared with chemotherapy. For example, a large multi-institutional study from the Italian Cooperative Study Group published in 1994³⁴⁴ demonstrated a statistically significant improvement in overall survival for patients treated with IFN- α compared with conventional therapy with hydroxyurea or busulfan, with median survival times of 72 months versus 52 months, respectively. Other investigators have demonstrated a similarly significant improvement in overall survival for those patients achieving a complete, major, or minor cytogenetic response versus those not achieving a cytogenetic response or historical controls treated with standard chemotherapy.^{345,346} The French Chronic Myeloid Leukemia Study Group reported that treatment with IFN- α together with cytarabine conferred a significant improvement in survival (a 3-year survival rate of 85.7% versus 79.1%; $p=0.02$) as well as a higher hematologic response rate ($p=0.003$) when compared with treatment with IFN- α alone.³⁴⁷ Major cytogenetic responses were observed 12 months after randomization in 126 of 311 patients treated with combination therapy (41%) compared with 75 of 314 patients with IFN- α alone (24%; $p<0.001$).

The recent introduction of imatinib (STI571, Gleevec/Glivec) has transformed the results of non-transplant therapy for CML. In newly diagnosed patients with CML, imatinib has been reported to induce complete cytogenetic remissions in 68% of patients.³⁴⁸ Most patients who achieve complete cytogenetic remission remain PCR-positive for the *BCR-ABL* transcript, which suggests that imatinib is probably not curative. However, the reported incidence of progression to accelerated or blastic phase in these imatinib-treated patients was only 1.5% at 1 year. These exciting results have made the decision

on which patients should proceed to allogeneic BMT more difficult. The lack of long-term follow-up in imatinib-treated patients at present only makes this decision more problematic.

Although imatinib has dramatically improved the response rates in patients with CML, at present, only allogeneic BMT has induced extended *disease-free* survival or cure for a significant proportion of patients, dependent on the phase of disease at BMT. Long-term survival rates ranging from 50% to 60% in multicenter studies and from 70% to 90% in single-institution trials have been achieved in patients transplanted in first chronic phase.^{6,338–340} A retrospective study by the IBMTR, evaluating survival in patients given an HLA-matched sibling BMT versus hydroxyurea or IFN- α therapy, has demonstrated at least a 7-year survival advantage in recipients of BMT.³⁴⁹ In patients transplanted in later stages of CML, eradication of disease with BMT has been less successful. Long-term DFS has been achieved in 10–40% of patients transplanted in accelerated phase and 10–20% of those transplanted in blast crisis.^{350,351}

Multiple factors have been analyzed to determine their effect on disease recurrence and non-leukemic mortality following a transplant for CML. Disease status at the time of transplant and time from diagnosis to transplant are viewed as significant predictors of subsequent relapse and survival.^{352–354} In the three largest series reported to date,^{178,354,355} patients transplanted in first chronic phase had a 5–30% probability of relapse, while those transplanted in accelerated phase had a 40% probability and patients transplanted while in blast crisis had a 60–80% probability.³⁵⁶ The type and intensity of cytoreduction used to prepare patients may also affect post-transplant relapse rates. While the overall results of transplants administered after TBI and cyclophosphamide or conventionally dosed busulfan and cyclophosphamide are not significantly different,⁶ a study from the Fred Hutchinson Cancer Research Center³⁵⁷ demonstrated that higher steady-state plasma busulfan levels were associated with a statistically significant reduction in the cumulative incidence of relapse. Non-relapse mortality appears to be influenced by various other factors. Timing between diagnosis and transplant appears to have a significant impact on non-relapse mortality. An early study from the Fred Hutchinson Cancer Research Center³⁵⁴ demonstrated a statistically significant advantage in actuarial survival for patients transplanted within the first 17 months from diagnosis compared with those transplanted beyond 17 months: 73% versus 54%, respectively. Their more recent results suggest that this difference is significant only when the transplant is delayed beyond 2 years from diagnosis.³³⁸ A report from the IBMTR³⁴⁰ demonstrated that chronic phase patients transplanted 1 year or less from diagnosis have significantly lower regimen-related mortality and relapse rates, resulting in a significantly higher overall DFS compared with patients transplanted later than 1 year from diagnosis. These analyses are important for assessing the optimal timing for transplant in view of recent data regarding the efficacy of imatinib in the treatment of patients with CML. Identification of variables such as Sokal score that predict response to imatinib would greatly facilitate the selection of treatment options. At this time, many oncologists are questioning the role of allogeneic BMT as the first-line treatment of patients with newly diagnosed CML. Randomized trials comparing results of transplants administered early after diagnosis versus imatinib treatment will be required in these patient populations to resolve this issue.

The type of chemotherapy used prior to transplant also affects transplant results. The IBMTR found significantly lower disease-free and overall survival rates in the group of patients who had been treated with busulfan compared with hydroxyurea,³⁵⁵ which was directly related to a significantly higher non-leukemic mortality in the busulfan-treated group. In a multivariate analysis of these results, both pre-transplant treatment and time to treatment were found to be independent predictors of outcome. On the other hand, T-cell-depleted marrow transplants that are effective in reducing or eliminating acute and chronic forms of GVHD are associated with a marked increase in the incidence of post-transplant relapse.^{163,186,187} Indeed, relapse rates of 50–60% have been recorded among recipients of T-cell-depleted grafts,^{163,186,187} compared with rates of 5–30% in recipients of unmodified marrow grafts.^{6,358} Prior treatment with busulfan had a negative impact on transplant outcome, regardless of the time to transplant—presumably owing to the additional host toxicity induced by cumulative exposure to this drug. This study suggests that treatment with busulfan should be avoided in patients who are likely to undergo allogeneic BMT.

The presence or absence of acute and/or chronic GVHD can also impact significantly on the outcome of transplants for patients with CML. Although moderate to severe forms of acute GVHD can have a negative impact on overall survival (35% at 4 years in patients with moderate to severe acute GVHD, versus 74% in those with no or mild acute GVHD),¹⁷⁰ the development of GVHD is associated with a lower relapse rate - the so-called 'graft-versus-leukemia' (GVL) phenomenon. Indeed, an inverse correlation exists between the severity of acute GVHD and the incidence of relapse.³⁵⁹ There is also a lower risk of relapse in patients who develop *de novo* chronic GVHD.¹⁸⁵

As previously discussed, direct evidence of a GVL effect has been provided by numerous studies demonstrating the efficacy of donor leukocyte infusions for the induction of complete hematologic, cytogenetic,

and molecular remissions in patients with CML relapsing post BMT.^{188–198,360} The probability of attaining a molecular remission has been reported to be as high as 90% in patients who have received donor leukocyte infusions in cytogenetic or molecular relapse, compared with 70% for patients treated in hematologic chronic phase and 40% (n=20) for patients relapsing in accelerated phase (p=0.009).

Because of the striking results achieved with donor leukocyte infusions, several transplant groups have begun to re-evaluate T-cell-depleted transplants used in combination with post-transplant donor leukocytes to prevent and/or treat disease recurrence post allogeneic BMT as an approach for reducing non-leukemic mortality in older patients and patients who have received prolonged therapy prior to referral for transplant. Although several early studies demonstrated that T-cell-depleted transplants for CML are associated with high relapse rates, T-cell depletion reduces both the incidence and severity of acute and, in some cases, chronic GVHD, leading to decreased peritransplant morbidity and mortality, particularly in older patients.^{178,339} A strategy currently under investigation in these 'older' patients is T-cell-depleted BMT followed by prophylactic or therapeutic donor leukocyte infusions 9–12 months post transplant, when the dose of T cells required to induce GVHD is higher. This strategy is particularly practical in patients with CML, because most relapses occur later than 6 months post transplant, and can be detected early by molecular techniques.^{361,362} Studies have shown that repeated tests detecting *BCR-ABL* mRNA transcripts by PCR-amplified assays in the blood or marrow of patients post transplant is highly predictive of subsequent clinical relapse.³⁶² Ongoing studies are currently examining this approach for the treatment of CML.

Myelodysplastic syndromes

The myelodysplastic syndromes (MDS; see Chapter 40) are a heterogeneous group of clonal hematologic disorders characterized by peripheral cytopenias and normal to increased marrow cellularity. In over 70% of cases, clonal cytogenetic abnormalities are observed, particularly single deletions of 5q, monosomy 7, and trisomy 8. According to the French—American—British (FAB) classification, five categories of MDS have been described, based on the percentage of blast cells in the marrow or blood, the presence of Auer rods in myelogenous precursors, and the presence of ringed sideroblasts (see Chapter 40): these include refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-t) and chronic myelomonocytic leukemia (CMML).³⁶³ A subgroup of patients exhibiting 'hypoplastic MDS' characterized by a hypocellular bone marrow with dysplastic features has been described.³⁶⁴ Hypoplastic MDS is often confused with aplastic anemia (AA), particularly when there are no cytogenetic abnormalities or overt dysplastic features. As idiopathic myelofibrosis is often included in studies evaluating transplantation in patients with MDS, despite it being a myeloproliferative disorder, this discussion will include patients with this disorder (see also Chapter 42).

For patients lacking an HLA-matched donor, particularly older adults, treatment is primarily supportive. Intensive chemotherapeutic regimens have yielded only short-term remissions, and have been associated with significant morbidity and mortality.³⁶⁵ Although certain subgroups of patients may respond to treatment with danazol, oxymethalone,³⁶⁶ low-dose cytarabine,³⁶⁷ azacytidine,³⁶⁸ and supportive measures, such as the use of G-CSF or granulocyte-macrophage colony-stimulating factor (GM-CSF) to induce production of mature neutrophils^{369,370} and/or erythropoietin to stimulate red cell production, these strategies have failed to produce sustained complete remissions in the majority of patients.

In contrast to these results, allogeneic BMT administered to patients prepared with TBI or busulfan and cyclophosphamide have led to sustained remissions of disease in approximately 30–73% of cases, depending on the disease status at the time of transplant.^{371–375} Accumulated experience suggests that patients transplanted for RA or RARS enjoy better prospects for DFS (53–73%) than patients with RAEB (20–38%) or RAEB-t (14–27%). This difference reflects the extremely low incidence of disease relapse among patients transplanted for RA or RARS (0–6%), which contrasts with the high relapse rates (45–61%) associated with transplants for RAEB or RAEB-t.^{371,372} A 10-year retrospective analysis of factors influencing the outcome of 71 consecutive recipients of an allogeneic transplant for the treatment of MDS demonstrated that younger age (less than 37 years), favorable FAB classification (i.e. RA), lack of prior chemotherapy before BMT, and cytoreduction with TBI and cyclophosphamide were significantly associated with better outcome.³⁷⁶ Because of the improved outcome of transplantation for RA, new strategies are now being explored for the treatment of patients with RAEB and RAEB-t that either intensify the pretransplant cytoreductive regimen³⁷⁷ or attempt to induce less than 5% blasts with intensive chemotherapy prior to proceeding to transplant.³⁷² These strategies are based on the hypothesis that reduction or elimination of blasts or cytogenetic evidence of disease prior to transplant may reduce the incidence of post-transplant relapse. However, these strategies will be successful only if peritransplant

mortality is not increased by the more intensive therapy.

Cumulative evidence derived from single-patient reports indicates that patients treated with HLA-matched BMT for severe myelofibrosis and malignant myelosclerosis, once engrafted, may recover normal hematopoiesis and achieve complete resolution of fibrosis with sustained DFS.^{378,379} However, the presence of marrow fibrosis may be associated with a delay in engraftment and with graft rejection.³⁷¹ Experience with BMT for this group of patients remains too limited to provide a meaningful probability of DFS.

Lymphomas

Approximately 50% of adults and over 70% of children with intermediate and high-grade NHL will be cured by current dose-intensive multi-agent chemotherapy (see Chapter 36). Similarly, primary treatment of Hodgkin's disease is now curative for over 70% of cases (see Chapter 35). In view of these results, BMT has largely been reserved for patients who fail to attain or sustain a primary remission.

Although experience with allogeneic BMT for the treatment of NHL is fairly limited,³⁸⁰ studies indicate that disease status at transplant as well as sensitivity to prior chemotherapy are the most important prognostic indicators of long-term DFS. Whereas patients with chemotherapy-refractory disease have only a 10–23% probability of extended DFS when treated with chemotherapy,^{381–383} 25–44% of those transplanted in second remission and 88% of those transplanted in first remission have experienced long-term DFS.^{384,385} To date, four published studies (three retrospective and one prospective) have comparatively addressed the relative merits of allogeneic BMT versus autologous BMT for adults with NHL, and have yielded conflicting results. In retrospective analyses, the probabilities of disease progression were not different for the allograft and autograft recipients in the Seattle series,³⁸⁶ they were lower in allograft recipients in the Johns Hopkins series,⁸ and they were lower only in allograft recipients with lymphoblastic lymphoma in the EBMT Registry series.⁷ In the one study that demonstrated a lower rate of disease progression in allograft recipients, the overall progression-free survival was not significantly different in the allogeneic versus autologous BMT recipients—primarily because of GVHD complications in the allograft recipients.⁷

Evidence of an allogeneic graft-versus-lymphoma effect has been provided by a prospective comparative trial of allogeneic versus autologous BMT.³⁸⁴ The progression-free survival rate was 24% in the autologous transplant group and 46% in the allogeneic transplant cohort at 2 years—a difference that was not statistically significant. However, the differing probabilities of disease progression (69% in the autologous group and 20% in the allogeneic group) were statistically significant. This distinction was seen both in patients with chemosensitive disease (60% versus 18%) and in those with chemoresistant disease (87% versus 18%). Disease progression was the cause of death in 82% of the autograft recipients but in only 25% of the allograft recipients. The allograft arm, however, had a significantly higher rate of non-relapse deaths—most commonly attributable to infection in the context of GVHD. Of the allograft recipients, 52% developed acute and 35% chronic GVHD respectively. Multivariate analysis revealed that the probability of relapse was lower in patients with chemosensitive disease and in patients receiving an allograft. While this study supports the notion that allogeneic BMT may contribute to a reduced risk of post-transplant relapse, this study and the Johns Hopkins trial⁸ have also documented high allotransplant-related mortality rates, which have essentially eliminated any improvement in survival or DFS rates in the allogeneic BMT recipients.

Stem cell transplantation has been applied to children with NHL only after they have failed chemotherapy alone. For these patients, the use of allogeneic versus autologous transplantation depends on the quality of autologous marrow or PBSC that can be collected and the availability of a donor. Results accrued from the most recently published series of transplants for childhood NHL have documented results similar to those recorded in adults.^{8,386–388}

These data indicate that if the allogeneic graft-versus-lymphoma effect could be harnessed without a prohibitive transplant-related mortality, this might result in improved DFS for patients with lymphoma. Recent studies using non-myeloablative or reduced-intensity conditioning regimens have demonstrated a marked reduction in mortality rates; however, longer followup will be needed to assess the ultimate relapse rates and DSF.

Multiple myeloma

Until recently, therapy for multiple myeloma (see Chapter 34) has been limited to combination chemotherapy with or without IFN- α .^{389–391} Although response rates of 40–70% have been achieved with a variety of different regimens, the median event-free survival is still only 3 years.^{391,392} In view of the results of conventional chemotherapy and IFN- α , the use of more intensive, myeloablative chemotherapy regimens followed by allogeneic or autologous hematopoietic stem cell grafts is being explored.^{393–395} Although several hundred patients have been treated with such transplants, relapse following autologous

stem cell transplantation and transplant-related mortality following allogeneic BMT have remained major obstacles.^{396,397}

Overall success rates with either approach have been modest. The 3-year survival rates at different stages of disease currently range from 30% to 60%.^{398,399} The EBMT revealed overall survival rates of 32% at 4 years and 28% at 7 years for allograft recipients following TBI and intensive chemotherapy or high-dose chemotherapy alone.³⁹⁹ The relapse-free survival rate for those patients rendered disease-free post BMT was 34% at 6 years. Favorable pretransplant prognostic factors that predicted a better outcome post transplant included female sex, stage I disease at diagnosis, one course of previous treatment, and the achievement of a complete remission before pretransplant conditioning. In addition, low levels of β 2-microglobulin and the diagnosis of IgA myeloma predicted a better outcome. Following transplant, only the attainment of a complete remission predicted improved transplant outcome. A comparison between 24 patients with myeloma treated with allogeneic BMT and a similarly treated group of patients treated with an autologous PBSCT⁴⁰⁰ revealed no significant differences in event-free survival (median 16.7 for autologous PBSCT versus 31 months for allogeneic BMT; $p=0.8$). Transplant-related mortality was 12.5% in the autologous PBSCT recipients versus 25% for the allogeneic BMT group.

Cumulative results derived from single case reports and small published series have suggested that an allogeneic graft-versus-myeloma effect exists similar to that seen in CML. Vesole et al⁴⁰¹ were the first to report a marked tumor reduction after donor leukocyte infusions in patients with relapsed or persistent multiple myeloma following a marrow allograft. In a retrospective study by Lokhurst et al⁴⁰² of 13 consecutive recipients of donor leukocyte infusions administered for relapsed multiple myeloma post transplant, 4 achieved a partial remission and 4 a complete remission. Responses were observed at a median of 6 weeks (range 4–10 weeks). In this retrospective study, the only predictors of response were infusion of at least 10^8 cells/kg, and induction of overt GVHD.⁴⁰¹ Using a different approach, Kwak et al⁴⁰³ succeeded in transferring myeloma idiotype-specific immunity from an actively immunized marrow donor, and hypothesized that this myeloma-specific form of adoptive cell therapy may also be used to enhance the antimyeloma effect of the allogeneic graft.

These developments in the treatment of multiple myeloma are promising. Translation to improved DFS will depend upon better selection of patients likely to benefit from this intensive approach, introduction of transplant earlier in the disease, and the development of better-tolerated transplant regimens. As in the case of lymphoma, one option is to employ the well tolerated, less-intensive, non-myeloablative preparative regimen that can now be used with allogeneic PBSCT to secure durable engraftment.

BMT for patients lacking an HLA-identical sibling donor

Over the last 15 years, there has been an enormous expansion in the use of allogeneic stem cell transplants from HLA partially mismatched related donors as well as from HLA-matched unrelated marrow or cord blood donors for the treatment of patients lacking an HLA-matched sibling. Experience with these transplants has also engendered several improvements in tissue typing and donor selection as well as new approaches to infection prophylaxis and supportive care, which have resulted in a limited but encouraging improvement in overall results. Thus, while the DFS rate for good-risk patients reported by the National Marrow Donor Program in 1993 was only 43%, several centers have recently reported 50–70% event-free survival rates for young adults and children with acute leukemias transplanted from early remission and first-chronic-phase CML. Similarly, unrelated cord blood transplants have been associated with a 40–50% DFS rate in good-risk patients.^{404–406} In this section, we shall briefly review the current status of these different transplant approaches in the treatment of patients lacking a matched sibling donor.

Unmodified marrow grafts from partially matched related donors

Ever since the first recognition of the importance of the HLA system in the definition of histocompatibility for BMT, multiple groups have explored the use of HLA partially matched related donors in an attempt to identify tolerable histoincompatibilities within the HLA region. The early studies focused on the use of HLA-haplotype-identical but MLC-compatible related donors because of murine models that had indicated that transplantation from MHC class II disparate donors were most likely to result in lethal GVHD.⁴⁰⁷ Initial studies, conducted in children with SCID, supported this approach to donor selection, since allodisparities for HLA-A and/or -B on one haplotype were tolerated without lethal GVHD.^{408,409} In a review of 10 such transplants,⁴¹⁰ 8 patients developed GVHD, which was severe in only 2. Five of these patients, however, died of infection less than 100 days post BMT, precluding an assessment of the incidence or severity of chronic GVHD. Of three patients who received HLA-D-incompatible marrow, none survived long enough to assess GVH reactions. Patients with SCID transplanted from donors HLA-disparate for both class I and class II determinants had a poor

outcome. Of 19 evaluable patients, 3 had graft failure and 10 developed severe, fatal GVHD—none survived.

Experience with partially matched related donor marrow grafts in patients with aplastic anemia underscores the incremental risk of graft rejection when HLA-disparate grafts are administered to immuno-competent hosts, even after intensive treatment with immunosuppressive agents. In one large series of patients cytoreduced with cyclophosphamide alone, HLA-phenotypically matched non-sibling donor transplants were associated with consistent engraftment, while 7 or 11 grafts from one-HLA-locusdisparate donors and 3 of 3 transplants from two-locus-disparate donors were rejected.⁴¹¹ Of the 13 patients who achieved sustained engraftment, grade II-IV GVHD was observed in 5 of 8 phenotypically matched and all 4 single-HLA-allele-disparate recipients.

In 1985, Beatty et al⁴¹² reported that 75% of leukemic patients who received a one-antigen-mismatched related transplant following preparation with TBI and cyclophosphamide developed grade II-IV GVHD. However, the long-term DFS was similar to that observed following HLA-matched sibling BMT. In this series, no single allelic disparity (i.e. HLA-A, or -B, or -D) could be identified that resulted in a greater risk of severe GVHD. Subsequent studies on an expanded patient population from the same group, however, have modified this definition of tolerable incompatibilities in that donor-recipient pairs differing for HLA class II alleles on one haplotype have experienced a higher incidence of severe GVHD.⁴¹³ Graft rejections were observed in up to 9% of these single-HLA-allele-disparate transplants—an incidence higher than the less than 1% incidence of graft failure following an HLA-matched sibling graft. Transplants for leukemia from related donors differing at more than one HLA allele on the unshared haplotype had a 21% incidence of graft rejection and an 80–85% incidence of severe acute and chronic GVHD. In this latter group of patients, the overall survival rate was markedly inferior (<15%) to that observed following HLA-phenotypically matched or single-HLA-allele-disparate marrow transplants (40–45%). These data indicated that engraftment of unmodified bone marrow from a donor exhibiting unique HLA disparities requires a higher degree of pretransplant immunosuppression than that provided by TBI and cyclophosphamide in order to ensure consistent engraftment. In addition, such transplants were associated with a significantly higher incidence of severe acute and chronic GVHD. The complications of HLA-A or HLA-B single-alleledisparate marrow grafts—at least in patients transplanted for leukemia—are tolerable and may be associated with long-term DFS rates comparable to those achieved following HLA-matched sibling grafts.

Transplants of unmodified marrow from unrelated donors

In 1977, the successful reconstitution of immunologic function in a child with SCID transplanted with marrow from an HLA-compatible unrelated donor was reported by our group.⁴¹⁴ Subsequent reports demonstrated that transplants from unrelated donors could restore hematopoiesis in patients with leukemia and aplastic anemia.^{415,416} In 1988, the results of 40 patients with refractory forms of leukemia and aplastic anemia who received marrow grafts from unrelated, HLA-matched or partially mismatched donors obtained from a statewide registry developed in Iowa were reported.⁴¹⁶ Of these patients, 15% survived disease-free for longer than 1 year post transplant, albeit with severe acute GVHD in 67% of patients and chronic GVHD in all but one case. Although consistent engraftment was observed in leukemic patients prepared with TBI and cyclophosphamide, two out of four patients with aplastic anemia experienced graft failures despite cyto-reduction with total lymphoid irradiation and cyclophosphamide.⁴¹⁶ Of five patients with aplastic anemia reported by Gajewski et al,⁴¹⁷ one suffered graft failure after preparation with total lymphoid irradiation and cyclophosphamide. These early experiences indicated an increased risk of both GVHD and graft failure following unrelated BMT.

Early results of unrelated BMT for the treatment of CML were more encouraging. In one study, 102 patients with CML received an unrelated transplant at one of four centers, 29% of whom experienced extended DFS.⁴¹⁸ In this series, those patients who received serologically matched unrelated transplants achieved a somewhat better long-term DFS (39%) than those transplanted from single-antigen-disparate unrelated donors (27%). Eighty percent of recipients of an unmodified unrelated graft in this series developed severe GVHD. In this series, although T-celldepleted marrow transplantation was associated with less severe GVHD, long-term DFS was comparable to that observed following unmodified marrow transplants. In a subsequent report from Seattle of 52 patients with leukemia who received serologically matched unrelated marrow,⁴¹⁹ the incidence of grade II-IV acute GVHD was 79%, compared with 36% for patients transplanted from HLA-matched siblings. This incidence of grade II-IV GVHD is comparable to that seen following transplants of marrow from one or two-HLA-allele-disparate related donors.⁴²⁰

Kernan et al⁴²¹ analyzed the initial 462 recipients of an unrelated BMT reported by the National Marrow Donor Program. Of these patients, 352 were transplants for leukemia, 38 for MDS or lymphomas, and 72 for non-malignant disorders, such as aplastic anemia and congenital disorders of immunity or metabolism. In this series, early or late graft failures were observed in 14% of cases, grade II-IV acute GVHD in

64% of cases, and grade III-IV acute GVHD in 47% of cases.⁴²¹ The incidence of severe grade III-IV acute GVHD was significantly increased among recipients of non-T-cell-depleted marrow grafts (60%) when compared with recipients of T-cell-depleted marrow (30%). Limited or extensive chronic GVHD was observed in 55% of patients—particularly among recipients of unmodified, marrow grafts. Despite the increased incidence of graft failure and severe acute and chronic GVHD, the DFS rate in good-risk patients was approximately 40%. However, for patients with advanced leukemias, the DFS rate was 20% or less. Similarly, patients with MDS or aplastic anemia had 18% and 29% DFS rates, respectively. A detailed analysis of the 196 patients with CML transplanted in this series⁴²¹ was subsequently reported,⁴²² demonstrating a two-year DFS rate of 45% for patients in first chronic phase transplanted within 1 year of diagnosis. For patients transplanted later than 1 year from diagnosis, a 36% DFS rate was observed.

As experience with matched unrelated BMT has increased, the results of these transplants have continued to improve. This progress probably reflects, in part, the introduction of molecular typing for HLA class II determinants, which has improved the selection of histocompatible donors. Recognition of the more profound and prolonged states of immunodeficiencies experienced by recipients of unrelated grafts^{423,424} has also led to more aggressive and more extended use of antiviral and antifungal agents for prophylaxis against infections—particularly those due to CMV. In addition, as the follow-up of unrelated marrow grafts has lengthened, a strikingly reduced risk of relapse associated with unrelated donor-derived transplants when used in the treatment of several forms of leukemia, including CML and Ph⁺ ALL, has become apparent. As a result, DFS rates for adults younger than 50 years transplanted for CML in the first year after diagnosis have improved to up to 74% in the Seattle series.⁴²⁵ In one series of patients who received an unrelated marrow graft for Ph⁺ ALL, the 2-year leukemia-free survival rate was 49%⁴²⁶—a result that is comparable to or better than results achieved with HLA-matched sibling transplants.⁴²⁷

The marked increase in severe acute and chronic GVHD in recipients of HLA-phenotypically matched unrelated marrow probably reflects alloreactions generated against molecular differences in class I and II alleles that can only be detected by more discriminatory molecular tissue typing approaches. Molecular differences at HLA-A, -B, -C as well as class II alleles undoubtedly also contribute to the increased frequency of alloreactive T cells generated in mixed lymphocyte cultures between HLA-phenotypically matched unrelated donor-recipient pairs when compared with mixed lymphocyte cultures between HLA-matched siblings.⁴²⁸ Early studies using molecular typing techniques demonstrated that up to 30% of HLA serologically matched unrelated donors will differ from their intended recipient by one or two alleles when analyzed by isoelectric focusing.^{429,430} Subsequent reports demonstrated that microvariant disparities for class II determinants also occur at significantly increased frequency among HLA serologically matched unrelated donor—recipient pairs and that these disparities have major clinical significance.^{144,307} More recent studies have also demonstrated that among HLA-A, -B serologically matched, DRB1 molecularly matched unrelated donor-recipient pairs, 48% will demonstrate at least one microvariant disparity at HLA-A or -B by molecular typing.⁴³¹ Differences among HLA-C typing have also been uncovered among HLA-A, -B serologically matched unrelated donor-recipient pairs.⁴³²

The clinical significance of these molecular disparities is currently under study. In one published report,⁴³³ HLA-C disparities were found to be associated with an increased risk of graft rejection. However, this has not been confirmed in other studies. An increase in severe GVHD has also been reported following BMT from HLA-A or HLA-B singly mismatched unrelated donors.^{434,435} Although overall survival was not significantly affected by single HLA-A or HLA-B disparities in young patients, it was markedly reduced among adult single-alleledisparate patients (19–49 years).⁴³⁵ In addition, Petersdorf et al⁴³⁶ had reported severe GVHD in 48% of recipients of unmodified HLA-A, -B serologically matched, DRB1-matched unrelated marrow transplants versus 70% among recipients with DRB1 mismatches. Recent reports from the NMDP have suggested that HLA DQ mismatching was the more important than mismatching at other loci in determining the outcome of unrelated transplantation in CML.⁴³⁷ Other studies have found that mismatching for HLA-A or -C significantly increases the incidence of GVHD, while mismatching at class II was not linked to GVHD.²¹⁰ Similarly, there are conflicting reports on the significance of HLA-DP mismatching in the unrelated donor setting.^{438–440} In summary, mismatch at the molecular level leads to an increased incidence of GVHD that usually, but not always, impacts adversely on survival. However, which of the HLA alleles are most important for this effect remains controversial and will require further study.

Allogeneic cord blood transplants from related and unrelated donors

In 1984, Broxmeyer and co-workers first presented data from murine models supporting the possibility that umbilical cord blood might contain sufficient hematopoietic progenitors to reconstitute lethally irradiated allogeneic recipients.⁴⁴¹ This hypothesis was tested clinically in 1989 by Gluckman et al,⁴⁴² who reported a successful transplant of a patient with

Fanconi anemia using cord blood derived from an HLA-identical sibling. Subsequently, the number and characteristics of hematopoietic progenitor cells and lymphocytes in human umbilical cord blood have been extensively analyzed.^{441,443} These studies have shown that the concentrations of colony-forming units granulocyte-macrophage (CFU-GM) and of colony-forming units granulocyte-erythroid-macrophage-megakaryocyte (CFU-GEMM) are 17- to 28-fold greater in umbilical cord blood than in adult blood,⁴⁴⁴⁻⁴⁴⁶ and that early CD34+CD38- progenitors in umbilical cord blood have a much greater proliferative potential^{447,448} and capacity for self-renewal.^{448,449}

Based on these studies, several centers have initiated programs exploring the application of umbilical cord blood transplants derived from either HLA-matched or partially matched related or unrelated donors for the treatment of leukemias, aplastic anemia, and congenital disorders of hematopoiesis and metabolism.^{404,450} Furthermore, cord blood banks have now been established at several centers, modelled on the cord blood program established at the New York Blood Center,⁴⁵¹ to provide a source of typed cryopreserved unrelated cord blood grafts for transplant purposes. Certain of these banks now include over 20 000 HLA-typed cord blood specimens, prescreened to exclude the possibility of transmission of congenitally acquired infections. The HLA typings of the cord bloods stored at these banks are now computer-linked with the major marrow donor registries, including the National Marrow Donor Program.

To date, cord blood transplants have been predominantly applied to the treatment of children and adolescents with leukemia, acquired aplastic anemia, or severe congenital cytopenias. This relatively restricted approach has been governed by concerns regarding the capacity of limited numbers of umbilical cord mononuclear cells to engraft in fully grown adults. Many adults have now been successfully engrafted with HLA-matched umbilical cord blood⁴⁰⁶ - a fact that has kindled greater interest in the potential of such grafts in older patients. On the other hand,⁴⁵² retrospective analyses have supported concerns that low doses of cells place the patient at risk of graft failure. By 1995, it was estimated that over 450 unrelated cord blood transplants had been performed worldwide.⁴⁵² Two recent retrospective analyses of centers reporting to the International Cord Blood Registry^{452,453} and to EuroCord,⁴⁰⁶ coupled with two of the larger single-institution experiences,^{405,454} have reported, and can be briefly summarized.

Umbilical cord blood transplants derived from sibling donors have enjoyed considerable success in the treatment of young patients with leukemia and other hematologic diseases. In an analysis of 62 patients transplanted between 1988 and 1995 who were reported to the International Cord Blood Registry and 78 patients (many or most of whom were also reported to the Registry) reported to the EuroCord Registry, cord blood grafts induced durable engraftment and hematopoietic reconstitution in 91% of the patients transplanted. Doses of nucleated cells varied, but median dose estimates in the two series were 3.7×10^7 and 4.7×10^7 nucleated cells/kg recipient weight, respectively. In the EuroCord Registry analysis, transplant doses providing less than 3.7×10^6 nucleated cells/kg were associated with a significantly increased risk of graft failure. Among those engrafted, low cell dose delayed recovery of platelets and, to a varying but lesser degree, neutrophils. The incidence of acute GVHD of grade II-IV severity was only 2% and 9% in the two series for patients receiving HLA-matched or one-HLA-allele-disparate grafts; and only 40-50% in two- or three-HLA-allele-disparate recipients. Survival at 1 year post transplant for the patients reported to the EuroCord Registry was 63%—a result similar to that which might be achieved in a comparable group of young patients transplanted with unmodified marrow.

The results of unrelated HLA-matched or partially compatible cord blood grafts in the two registry series and the single-institution experiences are inferior to those recorded for related cord blood grafts, but they are quite encouraging. The overall incidence of graft failure in recipients of unrelated cord blood grafts is strikingly similar to that recorded for related cord blood grafts (6-7% versus 9%). The risk of graft failure in each series is inversely proportional to cell dose, and increases with greater degrees of HLA disparity. On the other hand, the overall incidence of grade II-IV acute GVHD is much higher (57%), ranging from 33% in HLA-matched hosts to 73% in two- or three-HLA-allele-disparate hosts. Overall, however, the results from each series suggest a lower incidence of severe GVHD following a cord blood graft than a marrow graft for a given level of HLA disparity.

The basis for the apparent reduction in the capacity of a cord blood graft to induce GVHD is still unclear. The proportion of naive T cells is increased in umbilical cord blood relative to adult marrow, but the capacity of these cells to proliferate in response to an allogeneic stimulus is similar.^{455,456} However, the effector functions of these T cells may differ in that activated umbilical cord blood T cells produce less inflammatory cytokines such as IL-2 and IL-12, and have less cytolytic activity than their adult T-cell counterparts in marrow allografts.^{452,456-458} The NK cells in umbilical cord blood are comparable in number and general function to those detected in adult marrow.⁴⁵⁹ Whether the antigen-presenting accessory cells, such as dendritic cells, are comparable in their function is still under study.

The overall results of unrelated cord blood grafts are strikingly inferior to those achieved with matched

related cord blood or marrow allografts. In the European Registry,⁴⁰⁶ survival at 12 months was 29% versus 63% in recipients of related cord blood grafts. This difference may, in part, reflect the consequences of the higher incidence of severe GVHD in unrelated cord blood transplant recipients. However, a major difference lies in the incidence of lethal infections particularly infections due to CMV. Such infections may be particularly difficult to reverse when an immunologically naive, CMV-seronegative cord blood graft is transplanted into an unrelated adolescent or adult already harboring a latent infection.

Taken together, the results of unrelated cord blood transplants accrued thus far suggest that such transplants may be comparable to unrelated BMT when applied to children and young adults with leukemia or other lethal hematologic disorders. Such transplants appear to have certain unique advantages over unrelated BMT, including their immediate and enduring availability, their low risk of infection transmission, and their reduced potential to induce severe GVHD. Furthermore, pools of potential cord blood grafts can also be recruited from selected ethnic groups under-represented in existing marrow donor registries. Accurate assignments of donor HLA haplo-types can also be ascertained, since the maternal donors are usually also HLA-typed. On the other hand, these transplants also have several potential limitations in that the doses of progenitor cells and adequately competent alloreactive T cells are limited, which may limit the capacity of umbilical cord blood transplants to achieve engraftment in larger adults particularly those presensitized to alloantigens by prior transfusion or pregnancy. The recovery of platelets in recipients of such grafts is also often delayed. Furthermore, the immunologic naivete of umbilical cord lymphocytes may preclude a sufficiently rapid and effective response to infection in adolescents and adults harboring latent herpesvirus infections such as CMV. Whether cord blood grafts will be comparable to adult marrow grafts in their capacity to confer enhanced leukemia resistance to the allogeneic host remains to be determined.

T-cell-depleted HLA non-identical related and HLA-compatible unrelated marrow grafts

The principal limitation to the use of transplants from suitable matched unrelated donors is that such donors are not available for 30–50% of the patients lacking an HLA-matched sibling. Development of more sensitive techniques for the selection of unrelated donors, while important to our understanding of incompatibilities contributing to graft rejection, GVHD, and immunodeficiency, will nevertheless only serve to further restrict the number of patients for whom an 'adequately compatible' donor will be identified. There remains a continuing need to develop transplant approaches that will result in consistent hematologic and immunologic reconstitution without severe or lethal GVHD when patient and donor are disparate at one more HLA alleles.

The potential of T-cell-depleted transplants from HLA-non-identical donors, including donors who are haplotype-disparate, has been clearly demonstrated when applied to BMT for the correction of SCID. In 1981, our group⁴⁶⁰ reported that transplants of HLA-A, -B, -DR haplotype-disparate parental marrow depleted of T cells by agglutination with a soybean lectin followed by resetting with sheep red blood cells could reconstitute hematopoietic and lymphoid function in children with leukemia or SCID without GVHD. Over the last 20 years, of our series of 55 children with SCID transplanted with HLA-haplotype-disparate parental marrow depleted of T cells by this technique, 74% currently survive with reconstitution of immunity and stable donor T-cell chimerism. In this series, fewer than 10% developed grade I acute GVHD. The actuarial DFS for this group is not different from that observed following unmodified HLA-matched grafts for SCID. Other centers incorporating this and other approaches to T-cell depletion have reported similar results.

Unfortunately, until recently, T-cell-depleted HLA-non-identical BMT for the treatment of leukemia and other acquired and genetic diseases of hematopoiesis was considerably less successful owing to the associated increased risk of graft failure. However, the introduction of more intensive cytoreductive and immunosuppressive regimens and alternative, less-extensive T-cell depletion techniques achieving only a 2.0–2.5 \log_{10} depletion of T cells has reduced the frequency of rejection following transplants of T-cell-depleted marrow from HLA-matched unrelated or HLA-mismatched related donors without unduly increasing the incidence of severe GVHD. For example, in one series of patients transplanted with unrelated donor marrow depleted of T cells with the T10B9 monoclonal antibody plus complement, patients with acute leukemia in early remission or chronic phase CML achieved a 48% extended DFS.⁴⁶¹ In this series, in which a 2 \log_{10} level of T-cell depletion was achieved, HLA-matched unrelated marrow grafts were associated with only a 20% incidence in grade II-IV GVHD. Similarly, in a compendium of unrelated marrow transplant results from four centers in the UK by Howard et al,⁴⁶² the incidence of engraftment was comparable to that observed following unmodified BMT. T-cell-depleted grafts in this series, which were associated with a markedly reduced incidence of acute GVHD, were also associated with a significantly improved DFS rate (60% versus 29% at 3 months)—a difference not observed among HLA-matched sibling transplant recipients. In a review of results of marrow grafts from donors identified by the National Marrow Donor Program for the treatment of

CML, McGlave et al⁴⁶³ found that durable engraftment following T-cell-depleted grafts did not differ from that following unmodified grafts (94% versus 88%), reflecting the use of more effective immunosuppressive cytoreductive regimens for the T-cell-depleted grafts. In addition, the incidence of relapse following a T-cell-depleted unrelated graft (16% at 2 years) did not differ significantly from that observed following an unmodified graft (10% at 2 years). The finding of a low relapse rate following unrelated T-cell-depleted grafts applied to patients with CML stands in striking contrast with the markedly increased incidence of relapse of CML observed following T-cell-depleted grafts derived from matched siblings.^{463,464} As a result, T-cell-depleted grafts were associated with a significant improvement in long-term DFS.

Over the last 10 years, the results of T-cell-depleted partially matched related and HLA-compatible unrelated marrow transplants in children have yielded particularly promising results. In 1989, Camitta et al⁴⁶⁵ reported that 5 of 10 children with aplastic anemia achieved long-term reconstitution following transplantation of T10B9+C⁺ T-cell-depleted marrow derived from partially matched related or unrelated matched donors. A subsequent report published by this group in 1996 demonstrated that 15 of 28 (54%) children with aplastic anemia were alive, transfusion-independent, with a median follow-up of 2.75 years (range 1.1–8 years) following a T10B9 T-cell-depleted unrelated BMT. Casper et al⁴⁶⁶ reported a 44% extended DFS rate in 50 children with leukemia who received T-cell-depleted (T10B9) unrelated transplants from serologically matched ($n=13$) or mismatched ($n=37$) donors. Similar DFS rates in children following unrelated transplants were reported utilizing both T-cell-depleted and T-cell-replete marrows for the treatment of first chronic phase CML and acute leukemia in early remission.^{467,468}

Although HLA-A, -B, -DR haplotype-disparate BMT from related donors, if suitably depleted of T cells, can induce full hematologic and immune reconstitution without GVHD, the high risk of graft rejection in patients other than children with SCID has, until recently, limited its use in patients with leukemia. Over the last 15 years, however, more tolerable, intensive immunosuppressive cytoreductive regimens have been designed, often combining high-dose thiotepa or cytarabine with TBI and cyclophosphamide or fludarabine. In addition, supplementary immunosuppression with ATG, T-cell-specific monoclonal antibodies, and/or high-dose steroids has been employed to eliminate residual host T cells that could mediate immune rejection. These regimens have almost eliminated the risk of graft failure following T-cell-depleted grafts from matched related donors, and have markedly reduced graft rejection following transplants of T-cell-depleted mismatched related and unrelated donors.^{469,470} The groups of Reisner et al and Weissman et al introduced another approach to overcome host resistance, demonstrating^{471–474} in murine models that the incidence and quality of engraftment of T-cell-depleted MHC-disparate grafts could be strikingly enhanced by increasing the stem cell dose. Based on these findings, Aversa et al⁴⁷⁵ investigated the use of haplo-identical T-cell-depleted bone marrow plus G-CSF-stimulated peripheral blood progenitor cells depleted of T cells by lectin agglutination and resetting with sheep red blood cells.^{476,477} Combining T-cell-depleted bone marrow with G-CSF-stimulated PBSC resulted in a 5- to 10-fold increase in the number of CD34⁺ progenitor cells transplanted. Patients did not receive any post-transplant GVHD prophylaxis. Of the initial 17 patients transplanted with this technique (most with advanced or refractory leukemia), 16 achieved durable, full hematopoietic reconstitution, with grade III-IV GVHD developing in only one patient.⁴⁷⁵ In an effort to reduce peritransplant mortality, this group subsequently substituted fludarabine for cyclophosphamide, in a cytoreductive regimen also including 8 Gy single-fraction TBI, thiotepa, and ATG. In a later series of patients, 54 of 60 patients transplanted achieved sustained engraftment and hematopoietic reconstitution. Twenty-six patients (43%) were alive disease-free 2–22 months (median 8 months) post transplant. Grade II or more GVHD was observed in fewer than 5% of patients, and chronic GVHD in none.

The group of Henslee-Downey et al⁴⁷⁸ also reported promising results following partially T-cell-depleted mismatched related donors given cytarabine post transplant for the prevention of GVHD. Using T10B9-depleted bone marrow and cytoreduction with fractionated TBI, cytarabine, and cyclophosphamide, 72 patients received a one- ($n=13$), two- ($n=35$), or three ($n=24$) HLA-allele mismatched transplant for goodrisk ($n=20$) or high-risk ($n=52$) leukemia ($n=66$) or aplastic anemia/MDS ($n=6$). Of the 72 patients, 62 (87%) ultimately achieved durable engraftment and hematopoietic reconstitution. The risk of graft failure for transplants expressing one or two donor-unique HLA alleles was less than 5%; however, it was over 30% for HLA-A, -B, -DR-disparate grafts. The incidence of grade II-IV acute GVHD was low (16%), irrespective of the degree of HLA disparity. Chronic GVHD developed in 17–40 (35%) patients evaluable. The probability of DFS for the whole group was 30%, and was 53% for patients transplanted for acute leukemia in first or second remission or for chronic phase CML (good risk), and 23% for patients with more advanced or refractory disease. As in the Perugia series, infections, and, in the high-risk group, leukemic relapses, constituted the principal causes of death.

Taken together, these studies suggest that T-celldepleted HLA-haplotype-disparate transplants, which have long been established as an efficacious

treatment for SCID, are now becoming increasingly effective for the treatment of patients with leukemia. If these trends continue, this transplant approach should secure the possibility of an allogeneic transplant for almost all patients for whom a transplant is currently recognized as a treatment of choice. In the future, the choice between an unrelated bone marrow or cord blood donor or an HLA-mismatched related T-cell-depleted graft may increasingly be based on the relative ability of each type of stem cell graft to induce durable and complete hematopoietic and immunologic reconstitution as well as resistance to recurrent leukemia.

Non-myeloablative/reduced-intensity conditioning regimens for allogeneic transplantation

Conventional allogeneic transplantation for patients with hematological malignancies involve conditioning with high-dose chemotherapy with or without TBI to both eradicate the underlying malignancy and suppress the patient's immune system to prevent graft rejection. The bone marrow or PBSC serve to rescue patients from the lethal stem cell toxicity of the conditioning regimens. Consequently, the conditioning therapy's intensity would be limited only by toxicities to non-marrow organs, such as gut, lung, kidney, heart, and liver. These toxicities have generally restricted allogeneic transplantation to younger, medically fit patients. As the median age at diagnoses of patients with most hematologic malignancies range from 65–70 years, it follows that conventional allogeneic transplantation benefits only a minority of patients with candidate diseases.

Many hematologic malignancies are not always eradicated by high doses of chemoradiotherapy, and some of the observed cures after allogeneic stem cell transplantation are likely due to immunologic graft-versus-tumor reactions. These observations, together with a better understanding of how to control both host and donor immune cell functions, resulted in a re-evaluation of how to perform allogeneic transplantation. Specifically, instead of relying on tumor eradication through intensive and toxic chemoradiation, the donor's immune cells might be used for that purpose, invoking graft-versus-tumor effects. Removing the high-dose cytotoxic therapy would allow treatment of those patients who are too old or medically infirm to qualify for conventional allogeneic transplantation. Therefore, in general, these regimens are most appropriate for these hematologic malignancies that are susceptible to the GVL effect of donor T cells. The best examples of these are CML, chronic lymphocytic leukemia (CLL), and follicular lymphoma; however, GVL effects have been documented to a lesser extent in myeloma and acute leukemia.⁴⁷⁹

In general, two different types of regimen have emerged. The first is based upon immunosuppressive chemotherapeutic drugs—usually fludarabine in combination with an alkylating agent.^{480–484} The other approach is based upon low-dose (2 Gy) TBI with or without fludarabine.⁴⁸⁵ A number of regimens have been proposed to reduce the toxicity associated with allogeneic transplantation. As a working definition, a truly non-myeloablative regimen should not eradicate host hematopoiesis and should allow relatively prompt hematopoietic recovery without a transplant. Many of the reduced-toxicity regimens referred to as non-myeloablative that include busulfan or melphalan may require a transplant for hematologic recovery, and if the graft is rejected, prolonged aplasia typically occurs. These should be referred to as reduced-intensity regimens.

The major advantage of these regimens is a substantial reduction in transplant-related mortality. This has been achieved by a reduction in regimen-related toxicity, a short duration of neutropenia, and a reduced incidence of acute GVHD in the first few weeks after transplantation. There are also potential disadvantages of using these less intensive regimens. The major disadvantages are relapse of the underlying malignancy and consequent extensive chronic GVHD caused by early discontinuation of immunosuppression or donor leukocyte infusions to promote GVL effects. Inclusion of *in vivo* Campath-1H as part of the conditioning regimen has been reported to produce a low rate of both acute and chronic GVHD in both sibling and unrelated donor transplantation.

Most studies of non-myeloablative hematopoietic transplantation have been performed in elderly or medically debilitated patients unable to tolerate an ablative preparative regimen. Some studies have included younger patients with standard eligibility criteria; differences in patient selection generally preclude meaningful comparisons among regimens. The MD Anderson group initially evaluated the use of standard-dose purine analog-based chemotherapy as a non-ablative preparative regimen in patients with advanced myeloid leukemias.⁴⁸⁶ Giralt et al⁴⁸⁷ subsequently reported a study combining melphalan and fludarabine for the treatment of advanced acute leukemia; this is a more myelosuppressive regimen that should be considered a reduced-intensity regimen. It was sufficiently immunosuppressive to allow for engraftment from unrelated donors as well as matched siblings. The additional cytoreduction resulted in improved disease-free survival in AML patients, and suggests that cytoreduction of the malignancy by the preparative regimen has value. Slavin et al⁴⁸⁴ reported the use of a reduced-toxicity preparative regimen consisting of busulfan (8 mg/kg), fludarabine, and ATG. Although less toxic than the commonly used ablative preparative regimens, this regimen has been particularly encouraging in CML. Khouri et al^{482,488} reported the use of fludarabine plus cyclophosphamide in 20 patients with indolent

lymphoma; 9 patients received rituximab in addition to the chemotherapy. All patients achieved engraftment of donor cells. The cumulative incidence of acute grade II-IV GVHD was 20%. All patients achieved complete remission. None has had a relapse of disease at a median follow-up period of 21 months. The actuarial probability of being alive and in remission at 2 years was 84%. This regimen has been effective in achieving engraftment and its use has been extended to a range of malignancies by a number of investigators. The Seattle group has used minimally toxic conditioning with low-dose (2 Gy) TBI, with postgraft mycophenolate mofetil and cyclosporine to facilitate stable allogeneic engraftment.⁴⁸⁵ Forty-five patients with hematologic malignancies, HLA-identical sibling donors, and relative contraindications to conventional stem cell transplantation were reported. Regimen toxicities and myelosuppression were mild, allowing 53% of eligible patients to have entirely outpatient transplantations. Non-fatal graft rejection occurred in 20% of patients. Grade II-III acute GVHD occurred in 47% of patients with sustained engraftment. With a median follow-up of 417 days, the survival rate was 66.7%, the non-relapse mortality rate 6.7%, and the relapse mortality rate 26.7%. Of the patients with sustained engraftment, 53% were in complete remission. Fludarabine has recently been given to some patients receiving this regimen as additional immunosuppression to reduce the incidence of graft rejection.

Allogeneic bone BMT is associated with a high risk of treatment-related mortality in multiple myeloma. Use of a non-ablative preparative regimen may reduce this morbidity while still inducing a graft-versus-myeloma effect. Giralt et al⁴⁸⁹ reported results in 22 patients with myeloma who received a reduced-intensity conditioning regimen with fludarabine and melphalan. All patients received unmanipulated grafts from either HLA-matched sibling donors ($n=13$) or matched unrelated donors ($n=9$). Seven patients achieved complete remission. Six patients were alive with a median follow-up of 15 months. The actuarial survival and progression-free survival rates were 30% and 19% at 2 years. Others have reported similar results. This promising approach requires further study. A novel strategy under study in myeloma is the use of tandem autologous and allogeneic transplantation. High-dose therapy with autologous transplantation is initially performed to cytoreduce the malignancy, followed by a non-ablative allogeneic transplant with the goal of eradicating minimal residual disease. The preliminary results of this strategy were recently reported, with a low transplant-related mortality and a high complete remission rate, although follow-up is still limited.⁴⁹⁰

In summary, non-myeloablative or reduced-intensity conditioning regimens allow engraftment and generation of GVL effects. This approach is potentially curative for susceptible malignancies and reduces the risks of treatment-related mortality. This strategy can extend the use of allogeneic transplantation to older patients and those with comorbidities that preclude high-dose chemoradiotherapy. The indications for a non-myeloablative allogeneic transplant versus conventional transplant and non-transplant strategies need to be defined for each target malignancy in controlled clinical trials.

30 Epidemiology

Jørgen H Olsen

Introduction

Hematopoietic tissue is a prevalent site of cancer in large parts of the world. The number of new cases in 1990 was estimated at 570 000 (7% of all new cancers), which is only surpassed by cancers of the lung (1 040 000), breast (800 000), stomach (800 000), and colon/rectum (780 000).¹ In this chapter, the term 'hematological malignancies' includes the leukemias, Hodgkin's disease, the many forms of non-Hodgkin lymphoma (NHL), and multiple myeloma. The descriptive epidemiology of this heterogeneous group of cancers has been hampered by the many changes in disease classification that have been introduced over time; furthermore, different classification schemes have been used simultaneously in different countries and even in different regions of the same country. This chapter on the epidemiology of hematological malignancies emphasizes only the major diagnostic groups of leukemias, Hodgkin's disease, NHL, and multiple myeloma, although some aspects of the leukemias and NHL are discussed in further sub-groupings.

Incidence and mortality

Research into the causation and prevention of cancer has traditionally been based on descriptive statistics. A prominent example of such basic work is the series *Cancer Incidence in Five Continents*, published by the International Agency for Research on Cancer (IARC).² These publications describe the burden and patterns of hematological and other cancers in diverse populations, and can thus give rise to hypotheses that might explain the observed differences in risk.

The commonest measures used in descriptive statistics are incidence and mortality rates. The incidence rate is the number of new cases of a certain disease that develop in a population at risk, normally expressed as a number per 100 000 persons during 1 year. The incidence rate is widely used in epidemiology because it indicates disease frequency—or risk. The incidence rate directly reflects the burden of disease-causing agents, taking into account the latency of the disease measured. If exposure of a population to, for example, leukemogenic agents becomes more prevalent, the incidence of leukemia will eventually rise to a level that is determined simply by specific interactions between the target cells and the carcinogens. The rate of mortality from the disease is a more complex measure of disease burden, as the number of patients who are cured of the disease or who survive long enough to die from another cause influences it. With high cure rates and advantageous 5-year survival rates, as seen for many types of hematological cancers, the mortality rate typically underestimates the size of the cancer problem in a given population. However, often the mortality rate is used in epidemiology and clinical research when a proper instrument for population-based case finding—such as a cancer registry—is absent.

In Europe, nationwide incidence rates of hematological malignancies and other cancers are known only for the Nordic countries, Scotland, Estonia, Latvia, the Czech Republic, Slovakia, and Slovenia. England and Wales are covered by regional cancer registries with substantial variations in registration and completeness. Nationwide cancer registration either is in progress or has been initiated recently in the Netherlands, Belgium, Portugal, Greece, Austria, Cyprus, and Belarus. Well-functioning regional cancer registration exists to a greater or lesser extent in other European countries, including Ireland, Germany, France, Spain, Italy, Romania, Hungary, Poland, and Russia, but in general with a coverage of less than 10% of the national population.²

Outside Europe, all of Canada, New Zealand, and a major part of Australia are covered by cancer registration. About 10% of the population in the USA located in nine selected areas of the country is covered by population-based cancer incidence registries; these latter registries are coordinated by the Surveillance, Epidemiology, and End Results (SEER) program

under the responsibility of the National Cancer Institute.³ Few areas of the rest of the world are covered by routine cancer registration.

Standardization of rates

With the striking exception of Hodgkin's disease, age is a major determinant of risk for hematological malignancies; for example, in the Nordic countries, the risk of NHL increases by 30-fold for men as well as women between the ages of 20 and 75 years (Table 30.1). This dependence on age means that it is important to adjust for differences in age composition when comparing the occurrence of hematological malignancies in two or more populations. Comparisons are usually made in one of two ways:

- by calculating age-adjusted (age-standardized) rates, which are averages of age-specific incidence rates weighted against a standard population;
- by calculating the cumulative incidence rate between age 0 and, for example, 74 years, which gives a number (lifetime risk) that indicates the probability that a person will develop the disease within the age range if still alive.

Examples of both measures are given in Table 30.2 for the commonest cancers and for all cancers combined for men and women in England and Wales and for

Table 30.1 Annual age-specific incidence of non-Hodgkin lymphoma in men and women in the five Nordic countries (Denmark, Finland, Iceland, and Sweden): 1993–97⁴

Age (years)	Rate per 100 000	
	Men	Women
0–5	1.2	0.7
5–9	1.9	0.6
10–14	1.6	0.8
15–19	2.1	1.2
20–24	2.2	1.4
25–29	3.0	1.6
30–34	4.0	3.0
35–39	6.5	3.4
40–44	8.8	5.8
45–49	13.6	10.4
50–54	20.4	14.9
55–59	24.6	19.8
60–64	33.8	25.6
65–69	44.9	35.1
70–74	61.4	45.1
75–79	74.7	51.3
80–84	92.8	61.1
85+	84.8	54.4

similar sites in Japan (Hiroshima City). The incidence of hematological malignancies in England and Wales is believed to be representative of that of a large part of the European population. Grouped together, these malignancies rank fourth among men in England and Wales, with 24 new cases per 100 000 per year (only surpassed by cancers of the lung, colon/rectum, and prostate), and fourth among women, with 16 new cases per 100 000 per year (only surpassed by cancers of the breast, colon/rectum, and lung). These numbers are equivalent to lifetime risks (age 0–74 year) of 2.5% and 1.6%, respectively. Hematological cancers occur more rarely in Japan, where cancer of the stomach is by far the commonest type of cancer among both men and women (83 and 36 per 100 000 per year, respectively) (Table 30.2).

Geographical variation

For most types of cancers, striking differences in frequency exist between countries. This is less true for hematological malignancies, but some international

Table 30.2 Annual age-adjusted (World Standard Population) rates and cumulative incidence rates to age 74 years for all types of cancer combined for the five most frequent cancers among men and women in the UK and for similar sites in Japan

^cAll sites but non-melanoma skin.

variation is seen for each of the main diagnostic groups of leukemia, Hodgkin’s disease, NHL, and multiple myeloma. This is illustrated in Figures 30.1–30.4, which show the incidence of the hematological malignancies in selected countries around the world during the early 1990s. Some of the data were derived from particular areas within the countries, and do not necessarily represent national rates. In view of the variations in diagnostic practices and tumor classifications mentioned above, international comparisons should be interpreted with caution.

The leukemias (Figure 30.1) seem to occur at the highest rates in certain areas of Canada (Quebec, Ontario, Saskatchewan, and Yukon), among both men and women. Rates are also high among Whites in the USA, Australia, and Denmark. Leukemias are also relatively more common in other Western countries than registered in most parts of the world. There is little variation worldwide among women.

The highest rates for Hodgkin’s disease (Figure 30.2) are reported in several areas of Europe and among Whites of each sex in many parts of the USA—Connecticut in particular (4.1 and 3.6 per 100 000 men and women, respectively). The lowest incidence rates are seen in Polynesia and in Asian populations.

In comparison with the incidence rates of Hodgkin’s disease, relatively more international variation is seen for the combined group of NHL (Figure 30.3), with the absolutely highest rates in men and women observed in North America and Australia. An excep-

Figure 30.1 Annual incidence of leukemia per 100 000 men and women (World Standard Population) in selected countries during the early 1990s.²

tionally high rate is seen among White males in San Francisco, with 25 new cases annually per 100 000 (lifetime risk 2.6%). For the group of NHL, the lowest rates are reported from Asia and Africa. However, Burkitt lymphoma, which is grouped with the NHL,

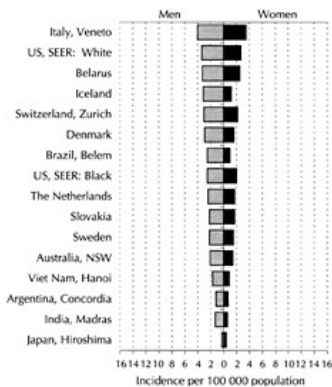

Figure 30.2 Annual incidence of Hodgkin’s disease per 100 000 men and women (World Standard Population) in selected countries during the early 1990s.²

Figure 30.3 Annual incidence of non-Hodgkin lymphoma per 100 000 men and women (World Standard Population) in selected countries during the early 1990s.²

Figure 30.4 Annual incidence of multiple myeloma per 100 000 men and women (World Standard Population) in selected countries during the early 1990s.²

occurs endemically among children in tropical Africa and lowland New Guinea. In such high-risk areas, the rate is 5–8 cases per 100 000 children per year, which is double the rate of leukemia seen in children of Caucasian origin.

The highest incidence rates of multiple myeloma in the world (Figure 30.4) are found almost consistently among American Blacks. The lowest rates are seen in areas outside the Western world.

Table 30.3 lists the registered or estimated incidence rates of all hematological malignancies combined for those areas of the world with some reliable population-based cancer registries. The group of hematological malignancies represents approximately 8–9% of all cancers in men and around 8% of all cancers in women in Australia, the USA, and Canada. The proportion appears to be slightly lower in the European Union.

The proportion also varies by age (Figure 30.5). In England and Wales, the combined group of hematological malignancies accounts for up to 40% of all cancers during the first decade of life, but the proportion reveals a steep decline in subsequent age groups, reaching minimum of 5% around age 50 years.

Table 30.4 gives the incidence rates of each of the main diagnostic groups of hematological malignancies. Although the rates are higher among men than women, the relative distribution of hematological cancers into the different diagnostic groups is almost

Table 30.3 Incidence rates of hematological cancers and their proportion relative to all cancers in major areas of the world served by reliable cancer registries^{2,5,6}

the same for each sex. Some variation exists, however, between areas and between ethnic groups (Figure 30.6). Leukemia represents almost 35% of all hematological malignancies in Europe, a little more than 30% in the USA (Whites) and Canada, and some 25% among Black Americans. NHL is relatively more frequent in Canada and among Whites in the USA than in other populations, while multiple myeloma is a major hematological diagnosis among Black Americans.

Time trends and age curves

In Denmark, where cancer registration has been maintained on a nationwide scale for more than 50 years, the incidence of hematological malignancies has evolved as shown in Figures 30.7. Registration was also established relatively early in Norway (1953), Finland (1953), Iceland (1955), and Sweden (1958), which together with Denmark covered a population of 24 million in the 1990s. The evolving incidences in those countries are similar to those among men and women in Denmark. Although the rates differ between the sexes, the trends in rates are similar for men and women: there was a marked and relatively uniform increase for the group of NHL, which today is slightly more frequent than the combined group of leukemias; and a moderate increase was observed for the group of leukemias up to the mid-1980s, followed by a stable incidence. A slight but continuous increase was seen for the group of multiple myelomas, while the rate of Hodgkin's disease hardly changed.

Epidemic of NHL

A steep increase over time in the incidence of NHL has been observed in many places other than the Nordic countries. Incidence data from the SEER program^{7,8} and the IARC indicate that both mortality and incidence rates have been increasing for many years.⁹ Greater increases among older persons, however, suggest a role for improvements in diagnosis, particularly during the 1950s and 1960s, but overall it is judged unlikely that the marked increase in time trends seen across country borders can be attributed entirely to data artifacts.¹⁰ Accordingly, careful analyses of incidence data on NHL from Connecticut, USA show that there has been a 10.3% increase in risk every 5 years

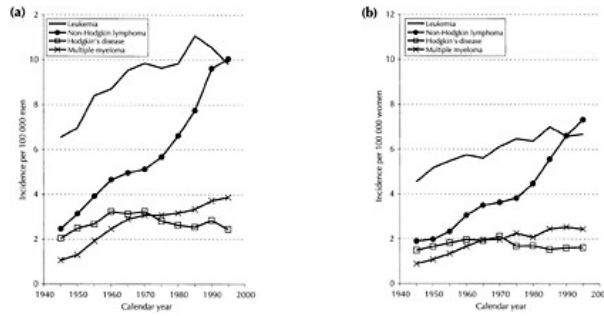

Figure 30.7 Time trends in incidence rates of hematological malignancies among (a) men and (b) women in Denmark, 1943–98 (World Standard Population). *Source:* The Danish Cancer Registry (unpublished data).

since 1965 for women and a 9.2% increase for men.¹⁰ On the basis of SEER data, Groves et al⁸ found age-adjusted total NHL incidence rates that during the periods 1978–83 to 1990–95 increased by 77% and 53% in Black and White men, respectively, and 39% and 33% among Black and White women, respectively.

Age curves and cohort of birth

Figure 30.8 gives the age-specific incidence rates over time (age curves) for each of the major diagnostic group of hematological diseases in the population of Denmark. The incidence rate per 100 000 is plotted on a logarithmic scale. The distribution of each malignancy by age at diagnosis is somewhat different. While some 25% of cases of multiple myeloma are diagnosed in people under the age of 60 years, 75% of cases of Hodgkin’s disease are diagnosed in people under that age and 25% under the age of 30. Leukemias and NHL have an intermediate age distribution, with 40% of cases diagnosed in people under the age of 60.

Age-specific curves give a summary measure of the level of risk in each of a number of defined age groups; however, it must be kept in mind that each of the age groups are composed of individuals belonging to different generations. This will strongly influence the shape of the age-specific curve if the risk of cancer increases or decreases with time. To better evaluate the importance of changing exposure to carcinogens over generations, age-specific incidence curves are

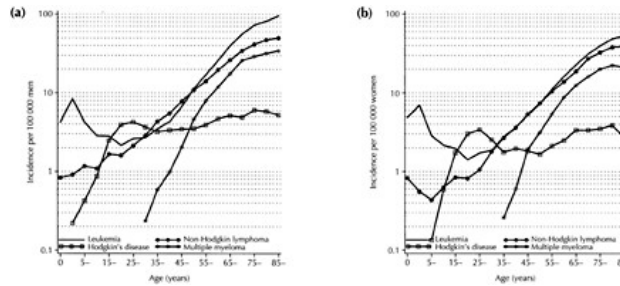

Figure 30.8 Age-specific incidence rates of hematological malignancies, among (a) men and (b) women, 1943–98. *Source:* The Danish Cancer Registry (unpublished data).

Figure 30.9 Age-specific incidence rates of non-Hodgkin lymphoma among (a) men and (b) women, in Denmark, 1943–98, in selected 10-year birth cohorts. One point is shown for each mid-cohort. *Source:* The Danish Cancer Registry (unpublished data).

sometimes drawn for year-of-birth cohorts, as shown in Figure 30.9 for NHL in Denmark. The presentation of incidence data in this way shows clearly that the age-specific rates of NHL for both men and women are consistently higher in younger generations than in older generations, which also indicates that the overall incidence of NHL in Denmark—and in other Western countries—will continue to increase, at least in the forthcoming two to three decades. This is so because the incidence rates of NHL in young adults may be used to make a prediction of the future lymphoma burden of the entire population, since the shape of the incidence curve in young adults indicates the magnitude of the NHL problem that will eventually be carried over to people of older ages.

The leukemias

The leukemias are a group of malignancies of precursor cells of blood and tissue lymphocytes. For general purposes, they are distinguished by their cell type of origin (mainly lymphocytes, myelocytes, and monocytes) and by their clinicopathological behavior (acute, subacute, and chronic). Comparisons of the different subtypes are difficult because diagnostic methods and the accuracy of diagnosis vary, with different proportions remaining unspecified. Table 30.5 gives data on the frequencies of the subtypes of leukemia in general use in 18 selected populations.

A more detailed picture of the distribution of leukemias by subtype is given in Tables 30.6 and 30.7, which are based on approximately 13 700 notified cases of leukemia in Denmark during the period 1978–98. The two commonest diagnosis used by oncologists during that period were ‘lymphatic’ (50%) and ‘myeloid’ (43%) leukemia, followed by ‘leukemia not otherwise specified’ (3%), ‘hairy cell leukemia’ (1%), and ‘monocytic leukaemia’ (1%) (Table 30.6). While some 80% of lymphatic leukemias are chronic and some 20% acute, the clinical pattern of the group of myeloid leukemias is almost the reverse, with some 30% of cases regarded as chronic and 70% as acute (Table 30.7). The picture may, however, be imprecise, since it reflects routine diagnosis in the healthcare system applied to a European national population over a 20-year period.

Childhood leukemia

Although rare, leukemia is the most frequent cancer in children, accounting for one-third of all new cases. Unlike most other malignancies, it shows a distinct peak in childhood, rising to about 9–11 cases per 100 000 in children aged about 3 years, and decreasing in later childhood to around 2 cases per 100 000 per year (Figure 30.10). About 30% more cases are seen in boys than in girls, and some 80% are acute lymphoblastic leukemia (ALL).

During the last 50 years, when cancer registration has been in operation in the Nordic countries, the rate of childhood leukemia has remained stable. Interestingly, over this relatively long period, the peak of leukemia in childhood has also remained unchanged, with respect to both its extent and the age group most clearly affected. The incidence of

Table 30.5 Age-standardized incidences of leukemias of different subtypes in Selected areas of the world in the early 1990s (per 100 000 population)²

Area of registration	Leukemia subtype

childhood leukemia seems to be lower in most non-Caucasian populations, and the peak at age of 3 years is less marked. In Africa, there seems to be no childhood peak at all.¹²

Hodgkin's disease constitutes a rather uniform subgroup of lymphomas, distinguished by its histological appearance (the presence of Reed-Sternberg giant cells) and its clinical features, the remaining, largest group of lymphomas, namely NHL, is heterogeneous. The various subclassifications that have been proposed over the years are probably of little relevance to the etiology or these tumors.

On the basis of data from Europe and the USA, we know that extranodal NHL comprise approximately 30% of cases in adulthood. Of these, some 50% arise in the gastrointestinal organs (the stomach in particular) and some 10% each in the respiratory system, the central nervous system, and the urogenital organs. The remaining 20% of extranodal lymphomas can affect almost any other organ of the body.

Figure 30.10 Age-specific incidence rates of childhood leukemia, 1943–98.¹¹

An analysis of the NHL reported to the SEER registries in the USA showed the following distribution according to the Working Formulation subtypes: diffuse subtypes (43%); follicular subtypes (18%); high-grade subtypes (12%); small lymphocytic lymphomas (9%); peripheral T-cell lymphomas (4%); and lymphomas not otherwise specified (NOS) (14%).⁸ The analysis also showed that the follicular histological subtypes were two or three times more frequent among Blacks than among Whites, and that high-grade lymphomas were two to three times more frequent in men than in women.

Burkitt lymphoma

Burkitt lymphoma is a distinct pathological entity arising from B lymphocytes. The classical picture of the malignancy is that of a rapidly growing tumor of the jaws or abdominal viscera in a child aged 5–8 years. In most series, twice as many boys as girls develop the disease. In the endemic form, which is seen in tropical Africa and lowland New Guinea, evidence of the Epstein—Barr virus (EBV) is seen consistently in tumor tissue. The areas of high risk for Burkitt lymphoma coincide with those regions affected endemically by malaria; this environmental link with malaria is supported by studies of migrants.¹³

Awareness of the characteristics of Burkitt lymphoma has led to the observation that it seemingly constitutes a significant percentage (20–30%) of childhood NHL in most countries,¹⁴ although the incidence rates are much higher in Africa (8 per 100 000 children, compared with 0.2 per 100 000 in Whites in the USA).

Etiology

During the last five decades, a variety of risk factors for hematological malignancies have been suggested, many of which, however, have been based on unconfirmed data and inconsistent findings across studies. Taken together, verified risk factors explain only a minor proportion of these cancer types.

The leukemias

Genetic factors seem to be involved in some cases of leukemia, childhood leukemia in particular. A well-known example is that persons with Down syndrome (trisomy 21) have an estimated 20- to 30-fold increased risk of developing acute leukemia of various cell types.¹⁵ Although most common during childhood, all ages are apparently affected.¹⁶ Other congenital disorders with extra chromosomes associated with leukemia are Klinefelter syndrome and D-trisomy. Children with certain hereditary or congenital conditions accompanied by a tendency to chromosomal abnormalities or breaks have an elevated risk of acute leukemia. These disorders include Bloom syndrome, Fanconi anemia, and ataxia telangiectasia.¹⁷ Von Recklinghausen's disease (neurofibromatosis type 1) is yet another congenital disorder that in some cases is linked with leukemia, particularly the rare juvenile chronic lymphocytic leukemia (CLL). The Li-Fraumeni cancer family syndrome, which is likely caused by germline mutations in the *p53* gene, and possibly other more or less well-characterized family syndromes and congenital disorders, have likewise been associated with increased risk of leukemia.¹⁷ However, with the exception of the trisomies, these genetic and congenital abnormalities occur extremely rarely in the population and account for only a small proportion of leukemias.

There is overwhelming evidence that ionizing radiation is a risk factor for leukemia. The tumors induced are either acute forms or chronic myeloid leukemia (CML), with a mean latency of approximately 10 years.¹⁸ The atomic bomb survivor studies carried out in Hiroshima and Nagasaki in Japan provide an important human experience from which estimates have been derived. The population is large and not selected because of disease or occupation. Studies of atomic bomb survivors, patients irradiated for benign diseases (ankylosing spondylitis, tinea capitis, or gynecological diseases), or given fluoroscopy for tuberculosis, and patients treated by ionizing radiation for malignant diseases show a dose-effect relationship measurable in absorbed doses over 0.1 Gy (10 rad).^{18,19} The dose-response curve for doses below this level remains uncertain.

However, authoritative estimates predict that continuous lifetime exposure of 100 000 persons to an

equivalent dose of 1 mSv of ionizing radiation per year will induce about 65 leukemias.²⁰ The greatest population exposure to ionizing radiation stems from natural background sources, which are about 2.9 mSv/year.²¹ These sources include cosmic rays (0.27 mSv/year) and terrestrial radiation (0.28 mSv/year), internally deposited radionuclides (0.39 mSv/year), and radon (2.0 mSv/year), the last of which seems to be of relevance for lung cancer only. The greatest source of man-made radiation is from medical uses—therapeutic as well as diagnostic (0.53 mSv/year). Occupation, nuclear power, fallout from nuclear testing, and consumer products make only a minor contribution (0.11 mSv/year).²¹ On the basis of these exposure assessments, it has been estimated that approximately 14% of all acute leukemias arising in a typical Western population are due to ionizing radiation from background sources.¹⁹

The excess risk, if any, of leukemia following low-dose radiation exposure of workers in nuclear installations in the UK and North America has been difficult to assess. Even the largest studies have had difficulties in providing risk estimates of useful precision, because the ranges of exposures were very small.^{22–24} However, in a combined analysis of mortality data on approximately 96 000 workers employed for 6 months or longer in the nuclear industry in the USA, the UK, and Canada, the authors found that mortality from leukemia, excluding CLL, was significantly associated with cumulative external radiation dose. The analysis, which was based on 119 non-CLL leukemia deaths, suggested that the risk for these types of leukemias was increased by 22% for a cumulative protracted dose of 100 mSv compared with the no-exposure situation (0 mSv).²⁵

A case-control study conducted in Denver, Colorado, USA first linked childhood cancer mortality with residential proximity to electric power lines, noting correlations between the current flow of the lines, their wiring configurations, and the estimated magnetic field exposures within residences.²⁶ Concurrently, in death certificate studies, positive associations were observed between adult leukemia and employment in an ‘electrical occupation’, suggesting a carcinogenic effect of electromagnetic fields from the electric power system.^{27,28} Since then, numerous studies have investigated the relationship between extremely low-frequency (ELF) magnetic fields (in the 50–60 Hz frequency range) and cancer—leukemia in particular. The scientific evidence for an association has been assessed by an IARC working group.²⁹ The working group found that pooled analyses of data from a number of well-conducted studies showed a fairly consistent statistical association between a doubling of risk of childhood leukemia and ELF residential magnetic field strengths above 0.4 µT. The group concluded that there is limited evidence in humans for the carcinogenicity of ELF magnetic fields in relation to childhood leukemia, and inadequate evidence in relation to all other cancers.

There is sufficient evidence that benzene causes acute myeloid leukemia (AML) in humans.³⁰ Since 1928, there have been many reports of leukemia in benzene-exposed shoe and leather workers. Benzene exposures are probably also the reason for the increased leukemia rates observed among rubber manufacturing workers, petroleum refinery workers, painters, pressmen, and printers. Table 30.8 lists the chemicals and industries that have been associated most consistently with an increased risk of leukemia. Most of the evaluations were made by working groups convened by the IARC on the basis of available scientific literature.

Table 30.8 Drugs, chemicals, and industries recognized as presenting a leukemogenic risk

Type of exposure	IARC group ^a

^aIARC, International Agency for Research on Cancer. Group 1, The agent is carcinogenic to humans. Group 2A, the agent is probably carcinogenic to humans. Group 2B, the agent is possibly carcinogenic to humans. Group 3, the agent is not classifiable as to its carcinogenicity to humans.

^bNot evaluated by the IARC.

Several alkylating drugs and other chemotherapy agents are linked with highly increased risks of secondary AML among patients treated for various hematopoietic malignancies, and patients treated for some types of solid tumors, including ovarian cancer, small cell lung cancer, gastrointestinal malignancies, male germ cell tumors, and female breast cancer. Table 30.8 also lists these and other drugs associated with leukemia.

Leukemia has been linked with viral diseases in experimental settings; however, no conclusive epidemiologic evidence exists that confirm an association (but see ATLL under the discussion of NHL in the next subsection).

Hodgkin's disease

Little is known about the etiology of Hodgkin's disease. There have been numerous reports of multiple occurrence of Hodgkin's disease within families, but such aggregations have not clearly been confirmed in population-based studies. No mutations that predispose to Hodgkin's disease have been identified to date.

There have been reports of unusual clusters of the disease in time and space (e.g. in high schools), which suggest that Hodgkin's disease might be contagious. Large, well-designed studies, however, have failed to confirm the initial reports,³¹ although the potentially infectious nature of Hodgkin's disease is still debated. The candidate as an etiological infectious agent is the ubiquitous herpesvirus, the Epstein-Barr virus (EBV). Thus, in several case-control studies of patients with Hodgkin's disease, a moderate association was found with previous infections mononucleosis, a disease caused by EBV, and in support of such an association, molecular studies of tumor tissue from Hodgkin's disease patients have shown that 30–50% of cases in general are EBV-genome-positive.³¹

Overall, there is some evidence that occupational groups such as carpenters, joiners, and other woodworkers have a slightly increased risk of Hodgkin's disease, but the relevant exposures have not been identified.³²

NHL, other than Burkitt lymphoma

An increased risk of NHL has been clearly associated with immunodeficiency. Highly increased rates during childhood and early adulthood have been reported among patients with primary immunodeficiency disorders such as ataxia telangiectasia, common variable immunodeficiency, X-linked lymphoproliferative syndrome, or Wiskott-Aldrich syndrome, all of which are rare disorders. A much lower, but clearly excessive, risk of NHL is seen among patients with secondary, or acquired, immunodeficiency, such as that following immunosuppressive therapy in conjunction with organ or bone marrow transplantation, or human immunodeficiency viral (HIV) infection.^{13,33} There is some evidence that several chronic connective tissue disorders, such as rheumatoid arthritis, systemic lupus erythematosus, and Sjögren syndrome, increase the risk of subsequent NHL.

Adult T-cell leukemia/lymphoma (ATLL), which constitutes only a small proportion of NHL in Western countries, but occur in clusters in, for example, Japan, is most likely caused by the human T-cell lymphotropic virus type I (HTLV-I). The presence of HTLV-I in endemic areas is thought to be the chief cause of lymphomas in persons under 60 years of age;¹³ however, in general, this is a relatively rare infection and contributes little to the overall NHL incidence.

Not only viral infections seem to be related to NHL an increasing body of evidence links chronic gastric infections with *Helicobacter pylori* to the development of malignant gastric neoplasia, including lowgrade lymphomas arising from mucosa-associated lymphoid tissue (MALT).³⁴ In developing countries, the prevalence of infection with *H. pylori* increases rapidly during childhood, and continues to increase gradually throughout adult life, to reach a level of 80–90%. In most developed countries, the prevalence of infection is below 50%, with markedly decreasing trends over time. A low level of education and poor housing conditions have been associated with infection. Both oral-oral and oral-fecal routes of transmission of the bacteria have been postulated.³⁴

Several studies have shown that blood transfusion recipients are at an increased risk of developing NHL, which suggests that a bloodborne agent may be responsible for this disease.^{35–37}

A number of occupational exposures have been considered causes of NHL. Farming and herbicide application seem to be associated with increased rates of this malignancy, although the association is not definitively proven,^{38,39} since specific exposures that may account for the increased risk have not been identified. Exposures to pesticides, including phenoxyacetic acid herbicides, have regularly been implicated. Besides farming, employment in rubber manufacture and in styrene-butadiene rubber production have been linked with increased risks of NHL.³⁰ Industrial exposures to ethylene oxide, chlorinated solvents (such as perchloro- and trichloroethylene), inks in the printing industry,^{40,41} and of hairdressers and barbers to chemicals,⁴² have been associated with this disease in some but not all studies. The general importance of these occupational exposures, some of which (pesticides and hair colorants) also affect the general population, is at present unknown. Exposure to radiation probably has little effect on the risk of NHL.

Multiple myeloma

Individuals with monoclonal gammopathy of unknown significance (MGUS) are predisposed to developing multiple myeloma.⁴³ MGUS is an asymptomatic, non-malignant disorder involving proliferation of plasma cells and production of M-components. However, the cause of MGUS is unknown, and other causes of multiple myeloma are largely unrecognized. The increased incidence of the disease among US Blacks, however, indicates that genetic factors may be involved, although the higher rate could also be explained by race-specific environmental differences. In some but not all studies of occupation and industrial activities, farming was associated with multiple myeloma. Positive associations have also been reported for a history of occupational exposure to petroleum products. There is no convincing evidence of an association between exposure to ionizing radiation in therapeutic doses and multiple myeloma.

Survival

Many reports are available on the prognosis of patients with hematological malignancies involved in clinical trials the main purpose of which was to test the efficacy of new treatments. The outcome, therefore, does not usually reflect the survival experience of patients with these malignancies in general, nor is it possible on the basis of trials to evaluate trends in survival over time. In contrast, population-based cancer registries continuously collect information on the incidence of and survival from malignant diseases over time in a defined population, i.e. on all individuals included in the population, regardless of prognostic factors.

Survival can be recorded as crude or relative. Crude survival rates represent the observed numbers of patients in a given population who survive a given length of time relative to the size of the initially diagnosed study population. Relative survival rates are adjusted for deaths due to causes that are not related to the disease under study and are computed by dividing the observed proportion or rate of patients who survive by the equivalent proportion of the background population of the same age and sex composition. If this survival ratio is 1.0, then the chance of the patients surviving is similar to that of the general population; if the ratio is below 1.0, then the patient group has less chance of surviving than the general population.

Recently, efforts have been made to collect data on cancer survival from population-based cancer registries in Europe in order to make reliable comparisons of survival in different European populations by performing standardized analyses (the EUROCORE studies). The first EUROCORE study, published in 1995, covered survival of cancer patients in 30 registries, and the second study, published in 1999, was extended to cover 44 cancer registries in 17 countries.^{44,45} In the USA, population-based information on incidence of and survival from cancer is collected within the SEER program.³

Leukemias

Figure 30.11 shows overall sex-specific, 1-year and 5-year survival rates for all leukemias combined in 17 European countries, 1985–89. The figure shows the relative survival (in %), as the mortality of the general population has been subtracted from the patients' mortality prior to the calculation of survival. This also implies that one minus the relative survival may be interpreted as the proportion of patients who die as a consequence of the cancer at the 1-year and 5-year points after diagnosis.

The survival analyses were based in some countries on few regions, in other countries on the entire population (Denmark, Estonia, Iceland, Scotland, Slovakia, and Slovenia). At the bottom of Figure 30.11, survival rates are shown for men and women in Europe, on the basis of all data available.⁴⁵

Again, on the basis of all data available, Figure 30.12 gives the population-based relative survival rates for each of four major subtypes of leukemia in Europe. A marked variation in survival by subtype is evident in each sex.

Figure 30.11 Relative 1-year and 5-year survival rates (age-standardized) from all types of leukemia combined among patients in the EUROCORE II study, 1985–89.¹⁵

Figure 30.12 Relative 1-year and 5-year survival rates (age-standardized) from chronic lymphocytic leukemia (CLL), chronic myeloid leukemia (CML), acute lymphoblastic leukemia (ALL), and acute myeloid leukemia (AML) among men and women in Europe.¹⁵

Lymphomas

Figure 30.13 shows overall 1-year and 5-year survival rates for Hodgkin’s disease and NHL, in European men and women diagnosed during 1985–89 (data on Hodgkin’s disease were not available for Iceland and Spain). Considerable geographical variation in survival within Europe was reported, ranging from 41% (Estonia) to 85% (Austria) for 5-year survival after Hodgkin’s disease, and from 21% (Estonia) to 61% (Austria) for 5-year survival after NHL.⁴⁵

Multiple myeloma

Finally, for the same areas of Europe and on the basis of the EUROCARE II study, Figure 30.14 shows the sex-specific relative survival rates for multiple myeloma (data on multiple myeloma were not available for France and Poland). Again, a marked variation is seen within Europe, some of which, however, may be due to random variation due to small numbers of cases.

Survival in European and US populations

A comparison was undertaken of population-based, age- and sex-adjusted cancer survival data from the adult population in the USA and Europe.⁴⁶ The study considered 12 types of cancers, Hodgkin’s disease and NHL included, diagnosed during 1985–89 and reported to one of the 41 EUROCORE cancer registries of 17 European countries or to one of the nine SEER registries in the USA, covering the populations of the states of Connecticut, Iowa, Utah, New Mexico, and Hawaii, and the metropolitan areas of Atlanta, Detroit, Seattle, and San Francisco-Oakland, which add to approximately 10% of the US population.

Figure 30.15 shows the 5-year survival (in %) in Europe and the USA, respectively, in patients with one of 12 selected cancers. Cancer types are ordered according to decreasing survival probability. In general, European patients had significantly lower survival rates than American patients. The authors found that differences in the method of data collection, the quality of registration, and the type of analysis had only marginal effect on the difference in survival. They speculated that the observed differences in favor of patients in the USA could be due to three factors: earlier cancer detection, better response to treatment at an earlier disease stage, and more effective treatment protocols.⁴⁶ For Hodgkin’s disease and NHL, in particular, the relative excess risks for dying before 5 years of follow-up were 1.15 and 1.11, respectively, to the disadvantage of Europe (Figure 30.15).

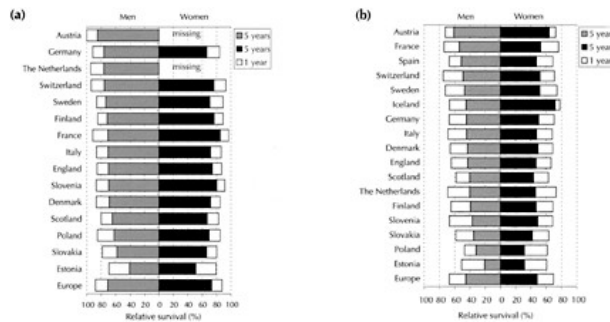

Figure 30.13 Relative 1-year and 5-year survival rates (age-standardized) from (a) Hodgkin’s disease and (b) non-Hodgkin lymphoma among patients in the EUROCORE II study 1985–89.¹⁵

Figure 30.14 Relative 1-year and 5-year survival rates (age-standardized) from multiple myeloma among patients in the EUROCORE II study 1985–89.¹⁵

Conclusions

The hematological malignancies are a heterogeneous group of disorders, and their descriptive epidemiology as well as the identification of etiologies has been hampered by the many changes over time in diagnostic practice and disease classification. Some rather limited international variation is seen for each of the main diagnostic groups of leukemia, Hodgkin's disease, NHL, and multiple myeloma. Overall, the group of hematological malignancies represents approximately 8–9% of all cancers in men and 8% of all cancers in women in Australia, the USA, and Canada. The proportions appear to be slightly lower in the European Union. In these areas of the world, leukemias and NHL are the most prevalent hematological cancers, with markedly increasing time trends for the NHL. The group of NHL is relatively more frequent in Canada and among Whites in the USA than in other populations, while Black Americans clearly form a high-risk population with regard to multiple myeloma.

Figure 30.15 Standardized 5-year relative survival for 12 selected cancers in adult patients in Europe and the USA, 1985–89.⁴⁶

Little is known about the etiology of the hematological malignancies. Genetic factors as well as ionizing radiation (the leukemias), chemotherapeutic agents, viral and bacterial infections (the lymphomas), and a limited number of occupational exposures have been implicated. Population-based surveys of cancer patients in Europe, diagnosed in 1985–89, have shown 5-year survival rates from leukemia, Hodgkin's disease, NHL, and multiple myeloma of 34%, 71%, 45%, and 29%, respectively, among men, and 35%, 73%, 48%, and 27%, respectively, among women. Considerable geographical variation within Europe was reported for each of the main diagnostic groups. For a number of selected cancer types, Hodgkin's disease and NHL included, a comparison of the European rates with those of a similar population-based survey from the USA showed that American patients tended to have a markedly better survival than European patients, which is possibly due to a combination of earlier cancer detection, better response to treatment at an earlier disease stage, and more effective treatment protocols.

Lymphoid malignancies in children

Raul C Ribeiro and Ching-Hon Pui

Introduction

Lymphoid malignancies are clonal disorders of the immune system that result from the transformation of immature lymphoid progenitor cells at a particular stage of differentiation. Because the lymphoid system is functionally diverse, has a wide anatomic distribution, interacts with other cellular systems, and, during childhood and adolescence, undergoes continuous remodeling, the clinical and biological characteristics of lymphoid malignancies in young patients vary substantially. Traditionally, pediatric lymphoid malignancies have been grouped in two broad categories: acute lymphoblastic leukemia (ALL) and non-Hodgkin lymphomas (NHL). These malignancies are further classified depending on the type of lymphoid lineage involved in the process. B-lineage malignancies account for more than 88% of cases of ALL and 50% of cases of NHL (Burkitt, lymphoblastic, and large B-cell lymphomas), whereas T-lineage malignancies account for about 12% of ALL cases and 50% of NHL cases (lymphoblastic and anaplastic large-cell lymphomas). Understanding the mechanisms by which the human lymphoid system develops and acquires functional diversity has led to an integrated view of the lymphoid malignancies that occur in childhood. From that perspective, childhood ALL and NHL represent a spectrum of the same disorder. Because a lymphoid malignancy is usually associated with a particular lymphoid compartment, each group of pediatric malignancies may be viewed in a functional context, as shown in Figure 31.1.

In this chapter we review the pathophysiology and clinical manifestations of ALL and NHL, re-examine the mechanisms of these disorders in the light of the new molecular genetic findings, and discuss the role of these findings in improving therapy for ALL and NHL.

Epidemiology and risk factors

In the US, of the 12 400 new cases of cancer diagnosed per year in children, adolescents, and young adults

Figure 31.1 Schematic representation of the origins of normal B and T cells and their routes of circulation in primary (bone marrow, lymph nodes, thymus) and secondary lymphoid organs (skin and lymphoid tissue associated with mucosa and the gastrointestinal tract). lymph nodes and thymus are both primary and secondary lymphoid organs). The CD antigens characteristic of each cell type are shown, and the types of leukemia and lymphoma that arise from each subset of cells are indicated. DR, leukocyte histocompatibility antigens; H(R), rearranged immunoglobulin heavy chain; HSC, hematopoietic stem cell; TdT, terminal deoxynucleotidyl transferase; μ , immunoglobulin heavy chain; ψ , pseudo-light chains.

less than 20 years old, 2400 (19.4%) are ALL and 800 (6.5%) NHL.^{1,2} Together, ALL and NHL represent the most common types of pediatric malignancy and account for about one-third of all childhood cancers. Acute lymphoblastic leukemia represents 17% of all pediatric cancer affecting neonates and infants, 46% of cancer occurring in children between the ages of 2 and 3 years, and 9% of cancers occurring just before the age of 20 years. Non-Hodgkin lymphoma affects 3% of children less than 5 years old and 9% of those between the ages of 15 and 19 years (Figure 31.2). A

Figure 31.2 Age-specific rates, for all races and both sexes, of acute lymphoblastic leukemia (ALL; circles) and non-Hodgkin lymphoma (NHL; squares). Data from the Surveillance Epidemiology End Results (SEER; with permission).^{1,2}

prenatal origin of some cases of childhood ALL, first suggested by genetic studies of identical twins with concordant leukemia, was established by examining the neonatal blood (archived blood spots) of children who later developed leukemia. In this neonatal blood were cells that contained transcripts of leukemia-specific fusion genes or clonotypically rearranged genes at the loci encoding immunoglobulin or T-cell receptors. Because of the relatively low rate of concordance of some types of leukemia in identical twins, the sometimes long delay after birth before leukemia develops, the variety of presenting features and outcome, and the failure of fusion transcripts alone to induce leukemia in model systems, it is thought that additional postnatal events are required for full leukemic transformation.³⁻⁷

Over the past 20 years, there has been an apparent increase in the incidences of ALL and NHL in the US. It is estimated that between 1977 and 1995, the incidence of ALL increased by 0.9 % per year. This increase in the rate of leukemia was not observed in black children. Similarly, the rates of other types of leukemia did not increase during this period. The incidence of NHL in children younger than 15 years remained stable from 1975 through 1995, but during this period the incidence of NHL in adolescents increased from 10.7 per million (1975–1979) to 16.3 per million (1990–1995).¹ The reasons for these increased incidences of ALL and NHL are not known. Some investigators have suggested that the apparent increase in incidence of ALL is a result of improvement in diagnostic specificity from the mid 1970s, which led to the recognition as ALL of forms of lymphoid leukemia that were previously not specified as ALL.⁸

The incidences of ALL and NHL are higher in boys than in girls, and the rates of ALL and NHL are markedly higher for white children than for black children in all age groups. The incidence rate of ALL in white children younger than 5 years, which is a good measure of the incidence peak, is more than double that in black children (63.2 vs. 26.9 per million). Therefore, the difference in incidence reflects mainly the lower rates of ALL among black children younger than 5 years.

International variation in the incidences of ALL and NHL has been reported.^{9,10} However, the lack of population registry makes comparison between countries difficult. The peak in ALL incidence noted in children in developed countries is absent or diminished for children in developing countries. This observation has been used to support the ‘hygiene theory’ in which the greater peak incidence in children aged between 2 and 5 years in industrialized countries compared with that in developing nations reflects the delayed exposure of children in developed countries to common childhood infectious diseases.¹¹ In NHL, there is a clear relation between Epstein-Barr virus (EBV) infection (with malaria as a cofactor) and the incidence of Burkitt lymphoma.¹² Moreover, acquired immunodeficiency syndrome (AIDS) resulting from human immunodeficiency virus (HIV) infection has been associated with an increased risk of NHL.¹³ However, for the most part, the factors contributing to the increased incidence of NHL are unclear.

Causes of childhood lymphoid malignancies are largely unknown. Most children with ALL or NHL do not appear to have predisposing factors. Moreover, recent observations suggest that different subtypes of lymphoid malignancies may involve different etiologic factors. For example, ALL in infants, which is consistently associated with 11q23 chromosomal abnormalities, has epidemiological associations that are different from those of ALL in other age groups. Because this chromosomal region is also affected in cases of secondary acute myeloid leukemia AML due to the use of topoisomerase II inhibitors,¹⁴ some investigators have proposed that nontherapeutic or naturally occurring topoisomerase II inhibitors may have a role in the etiology of infant ALL.¹⁵⁻¹⁷

Certain factors and specific constitutional syndromes have been associated with an increased predisposition to ALL or NHL.¹⁸ Increased risk of ALL has been associated with Down syndrome,^{19,20} neurofibromatosis,²¹ Shwachman syndrome,²² Bloom syndrome,²³ ataxia telangiectasia,^{24,25} and Klinefelter syndrome.²⁶ Patients with congenital immunodeficiencies such as Wiskott-Aldrich syndrome,²⁷ X-linked lymphoproliferative syndrome, and severe combined immunodeficiency^{28,29} have a significantly higher risk of developing NHL than do individuals in the general population. Exposure to ionizing radiation has been implicated in the development of childhood ALL.^{30,31} Less clear is the association between electromagnetic fields (EMF) and the development of ALL; a recent

analysis of pooled data from several studies found little or no association between the risk of ALL and EMF.³²

Pharmacogenetics, a rapidly advancing biological field that investigates the genetic basis for inherited differences among individual responses to specific drugs or environmental xenobiotics,³³ has the potential to provide clues to the different incidences of ALL and NHL that occur across diverse ethnic groups and geographic regions. The implication is that individuals with altered drug-metabolizing enzyme activities resulting from genetic polymorphisms are more susceptible to carcinogens. Indeed, a higher prevalence of polymorphisms that result in inactive detoxifying enzymes has been associated with *de novo* ALL in infants and children, AML in adults, and therapy-related leukemia.^{34,35} Other xenobiotic-metabolizing enzymes have also been implicated in the development of leukemia.³⁶ New methods, such as the use of microchip arrays and genome-wide DNA analysis, are now being applied to the interpretation of several of the genes encoding drug- and xenobiotic-metabolizing enzymes to elucidate the roles of these enzymes in drug response and disease production.

Diagnosis and classification

The examination of bone marrow or tumor mass (nodal or extranodal) is mandatory for the definitive diagnosis of ALL or NHL, respectively. Occasionally, the bone marrow can be difficult to aspirate because of fibrosis, necrosis, or tightly packed marrow. Sampling of the most accessible, representative nodal or extranodal tumor is the best approach in patients suspected to have NHL. In patients with a large mediastinal mass, who are at very high risk of complications during anesthesia, pleural effusion can provide an adequate number of tumor cells for diagnosis. Alternatively, needle biopsy of regional lymph nodes, which can be performed without general anesthesia, may also yield adequate material for diagnosis of primary mediastinal NHL.

The diagnosis of acute leukemia is established by morphologic criteria, from Romanowsky-stained bone marrow films. The arbitrary proportion of 25% or more blast cells is required for the diagnosis of leukemia. Further characterization of the leukemic cells by a panel of cytochemical stains separates lymphoid and myeloid leukemias. Approximately 80% to 85% of cases of childhood ALL have the bone marrow totally replaced by lymphoblasts. Acute lymphoblastic leukemias have been classified according to the criteria of the French-American-British (FAB) Cooperative Group as L1 (80%), L2 (18%), or L3 (2%),³⁷ but this system has largely been abandoned due to the lack of correlation with immunophenotypic or genetic features. The ALL blasts are always negative for myeloperoxidase (MPO) activity and rarely positive for Sudan black B staining. The periodic acid-Schiff stain, which detects glycogen deposits, is positive in about 70% of cases of ALL. Flow cytometric analysis, using antibodies to lymphoid and myeloid antigens, is crucial for the precise classification of lymphoid leukemias and recognition of hybrid or mixed-lineage leukemia.³⁸

About 88% of childhood ALL is of B-cell origin. Of these B-lineage cases, less than 2% are leukemias arising from the expansion of mature B cells and are classified as Burkitt leukemia; the remaining B-lineage cases comprise ALL derived from B-precursor cells. T-cell ALL accounts for about 12% of cases of ALL. There is a loose association between these main immunophenotypic groups and the clinical features present at the time of diagnosis. For example, patients with mature B-cell leukemia usually have an abdominal mass or other extranodal tumor deposits at the time of initial examination. Patients with T-cell ALL tend to be adolescent (median age, 10.5 years) males with a mediastinal mass, leukocytosis, an elevated serum lactate dehydrogenase (LDH) concentration, and central nervous system (CNS) leukemia.³⁹ Patients with precursor B-cell ALL tend to be younger (median age, 4.6 years) and to have a small tumor burden at the time of diagnosis.

Until recently, the main contribution of the immunophenotypic classification was to reveal that the standard treatment of ALL was not adequate for certain immunophenotypic subgroups.^{40–42} Therefore, for treatment purposes, grouping cases into mature B-cell, T-cell, and precursor B-cell (pre- and pro-B) categories is necessary.⁴³ A caveat to this approach is that, in rare situations, there are morphologically typical lymphoblasts that express lineage-specific myeloid markers. These lymphoblasts can express a combination of MPO and either B-cell or T-cell markers. Recent experimental evidence suggests that there are separate myeloid and lymphoid progenitors for B and T cells.⁴⁴ The prognosis is usually poor in this type of leukemia, and treatment has not been standardized.⁴⁵ Another important contribution of the immunophenotype is to the parametric flow cytometric analysis that defines the unique combination of antigens expressed by the leukemic cells in each case.⁴⁶ This unique profile provides a very sensitive tool with which to follow the kinetics of blast cell clearance during treatment and enables the detection of minimal residual disease.⁴⁷

Cytogenetic characterization of the leukemic cells is an integral part of the initial evaluation of childhood ALL.^{42,47,48} In virtually all cases of ALL, a genetic abnormality can be detected.

Numerical chromosome abnormalities, which occur in about 50% of cases of ALL, can be determined

directly, by conventional cytogenetic analysis, or indirectly, by quantifying the DNA content of the leukemic cells by using flow cytometric methods to obtain the DNA index.⁴⁹ By convention, normal diploid (46 chromosomes) cells have a DNA index of 1. Numerical chromosome abnormalities in ALL are classified into four subgroups. The frequency of each subgroup of ALL, classified on the basis of numeric chromosomal abnormalities, is listed in Table 31.1. Structural rearrangements or translocations that can be detected by using conventional cytogenetic or molecular methods are present in about 40% of cases. The most common structural abnormalities found in ALL are listed in Table 31.2. Lately, the combination of advanced computer and optical technology has added another dimension to conventional cytogenetic analysis and is providing important insights into the pathobiology of the disease. Routine methods now available for the genetic characterization of ALL, such as spectral karyotyping or chromosome painting, provide reliable and precise information on the chromosomal location of material involved in leukemia-associated gene rearrangements.⁵⁰

Although the classification of NHL in general is very complex and still evolving,⁵¹ the classification of pediatric NHL is relatively simple and straightforward. Virtually all childhood NHL can be classified into one of three groups, each of which exhibits dif

Table 31.1 Frequency of abnormal numbers of Chromosomes in in lymphoblastic leukemia in children

Blast cell ploidy	Frequency (%)
46, Diploid (normal)	10–20
46, Pseudodiploid (structural abnormalities)	30–40
<45, Hypodiploid	7–8
23–29, Near haploid	<1
30–44, Low hypodiploid	<1
>46, Hyperdiploid	40–50
47–50, Low hyperdiploid	10–15
51–65, High hyperdiploid	30–55
66–80, Near triploid	1
>80, Near tetraploid	1

fuse histologic characteristics: Burkitt, lymphoblastic, and large-cell rymphomas. In one series, histology revealed only 17 (1.3%) cases of follicular (nodular) NHL among 1336 children or adolescents.⁵² Burkitt lymphoma is composed of sheets of monomorphic lymphoid cells. Commonly, macrophages dispersed throughout the tumor give it the classic ‘starry sky’ appearance. In the bone marrow or blood, the Burkitt cells (in FAB L3 subtype ALL) are relatively uniform

Table 31.2 frequency of the most common structural abnormalities of chromosomes in lymphoblastic leukemia in children

with a moderate amount of deeply basophilic cytoplasm containing sharply defined, clear vacuoles and with round nuclei containing coarsely reticular chromatin. The cells express monotypic surface IgM (either K or λ , light chains) and harbor specific chromosomal translocations involving the *C-MYC* oncogene. The most common of these cytogenetic abnormalities, present in 80% of cases, is the t(8;14)(q24;q32) translocation. The t(2;8)(p12;q24) and t(8;22)(q24;q11) account for the remaining cases.⁵³

Lymphoblastic NHL arises from transformed, immature T or B cells. The T-cell immunophenotype, which accounts for more than 80% of all lymphoblastic NHL, expresses an immunophenotypic profile similar to that of normal thymocytes at an intermediate or late stage of differentiation. As with Burkitt NHL, T-cell malignancies involve several cytogenetic abnormalities that lead to the activation of transcription factors, as a result of specific translocations in the T-cell receptor genes. Typically, these translocations are juxtaposed with a small number of developmentally important transcription factor genes, including *HOXII (TLX1)*, *TAL1 (SCL)*, *TAL2*, *LYL1*, *BHLHB1*, *LMO1*, and *LMO2*.⁵⁴

Large-cell NHL is the most heterogeneous group of all subtypes of pediatric NHL. Immunophenotypic analysis of large-cell NHL reveals that the neoplastic cells can be of T-cell or B-cell lineage or have no lineage-specific markers (null cells). Regardless of the immunophenotype, about 40% of large-cell NHL cases express the CD30 (Ki-1) antigen.⁵⁵ In a classification system adopted by the World Health Organization, large-cell NHL is divided into diffuse B-cell and anaplastic large-cell lymphoma (ALCL). Classification as ALCL requires the coexpression of CD30 and the membrane epithelial antigen (MEA) in lymphoma cells expressing T-cell or null-cell markers.⁵¹ About 80% of ALCL cases identified by this criterion harbor the t(2;5)(p23;q35) chromosomal rearrangement.⁵⁶ The result of this translocation is the fusion of the gene encoding anaplastic lymphoma kinase (ALK) with regulatory elements of the gene encoding nucleophosmin (NPM), a nonribosomal nucleolar phosphoprotein.⁵⁷ Fusion of the *ALK* gene can also result from other translocations, including t(1;2), t(2;3), inv(2), and t(2;22). Importantly, ALK protein can be detected by immunohistochemistry with polyclonal and monoclonal antibodies on paraffin sections, which aids diagnosis.

Clinical manifestations

The initial clinical manifestations of ALL in children vary widely. The symptoms and signs are determined by the degree of bone marrow failure and the propensity of the leukemic cells to infiltrate extramedullary sites. In addition, the leukemic cells are metabolically active and produce numerous pro-inflammatory mediators, which can make the presenting features even more varied. Fever resulting from infection or, more commonly, inflammatory mediators is one of the most common signs, occurring in about 60% of patients. Pallor, fatigue, lethargy, petechiae, ecchymosis, and bone pain are also common. Other frequent findings disclosed by physical examination include liver, spleen, and lymph node enlargement. Subclinical involvement of the testis is very common in ALL.⁵⁸ However, clinically detected testicular enlargement occurs in approximately 2% of male patients. Bone pain and arthralgia are very common presenting features of ALL.⁵⁹ Stretching of the periosteum as a result of expansion of the medullary cavity is thought to be the mechanism underlying bone pain. Central nervous system manifestations are very rarely present at the time of initial examination. The signs and symptoms of CNS involvement are related to increased intracranial pressure and include irritability, lethargy, headaches, nausea, and vomiting. Cranial nerve palsies, most commonly of the seventh cranial nerve, may be present. Examination of the optic fundus can reveal papilledema and, occasionally, leukemic infiltration of the optic nerve and retina. Patients with T-cell ALL can present with a large, anterior mediastinal mass, sometimes with large pleural effusions (Figure 31.3). These patients may have a brassy cough, dyspnea, stridor, cyanosis,

Figure 31.3 (A) A 5-year-old boy with respiratory distress and clinical signs of superior vena cava syndrome (note the facial edema and plethora). A CT scan of the chest revealed (B) an anterior mediastinal mass (10×8×10 cm) that compressed the trachea and (C) bilateral pleural effusion and collateral venous flow to the intercostal vessels. Examination of the pleural effusion revealed a WBC count of $37 \times 10^9/L$ and 80% lymphoblasts (D). Immunophenotyping confirmed that the child had ALL of T-cell lineage.

facial and upper torso edema (Figure 31.3A), and venous engorgement resulting in collateral venous circulation over the chest and abdomen (Figure 31.3B). In addition, a mediastinal mass can compress the trachea and superior vena cava, to various degrees. Mediastinal involvement represents a medical emergency and an early management challenge (see below).

Similarly to ALL, the presenting features of childhood NHL are extremely diverse. The dominant clinical manifestations depend on the tumor's location and the extent of the disease. Virtually any lymphoid tissue can be involved, including peripheral lymph nodes, tonsils, thymus, spleen, and intestinal lymphoid aggregates (Peyer's patches). In addition, extra-lymphatic extension to include the bone marrow, CNS, bone, and skin is also common in childhood NHL.

Painless enlargement of the cervical lymph nodes is the most common clinical presentation. In a St Jude review,⁶⁰ one-third of children with NHL had palpable lymph nodes in the head and neck region. One-third of patients with NHL presents with primary mediastinum involvement, which is commonly associated with supraclavicular and axillary adenopathy. The clinical presentation of patients with a large mediastinal mass is described above. Abdominal presentation of childhood NHL is associated with a palpable mass. Tumors in the gastrointestinal tract usually affect the distal ileum, cecum, and mesenteric nodes. Retroperitoneal and renal extension is also common. Patients complain of intermittent pain in the periumbilical region or right iliac fossa. Nausea, vomiting, and weight loss are also common features. Occasionally, signs of an acute abdomen due to intussusception are the dominant feature. Generally, the primary tumor site is associated with a particular histologic subtype. An abdominal mass is most common in Burkitt NHL; mediastinal and peripheral lymph node tumors are most common in lymphoblastic or diffuse, large B-cell NHL; and skin, bone, and soft tissue tumors are most common in ALCL. In disseminated cases it is often impossible to determine the tumor's primary site. Less common presentations of NHL include subcutaneous lesions, thyroid and parotid enlargement, proptosis, and spinal cord compression. Spinal cord compression, albeit rare, should be considered a medical emergency and be treated urgently to prevent permanent neurologic deficits. The histologic, immunophenotypic, and cytogenetic characteristics of childhood NHL are listed in Table 31.3.

Laboratory findings

Almost all cases of childhood ALL have one or more abnormalities of the blood counts. Abnormalities of two or more hematologic lineages should raise high suspicion of leukemia in a child. Because anemia develops over a relatively long period, it usually does not compromise the cardiovascular system. Patients with T-cell ALL tend to have normal or minimally abnormal hemoglobin levels. The WBC count is elevated in more than 50% of cases, and is above $50 \times$

Table 31.3 Clinically relevant histologic types, immunophenotype, and cytogenetic features of non-Hodgkin lymphoma (NHL) in children

Histologic type*	Immunophenotype	Cytogenetic abnormality	Fusion gene

* World Health Organization classification; † ALL, acute lymphoblastic lymphoma.

$10^9/L$ in 20% of cases. About 45% of patients have a WBC count lower than $10 \times 10^9/L$. Lymphocytes and lymphoblasts account for most cells in the differential count. Neutropenia is a common finding. Thrombocytopenia is a very common finding in ALL. About 70% of patients have platelet counts below $100 \times 10^9/L$; some patients present with apparent isolated thrombocytopenia. Overt bleeding is rare, even in patients with platelet counts less than $20 \times 10^9/L$. Coagulation parameters are usually normal, and plasma fibrinogen concentrations tend to be elevated, reflecting a systemic inflammatory response. Mild coagulopathy with slightly increased prothrombin time and partial thromboplastin time and a low fibrinogen concentration is a relatively common finding in T-cell ALL and generally has no clinical consequences.⁶¹ Disseminated intravascular coagulation (DIC) has been associated with pre-B ALL and the rare $t(17;19)(q22;p13)$ chromosomal abnormality.⁶²

Elevated serum urate concentrations and increased urinary excretion of uric acid, which are common presenting features, reflect an increased rate of purine metabolism. Serum LDH concentrations are increased, particularly in patients with a large leukemic cell burden. Hypercalcemia, which is present in less than 1% of patients with ALL, results from the release by the leukemic cells of parathyroid hormone-related peptide or other cytokines. These patients may have multiple osteolytic lesions. Hyperphosphatemia is a relatively common presenting feature of ALL and usually indicates renal impairment resulting from dehydration or tumor lysis. Chest radiography is required and easily identifies a mediastinal mass and pleural effusion. Skeletal involvement, which is very common in ALL, includes metaphyseal bands, periosteal reactions, osteolytic lesions, osteosclerosis, and osteopenia. However, a routine skeletal survey or bone scintigraphy is not warranted in these patients because these abnormalities do not have clinical or prognostic implications and resolve with treatment. However, rarely, osteopenia can be severe and lead to vertebral collapse and severe back pain.⁶³ Lumbar puncture and examination of the cerebrospinal fluid (CSF) are integral components of the initial evaluation of a child with ALL. About 3% of these patients have overt CNS leukemia, which is defined as a WBC count of 5 or more per microliter of CSF, with leukemic cells confirmed by morphologic examination of a cytocentrifuge preparation; CNS leukemia may also be suspected from the presence of cranial nerve palsies. Even in the absence of pleocytosis, the presence of leukemic cells in cytocentrifuge preparations has clinical implications: these patients have an increased risk of CNS relapses⁶⁴ and require more intensive CNS-directed therapy. Recently, there has been a concern that the lumbar puncture itself can seed leukemic cells into an otherwise clean CNS (traumatic tap) and thus increase the risk of CNS relapse.⁶⁵

In patients with NHL, the blood counts are usually normal. Anemia, thrombocytopenia, and circulating lymphomatous cells are present in patients with bone marrow involvement. As in patients with ALL, serum concentrations of uric acid and LDH can be elevated. Although CNS involvement is rare at presentation of NHL, particularly in those with large-cell lymphoma, lumbar puncture and CSF examination should be performed in all patients. An expeditious radiologic investigation is required to demonstrate areas of tumor involvement and is used in monitoring the tumor's response to therapy. Whole-body computerized tomography (CT) is the imaging modality of choice to determine the extent of the tumor, and radionuclide scanning with both technetium-99 and gallium-67 is generally performed in all patients. The roles of magnetic resonance imaging (MRI), photon emission CT, and thallium scanning in childhood NHL have not yet been defined. Bone marrow examination is mandatory in the initial evaluation of NHL. Bone marrow biopsy may disclose tumor involvement that is not clear from examination of the bone marrow aspirate and is, therefore, recommended by most investigators as part of the work-up to determine disease stage.

Differential diagnosis

Because of their varied clinical and laboratory manifestations, childhood ALL and NHL can mimic several nonmalignant and malignant diseases. Rheumatoid arthritis is commonly misdiagnosed in patients with ALL who present with bone and joint pain. The inflammatory process in the joints of patients with ALL can be migratory, as in rheumatoid arthritis, and quiescent for days or weeks. Of interest, these patients usually have near-normal blood counts. In addition, they tend to have persistent fever, a prolonged erythrocyte sedimentation rate, and increased serum concentrations of C-reactive protein. If patients are given steroids or methotrexate, two drugs commonly used in the treatment of rheumatoid arthritis, the diagnosis of leukemia can be delayed for several months. Aplastic or hypoplastic anemia followed by spontaneous remission can precede ALL. Typically, at the time of initial examination, patients have pancytopenia and hypocellular bone marrow, to varied extents, and no leukemic cells; they improve within 1 to 4 weeks with supportive care only. Sometimes this process is referred to as preleukemia because overt ALL, usually of B-cell lineage, is frequently diagnosed within 3 to 9 months of the initial insult.⁶⁶ Hypereosinophilia, which is usually associated with several benign disorders, can also be the first sign of ALL. The leukemic cells sometimes harbor the $t(5;14)(q31;q32)$.⁶⁷ Rarely, patients with solid tumors (including neuroblastoma and rhabdomyosarcoma) present with pancytopenia and circulating blasts.

Most often, however, other presenting features and the immunophenotype of the malignant cells indicate the correct diagnosis. Immune thrombocytopenic purpura (ITP) is also frequently the presumptive mis-diagnosis of childhood ALL. However, a detailed analysis of blood counts reveals at least one or more abnormalities of the blood counts if the diagnosis is ALL,⁶⁸ whereas the blood counts are, except for the platelet count, completely normal in ITP. Infectious mononucleosis and other viruses produce severe hematologic responses that are occasionally confused with leukemia. Careful characterization of the circulating cells will establish the correct diagnosis.

Differentiating between a reactive lymphoproliferative process and NHL rarely presents a difficulty. Delay in diagnosis of NHL occasionally occurs in patients with localized, painless adenopathy because histologic studies of the lymph nodes were inconclusive for the presence of malignancy. Patients with persistent, painless enlargement of the lymph nodes after a trial of antibiotic therapy for 10 to 14 days should undergo a lymph node biopsy, preferably surgically, to provide adequate tissue for immunophenotyping, molecular, and conventional studies. Persistently enlarged lymph nodes in patients with acquired or congenital immunodeficiency represent a significant diagnostic dilemma. Collectively, these abnormalities have been classified as lymphoproliferative disorders (LPD) and range from reactive polyclonal hyperplasia to true monoclonal malignant lymphomas. Children presenting with an isolated mediastinal mass present a diagnostic challenge. Several malignant and nonmalignant conditions, including histoplasmosis, sarcoidosis, Hodgkin disease, germ cell tumor, thymic carcinoma, neuroblastoma, and myeloblastoma, may present with a mediastinal mass. Results of serologic studies may provide evidence for some of these diseases, but usually, CT-guided needle biopsy is necessary to provide tissue for diagnosis. Primary lymphoma of the bone is commonly mis diagnosed. Indeed, in a St Jude study, 10 of the 11 patients with primary lymphoma of the bone had received an alternative initial diagnosis.⁶⁹ To differentiate between primary lymphoma of the bone and other small blue cell tumors, immunohistochemical studies with an extensive panel of markers are required in addition to histologic studies.

Prognostic factors

Despite effective treatment of childhood lymphoid malignancies, about 20 to 25% of children with lymphoid malignancies die from their diseases. In general, the presenting features of patients who have a poor outcome tend to differ from those whose disease is cured by current treatment modalities. Prognostic factor analysis is an attempt to disclose subgroups of patients who have dissimilar outcomes. Factors found to be associated with poor outcome in patients with ALL include age less than 1 year or more than 10 years, hyperleukocytosis or clinical evidence of massive leukemia burden, CNS involvement, T-cell immunophenotype, certain genetic abnormalities in the leukemic cells, and persistence of leukemia after induction therapy.⁴² Treatment can modify the prognostic value of certain variables. For example, hyperleukocytosis, which is a common presenting feature of leukemia in infants, T-lineage leukemia, and subsets of B-lineage leukemia, is a strong predictor of poor outcome in many studies of childhood ALL. However, with new, effective strategies to treat T-cell leukemia, hyperleukocytosis is no longer an adverse prognostic indicator for this subset of leukemia, but continues to be a strong prognostic indicator in B-lineage leukemia. Prognostic factor analysis has also led to the identification of subtypes of leukemia that can be treated less intensively. For example, patients with subtypes of ALL in which the leukemic cells are hyperdiploid (>50 chromosomes) or have the *TEL-AML1* fusion have a very good outcome with standard therapy. Recently, a highly favorable outcome was observed in T-cell ALL with HOX11 expression of MLL-ENL fusion.⁵⁴ Conversely, some subtypes of ALL, such as ALL with any 11q23 chromosomal abnormality in infants or ALL with the Philadelphia chromosome, have poor outcome regardless of treatment strategy.^{70,71}

However, there is clinical heterogeneity even among specific genetic subtypes of ALL. For example, among patients with ALL and the Philadelphia chromosome, those 1 to 9 years old with a low leukocyte count at the time of the initial examination have a relatively favorable outcome.⁷¹ Infants with 11q23 abnormalities fare worse than do children 1 or more years old with this type of abnormality.⁷⁰ The predictive value of presenting features can be improved by including information on the patient's response to initial therapy. For example, molecular and flow cytometric methods can be used to follow the kinetics of leukemic cell clearance and to check for the persistence of leukemia after induction or consolidation therapy. Approximately 20 to 25% of patients for whom induction therapy has achieved complete remission by morphologic criteria have evidence of leukemia, shown by flow cytometric and molecular methods, with the bone marrow containing between 0.001% and 4% mononuclear cells. The use of these methods has disclosed that rapid, early clearance of leukemic cells is associated with a good prognosis, whereas persistence of leukemia after remission induction therapy is associated with an increased risk of relapse.⁷² Patients who have less than 0.01% leukemic cells after 2 weeks of remission induction treatment have a particularly favorable prognosis. An integrated model for using prognostic features is depicted in Figure 31.4. Prognostic factor analysis of

ALL may improve further with the use of gene expression profiling, a method used recently⁷³ to accurately identify patients at high risk of relapse (Figure 31.5). In NHL, staging systems have been used to identify groups of patients with diverse prognoses. The most used of these systems, introduced by St Jude, is applicable to all subtypes of NHL (Table 31.4).⁶⁰ The

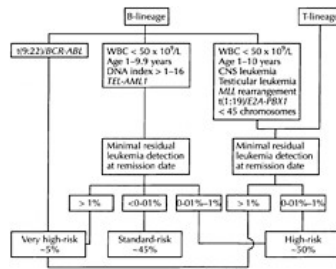

Figure 31.4 Risk classification in the current (Total Therapy Study XV) St Jude Children’s Research Hospital ALL trial. Infants (12 months or younger) are treated on a separate treatment protocol. Estimated proportions of patients classified in each of the three risk groups are shown in the respective boxes. (Reproduced with permission, from *Lancet Oncology* 2002; **10**:597.)

The Gene-Bank accession number and the gene symbol or DNA sequence name are listed on the right side of each panel. (From Yeoh EJ, Ross ME, Shurtleff SA et al. Classification, subtype discovery, and prediction of outcome in pediatric acute lymphoblastic leukemia by gene expression profiling. *Cancer Cell* 2002; **2**: 133–143, with permission.)

Table 31.4 The St Jude staging system for non-Hodgkin lymphoma (NHL) in children

Stage	Description
I	A single tumor (extranodal) or single anatomic area (nodal), excluding mediastinum or abdomen
II	A single tumor (extranodal) with regional node involvement on same side of diaphragm: <ul style="list-style-type: none"> (a) Two or more nodal areas (b) Two single (extranodal) tumors with or without regional node involvement A primary gastrointestinal tract tumor (usually ileocecal) with or without associated mesenteric node involvement, grossly completely resected
III	Two or more tumors on both sides of the diaphragm: <ul style="list-style-type: none"> (a) Two single tumors (extranodal) (b) Two or more nodal areas All primary intrathoracic tumors (mediastinal, pleura I thymic) All extensive primary intraabdominal disease; unresectable All primary paraspinal or epidural tumors regardless of other sites
IV	Any of the above with initial CNS or bone marrow involvement (<25%)

main value of this classification scheme is in separating patients with localized disease from those with advanced disease. More recently, information on immunophenotype and molecular findings has been incorporated into classification schemes. This approach established the foundations on which investigators can develop treatment regimens specific to immunophenotype and disease stage. As in ALL, response to therapy has been used to make treatment decisions in NHL as well. French investigators proposed using imaging studies to estimate the reduction in tumor mass after one week of cyclophosphamide, vincristine, and prednisone (COP) treatment in patients with B-cell lymphoma. Patients whose primary tumor was reduced by less than 20% received a more intensive treatment strategy.⁷⁴ Recently, gene chip arrays have been developed to identify the molecular features associated with NHL.⁷⁵ Whether this method will add meaningful prognostic information remains to be determined.

Treatment

Acute lymphoblastic leukemia

Lessons from the past

The treatment of childhood ALL is one of the major successes of modern medicine. Current treatments are

expected to cure about 80% of newly diagnosed ALL.⁴² Over the years, several treatment principles have endured. First, a combination of several chemotherapeutic agents is superior to a single agent in inducing remission of ALL.⁷⁶ Second, certain classes of drugs are appropriate to induce remission, whereas others are appropriate to maintain it.⁷⁷ Third, after remission is achieved by induction therapy, combination chemotherapy is required for a prolonged period to eradicate leukemic cells.⁷⁸ Fourth, the complete elimination of leukemic cells requires that specific components of the therapy be targeted to subclinical leukemic involvement of the CNS.⁷⁹ Fifth, it must be recognized that ALL is a heterogeneous disorder with many subtypes that respond differently to specific treatment strategies.⁸⁰ Finally, properly conducted clinical trials on the efficacy of risk-directed therapy for ALL are important.^{41,81} For example, contemporary clinical trials have similar overall outcome (Table 31.5), but different trials have disclosed diverse treatment facets. Some trials have proved particular treatment components to be more effective in certain subtypes of leukemia and others to be associated with unique complications. Careful analysis of these data has enabled investigators to combine components of these trials to increase efficacy and reduce morbidity.

Induction of remission (early therapy)

The first objective in the treatment of childhood ALL is to induce complete remission. To achieve complete remission, the leukemic burden has to be reduced by 99%, or from 10^{12} to 10^{10} leukemic cells. Treatment with a combination of glucocorticoids (prednisone, prednisolone, dexamethasone) and vincristine can induce complete remission of ALL in about 85% of children. Prednisone and prednisolone have been the most used types of steroids. Dexamethasone appears to be more potent and penetrates the CNS better, but its use may be associated with higher mortality rates.⁸² The addition of L-asparaginase to the treatment regimen, with or without an anthracycline, increases the rate of complete remission to above 95% within 4 to 6 weeks. The role of L-asparaginase in prolonging remission has been documented.⁸³ Delaying L-asparaginase administration to the postremission phase does not jeopardize the rate of complete remis

[‡] The standard-risk group included children 1–9 years old with leukocyte count $<50 \times 10^9/L$; all others (except infants) were placed in the high-risk group. The differences in 'overall' results are partly related to the disproportion of high-risk cases referred to some institutions. SE, standard error.

sion or event-free survival and is associated with fewer thrombotic complications.^{84,85} CNS-directed therapy, which begins concomitantly with the administration of these systemic agents, is described later in this chapter. After the induction of remission is achieved, many treatment regimens prescribe additional chemotherapeutic components. These have been used early in the induction process⁸⁶ or after 4 weeks of standard chemotherapy.

Consolidation and intensification therapy

The concept of consolidation and intensification of therapy is widely accepted as essential components of the overall treatment of ALL. This strategy was pioneered by investigators in the Berlin-Münster-Frankfurt (BFM) consortium.⁸⁷ Consolidation therapy is delivered immediately after induction therapy, when bone marrow function has been restored, and intensification (re-induction) therapy, between 2 and 4 months later, during maintenance therapy. There are many different ways to intensify postremission therapy. For example, investigators at the Dana-Farber Cancer Institute demonstrated that postremission therapy with L-asparaginase and doxorubicin was associated with an improved outcome in patients with T-cell leukemia.^{88,89} Investigators of the Children's Cancer Group (CCG), like the BFM investigators, found that two phases of delayed intensification ('double delayed intensification') also improved the outcome of patients with high-risk leukemia.^{90,91} The availability of these data has allowed St Jude investigators to develop an innovative approach to early therapy (about the first 4 months after remission). All patients receive high-dose methotrexate as consolidation therapy. Very high-dose (Sg/m^2) methotrexate has been shown to improve outcome in T-cell ALL.^{92,93} Patients with T-cell leukemia also receive extended and intensive L-asparaginase and doxorubicin therapy following consolidation therapy, as in the Dana-Farber protocol. Re-induction phases (essentially a repetition of the induction therapy) occur on weeks 7 and 17 of postremission therapy, as proposed by BFM and CCG investigators. Patients with persistent disease after induction and consolidation therapy or ALL with the Philadelphia chromosome receive a block of intensive chemotherapy consisting of cytarabine, etoposide, dexamethasone, and L-asparaginase followed by hematopoietic stem cell transplantation (HSCT); patients with low-risk ALL receive postremission therapy that is of relatively low intensity and well tolerated.

Maintenance therapy

Because the early postremission therapy—consolidation and intensification therapy and interim chemotherapy—extends through the first 2 to 6 months, maintenance therapy, which follows these phases of therapy, can be considered the final phase of treatment. The mechanism of the eradication of the leukemic clone after remission is poorly understood; the drugs and schedules prescribed in this phase have evolved over five decades and remain largely based on empiric evidence. In most protocols, this phase of therapy continues for 2 to 3 years from the time of remission. In the current St Jude study, girls receive chemotherapy for a total of 2.5 years and boys for 3 years. Attempts to reduce the duration of remission induction therapy have not been successful the few times they have been tried.^{94,95} Similarly, there has been no evidence that prolonging the duration of maintenance therapy beyond 3 years has any added benefit. Daily oral doses of 6-mercaptopurine (6-MP), preferably taken at night on an empty stomach, and weekly doses of parenteral methotrexate constitute the framework of maintenance chemotherapy. Adjusting the dosage of these agents on the basis of the absolute neutrophil count is associated with a better prognosis.⁹⁶ However, the tolerance of 6-MP depends on the function of thiopurine S-methyltransferase, an enzyme produced by several autosomal codominant alleles. About 10% of patients with ALL have an inherited deficiency of this enzyme, which results in poor tolerance of 6-MP. To avoid prolonged myelosuppression, many patients with this enzyme deficiency need to be given lower 6-MP doses commensurate with their level of enzymatic activity.^{97,98} Recently, it has become possible to determine, from the patient's genotype, which patients are at higher risk of toxicity from 6-MP, and thus require a lower dose. The addition of intermittent pulses of vincristine plus dexamethasone to the regimen has been shown to decrease the rate of relapse and is widely accepted.⁹⁹ Further intensification of therapy, usually for patients at high risk of relapse, can be attained by adding other drug pairs. Because of the need for prolonged maintenance therapy, the possible benefit of further intensification has to be weighed against the potential long-term side-effects of this strategy. These side-effects include secondary AML, infertility, and cardiac dysfunction.

Central nervous system involvement

Overt CNS involvement at the time of diagnosis of ALL is relatively rare, affecting about 3 to 5% of newly diagnosed patients. Features that are associated with overt CNS leukemia at the time of diagnosis include age less than 1 year, the presence of T-cell markers, a hypodiploid karyotype, presence of the Philadelphia chromosome, and high WBC counts. These features and the presence of any amount of leukemic cells in the CSF (including those introduced iatrogenically into the spinal canal during a diagnostic spinal tap) increase the risk of CNS relapse.⁶⁵ Even patients who have no discernible adverse presenting features are at risk of CNS leukemia if they do not receive appropriate CNS-directed therapy. In the mid

1960s, St Jude investigators elegantly demonstrated that 2400 cGy delivered to the cranium and 1500 cGy to the spine reduced the rate of CNS relapse from 50% to 5%. Subsequently, they showed that intrathecal methotrexate could replace spinal radiotherapy. Because the toxicity associated with radiotherapy is substantial, several modifications aiming to reduce neurological toxicity have been tested during the past 30 years. First, it was found that the dose and fields of irradiation can be reduced when appropriate intrathecal and systemic therapies are provided.⁸⁷ Second, radiation therapy can be eliminated completely for patients with low-risk ALL.¹⁰⁰ Third, preventive CNS-directed therapy is not necessary beyond 1 year after complete remission. Fourth, intensive use of intrathecal therapy is effective in preventing CNS leukemia in more than 80% of children with ALL.^{101,102} Finally, in high-risk cases, the radiation dose can be reduced to 1200 cGy without increasing the risk of CNS relapse, provided that effective systemic chemotherapy is used.⁸⁷ We and Dutch investigators are testing the hypothesis that in the context of intensive systemic and intrathecal therapy, cranial irradiation can be omitted, irrespective of the adverse prognostic features present at the time of the initial examination.

Non-Hodgkin lymphoma

Progress in the treatment of children and adolescents with NHL parallels that of ALL. Results of most contemporary clinical trials are revealing survival rates approaching 90%.^{74,103,104} Moreover, the use of risk-adapted strategies specific for disease stage and immunophenotype in conjunction with a wide range of effective agents, which are largely responsible for the improved survival rates, has practically eliminated the relevance of clinical and biologic prognostic factors. Treatment has emerged as the single most important determinant of successful outcome for patients with NHL. Clinical and biologic features that guide the therapeutic strategy include the extent of the disease at the time of diagnosis, sites of involvement, immunophenotype, morphology and immunohistochemistry of tumor cells, and early response to therapy.

Lower-risk non-Hodgkin lymphoma (localized disease)

Patients with low-risk NHL, which accounts for about 10 to 20% of pediatric NHL, are those that after treatment with only two or three courses of chemotherapy have an excellent prognosis, with a probability of survival of more than 90%. Typically, these chemotherapy courses consist of a combination of corticosteroids, cyclophosphamide, vincristine, and doxorubicin (CHOP, COPAD) at standard dosages and given every 3 weeks. The Pediatric Oncology Group has conducted several studies¹⁰⁵ on patients with stage I or II NHL, the results of which can be summarized as follows: (1) local radiotherapy can be safely omitted; (2) chemotherapy cycles of moderate intensity (4 agents) are sufficient for the eradication of NHL; (3) the duration of chemotherapy should be no longer than 6 months for these patients; (4) CNS-directed therapy is indicated only for patients with primary tumors in the head and neck region; (5) lymphoblastic lymphoma, which accounts for only 10 to 15% of disease of limited extent, requires maintenance chemotherapy with daily 6-MP and weekly methotrexate administration. Similar results have been achieved by other pediatric cooperative groups using modified versions of the St Jude staging system.

Higher-risk non-Hodgkin lymphoma (advanced-stage disease)

Patients who are not classified as having limited or low-risk disease are collectively grouped as high-risk patients. Naturally, patients placed in this category have a wide range of tumor burdens and are likely to have diverse prognoses. Because of this diversity, there are large discrepancies between treatments given depending on the staging system used. For example, a patient with Burkitt lymphoma without CNS involvement and <25% blast cells in the bone marrow is considered to have disease stage IV according to the St Jude system, but is placed in group B in the SFOP staging system (the SFOP system stipulates 70% or more of bone marrow involvement for group C). Treatment of group C disease is much more intensive than that of group B.¹⁰⁶ Other investigators define risk categories among patients with advanced-stage disease on the basis of serum LDH concentrations.¹⁰⁷

The highly successful protocol developed by French investigators, the LMB89,⁷⁴ for patients with B-cell NHL (Burkitt, Burkitt-like, and large B-cell lymphomas) has become the benchmark for other protocols. Intensive, high-dose treatment of short total duration (5 to 8 months) and a reduced interval between treatment cycles are the hallmark of all effective combinations for patients with B-cell (Burkitt, Burkitt-like, small noncleaved-cell, large B-cell) NHL. CNS-directed therapy is mandatory and is intensive in patients with evidence of CNS involvement or those in the high-risk category. In developing treatment for advanced-stage lymphoblastic NHL, it has been assumed that this form of the disease behaves the same as does T-cell ALL. This observation is derived from the seminal Children's Cancer Group study, reported about 20 years ago, showing that the LSA₂L₂ regimen, an ALL-type therapy, was significantly more effective than pulse chemotherapy (COMP) for patients with lymphoblastic NHL.¹⁰⁸ However, because most lymphoblastic NHL is of T-cell immunophenotype, ALL regimens that have not been particularly successful in treating T-cell ALL are expected to yield poor results in treating lymphoblastic NHL as well. The BFM-90

protocol for NHL represents one of those treatment strategies that incorporated treatment components found to be effective in T-cell ALL. This treatment was associated with a 5-year event-free survival (EFS) rate of 92% in more than 100 patients with lymphoblastic lymphoma—a truly remarkable achievement.

The third largest group of childhood NHL, comprising about 15% of all pediatric NHL, is ALCL. By definition, this includes tumors with T-cell markers or a null-cell immunophenotype.¹⁰⁹ Because the clinical and biologic characterization of this subtype of NHL is still evolving, the interpretation of treatment programs for this disease is difficult. B-cell and ALL-type treatment strategies for ALCL have been reported. Only a few pediatric cooperative treatment groups have reported their results in patients selected by the contemporary definition of ALCL—co-expression of CD30 and the epithelial membrane antigen in cells with T-cell or null immunophenotype. Remarkably, the results, albeit inferior to those noted in pediatric B-cell or lymphoblastic NHL, have shown that about 60 to 80% survival rates can be achieved with either treatment strategy. The SFOP used a protocol¹¹⁰ based on the treatment of B-cell NHL that prescribes two cycles of COPAD plus high-dose methotrexate followed by 5 to 7 months of maintenance chemotherapy. Complete responses were achieved in 95% of the patients; 21 patients experienced an adverse event. BFM investigators using a strategy developed for B-cell NHL have reported improved results. The 5-year EFS rates for 55 patients with stage III and 6 patients with stage IV NHL were 76% and 50%, respectively. The duration of treatment was only 5 months in the BFM study, but 10 to 24 months in others.¹⁰³

Salvage therapy (partial responses or relapse)

The development of methods to detect the presence of minimal amounts of disease has revealed a new dimension to the concept of relapse in childhood lymphoid malignancies. Alternative therapeutic strategies or salvage therapy are now recommended for patients who have subclinical evidence of persistent disease. Because patients destined to experience a relapse of the disease are being identified early in the relapsing process, the actual number of patients in whom classic clinical and laboratory manifestations of relapse develop is becoming progressively small. Thus, patients who experience relapse after contemporary, effective, risk-adapted therapy present true medical challenges.

Acute lymphoblastic leukemia

Traditionally, ALL relapse has been classified as hematologic, extramedullary, or combined. Hematologic and bone marrow relapse are usually further defined as being early (during or <6 months after cessation of therapy) or late relapses. Poor prognostic factors at the time of relapse include a short first remission period, hematologic relapse rather than extramedullary relapse, high intensity primary therapy, T-cell immunophenotype, Philadelphia chromosome, and a high WBC count. A first remission lasting more than 30 months, an isolated extramedullary relapse, or presence of the *TEL-AML* gene fusion has been associated with a higher likelihood of achieving a second, durable remission.¹¹¹ Usually, the treatment used to obtain a second remission includes a combination of dexamethasone, vincristine, L-asparaginase, anthracycline, etoposide, high-dose cytarabine, and high-dose methotrexate. A second course of CNS-directed therapy is included during this phase. For many years, there was controversy over the best approach for second postremission therapy. Some investigators defended the use of intensive chemotherapy for patients who experienced late relapse, whereas others recommended HSCT.¹¹² At present, there is a consensus that patients with early hematologic relapse should proceed to HSCT after the achievement of a second remission.^{113, 114}

Isolated relapses in extramedullary sites usually involve the CNS or the testes. Although they are considered isolated, most of these cases are likely to have subclinical bone marrow involvement. The type and intensity of previous CNS therapy can influence the rate of CNS relapse. Investigators at the Dana-Farber Cancer Institute⁸⁶ showed that boys with standard-risk ALL who did not receive radiation therapy as part of their CNS-directed therapy had an unexpectedly high incidence of CNS relapse. The management of 'isolated' CNS relapse includes intensive intrathecal treatment along with systemic chemotherapy consisting of at least 1 year from the event. Cranial irradiation of induction, consolidation, and maintenance radiotherapy is mandatory in these cases. There is controversy about the timing of delivery of cranial irradiation; it appears that systemic and intrathecal treatment for 4 to 6 months before definitive radiotherapy is associated with better long-term disease control. Intrathecal treatment should not be given after cranial radiotherapy because of an increased risk of neurotoxicity. Because of the high rate of success of salvage therapy for patients with isolated CNS relapse, HSCT is not recommended for these patients.

Isolated testicular relapse, a rarity with current treatment modalities, usually involves both testicles. Patients with clinical evidence of testicular involvement during therapy have a poor prognosis. Relapse occurring after completion of therapy is associated with a better prognosis. The principles of management are similar to those applied to CNS relapse: patients should receive intensive systemic therapy for at least 1 year and, after completion of induction ther

apy, irradiation of both testicles. Whether the use of testicular radiotherapy can be avoided by administering high-dose methotrexate remains to be determined. In patients with clinical evidence of unilateral testicular relapse, some investigations advocate orchiectomy of the testis involved and no irradiation of the 'uninvolved' testis, in an attempt to preserve testicular function.

Non-Hodgkin lymphoma

Persistent or relapsed NHL presents serious management problems. Because contemporary, risk-directed therapies are usually very intensive, the overall prognosis for these patients is dismal. In patients with a residual mass after induction and consolidation therapy, persistent disease should be confirmed by biopsy, because imaging studies commonly detect nonviable tumor. When persistent disease during therapy or relapse is documented, the options for salvage therapy depend on the intensity and types of agents used in the primary therapy, histologic type of disease, and timing of the relapse. Because primary therapy for Burkitt lymphoma or large B-cell lymphoma includes most of the known effective agents, salvage therapy is usually based on regimens containing cisplatin or carboplatin. A widely used combination is ifosfamide, carboplatin, and etoposide (ICE). Monoclonal antibodies to B-cell antigens have been successfully used to treat B-cell lymphomas.^{115–117} These antibodies have been used in combination with conventional chemotherapy or conjugated to radioisotopes.^{118,119} The monoclonal anti-CD20 (rituximab), for example, has been widely used in combination with standard chemotherapy. Because a second complete response to non-cross-resistant chemotherapy regimens, if achieved, is usually short, HSCT is recommended. The principles of management of relapsed lymphoblastic NHL are similar to those of relapsed ALL. When a second remission is obtained, HSCT is also indicated. The outcome is very poor for patients who have residual disease after salvage therapy. Contrary to what is observed in Burkitt and lymphoblastic NHL, second remission is usually possible in ALCL. Salvage treatment has included intensive chemotherapy with or without HSCT. In a recent study by the SFOP, a second remission was achieved in 36 of 41 cases of relapsed ALCL.¹²⁰ It is noteworthy that 8 of 13 patients had prolonged remission with the use of a single agent, vinblastine (given weekly), which suggests that several relapses of ALCL do not preclude a long period of disease-free survival.

Supportive care

Patients with lymphoid malignancies often present with respiratory, cardiovascular, neurologic, renal, hemorrhagic, infectious, and metabolic complications. Intense tissue remodeling—cell proliferation and cell death—results in a large tumor burden and rapid turnover of nucleoproteins, both of which are responsible for the dysfunction of these organ systems. Prompt recognition, careful clinical and laboratory evaluations to determine the presence of these complications, and early intervention have decreased the mortality rate resulting from these complications (i.e., deaths not due directly to the leukemia or lymphoma) to less than 1%.

White blood cell counts $>300 \times 10^9/L$ at the time of initial examination can be associated with leukostasis syndrome in ALL, although this complication is rare. Neurologic and pulmonary signs and symptoms sometimes observed include dizziness, visual blurring, tinnitus, ataxia, confusion, somnolence, stupor, coma, tachypnea, dyspnea, pulmonary infiltrates, and progression to frank respiratory failure. The management of leukostasis is controversial, but many investigators consider leukopheresis for patients with an initial leukocyte count approaching $300 \times 10^9/L$. It is also recommended that specific antileukemia chemotherapy should begin (with corticosteroid and vincristine) on the first day and the outcome closely monitored. As the patient improves clinically, other chemotherapeutic drugs are added. On the rare occasions in which coagulopathy is symptomatic at the time of diagnosis of ALL, platelet transfusions, plasma cryoprecipitate, and fresh frozen plasma should be given to keep platelet counts above $50.0 \times 10^9/L$ and fibrinogen concentration above 1.0 g/L . The use of heparin is not indicated in these instances because the coagulopathy usually resolves within 24 to 48 hours of starting antileukemic treatment.

Respiratory distress from compression of mediastinal structures is common in lymphoblastic NHL. Compression of the vessels of the mediastinum can lead to intraluminal thrombosis (Figure 31.6) and sudden death. In cases of severe compression, general anesthesia is not recommended, because of an increased risk of complete, irreversible airway block. In an emergency it is sometimes necessary, before diagnosis is made, to reduce the risk of airway compression by administration of corticosteroids or local radiotherapy (or both). Massive ascites and intra-abdominal involvement in Burkitt lymphoma can cause compression of the bowel and ureters. In addition, compression of abdominal blood and lymphatic vessels can occur, which results in reduced blood flow and lymphatic return and in edema of the lower extremities.

Patients with leukemia and NHL are at particularly high risk for biochemical complications because of the high rate of cell turnover and the high sensitivity of the malignant cells to chemotherapy. Often, biochemical abnormalities are present before the initiation of chemotherapy and are induced by fever,

Figure 31.6 Autopsy findings from a 12-year-old boy with non-Hodgkin lymphoma who died of cardiopulmonary arrest after sudden respiratory failure. A thrombus occluding the left pulmonary artery can be seen.

infection processes, dehydration, and even spontaneous cell lysis. These metabolic abnormalities, which include hyperuricemia, hyperphosphatemia, hypocalcemia, hyperkalemia, and azotemia, are characteristic of tumor lysis syndrome (TLS). The pathogenetic consequences of this syndrome result from the release of cellular breakdown products that exceed the hepatic and renal anabolic and catabolic capacities. The deposition of uric acid, its precursors (hypoxanthine and especially xanthine), or both, and phosphorus in the lumina of the renal tubules is believed to be central to the development of renal insufficiency. If these metabolic abnormalities become severe, renal failure, cardiac arrhythmia, respiratory distress, and death can follow.

Features associated with increased risk of TLS include hyperleukocytosis, massive organomegaly, renal enlargement, extrinsic compression of the genitourinary tract, and elevated serum LDH activity. Patients with established TLS or at high risk for TLS should be monitored carefully. Preferably, they should be admitted to an intensive care unit and cared for by a multidisciplinary team. Adequate urinary flow is the single most important measure to accomplish before chemotherapy is started. To determine the adequacy of renal function, a slightly hypotonic solution without potassium should be administered intravenously at a daily rate of 2 to 5 L/m² per day. Administration of fluids dilutes intravascular solutes such as urates and phosphates, increases renal blood flow and glomerular filtration, and flushes precipitated solutes from the renal tubules. The availability of recombinant urate oxidase (rasburicase) has dramatically facilitated the prevention and management of hyperuricemia.¹²¹

Acute lymphoblastic leukemia in adults

Dieter Hoelzer and Nicola Gökbuget

Introduction

Incidence

Acute lymphoblastic leukemia (ALL) is a malignant disease characterized by a clonal proliferation of malignant lymphoblasts. It is a rare disease in adults. According to the most recent report of the National Cancer Institute (NCI) the incidence per 100 000 is 1.5 in whites and 0.8 in blacks. The male to female ratio was 1.6:0.8. After a first peak in children younger than 5 years of age (6.7/100 000) the incidence decreases continuously. There is a slight increase after the age of 50 years and a second minor peak in the age group of 80–84 years (1.5/100000). In the period from 1973 to 2000, a slight increase in age-adjusted incidence rates from 1.2 to 1.4/100 000 was observed.¹

Etiology

Genetics

Children with rare disorders such as Down syndrome, Klinefelter syndrome, Fanconi's anemia, Bloom syndrome, ataxia telangiectasia, and neurofibromatosis have an increased risk of developing acute leukemias, preferentially acute myeloid leukemias (AML), but also ALL. Genetic predisposition may also be inferred from simultaneous development of ALL in identical twins, but this is mainly indicative of an intrauterine event affecting both twins.

Irradiation

The incidence of acute leukemia was increased 20-fold in survivors of the atomic bomb explosions (>1 Gy exposure) in Japan. Emission from nuclear power stations has also been raised as a possible leukemogenic risk. Whether the Chernobyl accident led to an increased incidence of leukemia is still controversial.

Chemicals

It has been known for a considerable time that chemical agents such as benzene, chloramphenicol and others causing bone marrow aplasia can eventually lead to the development of acute leukemias. More recently, secondary therapy-related leukemias have become an appreciable problem. Acute myeloid leukemias have occurred after exposure to alkylating agents such as cyclophosphamide, epipodophyllotoxins, topoisomerase II inhibitors and (rarely) anthracyclines that are used extensively in the treatment of ALL. Secondary ALL occurs rarely as a second neoplasm.

Viral

There is no direct evidence that a virus causes human ALL, but there are indirect suggestions for its involvement. In the endemic African type of Burkitt lymphoma, the Epstein-Barr virus (a DNA virus of the herpes family) has been implicated as a potential causative agent (see also Chapter 14). Endemic infection with human T-cell leukemia/lymphoma virus type I (HTLV-I) in Japan and in the Caribbean is an etiologic factor for adult T-cell leukemia/lymphoma (see also Chapter 13).

Diagnosis

For classification of leukemic blast cells in ALL, morphological and cytochemical studies, immunophenotyping, and cytogenetic and molecular genetic analysis are required.

Morphology

Morphology remains the means by which acute leukemia is initially detected, and, together with cytochemical reactions, it can distinguish between ALL and AML. The French-American-British (FAB) classification which classifies leukemic blast cells by their cytological features (L1, small monomorphic type; L2, large, heterogeneous type; L3, Burkitt cell type) is of no prognostic value except for the identification of the L3 subtype, which is indicative of B-lineage ALL(B-ALL).

Immunophenotype

Immunophenotyping of ALL blast cells is the major classification of ALL subtypes (Table 32.1). ALL blast cells can be subdivided into B-lineage or T-lineage by detection of lineage-specific antigens. Within the B-lineage or T-lineage ALL, the subtypes are defined according to their stage of differentiation.

B-lineage ALL

Pro-B-ALL (also termed early pre-B-ALL or prepre-B-ALL) expresses HLA-DR, TdT and CD19, but shows no expression of other differentiation B-cell antigens. It occurs in about 11% of adult and 5% of childhood ALL.

Common ALL is the major immunological sub-type in childhood as well as in adult ALL. It comprises about 50% of cases of adult ALL. Common ALL is characterized by the presence of CD10 (formerly CALL A).

Pre-B-ALL is identical to common ALL, except for the expression of cytoplasmic immunoglobulin. Only very rarely, CD 10 may be absent in this subtype. Pre-B-ALL comprises nearly 10% of adult ALL.

Mature B-ALL is found in about 4% of adult ALL patients. The blast cells express surface antigens of mature B cells, including surface membrane immunoglobulin. CD10 may be present and occasionally also cytoplasmic immunoglobulin.

T-lineage ALL

Approximately 25% of adult ALL cases have blast cells with a T-cell phenotype. All cases express the T-cell antigen gp40 (CD7), and in addition they may, according to their degree of T-cell differentiation, express other T-cell antigens, for example CD2 and/or the cortical thymocyte antigen CD1. A minority of T-ALL blast cells may also express CD10 together with T-cell antigens. In most cases of T-ALL, one or more of the T-cell receptor genes is rearranged. These properties make it possible to classify T-cell ALL according to their stage of differentiation.

Early T-precursor ALL accounts for 6% of adult ALL. It shows characteristic T-cell markers (cyCD3 and CD7) but no further differentiation markers.

Thymic (cortical) T-ALL is the most frequent sub-type of T-ALL (10%). It is characterized particularly by the expression of CD1a. Surface CD3 may be present. Since this subtype is associated with a better prognosis, its identification is of particular importance.

Mature T-ALL has a frequency of 6%. The blast cells do not express CD1a but they are positive for surface CD3.

Cytogenetics

Cytogenetic abnormalities are independent prognostic variables for predicting the outcome of adult ALL.

Table 32.1 Immunologic classification, corresponding cytogenetic and molecular aberrations and frequencies in adult acute lymphoblastic leukemia (ALL)

	EGIL	Adults (%) [*]	Surface marker	Cytogenetics ^{**}	Molecular genetics ^{**}
B-lineage			HLA-DR ⁺ , TdT ⁺ , CD19 ⁺ and/or CD79a ⁺ and/or CD22 ⁺		
Pro B-ALL	B-I	11	No further differentiation markers	t(4;11)	ALL1 (MLL)-AF4

B-ALL	B-IV	5	CD10 ^{+/-} , surface immunoglobulin (sIgM ⁺)	t(8;14)	CMYC-IgH
T-lineage^{***}			TdT ⁺ , cytoplasmic CD3 (cyCD3 ⁺) or surface CD3 (sCD3 ⁺)		
Early T-ALL	T-I	6	cyCD3 ⁺ , CD7 ⁺ , CD5 ^{+/-} , CD2 ^{+/-}		
	T-II				
Cortical T-ALL (Thy ALL)	T-III	10	cyCD3 ⁺ , CD7 ⁺ , CD1a ⁺ , sCD3 ^{+/-}	t(11;14)	LMO1/-TCR α / δ
Mature T-ALL	T-IV	6	sCD3 ⁺ , CD1a ⁻	t(10;14)	HOX-11-TCR α / δ

^{*} Frequencies according to central immunophenotyping of the GMALL Study group; personal communication of Prof. Dr. E. Thiel and Dr. S.Schwartz, Free University of Berlin, Germany and EGIL²; ^{**} most frequent, typical aberrations; ^{***} The EGIL classification subdivides T-ALL into four subgroups; however, only the differentiation between early, mature and thymic T-ALL is of clinical relevance.

In three recent studies, clonal chromosomal aberrations could be detected in about 62–85% of adult ALL patients.^{3,4,5} Between 15% and 38% of the cases had normal metaphases.

The major cytogenetic abnormalities in ALL are clonal translocations such as t(9;22), t(4;11), t(8;14), t(1;19) or t(10;14) and other structural abnormalities such as 9p, 6q or 12p abnormalities. In addition, the abnormalities can be classified according to the modal chromosomal number (<46, 46 with other structural abnormalities, 47–50, >50).

The demonstration of chromosomal abnormalities in ALL is relevant for several reasons: the presence of such defects may confirm the diagnosis if a karyotype specific for ALL is found; chromosomal abnormalities are closely correlated with clinical features and immunological subtypes; and they are independent prognostic variables for predicting leukemia-free survival.

Molecular genetics

Molecular analyses—detecting gene rearrangements in ALL by the polymerase chain reaction (PCR), Southern blot analysis, or fluorescent in-situ hybridization (FISH) with chromosome-specific DNA probes—are useful approaches to establish more precise diagnosis and to define the quality of remission, and may also give insights into the pathophysiology of the leukemic process (e.g. the mechanisms of leukemic cell stimulation by BCR-ABL fusion proteins).

The most frequent molecular markers in ALL are BCR-ABL and ALL1-AF4. The Philadelphia (Ph) chromosome t(9;22)(q34;q11) results from a translocation involving the breakpoint cluster region of the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. The *BCR-ABL* gene rearrangement can be demonstrated by molecular techniques. PCR analyses have revealed an incidence of 20–30% *BCR-ABL*⁺ ALL in adults⁶ compared with 3% in childhood ALL patients. One-third of adult ALL patients with a Ph chromosome show M-*BCR* rearrangements (resulting in a 210 kDa protein), similar to patients with chronic myeloid leukemia (CML), whereas two-thirds have M-*BCR* rearrangements (resulting in a 190 kDa protein). It is noteworthy that *BCR-ABL* is more frequently detected than the corresponding chromosome abnormality t(9; 22), owing to occasional difficulties in obtaining sufficient material for cytogenetic analysis.

t(4;11)(q21;q23) is the most frequent form of 11q23 abnormality in ALL. The involved gene on chromosome 11 is named *MLL* (for mixed-lineage leukemia). Synonyms are *ALL-1*, *HRX* and *HTRX1*. The *MLL* gene is fused to a gene located on chromosome 4 that is named *AF-4* (also referred to as *FEL*). The fusion gene *ALL1-AF4* is frequently detected in infant leukemia and in patients with pro B-ALL (CD10⁻). The overall incidence in adults is about 6%.

Other molecular aberrations occur more rarely and are allocated to specific subtypes as shown in Table 32.1.

Clinical manifestations

Most adult patients initially present with clinical symptoms resulting from bone marrow failure. Pallor, tachycardia, weakness and fatigue are due to anemia; petechiae or other hemorrhagic manifestations are attributable to thrombocytopenia; infectious complications are due to neutropenia. Clinical signs of leukemia are related directly to infiltration of organs with leukemic blasts, such as lymphadenopathy, splenomegaly and hepatomegaly, are present in most patients, but are infrequently problems for which the patient first seeks medical advice.

Patient characteristics and clinical symptoms

Characteristic symptoms and clinical manifestations are given in Table 32.2. There is a male preponderance in T-ALL and mature B-ALL. In T-ALL, there is a higher proportion of adolescent patients and a significantly lower frequency of patients above 50 years. One-third of ALL patients had infection or fever at presentation, and one-third presented with hemorrhagic episodes. Hepatomegaly and splenomegaly was observed in about half of the patients; lymphadenopathy was more often seen in T-ALL, as well as mediastinal tumor and central nervous system (CNS) involvement. Massive thymic enlargement can cause dyspnea, especially when associated with pleural effusions. CNS involvement at presentation was seen overall in 3% of adult ALL patients with higher incidences in T-ALL (8%) and in mature B-ALL (13%). Less than half of these patients initially had CNS symptoms such as headache, vomiting, lethargy, nuchal rigidity, and cranial nerve or peripheral nerve dysfunction. In the remaining patients, the diagnosis of CNS involvement was made by demonstration of leukemic blast cells in the cerebrospinal fluid. Very rarely there is leukemic CNS involvement without lymphoblasts in the CSF, but verified by computed tomography (CT scan) or related clinical symptoms only.

Virtually any organ can be infiltrated by ALL blast cells; 15% of T-ALL and one-third of mature B-ALL patients had such organ involvement (Table 32.2).

Laboratory evaluation

The peripheral blood-cell values at diagnosis in a large cohort of patients are shown in Table 32.3. The

elevated leukocyte count in more than half of the patients should be noted; leukopenia can also be found, but most patients had leukemic blast cells in the peripheral blood, and 'aleukemic leukemias' are rare. In patients with normal or decreased leukocyte counts, the diagnosis may be missed by automated blood cell assay, and thus the importance of microscopic examination of blood smears is stressed. Neutropenia and thrombocytopenia in a third or less of the patients correspond roughly with symptoms of infection and bleeding.

An initial lumbar puncture should be done to determine whether the CNS is involved. It should, however, be postponed as long as there is a risk of bleeding due to a very low platelet count, or a risk of blast cell contamination due to leukemic blast cells in the peripheral blood. When the leukocyte count in the spinal fluid is low or the morphological detection of blasts is inconclusive, demonstration of an immunologically defined blast cell population can confirm a diagnosis of CNS involvement.

Therapy

Initial evaluation and supportive therapy

At diagnosis, the evaluation of an adult with ALL should include a history and a careful physical examination. Speed in clinical evaluation and diagnosis is important in order to initiate supportive measures and to decide on appropriate therapy. In only a few cases is the leukemic process so far advanced that immediate treatment of leukemia is necessary—for example, in patients with symptoms due to a large mediastinal mass and pleural effusions or to a rapidly progressing B-ALL.

A few general measures should be initiated at once. Sufficient fluid intake to guarantee urine production of 100 ml/h throughout induction therapy should be maintained to reduce the danger of uric acid formation. Parenteral fluid administration may be required when the patient's oral intake is inadequate owing to nausea or difficulty in swallowing. Placement of an implantable port system is advantageous when anticipating a long period of induction therapy or when part of the therapy will be carried out on an outpatient basis.

Patients should receive allopurinol to reduce the formation of uric acid and avoid the danger of urate nephropathy. Allopurinol should be given at a dose of 300 mg/day, which may be increased to 600 mg/day if high leukocyte counts or organomegaly persist. The dose of allopurinol has to be reduced when 6-mercaptopurine (6-MP) is given, since it potentiates the action of 6-MP. Rasburicase is a new recombinant urate oxidase enzyme which catalyzes the oxidation of uric acid to allantoin.⁷ Recently it has been demonstrated that rasburicase can reduce high uric acid faster and safer than allopurinol thereby preventing a tumor lysis syndrome in almost all cases.⁸ It might, therefore, be an alternative in patients with high risk of tumor lysis syndrome. During the induction period, patients are at high risk of infections and hemorrhagic complications, since thrombocytopenia and granulocytopenia are aggravated by chemotherapy.

Bleeding prevention

In general, platelet transfusions should be given in response to bleeding episodes and to prevent bleeding when platelet counts fall below $20\,000 \times 10^6/L$, especially during febrile periods. Most often, daily platelets are given until bleeding ceases. HLA-matched platelets are given to patients who become refractory to random donor platelets. The incidence of fatal hemorrhage during induction therapy has been significantly lowered by these measures.

Infection prophylaxis

resulted not only in improved response rates of malignancies but also in higher infection-associated morbidity and mortality.⁹ Long-term neutropenia is the most important risk factor, but CD4 lymphopenia, antibody deficiency, and multiple immunosuppression in allogeneic stem cell transplantation also lead to severe and lethal infections. Whereas formerly gram-negative microorganisms were the leading cause of febrile neutropenia, in the last decade gram-positive bacterial infections, mostly caused by staphylococci, have increased and are frequently correlated to indwelling central venous access. Invasive fungal infections are, however, the most dangerous development with an increasing frequency particularly of mold infections.¹⁰ The successful management of febrile neutropenia is based on hygienic procedures including body hygiene, germ-reduced food, reverse isolation or high-efficiency particulate air filtration, antibiotic prophylaxis, sufficient diagnostics, and consequent empirical antimicrobial therapy.

For antibacterial prophylaxis, sulfamethoxazole-trimethoprim or fluoroquinolones, both mainly directed against gram-negative organisms, have mostly been used.¹¹ Co-trimoxazole also reduces the incidence of *Pneumocystis carinii* pneumonia, which occurs in approximately 20% of ALL patients without prophylaxis.¹² Although antifungal prophylaxis with oral amphotericin B solution or triazoles may successfully reduce *Candida* colonization and prevent local *Candida* infections, the prophylactic procedures for reducing systemic mycoses are disappointing. Fluconazole has been reported to reduce only systemic *Candida albicans* infections in stem cell trans

plantation (SCT) patients, but *non-albicans* infections, especially by fluconazole-resistant *Candida krusei*, are emerging. Because of its high lethality and difficult diagnostic approval, *Aspergillus* infection is a particular problem. Attempts to prevent aspergilloses have included prophylaxis with itraconazole, intravenous low-dose amphotericin B, liposomal amphotericin B, and inhalation of aerosolized amphotericin B, but in randomized studies no clear benefit could be shown.¹³

In febrile neutropenia consequent and early diagnostic procedures are necessary. They include physical examination, microbiological investigations, imaging procedures and biopsies. Cultures of blood, urine, sputum, and other infected areas are mandatory. *Aspergillus* galactomannan antigen test (Platelia) may be advantageous in supporting diagnostic efforts in suspected aspergillosis. Furthermore PCR methods are investigated for early detection of fungal infections.¹⁴ Imaging procedures such as chest X-ray or abdominal ultrasound are routine diagnostic tools. High-resolution computed tomography of the lungs is one of the most important diagnostic steps for the early diagnosis of *Aspergillus* pneumonia. Fungal pneumonias also may be microbiologically proven with bronchoalveolar lavage or biopsy.

Successful treatment of febrile neutropenia is based on immediate empirical administration of broadspectrum antibiotics. As initial therapy, combinations such as β -lactam antibiotics plus aminoglycosides or monotherapy (e.g. with carbapenems, piperacillin/tazobactam or cephalosporins of class 3 and 3a) are actual standard.¹⁵ Considering the increasing problems of invasive fungal infections, empiric antimycotic treatment with amphotericin B or fluconazole for patients with refractory fever or pulmonary infiltration has been established.¹⁵ So far, conventional amphotericin B, amphotericin lipid formulations, 5-flucytosine, fluconazole and itraconazole represented antimycotic standard treatment in proven or suspected invasive mycoses. This standard, however, is now changing by introduction of highly potent new antimycotics such as voriconazole (effective in the treatment particularly of aspergillosis, but also of fluconazole-resistant candidosis or fusariosis) and caspofungin (successful treatment for candidoses and aspergilloses).¹⁶

Hematopoietic growth factors

The use of hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) is a valuable component of supportive therapy during the treatment of ALL. There is no indication that these CSFs stimulate leukemic cell growth in a clinically significant manner.

The majority of clinical trials have demonstrated that the prophylactic administration of G-CSF significantly accelerates neutrophil recovery,^{17–20} and several prospective randomized studies have also shown that this is associated with a substantially reduced incidence and duration of febrile neutropenia and of severe infections.^{19,20} The enhanced marrow recovery allows closer adherence to the dose and schedule of chemotherapeutic regimens. However, it still remains an open question whether the increased dose intensity translates into an improved leukemia-free survival (LFS).

The advantage of G-CSF administration is particularly evident in selected high-risk patients receiving multiple treatment cycles, whereas clinical effects appear to be negligible in patients at low risk of infectious complications. The scheduling of G-CSF is of great importance. It is noteworthy that G-CSF can be given in parallel with chemotherapy without aggravating the myelotoxicity of these specific regimens.^{20–22} Since patients with initial neutrophil count $<500/\mu\text{l}$ had an increased rate of severe infections in an ongoing German multicenter trial for adult ALL (GMALL), all patients with this feature receive G-CSF already on the first day of chemotherapy.

On the other hand, it was demonstrated that after short consolidation cycles G-CSF application may be postponed. Therefore, in the context of a regimen based on high-dose cytarabine/mitoxantrone, the G-CSF application could be postponed from day 12 to day 17 without negative effects on duration of neutropenia.²³ Similar results were reported for consolidation therapy with the hyper-CVAD (cyclophosphamide, vincristine, Adriamycin [doxorubicin], dexamethasone) regimen.²⁴

See also Chapter 20 on the use of hematopoietic growth factors.

Chemotherapy

The chemotherapy of ALL is generally divided into several phases, beginning with remission induction. The objective of induction chemotherapy is to achieve complete remission (CR), that is, eradication of leukemia as determined by morphological criteria and recently also by molecular markers. Whereas the induction phase of therapy is usually well defined, postremission therapy can be subdivided into intensification/consolidation and maintenance phases. Usually a prophylactic treatment of the CNS is added (Table 32.4).

Remission induction therapy

Exact diagnosis and management of initial complications are the prerequisites for successful induction therapy. A cautious cell reduction phase is recommended for patients with a large leukemic tumor

mass and/or a high leukocyte count ($>30\,000 \times 10^6/L$). Patients with extreme leukocytosis ($>100\,000 \times 10^6/L$) have been treated initially with leukapheresis. However, these patients can also be managed with vincristine and prednisone in nearly all cases without complications. For mature-B-ALL, initial treatment with cyclophosphamide and prednisone for one week usually results in safe reduction of large tumor masses.²⁵

Standard induction therapy for ALL in most studies consists of vincristine, prednisone, asparaginase and an anthracycline. Prednisone and prednisolone have been most frequently administered, although dexamethasone shows a higher antileukemic activity in vitro and a better penetration to the cerebrospinal fluid.²⁶ The addition of the anthracyclines daunorubicin or doxorubicin (Adriamycin) results in a CR rate of 80–85%. Whereas formerly daunorubicin was mostly administered at a weekly schedule, recently many trials include dose intensification with doses of 30 to 60 mg/m² at a 2–3 day schedule.^{22,27,28}

Asparaginase does not affect the CR rate, but probably improves LFS and if not used during induction therapy it is often included as part of the consolidation treatment. Evidence comes from pediatric studies where the addition of asparaginase to vincristine and prednisone has led to improved CR rates in relapsed ALL patients. Leukemia-free survival has also been improved by the administration of post-induction doses of asparaginase. The addition of asparaginase to conventional induction therapy did not improve the CR rate in one trial in adult ALL, but there was a trend towards a higher LFS.²⁹ Three different asparaginase preparations with significantly different half-lives are available: Native *Escherichia coli* (1.2 days), *Erwinia* (0.65 days) and PEG-*E. coli* (5.7 days).³⁰ The availability may vary between different countries. In order to reach equal efficacy the application schedule has to be adapted according to half-life.

The next step in improving induction therapy was the addition of cyclophosphamide and cytosine arabinoside (AC, cytarabine). This does not raise the overall CR rate, but possibly improves the remission quality. Cyclophosphamide and cytarabine therapy is particularly useful as initial treatment for special ALL subgroups such as T-ALL. A randomized study by the Italian GIMEMA group comparing a three drug induction with and without cyclophosphamide did not show a difference in terms of CR rate (81% vs. 82%).³¹ However, in several non-randomized trials, high CR rates (85–91%) were achieved with regimens including cyclophosphamide pretreatment,^{22,32} particularly in adult T-ALL.³³

High-dose treatment

Another strategy is to add high-dose cytarabine (HDAC; 1–3 g/m², usually for 12 doses) before or after the standard induction therapy. This approach has resulted in a median CR rate of 79%, which is not superior to that obtained with conventional treatment, and it remains uncertain whether and for which subgroups it may be beneficial for LFS.⁵³ Up-front application before conventional chemotherapy yielded higher CR rates^{27,40,54–56} than application after induction therapy,^{32,41,57} which was in part related to a higher induction mortality. Furthermore, any type of induction therapy with HDAC may lead to an increased incidence of severe neutropenia after subsequent chemotherapy cycles (Table 32.5). So far there are no data demonstrating that LFS can be improved by the use of HDAC during induction.

In conclusion, all approaches for induction therapy including high dose treatment—result in a CR rate of approximately 80% in adult ALL. However the molecular CR rate is clearly lower (see chapter on MRD) and the addition of new therapeutic approaches other than chemotherapy—such as molecular targeting or antibody treatment may be the future approach to increase the molecular CR rate.

Failure during induction therapy or refractory ALL

Between 15% and 20% of adult ALL patients will not achieve CR after induction therapy, in contrast to fewer than 5% of children with ALL. Less than 10% of adult ALL patients die during the induction period. Mortality during induction is age-dependent, increasing with age from less than 3% in adolescents to 20% in patients over 60 years of age. The main cause of death is infection, particularly fungal infection. The remaining nonresponders may achieve a partial remission or may be refractory to standard treatment. The number of patients (approximately 10%) who are refractory to chemotherapy is steadily decreasing with the use of more intensive induction regimens, which do, however, lead more frequently to aplasia or toxic death. This stresses the need for optimal supportive treatment. All patients who are refractory to induction therapy are candidates for stem cell transplantation whenever possible.

Intensification therapy

Consolidation therapy refers to high-dose chemotherapy, to the use of new agents or to readministration of the induction regimen. These measures are aimed at eliminating clinically undetectable residual leukemia after induction chemotherapy, and thereby preventing relapse as well as the emergence of drug-resistant cells.

Intensification schedules include teniposide, etoposide, m-amsacrine, mitoxantrone, idarubicin and HDAC, and intermediate- or high-dose methotrexate. There is evidence that intensification therapy can prolong LFS in adult ALL (Table 32.5).

Randomized trials have failed to demonstrate a clear advantage of any particular consolidation regimen. In two earlier studies by the Italian GIMEMA group, focusing on the impact of intensified versus conventional maintenance treatment, no advantage could be demonstrated for the intensified regimen.^{31,47} In a Cancer and Leukemia Group B study using consolidation courses of AML-like therapy with daunorubicin and cytarabine in addition to 6-mercaptopurine and methotrexate, the outcome was not superior to conventional maintenance alone.³⁷ Also in a GIMEMA study an AML-like regimen yielded no benefit. In a randomized trial by the British Medical Research Council (MRC), however, there was a reduction in the risk of relapse in patients receiving early and/or late intensification.⁵¹ Additional evidence for the value of intensification therapy comes from childhood ALL studies.

High-dose chemotherapy

High-dose chemotherapy in consolidation has been used mainly to overcome drug resistance or to achieve therapeutic drug levels in the cerebrospinal fluid.

High-dose cytarabine (HDAC): Although there is wide experience with HDAC for the treatment of ALL,^{53,59,60} it still remains uncertain what dose is optimal and if there is actually a benefit. Usually doses ranging from 1 to 3 g/m² every 12 hours for 4–5 days are given within combinations. It has been included in several trials in adult de novo ALL as part of consolidation therapy^{48,57,61,62} or during induction and consolidation treatment^{32,56}. With a weighted mean for the LFS of 30% (26–50%), the results are not superior to trials without HDAC.

It is possible that specific subgroups of ALL may profit from HDAC treatment; thus excellent results are achieved for pediatric B-ALL with LFS of greater than 80%,⁶³ for adult mature B-ALL,⁶⁴ and apparently for adult pro-B-ALL with LFS of 50–60%.⁶⁵ For other adult poor-risk groups such as late responders, Ph⁺ ALL or pre-T-ALL, the value of HDAC was not demonstrated.

High-dose methotrexate (HDM): The use of HDM has been extensively studied for the treatment of childhood ALL and, to a lesser extent, adult ALL.⁶⁶ A wide range of doses (0.5–8 g/m²) has been used. HDM appears to be effective in preventing systemic and testicular relapses in childhood ALL.⁶⁷ The effect of HDM on CNS leukemia may contribute to the favorable results

reported with its use. Overall the intensive use of HDM may have had a major role in improvement of outcome in pediatric B-ALL. Several studies have investigated the efficacy of HDM in adult ALL—as consolidation^{68–70} or during consolidation and induction treatment.^{38,71} The weighted mean for LFS of six studies, which also comprised a variety of other drugs, is 41%, with a wide range (31–56%). Most favorable results have been achieved in small trials with HDM as part of intensive multidrug consolidation regimens. **HDAC together with HDM:** The combination of cycles having HDAC with cycles having HDM during consolidation was reported from six trials with a weighted mean for LFS of 32% (17–48%).^{31,32,39,47,72} Therefore, there is some evidence that the inclusion of HDAC and HDM as part of multidrug consolidation treatment may improve overall results.

Maintenance therapy

The optimal duration and form of maintenance therapy in adult ALL is unknown. Because the aim of maintenance or continuation therapy is to eliminate minimal residual disease (MRD), the optimal form of maintenance therapy may be identified with reliable methods for the detection of MRD (see Chapter 32). Standard maintenance is based on combination treatment with 6-mercaptopurine and methotrexate. The potential effects of further intensification cycles for specific subgroups of ALL remain open. In a large Italian multicenter study (GIMEMA 0183), the randomized comparison of intensive and conventional maintenance showed no difference.⁴⁷ However, attempts to omit maintenance altogether after induction and consolidation therapy have resulted in inferior results.^{38,48,49,73} There is a need for prospective trials with maintenance schedules adapted to immunological subtypes of ALL (e.g. longer for common ALL, shorter for T-ALL, and none for B-ALL) and particularly adapted to MRD.

Prophylaxis of central nervous system leukemia

Adult ALL patients without initial CNS involvement who do not receive specific prophylactic CNS treatment had a CNS relapse rate of 30% (29–32%) in early studies. Thus treatment and prophylaxis of CNS leukemia is an important part of ALL treatment. Several options are available: intrathecal methotrexate alone or in combination with cytarabine or prednisone/dexamethasone, cranial irradiation, or systemic treatment with HDAC or HDM (reviewed in ⁷⁴). Rarely, CNS directed therapy is administered as intraventricular therapy in adult ALL.

With intrathecal chemotherapy alone, the rate of isolated and combined CNS relapses could be reduced to 13% (8–19%). In many adult ALL trials, additional prophylactic CNS irradiation (24 Gy) has been included. This combined approach further reduces the CNS relapse rate to 9% (3–19%). It is questionable whether systemic high-dose treatment alone provides sufficient CNS prophylaxis, since the CNS relapse rate is about 14% (10–16%). For high-dose chemotherapy together with intrathecal therapy, the rate of CNS relapses was 7% (2–16%); with additional CNS irradiation, it was 6% (1–13%). Therefore, the combination of several CNS-active measures is preferable. This is also evident from a retrospective analysis from the MD Anderson Cancer Center, where the lowest CNS relapse rate (2%) was achieved in a recent trial with early high-dose chemotherapy and intrathecal therapy but without CNS irradiation for all patients.³⁵

Prophylactic treatment of the CNS may result in acute or chronic neurotoxicity. Adverse effects include febrile reactions, arachnoiditis, leukoencephalopathy, and subclinical dysfunctions, including learning disabilities. In adult ALL patients chemical meningitis after intrathecal therapy (e.g. indicated by headache) occurs often and may even lead to reduction of the planned schedule.

Therapy for relapsed and resistant leukemia

Patients who fail to achieve CR or those who relapse subsequently have been treated with a variety of protocols (summarized in ⁷⁵ and ⁷⁶). The repetition of regimens including vincristine, anthracyclines and steroids similar to standard induction treatment in earlier studies led to CR rates of 61%. This is a reasonable approach particularly in patients with preceding remission duration of more than 18 months.⁷⁷

In patients with a first remission duration below 18 months the CR rate is clearly below 50%, again with a wide variation that may be attributed to patient selection and non-uniform intensity of pretreatment. Therefore, new combinations with idarubicin (46–64% CR rate) or fludarabine (67–83% CR rate) have been evaluated. Other new approaches, such as antibody therapy, Imatinib in Ph/BCR-ABL positive ALL or new cytostatic drugs such as Nelarabine in T-ALL, are currently under investigation and may lead to better CR rates in relapsed ALL.

For all chemotherapy regimens, the duration of second remission is usually short (<6 months), and longterm survival with chemotherapy alone is less than 5%. Consequently, the only curative chance for adult patients with relapsed or resistant ALL is SCT. The major aim of relapse treatment is the induction of a second CR or good partial remission and to proceed immediately to a SCT.

Stem cell transplantation

Stem cell transplantation (SCT) from peripheral blood and, to a lesser extent, from bone marrow is the major postremission strategy for eradication of residual disease in adult ALL and can replace consolidation/maintenance treatment (reviewed in references ⁷⁸ and ⁷⁹). Prognostic factors for remission duration after chemotherapy (i.e. age, WBC count, immunophenotype, BCR-ABL status) are also predictive for the outcome after SCT.

Allogeneic SCT from sibling donors

In a total of 1100 adult patients in first CR, LFS after allogeneic SCT was 50%, with an RI of 24% and a TRM of 27% (Table 32.6). In the International and European bone marrow transplant registries (IBMTR and EBMT), a substantial number of adult ALL patients has been collected. Among recipients of HLA-identical sibling transplants in first remission, reported to the IBMTR between 1994 and 1999, the survival after 3 years was 61% for 561 patients <20 years of age and 48% for 909 patients >20 years of age.⁸¹ Age is a risk factor for TRM and RI, which were 28% and 29% respectively in patients below 40 years compared with 37% TRM and 38% RI in older ones.⁸² Relapse incidence is reduced in patients with limited graft-versus-host disease (GvHD) compared with those without GvHD or with extensive GvHD, probably owing to a graft-versus-leukemia (GvL) effect resulting in a better LFS in the former patients.

After allogeneic SCT beyond first CR or relapsed/refractory ALL, LFS is 34% and 20% respectively (Table 32.6). The RI of 47% and 71% is still high.

Matched unrelated SCT

Only one-third of potential SCT candidates with ALL will have an HLA-identical sibling donor. To extend the possibilities of allogeneic SCT by enlarging the number of potential donors, matched SCT from unrelated donors (MUD) and to a smaller extent mismatched SCT from related donors (MM) is increasingly being employed. The lower relapse rate with both approaches is probably due to the more pronounced GvL reaction, which is, however, outweighed by the high TRM of approximately 40%.^{80,83} Matched SCT from unrelated donors can result in long-term survival of about 39% for patients transplanted in first CR and 27% for patients in CR2 (Table 32.6). Among 223 patients >20 years of age who received unrelated donor transplants for ALL in first remission reported to the IBMTR, the probability of survival after 3 years was 40%.⁸¹

This might be increased by improved donor selection, less toxic preparative regimens, better management of GvHD and improved supportive care. Overall the results of MUD SCT in ALL seem encouraging. MUD SCT is the treatment of choice for high-risk patients in CR1 if a sibling donor is not available. For patients with Ph/BCR-ABL positive ALL the results of MUD SCT are already approaching those of sibling SCT. Mismatched or haploidentical SCT in adult ALL is still experimental and an option only for rare cases; it is explored by few very experienced SCT centers.

Abbreviations: LFS, leukemia-free survival; MUD, matched unrelated donor; NMSCT, nonmyeloablative SCT; OS, overall survival; Rel, relapsed; refr, refractory; TRM, transplant related mortality

Autologous SCT

Autologous SCT is a readily available alternative, and can be performed in patients up to 65 years of age owing to its low TRM (2–8%) (Table 32.6). The major disadvantage is the high relapse rate (51%), probably caused to some extent by the reinfusion of leukemic blasts but more by the lack of GvL effects. Purging of the marrow graft with chemotherapeutic agents (e.g. mafosfamide) or monoclonal antibodies may reduce the leukemia cell burden. Thus purging with immunomagnetic beads can reduce tumor load by 2 log in Ph/BCR-ABL positive ALL.⁸⁴ Purging is how-ever not routinely used.

The LFS of 42% for autologous SCT in first remission is inferior to that for allogeneic SCT, although it may be better than chemotherapy. In advanced stages, the results are again inferior (24% LFS) to those of allo-geneic SCT, but still superior to chemotherapy (Table 32.6).
 with 6-mercaptopurine/methotrexate) after autolo- The administration of maintenance treatment (e.g. gous SCT may contribute to a reduction in RI.⁸⁵ Collection of peripheral blood stem cells is now the major stem cell source for autologous SCT and bone marrow is only used if mobilization fails.

Nonmyeloablative SCT

Nonmyeloablative SCT (NMSCT) or reduced inten-sity conditioning regimens is a new approach, which deserves evaluation in ALL and may lead to an exten-sion of indications for allogeneic SCT. In contrast to conventional SCT, which mainly relies on cell kill by high-dose chemotherapy and total body irradiation (TBI), NMSCT aims at the utilization of GvL effects. Immunosuppression (e.g., with purine analogs, other cytostatic drugs and/or low-dose TBI) is followed by the infusion of donor stem cells from siblings or MUD with adapted immunosuppression to establish host tolerance.⁸⁶

So far, in more than 100 adult ALL patients with high median age and poor prognostic features the probabil-ities for survival after NMSCT was around 23% with relapse rate of 47% and TRM of 42%⁸⁷ (Table 32.6). Overall, it seemed to be of some benefit in patients in CR1.^{88,89} In patients with advanced refractory or relapsed ALL due to a high TRM rate, this form of SCT is at present not successful.

Indications for SCT in first complete remission

The overall LFS of 50% after allogeneic SCT is supe-rior to that obtained with chemotherapy alone and also to that of autologous SCT.^{45,90,91} Several study groups failed, however, to demonstrate a significant advantage in terms of overall survival for allogeneic or autologous SCT in first CR compared with chemotherapy.^{42,92–95} As autologous SCT seems to pro-duce similar results to chemotherapy, the argument that autologous SCT requires a shorter duration of treatment compared with chemotherapy may be made.

In high-risk patients, however, LFS and overall sur-vival was superior after allogeneic SCT (39%) com-pared with the control group including autologous SCT and chemotherapy patients (14%).⁹⁶

Therefore, at present it appears advisable that lowrisk patients having an LFS of about 50% after chemotherapy should receive a SCT only after relapse. For high-risk adult ALL patients, allogeneic SCT in first CR is advisable. In very high-risk cases (such as Ph/BCR-ABL positive ALL) without a com-patible family donor, MUD SCT is recommended in younger patients. Older patients should receive autol-ogous SCT or NMSCT.

Prognostic factors

The major risk factor for attaining a CR is advanced age and Ph⁺ ALL. Prognostic factors are of greater importance for duration of remission and survival (Tables 32.7 and 32.8).

MRD, minimal residual disease

Age

There is a continuous decline in CR rate from 95% in children to 40–60% in patients over 50–60 years of age.⁹⁹ Most trials demonstrate that increasing age is also associated with shorter remission duration and survival and that LFS is inferior in patients over 50–60 years.

Immunophenotype, cytogenetics, and molecular genetics

The immunophenotype is an independent prognostic variable in ALL, despite the fact that with modern treatment strategies the previously poor prognosis of phenotypes such as T-ALL and mature B-ALL has been changed. In ongoing recent trials, there is a tendency to use the immunophenotype to adjust treatment regimens accordingly (e.g. for mature B-ALL).

T-lineage ALL

Results for T-ALL have recently improved, with CR rates of greater than 80% and LFS of 46% compared with earlier results with remission duration of less than 10 months and survival rates below 10%. The addition of cyclophosphamide and cytarabine to the usual cytostatic drugs for ALL is mainly responsible for this improvement.^{33,100} There is, however, a substantial difference in outcome for the T-ALL subtypes. Thymic T-ALL, which accounts for half of the adult T-ALL patients, has a favorable outcome with CR rates of 85–90% and survival >50% at 5 years. Early T-ALL and mature T-ALL have a poorer outcome with CR rates of 70% and LFS rates of approximately 30%.¹⁰¹

High-dose methotrexate (HDM) contributed to the improvement of survival in children with T-ALL,^{102,103} as did HDAC,¹⁰⁴ which improved the prognosis for adult ALL patients with high WBC counts and T-cell ALL.^{104,105} For adults, the benefit of HDM in T-ALL has to be confirmed in larger trials. New treatment approaches in adult T-ALL include purine analogs such as cladribine and compound GW506U78 (Nelarabine)^{106,107} or antibody therapy such as antiCD52. Also SCT for early/mature T-ALL patients in CR 1 seems promising.¹⁰⁸

B-lineage ALL

In *common and pre-B-ALL*, CR rates in adult trials have improved to 80% or more, but patients still relapse in most studies over a period of up to 5–6 years, and only one-third survive. This may in part be explained by the fact that approximately 30% of adult patients with common/pre-B-ALL are Ph/BCR-ABL positive and their prognosis remains poor. But the results are also not encouraging for adult patients with Ph-negative common/pre-B-ALL. Higher doses of anthracyclines given in induction and reaching a certain cumulative amount may be beneficial.¹⁰⁹ The outcome for patients with *pre-B-ALL* seems to be similar to that for common ALL.

Within common/pre-B-ALL prognostic factors are decisive for outcome; high-risk patients with adverse prognostic features such as high WBC (>30000/ μ l) and/or late achievement of CR (>3–4 weeks) (Table 32.8) have a survival of 25% or less whereas standard risk without any of those features have a 5-year survival of >50%.¹¹⁰

Ph/BCR-ABL⁺ ALL (Ph⁺ ALL) as a subtype of common/pre-B-ALL has the worst prognosis in children as well as in adults. In 13 studies with a total of 384 patients, the mean CR rate is 67% (44–76%). The median remission duration in all series is short (5–11 months), and the survival, from 0% to 20% at 3–5 years, is extremely poor in all reports. The only curative chance for adult Ph⁺ ALL patients is SCT—including allogeneic sibling and matched unrelated SCT. The introduction of the ABL-tyrosine kinase inhibitor Imanitib (formerly STI571) leads to a promising new treatment modality for Ph⁺ ALL.

Adults with the subtype *pro-B-ALL* or the t(4; 11) translocation, which nearly exclusively occurs in this subgroup, had a poor prognosis, as did infant ALL patients.¹¹¹ With intensive regimens including HDAC and mitoxantrone as consolidation therapy, the results for adults seem to improve.⁶⁵ Pro-B-ALL patients have also a benefit from allogeneic SCT in CR1 with survival rates of 60%,¹¹² as well as from autologous SCT.

A decade ago, CR rates for adults with *mature B-ALL* were low (<50%), and remission duration and

survival were short (11 months). A change was brought about by innovative childhood B-ALL studies, which significantly improved outcome, with CR rates of 80–94% and LFS of 63% (weighted mean). The most important drugs for this improvement are apparently high doses of fractionated cyclophosphamide or ifosfamide, HDM (0.5–8 g/m²) and HDAC, in conjunction with the conventional drugs for remission induction in ALL, given in short cycles at frequent intervals over 6 months. The application of these childhood B-ALL protocols in original or modified form also brought about a substantial improvement for adult patients with B-ALL. Complete remission rate is now approximately 75% (62–83%) and the LFS 55% (20–71%).^{25,64,113}

B-cell ALL has a higher incidence of CNS involvement at diagnosis and of CNS relapse. Therefore, effective measures against CNS disease, such as HDM and HDAC as well as intrathecal therapy, are important components of treatment regimens. On the other hand, maintenance treatment has been omitted. Because relapses occur almost exclusively within the first year in childhood as well as in adult B-cell ALL studies, patients thereafter can be considered as cured.

Recent treatment protocols include antibody therapy with anti-CD20 (rituximab), since more than 80% of the patients are CD20⁺, with quite promising preliminary results.^{60,114,115}

In mature B-ALL, because of too small patient cohorts it is difficult to extract significant prognostic factors, but older age (>50 years), high WBC (>30000/μl), bone lesions, and mediastinal involvement are associated with inferior outcome.

Other prognostic factors

Chromosomal abnormalities correlate markedly with outcome in ALL, independently of other features. Hypodiploidy and translocations, particularly t(9;22) Ph⁺, are unfavorable findings in adults. The prognostic impact of cytogenetic aberrations may, however, differ between protocols since it depends on the applied treatment. This is evident for the t(4;11) translocation, a formerly extremely unfavorable group, which has now an improved outcome in some protocols. The translocations t(8;14), t(2;8) and t(8;22) are present in most cases of mature B-ALL and in Burkitt lymphoma and have lost their poor prognostic impact owing to the improved treatment for patients with B-ALL or Burkitt lymphoma.

Extensive organ involvement at presentation (e.g. hepatomegaly, splenomegaly, CNS leukemia and mediastinal involvement) has been found in some studies to have an adverse influence on remission duration. CNS leukemia is considered an adverse prognostic factor in some reports. However, in other studies, the LFS for patients with initial CNS involvement was not inferior. Mediastinal mass, although indicative of a large tumor burden, had no adverse influence on either CR rate or remission duration in several adult ALL series. Most ALL patients with mediastinal tumors have the T-ALL subtype, so that any adverse influence of mediastinal mass is probably outweighed by the recent improvement in treatment of T-ALL.

Future directions

Minimal residual disease

Recent advances in molecular and immunological techniques have allowed the detection of minimal residual disease (MRD), defined as leukemic cells undetectable by morphological examination (see Chapter 17). The most relevant methods for ALL are flow cytometry and PCR analysis, with sensitivities ranging between 10⁻⁴ and 10⁻⁶ (summarized in references^{116–118}). Flow cytometry allows the detection of characteristic constellations of two or more cell-surface antigens. PCR methods—and nowadays real-time PCR—are directed towards the detection of fusion proteins resulting from specific translocations (e.g. BCR-ABL, E2A-PBX1, MLL-AF4 and TEL-AML1). These are present in 20–30% of adult ALL patients. In addition, PCR methods target clonal rearrangements of immunoglobulin chain genes (IgH, IgK) or T-cell receptor genes (TCR-β, -δ, -λ, -γ). IgH rearrangements can be detected in 96% and 20% of B- and T-lineage ALL patients respectively. The frequency of detectable TCR rearrangements is 36–57% and 25–93% respectively.¹¹⁹ A prerequisite is the identification of individual rearrangements at the time of diagnosis in each patient, which is possible in more than 90% of ALL patients with combinations of two or three targets.

Clinical MRD studies in childhood ALL (reviewed in^{116–118}), mostly evaluating MRD by PCR analysis, have shown a widespread pattern. A considerable proportion of patients have detectable MRD after induction treatment, despite morphological CR. This only partly limits the predictive value of MRD evaluation, since the quantitative amount of MRD is correlated with relapse risk. Patients with MRD above the threshold of 10⁻³–10⁻⁴ have a significantly lower LFS compared with those below. Not all patients with positive MRD, however, eventually relapse, and so the kinetics of MRD are apparently another prognostic parameter. The continuous decrease of MRD or very low levels are associated with a low relapse risk. Thus, in patients remaining in continuous CR, the incidence of MRD positivity decreased from initially 36% to 10% after more than 24 months (Table 32.9). On the other hand, in patients with final relapse, the proportion of positive MRD results remained consistently high (78%) during month 1 to 24 of therapy.

Table 32.9 Kinetics of MRD detection and outcome in adult and childhood ALL

Studies	Patient outcome after CR	Time after complete remission (months)					
		1–6		7–24		>24	
<i>N</i>		<i>N</i> ¹	MRD ⁺²	<i>N</i> ¹	MRD ⁺²	<i>N</i> ¹	MRD ⁺²
20	CCR	343	36%	260	18%	257	10%
10	Relapse	140	78%	51	78%	72	58%

¹ Number of patients analyzed for MRD
² Percentage of patients with positive MRD status

In adult ALL, the results in childhood ALL were overall confirmed—but with some specific differences.¹²⁰ A very good response as indicated by an early and rapid decrease of MRD already during induction may be associated with a very low relapse risk.¹²¹ However, in general the decrease of MRD occurs more slowly in adults and fewer patients reach a negative MRD status. This applies particularly for patients with low MRD immediately after induction, who still show a considerable relapse rate of approximately 50%.^{122–124} Thus the longitudinal course of MRD may be more important in adults compared with children. High MRD at any time-point after induction is associated with a higher relapse risk,^{125–126} and the predictive value increases at later time-points (months 6–9).¹²⁷

The predictive value of MRD evaluation depends on the technical quality, such as sensitivity or number of target genes, and on the frequency of evaluations in individual patients. In a retrospective study of the GMALL a broad spectrum of target genes (IgH, IgK, and TCR rearrangements) was measured quantitatively with high sensitivity ($<10^{-4}$).¹²⁸ Based on these results MRD-based risk groups could be defined¹²⁹ for the ongoing GMALL study.

There is a need for larger prospective studies to evaluate the potential of MRD determination and to justify therapeutic decisions based on MRD detection. Such decisions could be various: the redefinition of CR in patients who are in morphological CR but with detectable MRD, or the evaluation of the effectiveness of specific treatment elements (e.g. MRD evaluation before and after high-dose cycles or bone marrow purging chemotherapy, antibody treatment, molecular therapy, SCT).^{120,129} Furthermore, in patients with repeatedly negative MRD, treatment could be stopped earlier, whereas in those with high levels or continuously positive MRD, alternative treatment approaches such as SCT could be considered. Thus in the ongoing GMALL study in patients with low risk according to MRD treatment is stopped after 1 year, whereas in MRD high-risk patients intensification with SCT or experimental treatment is intended. It is unclear at present how to proceed with MRD intermediate-risk patients, who cannot be allocated to either group and form a rather large patient cohort.¹³⁰

Treatment with monoclonal antibodies

Targeted therapy with monoclonal antibodies (MoAbs) is a new treatment option in adult ALL. Acute lymphocytic leukemia blasts express a variety of specific antigens—such as CD19, CD20, and cyCD22 for B-lineage ALL; or CD25, CD7, CD3 for T-lineage ALL and CD5 2 or CD3 3 for both—which may serve as targets for treatment with monoclonal antibodies (MoAbs). The presence of the target antigen on at least 20–30% of the blast cells is generally considered as a prerequisite for MoAb therapy. First results with the combination of chemotherapy and rituximab are promising in mature B-ALL. Other MoAbs such as anti-CD52 (Campath-1H), B43(Anti-CD19)-Genistein, B43(Anti-CD19)-PAP; Anti-B4-bR (Anti-CD19) in B-Lineage ALL and Anti-CD7-Ricin in T-lineage ALL have been investigated in phase I-II pilot trials in ALL.¹³¹

Anti-CD20

The inclusion of rituximab, which is a chimeric MoAb to CD20 lead to an improvement of results in B-cell non-Hodgkin lymphoma (NHL). CD20, defined as expression on more than 20% of the blast cells is, however, also present on one-third of B-precursor ALL blasts, particularly in elderly patients (40–50%), and the majority of mature B-ALL blast cells (80–90%). This provides a rationale to explore rituximab in B-precursor ALL, mature B-ALL and Burkitt lymphoma. Favorable results were observed in two trials where rituximab was used in combination with intensive chemotherapy. Nineteen patients with newly diagnosed Burkitt NHL or mature B-ALL received anti-CD20 together with the hyper-CVAD regimen for a total of 8 doses. Eighty-nine percent complete responses (CR) were observed.¹³² In a GMALL study with 53 patients (mature B-ALL, Burkitt and other high-grade NHL) the remission rate was 91% in mature B-ALL and in Burkitt NHL a

response rate of 96% (PR, CR) was achieved after 2 cycles.¹¹⁵ The interim results indicate that there was apparently no additional toxicity compared with the previous protocol with chemotherapy only. The GMALL study group has recently started prospective trials with a combination of anti-CD20 and chemotherapy for patients with B-precursor ALL.

Anti-CD52

The CD52 antigen is expressed in most lymphatic cells and to a higher degree in T-lymphoblasts compared with B-lymphoblasts. CD52 antibodies were first used for ex-vivo T-cell depletion of allogeneic bone marrow grafts in order to prevent GvHD. The humanized antibody Campath-1H showed antitumor activity in chronic lymphocytic leukemia, T-cell prolymphocytic leukemia and other T-NHL. In ALL only case reports are available. Nevertheless several studies with Campath-1H in ALL are ongoing, for those in relapse (also in combination with chemotherapy), in status of positive MRD, or even in de novo ALL as consolidation treatment.

ABL tyrosine kinase inhibitors in Ph/BCR-ABL positive ALL

In Ph/BCR-ABL positive (Ph⁺) leukemia the *BCR-ABL* fusion gene is causally involved in leukemogenesis and is considered to be essential for leukemic transformation. With an inhibitor of the ABL tyrosine kinase (STI571, Imatinib) cellular proliferation of BCR-ABL⁺ CML and ALL cells can be inhibited selectively.¹³³

Clinical experience with Imatinib in advanced Ph⁺ ALL

First studies in relapsed or refractory Ph⁺ ALL patients yielded a hematologic response rate of 60% and a CR rate of 19% with an Imatinib monotherapy at a daily dose of 600 mg orally. Rapid blast cell clearance occurred within 1 week of treatment in the majority of patients, but this PB response did not necessarily correspond with a bone marrow response. The median time to progression was short for ALL patients (2 months).¹³⁴ Hematologic toxicity of grades III and IV was frequent, but was rarely associated with serious infectious or hemorrhagic complications. Non-hematologic toxicity attributed to Imatinib consisted primarily of mild-to-moderate gastrointestinal discomfort, peripheral and facial edema, and muscle cramps, and was readily manageable. Thus Imatinib was well tolerated even in heavily pretreated patients. One important issue is probably that, owing to a low penetration to the CSF, prophylaxis of CNS relapse should be given in parallel to Imatinib therapy.¹³⁵

Imatinib and allogeneic stem cell transplantation in Ph⁺ ALL

The efficacy of Imatinib was also explored in patients with Ph⁺ ALL who relapsed after allogeneic SCT. The CR rate in 20 patients was 50%.¹³⁶ Donor cell chimerism increased to above 96% in both BM and PB within the first 4 weeks of Imatinib in responding patients, indicating a selective expansion of Phdonor cells over the leukemic clone. Disease-free survival after 2 years is approximately 20% and overall survival 40%, due to subsequent salvage therapy.¹³⁷ Therefore, Imatinib as a single agent induces remissions in a substantial proportion of patients relapsing after allogeneic SCT and, in a few cases, even molecular remission can be achieved.

Current concepts for Imatinib treatment in de novo Ph⁺ ALL

As a consequence of the results in relapsed/refractory ALL, Imatinib has now entered trials in de novo ALL. Imatinib was given for 4 weeks after induction therapy in de novo Ph⁺ ALL with CR. The BCR-ABL level after induction therapy decreased by more than 0.5 log in half of the cases, remained unchanged or increased in 40%, and approximately 10% of the patients achieved a molecular CR. In a subsequent study, Imatinib was given in parallel with the second phase of induction therapy.¹³⁸ Preliminary encouraging results of a combination regimen have also been shown by the group at MD Anderson. Patients with Ph⁺ ALL received Imatinib parallel to intensive chemotherapy (hyper-CVAD regimen) for several cycles without serious unexpected toxicity.¹³⁹ Imatinib as first line therapy in patients with newly diagnosed Ph⁺ ALL is also currently being tested by the GMALL Study Group in a randomized trial in elderly (≥55 years) patients with de novo Ph⁺ ALL. First results show that this combination is safe, that complete remissions can be achieved by a Imatinib monotherapy, and that the combination of Imatinib and chemotherapy is feasible.¹⁴⁰

33 Chronic lymphoid leukemias

Emili Montserrat

Introduction

Chronic lymphoid leukemias are lymphoproliferative disorders due to the proliferation of lymphoid cells arrested at a mature stage of their differentiation pathways. These diseases have in common the mature (peripheral) origin of the lymphoid cells from which they arise and that neoplastic cells, besides involving lymphoid tissues such as lymph nodes or spleen, are also present in bone marrow and peripheral blood.

Classification and diagnosis

Chronic lymphoid leukemias are classified as shown in Table 33.1. Morphology, immunophenotype, cytogenetics and molecular characteristics contribute to the classification of these diseases (Tables 33.2 and 33.3). The diagnosis is based on a careful review of peripheral blood films and immunophenotyping. Nevertheless, the histopathological study of lymph nodes, spleen and bone marrow, as well as any other tissue involved by the disease, can be essential for the diagnosis. Moreover, in some cases, cytogenetics and molecular biological studies contribute important information.

Chronic lymphocytic leukemia

Galton and Dameshek made, in 1966 and 1967 respectively, seminal descriptions of chronic lymphocytic leukemia (CLL), in which this disease was considered as being due to the progressive accumulation (rather than to an abnormal rapid proliferation) of immunoincompetent small lymphocytes.^{1,2} Since then, important progress has been made in the understanding of CLL, and different entities have been sorted out from what was formerly known as CLL.³⁻⁶ In the World Health Organization (WHO) classification, CLL is considered the leukemic counterpart of the small lymphocytic lymphoma.⁷

Table 33.1 Chronic lymphoid leukemias. Classification.

B-cell origin
Chronic lymphocytic leukemia
Prolymphocytic leukemia
Hairy-cell leukemia
● classical
● variant
Non-Hodgkin lymphoma with leukemic expression
● splenic lymphoma with villous lymphocytes
● follicular lymphomas
● lymphoplasmacytic/Valdenstrom's macroglobulinemia
● mantle-cell lymphoma
● others
T/NK-cell origin
Prolymphocytic leukemia
● classical
● small variant
Lymphoproliferative disease of granular lymphocytes
● T-cell type
● NK-cell type
Sezary syndrome
Adult T-cell leukemia/lymphoma
Peripheral T-cell lymphomas (others)

Epidemiology

The median age of patients at diagnosis is about 70 years.^{3,4} Chronic lymphocytic leukemia is rare in people under the age of 40. The overall incidence is about 5 cases per 100 000 people per year and increases with age,³⁻⁶ and it is the most frequent form of leukemia in Western countries, where it accounts for 30% of all leukemias. In contrast, CLL constitutes only 10% of all leukemias in Asian populations; this variation reflects real differences in the incidence of the disease among different races.⁸ In most series, CLL is more frequent in males than in females.³⁻⁶

Table 33.2 Immunophenotype, cytogenetic and molecular features of B-cell chronic lymphoid leukemias

Disease	Smlg	CD5	CD43	CD22	CD23	CD25	FMC7	CD103	CD11c	CD10	CD79b	Other features
CLL	-/+	+	+	-/+	+	+/-	-/+		-/+	-	-	+12/ del13q14, 6q-, 11q+, 14q+
Lymph	++	-/+	+/-	+	-	-/+	+	-	-/+	-	+/-	(Clg+, 100%), +12, 13q-, 14q+, 11q+, t(9;14), PAX-5

All express pan-B cell markers (e.g. CD19, CD20) and HLA-DR class II antigens.
 CLL=chronic lymphocytic leukemia; Lymph=lymphoplasmacytoid lymphoma/immunocytoma; PL=prolymphocytic leukemia; HCL=hairy-cell leukemia; SLVL=splenic lymphoma with villous lymphocytes; MCL=mantle-cell lymphoma; FL=follicular lymphoma; Clg=cytoplasmic immunoglobulin.

Table 33.3 Immunophenotypic, cytogenetic and molecular characteristics of T-cell and NK-cell chronic lymphoid leukemias

Disease	CD2 CD3 CD5	CD4	CD8	CD56 6	Cytogenetic and molecular features
T-PL	+++	++	-/+	-	inv(14), trisomy 8, t(14;14), TCL-1 (+), del(11q)/ATM gene TCR genes rearranged
Sézary	+++	++	-	-	TCR genes rearranged
CD3 ⁺ LDGL	CD3 ⁺ CD2 ⁺	-	++	-	TCR β gene rearranged
NK ⁺ LDGL	CD3 ⁻ CD2 ⁻	-	-	+	Germinal TCR genes
ATLL	+++	++	-/+	-	TCR genes rearranged, HTLV-I ⁺

T-PL: T-cell prolymphocytic leukemia; LDGL: lymphoproliferative disease of granular lymphocytes; ATLL: adult T-cell leukemia-lymphoma.

Etiology

The etiology of CLL is unknown. It is not associated with exposure to radiation or other cytotoxic agents.⁹ Familial cases of CLL support the existence of a genetic basis for this disease.¹⁰ An interesting observation is the so-called 'anticipation phenomenon' whereby, in younger members of the affected family, CLL presents, on average, 20 years earlier than in the older members.¹¹ In about 5% of first-degree relatives of patients with CLL, it is possible to demonstrate in peripheral blood a population immunophenotypically identical to that of CLL; the clinical significance of this observation is still unclear.¹²

Biology

The CD5⁺ B cells from which CLL arises constitute a small subpopulation of B lymphocytes with a characteristic immunophenotype that resembles that of lymphocytes normally present in the mantle zone of lymphoid follicles; these cells may also be found in the peripheral blood of a small proportion (2–3%) of normal subjects, a finding of uncertain clinical significance.¹³ Chronic lymphocytic leukemia results from the neoplastic transformation and accumulation of such B lymphocytes. The majority of these cells are arrested in the G₀ phase of the cell cycle. They also express large amounts of anti-apoptotic BCL2 proteins whereas the pro-apoptotic BCLX proteins are decreased. This, together with the interaction of neoplastic and stromal cells through a number of chemokines, leads to the accumulation of leukemic cells.^{3–6}

Immunophenotypically, the neoplastic lymphocytes from CLL express surface membrane immunoglobulin (SmIg), usually of IgM or both IgM and IgD types, in small amounts ('weak' SmIg expression), and a single Ig light chain (K or λ). They also express CD5, HLA-DR and B-cell antigens (e.g. CD19, CD20); in most cases they are CD23⁺ whereas CD22 and CD79b are infrequently or weakly expressed.

From the cytogenetic standpoint, in approximately 90% of the patients it is possible to demonstrate chromosomal abnormalities by fluorescent in-situ hybridization (FISH).^{14–17} The most frequent abnormalities are del(13q), del(11q), trisomy 12 and del(6q). Karyotypic evolution is observed in around 20% of the patients, usually in relation to disease progression.^{18,19}

No genes have been consistently associated with CLL. Putative oncogenes have been identified in the band 13q14.^{20,21} In cases of disease progression, del(11q), overexpression of the *c-myc* oncogene, deletions of the *Rbl* gene, and mutations of the p53 tumor-suppressor gene have been reported.^{18,19}

Chronic lymphocytic leukemia has long been considered a homogeneous disease of naïve CD5⁺ B cells, pre-germinal cells not exposed to antigenic stimulation. In 1999, two different groups made an important breakthrough in the understanding of CLL by showing that whereas in some cases IgV_H genes are unmutated in others IgV_H genes are mutated.^{22,23} As discussed later, these two forms have different clinical behavior. Since somatic mutation takes place in the germinal centre of lymphoid follicles, CLL can be either a tumor of pre-germinal-center B cells or a tumor of

post-germinal-center B cells. These two forms, however, share the same genetic signature as determined by microarrays and, because of this, CLL is considered to be a single disease with two variants (i.e. mutated, unmutated).²⁴

Clinical features

About 70% of CLL patients are diagnosed in an asymptomatic phase on the occasion of a routine medical examination. In symptomatic patients, the most frequent findings are generalized lymphadenopathy, fatigue, and weight loss. A history of repeated infections in the months preceding the diagnosis is not infrequent. Infections are primarily due to hypogammaglobulinemia. Most of the infections are caused by common bacteria such as *Streptococcus pneumoniae*, *Staphylococcus* and *Haemophilus influenzae*. Herpes zoster is also a common complication. The use of new treatment agents with a highly immunosuppressive effect has led to the observation of infections due to opportunistic organisms such as *Legionella pneumophila*, *Pneumocystis carinii*, *Listeria monocytogenes*, and cytomegalovirus (CMV). *Candida* and *Aspergillus* species are also of concern.^{25,26}

The infiltration of extralymphatic tissues (e.g. pleura, lung, skin, and the CNS) is extremely rare.^{27,28} In addition, vasculitis,²⁷ hypercalcemia,²⁹ and nephrotic syndrome³⁰ have occasionally been described. In rare cases (<1% of patients), spontaneous remissions may be observed at some time during the course of the disease.^{31,32}

Some cytogenetics abnormalities correlate with particular clinical features. Thus, del(11q) is particularly frequent in young males with bulky disease; trisomy 12 is commonly associated with atypical morphology of the lymphocytes in peripheral blood; del(6q) may be more common in cases with lymphoplasmacytoid cells; finally, del(17p) with mutations of *p53* are observed in transforming disease conveying refractoriness to treatment.^{14,18}

Laboratory features

The hallmark of the disease is the presence of an increased white blood cell (WBC) count with more than 90% small, mature-appearing lymphocytes (Figure 33.1). Usually, the more advanced the disease is, the higher is the WBC count. About 20% of patients present with anemia or thrombocytopenia. Autoimmune phenomena are frequent. For example, a positive direct antiglobulin test may be found in less than 2% to up to 35% of patients, depending on the series analyzed.^{33–36} The antibodies are typically warm antibodies of the IgG class. Autoimmune hemolytic anemia occurs in 10–25% of patients, and may be triggered by cytotoxic agents used to treat the

Figure 33.1 Chronic lymphocytic leukemia (peripheral blood).

disease. Immune thrombocytopenia is observed in only 2% of cases. Pure red-cell aplasia and immune neutropenia are even less frequent, and, as it occurs with immune thrombocytopenia, can be difficult to document.

Hypogammaglobulinemia, which is rare at diagnosis, may eventually occur in about 60% of patients during the course of the disease.³⁷ On the other hand, a marked monoclonal (M) immunoglobulin component, usually of IgM type, can be found in about 5% of cases,³⁸ but a small M component can be detected in the serum or urine of 80% of patients using high-resolution techniques.³⁹

Disease transformation

In approximately 3–10% of patients the disease undergoes a transformation into a more aggressive type, most commonly large-cell lymphoma (Richter syndrome).⁴⁰ In such cases, fever, weight loss, night sweats, enlarged lymphadenopathy, increased lactate dehydrogenase (LDH) serum levels, anemia, hypercalcemia, thrombocytopenia, and monoclonal gammopathy are the most frequent features.⁴¹ Diagnosis is not always easy, since the histological transformation may be a phenomenon localized in an isolated organ (e.g. spleen, lymph nodes of a given territory, extralymphatic tissue) rather than a generalized event. The immunological, cytogenetic and molecular characteristics of the lymphoma may be the same as or different from those of the original CLL.⁴² In some cases disease transformation is associated with the presence of Epstein-Barr virus (EBV) in the tumor. The prognosis in cases of transformation into large-cell lymphoma is poor, with a median survival of less than 6 months.⁴⁰ Transformation into prolymphocytic leukemia can also be observed.⁴³ Chronic lymphocytic leukemia can also transform into Hodgkin lymphoma, which is considered as a variety of Richter syndrome.^{40,44}

Second malignancies

Patients with CLL have an increased risk of suffering other cancers.^{45–47} However, risk assessment is not easy owing to the variability in the criteria used to evaluate it. In a study based on data from population-based cancer registries, the observed/expected ratio was 1.20, with an increased risk for Kaposi sarcoma, malignant melanoma, larynx cancers, lung cancer, and also bladder and gastric cancer in men. No relationship was found between the characteristics of the disease and its treatment and the incidence of secondary cancers.⁴⁷

Diagnostic criteria

The National Cancer Institute/Working Group⁴⁸ and the International Workshop on CLL⁴⁹ independently proposed criteria for the diagnosis of CLL. These criteria are summarized in Table 33.4. Nevertheless, CLL can be diagnosed whenever there is an absolute increase in the number of lymphocytes in the blood that are morphologically and immunophenotypically consistent with the diagnosis (i.e. SmIg^{+/-} CD5⁺, CD 19⁺, CD20⁺, CD23⁺, FMC7⁻). Bone marrow examination should no longer be considered a necessary diagnostic criterion, although it may provide important information regarding tumor burden and the origin of cytopenias (central vs. peripheral).

Table 33.4 Diagnostic criteria for chronic lymphocytic leukemia^{81–85}

1. Absolute lymphocytosis in peripheral blood $>5 \times 10^9/L$ (NCI/Working Group) $>10 \times 10^9/L$ (IWCLL)
2. The majority of lymphocytes should be small and mature in appearance Morphological subtypes:
 - 2.1. *Typical or classic CLL*: $<10\%$ atypical lymphocytes
 - 2.2. *CLL/PL*: pro lymphocytes in blood between 11% and 54%
 - 2.3. *Mixed*: variable proportion of atypical lymphocytes; $<10\%$ prolymphocytes
3. Characteristic immunophenotype
SmIg^{+/-}, CD5⁺, CD19⁺, CD20⁺, CD23⁺, CD22^{+/-}, CD79b⁻
4. Bone marrow infiltration
 $>30\%$ lymphocytes in bone marrow aspirate or consistent pattern in bone marrow biopsy

CLL: chronic lymphocytic leukemia; IWCLL: International Workshop for Chronic Lymphocytic Leukemia; NCI: National Cancer Institute; PL: prolymphocytoid

Chronic lymphocytic leukemia has been divided into different morphological variants on the basis of the proportion of atypical cells in peripheral blood. The FAB Group distinguished the following types (Table 33.4)⁵⁰:

- *Typical*, in which most lymphocytes are small and mature in appearance, with less than 10% being atypical
- *CLL/prolymphocytoid (CLL/PL)*, when the proportion of prolymphocytes (larger lymphocytes with prominent nucleolus) is between 11% and 54%
- *Mixed* form, which is a more vaguely defined variety in which there is a variable proportion of atypical lymphocytes but less than 10% prolymphocytes.

The most recent WHO classification only refers to *typical CLL*, with less than 10% prolymphocytes, and to *CLL with increased prolymphocytes (CLL/PL)*, defined as those cases with more than 10% and less than 55% prolymphocytes.⁷ In practice, the diagnosis of atypical CLL should not be accepted unless other diagnostic possibilities are carefully discarded.

Prognosis

The median survival of patients with CLL is about 10 years. Besides patients who have a survival not different from that of the general population, there are others who have a rapidly fatal course. Clinical stages (early vs. advanced), degree of bone marrow infiltration (non-diffuse vs. diffuse histopathological pattern, or $<80\%$ vs. $>80\%$ lymphocytes in bone marrow aspirate), blood lymphocyte levels (low vs. high), lymphocyte doubling time (>12 months vs. ≤ 12 months), lymphocyte morphology (typical vs. atypical) and cytogenetic abnormalities [normal karyotype, de(13q) as single anomaly vs. complex abnormalities, del(11q), del(17p)] are good predictors of survival.^{51–53} Thymidine kinase, LDH, B2-microglobulin, CD23, CD25, and CD20 serum levels have also been found to be of prognostic value in some studies.^{54–58} Overexpression of *MDR-1* and *MDR-3* genes and P-glycoprotein detection on neoplastic cells, as well as mutations of the *p53* tumor suppressor gene, have been correlated with resistance to therapy and poor prognosis.⁵⁹ Finally, response to therapy is associated with a better outcome.⁶⁰

Clinical stages have been the most useful prognostic parameters in CLL (Table 33.5; Figure 33.2). They do, however, have some limitations. For example, progressive and indolent forms of the disease are not identified. Moreover, the mechanisms accounting for cytopenias are not taken into consideration, yet there is some indication that patients with cytopenias of immune origin may have a better outcome than those in whom the cytopenia is caused by a massive infil

Table 33.5 Staging systems used for chronic lymphocytic leukemia

Staging system	Stage	Clinical features	Median survival (years)
Rai			
Low-risk		Lymphocytosis alone	14.5
Intermediate-risk		Lymphocytosis Lymphadenopathy	
High-risk	III	Lymphocytosis Spleen or liver enlargement Hemoglobin <11 g/dL	7.5
	IV	Lymphocytosis Platelet <100000/microliter	2.5
Binet			
Low-risk	A	No anemia, no thrombocytopenia <3 lymphoid areas* enlarged	15.5
Intermediate-risk	B	No anemia, no thrombocytopenia ≥3 lymphoid areas enlarged	5.5
High-risk	C	Hemoglobin <10 g/dL or Platelets <100000 microliter	3

* The Binet staging system⁵² takes into consideration the following lymphoid areas: lymph nodes (whether unilateral or bilateral) in the head and neck, axillae, groin, spleen and liver.

Figure 33.2 Survival probability of 685 patients with chronic lymphocytic leukemia (CLL) followed up at the Department of Hematology/Postgraduate School of Hematology 'Farreras-Valenti' of Barcelona according to Binet's stages.

tration of the bone marrow by neoplastic cells.⁶¹ Furthermore, clinical stages are a mere reflection of the biological diversity of the disease. In this regard, the correlation of certain cytogenetic abnormalities, as well as that of the mutational status of IgV_H genes, with the clinical outcome has signified an important progress in the understanding of the natural history of CLL. The mutational status of IgV_H genes separates CLL into two forms with distinct presenting features

Figure 33.3 Survival probability of 178 patients with chronic lymphocytic leukemia (CLL) followed up at the Department of Hematology/Postgraduate School of Hematology 'Farreras-Valenti' of Barcelona according to the expression of ZAP-70 on neoplastic lymphocytes as detected by cytofluorometry.

and outcome. Thus, compared with those who have IgV_H mutations, patients who have unmutated IgV_H genes have a more malignant disease, including evidence of advanced, progressive disease, atypical cell morphology, adverse cytogenetic features, and resistance to therapy.^{22,23} Unfortunately, studying IgV_H mutations is not possible on a routine basis. CD38 expression correlates, although not absolutely, with

IgV_H mutations; moreover, CD38 expression may vary over time.⁶² Recently, it has been demonstrated that ZAP-70 expression, as evaluated by cytofluorometry or polymerase chain reaction (PCR), strongly correlates with IgV_H mutations and has important prognostic significance by itself.^{63,64} (Figure 33.3).

Treatment

There is not a curative therapy for CLL, and the impact of the disease on patients' survival is highly variable. Therefore, not all patients with CLL require treatment. Therapy is considered justified when any of the following features is present:

- General symptoms (i.e. weight loss, extreme fatigue, night sweats or fever without evidence of infection)
- Increasing anemia or thrombocytopenia due to bone marrow failure
- Bulky or progressive lymphadenopathy
- Massive or progressive splenomegaly
- Autoimmune cytopenias not responsive to corti-costeroids
- Rapidly increasing lymphocyte counts in peripheral blood.

Marked hypogammaglobulinemia or increased WBC counts, in the absence of any of the above criteria, are not sufficient to initiate treatment.⁴⁹

Treatment approaches

Patients with low-risk disease

Treatment of patients in early stage (Binet A; Rai 0) has resulted in a delay in the rate of disease progression but no survival benefit.^{65,66} It should be noted, however, that this notion derives from studies in which the treatment employed was chlorambucil or other alkylating agents. Whether patients with CLL in early stage might gain benefit from early intervention with the newer and more effective therapies is being addressed in clinical trials.

Patients with intermediate- and high-risk disease

A proportion of patients in intermediate stage (Binet B; Rai I and II) have indolent disease; these patients may be followed with no therapy, as for those with low-risk disease. However, the majority of patients with intermediate stage of the disease and virtually all patients with advanced stage (Binet C; Rai III and IV) due to bone marrow infiltration require therapy.

Over the last two decades, chlorambucil has been the treatment of choice. The number of complete responses obtained with chlorambucil is low (10%) and, besides symptoms palliation, it is doubtful that it has any impact on the natural history of the disease. Because of this, chlorambucil is usually given to patients not likely to tolerate more intensive therapies due to associated comorbidity. Likewise, radiation therapy has a limited role in the treatment of CLL, although it may be useful to treat bulky lymphadenopathy or splenomegaly causing compressive problems in patients not suitable for chemotherapy.³⁻⁶

Purine analogs, particularly fludarabine, are the most effective agents to treat CLL. Treatment with fludarabine results in a much higher complete remission (CR) rate than chlorambucil or alkylating based chemotherapies (20–40% vs. 10%) and a longer disease-free interval, although survival is not prolonged.⁶⁶⁻⁶⁹ Fludarabine (given intravenously or orally) is now considered the treatment of choice for most patients with CLL. The efficacy of fludarabine may be improved by combining it with other agents (e.g. cyclophosphamide, mitoxantrone, rituximab).⁷⁰⁻⁷³ There are already data indicating that the combination of fludarabine plus cyclophosphamide not only results in a superior response rate than fludarabine alone but also a longer freedom from progression and, perhaps, a longer survival.^{71,72}

The most important side-effects of purine analogs are myelosuppression and infections. Infections due to opportunistic organisms may be observed. This seems to be more frequent in patients receiving corticosteroids and, particularly, in those who have been heavily pretreated.^{22,26,74} Although the cause is not clear, the risk of contracting opportunistic infections is attributed in part to the decrease in CD4 lymphocytes caused by purine analogs. Owing to the risk of infection, it is reasonable to employ antibiotic and antiviral prophylaxis (e.g. sulfamethoxazole-trimethoprim, acyclovir) in patients receiving purine analogs. Another side-effect of concern is the triggering of autoimmune hemolytic anemia (AIHA), which in some cases can be fatal.^{75,76} Because of this, purine analogs should be avoided in patients with AIHA or a positive Coombs' test.

Anecdotal cases of pulmonary toxicity^{77,78} and tumor lysis syndrome⁷⁹ have been reported. In addition, several cases of transfusional acute graft-versus-host disease have been described.^{80,81} As far as long-term complications are concerned, several reports of myelodysplasia in heavily pretreated patients have been reported.^{82,83}

Patients with cytopenias due to an immune mechanism (e.g. stage C (III, IV) immune)

These patients should initially be treated with corticosteroids, with cytotoxic agents added only when there is no response after 2–4 weeks of treatment. In patients with AIHA that is not responding to or is difficult to control with corticosteroids plus cytotoxic agents, high-dose immunoglobulin, cyclosporine, or rituximab may be tried. A proportion of these patients, however, will eventually require splenectomy.⁸⁴ Purine analogs should be avoided in patients

with AIHA as well in those with a positive Coombs' test. Pure red-cell aplasia (PRCA) may occasionally be associated with CLL; the treatment of choice is cyclosporine; rituximab can also be effective.^{3-6,85}

Patients with hypersplenism

In such cases, splenectomy or low-dose radiotherapy over the spleen may be of benefit.

Patients with systemic complications

Hypogammaglobulinemia is frequent in CLL and is the major cause of infections, which are the major cause of death and a significant cause of morbidity. In a number of studies, high and intermediate doses of immunoglobulin have been found to be of some value in preventing infections.^{86,87} Cost/benefit considerations, however, make the routine use of immunoglobulin in all patients with hypogammaglobulinemia questionable.⁸⁸ Hematopoietic growth factors (i.e. GM-CSF, G-CSF) may overcome treatment-related neutropenia.⁸⁹ Finally, erythropoietin may be useful to treat anemia unresponsive to other measures.⁹⁰

Disease transformation

Although the prognosis of such an event is usually poor (median survival <6 months), patients responding to aggressive lymphoma-type chemotherapy may have long survival.

New treatment approaches

Monoclonal antibodies

Alemtuzumab (Campath-1H) is an anti-CD52 antibody of which antigen is present on most B and T cells. In a number of studies, response rates of about 50% have been reported, with these being higher in peripheral blood and bone marrow than in lymph nodes and spleen. In fact, alemtuzumab has been used in patients who have achieved a good partial response to improve the response and to clear peripheral blood from leukemic cells before autologous transplantation. Interestingly, alemtuzumab has proved to be effective in patients refractory to fludarabine. Toxicity includes rigors, chills, fever, immunosuppression, and lymphocytopenia. Opportunistic infections can be observed. Cytomegalovirus (CMV) reactivation is a problem that deserves monitoring and preemptive therapy.⁹⁰⁻⁹⁴ Different trials are underway to evaluate the optimal dose, schedule, and route of administration (i.e. subcutaneous vs. intravenous), as well as the combination of alemtuzumab with other agents (e.g. fludarabine, rituximab).

Rituximab is an anti-CD20 antibody. In CLL the amount of CD20 on the surface of neoplastic cells is moderate, this being a possible reason for the low response rate to rituximab when given alone.^{90,95} However, rituximab acts synergistically with fludarabine and cyclophosphamide, with impressive preliminary treatment results having been reported.^{72,73,91} Patients with high WBC counts (i.e. higher than 50000/ μ L) may develop the so-called cytokinerelease syndrome characterized by fever, rigors, skin rash, nausea, vomiting, hypotension, and dyspnea, upon rituximab administration.

Stem cell transplants

An increasing number of subjects with CLL are being offered stem cell transplants.⁹⁶⁻¹⁰⁰ Autologous transplants do not cure the disease but may prolong survival in selected patients (i.e. sensitive to chemotherapy, without unfavorable prognostic factors, and transplanted early in the course of the disease). In contrast, allogeneic transplants can cure about 40% of the patients, but at the cost of a high toxicity and mortality (25-50%). Because of this, and the advanced age of most patients with CLL, the role of allotransplants with reduced intensity conditioning regimens is being intensively investigated; preliminary results are encouraging, with TRM of 10-20% (at 1 year) and an overall survival of about 60% (at 1 year).⁹⁸

Other treatments

Other more experimental treatments include the protein kinase C inhibitor UCN-01, the protein kinase C activator bryostatin, the cyclin-dependent kinase inhibitor flavopiridol, the topoisomerase-I inhibitor 9-aminocamptothecin, depsipeptide and bcl-2 antisense oligonucleotides, as well as new monoclonal antibodies (e.g. anti-CD23, anti-HLA-DR).³⁻⁶

B-cell prolymphocytic leukemia

Prolymphocytic leukemia (PL) was described by Galton et al in 1974 as an entity that should be separated from CLL and other forms of leukemia.¹⁰¹ This is an extremely infrequent disease (less than 1% of all leukemias), characterized by a high WBC count and the presence in peripheral blood of a high number of large lymphocytes with prominent nucleolus (prolymphocytes). Clinically, the most frequent feature is a huge splenomegaly. The disease predominates in males, and its prognosis is poor. Although recognized in the WHO classification as an entity on its own, it is extremely likely that many cases of B-cell PL, as diagnosed in the past, actually corresponded to other diseases such as mantle-cell lymphoma with leukemic expression.

Biology

The normal counterpart of prolymphocyte has not been fully identified. The presence of mutated IgV_H genes in a proportion of cases suggests that, at least in

some cases, prolymphocytes are post-germinal cells that have undergone antigen-driven selection.¹⁰² The neoplastic cells of B-cell PL express strong SmIg (as opposed to CLL, in which SmIg is weak) and pan-B-cell markers (e.g. CD19, CD20); they are usually negative for CD11c and CD23, variably positive for CD5, and may show weak expression of CD10. In contrast to the small lymphocytes of CLL, prolymphocytes express FMC7 and CD22.

A marker chromosome 14q⁺, which has a breakpoint at 14q32, the locus for the IgV_H gene, is found in two-thirds of patients. The translocations involving chromosome 14 are not always well defined, although the most frequent is t(11;14)(q13;q32). Most cases of B-cell PL with t(11;14), however, are likely to represent mantle-cell lymphoma with leukemic expression.¹⁰³ In half of the cases, p53 mutations are observed.

Clinical features

The median age of patients at diagnosis is about 70 years, and males predominate over females (4:1). The diagnosis is often made because of the discomfort caused by a massive splenomegaly. In all cases, the WBC is high and usually exceeds 100 000/ μ L. Anemia and thrombocytopenia may be observed in up to 30% of patients. The majority of them (90%) have splenomegaly that can be of huge size. Lymphadenopathy is rare or absent.

Diagnosis

A marked increase in WBC count is a constant feature of the disease. The diagnosis is based on the finding of a large proportion of prolymphocytes in the peripheral blood. Morphologically, prolymphocytes are usually larger than the small lymphocytes of CLL, and also have a more abundant cytoplasm with moderate basophilia; the nucleus is round with a clumped chromatin pattern, and the presence of a prominent vesicular nucleolus is a prominent feature (Figure 33.4). Conventionally, more than 55% of prolymphocytes

Figure 33.4 B-cell prolymphocytic leukemia (peripheral blood).

are required to make the diagnosis, although in most instances the percentage is 70–80%. B-cell PL must be differentiated from CLL with ‘prolymphocytoid’ transformation, as well as the so-called CLL/PL, in which patients with CLL have a variable proportion (<55%) of prolymphocytes in the peripheral blood at diagnosis; CLL/PL is closer to CLL than to PL.¹⁰⁴ The disease should also be differentiated from marginal zone lymphoma with leukemic expression (splenic lymphoma with villous lymphocytes). Finally, cases of B-cell PL with t(11;14) constitute a confusing area since most of these cases actually correspond to mantle-cell lymphoma.¹⁰³ The immunophenotype of B-cell PL is shown in Table 33.2.

Prognosis

The prognosis is poor, with a median survival of approximately two years. There are patients, however, in which the disease has a more benign, smoldering course.

Treatment

Patients with B-cell PL are usually refractory to treatment. Splenectomy may be useful to control the disease for variable periods of time. Fludarabine alone or associated to other agents (e.g. cyclophosphamide) may produce a significant number of responses. Alemtuzumab has been shown to be highly effective in T-cell PL, the experience in B-cell PL being less. In younger patients with aggressive disease, stem cell transplantation should be considered.

Hairy-cell leukemia

Hairy-cell leukemia (HCL) was first recognized by Bouroncle et al in 1958, and given the name ‘leukemic reticuloendotheliosis’.¹⁰⁵ The disease was rediscovered in the 1970s, and was called hairy-cell leukemia because of the ‘hairy’ aspect of the cells that proliferate in this disease. It is an infrequent disease, accounting for only 2–4% of all leukemias, in which hairy-cells infiltrate the bone marrow and the spleen.

Biology

In most cases, HCL has its origin in mature, memory B cells. However, on rare instances cases displaying T-cell markers have been reported. The cyclin D1 gene is overexpressed at mRNA and protein levels in a high proportion of patients. Nonetheless, the levels of expression are much lower than in mantle-cell lymphomas, and this overexpression is not associated with *BCL1* rearrangements or *CCND1* gene amplification.¹⁰⁶ The growth of malignant cells is regulated by cytokines (e.g. tumor necrosis factor (TNF)- α , interleukin (IL)-2, IL-4 and IL-6, and B-cell growth factor

(BCGF), probably through both autocrine and paracrine pathways.¹⁰⁷ Cytogenetically, trisomy 5, structural abnormalities involving the pericentromeric regions of chromosomes 5 and 2, and 1q42 abnormalities have been reported.¹⁰⁸

Clinical features

The median age of patients at diagnosis is about 60 years. The disease clearly predominates in males (5:1). The majority of patients manifest symptoms secondary to severe pancytopenia (i.e. bacterial infections, bleeding) and weakness. Sometimes, HCL presents with opportunistic infections secondary to the severe cellular immunodeficiency and monocytopenia. It is not unusual, however, to diagnose HCL in asymptomatic patients undergoing routine laboratory examinations.

Splenomegaly is found in 80% of cases. In rare instances, HCL may present with osseous involvement, vasculitis, nephrotic syndrome, and arthritis.^{109,110} Although peripheral lymphadenopathy is not observed, a proportion of cases present with or develop abdominal lymph adenopathy, a feature that has been associated with a poor response to therapy.¹¹¹

Diagnosis

Laboratory features frequently seen in HCL include anemia, neutropenia, and thrombocytopenia. Monocytopenia is a constant feature. Other laboratory features include elevation of the leukocyte alkaline phosphatase (LAP) level and high mean corpuscular volume (MCV) (>100 fL) of erythrocytes. Hypergammaglobulinemia and moderate abnormalities of the liver enzymes may also be observed. In some cases, monoclonal M components can be found.^{109,110}

In most cases (but not in all), a variable proportion of hairy cells are present in the peripheral blood (Figure 33.5). Almost always, hairy cells display tartrate-resistant alkaline phosphatase (TRAP) activity, but this finding is not specific for HCL. Immuno-

Figure 33.5 Hairy-cell leukemia (peripheral blood).

phenotypically, hairy cells have SmIg and are positive for pan-B-cell markers (e.g. CD19, CD20 and CD22); the most characteristic markers of HCL are positivity for CD11c, CD103, CD25 and Annexin A1 (ANXA1), this latter being highly specific.¹¹² (See Table 33.2).

Frequently, the bone marrow cannot be aspirated ('dry tap'). Therefore, a bone marrow biopsy is important to establish the diagnosis. Usually, the bone marrow is hypercellular. A patchy infiltration by hairy cells and a significant increase in reticulin fibers (which explains the difficulties in performing bone marrow aspiration) are the most characteristic features. However, some cases with hypocellular bone marrow, posing the differential diagnosis with aplastic anemia, have been reported. In these cases, immunohistochemical studies can be of great help in making the diagnosis. The spleen is also infiltrated. The fact that the red pulp of the spleen is primarily involved may be of help in differentiating HCL from other lymphoproliferative disorders that basically involve the white pulp of the spleen (e.g. splenic lymphoma with villous lymphocytes).^{109,110}

In the so-called HCL variant, there are a number of distinctive features separating it from classical HCL.¹¹³ The morphology of the leukemic cells is intermediate between those of hairy cells and prolymphocytes, with abundant basophilic cytoplasm with villous projections, and a centrally located nucleus with a prominent nucleolus. The cells are acid-phosphatase positive, but, in contrast to classical HCL, they are tartrate-sensitive. The immunophenotype is intermediate between those of HCL, PL, and splenic lymphoma with villous lymphocytes. CD25 and HC2 are usually negative. Moreover, the WBC is high and neither monocytopenia nor neutropenia are present; LAP and MCV are normal. HCL variant is resistant to treatment.

Prognosis

The prognosis of HCL has improved over the last decade as a result of its earlier diagnosis and better treatments. The 4-year survival from diagnosis is currently about 80%, as compared with 60% in patients diagnosed in the 1970s. In most studies, anemia, increased WBC counts, and degree of spleen enlargement predict survival.^{109,110}

Treatment

Not all patients with HCL need treatment. About 10% have an indolent or totally asymptomatic disease, and may be followed with no therapy until progression is observed. The criteria for giving treatment include¹⁰⁹:

- Anemia (Hb <10 g/dL)
- Neutropenia (granulocyte count <1000/ μ L)
- Thrombocytopenia (platelets <100 000/ μ L)

- Symptomatic splenomegaly
 - Recurrent infections
 - Extralymphatic disease
 - Autoimmune complications
 - Presentation in the leukemic phase of the disease
- Treatments for HCL have increased in the last few

years.^{114,115} Splenectomy and interferon alfa-2a (IFN- α_{2a}), which have been standard treatments for HCL, are being replaced by cladribine (2-chlorodesoxyadenosine) and pentostatin (2'-deoxycoformycin). Nevertheless there is still place for surgery in some patients with massive spleen enlargement. In patients requiring treatment, complete responses are obtained in 75–85% of cases treated with cladribine and in 33–89% of patients receiving pentostatin.^{116,118}

In a randomized study in which pentostatin was compared with IFN- α_{2a} in untreated patients, response rates were significantly higher with pentostatin than IFN- α_{2a} (79% vs. 38%; $p < 0.001$); relapse-free survival was also longer in those patients treated with pentostatin ($p < 0.001$). Hemoglobin level, young age, and no or small splenomegaly were associated with response achievement.¹¹⁸ Cladribine given in 2-hour infusion or subcutaneously seems to be as effective as when given by continuous infusion.¹¹⁹ Nevertheless, even in cases in which CR is achieved according to conventional clinical and hematological criteria, residual disease may be often identified in bone marrow by means of immunohistochemical studies.¹²⁰

Non-Hodgkin lymphomas with leukemic expression

Non-Hodgkin lymphomas differ from chronic lymphoid leukemias in that the primary site of the disease is usually the lymph nodes and other lymphoid tissues rather than the bone marrow and peripheral blood. Although all the lymphomas have the potential for spreading to bone marrow and peripheral blood, there are a number of them in which this is a relatively frequent event^{121–123} (see also Chapter 31 on non-Hodgkin lymphomas).

Splenic lymphoma with villous lymphocytes/marginal zone lymphoma of the spleen

Splenic lymphoma with villous lymphocytes (SLVL) and marginal zone lymphoma of the spleen are considered equivalent terms. SLVL presents with a variable number of circulating 'villous' lymphocytes in the peripheral blood, which also infiltrate the bone marrow and the spleen, and usually has a benign clinical course.^{124–126}

Biology

Tumor cells have surface IgM and IgD and are CD20⁺ and CD79b⁺. CD5, CD10, CD23, CD43, Bcl-6 and Cyclin D1 are typically absent. Immunoglobulin heavy and light chains are rearranged and somatic mutations can be observed in about half of the cases. In addition, intracлонаl variation has been observed, suggesting ongoing mutations. Allelic loss of chromosome 7q31–32 has been reported in up to 40% of the patients. Cases with 7q loss tend to show a more aggressive behavior, with more frequent tumoral progression.¹²⁷ Deletion of 17p has been observed in approximately 10% of the cases. Cases associated to hepatitis C virus have been described, particularly in Italy.¹²⁶

Clinical features

At diagnosis, the majority of patients are elderly (median 70 years), and usually present with massive splenic enlargement; lymphadenopathy is absent or limited to the splenic hilar lymph nodes. In many cases, the diagnosis is made on the occasion of a routine medical examination. The lymphocyte count is usually only moderately elevated (10 000–30 000/ μ L). Other features at diagnosis can be anemia and thrombocytopenia (in less than 20% of the patients), as well as monoclonal gammopathy (particularly of the IgM type), which can be found in up to 30% of cases. Autoimmune hemolytic anemia and immune thrombocytopenia may be also observed. Disease transformation into aggressive lymphoma occurs in 10% of cases.^{124–126}

Diagnosis

The diagnosis is usually made in the course of routine laboratory studies or when investigating a splenomegaly causing compressive problems. The WBC count rarely exceeds 30 000/ μ L. The proportion of villous lymphocytes (Figure 33.6) is variable.

In terms of differential diagnosis, the negativity of CD5 is useful in excluding chronic lymphocytic leukemia, absence of CD 103 in ruling out hairy cell leukemia, and absence of CD 10 in excluding follicular lymphoma. Sometimes, the diagnosis is eventually made after splenectomy. In contrast to HCL, in SLVL the white pulp rather than the red pulp is involved.¹²⁷

Prognosis

Median survival of patients with SLVL is around 10 years, and 5-year overall survival is about 80%. In many cases the disease runs an indolent clinical course. Increasing age, anemia, thrombocytopenia, high WBC count (i.e. >15 000/ μ L), autoimmune hemolytic anemia, serum M component, high beta-2

Figure 33.6 Splenic lymphoma with villous lymphocytes (peripheral blood).

microglobulin serum levels and p53 overexpression by neoplastic cells have been associated with a poorer outcome.^{128,129}

Treatment

Asymptomatic patients do not require treatment. Splenectomy may be useful not only to confirm the diagnosis but also to correct the anemia or thrombocytopenia caused by hypersplenism. Fludarabine can be useful in patients requiring systemic chemotherapy. In cases of SLVL associated to hepatitis C virus, interferon alone or associated to ribavirin may induce the regression of the disease.¹³⁰

Follicular lymphomas

A significant proportion of patients with follicular (centroblastic/centrocytic) lymphomas present with circulating lymphoma cells in the peripheral blood at diagnosis, and others develop a leukemic phase during the course of the disease. Overall, 10–30% of patients, depending on the series analyzed, show circulating neoplastic cells either at diagnosis or during the disease evolution. The proportion is higher if peripheral blood involvement is assessed by cytofluorometry or PCR, but the clinical significance of this latter finding is unsettled.

Bone marrow infiltration is present in a large number of patients (40–60%), frequently in the form of aggregates or nodules in paratrabecular position.

The lymphocyte count varies from moderately increased to very high levels. The cytological features of the atypical cells may also vary. There are cases in which most cells are small and cleaved cells (centrocytes) (Figure 33.7), whereas in others a mixture of small and large cells (centroblasts) is observed.

Immunophenotypically, these cells usually express CD10, pan-B-cell antigens (e.g. CD19, CD20, CD22),

Figure 33.7 Follicular lymphoma in leukemic phase (peripheral blood).

and in most cases are CD5- and CD43- (see Table 33.2).^{121–123} These cells can display the t(14;18) and express *BCL2*. Whereas the presence of atypical cells in peripheral blood has no prognostic significance by itself, the proportion of large circulating cells does correlate with poor prognosis; this is most likely due to the fact that large cells in blood indicate disease transformation.

Lymphoplasmacytic lymphoma/Waldenström's macroglobulinemia

Lymphoplasmacytic lymphoma/Waldenström's macroglobulinemia (LPL/WM) is a rare disorder (1.5% of lymphomas) characterized by a monoclonal lymphoplasmacytic proliferation accompanied by a serum monoclonal IgM. It is a disease of the elderly, the median age of patients at diagnosis being 65.¹³¹ In the WHO classification LPL and WM are considered equivalent diseases, although not all patients with LPL present with the classical syndrome described by Jan G Waldenström in 1944, consisting of anemia, lymphadenopathy, epistaxis, and hypergammaglobulinemia.

Biology

The disease has its origin in post-germinal center B cells that have undergone somatic mutations. Immunophenotypically, besides markers present in other B-cell lymphomas, some antigens typical of plasma cells (e.g. CD38 and CD71) may be observed. Intracytoplasmic immunoglobulin (cIg) is also present. Other typical markers include IgM⁺, IgD⁻, CD19⁺, CD20⁺, CD5⁻, CD10⁻, and CD23⁻. No specific cytogenetic features or molecular abnormalities have been identified, although del(6q) can be detected in about 50% of the patients.¹³² Expression of PAX5 due to

t(9;14)(p13;q32) has been reported in about 50% of lymphoplasmacytic lymphomas, although it seems to be restricted to cases without a serum monoclonal protein.¹³³

Clinical features

Clinical features are variable. Some patients are asymptomatic, whereas others present with constitutional symptoms, lymphadenopathy, splenomegaly, and hematologic abnormalities. The IgM paraprotein may cause hyperviscosity syndrome (i.e. mucosal hemorrhage, visual disturbances, headache, vertigo, somnolence), although this is only observed in 15% of patients. The physical characteristics of the IgM paraprotein may result in cryoglobulinemia, although most cases of type II mixed cryoglobulinemia are associated with hepatitis C infection, even in patients with LPL/WM. The IgM paraprotein may also function as an autoantibody and may produce cold-agglutinin hemolysis, autoimmune thrombocytopenia, acquired von Willebrand's disease or polyneuropathy. The WBC count is usually only moderately increased, and the proportion of atypical cells is variable (30–50%). The most usual phenotype is CD5⁻, CD10⁻, CD43^{+/-}, CD19⁺, CD20⁺, CD22⁺, CD79b^{+/-} (see Table 33.2).⁸⁴ Progression into aggressive lymphoma (e.g. immunoblastic) may be observed. Light-chain associated amyloidosis may also occur.¹³¹

Diagnosis

In patients with a classical presentation, evidence of mature lymphocytosis, or plasmacytoid cells in bone marrow, peripheral blood (Figure 33.8), and a serum monoclonal IgM protein, diagnosis is straightforward. There is no agreement on the minimum protein concentration needed for diagnosis, although it is usually >30 g/L in cases of typical WM. The diagnosis can be complicated by the fact that a serum monoclonal IgM protein can be observed in diseases other than LPL/WM, such as monoclonal gammopathy of unknown significance, multiple myeloma, marginal zone lymphoma, and CLL.

Prognosis

The median overall survival is around 6 years, although it may vary among series depending on the diagnostic criteria employed. The individual prognosis is highly variable. Unfavorable prognostic factors include advancing age, cytopenia, low albumin, and increased serum beta-2 microglobulin. Several prognostic systems have been proposed. Morel et al associated an increased risk with: patients who are 65 years or older, albumin <40 g/L, and cytopenia (hemoglobin <120 g/L, platelet count <150 000/ μ L, WBC count <4000/ μ L (with 1 cytopenia given 1 point and 2

Figure 33.8 Lymphoplasmacytic lymphoma with leukemic expression (peripheral blood).

or 3 cytopenias given 2 points). Patients were divided into low-risk (0 or 1 point and 87% 5-year survival), intermediate-risk (2 points and 62% 5-year survival), and high-risk (3 or 4 points and 25% 5-year survival).¹³⁴

Dhodapkar et al proposed a prognostic model based on 3 factors: serum beta-2 microglobulin, hemoglobin, and serum IgM concentration. Patients with low beta-2 microglobulin had the best 5-year survival (87% if hemoglobin was 120 g/L and 64% if hemoglobin was <120 g/L). Patients with a high beta-2 microglobulin level had the worst 5-year survival; 53% if they had an IgM \leq 40 000 mg/L and 22% if the IgM was >40 000 mg/L.¹³⁵

Treatment

Since LPL/WM is incurable, patients without symptoms should be only monitored, and treatment given only in case of disease progression. The basis for LPL/WM treatment consists of: plasmapheresis to treat the hyperviscosity syndrome, alkylating agents, purine analogs, and rituximab.

Alkylating agents convey the risk of myelodysplasia and because of this should be avoided, particularly in younger patients. Purine analogs (i.e. fludarabine, cladribine) are highly effective, although responses can be delayed. Rituximab is also useful. In patients receiving rituximab, however, IgM may increase during the first months of therapy to decrease thereafter, a fact of which treating physicians should be aware. The possibility of combining purine analogs with other agents (e.g. cyclophosphamide, rituximab) is appealing. Autologous stem-cell transplants may be considered in younger patients failing to respond to initial therapy; at present, allogeneic stem cell transplantation is considered an experimental procedure in LPL/WM.

Mantle-cell lymphomas in leukemic phase

Mantle-cell lymphomas (MCL) are neoplasias that arise in the mantle zone of lymph nodes and that account for 5–10% of all lymphomas. In 40–80% of the cases, neoplastic cells from MCL involve the bone marrow and peripheral blood.¹³⁶

Biology

The t(11;14)(q13;q32), with overexpression of the *cyclin D1* gene, is a highly characteristic feature of MCL.¹³⁷ Mutations of *p53* and deletions of the cyclin-dependent kinase inhibitors *p21^{Waf1}* and *p16^{INK4a}* have been associated with atypical morphology and poor outcome.^{138,139} In about one-third of the patients V_H genes are mutated. Immunophenotypically, MCL is CD5⁺, a marker also found in CLL. In contrast to CLL, however, SmIg expression is strong and in most instances MCL lymphocytes do not express CD23 and can be FMC7⁺ (see Table 33.2).

Clinical features

Mantle-cell lymphomas usually affect older males. Although a prominent splenomegaly is the most relevant feature, extranodal involvement is also common. In 40–80% of the cases, MCL involves the bone marrow and the peripheral blood, with this leading to a leukemic picture (MCL 'leukemia'), which may be confounded with CLL and other lymphomas in leukemic phase.¹⁴⁰

Diagnosis

The neoplastic cells characteristic of MCL are small to medium-sized, have an irregular, slightly indented or cleaved nucleus (Figure 33.9). Three morphological varieties are recognized: typical, small-cell, and blastoid. In the blastoid variant, the lymphocytes are larger and highly atypical. Although MCL in leukemic phase may be suspected from the examination of peripheral blood films, immunophenotyping, as well as cytogenetic and molecular studies, are necessary to confirm the diagnosis (see Table 33.2).

Prognosis

Mantle-cell lymphoma has a poor prognosis, with a median survival of 3–5 years. Elastic forms have a worse prognosis than the others. As mentioned above, mutations of *p53* and deletions of *p21^{Waf1}* and *p16^{INK4a}* have been associated with atypical morphology and poor outcome.^{138,139} Patients with mutated V_H genes may have a relatively better prognosis than those with unmutated V_H genes.¹⁴¹ Leukemic expression has also been associated with a poor prognosis. Well-recognized prognostic factors for lymphoma patients (e.g.,

Figure 33.9 Mantle-cell lymphoma (blastic variant) with leukemic expression (peripheral blood).

serum LDH and the International Prognostic Index) also apply to this disease.

Treatment

Mantle-cell lymphoma is refractory to standard lymphoma regimens. Chemoimmunotherapy (e.g. rituximab+CHOP; rituximab+FCM [fludarabine, cyclophosphamide, mitoxantrone]) offers the highest possibility of achieving a response, although most patients eventually relapse.¹⁴² Autologous transplantation may prolong survival but does not cure the disease. Allogeneic transplantation has been effective in some cases, and deserves further investigation.¹⁴³ Encouraging results have been reported with allotransplants with reduced intensity conditioning regimens.¹⁴⁴

T-cell prolymphocytic leukemia

T-cell prolymphocytic leukemia (T-cell PL) is one of the most frequent form of T-cell chronic lymphoproliferative disorder leukemic expression. This is a disease of adult people and predominates in males.

Biology

The neoplastic cells are TdT(-) and express pan-T-cell antigens (e.g. CD2, CD3, and CD5). CD7 is expressed in over 90% of patients. In approximately 70% of cases, the prolymphocytes express a helper-cell phenotype (CD4⁺, CD8⁻). The most consistent cytogenetic abnormality involves chromosome 14, usually inv(14) with breakpoints at q11 (the locus for T-cell a and b receptors) and q32, this leading to the overexpression of the *CTL-1* gene. Trisomy 8 is observed in half of the cases. Deletions of chromosome 11, namely del(11q), where the ataxia telangiectasia gene (*ATM*) is located, are found in a high proportion of patients. Finally, serology for HTLV-I is negative.¹⁴⁵⁻¹⁴⁷

Clinical features

The majority of the patients have constitutional symptoms and abdominal discomfort caused by a large spleen. In contrast to B-cell PL, lymphadenopathy and hepatomegaly may be present. Skin involvement is not rare. In the advanced phases of the disease pleural effusion, ascites, and CNS involvement may be observed. The WBC is high, with counts above 100 000 not being infrequent. Anemia and thrombocytopenia may be found in 30% of the patients.

Diagnosis

From the morphological point of view, a mixture of small and large atypical cells can be observed. The nuclei are regular or oval in half of the cases, and irregular with convolutions and folds in the other half. The cytoplasm shows protrusions or blebs. T prolymphocytes stain strongly with α -naphthyl acetate esterase. Under electron microscopy, the most important feature of the prolymphocyte is the presence of a large, centrally placed nucleolus, which is usually surrounded by a halo of heterochromatin. This can be useful to identify prolymphocytes of small size not easily identifiable by light microscopy. The immunophenotype of T-cell PL is shown in Table 33.3.

Prognosis

The prognosis is poor, the median survival being around 6 months.

Treatment

Alemtuzumab is the most effective single agent to treat T-cell PL.¹⁴⁸ Fludarabine-based therapies (e.g. fludarabine, cyclophosphamide, prednisone) followed by alemtuzumab have given promising results. Pentostatin can be also of benefit.¹⁴⁹ In younger patients, bone marrow transplantation should be considered.

Lymphoproliferative diseases of granular lymphocytes

Lymphoproliferative diseases of granular lymphocytes (LDGL), also known as large granular lymphocyte leukemias (LGL), are a heterogeneous group of disorders that result from the chronic proliferation of large granular lymphocytes. Formerly, these diseases had been known by terms such as chronic T-cell lymphocytosis with neutropenia, T8 chronic lymphocytic leukemia, and T-suppressor cell CLL, among others. The term 'lymphoproliferative diseases of granular lymphocytes' is better, since in most cases these disorders are not malignant, truly leukemic conditions. These diseases account for less than 5% of all chronic lymphoproliferative disorders and predominate in the adulthood.¹⁵⁰⁻¹⁵³

Biology

Lymphoproliferative diseases of granular lymphocytes may have either a CD3⁺ (T-cell) or a CD3⁻ (NKcell) phenotype. The etiology of LDGL is unknown, although in some cases the Epstein-Barr virus might be implicated.¹⁵⁴ Also, a higher frequency of the DR4 haplotype has been claimed in some studies, indicating some genetic predisposition.¹⁵³

Clinical features

The median age of patients at diagnosis is 60 years. The clinical presentation of T-cell LDGL is quite different from that of NK-cell LDGL.

T-cell LDGL, which accounts for up to 80% of cases of LDGL, has a chronic course with symptoms primarily resulting from the neutropenia, which can be severe. Recurrent bacterial infections (primarily involving skin, sinuses, and perirectal areas) are common. In addition, rheumatoid arthritis, as well as a number of serological abnormalities (e.g. hyper- or, more rarely, hypo-gammaglobulinemia, circulating immune complexes, positive tests for rheumatoid factor, antinuclear antibodies, antineutrophil antibodies, and antiplatelet antibodies), occur very frequently in T-cell LDGL. Pure red-cell aplasia and autoimmune (Coombs-positive) hemolytic anemia may be also encountered.¹⁵⁴ The course of the disease is stable or slowly progressive; few patients present with widespread disease and transformation into large cell lymphoma is exceedingly rare.

In about half of the patients, an enlarged spleen is found. Other less frequent features are hepatomegaly (about one-third of patients) and lymphadenopathy (less than 20% of cases); skin involvement is observed in less than 5% of patients.

In contrast, NK-cell LDGL usually presents as a disseminated disease, with fever without evidence of infection, night sweats, weight loss, and a rapid and aggressive clinical course.

Diagnosis

Currently, two different forms of LDGL are recognized (see Table 33.3):

- *T-cell LDGL*, in which the most frequent phenotype is CD3⁺, CD8⁺, TIA-1⁺, CD4⁻ with rearrangement of the T-cell receptor β (TCR β) and, more rarely, T-cell receptor γ (TCR γ).
- *NK-cell LDGL* with the phenotype CD3⁻, CD4⁻, CD8⁻, CD16⁺, CD11b⁺ CD56⁺, CD57⁻ (this entity is considered an aggressive leukemia).

Among the laboratory findings, the presence of granular lymphocytes in peripheral blood is the hallmark of the disease (Figure 33.10). In addition, severe neutropenia is frequent, and anemia and thrombocytopenia may also be observed. Bone marrow shows infiltration by atypical lymphocytes in about 80% of cases, although it is usually barely detectable or moderate. In some instances hypoplasia of the erythroid precursors, as well as 'maturation arrest' of myeloid precursors, may be found.

The existence of a granular lymphocytosis greater than 5000/ μ L lasting for more than 6 months in the peripheral blood has been considered as diagnostic criterion. However, there are cases in which the diagnosis can be established in patients presenting with a lower level of granular lymphocytes, provided that other important diagnostic criteria (i.e. cytogenetic and molecular analysis), as well as the clonality of the population, are demonstrated.¹⁵⁶ The latter is particularly difficult in CD3⁻ cases (NK-cell LDGL) owing to the lack of clonal markers; these cells do not rearrange TCR α , γ or δ genes. Cytogenetic abnormalities, if present, can be useful to demonstrate clonality. Among the monoclonal antibodies used to make the diagnosis, positivity of CD16 plays a central role. Since the CD3⁺/CD16⁺ subset accounts for less than 5% of normal cells in healthy subjects, the increase in that population is highly suggestive of CD3⁺ LDGL. Nevertheless, the differential diagnosis between LDGL (particularly those that are CD3⁻) and lymphocytosis reactive to infections, autoimmune disorders, or other clinical situations may be extremely difficult.

Treatment

Patients with T-cell LDGL may run a chronic course for years, not needing therapy or only requiring treatment because of recurrent infections or severe anemia. Treatment is indicated in patients with severe neutropenia leading to recurrent bacterial infections.

Corticosteroids, followed by oral cyclophosphamide in steroid-refractory or steroid-dependent cases,

Figure 33.10 Large granular lymphocyte in peripheral blood.

result in an overall response rate of approximately 70%. In patients not responding to these measures, cyclosporine A or G-CSF can be effective.^{157,158}

In contrast to the good prognosis of patients with T-cell LDGL, those with NK-cell LDGL usually die of disseminated disease within a few months of presentation, and this must be treated as an aggressive leukemia, including stem-cell transplantation whenever possible.

Sézary syndrome

Cutaneous T-cell lymphomas (CTCL) have a wide spectrum of presenting and evolving forms. Mycosis fungoides is an indolent lymphoma that primarily involves the skin in early stages of the disease. Nevertheless, after a variable period of time, it may progress and involve visceral sites and lymph nodes. Sézary syndrome, an entity described in 1938, is an erythrodermic variant of CTCL associated with the presence of circulating tumor cells in the peripheral blood.¹⁵⁹ Primary CTCL should be distinguished from other peripheral T-cell lymphomas that may involve the skin.¹⁶⁰⁻¹⁶²

Biology

The similarities between the skin lesions of mycosis fungoides and Sézary syndrome and those of adult T-cell leukemia-lymphoma has led to the consideration of a possible etiological role for a retrovirus (e.g. HTLV/II); human herpes viruses (e.g. herpes simplex virus) have also been implicated, although with inconclusive results.¹⁶⁰⁻¹⁶²

Clinical features

Sézary syndrome is mainly seen in elderly patients, with a median age at diagnosis of 65 years, and is more common in males. The disease may present either de novo or as part of the evolution of mycosis fungoides. The major cutaneous manifestation of Sézary syndrome is a generalized pruritic erythrodermia. Other features include edema, lymphadenopathy, hepatomegaly, alopecia, ectropion, onychodystrophy and palmar-plantar keratoderma. Characteristically, circulating Sézary cells are found. Sézary cells may be infrequent or very numerous. The neoplastic cells may all be small or may be a mixture of small and large cells. Cells have a highly infolded, complex nuclear form that is usually described as cerebriform or convoluted (see Figure 33.10). Cytogenetic studies show multiple chromosome abnormalities.

Diagnosis

The coexistence of cutaneous lesions, characterized histologically by the presence of atypical lymphocytes in the epidermis, either singly in lacune or more

definitively in clusters (Darier-Pautrier microabscesses), and Sézary cells in the blood (Figure 33.11) are essential requirements to make the diagnosis of Sézary syndrome. Nevertheless, in the early phases of the disease, CTCL may be difficult to differentiate from chronic inflammatory dermatoses. In turn, Sézary cells may be difficult to identify and to differentiate from reactive lymphocytes. Cytogenetic analysis and demonstration of aneuploidy by flow-cytometric quantification of DNA are useful for detecting peripheral blood involvement in CTCL. Ultrastructural studies are useful to define precisely the morphology of neoplastic cells. Immunophenotypically, Sézary cells express several T markers, particularly CD2, CD3, CD5 and, less consistently, CD7. The most common phenotype is CD4⁺, CD8⁻ (see Table 33.3).

Prognosis

The prognosis of patients with Sézary syndrome is variable. Kim et al identified a number of prognostic factors in mycosis fungoides/Sézary syndrome¹⁶³: age at presentation of 65 years or more, T classification, and presence of extracutaneous disease. Survival may range from less than 2 years (in patients with disseminated disease) to more than 10 years (in those with localized disease).

Treatment

Treatment of CTCL depends on whether the disease is limited to the skin or whether there is systemic

Figure 33.11 Sézary cell in peripheral blood.

involvement.^{161,164,165} Several types of therapy including radiotherapy and phototherapy (e.g. PUVA, psoralen followed by UVA irradiation), as well as extracorporeal photochemotherapy, may be effective to improve the skin lesions. However, patients with advanced disease such as those with Sézary syndrome require systemic chemotherapy such as that used in aggressive lymphomas. Interferon alfa-a2, pentostatin, cladribine, and alemtuzumab may be useful. Unfortunately, however, responses are usually partial and transient.

Adult T-cell leukemia-lymphoma

Adult T-cell leukemia-lymphoma (ATLL) was recognized in 1977 as a new clinicopathological entity.^{166,167} In 1980, the etiological relationship between the human T-cell leukemia virus I (HTLV-I) and ATLL was established.¹⁶⁸ Adult T-cell leukemia-lymphoma is endemic in Japan, the Caribbean basin, Africa, South America, and the South Eastern USA. It is increasingly seen in Europe among the population originating from AfroCaribbean areas, and also, although sporadically, in Caucasians.^{169,170} Besides rapidly evolving forms, there are others that run a more indolent, chronic course. Treatment has to be individualized based on the risk of each patient.¹⁷¹ This disorder is discussed in detail in Chapter 13.

Figure 33.12 Adult T-cell leukemia-lymphoma (peripheral blood).

Multiple myeloma

Nikhil C Munshi and Kenneth C Anderson

Introduction

Multiple myeloma is a clonal B-cell malignancy characterized by the accumulation of bone marrow plasma cells. The critical step in malignant transformation occurs late in B-cell differentiation after antigen selection and somatic hypermutation. These transformed cells then migrate to the bone marrow, where critical interactions between the malignant cell, extracellular matrix proteins, and bone marrow stromal cells promotes tumor cell growth, survival, and drug resistance.¹

The malignant plasma cells in myeloma generally produce one of the five major classes of immunoglobulins. IgG is the commonest variety, followed by IgA (Table 34.1). Other classes of immunoglobulins produced include IgM, IgD, and IgE. Except for IgM, produced in a variant of plasma cell disorder and in Waldenström's macroglobulinemia, the other types are only rarely observed. In a small number of patients, only the light chains of the immunoglobulin molecules are produced (i.e. Bence Jones proteinuria); rarely myeloma may be totally non-secretory by virtue of a lack of any immunoglobulin-related proteins.²

Table 34.1 Frequency of different types of monoclonal proteins produced by plasma cell tumors

Type of monoclonal protein	%
IgG	52
IgA	21
IgD	2
IgE	<0.01
IgM (Waldenström's)	12
Light chain only (κ or λ)	11
Heavy chain only (α , γ , μ)	<1
Two or more	0.5
None detected	1

The majority of myeloma patients have disseminated disease at diagnosis; however, a small number may present with localized myelomatous involvement (plasmacytoma). The type and nature of the myelomatous involvement, as well as associated cytokines produced, determines its manifestations. Specifically, the presenting symptoms are related to the extent of bone marrow involvement, the amount and type of immunoglobulins produced (especially with regard to renal manifestations), the immune reactivity of the monoclonal antibodies, and tumor cell microenvironmental interactions, with production of critical cytokines driving bone resorption. Presenting features may include bone marrow-related symptoms such as anemia, osteolytic lesions with pain, pathological fractures or development of vertebral collapse, immune deficiency with susceptibility to infections, and renal dysfunction. Especially in an early-stage myeloma, the disease is diagnosed in an asymptomatic setting on routine laboratory examination.

Due to recent advances in our understanding of the disease biology, therapeutic options are not limited to cytotoxic agents; both interactions between the malignant cells and microenvironment and factors in the bone marrow milieu are potential targets for novel therapies.

Epidemiology

Multiple myeloma is a relatively uncommon malignancy, accounting for only 1% of all cancers in the Caucasian population. However, it is the second most common hematological cancer, comprising 10% of malignancies. The median age at diagnosis is 71 years, with 14 600 new cases in the USA in 2003. The estimated annual US mortality was 10 900 in 2002. In the USA, the average annual age-adjusted incidence rates per 100 000 are 6.7 for men and 4.2 for women among Whites, and 12.9 for men and 10.4 for women among Blacks. There is a significant association with advancing age. As seen in Figure 34.1, there is a sharp

Figure 34.1 Multiple myeloma: average annual age-, sex-, and racespecific incidence per 100000 in the USA, 1997–2000. An increase in incidence is noted with advancing age, and a higher incidence is observed in males than females and in African-American than Caucasian populations.

increase in the incidence of myeloma beyond 50 years of age. The incidence is higher in men and twofold higher in Blacks in all age groups. A substantially lower incidence is observed in Chinese and Japanese populations, whereas the incidence in other ethnic groups, including Native Hawaiians, Americans, and Alaskans is higher than in US Caucasians in the same geographical area. The reason for the higher incidence of myeloma in African-Americans remains unclear, since social or economic conditions, household size, and family income cannot account for this.³

Risk factors

The etiology of multiple myeloma and monoclonal gammopathy remains obscure. However, a number of environmental and familial risk factors have been described.

Environmental exposures

The strongest single factor linked to an increased risk of myeloma is exposure to ionizing radiation.⁴ Evidence from atomic bomb survivors and people exposed to low levels of radiation (including radiologists and those handling radioactive materials) suggests an increased incidence of myeloma after a latent period of up to 20 years.^{5,6} There have been some reports of a potential risk of myeloma from exposure to metals (especially nickel), agricultural chemicals, benzene and petroleum products, other aromatic hydrocarbons, and silicones. However, the overall risk of developing myeloma following such exposure remains unclear.^{4,7–12} Alcohol and tobacco consumption has not been clearly linked to myeloma. Among medications, only mineral oil used as a laxative has been reported to be associated with an increased risk of myeloma in some patients.^{13,14}

Familial and genetic factors

Direct genetic linkage has not been established in myeloma;¹⁵ however, familial occurrence has been reported.^{16,17} It remains unclear whether these occurrences are a result of genetic factors or due to shared environmental conditions. The risk of developing myeloma appears to be enhanced in the setting of HLA-B5 and HLA-Cw2 in both African-American and Caucasian populations.¹⁸

Relationship with other medical conditions

A number of case-control studies have examined the relationship between myeloma and certain other medical conditions. Repeated infections or antigenic stimulation of the plasma cell compartment have been proposed as possible predisposing conditions for myeloma. A relationship between viral and bacterial infections, allergies, and autoimmune conditions has been studied; to date, conclusive evidence of an association is lacking.

Premyeloma conditions

The presence of a monoclonal protein at low levels without any other manifestations of myeloma occurs in 3% of the population older than 50 years. Although such monoclonal gammopathy of undetermined significance (MGUS) has been considered to be a premalignant condition, the rate of conversion to myeloma associated with additional genetic changes remains extremely low.^{19,20} MGUS in mice is dependent on the strain of mice, ageing, pre-existing immune status, and antigenic stimulation. In humans, MGUS is correlated with age and associated with immune disorders and infectious diseases. In one report, of 57 patients with MGUS who had undergone evaluation for *Helicobacter pylori* infection for various gastrointestinal symptoms, 39 (68%) had evidence of *H. pylori* infection and 11 of these 39 (28%) had normalization of the serum paraproteins following eradication of *H. pylori* infection.²¹ Seroprevalence of *H. pylori*, however, has not been consistently associated with MGUS.²² The development of MGUS has also been reported in the setting of T-cell deficiency, i.e. in AIDS.²³

Myeloma cells

Phenotype

The identification of myeloma cells is based on morphological characteristics observed with Wright-Giemsa staining as shown in Figure 34.2. Morphologically, it is difficult to distinguish myeloma cells from normal plasma cells, except for dysmorphic characteristics, including multinucleate forms, cells in clusters and sheets, and plasmablastic characteristics in myeloma. Myeloma cells express monoclonal light and heavy chains, evidenced by staining for cytoplasmic κ and λ light chain. Additionally, myeloma cells are CD138⁺, CD38⁺, and CD45⁻. Details of other markers are shown in Table 34.2.

Karyotypic abnormalities

Conventional chromosomal analysis is limited owing to the low mitotic activity of plasma cells, detecting abnormalities in only 20–30% of cases. This is a significant under-representation, as a majority of malignant cells are aneuploid on flow cytometry. However, newer techniques of multicolor fluorescence in situ hybridization (FISH) and spectral karyotyping (SKY), as well as refined G-banding techniques, have identified many non-random changes in a large fraction of patients.^{24,25}

Karyotypic abnormalities identified by FISH can already be detected in individuals with MGUS. Chromosomal abnormalities in myeloma are typically complex, with an average of 11 numerical and structural abnormalities per cell, and increase with disease progression.^{26–28} Structural abnormalities frequently include translocations involving 14q32 at the switch regions. Southern blot assay detects translocations that are not detectable by conventional karyotypic

analysis; these translocations induce dysregulation of several oncogenes and are hypothesized to be initiating events.²⁴ Spectral karyotyping affords additional help in defining these translocations.²⁵

Molecular abnormalities

Translocations involving the immunoglobulin heavy chain gene at 14q32 are detected in 20–30% of myeloma cases by conventional cytogenetics and in a higher percentage of patients using molecular techniques.^{26,27,29} These abnormalities are also present in MGUS, suggesting a role in the initial steps of the transformation.³⁰ The most frequent abnormality involving 14q32 is t(11;14), involving cyclin D1 on chromosome 11.^{29,31} (Table 34.3).

The 4p16 region contains the fibroblast growth factor receptor 3 (*FGFR3*) and *MMSET* genes. *FGFR3* is an oncogenic receptor tyrosine kinase, which may be activated by the Ig switch region translocation t(4;14)(p16.3;q32) in myeloma patients.^{32–35} Activating mutations of *FGFR3* trigger mitogen-activated protein kinase (MAPK) cascade signaling, resulting in growth of myeloma cells.³⁶ Mutated *FGFR3* has also been shown to confer resistance to caspase-3-mediated apoptosis.^{32,37} Spectral karyotyping has identified another non-random translocation, t(14;16)(q32;q22–23), involving the Ig switch region and the *c-MAF* oncogene.³⁸ The additional translocations t(9;14) and t(6;14) involve the *PAX5* and *IRF4*

Table 34.3 Non-Ig sites for illegitimate switch recombination

Chromosome	Frequency	Gene(s)	Function
11q13		30 Cyclin <i>D1</i>	induces growth

6p25		<1 <i>IRF4</i>	Transcription factor

genes, respectively;^{39,40} however, the translocating partner chromosome locus is not identified in the majority of cases. Furthermore, although 14q32 is commonly involved in translocations, its significance in myelomagenesis remains unclear owing to the variety of partner chromosomes involved and its lack of prognostic significance.

Cytogenetic abnormalities involving loss of either part or the whole of chromosome 13, or deletion of chromosome 11q, have been reported to predict poor outcome in a cohort of patients treated with high-dose melphalan and stem cell rescue.⁴¹ Perez-Simon et al²⁵ have confirmed the association of chromosome 13 abnormalities as assessed by deletion of the retinoblastoma gene (*RBI*) with advanced disease and poor outcome in a cohort of patients treated with conventional therapy. Using the *RBI* gene as a probe, FISH analysis reveals *RBI* deletion in over 40% of these patients.⁴² Additionally, constitutive phosphorylation of the retinoblastoma protein (pRB) in myeloma cells can be further enhanced by interleukin-6 (IL-6).⁴³ Abnormalities in *p16* and *p15* have been reported in 75% and 67% of myeloma patients, respectively, suggesting an important defect in the pRB regulatory pathway.⁴⁴⁻⁴⁷

Microenvironment

Myeloma cells express adhesion molecules that mediate interaction with the microenvironment, including both bone marrow stromal cell elements and extracellular matrix proteins (Table 34.4). Adhesion plays a significant role in the migration and localization of myeloma cells in the bone marrow and also induces tumor cell growth and survival. For example syndecan-1, a myeloma cell surface transmembrane heparan sulfate proteoglycan regulates growth of myeloma cells via interaction with type-I collagen; and mediates increased osteoclast activity.⁴⁸⁻⁵⁰ Elevated serum levels of syndecan-1 correlate with increased tumor mass, and poor prognosis.⁴⁸ Besides the adhesion-induced signaling mediating growth, survival, and anti-apoptosis, binding of myeloma

cells to bone marrow stromal cells also induces transcription and secretion of cytokines. As seen in Figure 34.3, adhesion of myeloma cell to bone marrow stromal cells triggers production of IL-6, insulin-like growth factor 1 (IGF-1), vascular endothelial growth factor (VEGF), stromal cell-derived factor 1 (SDF-1), and tumor necrosis factor α (TNF- α),⁵¹⁻⁵⁵ which mediate tumor cell growth, survival drug resistance, and migration.

The biological and clinical relevance of increased angiogenesis, have only recently been evaluated in multiple myeloma. Increased bone marrow microvessel density (MVD) has been reported in patients with multiple myeloma compared with individuals with MGUS.⁵⁶⁻⁵⁸ Moreover, in patients with myeloma, the degree of MVD has been correlated with prognosis.^{59,60} Immunohistochemical studies show that VEGF, an important angiogenic factor, is expressed by myeloma cells.⁶¹ Hepatocyte growth factor, which also promotes angiogenesis, is increased in the serum of myeloma patients and predicts a negative outcome, especially in patients with increased β_2 -microglobulin levels.⁶² Finally, novel agents that can overcome drug resistance in myeloma, such as thalidomide, inhibit angiogenesis.

Figure 34.3 Induction of cytokine secretion triggered by myeloma cell binding to bone marrow stromal cells (BMSC): IL-6, interleukin-6; VEGF, vascular endothelial growth factor; IGF-I, insulin-like growth factor I; SDF-1α, stromal cell-derived factor 1α.^{51,53–55}

Role of cytokines

Myeloma cells and bone marrow stromal cells through their interaction produces cytokines, including IL-6,⁵¹ IGF-I,⁵⁵ VEGF,⁵³ SDF-1,⁵⁴ TNF-α,⁵² transforming growth factor β (TGF-β),⁶³ IL-21,⁶⁴ and others that mediate tumor cell growth, survival, anti-apoptosis, migration, and development of drug resistance.

Interleukin 6

IL-6 is an essential growth and survival factor for myeloma. The IL-6 receptor (IL-6R), composed of two polypeptide components: the α chain (gp80, IL-6Rα) and the signal transducing element, the β chain (gp130), is expressed by myeloma cells. The gp130 component is shared by a family of cytokines, including oncostatin M (OSM) and leukemia inhibitory factor (LIF). Interaction of IL-6 with its receptor activates the RAS/RAF/MEK/ERK pathway mediating proliferation, JAK/STAT pathway modulating anti-apoptosis, and PI3K/AKT signaling pathway mediating cell cycle in development of drug resistance (Figure 34.4). IL-6 is mainly produced by stromal cells following binding of myeloma cells and is also triggered by other cytokines including TNF-α,⁵² IL-1β and VEGF in the bone marrow milieu.⁵³ IL-6 increases the proportion of myeloma cells in S phase, prevents apoptosis of malignant plasma cells, and confers resistance to antitumor agents such as dexamethasone. Dexamethasone induced apoptosis is mediated by caspase-9 and -3 activation; IL-6 blocks caspase-9 activation, thereby protecting cells. Soluble IL-6Rα, can amplify the responses of myeloma cells to IL-6; interestingly, both high serum IL-6Rα levels and high serum IL-6 levels are associated with poor prognosis. IL-6 and soluble IL-6Rα also mediate enhanced bone resorption by osteoclasts. IL-6 has been targeted therapeutically by antibodies specific for IL-6 or IL-6R, as well as by using an IL-6 superantagonist (SANT-7), which binds IL-6R but does not trigger downstream signaling. These treatment approaches have failed to show significant responses. Neutralizing anti-IL-6 murine monoclonal antibodies have been administered either locally (malignant pleural effusions) or intravenously in patients with advanced myeloma; although clinical responses were not seen, therapy reduced the survival and proliferation of malignant

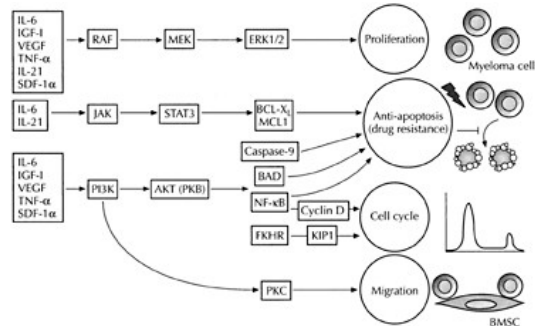

Figure 34.4 Cytokine-mediated signaling cascades inducing growth, anti-apoptosis (drug resistance), and migration in myeloma.

plasma cells, confirming a role for IL-6 in mediating myeloma growth in vivo.

Insulin-like growth factor I

IGF-I is also a growth and survival factor in myeloma. It activates the phosphoinositol 3'-kinase (PI3K) and MAPK signaling pathways mediating myeloma cell proliferation and anti-apoptosis.^{65,66} It induces more potent anti-apoptotic activity against dexamethasone, than does IL-6. IGF-I enhances tumor cell growth and survival by upregulating FLIP, XIAP, and A1/Bfl1,⁶⁵ and by increasing telomerase activity.⁶⁷ We have recently shown that IGF-I mediates adhesion and migration of myeloma cells via β_1 -integrin.^{55,68} These studies have provided a rationale for the use of IGF-I as a therapeutic target, and both anti-IGF-I antibodies and small-molecule inhibitors of IGF-I show promise in preclinical studies.

Vascular endothelial growth factor

VEGF has only modest direct effects on myeloma cells; however, it plays a significant role in triggering tumor cell migration and angiogenesis.^{69,70} Its production is upregulated both by myeloma cell adhesion to stromal cells and by IL-6.⁷¹ It is a specific endothelial cell mitogen, and elevated VEGF levels in myeloma may account, at least in part, for increased angiogenesis.⁶¹ Myeloma cells express VEGF receptor FLT1, and VEGF triggers its phosphorylation and the consequent activation of downstream MEK (MAPK/ERK kinase) and PKC α (protein kinase C α) signaling. These data have provided the preclinical rationale to evaluate VEGF as a therapeutic target. PTK787, a potent inhibitor of the VEGF receptor, has shown antimyeloma activity⁷² and is being evaluated in early clinical trials.

Other cytokines

A number of other cytokines play an important role in myeloma biology. TNF- α , secreted by myeloma cells, has little direct effect on myeloma cell growth and survival. However, it induces secretion of IL-6 by bone marrow stromal cells. It is also a strong inducer of NF κ B activation, thereby upregulating adhesion molecules, binding to the bone marrow stroma, and cell adhesion-mediated drug resistance (CAMDR). Although thalidomide and its IMiD analogs, which have potent anti-TNF- α activity, are effective in novel treatments, specific antibody inhibitors of TNF- α have not shown a clinical response.

SDF-1 α is expressed by bone marrow stromal cells, and its receptor CXCR4 is expressed by myeloma cells. It induces only a minimal proliferative effect; however, it mediates migration and adhesion, thereby inducing IL-6 secretion and drug resistance. IL-21 directly induces proliferation and anti-apoptosis independent of IL-6 signaling. TNF- α upregulates expression of both IL-21 and IL-21R. IL-21 triggers phosphorylation of Jak1, STAT3, and ERK1/2 (p44/p42 mitogen-activated protein kinases).

TGF- β is produced by myeloma cells and induces secretion of IL-6 by bone marrow stromal cells. It also mediates the immunosuppression characteristic of myeloma.

Signaling pathways

Drug resistance

As a result of intrinsic and acquired resistance to conventional chemotherapy only 50% of patients with multiple myeloma achieve a partial response, with only few complete responses. There are several drug resistance mechanisms operative in myeloma.⁷³ First, altered intracellular drug concentration due to overexpression of the multidrug resistance (*MDR1*) gene, which functions as an ATP-dependent drug efflux pump. Cyclosporine (cyclosporin A) and verapamil inhibit this function and have been tested as chemosensitizers, with only modest short-term benefit.⁷⁴ PSC833, a non-immunosuppressive and non-nephrotoxic derivative of cyclosporine D, has also been evaluated in a phase II trial, with limited success.^{75,76} Second, multidrug resistance-associated protein (MRP), a member of the ATP-binding cassette (ABC) transporter gene superfamily, may also be partially responsible for clinical drug resistance.⁷⁷ Third, expression of lung resistance related protein (LRP), a member of vault proteins (MVP), localized to the nuclear membrane and involved in the transport of substances such as alkylating agents to the nucleus is associated with poor response and shortened survival.⁷⁸ However, dose intensification of melphalan has been shown to overcome the resistance due to increased LRP expression.⁷⁹

Clinical features

The most frequent presenting symptom of multiple myeloma is bone pain, especially back pain, usually caused by lytic bone lesions or pathological compression fractures of one or more vertebrae. A radiographic survey of the entire skeleton, including both femora and humeri, identifies either osteopenia or lytic lesions in 80% of patients with myeloma. As the bone disease in myeloma is mainly lytic, due to increased osteoclastic activity and minimal osteoblastic activity, a bone scan is not useful in diagnosis or follow-up. More recently, magnetic resonance imaging (MRI) with inversion recovery imaging (STIR) has provided greater sensitivity to detect bone disease, as

well as bone marrow infiltration that is not detected on plain radiographs. Interestingly, the incidence of back pain as a presenting feature decreased from 68% in the 1960s and 1970s to 37% in the 1980s, and about 20% of myeloma patients are asymptomatic and are diagnosed by chance during routine laboratory examinations.

Acute or chronic renal failure is detected in about 20% of myeloma patients at presentation, and it increases during the course of the disease. Bence Jones proteinuria, with light-chain deposition disease or cast nephropathy, and hypercalcemia are responsible for more than 95% of renal impairment. Other causes of renal compromise include hyperuricemia, amyloidosis, pyelonephritis, and the use of non-steroidal anti-inflammatory drugs (NSAIDs) for pain control.

A normochromic anemia is present in about 60% of cases at diagnosis; this is usually due to bone marrow infiltration with plasma cells, other contributing factors being renal failure with decreased erythropoietin production, and plasma volume expansion.

Myeloma patients are susceptible to bacterial infections due to both the profound reduction of normal immunoglobulin production and the inadequate response to antigenic stimuli. The mechanism of immunosuppression is multifactorial. Pneumonia is the most common infection, followed by urinary tract infection. The deposition of immunoglobulin produced by the

myeloma cells may lead to organ dysfunction. This deposition may be predominantly localized to the kidney or may be systemic in the form of amyloidosis. Amyloidosis is diagnosed based on the demonstration of AL amyloid deposit in abdominal fat (sensitivity 80%), rectum (sensitivity 75%), or other target organs including kidney, liver, and heart. Clinical presentation of AL amyloidosis may include proteinuria, nephritic syndrome, renal failure, congestive heart failure, and hepatomegaly.

Diagnosis

The initial evaluation of myeloma includes a hemogram, serum and urine protein electrophoresis and immunofixation, quantitative serum immunoglobulin levels, urinary protein and Bence Jones protein excretion in 24 hours, complete skeletal radiographic survey, and bone marrow aspiration and biopsy. The diagnostic criteria for MGUS, smoldering and indolent myeloma, and multiple myeloma are based on the presence of monoclonal immunoglobulins in serum and/or urine, bone marrow plasmacytosis, and lytic bone lesions. The precise well-defined diagnostic criteria are shown in Table 34.5. Following establishment of diagnosis, more detailed cellular and molecular studies (Table 34.6) are required to stage myeloma and evaluate prognostic variables that may help to both plan appropriate therapy and predict patient outcome.

Table 34.5 Diagnostic criteria for multiple myeloma, myeloma variants, and monoclonal gammopathy of unknown significance (MGUS)

Multiple myeloma

Major criteria

- I. Plasmacytoma on tissue biopsy
- II. Bone marrow plasmacytosis with >30% plasma cells
- III. Monoclonal globulin spike on serum electrophoresis exceeding 3.5 g/dl for IgG or 2 g/dl for IgA \geq 1 g/24 h of A light-chain excretion on urine electrophoresis in the presence of amyloidosis

Minor criteria

- a. Bone marrow plasmacytosis 10–30%
- b. Monoclonal globulin spike present but less than the level defined above
- c. Lytic bone lesions
- d. Suppressed uninvolved immunoglobulins; IgM <50 mg/dl, IgA <100 mg/dl, or IgG <600 mg/dl

Diagnosis is confirmed when any of the following features are documented in symptomatic patients with clearly progressive disease:

- I+b, I+c, I+d (I+a not sufficient)
- II+b, II+c, II+d
- III+a, III+c, I+I+d
- a+b+c, a+b+d+d (i.e. three minor criteria must include a+b)

Indolent myeloma

Same as myeloma, except:

- No bone lesions or only limited bone lesion (\leq 3 lytic lesions): no compression fractures
- M-component levels: (a) IgG <7 g/dl; (b) IgA <5 g/dl
- No symptoms or associated disease features, i.e.
 - Performance status >70%
 - Hemoglobin >10 g/dl
 - Serum calcium normal
 - Serum creatinine <2 mg/dl
 - No infections

Smoldering myeloma

Same as indolent myeloma, except:

- No bone lesions
- Bone marrow plasma cells \leq 30%

Monoclonal gammopathy of unknown significance

- Monoclonal gammopathy
- M-component level:
 - IgG \leq 3.5 g/dl
 - IgA \leq 2 g/dl
- Bence Jones protein \leq 1 g/24 h
- Bone marrow plasma cells <10%
- No bone lesions
- No symptoms

Therapy

Combination chemotherapy has been used for the treatment of multiple myeloma for over 30 years. The advent of high-dose chemotherapy and autologous stem cell transplantation, combined with the recent development of novel biologically based therapies, has changed the way in which myeloma is managed. An important question is when to start treatment in a patient with myeloma, since early diagnosis and treatment do not form the basis of successful therapy in myeloma. A patient with asymptomatic or smoldering myeloma is currently not treated, since a randomized study in early-stage myeloma showed no difference in remission duration or overall survival in groups of patients promptly treated with early induction therapy versus initiation of chemotherapy only at the time of progression of disease.⁸⁰ Therapy can be safely deferred in the absence of symptomatic disease or signs of progression, including a rise in M-component in serum and/or urine, increase in number or size of the lytic bone lesions, anemia, renal failure, and hypercalcemia.

Response evaluation

Serum immunoglobulin levels, as well as monoclonal protein (M-protein) levels detected in serum or urine by protein electrophoresis, provide an easy and reliable method to evaluate response to therapy. In the past, various degrees of reduction in serum M-protein levels (>25% to >75%) were classified as partial responses (PR), while a complete response (CR) required the total disappearance of serum M-proteins. Due to higher renal catabolism, urine Bence Jones proteinuria is reduced more quickly, and response criteria have therefore required higher levels of reduction (>90%) to achieve partial response. At present, the European Group for Blood and Marrow Transplantation (EBMT) criteria are most commonly utilized.⁸¹ A CR requires the disappearance of M-protein in serum and urine confirmed by negative immunofixation, with normalization of bone marrow on two determinations 6 weeks apart. A PR requires a 50% reduction in serum or a 90% reduction in urine paraproteins, again on two determinations 6 weeks apart.

It should be noted that molecular evaluation using sensitive allele-specific polymerase chain reaction (PCR) techniques can detect minimal residual disease in patients otherwise considered in complete remission by the conventional criteria described above. Moreover, an early reduction in M-component by more than 50% during the first or second course of combination chemotherapy may be reflective of myeloma cells with higher proliferative potential and paradoxically portend a poor prognosis.⁸²⁻⁸⁵

Although improvement in bone lesions is not traditionally considered a response criterion since bony defects rarely heal, the appearance of new bone lesions is indicative of progressive disease. Disappearance of lesions observed on MRI and positron emission tomography (PET) scans have been described; however, this criterion has not yet been incorporated into the definition of complete response.

Measurement of free light chains in serum is a new test that provides an accurate measurement of disease burden, especially in patients with light-chain-only disease, with non-secretory or oligosecretory myeloma, and in AL amyloid. Due to the shorter half-life of free light chains, the degree of change in serum levels of free light chains, as well as the change in the $\kappa:\lambda$ ratio of the free light chains, required for achieving PR or CR, have not yet been defined.

Standard-dose chemotherapy

Melphalan in combination with prednisone (MP) has been a standard regimen with convenient oral dosing for over 30 years. Melphalan is administered orally at 0.25 mg/kg on days 1–4, and prednisone at 60–100 mg on days 1–4. Due to unpredictable

absorption, the dosage of oral melphalan is modified if the patient does not develop cytopenia. A partial response, defined by a greater than 50% reduction in M-protein, has been observed in over 50% of patients, but CR is rare. Patients achieving stable disease with MP also have improved survival. Subsequently, combinations of vincristine and doxorubicin with oral dexamethasone (VAD) were demonstrated to achieve more rapid responses in a significant fraction of patients. This regimen achieves 40–60% responses, with a median remission duration of 18 months and have extended the overall survival beyond 3 years.

Intensification of these regimens by adding other agents may result in higher response rates, but does not increase survival. The common chemotherapeutic combinations used in myeloma are listed in Table 34.7. A meta-analysis of 18 published randomized trials comprising 3814 patients comparing MP with other combination regimens failed to show any survival advantage over MP. Selection of initial combination therapy has therefore been determined based on toxicity and plans for future high-dose therapy and stem cell transplantation regimens. Since melphalan and other alkylating agents cause stem cell damage, these agents are avoided in patients who are potential candidates for stem cell transplantation.

High-dose therapy and stem cell transplantation

Conventional chemotherapy achieves a CR in no more than 5% of patients. Based on a log—linear dose-response effect in killing tumor cells in vitro by most alkylating agents, McElwain and Powles first reported on the ability of high doses of intravenous melphalan to overcome relative drug resistance and induce CR in previously treated myeloma patients.^{86,87} The Intergroupe Français du Myelome was the first to conduct a randomized clinical trial (IFM-90) comparing 1 year of standard-dose chemotherapy consisting of VMCP (vincristine, melphalan, cyclophosphamide, and prednisone) alternating with BVAP (carmustine, vincristine, doxorubicin, and prednisone) with a short course of the same standard-dose induction chemotherapy followed by consolidation with high-dose therapy (HDT) consisting of melphalan with total body irradiation (TBI) followed by autologous bone marrow transplantation.⁸⁸ An updated analysis of this randomized trial presented by Attal et al⁸⁸ confirmed the benefits of HDT in terms of higher CR rate (22% versus 5%), event-free survival (EFS) time (median 28 months versus 18 months), and overall survival (OS) time (median 57 months versus 44 months) than observed in patients treated with standard-dose chemotherapy (Figure 34.5).

A similar response and survival benefit has been reported more recently from the Medical Research Council (MRC)-VII trial, which randomized 407 patients to either standard-dose chemotherapy or HDT with stem cell transplantation.⁸⁹ A Spanish trial of 164 patients treated with HDT versus conventional therapy also showed a superior CR rate in the HDT arm, with a trend for prolonged EFS and OS in the HDT arm (Table 34.8).⁹⁰ In contrast, the MAG trial by Fermand et al⁹¹ of 190 newly diagnosed myeloma patients failed to show superiority of HDT. More recently, the US Intergroup study randomizing patients between HDT versus conventional therapy followed by delayed HDT at relapse failed to show superiority of HDT for either achievement of CR or overall survival.⁹² In this study, a significant fraction of patients received HDT as salvage therapy after relapsing in the conventional-therapy cohort. In this group, 52% of 161 patients failing conventional therapy received HDT as salvage; their response rate was 59% and their survival post relapse was 30 months versus 23 months for those not receiving salvage HDT ($p=0.05$). Although three out of five studies show a benefit of HDT (Table 34.8), the duration of benefit after HDT remains limited. The improvement in EFS and OS after HDT versus conventional-dose therapy has ranged from 4 to 12 months and from 1 to >23 months, respectively.

Table 34.8 Results of large randomized studies comparing standard-dose therapy versus high-dose therapy (HDT)

Ref	No. of patients	CR rate (%)	EFS (median, months)	OS (median, months)
88	Conventional	100	5 ^a 18*	37 ^a
	HDT	100	22 27	52% at 60
91	Conventional	96	— 18.7 ^a	50.4

Conditioning regimen

Melphalan with or without TBI is the most commonly employed regimen. Regimens commonly used in leukemia or lymphoma (namely, busulfancytosphamide, cyclophosphamide-TBI; BEAM (carmustine, etoposide, cytarabine, and melphalan), or CBV (cyclophosphamide, carmustine, and etoposide)) have also been tested in myeloma.^{93,94} None of these regimens has shown superiority over melphalan alone in the analysis of EBMT or American Bone Marrow Transplant Registry data.⁹⁵ Importantly, the addition of TBI adds significant morbidity without benefit. Data from retrospective studies—both single-center⁹⁶ and the EBMT Registry⁹⁷—show that patients receiving a regimen containing TBI fared poorly compared with those receiving melphalan alone. In a randomized study in 282 newly diagnosed patients by the Intergroupe Francophone du Myelome, patients receiving melphalan (200 mg/m²) had statistically superior survival compared with those receiving melphalan (140 mg/m²) with TBI (8 Gy). Patients on the melphalan-only arm also had significantly less toxicity. The response rates and EFS rates were identical in the two arms of the study.⁹⁸

Tandem transplants

Attempts to further improve the results of autologous stem cell transplantation have included intensification with tandem transplants. Harousseau et al⁹⁹ were the first to report the feasibility of tandem autologous bone marrow transplantation, with a 69% CR in a small select group of patients. Barlogie et al¹⁰⁰ investigated a sequential non-cross-resistant remission induction regimen, followed by tandem autologous transplantations ('total therapy'), in 231 newly diagnosed patients; 41% patients achieved CR after two transplants, and the median EFS and OS times were 43 months and 68 months, respectively.

Attal et al¹⁰¹ from the Intergroupe Français du Myelome have recently reported a randomized comparison (IFM-94) of single HDT (melphalan 140 mg/m² and TBI 8 Gy) versus double HDT (melphalan 200 mg/m², followed by melphalan 140 mg/m² and TBI 8 Gy) in 399 newly diagnosed patients. This study reports no significant improvement in CR or a very good PR rate between the two arms (42% versus 50%, respectively; $p=0.10$); however, there was a significant improvement in the probability of EFS at 7 years (10% versus 20%; $p=0.03$) and in the estimated OS rate at 7 years (21% versus 42%; $p=0.01$) in favor of the double-HDT arm (Figure 34.6). The Myelome Autogreffe Group (MAG) ($n=193$), DutchBelgian Hematology-Oncology Cooperative Group (HOVON) ($n=255$), and Bologna ($n=178$) trials have a median follow-up of 27–30 months, and have not yet shown a significant benefit for tandem transplantation.

Timing of high-dose therapy

Multi-institutional trials demonstrating that HDT as initial therapy prolongs remission duration and survival but is not curative have led to the exploration of the question whether HDT should be used early after diagnosis versus delayed as a treatment for relapsed myeloma. To evaluate this important question, Fermand et al⁹¹ randomized 185 newly diagnosed patients to undergo three or four cycles of VAMP (vinblastine, doxorubicin, methotrexate, and prednisone)

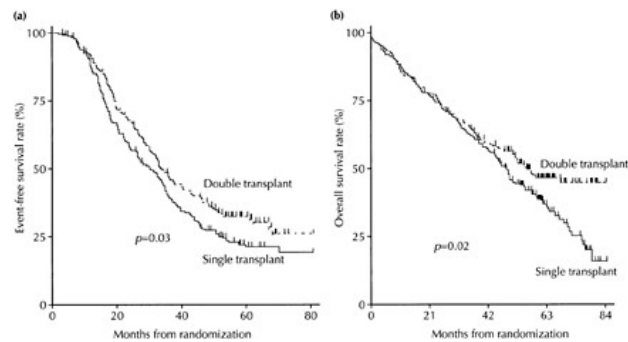

Figure 34.6 Event-free (a) and overall (b) survival with single versus double high-dose chemotherapy. IFM-94 randomized study.

followed by early HDT and autotransplantation (n=91), or conventional chemotherapy with VMCP for 1 year. The latter group of patients were offered HDT if they had primary refractory disease or upon relapse (n=94). Although patients who underwent early transplantation had significantly longer EFS times (39 months versus 13 months), the overall survival was identical in both arms (median 64.6 months and 64 months). Importantly, the time without symptoms and treatment analysis reflecting quality of life (mean 27.8 months versus 22.3 months) showed superior results for the early-HDT arm. Vesole et al¹⁰² have confirmed the effectiveness of high-dose chemotherapy as salvage therapy, achieving EFS and OS times of 21 months and >43 months, respectively, in 135 patients with advanced refractory myeloma. In this study, patients with primary unresponsive disease had superior outcomes to patients with resistant relapse progression on last-salvage chemotherapy, with EFS times of 37 months versus 17 months, respectively ($p=0.0004$), and OS times of ≥ 43 months versus 21 months, respectively ($p=0.0003$). Gertz et al¹⁰³ from the Mayo Clinic have also reported a similar experience in 64 patients undergoing elective delayed transplant at the time of progression following standard therapy.

Hematopoietic stem cell source and purging

Compared with bone marrow stem cells (BMSC), mobilized peripheral blood stem cells (PBSC) provide more rapid engraftment, and have therefore become the favored source of stem cells. For example, the IFM-94 study demonstrated more rapid hematopoietic recovery with PBSC support compared with BMSC support,¹⁰¹ with similar EFS and OS durations. Successful mobilization of adequate numbers of stem cells depends on the duration and type of prior chemotherapy, especially stem cell-damaging agents, and radiation to bone marrow-containing areas. As the duration of prior standard-dose chemotherapy increases, the ability to collect adequate numbers of stem cells decreases. In one study, 86% of patients who received less than 12 months of prior therapy successfully mobilized 2×10^6 or more CD34+ cells/kg, compared with 48% of patients with more than 24 months of prior therapy.¹⁰⁴ Additionally, myeloma patients who had received less than 1 year of prior therapy had more rapid granulocyte and platelet recovery after PBSC.

Virtually all stem cell products have detectable myeloma cells as evaluated by immunofluorescence techniques or PCR assays.¹⁰⁵ Purging of tumor cells using a monoclonal antibody cocktail containing CD 10 (the common acute lymphoblastic leukemia antigen, CALLA), CD20 (a pan-B-cell antigen), plasma cell-associated antigen 1 and complement lysing, or using peanut agglutinin and anti-CD 19 antibodies, has not improved outcomes. Positive selection of CD34+ cells to deplete myeloma cells results in 3–5 log reductions in contamination.^{106,107} However, the success in obtaining a tumor-free graft has not translated into any significant advantage in response or survival time. A large, multicenter, randomized study comparing CD34-selected cells versus unselected PBSC in 131 patients failed to show any significant differences in EFS or OS times.¹⁰⁷ Finally, a pilot study selecting very early hematopoietic stem cells (CD34+ Thyl+ Lur) devoid of any clonal B-cell contamination¹⁰⁸ resulted in delayed hematopoietic engraftment and prolonged immune suppression. Due to these results, emphasis is now on strategies to improve responses to HDT rather than purging autografts.

Management of older patients

As the incidence of myeloma increases with age, the role of HDT has been evaluated in patients over 65 years old. Older age has not been reported to affect stem cell mobilization or engraftment.¹⁰⁹ The feasibility and efficacy of HDT with PBSC transplantation in patients aged 70 years or older has been evaluated in 70 patients (median age 72 years, range 70–83 years) treated with melphalan (200 or 140 mg/m²).¹¹⁰ In this study, the treatment-related mortality rate was higher (16%) in the initial 25 patients receiving melphalan at 200 mg/m². Although CR was achieved in 27%, the median CR duration was only 1.5 years, with 3-year EFS and OS rates projected at 20% and 31%, respectively. Although this study confirms the feasibility of HDT in older patients with myeloma, it also indicates a higher risk in this patient population, and highlights the need for strict patient selection based on clinical status.

Management of patients with renal dysfunction

Although one-third of patients with symptomatic myeloma present with renal insufficiency, hydration, control of hypercalcemia and effective therapy, can reverse it in 50% of cases. Renal dysfunction of less than 6 months' duration, with rapid initiation of therapy and a reduction in M-protein, is associated with a higher likelihood of improving renal function. Improvement in renal function is mainly observed in patients with light-chain cast nephropathy and lightchain deposition disease; therefore, renal biopsy is used to identify these reversible conditions, where there is a need for aggressive treatment. Based on the observation that the pharmacokinetics of melphalan are unaltered by renal failure,¹¹¹ high-dose melphalan and PBSC transplantation was used to treat 81 patients with myeloma and renal failure (creatinine >2 mg/dl).¹¹² In this setting, renal failure had no impact on the quality of stem cell collection and/or engraftment. However, treatment-related mortality

rates were 6% and 13% after the first and second autologous stem cell transplants, respectively, and melphalan at 200 mg/m² caused excessive toxicity. A CR was achieved in 31 patients (38%) after tandem transplantation, and the probabilities of EFS and OS to 3 years were 48% and 55%, respectively. Dose reduction and close monitoring are needed to ensure the safety of the procedure, and the role of transplantation in the setting of renal failure remains investigational.

Recent developments in novel therapies have provided alternative strategies for the treatment of myeloma in the setting of renal failure. Thalidomide, bortezomib, and arsenic trioxide have all been evaluated in this setting. Ease of administration, limited toxicity, and effectiveness make these primary modes of therapy for myeloma patients with renal failure.

Maintenance therapy

Despite improvements in remission rates, there is no clear plateau in the survival curves following conventional therapy or HDT. Although the proportion of patients achieving CR has increased, all patients eventually relapse. Various maintenance therapies have been evaluated in myeloma in an effort to sustain remission. Interferon- α (IFN- α), the most widely evaluated agent as maintenance therapy, have only demonstrated modest improvements in EFS and OS times (5–12 months) in randomized studies in patients achieving remission with standard-dose therapy. The role of IFN- α following HDT has not been confirmed.¹¹³ Low-dose prednisone administered on alternate days has prolonged remission duration following standard-dose therapy in a single randomized study.¹¹⁴ Thalidomide and its analog IMiD3 (with and without added dexamethasone), bisphosphonates, and immune manipulations such as idiotype vaccination and protein-pulsed dendritic cell-based vaccination strategies are under evaluation as maintenance strategies to prolong EFS and OS in myeloma.

Allogeneic transplantation

Syngeneic transplantation

Bensinger et al¹¹⁵ have reported their experience with 11 patients receiving syngeneic transplants. Five patients achieved a CR and three achieved a PR. The most recent update shows one patient from either remission group alive 9 and 15 years after transplantation respectively. The EMBT Registry experience was reviewed by Gahrton et al.¹¹⁶ Twenty-five patients undergoing syngeneic transplantation were compared with 125 case-matched patients undergoing autologous or allogeneic transplantation. Although the CR rate (syngeneic 68%, autologous 48%, and allogeneic 58%) was not significantly different between the three grafts, patients undergoing syngeneic transplantation had a significantly superior median survival time compared with autologous (72 months versus 25 months; $p=0.009$) or allogeneic (72 months versus 16 months; $p=0.008$) transplantation.

Allogeneic transplantation

The older myeloma patient population with limited donor availability, coupled with frequent renal impairment, has restricted use of allogeneic transplantation in myeloma. Additionally, the almost 50% 1-year mortality rate has limited the use of this procedure to a high-risk patient population. Importantly, the allogeneic graft-versus-myeloma (GVM) effect may result in a favorable long-term outcome after allogeneic transplantation. A retrospective case-matched analysis of EBMT registry data compared 189 patients receiving allografts with an equal number of patients from the same time period receiving autografts. This study showed a superior median survival outcome for patients undergoing autologous compared with allogeneic transplantation (34 versus 18 months, respectively).¹¹⁷ The 1-year treatment-related mortality rate was significantly higher following allogeneic transplantation (41% with allografts and 13% with autografts). However, interestingly, patients undergoing allogeneic transplantation and surviving the first year had a tendency towards better progression-free survival and OS.

In a single-center experience from the Dana-Farber Cancer Institute a low transplant-related mortality rate of 10% has been reported with selective depletion of CD6+ T cells as the sole form of graft-versus-host-disease (GVHD) prophylaxis.¹¹⁸ However, the median progression-free survival time of 12 months, and the median OS time of 22 months was inferior to their previous experience with autologous transplantation. Another case-matched comparative single institution study has also failed to show a survival advantage for allogeneic transplants.¹¹⁹

Donor lymphocyte infusions

A GVM effect has been demonstrated by the induction of CR with donor lymphocyte infusion (DLI) following relapse after allogeneic transplantation.¹²⁰ Lokhorst et al¹²¹ have reported 6 CR and 8 PR following DLI in 27 patients after allogeneic transplantation. Five of these patients remained disease-free more than 30 months after DLI. However, DLI was associated with significant toxicity including acute GVHD in 55% and chronic GVHD in 26% of patients, five patients experiencing bone marrow aplasia, which was fatal in two cases. Strategies to reduce GVHD after DLI have included lowering the number of T cells infused, selective depletion of CD8+ T cells, and use of herpes simplex virus thymidine kinase gene (HSV-Tk)

transduction of DLI, which allows the use of ganciclovir to deplete T cells if significant GVHD develops.^{123–124} Immunizing donors with idiotype vaccine may allow selective transfer of T cells specific for GVM without increasing the incidence of GVHD.

Non-myeloablative transplants

Based on the canine model experience,¹²⁵ coupled with reduced day-100 transplant-related mortality in pilot studies in patients, allogeneic matched sibling transplantation in patients who were otherwise considered poor risk for the standard allogeneic preparative regimen has been performed. Badros et al first reported on 16 patients undergoing allogeneic transplantation following non-myeloablative conditioning with melphalan (100 mg/m²). The transplant-related mortality rate in the first 120 days was low (6%). Five CR were reported; however, acute GVHD developed in 10 patients (63%) and chronic GVHD was seen in 7 patients (44%) living beyond 4 months. Giralt et al¹²⁷ have used reduced-intensity conditioning with fludarabine and melphalan in 16 patients. Successful engraftment was observed in all patients; however, the 100-day mortality rate was 20% and the 1-year mortality rate was 40%, with only six patients alive after a median follow-up period of 15 months.

A combination of initial autologous transplantation for tumor cytoreduction followed by non-myeloablative matched sibling transplantation was evaluated by Maloney et al¹²⁸ in 54 patients. The treatment was performed in an outpatient setting, with a low 100-day mortality rate (2%). The overall response rate was 83%, with 53% CR. With a median post allograft follow-up of 552 days, the overall survival rate was 78%. However, GVHD remains a problem, with 38% of patients developing acute GVHD and 46% chronic GVHD requiring therapy.

While the early clinical results with non-myeloablative transplants are encouraging, this strategy is associated with significant morbidity due to acute and chronic GVHD and a mortality rate of up to 20% at 1 year. It should therefore only be utilized in the context of clinical trials.

Idiotype vaccinations

Myeloma is a clonal proliferation of B cells producing a monoclonal immunoglobulin. The unique idiotypic structures are expressed on the surfaces of myeloma cells, making them an attractive target for eliciting a tumor-specific immune response. Osterborg et al¹²⁹ have elicited tumor-specific T- and B-cell responses after repeated administration of monoclonal immunoglobulin mixed with alum and granulocytemacrophage colony-stimulating factor (GM-CSF). Similarly, specific T-cell responses has been reported by Kwak et al¹³⁰ in patients receiving post-transplant immunization. Vaccination with idiotype pulsed dendritic cells have also been successful in eliciting T-cell immune responses.¹³¹ It remains to be seen whether such immune responses translate into better survival.

Novel biologically based therapies

In the past three years, we and others have used *in vitro* systems and *in vivo* animal models to characterize novel therapeutic agents directed at targets specific to both the myeloma cell and its microenvironment. Improved understanding of myeloma cell survival in its microenvironment has provided such new targets. Myeloma cells adhere to the extracellular matrix and to bone marrow stromal cells, allowing myeloma cells to grow, survive, and have anti-apoptotic effects against conventional chemotherapies. These effects are mediated partly through adhesion-mediated signaling and partly through various cytokines, including IL-6, VEGF, TNF- α , and IGF-I. The molecular mechanisms mediating these effects include the RAS/RAF/MAPK, JAK-STAT, and PI3K/Akt pathways. The later pathway through N κ B provides drug resistance signals. This understanding has translated from bench to bedside in related clinical trials. Thalidomide and its analog immunomodulatory agents (IMiDs), the proteasome inhibitor Bortezomib, and arsenic trioxide (As₂O₃) are three agents that have already demonstrated marked clinical anti-myeloma activity even in patients with refractory relapsed myeloma, thus confirming the utility of our preclinical models for identifying and validating novel therapies.

Thalidomide

Although the first use of thalidomide in myeloma was based on its anti-angiogenic activity along with reports of increased angiogenesis in myeloma bone marrow, subsequent studies have demonstrated its effect both directly on myeloma cells as well as on their microenvironment.¹³² Thalidomide and the more potent analog IMiDs abrogate the adhesion of myeloma cells to bone marrow stromal cells and block the secretion of myeloma growth and survival factors such as IL-6, TNF- α , VEGF, and fibroblast growth factor (FGF), which are triggered by the binding of myeloma cells to bone marrow stromal cells (Figure 34.7). These agents also induce immune responses by improving antigen presentation by dendritic cells through inhibition of VEGF, expansion of the number and function of natural killer (NK) cells,¹³³ and providing T-cell costimulatory signals through the B7-CD28 pathway.^{134,135}

The first phase II study in 169 patients with advanced post-transplant relapsed myeloma investigated thalidomide in incremental doses of 200–800 mg, demonstrating at least partial responses in 26% of

Figure 34.7 Mechanism of action of thalidomide. (a) Direct effect on myeloma cells, (b) Effect on expression of adhesion molecules and adhesion of myeloma cells to bone marrow stromal cells (ICAM-1, intercellular adhesion molecule 1). (c) Decrease in cytokines produced by stromal cells and myeloma cells in response to their interaction (IL, interleukin; TNF- α , tumor necrosis factor α); (d) Anti-angiogenic effect due to a decrease in angiogenesis-promoting cytokines produced by myeloma cell-stromal cell interaction (VEGF, vascular endothelial growth factor; bFGF, basic fibroblast growth factor), (e) Immunomodulatory effects on T cells and natural killer (NK) cells (IFN- γ , interferon- γ).¹³³

patients, with an overall response rate of 34%.^{136,137} The efficacy of thalidomide was subsequently confirmed in several phase II studies, showing responses in 25–40% patients with relapsed myeloma.^{138–146} The major toxicities of thalidomide are somnolence, constipation, neurological symptoms, fatigue, and deep venous thrombosis.^{136,147} Based on in vitro results showing synergism as well as reversal of resistance, thalidomide has been combined with dexamethasone. This combination has achieved a response rate of over 50% in relapsed patients and a rate of 70% in newly diagnosed patients (Table 34.9).^{148,149} Excitingly, thalidomide is now being evaluated in combination with conventional therapies. Preliminary evidence suggests achievement of high CR rates. The study by Weber et al¹⁴⁸ showed a 16% CR rate with a combination of thalidomide and dexamethasone; other combinations with high CR rates include melphalan, prednisone, plus thalidomide, giving a 22% CR,¹⁵⁰ and pegylated doxorubicin, vincristine, reduced-frequency dexamethasone, plus thalidomide, giving a 46% CR or near CR rate.¹⁵¹

Based on in vitro and in vivo animal data, the thalidomide analog CC-5013 (IMiD3) has been evaluated in a derived phase I clinical trial and has shown at least a 25% reduction in paraprotein levels (minimal response) in 15 of 24 (63%) patients, including 11 patients who had received prior thalidomide. Stable disease (<25% reduction in paraprotein) was

Table 34.9 Results of combination of thalimide (T) plus dexamethasone (D) in relapsed and newly diagnosed multiple myeloma

Ref	Patient population	No. of patients	Therapy/dosing	Response rate (%)
Palumbo ¹⁵⁰ 2003	Relapsed		120 100 mg/dT + 40 mg D	52
Dimopoulos ^{150a} 2001	Refractory	44	200–400 mg/d T +20 mg/m2 D	55
148	Newly diagnosed	40	200–800 mg/d T +20 mg D	72
149	Newly diagnosed	50	200–400 mg/d T +40 mg D	64

observed in an additional 2 (8%) patients.¹⁵² Therefore, 17 (71%) of 24 patients demonstrated benefit from treatment. Although myelosuppression was the dose-limiting toxicity observed at the highest dose level, no significant somnolence, constipation, or neuropathy was seen in this study. These results therefore provide the basis for the evaluation of CC-5013, either alone or in combination, to treat patients with myeloma at earlier stages of the disease. A phase II trial of CC-5013 in patients with relapsed/refractory myeloma has achieved 10% CR, 25% PR and 40% stable disease rates. A formal evaluation of thalidomide or CC-5013, alone and/or with dexamethasone, is ongoing in newly diagnosed patients and as maintenance therapy.

Bortezomib

Bortezomib (Velcade), a boronic acid dipeptide and a novel proteasome inhibitor, has demonstrated significant activity against myeloma. Bortezomib blocks NF κ B activation and mediates anti-myeloma activity by inhibiting paracrine IL-6 production in bone marrow stromal cells. It also acts directly to induce apoptosis of myeloma cells resistant to conventional therapies, overcomes the protective effects of IL-6, and synergizes with dexamethasone for anti-myeloma effects. Importantly, it acts in the microenvironment to inhibit the binding of myeloma cells to bone marrow stromal cells, to inhibit the transcription and secretion of IL-6 triggered by adhesion of myeloma cells to stromal cells and to inhibit bone marrow angiogenesis.^{153–158} Based on exciting animal model results and a confirmed safety profile in a phase I study that in fact showed responses in both of two myeloma patients, a multicenter phase II trial of bortezomib in myeloma was completed in 2002. In this trial, 202 patients with refractory relapsed myeloma were treated with 1.3 mg of bortezomib per square meter of body-surface area twice weekly for 2 weeks, followed by 1 week without treatment, for up to eight cycles (24 weeks). Dexamethasone (20 mg orally daily for 4 days) was added to the regimen in patients with a suboptimal response. Among 193 evaluable patients, a 35% response rate was observed, including 7 CR and 12 near-CR with only immunofixation positivity.¹⁵⁹ The median duration of response was 12 months, and the median overall survival was 16 months. Grade 3 adverse events included thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), and neutropenia (11%). The drug was approved by the US Food and Drug Administration (FDA) for clinical application in patients with relapsed and refractory myeloma based on this study. Addition of dexamethasone in this study improved responses in 19% patients, confirming synergism between these two agents. A randomized study comparing bortezomib versus dexamethasone in relapsed myeloma was recently closed prematurely due to superior results with bortezomib. Evaluation of this agent in newly diagnosed patients and in combination with other agents is underway.¹⁶⁰

Arsenic trioxide

Arsenic trioxide is another agent that targets myeloma cells as well as the bone marrow microenvironment, and is available commercially. It induces apoptosis of drug-resistant myeloma cell lines and patient cells via activation of caspase-9 and decreases binding of myeloma cells to bone marrow stromal cells, thereby inhibiting secretion of IL-6 and VEGF induced by adhesion of myeloma cells to stromal cells.^{161,162} It also induces immune effects and inhibits telomerase. A phase I clinical study of arsenic trioxide showed at least a minimal response in 3 of 14 patients with refractory relapsed disease.¹⁶³ The most common toxicities include myelosuppression, neuropathy, and QT interval prolongation. An additive effect of arsenic trioxide with dexamethasone and ascorbic acid has been observed in vitro.¹⁶¹ Based on these results, an ongoing phase I/II study is evaluating the safety and efficacy of arsenic trioxide in combination with dexamethasone and ascorbic acid in patients with relapsed myeloma.¹⁶⁴

Bisphosphonates

Bisphosphonates have been extremely useful in reducing skeletal complications and bone pain in myeloma.^{165,166} Bisphosphonates, and specifically the aminobisphosphonates, have a direct effect on the bone marrow microenvironment, thereby decreasing IL-6 production and downregulating osteoclast activity. Furthermore, they activate γ/δ T cells with antimyeloma activity, and induce apoptosis of osteoclasts through inhibition of farnesyl and geranylgeranyl transferase activity.^{167,168} In addition to a reduction in skeletal events ($p=0.016$), a significant survival advantage was observed (21 months versus 14 months; $p=0.041$) in patients receiving salvage chemotherapy and pamidronate versus chemotherapy alone.^{165,169} In vitro cytotoxic effects of bisphosphonates have been observed in myeloma cell lines,^{170,171} patient cells in vitro, and tumor specimens in the SCID-hu model.¹⁷² In one report, pamidronate administered alone every 2 weeks showed a response or a delay in disease progression in occasional patients.¹⁷³ Zoledronic acid is one of the most potent bisphosphonates, and in animal studies it has been found to be superior to pamidronate in inducing osteoclast apoptosis.¹⁷² Pamidronate 90 mg, and zoledronic acid 4 mg are equipotent in reducing bone-related problems in myeloma; however, zoledronic acid has a more convenient schedule of administration over 15 minutes (compared to 1–2 hours for pamidronate). Patients may occasionally develop mild hypocalcemia and need to be closely

Figure 34.8 Novel therapies targeting myeloma cells in the bone marrow microenvironment.

observed for changes in renal function while on longterm bisphosphonate therapy.

Other potential agents

With improvements in our understanding of myeloma cell-bone marrow stromal cell interactions and of adhesion-mediated and cytokine-mediated signaling, both in vitro systems and in vivo animal models have been developed to characterize mechanisms that promote myeloma cell growth, survival, drug resistance, and migration in the bone marrow milieu. These model systems have allowed the development of several promising biologically based therapies that can target both the myeloma cell and the bone marrow microenvironment. Drugs with potential efficacy in myeloma and undergoing clinical evaluation include those that predominantly target myeloma cells (such as the telomerase inhibitor GRN 163, the heat-shock protein 90 (hsp90) inhibitor 17-AAG, TRAIL, statins, IGF-I receptor (IGF-IR) inhibitors, and farnesyl transferase inhibitors), those that target both myeloma cells and the microenvironment (such as thalidomide/revimid, bortezomib, the VEGF kinase inhibitor PTK787, the HPAC inhibitors SAHA and LAQ824, 2-methoxyestradiol, arsenic trioxide, and LPAAT inhibitors), and those that target only the bone marrow microenvironment (such as IκB kinase inhibitors and p38^{MAPK} inhibitors) (Figure 34.8).

Based on ongoing proteomic and genomic studies, these novel agents will be combined in a biologically rational approach in clinical trials to overcome drug resistance and improve patient outcome. For example, genomic studies have demonstrated the induction of hsp90, a molecular chaperone, in myeloma cells following exposure to a proteasome inhibitor. Preclinical results have shown synergistic effects with a combination of bortezomib and the hsp90 inhibitor 17-AAG, providing the rationale for molecularly based combination of these two agents. Similarly, these studies have defined the preclinical rationale for combining bortezomib with conventional DNA-damaging agents.¹⁶⁰ Ultimately, it may be possible to carry out gene profiling to define targets of sensitivity versus resistance in order to develop the next generation of more potent and less toxic therapeutics and to select combinations of targeted therapies.

35 Hodgkin lymphoma

Karolin Behringer, Volker Diehl, and Andreas Engert

Introduction

Hodgkin lymphoma (HL, Hodgkin's disease) is a malignant hematopoietic disease with annual incidence of 2.2 per 100 000 for women and 3.3 per 100 000 for men.¹ Histomorphologically, HL is characterized by Hodgkin (H) and Reed-Sternberg (RS) cells surrounded by a variety of reactive bystander cells such as lymphocytes, macrophages, neutrophils, histiocytes, and plasma cells. For more than a century, HL was regarded as a chronic inflammatory disorder, which is reflected in the old term 'lymphogranulomatosis'. After the detection of aneuploidy and monoclonality and the successful transplantation of H-RS cells into immunocompromised animals, HL is now considered a truly malignant disease.

The origin of the characteristic H-RS cells has been the subject of debate for a long time. Immunophenotyping and genetic analyses have demonstrated that up to 90% of cases have lymphocytic markers.^{2,3} H-RS cells consistently express activation antigens such as CD25, which forms the light chain of the interleukin (IL)-2 receptor, and CD30, originally detected by the monoclonal antibody Ki-1. Cloning of the CD30 molecule and its ligand CD30L demonstrated CD30/CD30L as new members of the tumor necrosis factor (TNF) receptor and ligand superfamily.⁴ Taken together, these data point towards a lymphoid origin of H-RS cells. This was further underlined by singlecell DNA sequence analysis of immunoglobulin (Ig) gene rearrangements amplified from single, micromanipulated H-RS cells, which showed that these cells largely represent clonal populations. The Ig gene rearrangements in H-RS cells strongly suggest B cells as their precursors.⁵

A possible etiological role of the Epstein-Barr virus (EBV) in HL has been discussed for many years. Data indicate that EBV is present in approximately 40% of cases^{6,7} (see Chapter 16). Thus, chronic viral infection, activation of cellular oncogenes, loss of tumor suppressor genes, and deregulation of cytokines may be factors involved in the pathogenesis of this disease.^{8,9}

Histopathology and correlation with age

The diagnosis of HL is based on morphological and immunohistochemical investigations. One of the most important criterion is the detection of H-RS cells in histological sections. In addition to the classical H-RS cells, another characteristic feature is the composition of the surrounding lymphoid and histiocytic cells. Usually, H-RS cells, which are considered the true tumor cells, represent less than 1% of the whole infiltrate. Lymphocytes, histiocytes, and other reactive cells constitute the overwhelming cell population.

According to histopathology, the bulk of classical HL can be subdivided into nodular sclerosis (NS) and mixed-cellularity (MC). NSHL shows sclerotic bands surrounding nodules in which lacunar cells are visible. These lacunar cells are variants of H-RS cells. NSHL occurs at a higher frequency among young adults and remains constant at a significantly lower level in the group over 30 years of age. According to the World Health Organization (WHO) classification, the new HL subtype lymphocyte-rich classical HL (LRCHL) and nodular lymphocyte-predominant HL (LPHL) are diagnosed at a frequency of 3–5%, and lymphocyte-depleted HL (LDHL) even less, at a frequency of less than 1%. Cases that do not fit into LP, NS, or LD subtypes or show partial infiltration are termed MCHL; their occurrence increases with age.^{10,11}

LPHL is now generally recognized as a distinct clinicopathological entity. Histologically, LPHL is characterized by large nodules composed of small lymphoid cells, usually mixed with groups of epitheloid cells. Classical H-RS cells are rare, whereas a variety of similar cells referred to as L&H cells are scattered in the nodular infiltrations. In addition to L&H and a few H-RS cells, the cellular composition, including the nodular destruction of lymph node architecture, forms a characteristic tumor mass relatively sharply demarcated from the reactive tissue. Most LPHL cases

Table 35.1 The ‘Cotswold’ staging classification

Stage	Defining features
I	Involvement of a single lymph node region or lymphoid structure (e.g, spleen, thymus, Waldeyer’s ring)
II	Involvement of two or more lymph node regions or lymphoid structures on the same side of the diaphragm
III	Involvement of lymph node regions or lymphoid structures on both sides of the diaphragm: III ₁ with or without splenic hilar, celiac, or portal nodes III ₂ with para-aortic, iliac, mesenteric nodes
IV	Involvement of extranodal site(s) beyond that designated ‘E’
Modifying characteristics	
A	No symptoms
B	Fever, drenching sweats, weight loss
X	Bulky disease; >one-third widening of mediastinum >10 cm maximum dimension of nodal mass
E	Involvement of single extranodal site, contiguous with or proximal to known nodal site
CS	Clinical stage
PS	Pathological stage

Table 35.2 Recommended procedures for staging of patients with Hodgkin lymphoma**History and examination**

B symptoms: weight loss >10% during 6 months, documented fever, night sweats

Hematology

Complete blood count

Erythrocyte sedimentation rate (ESR)

Bone marrow biopsy

Radiographic procedures

Chest X-ray

CT of neck and chest

CT of abdomen and pelvis

Ultrasound scanning

Bone scans

Under special circumstances

Magnetic resonance imaging (MRI)

Gallium scan

Positron-emission tomography (PET)

are of the nodular form. The rare cases of completely or almost completely diffuse infiltration can cause difficulties in the differential diagnosis between LPHL, T-cell-rich large B-cell lymphoma, peripheral T-cell lymphoma, and classical HL. LPHL cells express the CD20 antigen in up to 98% of cases and the CD79a antigen in 80%. In contrast, classical HL cells stain positive for CD30 in nearly all cases and for CD15 in 74% of cases.

Staging

A clinical-stage classification serves as a guide in determining the prognosis and treatment of the disease. The extent of HL is classified using the four-stage Ann Arbor classification. The absence (A) or presence (B) of systemic symptoms (fever, weight loss, and night sweats), introduced in 1965 by the Rye staging classification, is also used for staging HL.

At the Ann Arbor meeting, it was decided to classify limited direct extension from an adjacent nodal site as local extranodal extension (E).¹² The classification assumes that the local extension has a prognosis equivalent to that of nodal disease of the same anatomical extent.¹³ Patients with several extranodal sites are classified in stage IV. At the time of the Ann Arbor meeting, staging laparotomy was used routinely. Since then, staging laparotomy has been omitted from most diagnostic procedures. Thus, clinical staging has become the mainstay for staging this disease. Clinical stages (CS) are based on the results of physical examination, chest X-ray, contrast-enhanced computed tomography (CT) scan (neck, chest, and abdomen), abdominal ultrasound, skeletal and/or bone marrow radionuclide imaging, and bone marrow biopsy. A few additional recommendations were made at the Cotswold meeting in 1989.¹⁴ The classification included prognostic factors such as mediastinal mass, other bulky nodal disease, and the extent of sub diaphragmatic disease (Table 35.1).

Table 35.2 outlines the recommended staging procedures. Recommendations for staging should emphasize a careful history and physical examination to identify the presence of B symptoms and to determine whether palpable adenopathy is present. Diagnostic imaging methods must include chest X-ray, and CT scans of the neck, thorax, abdomen, and pelvis. Hematological studies require a complete blood count. All patients should have bone marrow aspiration and biopsy as well as bone marrow and/or skeletal radionuclide imaging performed. Biochemical tests should include liver function and renal function tests. Additional optional procedures, which may also be of value in selected cases, include positronemission tomography (PET) and magnetic resonance imaging (MRI).

Staging laparotomy

In the past, staging laparotomy was routinely performed in supradiaphragmatic clinical stage I and II patients. It was restricted to those patients for whom management decisions depended on the identification of sub diaphragmatic disease. Many centers found that after laparotomy 20–30% of patients had to be upstaged.^{15,16} For the majority of patients, it became apparent that laparotomy had disclosed occult disease in the spleen, which underlined the inaccuracy of the radiological methods at that time in assessing the spleen. Arguments against staging laparotomy included the severe side-effects of the procedure. The overall mortality rate ranged from 1.5% to 3.0% after splenectomy, including deaths from overwhelming sepsis (OPSI syndrome). The procedure became less frequently used with the introduction of effective chemotherapy programs for the majority of patients in early stages. The routine use of laparotomy for staging has subsequently become obsolete.¹⁷

Treatment groups and prognostic factors

Disease stage is the principal factor in selecting treatment strategies for patients with HL. Since the identification of generally applicable risk factors at diagnosis would allow a more individually tailored treatment strategy, several analyses assessing risk factors have been performed. Based on these data, the German Hodgkin Lymphoma Study Group (GHSG) defines three prognostic groups:

1. *Early stages*: patients in stages I and II without risk factors such as large mediastinal mass, extranodal disease, ESR ≥ 50 in A stages or >30 in B stages, or three or more lymph node areas involved.
2. *Intermediate stages*: patients in stages I and IIA with one or more of the following risk factors: large mediastinal mass, extranodal disease, ESR ≥ 50 in A stages or >30 in B stages, or three or more involved lymph node areas. Patients in stage IIB with ESR ≥ 30 and/or three or more involved lymph-node areas are also stratified into the intermediate-risk group.
3. *Advanced stages*: all patients in stages III and IV, and selected IIB patients having large mediastinal mass and/or extranodal disease.

In an attempt to more precisely define the risk of patients with advanced disease treated with COPP/ABVD-based regimens, Hasenclever and Diehl¹⁸ analyzed a variety of clinical and laboratory parameters to construct a prognostic index. The International Prognostic Score (IPS) consists of serum albumin <4 g/dl, hemoglobin <10.5 g/dl, male sex, stage IV disease, age 45 years or older years or older, white blood cell count (WBC) $15\ 000/\text{mm}^3$ or higher, and lymphocyte count less than $600/\text{mm}^3$ or less than 8% of WBC.

Treatment

Early stages

Radiotherapy using the extended-field (EF) technique was until recently considered the treatment of choice for patients with early-stage HL. As long-term follow-up has increased, it has become clear that EF radio-therapy results in significant long-term toxicity. Those who receive mediastinal radiation have an increased risk of experiencing a fatal myocardial infarction.¹⁹ Radiotherapy is also associated with an increased risk of second solid tumors in or adjacent to radiation fields. The cumulative risk varies between 7.8% and 23.3% at 15 to 25 years after first-line treatment; and shows no signs of leveling off even into the third decade after treatment.^{20–23}

Thus, in order to avoid long-term toxicities of the EF irradiation and to reduce the rate of relapse after irradiation alone, it was the aim of randomized clinical studies to evaluate the addition of chemotherapy in order to reduce the extent of radiotherapy.²⁴

Kaplan²⁵ demonstrated that the likelihood of disease recurrence at an irradiated site was inversely related to dose, with recurrence rates of less than 5% if 35 Gy was given and 2% at doses of 40 Gy. As a consequence of this analysis, a total dose of 40 Gy was regarded as standard in the radiotherapy of HL for many years. In the HD4 trial of the GHSG, a standard therapy consisting of 40 Gy radiotherapy delivered using the EF technique was then randomly compared with a radiotherapy of 30 Gy EF plus 10 Gy involved field (IF) in pathologically staged PS I/II patients. After a median follow-up of 86 months, there were no significant differences between the two groups in terms of relapse-free and overall survival rates.²⁶

Radiotherapy using the EF technique can induce complete remission (CR) rates of 90–98% in patients with early-stage favorable disease.^{27,28} but 30–40% will relapse and about 63–74% of these patients are alive after 10 years.^{29,30} Due to the high relapse rate after radiotherapy alone and the increased risk of secondary cancers, EF radiotherapy has been abandoned by most study groups.

Combined-modality treatment has been compared with EF radiotherapy alone in another study conducted by the GHSG, randomizing 617 favorable clinically staged CS IA–IIB patients to subtotal nodal and splenic irradiation alone or to two courses of ABVD (Table 35.3) following radiotherapy (the HD7 trial).³¹ The final analysis of this study revealed at a median follow-up of 7 years an advantage in terms of freedom

Table 35.3 The ABVD regimen

Drug	Dose	Route	Days
Doxorubicin ('Adriamycin')	25 mg/m ²	i.v.	1,15
Bleomycin	10 U/m ²	i.v.	1, 15
Vinblastine	6 mg/m ²	i.v.	1, 15
Dacarbazine	375 mg/m ²	i.v.	1,15
Recycle from day 29			

from treatment failure (FFTF) in patients receiving ABVD (96%) compared with those treated with irradiation alone (87%).

Other studies compared combined-modality treatment followed by IF radiotherapy with EF radiation alone. In the EORTC H7F trial, six cycles of EBVP (epirubicin, bleomycin, vinblastine, and prednisone) and IF irradiation was tested against mantle and paraaortic-splenic irradiation (subtotal nodal irradiation, STNI) for favorable-prognosis CS IA-IIA patients. The relapse-free survival rate after 5 years was significantly higher for patients receiving combined-modality treatment (90% versus 81%), whereas survival rates did not differ.³² Another study by the EORTC (H8F) randomized patients with early-stage favorable disease to two arms: three cycles of MOPP/ABV (mechlorethamine, vincristine, procarbazine, and prednisone/doxorubicin, bleomycin, and vinblastine; see below) with IF irradiation were compared with mantle and paraaortic-splenic irradiation. The relapse-free survival of the two groups differed significantly (99% versus 80%, respectively).³³ Hence, these observations underline the role of the combined-modality treatment as the new standard.

Today, most groups in the USA and Europe prefer combined treatment such as two cycles of ABVD followed by IF radiotherapy using 20–30 Gy. An without risk factors, which can be treated by excision exclusion is the LPHL subtype in favorable stage IA followed by a 'wait and see' strategy or IF radiotherapy with 20–30 Gy.

The main aim of currently ongoing studies is to reduce the long-term complications while retaining the good response. One example is the recently closed HD10 trial of the GHSG evaluating the optimal intensity of therapy for both chemotherapy and IF radiotherapy. Patients were randomized to either two or four cycles of ABVD followed by either 20 or 30 Gy IF radiotherapy.

Intermediate (early unfavorable) stages

It has become common practice to treat patients in early unfavorable stages with risk factors with a combined-modality approach using both chemotherapy and radiation. Radiotherapy alone cannot sufficiently control disease activity in this group. A combined-modality treatment consisting of four to six cycles of MOPP or ABVD (Table 35.3) plus EF radiation was for a long time regarded as standard treatment. Many European countries preferred COPP over MOPP (with the former containing cyclophosphamide instead of mechlorethamine).

A French group has compared IF versus EF irradiation with 40 Gy in a sandwich regimen using three to six cycles of MOPP in CS I, II, and IIIA patients. This study could not detect a significant difference in either disease-free or overall survival between the two treatment groups.³⁴

In the HD1 study of the GHSG, patients in CS/PS I, II, and IIIA with risk factors were treated with two cycles of COPP/ABVD followed by radiation (40 Gy EF versus 20 Gy EF plus 20 Gy bulk). The CR rate was 87%, showing no differences between the three risk groups having large mediastinal mass, extranodal involvement, or massive spleen involvement.³⁵

Table 35.4 The BEACOPP-baseline and escalated BEACOPP regimens

Drug	Dose	Route	Days
Bleomycin	10 U/m ²	i.v.	8
Etoposide	100 (200) mg/m ²	i.v.	1–3
Doxorubicin ('Adriamycin')	25 (35) mg/m ²	i.v.	1
Cyclophosphamide	650 (1250) mg/m ²	i.v.	1
Vincristine ('Oncovin')	1.4 mg/m ² ^b	i.v.	8
Procarbazine	100 mg/m ²	p.o.	1–7
Prednisone	40 mg/m ²	p.o.	1–14
Recycle from day 22			
^a Doses for escalated BEACOPP in parentheses.			
^b The vincristine dose may be capped at 2 mg.			

Survival and FTF of the 148 patients randomized were identical after a median follow-up of 48 months.

A reduction in the intensity of therapy might be possible for both chemotherapy and radiotherapy within the combined modality in order to minimize treatment-related side-effects. A possible reduction of toxicity might be achieved by a reduced radiation volume. In a large trial by the GHSG (HD8), patients with intermediate-stage disease were randomly assigned to four cycles of COPP alternating with ABVD plus 30 Gy EF or IF radiotherapy.³⁶ There were no significant differences between the two groups in terms of FTF, overall survival (OS) at 5 years, or CR. Based on these results and the better tolerability, a combined-modality approach of four cycles of ABVD followed by IF radiotherapy is the current standard for most trials.

Since the results in intermediate stages are not yet satisfying, most current clinical trials explore more effective chemotherapy. BEACOPP-baseline (Table 35.4) as a novel chemotherapy regimen for patients with intermediate stages was introduced in the recently closed HD11 trial of the GHSG. Patients were randomized between four cycles of ABVD or four cycles of BEACOPP-baseline followed by an IF radiation with 20 or 30 Gy.

Advanced stages

Advanced-stage HL was fatal until the development of effective poly chemotherapy regimens. The first four-drug combination chemotherapy for HL, using vincristine, methotrexate, cyclophosphamide, and prednisone (MOMP), produced remission rates of 80%.³⁷ In 1964, this regimen was modified, with the substitution of procarbazine for methotrexate and mechlorethamine (nitrogen mustard) for cyclophosphamide, and the duration was lengthened to 6 months.³⁸ The resulting MOPP regimen became the gold standard at that time for the treatment of advanced disease.³⁹ In Europe, some groups used COPP instead of MOPP (replacing mechlorethamine by cyclophosphamide) or ChIVPP (chlorambucil, vinblastine, procarbazine, and prednisone), with very similar results to those achieved with MOPP. In 1979, the Milan group⁴⁰ reported a combination that was effective in MOPP-resistant cases, namely ABVD (Table 35.3). ABVD was subsequently used together with MOPP in alternating monthly cycles (MOPP/ABVD). This combination, as well as ABVD alone, has demonstrated superior effects as compared with MOPP alone.^{41,42}

A possible strategy to improve treatment results is to develop time- or dose-intensified regimens of effective cytostatic drugs. This notion is based on retrospective data showing that the treatment outcome in HL is correlated with the dose intensity of cytostatic drugs.⁴³

There are two principal ways in which to enhance dose intensity:

- dose escalation of drugs on a constant time schedule;
- application of the same dose over a shorter period of time.

One example of a time-intensified protocol was reported by Klimo and Connors.⁴⁴ In their study, impressive results were obtained using a MOPP/ABV hybrid aimed at rapid alternation of cytostatic drugs. These data from a non-randomized pilot study were, however, not reproduced in a randomized multicenter trial comparing MOPP/ABVD with the MOPP/ABV hybrid.⁴⁰ Promising treatment results have been achieved with the brief Stanford V chemotherapy regimen in advanced HL.⁴⁵

In the three-armed HD9 trial of the GHSG, the new BEACOPP regimen,⁴⁶ given in standard and escalated doses (Table 35.4), was compared with the alternating COPP/ABVD regimen in a multicenter setting.⁴⁷ Radiotherapy was applied after eight cycles of chemotherapy to sites of initial bulky disease or residual disease after chemotherapy. The second interim analysis of this study identified superior outcome in both BEACOPP arms compared with COPP/ABVD. Thus, the COPP/ABVD arm was closed prematurely.⁴⁸ The final analysis of this study showed significant improvement at 5 years' median observation in terms of FTF rate (69% for COPP/ABVD, 76% for BEA-COPP-baseline, and 87% for escalated BEACOPP) (Figure 35.1) and OS rate (83% for COPP/ABVD, 88% for BEACOPP-baseline, and 91% for escalated BEA-COPP).

As an example of a time-intensified chemotherapy, the GHSG evaluated the BEACOPP-14 schedule which is BEACOPP-baseline, but given in 14-day instead of 21-day intervals. The aim is to achieve effective tumor control with reduced toxicity. The regimen was tested in a multicenter pilot study, with the final analysis showing an estimated FTF rate of 90% and an OS rate of 97% at 34 months median observation time. The acute hematotoxicity ranged between that of escalated and baseline BEACOPP-21. Consequently, eight cycles of BEACOPP-14 are included in the current HD15 trial of the GHSG.⁴⁹

With the advent of more effective treatment for patients in advanced stages, the role of additional radiation has become more questionable. The duration of chemotherapy is also still controversial. In a study by the Southwestern Oncology Group (SWOG), patients were randomized after three cycles of MOPP/ABVD between radiotherapy or no further treatment. The results were superior for irradiated patients.⁵⁰ In the HD3 study by the GHSG, patients who were in CR after three cycles of COPP/ABVD were randomized between additional radiotherapy or a fourth COPP/ABVD course. There was no significant

Figure 35.1 Freedom from treatment failure (FFTF) by treatment arm. Results of the HD9 trial of the German Hodgkin Lymphoma Study Group (GHSG).

difference between the two arms.⁵¹ Other studies addressing this question include the HD12 and HD15 trials of the GHSG, in which patients received either radiation to sites of initial bulky disease and residual disease after eight cycles of chemotherapy or no further treatment (HD12). Radiation in the HD15 trial is only given on PET-positive residual tumors. In the H34 (20884) trial of the EORTC, patients in CR after MOPP/ABV received further two cycles of chemotherapy followed by either radiotherapy with the IF technique or observation. The results showed that the additional radiotherapy did not improve relapse-free survival or OS in patients who had already achieved a CR with MOPP/ABV. In contrast, those patients who had a partial remission and additional IF irradiation had a similar overall outcome compared with those who had reached a CR after chemotherapy.^{52,53,54}

Salvage treatment

Treatment of relapses after radiotherapy

Patients who relapse after radiotherapy can be treated with standard chemotherapy such as six or eight cycles of ABVD or eight cycles of escalated BEACOPP, depending on stage. Radiation is additionally applied to outfield relapses.

Treatment of relapses after chemotherapy

Relapses after chemotherapy occur in about one-third of patients in CR. The optimal salvage therapy for these patients depends on the initial treatment and the duration of the response. Three risk groups can be identified (Figure 35.2):

- patients with no initial CR;
- patients with a short initial CR (<12 months);
- patients with a long initial CR (>12 months).

Due to the disappointing results of conventional chemotherapy, high-dose chemotherapy (HDCT) followed by autologous stem cell transplantation (ASCT) is the treatment of choice for most patients with progressive, early, and late relapsed disease. Patients with primary progressive HL have a particularly poor prognosis. Treatment consists of salvage chemotherapy, radiotherapy, and HDCT followed by ASCT.

Conventional chemotherapy in patients with late relapse can induce remission in up to 55% of cases.

Figure 35.2 Overall survival in patients with primary progressive, early, and late relapsed Hodgkin lymphoma after first-line polychemotherapy. GHSG 1988–99.

However, several studies, including the randomized HDR1 trial of the GHSG, demonstrated an improved FF2F after HDCT compared with conventional chemotherapy, even for late relapses. Another option is salvage radiotherapy for strictly localized relapses without B symptoms in previously non-irradiated areas.

More than 50% of highly selected patients who undergo HDCT achieve a CR.⁵⁵ The OS rate reported at 8 years is 25%. The data indicate that patients who responded to a previous salvage chemotherapy ('sensitive relapse') have a better prognosis with HDCT than patients who did not respond ('resistant relapse'). Thus, HDCT with ASCT has become the standard treatment for patients with chemotherapysensitive relapses. Since peripheral blood SCT (PBSCT) is more convenient than autologous bone marrow transplantation (ABMT),⁵⁶ this approach has become the standard procedure. A significantly improved outcome in patients treated with HDCT at relapse has been shown in two randomized studies, performed by the British National Lymphoma Investigation (BNLI) and the GHSG/EBMT (HDR-1).^{55,58}

In a large multicenter phase II trial, patients with either relapsed or refractory HL were enrolled, receiving initially two cycles of DHAP (dexamethasone, cytarabine, and cisplatin) followed by sequential high-dose chemotherapy (BEAM: carmustine, etoposide, cytarabine, and melphalan), and PBSCT. In the last interim analysis of this study, the response rate was 77% (68% complete and 9% partial), and freedom from second failure (FF2F) and overall survival (OS) were 59% and 79%, respectively, for all patients. Toxicity was tolerable.⁵⁹

These data demonstrate the feasibility and high effectiveness of this protocol in a large multicenter setting, and led to the GHSG randomized follow-up study (HDR2). Patients with early and late relapsed HL are randomized after two cycles of DHAP between BEAM or additional sequential high-dose chemotherapy followed by BEAM.

In several studies on patients with relapsed disease, prognostic factors were evaluated. In a retrospective analysis performed by the GHSG, early relapse, stage III or IV at relapse and hemoglobin (<10.5 g/dl female or <12 g/dl male) were associated with a particularly poor prognosis in multivariate analysis.⁶⁰

Rituximab for relapsed CD20⁺ Hodgkin lymphoma

Fourteen patients with relapsed LPHL or other CD20⁺ subtypes were enrolled in a phase II trial of the GHSG. Treatment consisted of the chimeric monoclonal anti-CD20 antibody rituximab given as a 4-weekly intravenous infusion. The results show an overall response rate of 86%, eight patients with CR, four with partial response, and two with progressive disease. Thus, rituximab is a safe and effective treatment with mild to moderate adverse events in the subgroup of CD20⁺ HL.⁶¹ Similar results in small cohorts of patients have been reported from other groups.

Treatment-related complications

The most serious long-term side-effect in patients successfully treated for HL is the development of second malignancies. Investigations of an international database covering 12 411 patients calculated a cumulative incidence rate for second tumors of 11.2% after 15 years,²⁵ including 2.2% acute leukemias, 1.8% non-Hodgkin lymphomas, and 7.5% solid tumors. In another study including 1253 HL patients, the 25-year cumulative risk of solid tumors was 23.3%, of leukemia and MDS 3.3%, and NHL 3.5%.⁶² Secondary lung cancer, breast cancer, and gastrointestinal cancer are most commonly observed.⁶³ Acute myeloid leukemias usually developed within 5 years after treatment.⁶⁴ The prognosis is generally poor, with remission rates of 30–40% and survival rates of less than 5%. Non-malignant sequelae include gonadal dysfunction. Male patients treated with COPP/ABVD show azoospermia rates of up to 86%.^{65,66} However, the majority of patients suffer from disease-related gonadal dysfunction, such as oligo-, astheno- or teratospermia prior to the initiation of treatment.^{67,68} The azoospermia in ABVD-treated patients appears to be less pronounced and reversible, developing in about 50% of cases. A more recent analysis including a total of 84 female patients with HD and Non-Hodgkin lymphoma treated with at least three cycles of chemotherapy with an alkylating agent or six cycles with procarbazine reported 34(40.5%) women with premature ovarian failure.⁶⁹ Furthermore the likelihood of amenorrhoea after treatment for HL is age-related. Other sequelae are thyroidal dysfunction, interstitial fibrosis, radiation-induced pneumonitis, cardiomyopathy, and ischemic coronary heart disease.⁷⁰

The risk of developing pneumonitis is two- to three-fold greater for patients with large mediastinal masses who receive combined-modality treatment including mantle field radiotherapy.⁷¹ In addition, radiotherapy can cause radiation pneumonitis and chronic fibrosis of the lung. Bleomycin may further increase this toxicity.

Future developments

Approaches with biological agents aiming at the selective destruction of residual tumor cells are being investigated. HL is a very good candidate for antibody-based immunotherapy because H-RS cells

express in high copy numbers on their cell surfaces lymphoid activation markers (CD25 and CD30) that are sparse on normal tissue.⁷² These are potential targets for antibody-based immunotherapy. A combined-modality treatment might be feasible using standard chemotherapy or radiotherapy regimens to reduce bulky disease and then using immunotherapy to destroy possible residual tumor cells.

Current monoclonal antibody-based experimental strategies involve immunotoxins, bispecific monoclonal antibodies,⁷³ radioimmunoconjugates, and completely human antibodies directed at CD30.⁷⁴ Ongoing clinical trials in patients with resistant HL indicate therapeutic effects of radioimmunoconjugates and human monoclonal antibodies.

36 Non-Hodgkin lymphomas

Anton Hagenbeek and Philip M Kluin

Introduction

Non-Hodgkin lymphomas (NHLs) form a heterogeneous group of approximately 50 different clinicopathologic entities (Tables 36.1–3). In western countries, the incidence of NHL is approximately 10/100 000 females per year and 14/100 000 males per year. In some countries, it has shown a steady trend to increase in recent decades. However, this increase may be partially artificial in view of the changes in diagnostic tools and criteria, and the change in the age distribution of the general population. The latter has a major impact, since NHL generally represents a disease of the elderly. Since most NHLs show hematogenic spread, and conversely some leukemia patients present with or develop lymphadenopathy during the

course of the disease, the boundaries between certain NHLs and leukemias are not very distinct. Examples are lymphocytic lymphoma and chronic lymphocytic leukemia, and Burkitt lymphoma and its leukemia variant, previously called acute lymphoblastic leukemia type L3.

In western countries, B-cell lymphomas make up approximately 85–90% of all NHLs. Approximately 65% of NHLs are primary nodal, and present at preexistent lymphoid sites such as lymph nodes and tonsils. Lymphomas that arise in the mucosa-associated lymphoid tissues and in sites without pre-existing lymphoid tissue such as the stomach, soft tissues, testis and brain are mostly called primary extranodal. The clinical presentation of NHL largely depends on the primary localization and spread of tumor cells. The significance of the site of presentation is particularly salient in primary extranodal lymphomas. Apart from mechanical discomfort, other features such as bone marrow failure caused by lymphomatous infiltration may contribute to the clinical presentation. Furthermore, B-cell lymphomas with a high content of plasma cells or plasmacytoid cells such as lymphoplasmacytic lymphoma may produce large quantities of paraprotein, leading to clinical symptoms. Tumor derived immunoglobulins (Igs) may show reactivity to auto-antigens, resulting in hemolytic anemia, thrombocytopenia, cryoglobulinemia, peripheral neuropathy, etc. Other symptoms such as fever and the occurrence of eosinophilia may be related to the production of cytokines by tumor cells or reactive bystander cells. These latter phenomena are particularly prominent in peripheral T-cell lymphomas and Hodgkin lymphoma.

Etiology and pathogenesis

The following etiological factors play a major role in the genesis of NHL:

1. Infection by oncogenic viruses
2. Inflammation and persistent proliferation
3. Illegitimate gene recombination
4. Impaired immunity of the host.

As in other malignancies, the etiology of malignant lymphoma is multifactorial. The best-documented example is African Burkitt lymphoma (see later). In approximately 50% of B-cell lymphomas, recurrent chromosomal translocations such as a t(14;18) can

Table 36.3 Immunodeficiency-associated lymphoproliferative disorders (WHO classification)

	Remarks
Lymphoproliferative diseases in primary immune disorders	
Fatal infectious mononucleosis	Mainly in XLP and SCID
DLBCL	EBV ⁺ , in all types
Lymphomatoid granulomatosis	EBV ⁺ , mainly in Wiskott-Aldrich syndrome
T-cell lymphomas/leukemias	Mainly in ataxia telangiectasia
Various	Ln ALPS
HIV-related lymphomas	
Burkitt lymphoma	30% EBV ⁺ +/- plasmacytoid
Diffuse large B-cell lymphoma	EBV ⁺
Plasmablastic lymphoma	EBV+ oral & other mucosa
Primary effusion lymphoma	Pleura, ascites; EBV ⁺ , HHV8 ⁺
PTLD-like lymphoproliferations (polymorphic)	
Extranodal marginal zone B-cell lymphoma	Extremely rare
Peripheral T-cell lymphoma NOS	
Hodgkin lymphoma	Rare
Post-transplant lymphoproliferative disorders	
Infectious mononucleosis-like	Ln, Waldeyer, primary infect; young children; polyclonal
Early plasmacytic hyperplasia	Ln, Waldeyer, children, EBV+; polyclonal
Polymorphic PTLD	Extranodal, graft, Waldeyer, Ln; poly-/oligo/monoclonal
DLBCL	Extranodal, graft, Waldeyer, Ln; monoclonal
Plasmacytoma-like PTLD/plasma cell myeloma	Intestine, other extranodal sites; bm; may be EBV negative; late lesions
T-PTLD	EBV ^{+/-} monoclonal
Hodgkin (like) PTLD	EBV ⁺ CD30 ⁺ , 15 ⁺

Ln: lymph node; bm; bone marrow; XLPL; X-linked lymphoproliferative disease; SCID: severe combined immunodeficiency; ALPS: auto-immune lymphoproliferative syndrome.

be identified. In at least three entities (Burkitt lymphoma, follicular lymphoma and mantle-cell lymphoma), specific translocations affect the majority of cases and hence are critical events. In most translocations, juxtapositions of Ig genes or T-cell receptor (TCR) genes (in B- and T-cell lymphomas, respectively) lead to deregulation of the involved (onco)genes and (over)production of otherwisenormal oncoproteins. In contrast to myeloid leukemias, the generation of fusion genes and abnormal protein products is relatively exceptional, and so far only documented in T-cell anaplastic large cell lymphoma and extranodal marginal-zone lymphoma of mucosa-associated lymphoid tissue (MALT) type (see later). In general, translocations involving Ig genes are more frequent in mature B-cell lymphomas than in precursor B-cell leukemias, whereas translocations involving TCR genes are more frequent in precursor T-cell leukemias than in mature T-cell lymphomas. This difference has not been fully explained, but may be related to the fact that T-cells undergo only one wave of T-cell receptor gene rearrangements, while B cells undergo three major waves: after the initial *V(D)J* recombinations of the immunoglobulin genes in precursor B cells, the mature germinal center B cells also undergo hypermutations and immunoglobulin class switch recombinations (Figure 36.1). Mechanistically, all recombinations in early B and T cells including the hypermutations and class

Figure 36.1 Normal B-cell development.

switch represent events that include the generation of double-strand DNA breaks, and in consequence they are potentially at risk to undergo erroneous recombinations, including chromosomal translocations. Many additional aspects have to be understood to fully appreciate the role of oncogenes and translocations in lymphomas:

- *The nature of the gene involved.* Genes involved in translocations are nuclear transcription factors (often affected in precursor B- and T-cell malignancies like acute lymphoblastic leukemia, ALL), cell cycle regulators (such as cyclin D1), antiapoptotic genes (such as *BCL2*), and genes coding for cytokines.
- *Their role in normal B- and T-cell development.* For instance, the effect of deregulation of the *BCL2* gene by t(14;18) can only be understood knowing the expression pattern and function of the BCL2 protein during normal B-cell ontogeny (the effect of the deregulation is restricted to germinal center B cells; see Figures 36.2 and 36.3).
- *Interaction with other genes or gene products.* For instance in the E2A/Rb pathway, cyclin D1 interacts with numerous other proteins, including many activators and repressors. This cascade ultimately leads to the release of E2 A involved in G₁/S-phase transition. The balance between type D cyclins, CDK4 and inhibitors and activators is crucial in normal cell cycle control, while disbalances may lead to both early G₁ transition and/or apoptosis.
- *The moment at which a translocation takes place during B- or T-cell ontogeny.* For instance, the translocation t(11;14)(q13;q32) is characteristic of mantle-cell lymphoma. In this lymphoma, it occurs during the first Ig gene rearrangements in early precursor B cells of the bone marrow. A t(11;14) with involvement of *cyclin D1* is occasionally found in multiple myeloma. However,

Figure 36.2 Molecular origin of follicular lymphoma and t(14;18).

the latter breakpoints at 14q32 localize at Ig switch sites, suggesting a later origin during Ig class switching in germinal center B cells.

The current knowledge of oncogenes, viruses, cell adhesion molecules and cytokines is of tremendous help in understanding many aspects of lymphomagenesis. However, the mechanisms by which the tumor cells are blocked at a certain level of maturation is still incompletely understood. This block in maturation in particular forms the basis of all current classification systems, the so-called 'frozen stage model' of neoplasia describing the more or less strict maturation block of tumor cells. It may be almost absolute, such as in mantle-cell lymphoma, or less strict, such as in follicular lymphoma and marginal-zone B-cell lymphoma (see later).

Initial tumorigenesis must be discerned from tumor progression. There is increasing evidence that progression in NHL is caused by gene alterations that differ from the original events. These 'secondary' events include inactivation of tumor-suppressor genes such as *p53* and *p16*, 6, amplification of genes such as *REL*, genomic instabilities leading to trisomy and disturbances in gene dosage, and less frequently translocations such as t(8;14) involving the MYC oncogene.

Many lymphomas present at sites that are normally devoid of lymphoid tissue. One explanation is that these lymphomas develop from chronic inflammation and subsequent induction of lymphoid tissue. Examples are the development of gastric extranodal marginal-zone type (MALT) B-cell lymphomas against a background of *Helicobacter pylori*-induced chronic gastritis with induction of MALT, and the development of B-cell lymphomas against a background of autoimmune-mediated inflammation in Sjögren disease.

Depending on the stage of differentiation, normal B and T cells circulate in the peripheral blood, and home to distinct peripheral lymphoid sites such as the peripheral lymph nodes, the spleen or the MALT. Circulation and homing are guided by the presence of many molecules, such as CD44, selectins and integrins on lymphocytes, and their specific ligands on (high) endothelial cells, stroma, etc. Lymphocytes are directed into specific lymphoid tissues by the presence of homing receptors and addressins on high endothelial cells. Spread after invasion in the lymphoid compartments is directed by chemokine receptors on lymphocytes and their ligands. Expression of these receptors is often inducible and dependent on (local) maturation of lymphocytes, and thus on the local microenvironment, including the presence of T cells, cytokines, etc. Many of these properties, which are retained in NHL, may explain not only the presence of different homing properties in NHL but also the presence of intratumor heterogeneity and the sometimes dramatic morphological and phenotypic alterations during the course of the disease.

A biological basis of classification

Previous classifications were mainly based on morphology (the Rappaport classification¹ and the International Working Formulation, WF² or on morphology and normal lymphoid development (the Kiel and Lukes-Collins classification^{3–5}). Most importantly, none of these classifications received world-wide support. Ideally, classifications should be based on the distinction of clinicopathologic entities defined by morphology, immunophenotype, genetic abnormalities, clinical presentation including pattern of dissemination and prognosis. Furthermore, they should be based on consensus amongst expert pathologists, immunologists, molecular biologists and hemato-oncologists. From this point of view, the REAL and more recently introduced World Health Organization (WHO) classifications^{6–8} are major achievements. It should be underlined that the WHO classification represents an update of the REAL classification, and that such a process of updating will remain necessary in the future as well.

Grading of malignant lymphoma

NHL represent a large number of distinct clinicopathological entities, each with a distinct presentation, behavior and prognosis. In the Kiel classification, grading was a histologic feature and exclusively based on the presence of blasts. In contrast, grading according to the WF was based on morphology and clinical outcome according to the therapeutic options in 1970–80. According to the current WHO and REAL classifications, grading is again an exclusively histologic feature, and only used for those entities in which the (variable) percentage of blasts might have clinical (prognostic) significance. So far, official proposals for grading have only been made for follicular lymphoma.^{8–10}

B-cell lymphomas

In western countries, the great majority of NHLs are B-cell lymphomas (Table 36.1). For most of these lymphomas, normal counterparts can be identified, and hence a ‘frozen stage model’ can be applied. In some subtypes, leukemic spread may occur at the onset of disease or may develop during its course, making distinction between leukemic NHL and primary leukemia rather arbitrary.

Lymphocytic lymphoma/B-CLL

Lymphocytic lymphoma/B-CLL (chronic lymphocytic leukemia) is defined as a lymphoma or leukemia that consists of small B lymphocytes with or without plasmacytoid cells. Lymphocytic lymphoma and CLL are lumped, since the borderline is equivocal. For instance, different numerical criteria (>4 to $>15 \times 10^9$ lymphocytes/L) are used in different classification systems.^{11,12} In western countries, lymphocytic lymphoma/CLL has an incidence of approximately 3.2 cases/100 000 inhabitants/year, but it shows a continuous increase in incidence with age, up to an incidence of approximately 75/100 000 inhabitants/year for people over 80 years old. Autoimmune phenomena, including autoimmune hemolytic anemia, occur in 10–20% of CLLs.

Genetics, etiology and pathogenesis

Using refined analysis with fluorescent in situ hybridization (FISH) and comparative genomic hybridization, the most common genetic abnormalities in lymphocytic lymphoma/CLL are del 13q14 in approximately 50% (so far no tumor-suppressor gene has been identified),^{13,14} deletions involving the ATM gene at 11q23 in 20–30% and trisomy 12 in 10–15% of cases. While initial studies on CLL showed that as many as 35% of all CLLs may have trisomy 12,^{15–20} later studies showed that this percentage is much too high, and more essentially, that this abnormality is associated with an atypical morphology and phenotype, as well a relatively poor prognosis. Other genetic abnormalities like t(11;14)(q13;q32), t(14;18)(q32;q21) and rearrangements centromeric of the *BCL2* gene at 18q21 occur in less than 5% of cases.^{21–24} Rearrangements of the Ig heavy- and light-chain genes and mutational patterns have been extensively studied. Most studies suggest a preferential use of certain VH gene segments, especially *51p1*, *V_H4.21*, *V_H4.18* and *VH251*.^{25–33}

In normal mature B cells, particularly follicle-center B cells, hypermutations affect the recombined *V_H*, *D_H* and *J_H* gene segments, especially at the CDR2 and CDR3 regions. Hypermutations are implicated in the process of affinity maturation of B cells, necessary for the generation of monospecific, high-affinity antibody normal counterparts (immature CD5 positive B cells), i.e. Originally it was thought that, like their putative most CLLs lack hypermutations^{26,34–36} and produce low-affinity multireactive antibodies like rheumatoid factor.³⁷ However, more recent investigations show that approximately half of all CLLs contain hypermutations, albeit at a lower level than in follicular lymphoma.^{38,39} This suggests two entities: one CLL that is pregerminal center B-cell derived and one CLL that is postgerminal center cell derived. The occurrence of hypermutations is strongly associated with the absence of ZAP-70, a protein with an unknown function in B cells, but in analogy to its function in normal T cells, it is likely involved in B-cell receptor (BCR) mediated signaling. Most importantly, CLL with hypermutations or with low ZAP-70 expression have

a relatively favorable prognosis, which is independent from other prognostic parameters.^{30,40–42} The presence of these unmutated and mutated forms of CLL supports the idea of two entities. However, hypermutations are not correlated with expression of activation-induced cytidine deaminase (AID—essential in the genesis of these mutations) neither with the occurrence of immunoglobulin class switching or class switch attempts. Furthermore, gene expression profiles as assessed by gene array analysis show only limited differences between unmutated and hypermutated CLL.^{43,44}

Morphology and immunophenotype

At the cytologic level, circulating cells show a typical nuclear morphology with round or indented nuclei and coarse chromatin. The cytoplasm may show some plasmacytoid differentiation. Smudge cells ('Gumprechtse Schollen') may be numerous. Less than 10% prolymphocytes are present in blood smears. The presence of nuclear clefts in some CLLs hinders distinction from leukemic NHL, particularly mantle-cell and follicular lymphoma. Lymph node histology often reveals the presence of so-called pseudo-follicles with accumulation of prolymphocytes. These structures can be mistaken for follicle centers, especially in the case of poor fixation, leading to a wrong diagnosis of follicular lymphoma. Their presence also excludes a diagnosis of immunocytoma and mantle-cell lymphoma, both potential differential diagnoses of CLL. Bone marrow aspirates and biopsies are positive in almost all cases. In bone marrow biopsies, the pattern is interstitial, nodular, nodular and interstitial, or diffuse. The presence of a diffuse pattern is independently associated with a poor prognosis.⁴⁵ Immunophenotypically, lymphocytic lymphoma/CLL can be confidently diagnosed on the basis of expression of faint Ig (mostly IgM), CD5, CD23 and BCL2 with lack of CD10, BCL6 and cyclin D1 (Table 36.4).⁴⁵

Progression

Approximately one-third of patients show morphological tumor progression during the course of the disease. Other patients will suffer from progressive disease due to resistance to chemotherapy, whereas approximately 50% of patients succumb to intercurrent infections, cancer or unrelated disorders. The most common type of morphological progression is prolymphocytoid transformation, defined by the presence of between 10% and 55% circulating prolymphocytes, progressive lymphadenopathy, splenomegaly and refractoriness to chemotherapy. Rare forms of progression are Richter syndrome showing progression to immunoblastic lymphoma or a Hodgkin-like lymphoma,^{46–49} so-called 'paraimmunoblastic' lymphoma,⁵⁰ and the very rare occurrence of a TdT⁺ lymphoblastic leukemia.^{51–52} CLL patients are at risk in developing secondary malignancies that might include secondary, clonally unrelated malignant lymphomas. Indeed in a significant part of the cases with Richter transformation, no clonal relationship could be demonstrated by any molecular means.

Mantle-cell lymphoma

The clinicopathological entity mantle-cell lymphoma (MCL) was first described in 1992.^{53–56} In western countries, it makes up approximately 5% of all NHLs. In the Kiel classification, MCL was called centrocytic lymphoma because it was originally thought to be a follicle-center- rather than a mantle-zone-related lymphoma. American authors previously called it intermediately differentiated lymphocytic lymphoma (ILL), lymphocytic lymphoma of intermediate differentiation, and mantle-zone lymphoma (MZL).^{57–59} MCL has not been recognized as a distinct entity in the WE

MCL is a disorder of elderly patients, with a median age of at least 65 years. Most patients present with generalized disease and involvement of lymph nodes, spleen, liver and bone marrow. Approximately one-third of these patients present with extranodal disease, especially of the gastrointestinal tract. In 'lymphomatous polyposis', numerous intestinal (especially ileocecal) polyps with extensive nodular infiltrates are formed. These tumor cells express lymphocyte Peyer patch adhesion molecule (LPAM), i.e. $\alpha 4\beta 7$ integrins, also expressed by normal intraepithelial T cells of the gut.⁶⁰ Some patients present with pronounced splenomegaly and a leukemic picture without lymphadenopathy.^{61–63} The leukemic cells may have a blastic appearance with prominent nucleoli. This variant may therefore be easily mixed up with either splenic marginal-zone lymphoma or prolymphocytic leukemia. In contrast to lymphomas and leukemias that may form a differential diagnosis, almost all MCL patients have a very poor prognosis, with a median survival of 2–3 years, unless they are treated with aggressive chemotherapy in combination with anti-CD20 monoclonal antibody therapy and autologous stem cell rescue, or allogeneic stem cell transplantation.^{56,64–67} This necessitates the use of firm criteria to distinguish these lymphoproliferative disorders.

Genetics, etiology and pathogenesis

In general, IgH genes are unmutated and have not undergone any attempts to class switching, however, approximately 15–20% of all cases show a low level of hypermutation, and this hypermutation seems to be associated with a preferential usage of certain VH gene segments. So far, and opposite to the situation in CLL, there is no obvious clinical difference between

Table 36.4 Immunophenotype of chronic B-cell leukemias, lymphomas and myeloma

unmutated and hypermutated cases.^{68–71} At the cytogenetic level, t(11;14)(q13;q32) can be detected in two-thirds of MCLs.⁷² Since the BCL-1 breakpoint on chromosome 11q13 involves an area of at least 220 kb, FISH analysis is the best method to detect all t(11;14) breakpoints.^{73–79} Using FISH, a BCL-1 breakpoint can be detected in at least 95% of the cases and due to the translocation, the *cyclin D1* (*CCND1*) gene is overexpressed in all these cases. This can be demonstrated by immunohistochemistry or quantitative RTPCR,^{78,80–82} especially since *cyclin D1* is not expressed in normal B cells and most other B-cell neoplasias (Hairy-cell leukemia is a regular exception with a weak expression but no translocation.^{83,84}) Of note, PCR is not appropriate for 11q13/BCL1 breakpoint detection, since only 30–40% of all 11q13/BCL1 breakpoints can be detected. In very few, MCL not cyclin D1 but cyclin D2 or D3 proteins may be overexpressed, leading to a similar deregulation of the cell cycle.⁸⁵ It should be noted that the t(11;14) is rarely, if not at all, found in other B-cell lymphomas and leukemias, except for 15–20% of multiple myelomas (MMs), in which the molecular make up of the break-points differs, however.^{86–90} Possibly, the rare cases of CLL^{21,22,57–59} and splenic lymphoma with villous lymphocytes (SLVL)⁶⁰ with a t(11;14), in fact represent variant MCL.^{91–94}

Similar to CLL, other (secondary?) genetic events include loss of 13q14.3 (up to 40%) and deletion of *ATM* at 11q23. In many CLLs and MCLs with these deletions, *ATM* has undergone truncating or missense mutations, small deletions or insertions.^{95–98} In MCL but not in CLL, ATM mutations are associated with an increased number of chromosomal imbalances and tumor progression. Other abnormalities in MCL are associated with tumor progression as well: approximately 25% of the so-called blastic and pleomorphic variants carry p53 mutations.^{99,100} Bi-allelic deletions of p16 have also been identified.^{101,102} Very recent cDNA microarray-based gene expression studies in MCL have shown that especially the proliferation status of the tumor as assessed by (over) expression of genes involved in proliferation is a very important denominator of prognosis.⁸⁵

Morphology and immunophenotype

Histologically, three growth patterns of MCL can be seen: mantle-zone, nodular and diffuse. All patterns are associated with the same poor prognosis. At the cytomorphologic level, three variants have been described:

1. *Classical type*, with small to intermediately sized cleaved cells
2. *Blastoid variant*, mimicking lymphoblastic lymphoma with a relatively dispersed chromatin
3. *Pleomorphic variant* with large cleaved or ovoid nuclei and often prominent nucleoli.

The immunophenotype of MCL is remarkably homogeneous: all MCLs represent B-cell lymphomas with strong expression of surface IgM and Ig light chains, CD5 and lack of CD10, CD23 and BCL6.^{103,104} Approximately 5% of the cases may lack CDS expression and extremely rare cases have both CD5 and CD10 expression. Virtually all MCLs express nuclear cyclin D1, however the intensity may vary considerably as detected by sensitive immunohistochemistry or RT-PCR.^{78,105,106} Another adjunct in its diagnosis is the demonstration of numerous dendritic reticulum cells (DRCs) with antibodies against CD21 or CD35. Ki-67/Mib-1 as a marker of proliferation fraction may be used as a prognostic marker.^{56,107–109}

Lymphoplasmacytic lymphoma

Lymphoplasmacytic lymphoma is a relatively rare B-cell disorder, with an estimated incidence of 0.5/100000 cases/inhabitants/year in western countries. It comprises less than 5% of all NHLs. In the REAL classification, the disorder has erroneously been designated as ‘immunocytoma lymphoplasmacytoid’, giving rise to much confusion, since this term was previously used for a subset of CLL with some plasmacytoid differentiation. Most patients with immunocytoma present with stage IV disease and localization in the bone marrow, lymph nodes and spleen. Although not synonymous, many cases of immunocytoma have a clinical picture of Waldenström disease with IgM paraproteinemia and symptoms of hyperviscosity. Furthermore, chronic, cold agglutinin-mediated, immune hemolytic anemia is a common feature.^{110,111} This is almost invariably associated with anti-*i*/I antibodies and Ig gene rearrangement to the *V_H4.24* gene segment.¹¹² Clinically related disorders are the Ig heavy-chain disorders, μ HCD and γ HCD. These disorders may be associated with specific morphological aspects of tumor cells, such as highly vacuolated plasma cells in μ HCD.¹¹³

Genetics, etiology and pathogenesis

Although previous genetic studies suggested a t(9;14)(p13;q32) or breakpoints at 9p13 with juxtaposition to other loci, involving the PAX-5 gene in approximately half of the cases, this could not be confirmed in a large series of cases.^{114–117} PAX-5 or BSAP is a nuclear transcription factor involved in proliferation and especially plasma-cell differentiation of B cells and myeloma cells.^{118–121} All reported four cases with the translocation presented as a lymphocytic lymphoma with plasmacytoid differentiation but without any paraprotein. Therefore, the translocation is most likely absent in bona fide lymphoplasmacytic lymphoma as defined by the World Health Organization (WHO) classification.

Morphology and immunophenotype

In almost all patients, the diagnosis is made by means of a bone marrow biopsy. The infiltrate may be patchy or diffuse, but not typically nodular-like in lymphocytic lymphoma/CLL. The tumor consists of a mixture of small lymphocytes, plasmacytoid cells and mature plasma cells. In some cases small, cleaved cells are also present. In a few cases there is a prominent plasmacytic differentiation imitating myeloma. Abnormally processed immunoglobulins may be visible as so-called Russell or Butcher bodies. Immunohistochemistry for B-cell and plasma-cell markers, especially intracytoplasmic immunoglobulins, is indispensable to establish the diagnosis—also because the aggregates may be very small. In the spleen, tumor cells typically tend to cluster in the red pulp. Immunohistochemistry shows the presence of CD20, CD45, CD79a and cytoplasmic immunoglobulins, mostly IgM, with absence of CD5, CD10 and BCL6; GD138 is present on the mature plasma cells only.¹²²

Follicular lymphoma

This lymphoma was called follicle-center lymphoma in the REAL classification. In western countries, follicular lymphomas represent approximately 20–30% of all NHLs. It usually presents in multiple lymph nodes, but extranodal sites may also be involved. The bone marrow is involved in approximately 55% of cases. Approximately 10% of patients present with stage I disease. Particular clinical subtypes are primary cutaneous follicular lymphomas and primary mesenteric and/or retroperitoneal follicular lymphomas with sclerosis.

Genetics, etiology and pathogenesis

Almost all follicular lymphomas carry the t(14;18)(q32;q21) involving the *BCL2* gene at 18q21 and the Ig gene complex at 14q32.¹²³ All translocations leave the coding domain of the *BCL2* gene intact. Three breakpoint clusters can be identified: approximately 60–70% of breakpoints occur downstream of the gene in the major breakpoint region (MBR), 10–15% in the minor breakpoint cluster (mcr) approximately 20 kb further downstream, and 5–15% in between the MBR and mcr. Few cases have a breakpoint at the other 5' side of the gene. Approximately two-thirds of all breakpoints within the MBR and mcr can be detected by standard PCR. No data are available for the occurrence of this translocation in the so-called 'diffuse follicle-center lymphomas'.

As shown in Figure 36.3, the t(14;18) translocation results in deregulation of one of the antagonists of apoptosis, the *BCL2* gene. This effect is most apparent during the follicle-center cell reaction: in normal follicle-center B cells, *BCL2* protein is downregulated and most B cells will not survive this 'killing field'

Figure 36.3 Deregulation of BCL-2 by chromosomal translocation t(14;18) in follicular lymphoma.

associated with proliferation and apoptosis necessary for affinity maturation of the BCR. However, t(14;18)carrying B cells have a strong survival advantage. Most likely, deregulation of *BCL2* is essential but not sufficient for tumorigenesis, and deregulation of other genes as well as BCR-mediated stimulation of proliferation and survival may play an important additional role. The latter possibility is supported by the molecular analysis of the Ig genes in follicular lymphoma (evidence for ongoing hypermutations, overrepresentation of replacement mutations in the antigen recognition sites, and especially the presence of dominant subclones).^{124,125} As expected, some follicular lymphomas have already undergone complete or abortive Ig class switching.¹²⁶

Follicular lymphoma was the first malignancy to demonstrate that cells with a tumor-specific translocation are circulating in normal individuals. Using sensitive PCR experiments and appropriate control experiments, t(14;18) translocations were demonstrated in one of 10^4 – 10^5 B cells of approximately 50% of all individuals with an increased incidence in elderly people as well as smokers.^{127–131} Single individuals may carry more than one independent clone. This suggests that the t(14;18) is generated in a more or less random way and that additional events ultimately lead to expansion of a single clone. Alternatively, these sporadic translocation-carrying cells do not overexpress the BCL2 protein, and therefore, do not have any advance over normal cells.

Morphology and immunophenotype

By definition, follicular lymphomas show a block in maturation at the level of normal follicle-center B cells, i.e. centroblasts and centrocytes. The neoplastic follicles closely mimic normal follicle centers in architecture and cellular composition. In most cases, a diagnosis can easily be made, whereas in other

cases, it may be very difficult to diagnose this tumor without the help of immunohistochemistry or molecular analysis. In some cases, follicular lymphoma seems to start against a background of follicular hyperplasia, making the diagnosis extremely difficult. In rare lymphomas, unusual growth patterns or extensive plasma-cell differentiation occurs.^{132,133} In the Kiel classification, follicular lymphomas were called follicular centroblastic-centrocytic or follicular centroblastic lymphoma, depending on the fraction of centroblasts in the tissue section.

Very few follicular lymphomas have a completely diffuse growth pattern ('diffuse follicle center cell lymphoma'). This variant has been overestimated in the past and many cases would currently have been classified as mantle-cell or marginal-zone lymphoma. Most likely the remaining cases represent follicular lymphomas with a big diffuse component or diagnoses obtained in relatively small biopsies such as needle biopsies with a high chance of sampling error.

For bone marrow staging of follicular lymphoma, a bone marrow biopsy is obligatory, since aspirates frequently give false-negative results. This is explained by the localization of tumor cells in especially seams along the trabecular surface in combination with deposition of reticulin fibers. In the few patients who have a leukemic type of follicular lymphoma (occurring in 10% of patients), the marrow may also contain many small lymphocytes with 'notched' nuclei.

Although it seems to be one disease, follicular lymphoma may be heterogeneous as well. The great majority of follicular lymphomas have a relatively monomorphic appearance with domination of centrocytes over centroblasts (grades 1, 2 and 3A lymphomas, see later). A small minority of the cases (probably 5% or less), however, mainly consist of centroblasts (grade 3B). The immunophenotype of the grade 1, 2 and 3A lymphomas is relatively consistent: approximately 90% of the cases express CD10, BCL6 and BCL2. Therefore, immunohistochemistry for the BCL2 protein is a very useful adjunct but not an absolute tool to distinguish follicular lymphoma from follicular hyperplasia.^{134–136} Note that BCL2 staining should *not* be used to discriminate follicular lymphoma from other B-cell neoplasias, which are often BCL2 positive as well. Most cases express IgM, sometimes with coexpression of IgD, whereas other cases have undergone class switching to IgG or IgA. The lack of Ig expression in approximately 10% of the cases must not be interpreted as lack of evidence of malignancy. This lack of expression is apparently caused by either double translocations affecting both IgH alleles at 14q32 or the occurrence of secondary mutations introducing stop codons in the Ig genes.¹³⁷ Since the tumor cells are often fragile and may form a minority, data obtained by cell suspension analysis should also be interpreted cautiously. In all lymphomas, aggregates of dendritic cells stained by antibodies against CD21 or CD35 are present; in many, there are residual follicle mantle-zone B cells and numerous T cells. In contrast to the lower grades, grade 3B follicular lymphoma often does not express CD10 and BCL2, and often does not contain a translocation t(14;18), supporting the idea that it represents a different disease.

Grading and tumor progression in follicular lymphoma

Follicular lymphomas are graded histologically according to the number of blasts or 'large transformed' cells. Different systems and cut-off levels have been used in the various classification systems. In the REAL classification, no definite system was proposed, however the WHO proposed to use the Berard grading system, as this is the single system that has been clinically validated.^{9,10,138} In brief, counting in 10 unselected high-power fields of 0.159 mm² each, grade 1 contains 0–5, grade 2 contains 6–15 and grade 3 contains more than 15 (centro- or immuno-) blasts per high-power field. Using this system, grade 1 and 2 lymphomas can be lumped, whereas grade 3 lymphomas should be considered as more aggressive ones. In spite of the strict rules of the grading system, it remains difficult to use, even in hands of highly experienced hematopathologists. This is caused by the difficulties in classifying large, small blasts and large centrocytes, the bias to select areas with an increase in blasts, and the current tendency to take small (needle) biopsies that do not allow to count in a sufficiently large tissue area. Moreover, as shown earlier, several studies suggest that the current distinction is artificial and that a distinction should be made between grade 1, 2 and 3A versus grade 3B. The reported difference in clinical outcome between grades 2 and 3 might be mainly dependent on other parameters such as the presence of diffuse areas in the lymphoma. In summary, grading of follicular lymphomas remains highly controversial, and probably it is most appropriate to wait for better, biologically supported and reproducible criteria. As an alternative for grading, assessment of the proliferation index as measured with the Ki-67/MIB 1 antibody has been proposed, however, although this seems to have some prognostic significance, it does not necessarily match with the histological grading.^{10,139}

Tumor progression occurs in at least 25% of patients and probably in more than 50%.¹⁴⁰ It is often characterized by histological transformation to large-cell lymphoma. A histological spectrum of centroblastic, immunoblastic or small noncleaved (non)Burkitt morphology has been described,¹⁴¹ whereas a few patients develop overt acute leukemia with or without expression of terminal transferase (TdT).^{142,143} Some cases contain many small blasts that mimic lymphoblasts, which express immunoglobulin and lack TdT. These

cells are called 'blastoid'.¹⁴⁴ Tumor progression may occur at the start of or during the course of the disease, and is independent of treatment.

Extranodal marginal-zone lymphomas of MALT

Primary extranodal marginal-zone B-cell lymphomas make up approximately 2–3% of all NHLs. The big majority of these lymphomas represent primary gastric lymphoma. Only this subtype will be described here. In contrast to the intestine, however, the normal stomach does not contain MALT, but MALT is induced by *Helicobacter pylori* (HP)-associated chronic inflammation. The normal intestinal MALT consists of several compartments:

1. The lamina propria contains a mixture of T cells and (IgA-expressing) plasma cells. T cells are found as mainly CD4⁺ lamina propria lymphocytes and CD8⁺ or CD4-CD8- intraepithelial lymphocytes (IELs). A proportion of exclusively the IELs expresses the TCR $\gamma\delta$ receptor. Both the intraepithelial and stromal T cells are expanded in celiac disease.
2. Peyer patches consist of follicles with prominent follicle centers surrounded by a distinct mantle zone and marginal zone. In contrast to the other zones, marginal-zone cells express IgM, CD21 and CD35, but no CD5 or CD 10 and no or weak IgD. The surface epithelium above the follicle may be populated with specialized intraepithelial B lymphocytes giving rise to the so-called lymphoepithelial lesions. Intra-epithelial B cells exclusively express a recently identified FcR-related molecule, IRTA1.¹⁴⁵

The first MALT lymphomas were described for the stomach. Subsequently, similar lymphomas were recognized at other mucosal and even nonmucosal sites such as the salivary glands,^{141,146} thyroid,^{148,149} orbit,^{150–152} breast,^{153–155} skin,^{156–160} thymus,¹⁶¹ bladder,¹⁶² and dura.¹⁶³ Later on, the analogy with the normal marginal zone of the spleen and lymph nodes and with the rare lymphomas primarily presenting in these organs (monocytoid B-cell lymphoma and splenic lymphoma with villous lymphocytes) led to the concept that there is one type of marginal-zone lymphoma that can present in the spleen, lymph node or at extranodal sites. However, there are many strong arguments against this concept, and most likely these three entities have nothing to do with each other. For instance, there is no clinical overlap or transition between the three disorders, and genetic abnormalities of the three types of marginal-zone lymphomas are entirely different. For that reason, they have been again separated in the WHO classification.

Genetics, etiology and pathogenesis

The current genetic data for gastric marginal-zone lymphomas are fascinating but still incomplete. Gastric MALT lymphomas are monoclonal neoplastic disorders with a very indolent behavior. Most likely they start as an oligoclonal and subsequently monoclonal expansion of marginal-zone B cells that are growth and cell survival dependent on inflammatory Th₂-type T cells. This process is triggered and maintained by HP-induced gastritis and induction of local MALT tissue. Early MALT lymphoma cells remain dependent on this HP-specific T-cell help, and eradication of HP leads to regression of these early lymphomas.^{164–168} At this early stage of the disease, no specific genetic alterations are known. However, because of the genetic instability in the proliferating cells, many tumors will acquire genetic abnormalities. The most common and specific translocation is the t(11;18)(q21;q21) involving the *MALT1/MLT* and *API2* gene leading to a chimeric transcript of both genes^{169–177} *MALT1* is a paracaspase and binds to BCL10, which itself is also involved in the t(1;14)(p22;q32) translocation rarely observed in gastric MALT lymphomas as well. Both *MALT1* and *BCL10* are involved in a specific signaling pathway, where *MALT1* is downstream of *BCL10*. *MALT1* is essential to induce NF κ B upon B-cell activation by T cells. Constitutive activation of *MALT1* by chromosomal translocation t(11;18) will, therefore, lead to constitutive NF κ B activation and result in enhanced proliferation and resistance to apoptosis.¹⁷⁸ Indeed MALT lymphomas with this translocation have a more aggressive behavior with transmural growth, and most essentially, they are often resistant to antibiotic treatment aiming at HP eradication.^{172,179,180} Therefore, patients with a t(11;18)-positive gastric MALT lymphoma probably should be treated with HP eradication supplemented with conventional (chemo)therapy. Interestingly, MALT lymphomas without these translocations seem to be more prone to acquire other genetic alterations such as trisomy 3. Progression to large cell lymphoma may be associated with p53 mutation or t(8;14) involving *MYC*.^{181–183}

Concomitant with their continuous T-cell mediated stimulation, re-entry in and recruitment from MALT-associated germinal centers, gastric MALT lymphoma tumor cells contain (ongoing) hypermutations associated with a (post-)follicle-center cell genotype.^{184–187}

Normal mature B cells, and especially memory B cells, show extensive circulation and re-circulation in the peripheral blood. B cells of the MALT show a limited pattern of circulation and specific homing to other MALT sites, including the draining (mesenteric) lymph nodes. This specific homing seems to be determined by specific homing receptors on lymphocytes and addressins on the high endothelial venules in lymphoid tissues, and may partly explain the limited dissemination of the lymphomas.¹⁸⁸ For instance, alpha4beta7 integrin may play a role in this process.^{189,190}

Morphology and immunophenotype

Macroscopically, MALT lymphomas of the stomach mostly present in the antrum with one or more small ulcerations or flat infiltrative lesions. In cases with large tumor masses, the appearance may be similar to carcinoma. In some cases, the lymphoma presents at multiple sites in the stomach, or even simultaneously or metachronously in the stomach, intestine, lungs or tonsils. Histologically, MALT lymphomas may be highly heterogeneous. Some lymphomas show a typical monomorphous appearance caused by expansion of 'centrocyte-like' B cells. In other cases, the cells are mixed with small lymphocytes, mature plasma cells and blasts. Cases with prominent plasma cell differentiation were previously interpreted as solitary plasmacytoma. In many cases, tumor cells tend to invade the epithelial lining and crypts, giving rise to 'lymphoepithelial lesions'. However, it should be noted that the presence of these lesions is not sufficient to call it malignant. Some MALT lymphomas additionally show 'follicular colonization', i.e. invasion of reactive follicles by tumor cells; in the past, this phenomenon was interpreted either as follicular lymphoma or as a sign of benignity.

Grading and tumor progression

Based on the percentage of blast cells, a clinically relevant grading system has been proposed.^{191,192} This system was originally based on a retrospective analysis in patients treated with radiotherapy alone and not with antibiotic treatment as presently used. The system also bears prognostic significance for the clinical response to HP eradication. However, it should be noted that grading of these lymphomas is severely impeded by the fact that almost all patients with gastrointestinal MALT lymphoma currently undergo endoscopic examination with biopsy and not a (partial) gastrectomy. Sampling error may occur, especially if few biopsies are taken.

Approximately half of all primary B-cell lymphomas of the stomach are dominated by blasts and lack features of MALT lymphomas such as lymphoepithelial lesions. Although many authors believe that these tumors represent progressed indolent MALT lymphomas, this has only been proved in a limited number of patients.¹⁹³ Of note, these tumors lack the chromosomal translocations $t(11;18)$ or $t(1;14)$ (Figure 36.4). In consequence, these large-cell tumors can only be lumped in the 'wastebasket' category of diffuse large B-cell lymphomas (DLBCLs).

Diffuse large B-cell lymphoma

In western countries, DLBCLs comprise approximately 30–40% of all NHLs. Clinically, morphologically and genetically, DLBCL is a heterogeneous disorder, comprising multiple separate entities that share a large-cell morphology. Approximately half of the lymphomas arise within lymph nodes, and the other half at extranodal sites such as the thymic region, stomach, small and large bowel, skin, thyroid, testis, bone, soft tissues, and brain. According to the WHO classification, primary mediastinal and primary intravascular DLBCLs have already been designated as distinct clinicopathological entities. According to the EORTC classification for primary cutaneous lymphomas, primary cutaneous large B-cell lymphomas should be separated as well, and even further distinguished according to the localization in the

Figure 36.4 Chromosomal translocations and their origin in B-cell neoplasia.

skin.^{159,194,195} Primary mediastinal DLBCL mainly affects young adults, and often presents with a very bulky mediastinal mass and a superior vena cava syndrome. It tends to remain localized, without dissemination to lymph nodes or bone marrow. Intravascular lymphoma is mostly encountered in the skin or brain. Tumor cells are localized within the lumina of blood vessels, but do not overtly circulate in the peripheral blood. Intracerebral intravascular DLBCL results in severe brain dysfunction.

Just as at primary presentation, DLBCL may also be very heterogeneous in dissemination upon relapse. For instance, nodal lymphomas tend to spread to other lymph nodes and the tonsils, DLBCL of the stomach to regional lymph nodes or other MALT sites, testicular lymphoma to the contralateral testis and cerebrum, and bone lymphoma to other skeletal sites. Primary cutaneous lymphomas of the head and trunk often lack any propensity to disseminate, and hence may be cured by local radiotherapy. Most likely, these patterns reflect the presence or absence of specific adhesion molecules involved in invasion, circulation, adherence to endothelial cells, etc.^{190,196,197} Thus, as in T-cell lymphomas, there is a strong tendency to distinguish DLBCL according to tumor site.

Genetics, etiology and pathogenesis

So far, DLBCL seems to be a genetic wastebasket. Genetic alterations often comprise complex abnormalities, including translocations, deletions, trisomies, amplifications and the presence of many marker chromosomes. The most frequent chromosomal breakpoint is at the *BCL6* gene at 3q27.^{198,210} These breakpoints are found in at least one-third of the cases, including acquired immunodeficiency syndrome (AIDS)-related lymphomas,^{211,212} but also occur in 5–10% of follicular lymphomas.^{213–215} Most *BCL6* breakpoints cluster in a small (regulatory) region of 10kb just upstream of the gene, however, an additional breakpoint cluster far upstream of the gene has recently been identified.²¹⁶ By translocation, *BCL6* is juxtaposed to a large number of different translocation partners (a ‘promiscuous gene’). Most translocations will lead to promoter-substitution of *BCL6*. Notably, mutations in the same regulatory region of *BCL6* occur at high frequency in all lymphomas of (post)follicular origin and even in myelomas, but most frequently in DLBCL.^{147,148} Exclusively in DLBCL, a part of these mutations affects regulatory elements and in consequence leads to activation of the gene.^{217–219} The *BCL6* gene codes for a zinc-finger protein with homology to *Drosophila* transcription factors, whereas it functions as a repressor of many other genes. *BCL6* plays an essential role in the formation and maintenance of normal germinal centers. Possibly, it controls the ability of B cells to interact with T cells by preventing CD40-induced expression of CD80, an essential costimulatory molecule in T-B-cell interaction.²¹⁰ Indeed, the bcl6 protein is present in all normal follicle center cells, all follicular lymphomas and in 75–80% of all DLBCLs, but not or only weakly in mantle-cell lymphomas, lymphocytic lymphomas/CLLs and postgerminal center B-cell lymphomas. In contrast to the original report,²⁰⁴ *BCL6* rearrangement is not associated with a favorable prognosis.^{208,220}

The second most frequent (15%) translocation in DLBCL is the t(14;18), with a breakpoint in *BCL2*. Interestingly, this translocation is mainly present in primary nodal DLBCL.^{221,222} Most likely, t(14;18)-positive DLBCL represents progressed subclinical follicular lymphoma. Unlike the situation in follicular lymphoma, there is a poor correlation between the presence of t(14;18) and expression of *BCL2* protein in DLBCL. In fact many cases without any detectable translocation show expression of the protein and this expression is associated with a relatively poor survival, especially a poor disease-free survival.^{223–226} Recent gene expression studies suggest that this overexpression (that is not caused by a t(14;18)) is specifically found in the subset of DLBCL with an activated B-cell profile (see later).

The third most common (5–10%) translocation in DLBCL is the t(8;14), with involvement of *MYC* at 8q24.^{221,227} Most breakpoints are 5' or in the first intron of *MYC*, and at IgH switch sites of 14q32. In a very few DLBCLs, a combination of t(14;18) and t(8;14) has been identified, and molecular analysis of these cases suggests that the t(8;14) is secondary to the t(14;18).²²⁸ Most DLBCLs with t(8;14) present at extranodal sites, especially the gastrointestinal tract. In primary extranodal DLBCL and especially primary mediastinal large B-cell lymphoma, a high frequency of amplification of the *REL* gene at chromosome 2p is found.^{229,231} This abnormality has gained much recent interest, especially since it leads to activation of NFκB and since a similar amplification is present in classical Hodgkin lymphomas.^{232–235} Discussion of the rapidly increasing number of chromosomal and specific gene alterations in DLBCL is beyond the scope of this chapter. They include a very frequent but thus far nonspecific deletion at 6q.^{236–238}

Since the first publication in 2000,²³⁹ much attention has been paid to gene expression analysis using cDNA or oligonucleotide array analysis. Several hundreds of DLBCLs, mainly of nodal origin, have been studied so far, whereas studies on specific categories of extranodal lymphomas have been done or are underway/ Most essentially, these studies show that nodal DLBCL can at least be distinguished in two types of lymphomas: one type has a gene expression profile of germinal center B cells (GCs); in the other type gene expression resembles that of activated B-cells (ABCs). These patterns corroborate expression of several markers of germinal center and post-germinal center B cells such as CD10 and MUM-1/IRF-4,

respectively. Furthermore, as expected, t(14;18) is almost exclusively found in DLBCL with a GC profile.²⁴² NFkappaB activation was especially observed in the DLBCL with an ABC profile.²⁴³ Clinically most relevant, DLBCLs with this ABC profile have a far worse prognosis than DLBCLs with a GC expression profile. In multivariate analysis, this prognostic factor is independent of the International Prognostic Index (IPI) prognostic index. Gene expression studies have also been used in reverse, i.e. to investigate whether DLBCL with a favorable vs. a poor response to standard chemotherapy has differences in gene expression.²⁴⁴

Morphology and immunophenotype

Large B-cell lymphomas are highly heterogeneous in morphology. Several attempts have been made to describe the various cells and subtypes, such as *monomorphic*, *polymorphic* or *multilobated centroblastic* and *immunoblastic*. Additionally, an *anaplastic* variant of DLBCL mimicking T-cell anaplastic large cell lymphoma and sometimes also expressing CD30 (see later) has been described. Finally, comparable with Hodgkin lymphoma, some DLBCLs contain a very dominant population of reactive cells, and dependent on the predominant component, these DLBCLs are called T-cell-rich B-cell lymphoma, histiocyte-rich B-cell lymphoma or epithelioid-cell-rich B-cell lymphoma. At first glance, this extensive subtyping of DLBCL looks absurd, but the significance becomes apparent if one considers that, from a pathologist's point of view, each subtype may have a completely different and often difficult differential diagnosis. For instance, even with additional immunophenotyping, the monomorphic centroblastic subtype may be very difficult to distinguish from Burkitt lymphoma; immunoblastic lymphoma may be impossible to distinguish from plasmacytoma, whereas T-cell-rich and histiocyte-rich B-cell lymphomas may be very difficult to differentiate from the diffuse variant of lymphocytopredominant Hodgkin lymphoma.

Other aspects of DLBCL

Approximately 10–30% of all DLBCLs have bone marrow localization, and a so-called 'discordant morphology' is observed in approximately half of these patients. Discordant lymphomas are lymphomas with different appearances at different sites—for instance DLBCL in a lymph node and predominantly centrocytes with a few centroblasts in the bone marrow biopsy. Most likely (but formally not proven), these lymphomas represent progressed low-grade (follicular) lymphomas. The clinical implications of this finding are obvious. Some studies have shown that after complete remission, patients with discordant disease follow the course of indolent follicle-center lymphomas, i.e. they have a short disease-free survival but a favorable overall survival.^{245–247} This may parallel the described effect of t(14;18) on disease-free survival. Therefore, bone marrow biopsies should always be analyzed carefully for the presence of tiny paratrabecular aggregates of abnormal lymphoid cells.

Burkitt lymphoma

Burkitt lymphoma was originally described as a clinical entity in equatorial Africa, with endemic malaria and other infections. The Epstein-Barr virus (EBV) was identified in 1964 and the characteristic t(8;14)(q24;q32) translocation in 1972²⁴⁸ (see Chapter 16). A specific localization of the breakpoints at 8q24 at the *MYC* locus (see later) further substantiated that these lymphomas are an entity. These lymphomas are called 'African type' or 'endemic' Burkitt lymphoma. Later on, lymphomas with a similar morphology and translocations (but different at the molecular level—see later) but with a different clinical context, and mostly without EBV infection, were identified elsewhere, including the USA and Europe. These lymphomas are called 'Burkitt lymphoma, non-African type' or 'sporadic Burkitt lymphoma', and represent approximately 2–5% of all NHL in western countries. Burkitt Lymphomas are extremely fast growing tumors with in some cases a doubling time of less than 24 h.

There is a very strong, so far unexplained male predominance, and especially male patients show a bimodal age distribution with a peak between 5 and 15 years of age. Pediatric Burkitt lymphomas mainly present at extranodal sites, whereas adult lymphomas tend to present more in the lymph nodes. The bestknown example is mesenteric/ileocecal Burkitt lymphoma in children. More recently, an increase in incidence has been observed due to the emergence of human immunodeficiency virus (HIV) infection and AIDS. Also, these lymphomas are mostly EBV negative, and of the 'non-African' type. Confusingly, some (non-African) Burkitt lymphomas, especially in adult patients, cannot be easily discerned from lymphomas with a variant morphology or DLBCL with a very high proliferation rate. A part of these lymphomas have been called 'Burkitt-like lymphoma' in the REAL classification, and are called 'atypical Burkitt lymphoma' in the WHO classification. Even very experienced hematopathologists have classification problems in this grey zone between DLBC and Burkitt lymphomas,²⁴⁹ and it certainly will be necessary to redefine Burkitt lymphoma on the basis of biologically relevant parameters such as specific gene alterations or gene expression patterns.

Genetics, etiology and pathogenesis

Using conventional banding analysis, almost all Burkitt lymphomas contain a t(8;14)(q24;q32), a t(2;8)(p12;q24) or a t(8;22)(q24;q11). The latter variant translocations involve the Ig light-chain loci. In

African Burkitt lymphoma, the frequency is up to 100%. In African Burkitt lymphomas, breakpoints mainly involve the J_H or D_H genes at 14q32 of the IgL genes at 2p12 and 22q11, and may have an origin from IgH hypermutations. In non-African Burkitt lymphoma, the breakpoints are more common at S_{μ} and S_{α} , indicating an origin from class-switching follicle-center B-cells. Within the 8q24 region, breakpoints are found within or immediately 5' of MYC (mostly in sporadic types), or far 5' and far (several hundreds of kb) 3' of MYC (mostly African types).^{250–255} Most likely, breakpoints can be best detected using FISH analysis.^{77,256} Studies on hypermutations in Ig genes in African Burkitt Lymphoma cell lines showed extensive hypermutations, indicating that the cells do represent mature B cells.^{257,258}

Morphology and immunophenotype

Most Burkitt lymphomas present with large and extremely rapidly growing tumor masses. The prototype of the non-African-type Burkitt lymphoma is a large mass in the ileocecal mesenteric region, with extension in the intestinal wall and generation of ascites. Polypoid masses in the submucosa may give rise to invagination. Tumor cells may be found in the peripheral blood and bone marrow, giving the appearance of an acute leukemia previously called ALL-L3. Most characteristically, the tumor cells show a diffuse, cohesive growth pattern with interspersed tingible body macrophages stuffed with apoptotic tumor cells. This combination creates the typical 'starry sky' pattern under low-level microscopy. Cytologically and immunophenotypically, Burkitt lymphoma cells resemble early blasts (small centroblasts) in normal follicle centers. This explains why a distinction between Burkitt lymphoma and the monomorphic centroblastic variant of DLBCL may be difficult (see earlier). To prevent autolysis and poor morphology, it is extremely important to speed up transfer of surgical material to the pathology laboratory. Cytological preparations (imprints or smears of ascites) are extremely helpful, since they may show diagnostic details such as lipid-containing vacuoles. Immunophenotypically, Burkitt lymphoma cells show strong expression of surface IgM. Like normal follicle-center cells and follicular lymphomas, almost all Burkitt lymphomas express CD 10 and BCL6, whereas TdT is consistently absent. BCL2 expression should be absent as well. The variant-type Burkitt lymphoma in elderly patients discussed earlier exhibits more pleomorphism, anisonucleosis, bigger nucleoli, and often plasmacytic differentiation with cytoplasmic staining in immunofluorescence for immunoglobulins.¹⁷⁶

Other B-cell lymphomas

As shown in Table 36.1, there are many other lymphomas that may be conceived as a clinicopathological entity. Splenic marginal-zone lymphoma either with or without villous lymphocytes (SLVLS) is a rare clinicopathological entity that, like other indolent B-cell lymphomas, has been associated with hepatitis C virus infection.^{259–261} In one study antiviral therapy appeared to be effective in only those lymphomas that were associated with the virus. In contrast to earlier reports that suggested a heterogeneous phenotype, this lymphoma should be characterized by the consistent absence of CD5, CD10 and cyclin D1 expression. Splenectomy preparations show a distinct infiltration of the white pulp with aggregates of tumor cells in the red pulp, which is different from the pattern in HCL, variant HCL and prolymphocytic leukemia (PLL).

Immune-deficiency-associated EBV-positive lymphomas

In the WHO classification, three main subgroups have been proposed (Table 31.3):

1. Immunoproliferative diseases associated with primary immune disorders (PIDs)
2. Lymphomas associated with infection by HIV
3. Post-transplant lymphoproliferative disorders (PTLDs).

There is a large number of primary immune disorders with an increased incidence of lymphoproliferative disorders, including diseases that present early during life such as severe combined immune deficiency (SCID) and disorders that present later on such as the autoimmune lymphoproliferative syndrome (ALPS). The incidence differs depending on the underlying disorder and the genetic background.^{262–264} Many disorders are X-linked and, therefore, preferentially present in males (SCID, X-linked lymphoproliferative syndrome, hyper IgM syndrome). With the exception of the lymphomas in ALPS, many of these lymphoproliferative disorders present at extranodal sites and almost all cases are EBV driven. In ALPS, that is caused by mutations in FAS/CD95, CD95 ligand/FADD, caspase 8 or caspase 10, a wide variety of lymphoproliferative disorders including Hodgkin lymphoma have been described.^{265–269} In common variable immunodeficiency, chronic antigenic stimulation rather than EBV may lead to the development of lymphomas. Large B-cell lymphoma is the most common type in PID, with the exception of T-cell lymphomas in ataxia teleangiectasia, as well as a very heterogeneous range of lymphomas in ALPS.

Lymphomas associated with infection by HIV comprise a wide range of disorders. Most cases are diffuse large B-cell lymphomas, but they also include Burkitt lymphoma, plasmablastic tumors, primary effusion lymphoma, peripheral T-cell lymphomas and Hodgkin lymphoma. Again many lymphomas involve extranodal sites, especially the mucosal sites, lungs,

pleural cavities, brain, and bone marrow.^{270–274} Most lymphomas are EBV driven and such lymphomas frequently lack expression of several lymphoid markers such as CD45 and CD20.²⁷⁵ This implies that the lymphoid nature may be missed if other markers (CD30, CD79a, GD138, Ig) are omitted. One example is the primary effusion lymphoma; these EBV-positive and human herpes virus type 8 (HHV-8)- or Kaposi sarcoma virus (KSV)-positive tumor cells lack almost all lymphoid markers, but contain monoclonal rearrangements of the Ig genes.^{276–278} Interestingly, the incidence of these lymphomas has dramatically decreased, which is caused by the currently very effective antiviral therapy in western countries, whereas some of the current patients present with disorders that have more analogy to PTL, especially the polymorphic lymphoproliferative disorder.

PTLDs also have a highly varying clinical and pathologic picture, which is very much dependent on the clinical context, age, and level of immune suppression. In some transplant patients and especially children, generalized disease with circulating tumor cells may be present. In some patients, the tumor preferentially involves the transplanted organ itself.^{279–284} Histologically, these lymphomas have a variable morphology, leading to a number of different classifications. Again, most disorders are EBV positive, but especially lymphomas that occur relatively late after transplant, including the so-called plasmacytomas, can be EBV negative. Immunophenotypically, the tumors often show cytoplasmic Ig, which is detectable in formalin-fixed and paraffin-embedded tissue. Depending on mainly host factors, especially the level of immune deficiency and time after transplant, immunoglobulin expression can be polyclonal, oligoclonal or monoclonal. This may reflect the evolution of these tumors from polyclonal B-cell infection by EBV, clonal evolution, and overgrowth by a single clone. The variable clonality status of the tumor cells is also observed using molecular analysis (Southern blot analysis or PCR) of Ig gene rearrangements. Depending especially on host factors, different types of EBV infection may be seen: latency type 1, but especially types 2 or 3, and even lytic infection may occur. Of note, many patients will respond to a combination therapy aiming at (temporarily) alleviating the immune suppression, to allow the patient to restore the immune status, in combination with monoclonal antibodies against the infected B cells (e.g. anti CD20). Furthermore, the current strategies to continuously monitor the EBV load in the peripheral blood and to start therapy as soon as possible will probably lead to the decrease and altered pathology of these disorders.

T-cell lymphomas

T-cell lymphomas comprise approximately 9–15% of all NHLs in western countries, but are far more frequent in Asian countries. This is probably not due to the presence of HTLV-1-related T-cell lymphomas in parts of Japan, but rather to the relatively low incidence of some B-cell lymphomas in combination with a relatively high frequency of EBV-positive nasal-type T/NK-cell lymphomas. Perhaps even more than B-cell lymphomas, T-cell lymphomas show a restricted presentation at specific sites of the body. Grossly, they can be categorized as primary nodal T-cell lymphomas such as angio-immunoblastic T-cell lymphoma, and other mainly extranodal lymphomas. Distinct examples of lymphomas with a restricted extranodal presentation and dissemination are mycosis fungoides (MF), Sézary syndrome, cutaneous anaplastic large-cell lymphoma/lymphomatoid papulosis, panniculitic-like T-cell lymphoma, nasal (type) T/NK-cell lymphomas, intestinal T-cell lymphoma associated with enteropathy, and hepatosplenic $\gamma\delta$ T-cell lymphoma. Phenotypically, most T-cell lymphomas represent malignancies of mature TCR $\alpha\beta$ + T-cells, and in some cases NK cells.²⁸⁵ Tumor cells in angio-immunoblastic T-cell lymphoma and MF/ Sézary syndrome are mainly CD4⁺ and lack cytotoxic molecules, however, many other lymphomas, especially the primary extranodal tumors have properties of cytotoxic T cells with expression of TIA-1 and granzyme B, either or not in combination with CD8 or CD4. These include the majority of anaplastic largecell lymphomas (ALCLs).^{286,287} Only a few lymphomas, in particular the EBV-positive nasal lymphomas, are derived from true CD56⁺ NK cells.²⁸⁸ In consequence, these tumors do not harbor clonal TCR gene rearrangements.

T-lymphoblastic lymphoma/T-ALL

T-lymphoblastic lymphoma is part of a spectrum of neoplasms derived from precursor T cells. In many patients, the tumor extends from the thymic region into the mediastinum, pleural cavities, cervical lymph nodes, blood and bone marrow. Therefore, differentiation between primary lymphoma and leukemia is arbitrary. There is a preference to affect young boys and adolescents. Because of the localization and extremely rapid growth, stenosis of the trachea may become life threatening within a few days or even hours, necessitating an extremely rapid diagnosis. In some patients, it is only possible to get a cytological aspirate and to perform limited immunocytochemistry before the start of therapy. Like their normal counterparts, the tumor cells are extremely sensitive to irradiation and corticosteroids.

Genetics, etiology and pathogenesis

T-ALL and lymphoblastic lymphoma are very interesting with respect to possible genetic alterations. This is discussed extensively in Chapter 18. In brief, a large number of different nuclear transcription factors

can be activated by juxtaposition with TCR genes, but, surprisingly, these translocations result in a similar phenotype.^{289,290}

Morphology and immunophenotype

In most patients, the tumor cells look like lymphoblasts as seen in ALL. The tumor cells show a high mitotic activity and sometimes a high degree of apoptosis. They may extensively infiltrate soft tissues. All lymphomas and acute leukemias should be immunophenotyped appropriately to determine the cell lineage and immaturity of tumor cells, the latter always by TdT. By further typing, the exact stage of maturation can be determined. For instance, the presence of CD1 with coexpression of CD4 and CD8 indicates a phenotype of cortical thymocytes.

Angio-immunoblastic lymphoma

Angio-immunoblastic lymphoma (AIL) is a clinicopathological entity mostly affecting elderly patients.^{291,292} Patients present with a syndrome that is characterized by generalized lymphadenopathy and many of the following features: initial skin rash, fever, hepatosplenomegaly, Coombs-positive hemolytic anemia, eosinophilia and polyclonal hypergammaglobulinemia. Almost all patients succumb to the disease, either due to progression to overt immunoblastic lymphoma or to secondary infections. Secondary infections seem to be caused by a severe cellular immune deficiency in combination with treatment. On the basis of strict histological and sometimes also molecular criteria (see later), especially early forms of AIL have to be differentiated from abnormal immune reactions. Originally, the disorder was thought to be a reactive process and was named immunoblastic lymphadenopathy (IBL) or angio-immunoblastic lymphadenopathy with dysproteinemia (AILD). After the introduction of strict histological criteria and the finding that at least 60% of these lesions harbor clonal TCR rearrangements, the name AILD-like T-cell lymphoma or its contraction AIL should be used.

Genetics, etiology and pathogenesis

Infection and hypersensitivity have been proposed but never proven to be etiological agents in AILD and AIL. Cytogenetic abnormalities, including trisomy 3 and oligoclonal abnormalities, have been reported.²⁹³ Studies of Ig and TCR gene rearrangements show that at least 60% have clonal TCR rearrangements. Approximately 20% have clonal Ig rearrangements without TCR rearrangement, and in fact some AILD lymphomas develop into immunoblastic B-cell lymphomas instead of a T-cell lymphoma. This is explained by secondary EBV infection of B cells due to depressed immune surveillance in these severely immune-deficient patients.^{294,295} This can be detected using RNA in situ hybridization for EBER and immunohistochemistry for LMP-1.

Morphology and immunophenotype

Lymph nodes involved by AIL show atrophy of follicles ('burned-out' follicles) and expansion of T-cell areas with extension in perinodal fatty tissues and obliteration of sinuses. Clusters of 'clear' blast cells should be identified. Tumor cells are present against an impressive background of numerous arborizing high endothelial venules, plasma cells, eosinophils, neutrophils and clusters of epithelioid histiocytes. The presence of large and very irregular aggregates of follicular (CD21⁺ and CD35⁺) dendritic reticulum cells is almost diagnostic for the disease. Recent studies have shown an aberrant expression of CD10 on many tumor cells.²⁹⁶ Possibly, the pleomorphic background in almost all cases is evoked by a cascade of cytokines. There may be an additional infiltrate of EBV-positive atypical immunoblasts (and plasma cells), which can be poly-, oligo- or monoclonal upon immunohistochemistry and molecular analysis. AIL often presents in the bone marrow as small, loosely arranged aggregates. A reticulin stain and immunohistochemistry are extremely helpful in unmasking these aggregates. Additionally, the skin is often involved by AIL.

Anaplastic large cell lymphoma

Anaplastic large cell lymphoma (ALCL) or large-cell anaplastic lymphoma (LCAL), previously also called Ki-1-positive lymphoma, may present in two different forms: primary cutaneous (see later) and primary systemic. The latter will be described here. Most ALCLs occur in children or young adults. Together with Burkitt lymphoma and T-lymphoblastic lymphoma, ALCL forms the great majority of NHLs of childhood. ALCLs can be misdiagnosed as Hodgkin lymphoma, metastatic carcinoma or melanoma because of incomplete phenotyping or an aberrant phenotype (see later). Some cases may mimic a reactive lymphadenopathy. B-cell lymphomas with anaplastic morphology should be excluded and classified as DLBCL. Finally, there is a distinct trend to restrict the term ALCL to those lymphomas that express the ALK protein (see later). This is supported by the observation that especially the patients with ALK-positive ALCL have a relatively very good outcome.²⁹⁷⁻³⁰¹ Primary nodal ALCL may disseminate to the skin and bones, and in approximately 10-20% of cases to the bone marrow. Note that secondary skin involvement must be differentiated from primary cutaneous ALCL, since exclusively cutaneous ALCL has an excellent prognosis (see later).

Genetics, etiology and pathogenesis

Approximately 60% or more of all nodal ALCLs contain a translocation with production of a fusion gene

between anaplastic large cell lymphoma kinase (*ALK*) and other genes.^{302–305} This frequency is even higher in ALCL of childhood. The translocation is absent in primary cutaneous ALCL as well as enteropathy-associated T-cell lymphomas with anaplastic morphology and CD30 expression (see later). The fusion protein can be visualized by RT-PCR or FISH, but also with an antibody against the ALK protein. After the first description of the classical t(2;5) involving *ALK* and nucleophosmin (*NPM*), many other fusion partners have been identified. In general approximately 70% of all breakpoints involve *NPM*, whereas in the remaining 30%, other translocations are identified. One peculiar type of B-cell lymphoma, ALK-positive diffuse large B-cell lymphoma is, however, also associated with chromosomal translocations involving the ALK gene, especially the t(2;7)(p23;q23) involving *CLATHRIN*.^{306–308} Analysis of Ig and TCR gene rearrangements are of little help in ALCL. Results are highly variable, and in many cases too few tumor cells are present to be detected by PCR and Southern blot analysis. In cases with clonal rearrangements, mostly monoclonal TCR but also Ig gene rearrangements have been reported.

Morphology and immunophenotype

Lymph nodes with the classical form of ALCL show a typical morphology: large, polymorphic so-called ‘hallmark cells’ with round, kidney-shaped or doughnut-like nuclei and often prominent nucleoli, are tightly clustered within afferent lymph vessels and sinuses, giving the appearance of metastatic carcinoma, melanoma or malignant histiocytosis. Other forms form tumor nodules or accumulations along high endothelial venules. Small-cell, giant-cell and Hodgkin-like variants of ALCL, as well as lymphohistiocytic and granulocyte-rich subtypes have been described.³⁰⁴ However, Hodgkin-like ALCL has been overemphasized in the literature, and most cases can now be assigned to the syncytial variant of the nodular sclerosing subtype of Hodgkin lymphoma. Many ALCLs evoke a pleomorphic background of reactive lymphocytes, plasma cells, eosinophils, neutrophils and especially histiocytes similar to Hodgkin lymphoma. Immunohistochemistry of these systemic ALCLs shows that approximately half of all ALCLs lack CD45, whereas epithelial membrane antigen (EMA) is present in approximately half of the cases, allowing the possibility of a misdiagnosis of metastatic carcinoma. Other positive markers are CD30 and CD25. Incomplete T-cell markers are present in more than 50% of the cases, as are cytotoxic molecules such as TIA-1 and granzyme B. In approximately 60% of the cases, ALK protein is easily found. Interestingly, highly dependent on the underlying chromosomal translocation, ALK may be present in the cytoplasm and nucleus (in case of the classical t(2;5) involving nucleophosmin, translocating the ALK protein to the nucleus) or in distinct cytoplasmic compartments. In contrast to Hodgkin lymphoma, CD 15 is commonly negative.

Nasal-type T/NK-cell lymphoma

Nasal-type T/NK-cell lymphoma^{288,309–313} has previously been described as ‘lethal midline granuloma’, ‘polymorphic reticulosis’ or ‘lymphomatoid granulomatosis’. It is especially common in some Asian regions. Almost all tumors present in the nasal cavity with ulcerative lesions or polypoid masses. This may lead to a suspicion of Wegener granulomatosis. The tumors show a locally destructive growth, sometimes with erosion of bone and even permeation into the base of the skull. Other unusual sites of primary presentation are the testis and intestine. Lymph node metastasis is uncommon, but metastasis may occur at extranodal sites. Histology often reveals extensive necrosis, and sometimes invasion of the walls of blood vessels—therefore termed ‘angiocentric lymphoma’. Since this feature is not present in all nasal-type lymphomas, and can also be seen in some B-cell lymphomas, this latter name has been omitted. Almost all lymphomas are CD2⁺, cytoplasmic CD3 ζ ⁺, CD56⁺, TIA-1⁺ and granzyme-B⁺, and are often also CD8⁺. No clonal T-cell receptor gene rearrangement is found. This corroborates a phenotype of NK or cytotoxic T-cells. Thus the presence of cytoplasmic CD3 ζ should not be interpreted as proof of T-cell origin. As demonstrated by immunohistochemistry, in situ hybridization, and other molecular studies, almost all (>90%) lymphomas are EBV positive.

Intestinal T-cell lymphoma

Intestinal T-cell lymphoma is a disease of the elderly, and is closely associated with enteropathy or overt celiac disease.^{314–320} Clinically, it may present with a period of increased abdominal discomfort and malabsorption. Other patients present with perforation of the jejunum or ileum with peritonitis. Surgical intervention shows one or more perforations and often multiple foci of tumor or ulcers. Histological examination may show large tumor masses, usually with a high degree of pleomorphism, but sometimes also very extensive multifocal ulceration without easily recognizable tumor cells. Extensive sampling may reveal only small tumor foci, often with an aberrant phenotype. In some cases there is an extensive eosinophilia that masks the tumor cells. At the cytological level, the tumor cells may vary from small to large, the large cell type often exhibiting anaplastic and pleomorphic nuclei. They have a phenotype of activated cytotoxic T cells (granzyme-B⁺). Approximately half of the cases show strong expression of CD30 mimicking ALCL, and in some cases the tumor cells have an anaplastic morphology including the presence of so-called ‘hallmark cells’, as well.

However, these tumors should not be considered as ALCL, which is supported by a consistent absence of the ALK protein. Small-celled types may show expression of CD56.³²¹ In view of the relationship with enteropathy, especially celiac disease, the adjacent mucosa of all specimens should be thoroughly examined for any increase in intraepithelial lymphocytes (IELs) or overt villous atrophy.

Peripheral T-cell lymphomas not otherwise specified

This group of lymphomas is more or less a wastebasket of lymphomas, including the so-called 'Lennert lymphoma'. The latter often presents with generalized lymphadenopathy and splenomegaly. Histologically, it is dominated by clusters of epithelioid histiocytes, interspersed small- and medium-sized T-cells, and few blasts. Most importantly, using additional stainings, pathologists should exclude a reactive process (Whipple disease and mycobacterial infection), angioimmunoblastic T-cell lymphoma, mixed-type Hodgkin lymphoma, immunocytoma and epithelioid/T-cell-rich B-cell lymphoma.

Cutaneous T-cell lymphomas: MF and Sézary syndrome

Mycosis fungoides and Sézary syndrome are the most common cutaneous T-cell lymphomas (CTCLs). However, other primary CTCLs should be recognized: pleomorphic and immunoblastic lymphomas, as well as CD30⁺ anaplastic large cell lymphoma and the 'borderline' condition lymphomatoid papulosis. Clinically, MF often presents on the trunk ('swimsuit localization'). Dermatological presentations may be in the form of patches, plaques and tumors. Especially in the tumor-forming stage, tumor cells may disseminate to local lymph nodes, followed by internal localizations. Based on lymph-node histology, a specific staging may be used.^{322,323} Variant forms of MF comprise (large) parapsoriasis en plaque, MF with mucinosis follicularis, follicular MF, Pagetoid reticulosis/Woringer-Kolopp disease and the extremely rare granulomatous slack skin disease.^{324–326}

No consistent cytogenetic data are available for MF. Monoclonal TCR gene rearrangements are easily identified during the plaque- and tumor-forming stages, however, clonality is difficult to demonstrate in the early patch stage, especially because of the presence of very few tumor cells that are admixed with reactive T-cells.³²⁷

In its classical form, the patch stage of MF is difficult to diagnose. Skin biopsies show a band-like infiltrate of T-cells with a few atypical large, so-called cerebriform nuclei in the dermal papillae, and especially in the lower part of the epidermis, where they may form Pautrier abscesses.

Immunophenotypically, the cells are CD2⁺, CD3⁺, CD4⁺, CD5⁺ and CD8⁻. In approximately 10–20% of cases, loss of both CD4 and CD8, and/or loss of CD5, may be of help in differentiating MF from reactive dermatitis. Occasional cases with CD8 expression have been described, and these neoplasias seem to have a more aggressive course.^{328–330} These CD8⁺ malignancies must be differentiated from actinic reticuloid. In the plaques, the lesions are more extensive and far easier to recognize. In the tumor lesions, extensive infiltration of the dermis is present. These deeper infiltrates often show extensive atypia, with presence of blast cells that show loss of T-cell markers. In some patients, the blasts may be very anaplastic and CD30⁺.

Epidermotropism may be lost in these lesions, and hence a diagnosis of MF can only be made in combination with previous or simultaneous biopsies of other, less advanced lesions. Involvement of lymph nodes develops along a certain sequence, and starts with dermatopathic lymphadenopathy, slight infiltration of tumor cells and partial infiltration, and ends with complete destruction of structures.

Sézary syndrome is an extremely rare disorder.³³¹ It is often lumped with MF; however, its clinical presentation is different, as well as its relatively poor prognosis. Clinically, patients present with red skin, palmar and plantar scaling, and extreme itching. Draining lymph nodes and blood are often involved from the start of the disease. Cerebriform tumor cells should be identified in blood smears or sections made from buffy coats. According to most criteria used, the blood should contain more than 1×10^9 abnormal (cerebriform) cells per liter and an abnormally high CD4/CD8 ratio. Sézary syndrome must be differentiated from reactive conditions, especially extreme forms of eczema and hypersensitivity to light.

Skin biopsies may show a picture similar to the patch or plaque of MF, but in many cases the infiltrate is more restricted to the dermis. Phenotypically, the tumor cells are CD4⁺. Lymph-node biopsies should always be taken, since the histology may differentiate between reactive processes and Sézary syndrome. In contrast to MF, sinuses and T-cell areas are infiltrated by abnormal cerebriform cells.

CD30⁺ cutaneous ALCL and lymphomatoid papulosis

Apart from the classical cutaneous T-cell lymphomas MF and Sézary syndrome, other T-cell lymphomas can be recognized. Most frequently, they present as a solitary or multiple nodules or tumors. Some tumors, especially those containing CD30⁺ tumor cells, cutaneous ALCL, show signs of (spontaneous) regression. Since these ALCL have an excellent prognosis as compared with the CD30⁻ lymphomas, and show overlap

with lymphomatoid papulosis (LP), they should be separately diagnosed and treated.^{332–338}

Cutaneous ALCL and LP have an unidentified etiology and pathogenesis. In contrast to the nodal counterpart, the t(2;5) translocation or any variant translocation involving the ALK gene is consistently absent. Clonal TCR gene rearrangements have been identified in both ALCL and LP. Metachronous ALCL and LP may develop in single patients. Histologically, these tumors show infiltrates of large pleomorphic cells (see earlier). Especially during regression, edema, fibrosis and infiltration by eosinophils and neutrophils may be prominent. LP is defined by the presence of (multiple) small papules that show a spontaneous tendency to ‘come and go’ in an asynchronous pattern. Histologically, LP can show a similar picture to ALCL or a picture more reminiscent of MF, or a mixture of both. In both ALCL and LP, immunohistochemistry invariably shows a strong staining for CD30 and variable staining for T-cell markers including CD4, but absence of GD15, ALK and EM A as well as all B-cell markers. Cytotoxic molecules such as TIA-1 and granzyme-B are present in 50% (ALCL) to 100% (LP). Since all lymphomas with CD30 expression on more than 75% of the tumor cells have a similar behavior, and the presence of CD30 seems to overrule morphology. It is strongly advised to stain for CD30 antigen in all primary cutaneous T-cell lymphomas.

Other primary extranodal T-cell lymphomas

Other distinct but uncommon T-cell lymphomas—surprisingly all associated with an (activated) cytotoxic phenotype—are the T-cell large granular lymphocytic leukemia, sometimes associated with rheumatoid arthritis, splenomegaly, granulocytopenia and (pseudo) Felty syndrome, subcutaneous panniculitis-like T-cell lymphoma, associated with hemophagocytosis, and hepatosplenic $\gamma\delta$ T-cell lymphoma. The latter mainly affects young, male patients, and is associated with cytopenias, especially thrombocytopenia.

Treatment

Staging and treatment evaluation

After the histological diagnosis has been made on a lymph-node biopsy, including appropriate immunophenotyping and (if indicated) cytogenetic and/or molecular biological investigations, the staging procedure is initiated, including:

- Patient’s history
- A thorough physical examination
- Measurement of the sizes of enlarged lymph nodes, liver and/or spleen, and extranodal localizations, if present
- Inspection of Waldeyer ring by an ear, nose and throat specialist, with biopsies if doubtful lesions are observed
- CT scans of the neck, thorax and abdomen
- A bone marrow biopsy, including immunopathology
- Routine blood hematology and chemistry investigations, including the β_2 -microglobulin and the serum lactate dehydrogenase serum levels and serum immunoelectrophoresis to detect paraproteins.

In recent years ^{67}Ga scintigraphy and ^{18}F FDG photon emission tomography (PET) have been increasingly introduced as methods of nuclear diagnostics in NHL. It has become clear that ^{67}Ga scintigraphy does not offer additional value as compared to conventional staging by CT scans.^{339–341} However, ^{18}F FDG appears to be at least complementary to conventional staging, but may in 10–15% of patients detect additional localizations of NHL, thereby changing the stage and treatment strategy.^{342–344} Obviously, site-specific investigations should be performed based on specific symptomatology, e.g. a work-up of the gastrointestinal tract, lumbar puncture, nuclear magnetic resonance imaging (MRI) of the central nervous system and/or spinal cord, and other extranodal sites, and X-rays of bones. While performing the staging procedure, one should be aware that NHL can manifest itself at various exotic locations such as the orbits, conjunctivae, thyroid gland, mammae, skin, kidney, urinary bladder, testicles, cervix uteri and bone. In cases where anemia, granulocytopenia and/or thrombocytopenia are present, it should be remembered that, apart from bone marrow infiltration with NHL or hypersplenism in the case of splenomegaly, autoimmune phenomena might be the underlying cause as a consequence of a disordered immune system.

In general, for NHL, the Ann Arbor staging system that was developed for Hodgkin lymphoma is still in use (Table 36.5). The absence or presence of fever, night sweats and/or unexplained loss of 10% or more of body weight in the 6 months preceding admission are to be denoted in all cases by the suffix letters A or B, respectively. Only 20% of all patients with NHL present in stage I. In most patients, disseminated disease is present at diagnosis. In this respect, the Ann Arbor staging seems to be less relevant for NHL as compared with Hodgkin lymphoma, which shows a more contiguous spread. Certain subtypes of NHL have their own staging nomenclature (MALT lymphoma and NHL of the skin; see later).

To assess the response to treatment, complete restaging after the completion of treatment is of utmost importance, employing the relevant methods mentioned earlier. The following response criteria were assessed by an International Working Group as summarized in Table 36.6.³⁴⁵

Table 36.5 Arbor staging*

Stage	Definition
I	Involvement of a single lymph node region (I) or of a single extralymphatic organ or site (I _E)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II), or localized involvement of an extralymphatic organ or site and of one or more lymph node regions on the same side of the diaphragm (II _E)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by involvement of the spleen (III _S) or by localized involvement of an extralymphatic organ or site (III _F) or both (III _{SE})
IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues, with or without associated lymph node involvement

* Adopted at the Workshop on the Staging of Hodgkin Disease held at Ann Arbor, MI, USA in April 1971.

In particular, problems may arise in judging whether a patient is in complete or partial remission when small residual masses are left after therapy. In general, one should try to obtain material for cytology/ immunophenotyping or histopathology to determine if lymphoma is still there. Residual masses, which occur in 40–60% of treated patients, quite often do not contain vital lymphoma tissue.³⁴⁶ Again here, there is a role for nuclear diagnostics to determine whether vital lymphoma is still present in these residual lesions. In particular ¹⁸F-DG PET scanning has demonstrated a low percentage of false positivity and a high specificity (>90%). In 83 patients with aggressive NHL the 2-years disease-free survival rate was 85% in patients with a negative PET scan after chemotherapy was completed vs. 4% in those with persistent ¹⁸F-DG uptake.³⁴⁷ Due to the high physiological uptake below the diaphragm in liver, spleen and colon ⁶⁷Ga scintigraphy is particularly valuable to investigate residual masses in the mediastinum. Currently, prospective clinical studies are being performed to define the impact of these new tools in restaging the patient.

In summary, after the histopathological diagnosis of NHL has been made, it has now become feasible without invasive procedures to accurately stage the disease at the time of presentation, with methods ranging from physical examination to molecular diagnostics. In performing prospective (randomized) clinical trials, it should be emphasized that all participants must use the same staging procedures and employ similar response criteria to guarantee the interpretation of the results.

An extensive review of advanced methods to detect minimal residual disease in lymphoid malignancies is presented in Chapter 21. In general, it is obvious that establishing the immunological/molecular biological phenotype at diagnosis allows the specific detection of small numbers of NHL cells that might have survived treatment.

Prognostic factors

A first impression on the prognosis of a patient with NHL is provided at the time of histological diagnosis. Although the WHO classification of B- and T-cell lymphomas does not include malignancy grades, based on the knowledge of biological behavior, a global estimate can be given of the course of the disease if current appropriate treatment can be given according to the NHL subtype, i.e. of indolent, aggressive or very aggressive nature (Tables 36.1–36.3). However, based on results from staging procedures in large cohorts of patients and final treatment outcome, a more refined predictive model was developed in 1993—in the first place applicable to aggressive NHL subtypes. The major prognostic factors include age, stage, serum lactate dehydrogenase level, performance status and number of extranodal disease sites. In this way, four risk groups could be predicted with different survival rates (Table 36.7).³⁴⁸ Later, this IPI also proved to be valid for patients with low-grade, malignant, indolent NHLs.^{349,350} Recently a prognostic model for follicular, low-grade malignant NHL has been developed. This Follicular Lymphoma International Prognostic Index (FLIPI) is based on slightly different parameters at diagnosis as compared with the IPI for the aggressive lymphomas, i.e. age, stage, serum lactate dehydrogenase level, hemoglobin level and number of nodal disease sites involved.³⁵¹ By employing these prognostic indices, a new era of NHL treatment is entered, with the initiation of prognostic factor-tailored treatment strategies, just as has been introduced earlier in the treatment of Hodgkin lymphoma, and are now being evaluated in other hematological malignancies such as the acute leukemias. This new development should prevent under- and overtreatment, limiting at the same time unnecessary (late) side effects.

Apparently, a new set of prognostic factors appears during the course of therapy, such as the dose intensity of the cytostatic drugs administered, the response to initial treatment, the time to relapse, and the sensitivity to second-line chemotherapy.

To date, several International Working Groups are evaluating the prognostic significance of cytogenetic abnormalities, aberrant expression of oncogenes and a number of other biological markers both in patients with indolent NHL and aggressive NHL (see also Chapter 18). This should obviously lead to a further refinement of the currently employed IPI for aggressive NHL as well as the FLIPI for follicular NHL.³⁵² In

Table 36.6 Response criteria based on criteria assessed by an International Working Group**Complete response (CR) requires:**

1. Complete disappearance of all detectable clinical and radiographic evidence of disease and disappearance of all disease-related symptoms if present before therapy.
2. Normal LDH (i.e. upper level of normal-ULN). An elevated LDH detracts from a CR unless it is attributable to causes not related to NHL, e.g. hemolysis.
3.
 - All nodes and nodal masses must have reduced in size to 1.0 cm in greatest transverse diameter, or
 - If some nodes have regressed to a size between 1.0 and 1.5 cm in greatest transverse diameter from a size over 1.5 cm, while none have a size over 1.5 cm, the SPD (sum of the product of the largest perpendicular diameters) of the indicator lesions must have regressed by more than 75%.
4. The spleen, if considered to be enlarged before therapy on the basis of a CT scan, must have regressed in size and must not be palpable and/or no longer considered enlarged on physical examination, however, no normal size can be specified, because of the difficulties in accurately evaluating splenic size. Similarly, other organs considered to be enlarged before therapy due to involvement by lymphoma, such as liver and kidneys, must have decreased in size.
5. Any nodules in liver or spleen must have disappeared.
6. If the bone marrow was involved by lymphoma before treatment, the infiltrate must be cleared on repeat bone marrow aspirate and biopsy of the same site.

CR/unconfirmed (CRu) includes those patients who fulfill criteria 1, 2, 4 and 5 above, but with one or more of the following features/exceptions:

1. A residual lymph node mass 1.5 cm in greatest transverse diameter that has regressed by more than 75% as regards the product of the largest perpendicular diameters. Individual nodes that were previously confluent must have regressed by more than 75% in their size compared with the size of the original mass. The SPD size of the indicator lesions must have regressed by more than 75%.
2. Indeterminate bone marrow (increased number or size of aggregates without cytologic or architectural atypia). In case of apparent CRu it is recommended to perform, if possible, a cytological aspiration or biopsy of a residual lymph node mass to determine the cytopathological status. It is also recommended in case of CRu to repeat CT or ultrasound of the residual lesions after 2–4 months.

Partial response (PR) requires:

1. >50% decrease in SPD of the indicator lesions,
2. ≥50% decrease in SPD of splenic and hepatic nodules if present and bi-dimensionally measurable at the start of treatment.
3. No increase in the size of any single node, nodule, liver, or spleen by more than 25%.
4. No new sites of disease.
5. All patients who meet criteria for CR or CRu except for:
 - an LDH>ULN that is not attributable to other causes than NHL, or
 - with remaining but decreased number of nodules in liver or spleen, or
 - with remaining assessable disease are classified as PR,

Stable disease (SD)

1. Is defined as less than PR (see above) but is not progressive disease (see below).

Progressive disease (PD) requires:

1. ≥50% increase in the product of the largest perpendicular diameters of any at baseline identified abnormal node, nodal mass or nodule.
2. Appearance of any new lesion during or at the end of therapy.

particular RNA expression patterns in NHL as assessed by microarray technology (see also Chapter 20) have yielded within a distinct histological entity of NHL subgroups with significantly different prognoses. For example, in diffuse large B-cell NHL, as described before, two subtypes were recognized: germinal center B-like lymphoma and activated B-like lymphoma. Independent of the IPI, there was a remarkable difference in overall survival rate at 5 years: 76% vs. 16%, respectively.³⁵³ Subsequently, immunostains based on the specific gene expression profile predicted similar overall survival as compared to the DNA microarray-based prognostic factors.³⁵⁴ Similar data are currently becoming available for a variety of other subtypes of NHL. The prognostic roles of these new factors underline the biological heterogeneity of patients with NHL.

Table 36.7 International prognostic Index predicting the outcome of treatment in patients with aggressive NHL *

Index (n=2031)	No. of risk factors	% of patients	CR+ rate (%)	RFS‡ at 5 years (%)	OS§ at 5 years (%)
Low	0 or 1	35	87	70	73
Low intermediate	2	27	67	50	51
High intermediate	3	22	55	49	43
High	4 or 5	16	44	40	26

* According to Shipp et al³⁴⁸; +CR=complete remission; ‡ RFS=relapse-free survival;

§ OS=overall survival.

Treatment of indolent NHL

Stages I and II

Follicular NHL, the most frequent type of indolent NHL, representing 20–30% of all patients with NHL, presents at diagnosis with stage I or II localized disease in only 10–20% of patients. Local treatment, e.g. involved-field radiotherapy, is generally accepted as the treatment of choice. Usually radiation doses of 30–36 Gy are employed. Results from four retrospective studies in large cohorts of patients with significant follow up are presented in Table 36.8.^{355–358} From these, it appears that relapse-free survival at 10–12 years after radiotherapy ranges from 44–56%. If patients have remained free of disease for a least 10 years, their chance of relapse is very low. It may be concluded that about half of the patients were understaged at the time of diagnosis, since they relapsed later on, usually in nonirradiated areas. In this respect, it is noteworthy that in up to 75% of patients, with a t(14;18)-positive follicular NHL, who are clinically staged stage I or II, t(14;18)-positive cells are detected the peripheral blood and bone marrow, which may indicate that the disease is indeed already disseminated.³⁵⁹

Circulating lymphocytes with the t(14;18) translocation have been observed in patients for many years after treatment without signs of a clinical relapse.³⁶⁰ It has been hypothesized that these cells represent a premalignant clone that does not lead to clinical overt disease.

Finally, more extensive radiotherapy (e.g. total lymphoid irradiation) or adjuvant chemotherapy in addition to local radiotherapy showed an improved relapse-free survival in some studies, although no effect on overall survival was noted.^{361–363}

In conclusion, there is certainly a need to add new treatment modalities (e.g. monoclonal antibodies) to radiotherapy alone to decrease the significant relapse rate in these early-stage patients.

Stages III and IV

The treatment of patients with disseminated indolent NHL (stages III and IV) is a major challenge in hematooncology today. Currently available treatment modalities in follicular NHL are summarized in Table 36.9.

Wait and see approach vs. chemotherapy

Despite numerous treatment efforts ranging from single-agent chlorambucil therapy to low-dose totalbody irradiation or (aggressive) combination chemotherapy, the median survival time of 7–9 years, reflecting the biological behavior of the disease, has not really changed over the past 30 years.^{364,365}

Table 36.8 Results of radiotherapy for stages I and II indolent NHL.

No. of patients	Median follow up (years)	Years of observation	RFS* (%)	os+ (%)	Ref No.
124	5.5	10	54	68	355
190	9.1	12	53	58	356
144	8.7	10	56	69	357
177	7.7	10	44	64	358

* RFS=relapse-free survival; +OS=overall survival.

Table 36.9 Treatment modalities in follicular NHL

- Wait and see policy
- Mono- or combination chemotherapy
- Radiotherapy
- Marrow ablative chemo-radiotherapy followed by autologous peripheral blood stem-cell transplantation
- Immunotherapy
 - Interferons
 - Allogeneic stem-cell transplantation
 - Monoclonal antibodies
 - Radio-immunotherapy
 - Vaccination strategies

Although aggressive up front chemotherapy has shown a significant increase in disease-free survival, the over-all survival was not different from that obtained in patients in which the ‘wait and see’ approach was followed.³⁶⁶ In a recent follow-up study in 151 patients, in the ‘wait-and-see’ arm of a randomized trial by the British National Lymphoma Investigation (BNLI) Group, it was observed that 72% of patients subsequently received systemic chemotherapy at a median time of 2.7 years after diagnosis, 16% died without receiving systemic chemotherapy from other causes than NHL at a median time of 3.8 years after diagnosis, and 12% of the patients had still not received any systemic treatment and were still alive at a medium observation time of more than 15 years (D Linch, personal communication). It is now generally recommended to treat patients who do not participate in prospective clinical trials with mild chemotherapy (chlorambucil), courses of CVP (i.e. cyclophosphamide, vincristine, prednisone) or fludarabine (see later) if clinically indicated. Criteria to start treatment after a period of watchful waiting are the occurrence of ‘B’ symptoms (including pyrexia, nightsweats and weight loss), pruritus and general malaise for which there is no other cause, progressive disease over a 3-month period, or critical organ involvement such as ureteric, esophageal or bronchial obstruction or evidence of bone marrow failure.

Interferons

In the late 1970s and 1980s, results from phase II clinical studies on the efficacy of natural and, later, recombinant interferons (IFNs) in low-grade malignant NHL were published.^{367–369} Response rates ranging from 30–55% were reported in patients who had previously been treated with chemotherapy, with responses lasting from 3–12 months. In addition, it appeared from preclinical and clinical studies that biological response modifiers are most efficacious if applied when the tumor load is small, i.e. during the phase of minimal residual disease. Several large, prospective randomized studies have been published since then. Two studies addressing the role of IFN—a maintenance treatment—after first-line remission induction chemotherapy, yielded quite similar results in terms of a prolongation of the median failure-free survival to about 2 years in the IFN- α arm vs. 1–1.5 years in the ‘no further treatment’ arm.^{370,371} However, so far, there are no indications that overall survival is significantly influenced. In two other trials, IFN- α treatment was combined with combination chemotherapy, and, apart from (again) an increase in failure-free survival, in one study a significant prolongation of overall survival was reported, namely 61.1 months for the chemotherapy group and 83.1 months for the chemotherapy/IFN- α group.^{372,373} In their new studies, only a few collaborative groups have now adopted IFN- α treatment as one of the standard components of the conventional treatment arm. In a recent meta-analysis performed on the results from 10 phase III prospective randomized clinical trials in 1939, newly diagnosed patients with follicular NHL with a median follow up of 7 years the following conclusions were drawn. When IFN is given in the context of relatively intensive initial chemotherapy including anthracyclines and at a dose 36×10^6 units per month with at least 5 million units per dose, IFN prolongs remission duration and overall survival.³⁷⁴ However, in conclusion IFN has not been included as a component of first-line treatment in follicular NHL, mainly because of its significant side effects, leading to both patients’ and doctors’ reluctance.

Fludarabine

Recently, purine analogues such as fludarabine and 2-chlorodeoxyadenosine (2-CdA) have been introduced in the treatment of indolent NHL. In phase II studies in previously untreated patients, response rates varying from 30% to 70% have been reported.^{375,376} From a recently analyzed prospective randomized EORTC (European Organisation for Research and Treatment of Cancer) study comparing fludarabine monotherapy with CVP chemotherapy as first-line treatment in stages III/IV patients with follicular NHL, it appeared that fludarabine induces more than twice as many complete remissions: 38% vs. 15%. However, there were no differences between both arms as regards progression-free survival and overall survival.³⁷⁷ Despite significant T-cell depletion by fludarabine, no increase in (opportunistic) infections was noted. However, in heavily pretreated patients, prolonged administration of purine analogues might increase the risk of opportunistic infections. Prophylactic administration of antibiotics might then be indicated. In recent years different combinations of fludarabine with other cytostatic drugs such as mitoxantrone and/or cyclophosphamide have been explored with response rates of up to 80–95%, including up to 80% complete remissions.³⁷⁸ In up to 80% of patients, a

molecular remission was achieved as defined as PCR negativity for bcl-2 in the peripheral blood and this corresponded to an enhanced failure-free survival and overall survival.³⁷⁹

Autologous stem cell transplantation

Encouraging data have recently been reported from a number of phase II clinical studies employing marrow-ablative treatment followed by autologous stem cell transplantation in patients with (relapsed) lowgrade malignant NHL. Disease-free survival rates have been reported to range from 60% to 85% at a median follow-up of 3–7 years.^{380–382} Several centers have introduced methods to purge autologous stem cell grafts employing monoclonal antibodies, and have reported an improved disease-free survival.³⁸³ Obviously, the potential beneficial effect of purging should be proven in randomized trials. From a recently published study in a small series of relapsed patients, purging of the autologous marrow graft with a cocktail of monoclonal antibodies did not yield an improvement in failure-free survival and overall survival as compared to unpurged marrow grafts.³⁸⁴ In summary, the positive results reported for stem cell transplantation so far should be looked at with some caution, because of possible selection biases that might have occurred in these phase II studies. Obviously, given the biology of growth of low-grade malignant NHL, it is too early to judge the influence on the median survival time in this patient category. Treatment-related mortality in these studies was below 5%. However, in addition, secondary myelodysplastic syndromes/acute myeloid leukemia have been reported after autologous stem-cell transplantation in patients with NHL.³⁸⁵ The exact role of marrow ablative treatment in patients with disseminated indolent NHL is currently being explored in ongoing prospective randomized clinical trials. At the most, a prolongation of progression-free survival is achieved; however, in a recently reported study from the French-Belgian Lymphoma Collaborative Group (GELA) a significant increase in overall survival was noted after autologous stem-cell transplantation applied in first remission as compared with prolonged chemotherapy in combination with IFN, i.e. 81% vs. 74% overall survival at 5 years.³⁸⁶ Obviously, these data need to be confirmed.

Allogeneic stem cell transplantation

So far, allogeneic stem cell transplantation seems to be the only curative treatment modality in patients with follicular NHL. About 50% of patients enjoy a prolonged disease-free survival with evidence for a plateau of the survival curve.³⁸⁷ Until recently, this approach has only been available for younger patients with an HLA-identical sibling donor. Obviously, given the relatively high median age of follicular NHL patients, most patients were not eligible to undergo marrow-ablative chemotherapy and allogeneic stem-cell transplantation. Besides, the rate of treatment-related mortality has been substantial (20–40%), mainly due to acute graft-versus-host disease, infections and organ toxicity. Recently, reduced intensity conditioning was introduced, employing low doses of cytostatic drugs and low-dose total-body irradiation. In combination with immunosuppressive agents, an allogeneic graft can be established and the observed anti-lymphoma effect is therefore mainly due to graft-versus-lymphoma activity exerted by the allogeneic donor lymphocytes. The first preliminary data show that there may be less treatment-related mortality and 50% survival with the first signs of a plateau in the survival curve.³⁸⁸ Most centers, so far, do not perform allogeneic stem-cell transplantation in first remission, but rather in a later phase of the disease. Relapse after allogeneic SCT is usually treated by a donor lymphocyte infusion to profit again from the graft-versus-lymphoma effect. Finally, if no HLA-identical sibling is available, a matched unrelated donor transplant may be an option. Additional information is given in Chapter 29.

Of particular importance in the group of patients who present with a follicular NHL is the increasing chance of progressing to an NHL of higher malignancy grade. As described earlier, incidence rates between 25% and 50% have been reported.³⁸⁹ As soon as this de-differentiation occurs, the outlook is poor. In this subgroup of patients, marrow-ablative treatment followed by autologous or allogeneic stem-cell transplantation may be envisaged to be of benefit. Aggressive chemotherapy alone is not effective in the long run.

Monoclonal antibodies, radio-immunotherapy

Immunotherapy with anti-CD20 antibodies has been one of the most promising treatment modalities that has entered the treatment arena in NHL during the past years. In particular, the human-mouse chimeric monoclonal antibody MabThera (Rituximab) appears to be most efficacious. In previously treated patients MabThera monotherapy induces a response in 40–50% of the patients, with a median time to progression of slightly more than 1 year.^{390–394} A somewhat lower response rate is achieved upon retreatment with the antibody.³⁹² Currently, the role of MabThera maintenance treatment as part of the first-or second-line treatment is explored as well as its efficacy in combination with a variety of chemotherapy regimens. Currently available data point at a significant increase in progression-free survival with negligible additional toxicity from the monoclonal antibody treatment. In the years to come, it is expected that monoclonal antibodies will become an integral part of first-line and subsequent treatment regimens in follicular NHL.

In addition, radio-immunotherapy has been introduced, conjugating anti-CD20 antibodies to radioisotopes such as ^{131}I and ^{90}Y . Significant response rates have been achieved.^{393,394} However, this type of intravenous targeted radiotherapy leads to significant hematological toxicity as compared to the virtually nontoxic treatment with cold antibodies. The exact role of radio-immunotherapy in bulky vs. minimal residual disease is currently being investigated in prospective randomized studies. Chapter 25 provides a more detailed description of the currently available data on (radio-)immunotherapy in NHL.

Treatment of relapse in patients with indolent NHL

No standard treatment strategies are defined for patients with relapsed indolent NHL. Second-line chemotherapy regimens, monoclonal antibodies alone or in combination with chemotherapy, radioimmunotherapy, autologous or allogeneic stem cell transplantation, preferably in the setting of a clinical trial, local radiotherapy in particular for palliative purposes, or new treatment modalities (see later) are options in that situation, which is met in virtually all patients, given the rather long overall survival time.

Vaccination treatment

As regards new treatment modalities, it is of particular importance to mention the development of vaccination strategies employing NHL-specific idiotype vaccines in the treatment of patients with B-cell NHL. Preliminary data show that if a specific immune response occurs in vivo against the immunoglobulin expressed by the lymphoma cells, this is clearly related to a more favorable outcome in terms of an increase in progression-free survival and possibly even overall survival.^{395–397} Several prospective randomized clinical trials are ongoing to test the efficacy of vaccination strategies in the phase of minimal residual disease. Conclusive data are not yet available. Chapter 26 summarizes in more detail current mediated immunotherapy of cancer. achievements as well as perspectives on T-cell

MALT lymphoma

In the group of indolent NHLs, lymphomas of the MALT require separate consideration. As stated before, these primary extranodal marginal-zone B-cell lymphomas make up approximately 2–3% of all NHLs. A special staging system for the most frequent localization of this type of NHL in the stomach has been introduced.³⁹⁸ The role of *H. pylori* (HP) has been discussed before. By eradicating this micro-organism, biopsy-proven remissions can be achieved in up to 70% of these patients.³⁹⁹ However, it may take 1 year or more before a complete regression of the lymphoma has taken place. Therefore endoscopic follow up at regular times is of the utmost importance. MALT lymphomas characterized by a t(11;18) are usually resistant to HP eradication treatment and show a more aggressive growth.⁴⁰⁰ If no response is observed, involved-field radiotherapy may be given with curative intent to lesions limited to the stomach or its direct environment. Currently, there is no role for surgical intervention in this specific type of NHL. Disseminated MALT lymphoma is treated with chemotherapy with similar regimens as employed in follicular NHL.

Mycosis fungoides

Mycosis fungoides is one of the more frequent indolent lymphomas of the T-cell type. As mentioned before, a special staging system has been developed for this particular manifestation of NHL, based on the extent of cutaneous disease, type of cutaneous lesion, presence of nodal disease and involvement of other extranodal sites.⁴⁰¹ Depending on the stage at presentation, a variety of treatment modalities are recognized, including topical therapy (steroids, nitrogen mustard, ultraviolet light), local radiotherapy, systemic chemotherapy and total skin electron-beam irradiation. In general, high response rates are achieved, but, particularly in disseminated disease, the duration of complete remission is relatively short.⁴⁰²

CD30+ anaplastic large cell lymphoma of the skin

Finally, as a representative of the group of indolent NHLs, CD30⁺ anaplastic large cell lymphoma limited to the skin should be mentioned. Primary cutaneous localizations lack the translocation in which the ALK gene is involved, as mentioned before. When this lymphoma is present as a primary cutaneous lesion, the prognosis is excellent. Management should be conservative, and a 'wait and see' policy after surgical excision is justified.⁴⁰³

Treatment of aggressive NHL

Diffuse large B-cell lymphoma

Localized disease

Approximately 10% of this most frequent representative of the group of aggressive lymphomas present in stage I. From the extensive literature that is available on treatment outcome, it emerges that a limited number of chemotherapy courses followed by involvedfield radiotherapy is the treatment of choice, yielding a complete remission rate of more than 90% and a cure rate of 80–90%,⁴⁰⁴ With radiotherapy alone, there appears to be a higher relapse rate. As regards chemotherapy, an anthracycline-containing regimen appears to be most appropriate. Three courses of the CHOP chemotherapy regimen (cyclophosphamide,

Adriamycin, vincristine and prednisone) remain the gold standard. This is followed by involved-field radiotherapy, e.g. 30 Gy if complete remission is achieved with chemotherapy and 40 Gy if three courses of CHOP lead to a partial remission.

Disseminated disease

Before the IPI was developed, patients presenting with stages II, III or IV of diffuse large B-cell lymphoma were all treated according to the same guidelines. The CHOP regimen was one of the first effective regimens to treat aggressive lymphomas, resulting in 50% complete remissions, 60% of whom remained disease-free, so that overall about 30% of the patients could be cured. In the 1980s, various single-center studies were published on the results of second- and third-generation chemotherapy regimens, which are characterized by adding more active drugs to the original CHOP regimen and reducing the total duration of treatment.^{403,406} This would lead to an increase in the relative dose intensity, which was thought to be important to improve the results. Complete remission rates of up to 85% were achieved, followed by a significant increase in disease-free survival. However, when collaborative groups took these regimens into multicenter studies, the results were less good and approached those obtained with CHOP. Apparently, a selection bias in the phase II single-center studies must have played a role. Finally, a prospective randomized study comparing conventional CHOP chemotherapy with the new-generation regimens MBACOD, MACOP-B and ProMACE-CytaBOM revealed no differences as regards complete remission rate, disease-free and overall survival (Table 36.10).⁴⁰⁷ In addition, the more aggressive regimens were more toxic. These results clearly illustrate the importance of performing randomized studies. Only with this methodological approach can a new more effective treatment strategy be reliably developed. This requires many patients to be enrolled in studies in a short time, and this can only be done if collaborative groups embark on intergroup studies. Fortunately, this is occurring with increasing frequency throughout the world.

Since the introduction of a predictive model for aggressive NHL, modern therapeutic approaches incorporate prognostic-factor tailored treatment strategies. The International Prognostic Index appears to be a better tool to predict treatment outcome as compared with the classical Ann Arbor staging (Table 36.5). As stated before, the introduction of new biological prognostic markers and gene expression profiling of NHL is expected to further refine the prognostic index, thereby leading to a combination of the highest possible treatment efficacy and the lowest degree of toxicity. The ultimate goal of prognostic indices beyond the IPI should be tailor-made treatment for each individual patient. If this is achieved, prospective, randomized phase III clinical trials will no longer be necessary. Under- and overtreatment will thus be prevented.

Given CHOP as standard baseline chemotherapy, several studies have been published in which either dose escalation of cyclophosphamide and Adriamycin, or shortening of the usual 3-week interval between CHOP courses were explored. As regards dose escalation, prospective randomized studies employing hematopoietic growth factors are currently ongoing. So far, no definite data can be reported. Dose escalation without growth factors has not shown any significant benefit. Reducing the interval between CHOP courses to 2 weeks did not show an advantage in studies in younger patients with a favorable IPI score (Pfreundschuh, personal communication).

High-dose chemotherapy followed by autologous peripheral blood stem-cell transplantation in first remission

In a number of phase III randomized clinical trials the efficacy of high-dose chemotherapy followed by autologous peripheral blood stem-cell transplantation in first partial or complete remission was investigated.^{408_411}

Table 36.10 The SWOG/ECOG randomized trial comparing CHOP with second- and third-generation chemotherapy regimens in aggressive NHL*

Regimen	No. of patients	CR+ rated)	DFS‡ at 3 years	OS§ at 3 years
CHOP	225	44	41	54
mBACOD	223	48	46	52
MACOP-B	218	51	41	50
ProMACE-CytaBOM	233	56	46	50

* According to Fisher et al⁴⁰⁷; +CR=complete remission; ‡ DFS=disease-free survival; § OS=overall survival.

In general, these studies have not yielded an advantage in favor of high-dose, marrow-ablative treatment in first remission. From subgroup analyses it seems that IPI high-risk patients might possibly benefit from autologous stem-cell transplantation early in the phase of the disease.⁴¹² However, prospective randomized studies need to confirm this statistically non-valid analysis. In summary, introducing this treatment modality as a standard treatment in first remission outside clinical trials is not recommended. The role of allogeneic stem-cell transplantation is less clear. Although some patients show a graft-versusaggressive NHL effect, allogeneic transplantation is at the moment performed in only relatively few patients. For further reading, see Chapter 29.

Treatment of relapse in patients with aggressive NHL

Approximately 50% of patients relapsing from an aggressive NHL will respond to second-line chemotherapy. However, the majority of these patients will subsequently relapse and ultimately die from their disease. Many regimens, employing drugs that are noncross-resistant with the CHOP regimen, have been tested in the past years. All appear to have similar efficacy.^{413–415} A pivotal study at this stage of the disease appears to be the PARMA study, which addressed the question of the value of high-dose chemotherapy followed by autologous bone marrow transplantation in patients at relapse but still responding to second-line chemotherapy (responsive relapse). Patients responding to two courses of DHAP chemotherapy (dexamethasone, cytosine arabinoside and cisplatin) were prospectively randomized to receive either bone marrow transplantation or further DHAP courses. The outcome was significantly better for those patients receiving a marrow graft: the event-free survival at 5 years was 46% in the transplant arm and 12% in the conventional chemotherapy arm, with percentages of actuarial overall survival of 53% and 32%, respectively.⁴¹⁶ Thus, in patients younger than 65 years with a chemosensitive relapse, high-dose therapy with autologous stem-cell transplantation should be the standard approach. A possible role of involved-field radiotherapy in addition to chemotherapy or stem-cell transplantation is unclear as this has not been investigated in a prospective phase III clinical study.

Elderly patients with aggressive NHL

As more than 50% of patients with aggressive NHL are above the age of 60, this group poses a special challenge to the hemato-oncologist. As discussed before, in the IPI, age is an unfavorable prognostic factor. This is particularly due to the greater vulnerability of elderly patients when treated with aggressive chemotherapy. Impaired function of vital organs, altered metabolism of cytostatic drugs and severe myelosuppression preclude optimal dose intensity. However, if adequate treatment can be administered, complete remission rates as well as disease-free survival are quite similar to those achieved in younger patients.⁴¹⁷ In this patient category, CHOP is regarded as standard treatment. Recently, several collaborative groups have focused on the combination of chemotherapy with a hematopoietic growth factor (G-CSF) in an attempt to lower the incidence of granulocytopenia, with a subsequent reduction in the number of infections. In a recently published, prospective randomized trial, this was proven to be the case.⁴¹⁸ In a randomized Dutch HOVON study, adding G-CSF led to a significant increase in relative dose intensity, but no improvements were noted in the complete remission rate or in overall survival.⁴¹⁹

Shortening of the interval between CHOP courses was recently investigated in elderly patients. Results suggest that CHOP every 2 weeks is superior to CHOP every 3 weeks (Pfreundschuh, personal communication).

A major breakthrough in current NHL treatment occurred following the publication of Coiffier et al in January 2002 on the efficacy of CHOP chemotherapy in combination with MabThera in elderly patients with diffuse large B-cell NHL. In patients above 60 years of age, CHOP+MabThera induced a higher complete remission rate as compared to CHOP alone (76% vs. 63%) and with a median follow-up of 2 years, survival was significantly better for patients treated with CHOP+MabThera vs. patients treated with CHOP alone (70% vs. 57%).⁴²⁰ These differences are well maintained after 4 years of follow-up, as appeared from subsequently reported analyses (Coiffier, personal communication). Based on these results addition of MabThera to first-line CHOP chemotherapy has now become standard treatment in elderly patients with aggressive NHL in most treatment centers worldwide. Whether this will also hold for younger patients remains to be established.

Primary NHL of the brain

Primary NHL of the brain is a rare tumor, representing 1–2% of all NHLs. Most of these lymphomas are of the aggressive B-cell type. In general, the survival is poor, with a 5-year survival rate below 10%. In recent years, several phase II studies have been published, reporting an improved overall survival rate (median survival: 3 years) when either high-dose methotrexate or high-dose cytosine arabinoside, passing the blood-brain barrier, were introduced in the chemotherapy regimens and combined with whole-brain irradiation.^{421–423} However, these improved results go hand in hand with an increase in neurotoxicity.

Mantle-cell lymphoma

As stated before, this particular subtype of NHL, has a poor prognosis. From a retrospective clinicopatholog

ical comparison with other NHL subtypes, it appears that patients with mantle-cell lymphoma have a similar overall survival and response rate as patients with aggressive NHL, but a shorter duration of response and progression-free survival. Compared with patients with indolent NHL, their response rate, duration of response and progression-free survival showed no difference, while their overall survival was nearly half as long.⁴²⁴

In other words, in terms of survival, mantle-cell lymphoma behaves like aggressive NHL, while progression-free survival is quite similar to that observed in indolent NHL. At present, there is still no clue as to which combination of cytostatic drugs would be the treatment of choice. From retrospective analyses it appears that there is no major difference between treatment with alkylating agents or anthracycline-containing combinations. Both types of treatment induce complete remissions in 30–50% of the patients. However, most patients relapse within 12 months, with a median survival of 30 months.^{425–427} Phase II studies with Fludarabine, MabThera, high-dose methotrexate and cytosine arabinoside as well as marrow ablative chemotherapy followed by autologous peripheral blood stem-cell transplantation lead to complete remission rates of 60% in previously untreated patients with mantle-cell lymphoma.^{428–430} However, the real value of these regimens has to be established through properly designed randomized studies.

Peripheral T-cell lymphoma

As compared to diffuse large B-cell NHL, the prognosis of patients with a peripheral T-cell lymphoma (all types as indicated in the WHO classification) is less favorable.⁴³¹ Effective chemotherapy is lacking and most of the cases are treated with CHOP chemotherapy. The efficacy of anti-T-cell monoclonal antibodies is currently being investigated.

Treatment of very aggressive NHL

Lymphoblastic lymphoma/Burkitt lymphoma

Several entities are recognized in this group: lymphoblastic lymphoma of precursor B or T origin, Burkitt lymphoma, the acute form of adult T-cell lymphoma leukemia and most of the immunodeficiency-associated EBV-positive lymphomas (see later). Their highly aggressive nature, including a strong tendency to localize in the central nervous system (CNS), calls for very aggressive chemotherapy, including prophylactic treatment of the CNS. As regards the lymphoblastic/Burkitt lymphomas, usually similar treatment regimens are applied as in acute lymphoblastic leukemia. These are discussed in Chapter 32 and will not be repeated here.

Immunodeficiency-associated lymphomas

Post-transplantation lymphoproliferative disease (PTLD) usually is of B-cell origin and positive for EBV. Treatment consists of reduction or withdrawal of immunosuppressive agents and anti-CD20 monoclonal antibodies (MabThera). Up to 80% remissions can be achieved with a 1-year survival rate of 50–60%. Frequent monitoring of the serum EBV DNA load after allogeneic stem-cell transplantation and subsequent pre-emptive treatment with MabThera as soon as the EBV load increases appears to be very effective in preventing PTLD.⁴³² Finally, infusions of donor buffy coat cells directed against EBV antigens, have yielded remarkable remissions.⁴³³ Chemotherapy does not seem to play a major role, resulting only in short-lasting responses. Thus, humoral and/or cellular immunotherapy of these types of NHL appears to be promising.

AIDS-related NHL shows in 60–70% the histology of diffuse large B-cell NHL. The remainder is for the greater part of the Burkitt type. Standard CHOP in combination with highly active antiretroviral therapy (HAART) is the treatment of choice. In 50% of patients a complete remission is obtained, which may last longer than 1 year.^{434,435} In addition to progressive NHL, opportunistic infections are the major causes of death.

nose, stage and treat NHL have step-by-step become In conclusion, in general, the tools to accurately diagnose more refined during recent years. This has resulted in improved perspectives for many patients. Only by continuing carefully planned clinical studies can further improvements in today's lymphoma treatment be anticipated.

Acute myeloid leukemia in children and adolescents

GJL Kaspers and Y Ravindranath

Introduction

Today the cure rate in childhood acute lymphoblastic leukemia (ALL) has approached nearly 80% while that for acute myeloid leukemia (AML) continues to be between 35% and 50%, which is one of the lowest in all childhood cancers.¹ More recent studies suggest that survival rates above 50% are possible.^{2–5} Factors contributing to the low results are the heterogeneous features of AML, with multiple morphologic subtypes and distinct cytogenetic associations and a high frequency of extramedullary involvement at diagnosis compared with ALL. This heterogeneity precluded, until recently, identification of clearly definable subgroups of patients with defined outcome. An additional contributing factor was the prior strategy of using a uniform therapy regardless of the morphologic/cytogenetic variant. However within the last 15 years, the inclusion of high-dose cytarabine (cytosine arabinoside, Ara-C) has permitted the identification of distinct subgroups of AML patients with superior outcome: children with Down syndrome⁶ and AML with molecular lesions of the core binding factor complex (CBF)—i.e. AML with *inv(16)* and *t(8; 21)*.^{7–9} An additional major advance in treatment has been the demonstration of the unique sensitivity of acute promyelocytic leukemia (APL) with the *t(15; 17)* to retinoid-based therapy.^{10–13} These discoveries clearly raise the hope that with proper risk group-based definitions and risk-based therapeutic strategies, further improvements can be achieved in the treatment of all subgroups of patients with AML. In this chapter, we will explore the unique features of AML in children compared with adults, and review the treatment results of large pediatric studies within the last two decades and the lessons derived from these regarding future strategies.

Biology and classification

Unlike ALL, the incidence of AML is relatively uniform throughout the pediatric age group (Figure 37.1).¹⁴ Moreover, in contrast to ALL, the morphologic and cytogenetic variants in AML appear to be the same in both adults and children, except for the frequency of certain subgroups. For example, Down syndrome and AML is unique to children and there is a higher frequency of *t(8; 21)* and *11q 23* abnormalities compared with adults.^{15,16} In contrast, the incidence of *FLT3* gene internal tandem duplications and mutations are lower.^{17–22} Furthermore, within the last

Figure 37.1 Age-specific incidence rates for acute lymphoblastic and acute myeloid leukemias (ALL and AML) in childhood. From reference 14, with permission.

several years, it has been recognized that the previous FAB (French-American-British) classification excludes certain groups of de novo AML patients who might benefit from intensive chemotherapy because of the requirement of the presence of 30% blast cells for a diagnosis of AML.^{23,24} The recent modification to the FAB system suggested by the WHO clearly addresses these issues.^{25,26} These changes in classification are reviewed in Chapter 38. Other presentations needing special attention are cases of so-called isolated granulocytic sarcoma, as some of these cases may in fact represent FAB type M2 AML with t(8; 21) with a low blast percentage or acute megakaryocytic leukemia (AMKL), which in infants can present with chloromatous lesions and may even mimic neuroblastoma.²⁷ In each case, cytogenetic evaluation of the biopsy of the chloroma and bone marrow with appropriate histochemical stains and the use of platelet-specific markers should help resolve the diagnostic dilemma. Urinary catecholamine metabolites and abdominal ultrasound may be necessary in doubtful cases to exclude neuroblastoma.

A unique subgroup in childhood AML are those with Down syndrome. In Down syndrome, AML can present as transient myeloproliferative disorder (TMD) in the neonatal period or as AMKL or acute erythroleukemia (AEL) in later infancy.^{6,28–30} Interestingly, the AMKL in Down syndrome is not associated with the t(1; 22) cytogenetic marker found in AMKL in non-Down children.^{31,32} Regardless, the outcome is excellent—spontaneous recovery is the rule in TMD,^{33,34} and in later infancy AML in Down syndrome children is highly responsive to therapy, as initially reported by the Pediatric Oncology Group (POG).^{6,29,30,32,35–40}

Additional unique subgroups in children are cases of AML developing in children with constitutional aplastic anemias (notably Fanconi anemia and those with paroxysmal nocturnal hemoglobinuria, which is often associated with monosomy 7), children receiving granulocyte colony-stimulating factor (G-CSF)^{41–43} and AML with 11q23 abnormalities following epipodophyllotoxin therapy.^{44–46} Further, de novo 11q23 AML in neonates has been linked to maternal exposure to flavinoids.⁴⁷ We will explore further some of these unique features of childhood AML in relation to prognostic features, drug resistance, and treatment results.

Risk group definitions and prognostic features

As noted earlier, distinctive subgroups with differing outcome began to emerge with the introduction of high-dose cytarabine in the treatment of AML. It had been recognized for a long time, however, that patients with monocytic features have a poor outcome, while the M4Eo subgroup with abnormal eosinophils and inv(16) have a better outcome.⁴⁸ Subsequent large adult studies in the mid to late 1980s showed the importance of cytogenetics in the prognosis of AML and led to the identification of three cytogenetically based risk groups: good risk or favorable cytogenetics with inv(16), t(8; 21), and t(15; 17); an intermediate-risk group with normal cytogenetics; and those with all other genetic abnormalities, comprising a poor-risk (unfavorable cytogenetics) group.^{7,8,16} On the other hand, the Berlin-Frankfurt-Miinster (BFM) group used different strategies for risk group definition in pediatric patients. The BFM group did not include cytogenetics, but did include a centrally reviewed FAB morphology and centrally reviewed assessment of response to induction therapy.^{49,50} In a multivariate analysis, bone marrow blasts present on day 15, morphologically defined risk groups, and hyperleukocytosis proved to be of prognostic value. Since the specific karyotypes t(8; 21), t(15; 17), and inv(16) were closely associated with the favorable morphologic types M2, M3, and M4, respectively, the outcome was in the same range for these cytogenetic and FAB subgroups. The BFM group suggested that the standard-risk group should be defined by favorable morphology (M2 with Auer rods, M3, and M4Eo) and a significant blast reduction on day 15 (not required for the FAB type M3), comprising 31% of all patients. This risk group had an estimated 5-year survival rate of 73%, and an event-free survival (EFS) rate of 68% for patients treated on the BFM87 regimen.⁵⁰ The remainder of the AML patients would comprise the poor-prognosis group. Investigators from the UK Medical Research Council (MRC) combined cytogenetics and response to the first course of chemotherapy and identified three groups: good, comprising those with t(8; 21), inv(16), or M3 AML, irrespective of response status or presence of additional abnormalities; standard (neither good or poor); and poor, comprising those with cytogenetic abnormalities other than t(8; 21), inv(16), and t(15; 17) or normal cytogenetics or resistant disease.⁵¹ The survival rates for these three groups were 70%, 48%, and 15%, respectively, and the relapse rates were 33%, 50%, and 78% (both with $p < 0.0001$). In newer treatment strategies, most adult and pediatric patients with APL are being treated on protocols that use all-trans-retinoic acid (ATRA, which is not used in other AML cases), and there is an attempt at reducing therapy for Down syndrome children with AML. The POG conducted a recursive partitioning analysis of prognostic factors in a large cohort with complete cytogenetics and excluding patients with Down syndrome or APL.^{15,52} In this comprehensive study of 478 childhood AML cases, once again cytogenetics emerged as the most reliable predictor of outcome. In a multivariate analysis, patients with FAB type M5 had a poorer outcome, while those with inv(16) had

the best outcome, followed by t(8; 21) and those with normal cytogenetics; the difference between t(8; 21) and normal cytogenetic subgroups was not statistically significant. In the partitioning analysis, three groups emerged: female patients with t(8; 21), inv(16), or a normal karyotype had the best prognosis (the 4-year EFS rate was 55.1±5.7%); male patients with t(8; 21), inv(16), or normal chromosomes had an intermediate prognosis (4-year EFS rate 38.1%±5.3%); the third group comprised the remainder (4-year EFS rate 27%±3.2%). Only one other pediatric study suggested a better outcome in female patients.⁴⁰ Non-Down syndrome FAB type M7 AML patients, relatively rare, seem to have a poor prognosis.⁵³

Another cytogenetic feature with prognostic significance is the t(9; 11), occurring more frequently in children aged less than 1–2 years.⁵⁴ Investigators at St Jude Children’s Research Hospital reported that children with AML and a t(9; 11), most often associated with FAB type M5 and younger age, had significantly better outcome than other cases with an *MLL* gene rearrangement and than other FAB type M5 cases. In fact, this subgroup had the best overall prognosis compared with all other subgroups of AML.⁵⁵ Other groups have also reported that infants with AML have a relatively favorable prognosis.^{35,40,56}

In the past few years, another marker, the *FLT3* internal tandem duplication (ITD) has emerged as another important independent prognostic variable.^{17–22,57} In a select group of children with AML treated on the Children’s Cancer Group (CCG) 2891 study in whom *FLT3* ITD determinations could be done, the results for *FLT3* ITD emerged as the single most important prognostic variable.²¹ It should be recognized that not all of the patients included in this evaluation had complete cytogenetic information. On the other hand, the MRC group evaluated the role of *FLT3* ITD patients treated on the MRC AML10 and 12 trials, with a higher proportion with cytogenetic information.^{17,20} Both the CCG study and the MRC studies suggest that *FLT3* ITD may be present in about 20–27% of patients, and are associated with hyperleukocytosis and a high percentage of bone marrow blast cells. Complete remission was lower in patients with *FLT3* ITD, and there was a higher induction death rate in both studies, resulting in adverse EFS and overall survival. The MRC studies also confirmed the findings of the CCG 2891 study and showed that *FLT3* ITD was the most important significant prognostic factor. The MRC studies found no evidence that the relative effect of *FLT3* ITD differed between the cytogenetic risk groups. The conclusion was that the presence of *FLT3* ITD is an additive risk factor.

It is clear from the above that prognosis in AML is determined by biologic markers of blast cells—be they cytogenetics and thereby specific alterations of genes involved in leukemogenesis such as the *CBF* complex, constitutional events such as Down syndrome, or expression of certain myeloid proliferation signaling genes (*FLT3*) (Table 37.1). These observations raise the hope that more rationally designed therapeutic strategies will be developed for each of the AML variants, with their own set of cytogenetic and molecular aberrations. Recent technical advances, such as gene expression profiling and proteomic studies, will be helpful in identifying novel subgroup-specific treatment targets. Such targeted strategies, as opposed to the current practice of a single treatment protocol for the average patient, should pave the way for improved results of all cases of AML.

Treatment of AML

The modern treatment of AML started with the development of the now classic ‘3+7’ combination of daunorubicin and cytarabine by Yates et al^{58,59} and subsequently the concept of intensification of treatment by Weinstein et al.⁶⁰ Thereafter, treatment concepts focused on further intensification of either the induc

Table 37.1 Prognostic factors in pediatric AML at initial diagnosis

Factor	Good	Poor
Age	<1–2 years	>10 years
Sex	Female	Male
White blood cell count	<100	>100
Extramedullary disease	Absent	Present (skin, chloroma)
Initial treatment response	CR after first course	No complete response after first course
FAB type	M1/2 with Auer rods, M3, M4Eo	M0, M1, M5, M7 (non-Down)
Cytogenetics	t(15; 17), inv(16), t(8; 21), t(9; 11), constitutional trisomy 21	<i>FLT3</i> internal tandem duplication, chromosome 5/7 abnormalities, 3q abnormalities, complex karyotype without good-risk cytogenetics

tion regimen or postremission therapy using high-dose cytarabine, allogeneic bone marrow transplantation (BMT), and autologous BMT in first remission. These strategies have resulted in improved control of AML both in adults and in children, but with the results in pediatric age groups being significantly better than in adults. The major reasons for the better results in children are: (i) general better tolerance of therapy in this age group compared with adults and (ii) a somewhat higher frequency of true de novo AML in children, particularly those with core binding factor leukemias, namely t(8; 21) and inv(16).^{15,16} It is now possible to achieve remission in 80–90% of children with AML, and the long-term EFS (with remission failures, relapses, and deaths in remissions included) rate varies between 38% and 50%, or even higher.^{4,5,35,40,49,50,61–66} Within the last decade, the treatment of children with APL has been virtually identical to that in adults with APL (see Chapter 39). Further, as noted above, Down syndrome children with AML represent a unique subgroup, and the treatment strategies in these children will be described separately below. Regardless, it should be noted that, in general, the treatment of AML is very intensive compared with the therapy used in ALL. The period of myelosuppression is longer and therefore a higher risk for fatal complications from bleeding or infections. The risk for sepsis for α -hemolytic streptococcal infections is high, particularly after the use of high-dose cytarabine,⁶⁷ and there is a higher incidence of fungal infection. Thus, referral of these children to specialized treatment centers should be considered if such special support services are not available.

Remission induction therapy

Daunorubicin for 3 days and cytarabine for 7–10 days is the backbone of therapy in most protocols. In several treatment regimens, a third or fourth drug has been added—thioguanine in POG studies,^{62,68} thioguanine, etoposide, and dexamethasone in the DCTER regimen used by the CCG,⁶⁴ and etoposide instead of thioguanine in the MRC⁵ and BFM⁶⁹ trials. Other strategies that have been used to improve outcome are the use of high-dose cytarabine in the POG 9421 protocol,⁷⁰ the concept of intensified-timing DCTER by the CCG,⁶⁴ the use of mitoxantrone instead of daunorubicin by the French Society of Pediatric Hematology and Immunology (SHIP),^{2,66} and idarubicin in place of daunorubicin.^{4,71} What are the lessons from these strategies? How can these be applied for development of new therapies? In Table 37.2, we have summarized the results from these various studies in relation to drug dosage for daunorubicin and cytarabine with the first induction course and the duration of exposure to cytarabine. Caution needs to be exercised in the interpretation of the results as summarized in Table 37.2 because of the significant differences among the studies with relation to the eligibility criteria, such as the upper limit of age (e.g. up to age 21 years in the US studies versus up to 15 years in the MRC studies, and 17 years in the BFM group), inclusion or exclusion of secondary AML cases, the ethnicity/race-based heterogeneity of the population served, and the treatment center size. Another variable is the definition of complete remission; for example, the POG 8821 study³⁵ included patients with so-called M2A marrow (<15% blasts) as well as those with classic M1 marrow (<5% blasts), while the CCG, MRC and BFM studies required M1 marrow and ‘normalization’ of peripheral blood counts. Despite these limitations, some general conclusions can be drawn from these studies: (1) a total daunorubicin dosage of less than 100 mg/m² as in CCG 2891 standard timing is associated with lower remission rates as well as lower EFS and overall survival; (2) a total dose of cytarabine in excess of

Table 37.2 Dose intensity of daunorubicin/cytarabine induction therapy in pediatric AML and outcome

DNR, daunorubicin; Ara-C, cytarabine; Mitox, mitoxantrone; ED, early deaths; RD, resistant disease; CR, complete response rate; EFS, event-free survival rates at 3 years (EFS3) and at 5 years (EFS5); OS, overall survival rates at 3 years (OS3) and at 5 years (OS5).

1 g/m² or a total exposure of 10 days is superior to the standard dose of 100 mg/m² for 7 days. In fact, with regard to the cytarabine, there appears to be a dose/duration of exposure-dependent effect on EFS. For example, CCG 2891 standard-timing DCTER had only 4 days of exposure to cytarabine with the initial induction course and a 27% EFS rate at 3 years,⁶⁴ compared with the 42% 3-year EFS rate in POG 8821, and the 49% EFS rate at 5 years in the MRC AML10 trial,⁵ which used 2 g/m² of cytarabine over 10 days. Daunorubicin administration schedules also differ among the protocols. In the POG 8821 DAT induction regimens, daunorubicin was given on days 1, 2, and 3 as a bolus, while it was given as a continuous infusion in the CCG 2891 regimen, as a 90-minute infusion in two split doses in the BFM regimen,^{4,49} and as a 6-hour infusion on days 3, 5, and 7 in the MRC protocols. The known pharmacokinetic properties of daunorubicin and time to intercalation of daunorubicin with DNA suggest that a minimal infusion time of 90 minutes is required for the optimal binding of daunorubicin to DNA.⁷² Consistent with this, the results in the BFM87/93 and MRC AML10 studies are superior to those obtained in the POG 8821 study, which used a bolus schedule. The intensive-timing DCTER regimen in part compensated for this by administering two courses of DCTER on days 1 and 10, with a total of 160 mg of daunorubicin and 8 days of cytarabine in the first 2 weeks of therapy.^{64,65} Not unexpectedly, as the intensity of the treatment increased, the percent-age of children with treatment-related complications increased from a low of 4% in the POG 8821 study to a high of 11% in the intensified-timing DCTER.

Another feature of interest in the induction therapy is the role of a third drug besides the anthracycline and cytarabine. Both the POG and CCG studies included thioguanine, while the CCG, BFM, and MRC groups included etoposide during induction. The exact contribution from the third drug is not clear, although the rationale for the addition of etoposide is its effect on monocytic leukemia.^{73,74} In a direct comparison within the MRC AML10 trial, the difference in remission induction rates between the etoposide regimen and the thioguanine regimen was not statistically significant, nor was there any difference in event-free or overall survival, but subgroup analyses (e.g. within monocytic leukemia) were not shown.⁵

The POG 9421 studies tested standard-dose cytarabine 100 mg/m² × 7 versus 1 g/m² twice daily for 14 doses for intensification of treatment. In this study, which excluded Down syndrome and APL cases, preliminary results show no appreciable improvement in results based on this induction intensity.⁷⁰ This contrasts with the results obtained by increasing the intensity of cytarabine for induction in the adult studies of the Southwest Oncology Group (SWOG) and the Australian investigators.^{75,76} One reason for an apparent lack of effect of high-dose cytarabine for induction in children versus adults is the relatively high remission induction rate with standard-dose cytarabine in children.

Two current trials are exploring the role of idarubicin versus daunorubicin during induction in pediatric AML. Of these, the results of the BFM93 study have been published,^{4,71} while those from CCG 2961, in which idarubicin was substituted for daunorubicin in the DCTER regimen, are yet to be published. Idarubicin has the theoretical advantage over daunorubicin of a longer intracellular half-life and greater in vitro cytotoxicity. Further, the metabolite of idarubicin appears to be somewhat less susceptible to multidrug resistance-mediated efflux. In adult trials, there appears to be a slight advantage with idarubicin or daunorubicin.^{77,78}

The BFM93 results showed that idarubicin induction led to a significantly better blast cell reduction in the marrow on day 15.⁷¹ Event-free and overall survival in BFM93 were superior to those in BFM87, but the benefit from idarubicin appeared to be restricted to high-risk patients only. The toxicity of the BFM93 regimen, which included idarubicin for induction and high-dose cytarabine and mitoxantrone (HAM) in consolidation therapy, was somewhat higher compared with the previous BFM87 study. Thus, the results of the CCG 2961 trial are of interest in determining whether any significant improvement can be demonstrated with idarubicin. The SHIP used mitoxantrone in place of daunorubicin in the LAME 89–91 trial, with an 87% remission induction rate and a 48% disease-free survival rate for the chemotherapy group.²

Postremission therapy

The POG, CCG and MRC AML10 trials compared autologous BMT in first remission with intensive chemotherapy. In the POG³⁵ and CCG trials,⁶⁵ no advantage could be shown for autologous BMT, while in the MRC AML10 trial,⁵ there was a reduced relapse rate with autologous BMT, but this did not translate into a significant overall benefit. An earlier pediatric Italian study from the pre-high-dose cytarabine era also failed to show any survival benefit with autologous BMT in first remission.⁷⁹ These results contrast with those for adults in the European (EORTC) and MRC AML10 trials.^{80,81} Both the EORTC and MRC trials showed an advantage for adult AML patients with autologous BMT versus no further therapy. On the other hand, an intergroup adult trial in the USA⁸² showed no significant difference in 4-year survival rates among patients randomly assigned to high-dose cytarabine or autologous BMT. The exact reasons for the differences observed in these results are not clear. It is worth comparing the two pediatric US trials and the EORTC and MRC trial. For example, in both of the US pediatric AML studies, randomization occurred

immediately after achieving remission and patients assigned to chemotherapy received several additional courses of therapy. In the EORTC and MRC trials, all patients received equal numbers of courses prior to randomization and the comparison was between high-dose chemotherapy plus autologous BMT rescue versus no further therapy in the control group. It can be argued that the advantage seen for autologous BMT in the MRC AML10 and EORTC trials was simply due to an extra course of chemotherapy (preparative regimen), i.e. more therapy is better than less therapy, since a graft-versus-leukemia effect is not expected from autologous marrow infusion. In fact, in gene marking studies, relapse post autologous infusion of marrow in AML has been shown to be due to residual leukemic cells contaminating the harvested marrow.⁸³

Thus, what are the important components of the postremission chemotherapy strategy? In brief, most studies have included several courses of high-dose cytarabine, for example a six-dose schedule in the POG 8821 study and an eight-dose timed split-dose schedule in the CCG and Nordic trials.^{40,64,84,85} The MRC group included the combination of amsacrine, cytarabine, and etoposide (MACE), mitoxantrone/ cytarabine, and cytarabine/L-asparaginase (CLASP). Of these drug combinations, amsacrine is not available in the USA either commercially or as an investigational agent. Mitoxantrone is widely available, and appears to be an effective agent when used in combination with cytarabine or other agents in relapsed pediatric patients.^{86,87} The results from the LAME 89/91 studies^{2,66} and as well the recent BFM93 trial⁴ with the HAM (high-dose cytarabine and mitoxantrone) combination suggest that there may be some benefit from including this combination in the postremission phase of AML.

Maintenance therapy

The role of maintenance therapy remains controversial. Two studies suggest that maintenance does not result in added benefit after intensive consolidation.^{2,88} BFM AML studies continue therapy up to 1 year total.

CNS-directed therapy

It is of interest that despite a higher incidence of blasts in the cerebrospinal fluid (CSF) at diagnosis in AML than in ALL cases, central nervous system (CNS) relapse as a primary site is less common in AML. Perhaps this is due to the somewhat lower EFS and the early bone marrow relapse in AML compared with ALL. From 5% to 20% of children with AML have been reported to have blasts in the CSF at diagnosis.^{5,62,89} The CNS-directed therapy in AML has included four to six intrathecal doses of methotrexate or cytarabine (not concurrent or within 72 hours of systemic high-dose cytarabine) or cranial irradiation. The US studies used chemotherapeutic agents, whereas the BFM and MRC groups have given cranial irradiation for patients with CNS disease at diagnosis.^{5,89} Whether these particular features account for the differences between the BFM and MRC trials versus the US trials is uncertain.

Treatment for hyperleukocytosis

Abnormal clinical findings related to hyperviscosity from high leukocyte counts are uncommon.⁹⁰⁻² However, a portion of patients might demonstrate leukostasis in the CNS (Figure 37.2). Radiation has been used on occasion, as well as exchange transfusion or leukopheresis. In general, early institution of induction therapy appears to be the most efficient method of controlling hyperleukocytosis. However, it may be decided to give short-term single-agent low-dose cytarabine in these situations.

Treatment of CNS extramedullary disease (EMD)

Isolated granulocytic chloromatous presentation is most commonly seen with monocytic leukemia, patients with t(8; 21), and those with megakaryocytic leukemia. In general, most chloromatous lesions respond to chemotherapy, and if imaging studies show complete remission of the lesion then there appears to be no benefit from local irradiation. For lesions that cause organ dysfunction, such as compression of the spinal cord or the optic nerve, radiotherapy should be considered. Whether EMD contributes to an adverse prognosis remains controversial. It is of interest that patients with t(8; 21) may

Figure 37.2 Computed tomography (CT) image of brain in a child with monocytic leukemia, showing infiltrates.

present with chloromatous lesions, a group of patients whose prognosis appears to be the same as those patients with t(8; 21) without EMD. A high frequency of chloromatous lesions in t(8; 21) has been linked to coexpression of CD56 (neural cell adhesion molecule, NCAM) in this AML variant with good prognosis.^{93,94} In the previously cited report from POG,⁵² EMD did not add to a risk in either the favorable or the adverse cytogenetics group. A similar conclusion was reached by the Dutch investigators.⁹⁵

Down syndrome and AML

One of the more remarkable developments in childhood AML in the last decade and a half is the recognition that AML in Down syndrome (DS) is highly curable.⁶ In the original publication from the POG investigators, all 12 children with AML and DS survived, compared with an overall survival rate of 33% in non-DS children treated on the same protocol—a striking difference from earlier publications, in which DS children had similar or poorer outcome compared with non-DS children.⁹⁶ Since then, the POG, as well as other groups, have shown that over 75% of DS children with AML achieve long-term remission with current therapy.^{29,30,32,36–38,40,97,98} This improved outcome in DS children coincided with the inclusion of high-dose cytarabine in the treatment protocols, as children with DS treated on less intensive regimens or given no treatment fared poorly.^{32,40} On the other hand, there is some concern that treating DS AML cases on the present AML protocols with further intensification of induction and consolidation may expose these children to excessive toxicity and a high risk of treatment-related death. Hence, sufficient time must be allowed for full recovery of blood counts prior to the initiation of the next course of chemotherapy.^{30,97}

AML with DS and core binding factor (CBF) AML cases (inv(16) and t(8; 21)) constitute a unique group highly sensitive to high-dose cytarabine-containing regimens. There are several genes on chromosome 21 that alter the sensitivity not only to cytarabine but also to anthracyclines in both a specific and a non-specific manner.^{98–100} Increased activity of cystathionine β-synthase (CBS: 21q22.1) has been linked to the low levels of homocysteine, methionine and S-adenosylmethionine and the relative folate deficiency in DS. Further, it has long been proposed that the dysmorphology in DS is primarily from increased activity of CBS. Carbonyl reductase (CBR) is involved in the metabolism of anthracyclines, converting the parent drugs to less potent but longer-lasting alcohol derivatives (e.g. daunorubicinol). The neuronal damage in DS has been linked to increased oxygen radical generation,¹⁰¹ which may be altered by the chromosome 21-localized gene *SOD1* (superoxide dismutase 1).

The relative folate deficiency on account of CBS potentially primes the cells for cytarabine cytotoxicity. The net effect of increased CBS activity is decreased generation of deoxythymidine (dTTP): low dTTP results in feedback inhibition of deoxycytidine deaminase; therefore the levels of dCMP and dCTP will decrease, while deoxycytidine kinase (dCK) activity is upregulated because of low dCMP. In this setting, administration of cytarabine would result in a net increase in the generation of cytarabine triphosphate (Ara-CTP) and there is less competition from dCTP for binding to DNA and RNA polymerase.⁹⁸ In low endogenous dCTP and are significantly more sensitive to Ara-C in *in vitro* MTT assays;⁹⁹ there was a positive correlation of Ara-CTP values with CBS transcript levels (which were increased up to tenfold), and the IC₅₀ values, as expected, had an inverse relationship with the CBS expression level.¹⁰²

In addition to this unique endogenous modulation of cytarabine metabolism, DS AML cells are also unusually sensitive to daunorubicin and other drugs.^{100,103–105} These observations suggest that while there is a specific endogenous modulation of cytarabine metabolism in DS, the DS cells may be primed to undergo drug-induced apoptosis, presumably due to the well-known increased generation of oxygen radicals in DS cells.^{97,101,106}

Treatment of relapsed AML

The incidence of relapsed AML has significantly decreased recently, with more effective upfront therapy. However, relapses still occur in at least 30–40% of patients. This implies a rough incidence of 2–3 cases of relapsed AML in 1 million children annually. The literature on systematic studies of the treatment of relatively unselected groups of children with relapsed AML is limited. There is general agreement, however, that without high-dose chemotherapy and allogeneic BMT few relapsed children will be cured. Table 37.3 summarizes the results of several larger studies on pediatric relapsed AML. An older paper reported a probability of 6 years' survival after a bone marrow relapse of only 4%, and a median survival of less than 6 months.¹⁰⁷ The results of some recent studies are summarized below. Wells et al⁸⁶ reported preliminary data of a group of 37 evaluable patients with relapsed or refractory AML. CR was achieved in 73% of patients, with a 2-year DFS of 41%. Leahey et al¹⁰⁸ reported a CR rate of 66% in 15 children with refractory or recurrent AML, using idarubicin with continuous-infusion fludarabine and cytarabine. Dahl et al⁸⁷ reported a 35% CR rate in 66 children with refractory or recurrent AML using mitoxantrone, etoposide, and cyclosporine for reversal of increased drug efflux via *MDR1* (see below). Stahnke et al¹⁰⁹ report the most

Table 37.3 Clinical studies including longer follow-up in pediatric relapsed AML

Ref	No. of Patients	CR (%)	Long-term outcome
86	37	73	pDFS (2-yr) 0.41
110	125	69	pDFS (3-yr) 0.44 pOS (3-yr) 0.24
111	23	74	9 out of 17 DFS 9 out of 23 OS
112	48		pDFS (7-yr) 0.42 from autologous SCT
109	102	51	pOS(5-yr) 0.21

CR, complete response rate; pDFS, probability of disease-free survival; pOS, probability of overall survival; SCT, stem cell transplantation.

recent experiences of the BFM AML group. In about two-thirds of children with first-relapsed AML, intensive reinduction was applied, consisting of mitoxantrone, etoposide, and high-dose cytarabine in most patients. The overall CR rate was 51%. The 5-year probability of survival from relapse was 21%±5%. Children with an early relapse, defined as occurring within 1.5 years from diagnosis, did significantly worse than children with a late relapse, with probabilities of 5-year survival from relapse of 10% and 40%, respectively. In fact, time until relapse was the only significant prognostic factor. None of the patients who did not achieve second CR after reinduction chemotherapy survived, irrespective of further treatment. Post-reinduction therapy consisted of allogeneic and autologous stem cell transplantation, but 12 patients received chemotherapy only, and 5 of these were reported to be alive. The MRC group reported their experiences recently in patients who relapsed after initial treatment on the AML10 trial.¹¹⁰ Results in relapsed patients were not the result of a formal treatment protocol, and in about one-third of cases further treatment was withheld. With different types of reinduction chemotherapy, the overall complete remission rate was 69%. The majority of patients (about two-thirds) achieving a second CR later received a stem cell transplant, including autografts and matched unrelated and matched family donor allografts. Overall (including patients not further treated), the probability of survival at 3 years was 24%, and the probability of disease-free survival at 3 years from second CR was 44%. As in ALL, the length of first CR was the most significant predictor of outcome. If it was less than 1 year then the CR rate was 36% and the probability of 3-year survival 11%, compared with 75% and 49%, respectively, for patients who relapsed at least 1 year after achieving a first CR. Ida-FLAG (idarubicin with fludarabine, cytosine, and G-CSF) is another regimen that has been tried. In one study, Ida-FLAG was given to 23 patients, with a CR rate of 74%. A total of 9 patients were in continuous CR for 10–39 months (median 18 months), i.e. 40% of the total group.¹¹¹ Although not the subject of the study, Ida-FLAG was more myelotoxic than FLAG. Vignetti et al¹¹² reported that autologous BMT in 48 children in second CR resulted in an EFS rate of 42% at 7 years from diagnosis, with equal results in case of conditioning regimens with and without total body irradiation. Although this obviously concerns a selected group of patients who remained long enough in continuous CR, this series again illustrates that long-term survival in relapsed AML can be achieved in some patients without allogeneic stem cell transplantation. However, it should be recognized that most relapsed patients are already heavily pretreated, the options for reinduction therapy are limited by the degree of prior exposure to anthracyclines, and organ function may be significantly compromised. Thus, the question should be raised as to whether a child with relapsed AML should be offered intensive treatment with curative intent. For children with a later relapsed AML, occurring at least 1 year from diagnosis, the answer will normally be yes in view of the a priori chance of 50% for long-term survival. However, for children with early-relapsed AML, this chance is about 10%, and for these patients the individual situation will have a greater impact. The wish of the child and parents, the previously experienced side-effects, and perhaps remaining late effects, and other information unique to that patient should be taken into account. One may argue that if the condition of the patient allows it, an attempt at reinduction chemotherapy should be made in all patients. If the first course of intensive chemotherapy does not give a major response, arbitrarily defined as less than 20% leukemic cells in the bone marrow 4–6 weeks after the start of chemotherapy, it can always be decided at that time that further treatment is not indicated because of the very low chance of cure in this subset of patients.

Clinical relevance of cellular drug resistance testing

Cellular drug resistance is one of the main determinants of the success of chemotherapy, together with pharmacokinetics and the kinetics of minimal residual disease and its potential to relapse. Drug resistance itself is determined by a number of factors, including pharmacodynamics and pharmacogenomics, and the intrinsic properties of leukemic cells. Cellular drug resistance can be measured by several techniques. In the past, clonogenic assays were mostly used, with the assumption that measuring effects of anticancer agents on the clonogenic cells was of utmost importance. Total cell kill and apoptosis assays are now being used more frequently. Here, the results of both types of assays will be summarized, without any explicit statement regarding the value of one or the other. In general, cellular drug resistance testing does seem to provide clinically relevant information, and should ideally be included as add-on study in clinical trials.

Relation to cell biological features: FAB type, Down syndrome, and cytogenetics

In two publications, the group from Amsterdam reported on a comparison between pediatric ALL and AML samples obtained at initial diagnosis.^{103,113} In the largest series, it appeared that AML samples were significantly more resistant *in vitro* to several drugs, including glucocorticoids, vincristine, L-asparaginase, anthracyclines, etoposide, and other drugs. For some drugs, especially cytarabine and thiopurines, AML and ALL samples were similarly sensitive. The only drug that was more cytotoxic towards AML cells was 2-chlorodeoxyadenosine (cladribine), and this was largely due to its increased activity towards FAB type M5 samples.¹⁰³ For methotrexate, AML cells were significantly more resistant upon short-term exposure, but this difference disappeared upon long-term (21 hours) exposure to methotrexate.¹¹⁴ FAB type M5 samples displayed a remarkably sensitive profile, with increased sensitivity to most drugs as compared with non-M5 samples.¹⁰³ These drugs included cytarabine, etoposide, and anthracyclines. However, FAB type M5 samples were also more sensitive to the more typical ALL drugs vincristine, L-asparaginase, and methotrexate, and this sensitivity was in the same range as that of ALL samples.^{103,114} The favorable prognosis of AML in children with Down syndrome could be explained by a remarkably increased sensitivity of the AML cells to several drugs, including cytarabine and daunorubicin, as first reported by the Detroit group.¹⁰⁰ However, also for other drugs, AML cells of these patients appeared to be more sensitive, at least *in vitro*.¹¹⁵ These drugs included vincristine, etoposide, and thiopurines, which confirmed the data of a small pilot study by a Scandinavian group.¹⁰⁵ More recently, it was reported that leukemia-specific cytogenetic abnormalities also correlated with cellular drug resistance.¹⁰⁴ Especially, samples with abnormalities (monosomy or deletions) of chromosome 5 or 7 demonstrate a significantly increased resistance to cytarabine (borderline to daunorubicin), while samples with the t(9; 11) showed a remarkable sensitive profile, with significantly increased sensitivity to most drugs tested, including etoposide, daunorubicin, and amasacrine.

Resistance mechanisms for anthracyclines

Active outward transport of anthracyclines as a mechanism of resistance was recognized in the early 1970s.¹¹⁶ Subsequent work¹¹⁷ linked this anthracycline efflux with the expression of a 170 kDa glycoprotein (P-gp), the product of the *MDR1* gene, now localized to chromosome 7q21.1. Since then other members of the same ABC (ATP-binding cassette) transporter family have been discovered, including the multidrug resistance-related protein (MRP1)¹¹⁸ and the breast cancer resistance protein (BCRP, chromosome 4q22).¹¹⁹ In addition, a non-ABC family protein has been found to be associated with multidrug resistance: the lung resistance-related protein (LRP), also known as the major vault protein (MVP).¹²⁰ P-gp, MRP1, and BCRP are expressed at the cell surface, while LRP/MVP is predominantly cytosolic.

With regard to childhood AML, few studies have prospectively compared the relevance of expression of these drug-resistance proteins to outcome. Preliminary results of the studies that have been completed to date show that P-gp expression in the pediatric age group is lower than what has been encountered in adult studies. It appears that P-gp expression in diagnostic blast cell samples increases with age. Thus, in pediatric patients, P-gp expression is detectable in about 15–17% of cases of *de novo* AML,^{121–123} consistent with values in adults aged 20–35 years, compared with 27% for those between the ages of 35 and 49, 39% for those 50–65, and up to 70% in those aged over 65 years.^{124,125} Since P-gp expression can be induced by exposure to xenobiotics, including anthracyclines, as well as certain natural products such as grapefruit juice,^{126,127} it is conceivable that with age, there is a non-specific induction of P-gp in certain individuals. These data suggest that the level of P-gp expression may not be intrinsic to the leukemic cells (i.e. it might reflect the P-gp status in the somatic environment as a whole) and may not always be linked to a specific leukemic cytogenetic event. This is further illustrated by observations in AML with monosomy 7/7q-, which is associated with poor prognosis, and the contrasting superior outcome in AML with inv(16). Van den Heuvel-Eberink et al¹²⁸ found no evidence for

decreased expression or activity of *MDR1* in monosomy 7/7q- cases, contrary to what one may have expected from the localization of *MDR1* on 7q. A similar lack of loss of function of MRP in *MRP1*-deleted inv(16) cases (*MRP* and *LRP/MVP* are localized to 16p31–32) has also been demonstrated,¹²⁹ suggesting that the good prognosis of inv(16) may not be linked to decreased anthracycline efflux as originally proposed.¹³⁰ Van den Heuvel-Eberink et al¹³¹ also looked critically at P-gp expression in paired samples in the same patients from diagnosis and relapse, and found no evidence of increased expression/efflux or evidence for *MDR1* gene-related clonal selection at relapse.

Of considerable importance is the concept that *MDR1* expression in AML may not necessarily have a negative implication. For example, *MDR1*-overexpressing cells exhibit increased collateral sensitivity to nucleoside analogs.^{132,133} Supporting this finding are the clinical observations that *MDR1* is overexpressed in AML1 with t(8; 21)¹³⁴ and in AML blasts from Down syndrome patients.⁹⁷ Both AML with t(8; 21)⁹³ and AML in Down syndrome^{6,93} are highly sensitive to high-dose cytarabine containing regimens and are associated with a superior outcome.

It is not surprising from the foregoing discussion that studies with the drug-reversal agents cyclosporine and PSC833 for improving treatment response and long-term outcome have produced mixed results.^{87,135,136} In the SWOG 9126 trial, higher doses of cyclosporine (16 mg/kg/day), yielding a mean blood concentration exceeding 1600 ng/ml (a dose sufficient for modulation of P-gp-mediated efflux) produced a decrease in induction resistance and possibly increased relapse-free and overall survival.¹³⁵ Cyclosporine-treated patients had higher mean values for daunorubicin concentration, but response rates were different in patients with comparable daunorubicin concentrations whether or not they had received cyclosporine. These data would suggest that the cyclosporine may have a non-Pgp-linked beneficial effect on the response rate by increasing the cytotoxicity of daunorubicin.

A preliminary review of the large prospective randomized trial of cyclosporine during consolidation by the POG (9421) also demonstrated a probable non-specific benefit from this agent.⁷⁰ In the POG 9421 study, the patients were randomized to receive standard-dose cytarabine during induction versus high-dose cytarabine during induction and post remission; both groups were randomized to receive drug combinations with or without cyclosporine. The control arm with standard '3+7' daunorubicin and cytarabine and no cyclosporine had an inexplicably low remission induction rate. Nonetheless, a positive effect was noted when the two cyclosporine arms were compared with those not receiving this agent. Correlations with P-gp expression are not yet available from this study, but the low expression of P-gp in pediatric patients suggests that any benefit may not all be P-gp-linked. Cyclosporine can also block MRP- and BCRP-related drug efflux in a dose-dependent fashion. As suggested by List et al,¹³⁵ it is possible that some of the benefit is through the total blockade of efflux rather than the one mediated by P-gp alone. Alternatively, through its interaction with cyclophilin, cyclosporine may suppress angiogenic responses to vascular endothelial growth factor (VEGF), a cytokine that is implicated in myeloblast cell renewal and that confers an adverse prognosis in AML. Another possibility is that cyclosporine may potentiate the cytotoxicity of several drugs through augmentation of ceramide-mediated apoptosis, by inhibiting glycosylation of ceramide via the glucoceramide synthase pathway.¹³⁷ Several MDR-reversal agents appear to inhibit glucoceramide synthase, suggesting that their clinical effect may be partly related to this mechanism.

Drug resistance as a prognostic factor

There is relatively little data on the prognostic significance of in vitro cellular drug resistance in childhood AML. However, the studies that have been reported all strongly suggest a correlation between increased resistance of AML cells and a worse initial treatment response, as reviewed by Kaspers et al.¹³⁸ Data on the prediction of long-term clinical outcome, which was reported to be feasible in childhood ALL,^{138a,139} are less convincing in AML.^{104,140} Apparently, the AML cells responsible for a relapse are not always being tested appropriately by the current cellular drug resistance assays. Several studies have addressed the issue of differences in drug resistance profiles between untreated and relapsed AML samples of children. Hongo et al¹⁴¹ reported that within the FAB type M4 and M5 groups, relapsed samples were more resistant to cytarabine and also to etoposide. Similarly, Klumper et al¹⁴² reported a threefold increased resistance to cytarabine, but not to etoposide, in relapsed AML samples. Of potential interest, the group in Amsterdam have reported that although relapsed AML samples were more resistant to cytarabine, this was not seen for cladribine.¹⁴³ This was mainly explained by an increased antileukemic activity of cladribine in FAB type M5 samples, which is in agreement with data from clinical studies performed at St Jude's Children Research Hospital.¹⁴⁴

In conclusion, cellular drug resistance may be helpful in identifying novel agents as good AML agents, and may especially identify subgroups of AML patients that are more or less sensitive to certain drugs. Using these data enables a more rational design of subgroup-directed tailored treatment. This does, however, require a major change in the design of future treatment protocols. Instead of distinguishing two or three

subgroups, treatment will become much more individualized, based on information from pharmacogenomic, oncogenomic, and cellular drug resistance studies, and on the measurement of minimal residual disease as the ultimate test of response. To move from giving the average treatment to the average patient towards individualized treatment will be one of the biggest challenges in the coming few years.

Future directions

Numerous developments suggest that the study and treatment of pediatric AML will change in the future. Some interesting areas are briefly discussed below.

Genomics

In order to unravel the etiology of leukemia, and to identify novel drug targets, further studies on the molecular characterization of leukemic (and normal) cells are of the utmost importance.¹⁴⁵ Recent developments such as high-throughput gene expression profiling and proteomic studies will be helpful in this respect but not sufficient. Functional studies will remain necessary. In the same area of oncogenomics, pharmacogenomic studies will be helpful in individualizing drug treatment, taking more account of the unique characteristics of the host.

New drugs

New drugs may be old drugs in a new coat, or real novel agents. An example of an old drug in a relatively new formula is liposomal daunorubicin (DaunoXome). This agent has mainly been used to treat Kaposi sarcoma. Out of 979 Kaposi sarcoma patients treated with DaunoXome, 1 patient developed cardiotoxicity with clinical symptoms (Summary of Product Characteristics, Gilead Sciences, 5 June 2001). In general, liposomal anthracyclines cause less cardiotoxicity at higher cumulative doses than conventional anthracyclines.¹⁴⁶ Animal solid tumor studies showed that at equivalent daunorubicin dosages, DaunoXome had significantly increased antitumor activity and less toxicity compared with free daunorubicin.¹⁴⁷ Another drug that is clinically available but is not being used often is cladribine. Both preclinical and clinical studies suggest that this agent has marked antileukemic activity in acute monoblastic leukemia.^{103,143,144} A study performed in 17 relapsed AML patients demonstrated that single agent cladribine induced complete hematologic remissions in 47% of them.¹⁴⁸

Perhaps even more exciting are the vast number of truly novel drugs that are emerging.¹⁴⁹ Targeted agents mediated by or consisting of monoclonal antibodies (e.g. anti-CD33 linked to calicheamicin (gemtuzumab ozogamicin, Mylotarg®) and anti-CD20 (rituximab®)) or drugs directly targeted at leukemia-specific targets such as gene fusion proteins (e.g. imatinib (STI571, Gleevec/Glivec®)) or mutated tyrosine kinases (e.g. drugs targeted at FLT3, c-KIT, or VEGF) are promising agents with at least theoretically major selectivity towards the leukemic cells. The latter aspect is important in order to minimize side-effects in the short and long term. Other new types of drugs include farnesyl transferase inhibitors, histone deacetylase inhibitors, and proteasome inhibitors. Future clinical studies will have to teach us how to use these agents, on their own and, more importantly, in combination chemotherapy. The pressure on pharmaceutical companies to study their novel agents in the pediatric population will be helpful in this respect. All these developments will have the consequence, however, that our approach will have to change from giving the average treatment to the average patient towards a much more individualized approach taking into account the uniqueness of each leukemia and each patient. We will have to adjust the design of our randomized clinical studies in order to accomplish this, which will be a major but necessary challenge.

Minimal residual disease (MRD)

Data from measurements of minimal residual disease in ALL and in subgroups of AML have clearly demonstrated the prognostic significance of this information.^{150–152} For the majority of patients with AML, however, molecular biological studies are not applicable to measure minimal residual disease. Flow-cytometric identification of so-called leukemia-aberrant phenotypes is a good, perhaps cheaper, and certainly less labor-intensive alternative, and will be applicable in more than 90% of patients with AML to monitor minimal residual disease. The main question that should be addressed, however, is whether the sensitivity of this method will be high enough to detect low numbers of minimal residual disease. At least in ALL, most studies suggest that it is important to detect low levels of minimal residual disease (e.g. less than 1 in 10 000 cells) to identify good-risk patients.¹⁵² It seems likely that monitoring minimal residual disease in AML will become routine at some point, which will allow us to identify patients at low or high risk for a subsequent relapse and to adjust treatment. Another theoretical application is to quantify minimal residual disease for comparing the antileukemic effect of two or more different treatment regimens in patients in 'complete remission'.

Conclusions

In conclusion, with the use of intensive chemotherapy regimens that combine currently available drugs, and with improved supportive care, the prognosis for

AML in children and adolescents has improved considerably. Survival rates above 50% have been reported recently by several groups. The awareness of the uniqueness of each individual and his or her AML, together with significant technical improvements in genomic studies and drug development, raise justified hope that this prognosis can improve further. Other innovative research, such as studies on cellular drug resistance, apoptosis and cell death regulators, and minimal residual disease monitoring, will stimulate and support this expected rise in the number of children and adolescents who will be cured of their AML in the near future.

Acute myeloid leukemia in adults

Bob Löwenberg and Alan K Burnett

Cell of origin

Acute myeloid leukemia (AML) is a malignant clonal disorder of immature hematopoietic cells and is characterized by aberrant hematopoietic cellular proliferation and maturation. Leukemic blasts may express abilities for maturation to a variable degree, which leads to morphologic heterogeneity. Generally, the transformed leukemic stem cell is committed to the granulocytic lineage, but sometimes a predominance of blast cells from the erythroid or megakaryocytic lineage may be observed. The leukemic transformation may occur at the level of a pluripotent or a less primitive hematopoietic cell.^{1,2}

In certain patients, peripheral blood polymorphonuclear cells, erythroid cells, and platelets exhibit the clonal features characteristic of the leukemic cells, indicating that the leukemia originates from early precursor cells with pluripotential differentiation abilities.^{1,3,4} This is apparent from the presence of genetic markers in several blood cell lineages, for example unique cytogenetic abnormalities.⁴ Multilineage involvement is frequently seen in elderly patients with AML. In others, particularly children and younger adults, the erythroid cells and platelets often originate from normal stem cells.¹⁻³ A possible explanation for this observation is that in such patients, leukemic transformation has occurred at the level of a more mature primitive progenitor cell that is monopotent and committed to myeloid differentiation only. Even when overt leukemia has been eradicated with chemotherapy and apparently normal hematopoiesis has been reinstated (complete hematologic remission), clonal marrow or blood hematopoiesis may persist in a subset of patients. The fact that clonal hematopoiesis may be found during clinical remission suggests that, following therapy, the disease has reverted to an earlier evolutionary phase of its development. Most likely, preleukemic hematopoietic cells dominate the marrow and blood during those clonal remissions. These data are entirely consistent with the multistep pathogenesis of AML.

Cellular heterogeneity

Human AML is characterized by a heterogeneous cellular composition. This heterogeneity is an expression of hierarchical subpopulations of cells of different maturational stages within the neoplasm. The cellular hierarchy is apparent from morphologic examination, immunologic phenotyping, cytogenetics, and cell culture analysis.² The successive stages of maturation of AML cells can be ranked according to phenotype as well as proliferative potential. For instance, cells with high proliferative abilities (forming large colonies) may be distinguished from cells with low proliferative abilities (forming small colonies or clusters), or 'end' cells (non-proliferative in vitro). The colony-forming cells (AML-CFU) act as progenitors giving rise to in vitro colonies of daughter cells that are phenotypically more mature. However, in general, AML cells are unable to develop towards terminally differentiated cells⁵—they only generate partially and abnormally maturing progeny.⁶ Thus, the maturation block is not always absolute. Both the variable cellular stages at which cell transformation has taken place and the variable residual maturational abilities retained by these transformed cells probably determine the phenotypic diversity of clinical AML.

Concept of AML stem cells

The concept of tumor stem cells postulates that some cells in a tumor have the capacity to maintain longterm growth of the tumor. The progeny derived from these malignant stem cells lack these abilities for self-renewal. The in vivo significance of in vitro AML colony-forming cells is difficult to define, but in vitro observations indicate that in vitro colony-formers are relatively mature progenitors and do not function to maintain and expand the malignancy.^{6,7} Human AML cells may engraft in severe combined immunodeficient (SCID) mice or the variant non-obese diabetic SCID/NOD mice following intravenous injection.⁸⁻¹¹

The finding that human leukemia can be sustained in these immunodeficient mice for several months suggests that primitive AML progenitor cells are responsible for AML growth in these animals. The cell type that initiates outgrowth of human leukemia in vivo in these murine recipients has been characterized as a cell that may be discriminated from the AML in vitro colony-forming cell. It expresses a phenotype strikingly similar to that of primitive normal hematopoietic stem cells.^{11–14} For instance, the cell initiating AML in SCID animals appears to be CD34⁺, CD38⁻, HLA-DR⁻ and 5-fluorouracil (5-FU)-resistant. The repopulating AML cell in SCID mice is quiescent. It currently represents one of the best available approximations of the AML stem cell. Stroma-dependent cultures that permit the establishment of human hematopoiesis in vitro for a few months have recently also been applied to human leukemia. These long-term cultures of AML have been extrapolated from initial studies in the mouse. One of these methods, the cobblestone area-forming cell (CAFC) assay has proved convenient for both quantitative and qualitative studies of primitive AML progenitors (cobblestone area formation late in culture, i.e. beyond 6 weeks). These late-appearing CAFC mimic cells with repopulating abilities and express primitive progenitor phenotypes. Thus, for example, stroma-supported late-CAFC represent a subset of AML cells that are CD38⁻ CD34⁺ and 5-FU-resistant.^{13,14}

Leukemogenesis

It is generally accepted that leukemia is the result of a multistep process.^{15,16} According to this idea, the transformed hematopoietic progenitor cells initially acquire a single genetic lesion resulting in only slight variations in cell survival, proliferation, or maturational abilities as compared with their normal counterparts. Additional genetic lesions may result in full leukemic transformation. The search for the targets of the oncogenic events has indicated various mechanisms that may lead to leukemia. Genetic lesions may result in the activation of genes that contribute to leukemogenesis (oncogenes) or loss of activity of genes that prevent tumor growth (tumor suppressor genes).¹⁷ The genes involved in leukemia development affect specific cellular regulatory mechanisms: growth factor receptor function (e.g. the granulocyte colony-stimulating factor receptor (G-CSFR^{18,19} and FLT3^{20,21}; see below), signal transduction (e.g. the RAS family²²), and transcription (e.g. c-MYC²³). As a consequence, these processes may dysregulate critical biologic functions, in particular the abilities of proliferation (e.g. tyrosine kinase mutations) and differentiation (e.g. *PML-RAR* α^{24}), and programmed cell death (e.g. *TP53*).²⁵ Proliferation of AML cells is controlled by hematopoietic growth factors. In vitro, leukemic cells in some cases exhibit spontaneous proliferative activity. This may be caused by the autocrine production of hematopoietic growth factors or by the constitutional activation of metabolic pathways that are otherwise activated only when a growth factor activates its receptor.^{26,27} It has been shown that autonomous proliferation of AML cells in short-term culture predicts a comparatively high probability of relapse and poor survival.²⁸

Abnormal receptor complex formation and function in hematopoietic disorders

Mutations in hematopoietic growth factors receptor genes that interfere with normal receptor complex formation and function may play a role in the pathophysiology of hematopoiesis.²⁶ In murine models, it has been demonstrated that mutations in the extracellular domain of the macrophage colony-stimulating factor receptor (M-CSFR, CSF1R)²⁹ or in the erythropoietin receptor (EPOR)^{27,30} result in ligand-independent activation of these receptors and induce leukemia. On the other hand, structural abnormalities might also impair receptor function, and as a consequence hematocytopenia of one or more cell lineages may evolve. In particular, mutations have been found in the hematopoietic growth factor receptors FLT3^{20,21,31–39} and c-KIT.^{40–42}

FLT3 mutations

Internal tandem duplications (ITDs) and activating *FLT3* gene coding for the juxtamembrane (JM) segment point mutations have been reported in the part of the receptor. Elongation of the JM domain causes ligand-independent dimerization resulting in constitutive activation of STAT5 and MAPK in cell lines.³⁵ Primary AML blasts show a reduced responsiveness to stromal support in long-term culture.³³ *FLT3* ITDs have been reported to occur in approximately 13–20% of cases of AML^{20,34,36–39,43–47} and D835 point mutations in 5–7% of cases.²¹

The 5-year event-free survival (EFS) rate for patients with an *FLT3* ITD was 14%, which compared with a rate of 69% for patients without mutations.³⁸ In another study, the low response probability of childhood AML with *FLT3* ITD (40%, versus 74% in wildtype *FLT3* cases) and an EFS rate of only 7% were confirmed.³⁶ In several adult series of patients with AML, *FLT3* mutations conferred a poor prognosis.^{31,34,39,43,45,46} *FLT3* mutations express adverse prognostic significance independent of other prognostic variables. Of particular note is that among cytogenetically defined good-risk and intermediate-risk patients, a notably poor-risk subset can be distinguished according to the presence of *FLT3* mutations.^{34,36,43,46} *FLT3* mutations have also been associated with leukocytosis (an established unfavorable prognostic indication) in acute promyelocytic leukemia (APL) and with leukemic transformation of

myelodysplasia (MDS). In a study in 201 newly diagnosed patients, 46 had *FLT3* mutations of both ($n=3$) or one ($n=43$) allele and in addition independent *N-RAS* mutations in 25 cases. *FLT3* mutation correlated with reduced survival independently of other prognostic parameters and was the most significant negative predictor of outcome.

c-KIT mutations

The receptor tyrosine kinase *c-KIT* (which is the receptor for stem cell factor/Steel factor (SCF)) is expressed in the majority of cases of AML and also in patients with chronic myeloid leukemia (CML), but is uncommon in acute lymphoblastic leukemia (ALL). Levels of expression are of the same order as on normal hematopoietic precursors. These receptors have the ability to bind ligand, and are functional, as exposure to ligand will raise a proliferative or survival response. Mutations of *c-KIT* were initially identified in human mast cell lines. These mutations are usually located in the JM intracytoplasmic region of the receptor and involve point mutations leading to constitutive phosphorylation (in the absence of ligand). Mutant *c-KIT* receptors, upon transduction to cell lines, confer factor independence as well as tumorigenicity. A variable number of mutations have been reported, among which the D816V (aspartate to valine) and D816Y (aspartate to tryrosine) substitutions are comparatively common. These mutations may result in altered growth abilities not only as the result of receptor activation but also due to altered intracellular substrate specificity. It is currently assumed that *c-KIT* mutations might contribute to leukemogenesis, particularly in cooperation with other coexistent oncogenic events, as has been shown in a *c-MYB* transformation model.⁴⁸ In a minority of cases of human AML, *c-KIT* mutations have been identified.^{40,41,49} These and other mutations, including point mutations of the extracellular domain, have also been reported in patients with myeloproliferative with *c-KIT* mutations may show increased levels of syndromes as well as patients with AML.^{40,49,50} AML mast cell infiltration.⁵⁰ *c-KIT* mutations are commonly seen in AML with t(8;21) and inv(16) cytogenetics, the so-called core binding factor leukemias,⁴⁰ and recent evidence suggests that in the case of *c-KIT* mutations these leukemias show a greater tendency of relapse.⁴²

G-CSF, G-CSFR mutations

Patients with severe congenital neutropenia (SCN) or Kostmann's disease typically present in infancy with a quantitative lack of circulating granulocytes and an arrest of granulocytic maturation at the promyelocytic stage in the marrow, and suffer from recurrent and severe bacterial infections. They are predisposed to the development of AML. SCN was the first clinical condition in which structural hematopoietic receptor mutations in relation to leukaemia were revealed.^{18,19} These mutations generally represent nonsense mutations of the *G-CSFR* gene that encode for a receptor from which the cytoplasmic C-terminal part has been deleted. Approximately 10% of cases of SCN carry *G-CSFR* mutations, usually localized within a narrow stretch and resulting in a receptor lacking approximately 82–98 amino acids at its intracytoplasmic end. Patients with SCN and mutated *G-CSFR* have an approximately 30-fold increased risk to transform to AML.⁵¹ Thus SCN with mutated *G-CSFR* apparently represent preleukemic conditions. Cells transduced with the truncated G-CSFR show numerous molecular and biochemical abnormalities in signaling following activation by the ligand, resulting in abnormal biological responses as well. These abnormalities relate to altered cell survival and apoptosis, granulocytic cellular maturation, as well as cell cycling and proliferation rate.

G-CSFR variant mutations have also been reported some in the extracellular domain resulting in normal binding affinity of the receptor for ligand but loss of responsiveness to ligand stimulation.⁵² *G-CSFR* mutations have been described in sporadic cases of de novo AML.¹⁸ These point mutations in the *G-CSFR* gene may cause overexpression of non-functional G-CSFR splice variants that could interfere with normal G-CSFR function in a dominant negative fashion. The fact that mutations in the C-terminal region of G-CSFR, specifically disrupting the maturation signaling function of the receptor, may be involved in the pathogenesis of AML might suggest that signaling molecules that are specifically activated through the C-terminal domain of G-CSFR could be additional potential targets for transforming mutations leading to AML. The true frequency of *G-CSFR* mutations in primary AML or MDS remains to be settled, as current analysis has been based upon relatively small series.

Diagnosis and classification of AML

The diagnosis of AML is primarily based on morphological and cytochemical criteria. These criteria constitute the basis of the French-American-British (FAB) classification that is commonly used to distinguish subtypes of AML.^{53–56} These subtypes (see Table 38.1) include the categories M0 through M7. Immunophenotyping, cytogenetic analysis and molecular examination are employed to add specific information for a more precise diagnosis. Immunophenotyping using a panel of monoclonal antibodies adds further precision and objectivity to the diagnosis.

In recent years, it has become essential to add genetic and molecular information to the diagnostic process.

Table 38.1 Cytological criteria for the diagnosis of acute myeloid leukemia: French-American-British (FAB) classification

FAB subtype	Microscopy	Cytochemistry/immunology
M0	<ul style="list-style-type: none"> • Blasts $\geq 30\%$ of bone marrow nucleated cells • $< 3\%$ of blasts positive for Sudan black B or peroxidase • Myeloperoxidase positivity by ultrastructural cytochemistry 	Myeloid immunological markers (e.g. CD13, CD33, myeloperoxidase)
M1	<ul style="list-style-type: none"> • Blasts $\geq 90\%$ of bone marrow non-erythroid cells (i.e. excluding also lymphocytes, plasma cells, macrophages, and mast cells from the count) • $\geq 3\%$ of blasts positive for Sudan black B or peroxidase • Maturing granulocytic cells (i.e. promyelocytes towards polymorphonuclear cells) $< 10\%$ of non-erythroid cells • (Pro)monocytes of non-erythroid marrow cells 	
M2 with maturation	<ul style="list-style-type: none"> • Blasts 30–89% of bone marrow non-erythroid cells • Maturing granulocytic cells (i.e. promyelocytes to polymorphonuclear cells) $> 10\%$ of non-erythroid cells • Monocytic cells (i.e. monoblasts to monocytes) $< 20\%$ of non-erythroid cells and not meeting other criteria for M4 	
M3 (acute hypergranular promyelocytic leukemia)	<ul style="list-style-type: none"> • Promyelocytes (most hypergranular) $> 30\%$ of bone marrow nucleated cells 	
M3 variant	<ul style="list-style-type: none"> • Promyelocytes (hypogranular or microgranular) $> 30\%$ of bone marrow nucleated cells 	
M4 (acute myelomonocytic leukemia)	<ul style="list-style-type: none"> • Blasts $\geq 30\%$ of bone marrow nucleated cells • Granulocytic cells (myeloblasts to polymorphonuclear cells) $\geq 20\%$ of non-erythroid cells • Monocytic cells (monoblasts to monocytes) $\geq 20\%$ of non-erythroid cells and peripheral blood monocytes $\geq 5 \times 10^9/l$ (or) • Monocytic cells $\geq 20\%$ of non-erythroid cells and confirmed by cytochemistry or urinary lysozymes elevated (or) • Marrow resembling M2, but blood monocytes $\geq 5 \times 10^9/l$ and confirmed by cytochemistry or elevated urine lysozymes 	Positive for Sudan black B, peroxidase chloroesterase (granulocyte lineage) plus α -naphthyl esterase (monocyte lineage)
M5A (acute monoblastic leukemia)	<ul style="list-style-type: none"> • Blasts $\geq 30\%$ of bone marrow non-erythroid cells • Bone marrow monocytic component $\geq 80\%$ of non-erythroid cells • Monoblasts $< 80\%$ of bone marrow monocytic component 	
M5B (acute monoblastic monocytic leukemia)	<ul style="list-style-type: none"> • Blasts $\geq 30\%$ of bone marrow non-erythroid cells • Bone marrow monocytic component $\geq 80\%$ of non-erythroid cells • Monoblasts $< 80\%$ of bone marrow monocytic component 	
M6 (acute erythroleukemia)	<ul style="list-style-type: none"> • Erythroblasts $\geq 50\%$ of bone marrow nucleated cells • Blasts $\geq 30\%$ of bone marrow non-erythroid cells 	
M7 (acute megakaryoblastic leukemia)	<ul style="list-style-type: none"> • Blasts $\geq 30\%$ of bone marrow nucleated cells 	Blasts demonstrated to be megakaryoblasts by immunological markers, ultrastructural morphology or cytochemistry

This provides information that may have crucial implications for choice of treatment and prognosis. For example, the FAB M3 subtype is strongly associated with the t(15;17) reciprocal translocation resulting in the PML/RAR α fusion protein. This signifies a unique sensitivity to retinoic acid.

The AML M0 subtype is characterized by small to medium-sized blasts with a high nuclear-cytoplasmic ratio, open chromatin, multiple nucleoli, and moderately basophilic cytoplasm. Myeloperoxidase (MPO)-positive cells constitute less than 3% of the blast population. The blasts may be positive for anti-MPO, anti-CD33, anti-CD13, anti-CD7, and anti-TdT (terminal deoxynucleotidyl transferase) antibody staining. The cells may also be MPO-positive at the ultrastructural level. FAB M0 leukemia is considered

Table 38.2 WHO classification of acute myeloid leukemia^{57,58}

Acute myeloid leukemia with recurrent genetic abnormalities

Acute myeloid leukemia with t(8;21)(q22;q22) (*AML1-ETO*)

Acute myeloid leukemia with abnormal bone marrow eosinophils and inv(16)(p13q22) or t(16;16)(p13;q22) (*CBF β -MYH11*)

Acute promyelocytic leukemia with t(15;17)(q22;q22) (*PML-RAR α*) and variants

Acute myeloid leukemia with 11q23 (*MLL*) abnormalities

Acute myeloid leukemia with multilineage dysplasia

Following myeloid dysplastic syndrome (MDS) or MDS/myeloproliferative disorder (MPD)

Without antecedent MDS or MDS/MPD, but with dysplasia in at least 50% of cells in two or more myeloid lineages

Acute myeloid leukemia and myelodysplastic syndromes, therapy-related

Alkylating agent/radiation-related type

Topoisomerase II inhibitor-related type (some may be lymphoid)

Others

Acute myeloid leukemia, not otherwise categorized

Acute myeloid leukemia, minimally differentiated

Acute myeloid leukemia without maturation

Acute myeloid leukemia with maturation

Acute myelomonocytic leukemia (AMML)

Acute monoblastic/acute monocytic leukemia

Acute erythroid leukemia (erythroid/myeloid and pure erythroleukemia)

Acute megakaryoblastic leukemia

Acute basophilic leukemia

Acute panmyelosis with myelofibrosis

Myeloid sarcoma

to represent a poor-risk subtype of AML. Other special morphological variants of AML include AML with basophilia, especially associated with the translocation t(6;9)(p23;q34), AML with natural killer (NK)-cell phenotype, AML with erythrophagocytosis (especially those associated with the translocation t(8;16)(p11;p13)). Not infrequently AML at initial presentation may show trilineage myelodysplasia. These myelodysplastic abnormalities include nuclear abnormalities of the erythroblasts, hypogranulated neutrophils, and mononuclear megakaryocytes, which might indicate the development of AML from an antecedent myelodysplasia. AML with trilineage morphological abnormalities generally indicate a poor prognosis. Immunophenotyping of the leukemia may contribute to establishing the diagnosis of AML and distinguish the disease from ALL or other undifferentiated malignancies.

The impact of cytogenetics on prognosis will be discussed below, but the inclusion of this information has highlighted the heterogeneity of AML and has enabled distinct molecular entities to be identified. This has contributed to the newer WHO classification of AML^{57,58} (Table 38.2) whereby distinct molecular genetic entities, i.e. t(15;17), t(8;21), inv(16), and abnormalities of 11q23 (*MLL* gene) are grouped together as AML with recurrent abnormalities. In this category, there is uniquely no threshold for the marrow blast count. The second category is defined by the addition of multilineage dysplasia. The third category is defined by whether the disease is secondary to alkylating agents or to MDS. The fourth category, which is designated as AML not otherwise categorized, contains the remaining FAB categories, i.e. M0, M1, M2, M4, M5a, M5b, M6a, M6b, and M7. The point of this classification is to give greater recognition to the etiological, molecular genetic, and prognostic information that is now available. As more such information emerges, so the definitions will need to be altered.

Immunocytology and cytogenetics

The immunophenotypes are exponents of the heterogeneous cellular composition of the neoplasm.⁵⁹ The following markers are commonly applied for classifying AML: the progenitor cell markers CD34, CD117 (c-KIT), TdT, and HLA-DR, the myeloid markers anti-MPO, CD13, CD33, and CD14, the monocytic markers CD15, CD11b, CD11c, and CD68, the megakaryocytic markers CD61 and CD14, and the erythroid marker glycophorin A. Acquired cytogenetic abnormalities are frequently apparent in patients with AML. These abnormalities may include balanced translocations, inversions, or insertions without gain or loss of chromosome, or unbalanced aberrations (see also Chapter 17). In children and young adults, a predominance of

balanced translocations is seen. At an older age and in secondary leukemias, it is mainly numerical and unbalanced abnormalities (e.g. deletions of chromosomes 5 or 7) that are seen. Patients with secondary leukemia may present with complex abnormalities, which are generally defined as the presence of more than three distinct chromosome abnormalities. The chromosome abnormalities occur non-randomly and are therefore useful to distinguish specific subtypes of AML. They are also of value as indicators of AML with favorable, intermediate, or poor-risk prognosis. Molecular techniques to demonstrate molecular abnormalities by fluorescence in situ hybridization (FISH) and to detect hidden mutations or fusion genes by polymerase chain reaction (PCR) are rapidly gaining applicability in the clinical diagnosis of patients with AML, and can provide genetic information when cytogenetics has failed.

Remission induction treatment

It is well established that achieving a complete remission is a prerequisite for improved survival. Modern schedules will achieve remissions in about 75–80% of patients younger than 60 years⁶⁰ and around 50–55% in older patients (see below). There is a continuous decline in remission rate from childhood (90%) to old age (30%), with a reciprocal increase in resistant disease as a cause of induction failure. Some of the reasons for this age-related response will be discussed later. The mainstay drugs have been daunorubicin and cytosine arabinoside (cytarabine, Ara-C) given as a 7- or 10-day schedule. There appears to be little extra benefit in increasing the daunorubicin dose beyond around 50 mg/m², although higher doses are currently in clinical trial.⁶¹ Comparative studies of daunorubicin dose have been rare. In a comparison between 30 and 45 mg/m², there was a higher complete response (CR) rate (72% versus 59%) in the 45 mg/m² patients, but there was no survival advantage.⁶²

A third drug, such as thioguanine, has often been added. The addition of etoposide to a standard 7-day cytarabine with 3-day anthracycline has shown benefit in one study.⁶³ Although etoposide did not improve the CR rate, it did prolong remission. A very large (1600 patients) prospective comparison of thioguanine versus etoposide as the third drug showed no difference.⁶⁴ Combinations of cytarabine and daunorubicin with etoposide or thioguanine or a combination of mitoxantrone plus cytarabine did not result in relapse or survival advantages in older patients.⁶⁵

There have been a number of attempts to intensify induction by increasing the dose of cytarabine, which appear to be beneficial.^{66–68} This has been confirmed in randomized studies.^{69,70}

A number of trials have prospectively compared daunorubicin with an alternative anthracycline: idarubicin^{71–76} or mitoxantrone.^{65,77–79} In the six randomized comparisons of idarubicin, there was fairly consistent evidence to suggest that idarubicin could achieve a higher CR rate, but some of these studies had a control arm that was inferior to what could reasonably be expected. The overall advantage for idarubicin may be less clear in older patients. Four randomized comparisons of mitoxantrone also suggested that it could improve the CR rate, but not survival. Both of these newer drugs tend to produce more prolonged cytopenia, and if used in consecutive courses will require some dose reduction—which has raised questions about how superior they are on a dose-equivalent basis.

The possibility to apply growth factors in conjunction with chemotherapy as an approach to prime the leukemia for the cytotoxic action of the chemotherapeutic agents and thereby enhance the efficacy of remission induction therapy will be discussed below²¹² (see below modulation of resistance to chemotherapy with hematopoietic growth factors).

The message appears to be that more intensive treatment of younger patients will increase the remission rate. There is fairly convincing evidence that with a more intensive approach to induction, even though a higher remission rate may not be achieved, remissions will be achieved more promptly and there is a beneficial effect on long-term outcome.^{69,76,80} The MRC AML12 trial has recently been completed comparing a standard daily dose of cytarabine (200 mg/m²) with an intermediate dose (400 mg/m²), both over 10 days, or high-dose cytarabine in induction and consolidation. Neither has shown an improved outcome.⁸¹

Response evaluation after induction therapy

Attaining a CR is a prerequisite for long-term disease-free and overall survival. Therefore the assessment of CR is an important step in the management of patients with AML. CR has traditionally been defined as a cellular marrow with less than 5% blasts, no circulating blasts, no evidence of extramedullary leukemia, and recovery of granulocyte (PMN $1.5 \times 10^9/L$) and platelet ($100 \times 10^9/L$) counts. Since the NCI criteria for CR were published in 1990, treatment, however, has changed quite considerably, and this has challenged the current validity of the definition of CR. Chemotherapy has become more dose intensive. This directly impacts on the cellularity of the marrow following chemotherapy and the ability for prompt hematological recovery. Furthermore, the next cycle of

treatment often follows before full hematological recovery. In a recent analysis (still unpublished) in 1200 patients treated with contemporary strategies in 3 successive AML study protocols from HO VON (Dutch-Belgian Cooperative Hemato-Oncology) and SAKK (Swiss Cancer) Cooperative Groups, the prognostic impact of each of the definition elements of CR following cycle I was assessed. The analysis shows that % marrow blasts and extramedullary leukemia after induction therapy are powerful predictive hematological determinants of outcome (relapse, disease-free survival). It also reveals that the cutoff value of 5% is still valid. Thus, of the traditional CR parameters, % marrow blasts, absence of extramedullary leukemia and haematological recovery continue to stand out as predictors of outcome. In clinical management it has become quite common to conduct an “early” bone marrow assessment (at approximately days 7–10 after the first cycle) to identify those with refractory disease at an early point post-therapy. Recently, a group of experts have revisited the definition of CR and updated the scoring methodology for CR.²¹⁴ For reasons of international intercomparability between studies and standardization, they recommend to define CR in operational terms and distinguish morphological CR, CR with incomplete blood count recovery (CRi), cytogenetic CR (CRc), and molecular CR (CRm). Immunological approaches based on multiple parameter flow cytometry and quantitative (real-time) reverse transcriptase polymerase chain reactions for fusion genes in t(8;21) and inv(16) show promise as regards further refinement of the assessment of CR.

Postremission chemotherapy

As previously mentioned, remission induction treatment independently influences long-term outcome and it is therefore difficult to separate the impact of these two phases of treatment. While it is clear that further treatment is necessary after remission has been achieved, exactly what and how much is less clear. While there is at least one modern study that shows the benefit of maintenance,^{82,83} the fashion for younger patients has been to limit the duration of treatment, but to make it more intensive. For younger patients, the traditional concept of consolidation as a phase of treatment, perhaps with the same drugs but at lower dosage, should probably be consigned to history. It is now appropriate to administer treatment courses at an induction level of intensity. The question then is how many courses, and is there a best choice schedule?

There has been much interest in recent years in dose escalation of cytarabine. It certainly appears that a single course is superior to a maintenance approach.^{84,85} One of the most influential studies was carried out by the Cancer and Leukemia Group B (CALGB), who compared three dose levels of cytarabine given for four courses.⁸⁶ They reported a dose-response effect for patients under 60 years, with a 3 g/m² schedule being superior to a 100 or 400 mg group. Such a high dose was not found to be tolerable for older patients, and compliance was poor. Within the limits of analysis imposed by the small numbers involved, it was not possible to show a dose effect in older patients. The overall benefit of high-dose cytarabine has been confirmed by another major trial group.⁷⁰ The MRC AML10 protocol was primarily designed to assess the value of adding a stem cell transplant (i.e. a fifth course) to four courses of intensive treatment, which in themselves were able to deliver a 40% 7-year survival rate. While the interpretation of the outcome is a little complicated, it was clear that adding the extra course achieved a very substantial further reduction in relapse risk.⁸⁷ This provided the rationale for the MRC AML12 trial, which compared a total of four versus five courses. An initial analysis shows no benefit for the extra course of treatment. No high-dose cytarabine was included in this trial, which produced similar results to high-dose cytarabine schedules.^{88,203} Several older studies attempted to address the question of how many consolidation courses should be given, but it is probable that such studies are no longer relevant in the context of the more intensive approach given nowadays. There is some evidence to suggest that patients with favorable cytogenetics derive most benefit from high-dose cytarabine,⁸⁹ but in general evidence to match a particular schedule to a risk group is sparse.

Stem cell transplantation

In younger patients, it has become accepted practice to offer allogeneic bone marrow transplantation (BMT) to patients who have an HLA-matched donor (see also Chapter 29). This is based on consistent data from several centers that projected a long-term survival rate of around 55%,^{90,91} which was a lot more hopeful than contemporary chemotherapy schedules offering about 25% survival. Some early prospective comparative studies confirmed the superiority of this approach in spite of the increased procedural mortality and morbidity.^{91,92} No truly randomized trials were attempted. A number of concerns have been expressed about whether patients who received a transplant (allograft or autograft) have been selected as already being at a reduced risk of relapse. This is clearly the case, because they have spent a period of time either receiving consolidation treatment or awaiting transplant arrangements to be made. They are therefore patients who have avoided relapse or other treatment-related toxicities during this time period. In similarly ‘time-censored’ cohorts of

patients treated with chemotherapy alone, the outcome is better than the 25% referred to above, and more similar to the transplant results.⁹³

Since the general adoption of BMT as a standard treatment, chemotherapy results have improved as well, particularly in children. This has happened generally by deploying the skills developed from managing the transplant cases, thereby enabling much more intensive schedules to be given. It is clear that some of the prognostic factors referred to below also affect the outcome of transplantation. In particular, patients with an adverse karyotype have a poorer survival after allograft than other cases, mostly due to an increased risk of relapse.⁹⁴ In one prospective analysis taking into account risk factors, and evaluating allografts on the basis of donor availability versus inavailability, there was no advantage in good- or poor-risk patients, but there was an advantage for patients of standard risk.⁸⁷

Good-risk patients who relapse can fairly reliably be returned to a second remission, so it is probably appropriate to reserve transplant for second remission, particularly if other factors such as cost and patient morbidity and quality of life are taken into account. This has been supported by further analysis of the MRC AML10 trial, where the significant reduction in relapse risk in the favorable karyotype group was entirely due to the t(15;17) subset, who are now treated with retinoic acid, but not in the t(8;21) or inv(16) patients.⁸⁷ In two other donor/no donor comparisons, no significant advantages were noted with regard to disease-free survival or overall survival in any of the risk groups.^{95,96} The MRC AML12 trial did not prescribe transplant in good-risk cytogenetic groups. This did not result in a change in survival.⁸⁸

Autologous BMT has been widely used as a means of consolidation therapy for first remission.^{97–101} The advantages of this approach are that it is an option for patients who do not have a sibling donor and it will avoid some of the morbidity associated with allograft and therefore has the potential to be safely given to patients aged up to 60 years. Numerous single-center studies and registry data all confirm an expected outcome of 45–55%,¹⁰² i.e. not that different from what can be achieved with an allograft.

However, the same points about patient selection as mentioned above apply, and therefore it was realized that prospective trials were required to establish what role autografting may have. A substantial proportion of entrants to these trials are children, who by virtue of age and favorable karyotype preponderance already have a more favorable outlook. In this context, autografting has been shown to have limited if any benefit, particularly^{103,104} when the morbidity of the procedure is taken into account (e.g. growth retardation) and the fact that this subgroup of patients can be salvaged if they relapse is recognized. A large adolescent and pediatric trial reported by the Children's Cancer Study Group¹⁰⁵ did provide evidence that allogeneic transplantation improved results in children, but some concerns have been raised about the analysis of that trial.^{106,107} In any event, there is also evidence that the results of chemotherapy in children have improved greatly—probably again as a result of more successful supportive care.

Of the major trials reported in adults, in those conducted by the EORTC-GIMEMA, UK MRC, the GOELAM group in France, and the US Intergroup, around 1000 patients were randomized to compare autografting with further chemotherapy, or in the case of the MRC AML10 study to compare the addition of transplantation with intensive treatment.^{87,108–110} The EORTC and MRC trials showed a substantial reduction in relapse risk and a significant advantage in disease-free survival. An overall survival advantage was less convincing, because a proportion of the patients (particularly in the EORTC trial) who relapsed could be salvaged. The GOELAM group observed no survival advantage, while the MRC study showed a survival advantage that emerged late. The US Intergroup study did not show any advantage for either transplant approach when compared with high-dose cytarabine. In all of these studies—but most particularly the MRC and US Intergroup studies—there was a problem of substantial non-compliance with randomization and of delivering the autograft even when randomization was achieved.

The procedure has a higher mortality rate (up to 15%) than anticipated from the previous single-center studies (around 6–8%). This is often due to the consequences of poor engraftment. Were this to be rectified then autologous BMT would be much more clearly advantageous. This raises the issue of whether peripheral blood stem cells (PBSC) could be a better source for transplants. Collected data within the European Group for Blood and Marrow Transplantation suggest that hematopoietic recovery may be better for neutrophil recovery but less clear for platelets. There is no evidence to support the use of PBSC to reduce the risk of relapse. Augmentation of autologous marrow with PBSC seems to be capable of enhancing engraftment of neutrophils and platelets,¹¹¹ but it remains to be seen whether this modification of the technique has an impact on survival.²⁰⁴

It is emerging that transplantation for good-risk disease and children could reasonably be applied as a second-line option. There are no prospective studies comparing transplantation with chemotherapy in second remission, but a retrospective database analysis has indicated that allografting is better than chemotherapy for younger patients (below 30 years) and for patients with longer first remission (over 1 year) and, paradoxically, older patients with shorter

first remissions (less than 1 year). Although there are data to support the use of transplantation as first treatment of relapse,¹¹² on the basis that patients are not lost during reinduction therapy, this has not been widely adopted.

Allogeneic transplantation from unrelated donors is being more widely used, but it is largely untested in AML in prospective studies. Until the technique improves substantially, its role in AML is likely to be limited to areas where current treatment is inadequate, such as for the first-line treatment of young patients who are identified as being at high risk or as an option in second remission. Non-intensive transplantation protocols are now being explored. While they are feasible, the antileukemic effect is not yet clear.

Overall results of treatment

In an historical review of patients treated on MRC protocols for more than 25 years, there has been a steady improvement in outcome with time. While there may be a number of explanations, and there may be differences between the patients treated, it is likely that this reflects the more intensive approach that has been taken, which has been permitted by improved supportive care. For older patients, there is little sign of any improvement in outcome (Figure 38.2).

Factors determining treatment outcome

From what has already been said, several factors have been identified in recent years as reliable predictors of whether patients will respond to treatment and whether they are likely to relapse (Table 38.3).

Age

Age is a major determinant of what therapeutic options can be offered to patients, and will also have a major influence on how they respond to the treatment and whether or not they will subsequently relapse. There is a steady decline in success from remission induction treatment and an increase in the risk of relapse with age. Both effects are only partially explained by the uneven distribution of favorable or unfavorable karyotype or poorer performance score at diagnosis. In contemporary studies, remission rates of 90% for children under 15 years, 80% for patients aged 16–60 years, and around 50% for older patients are now the norm. The true position in older patients is not absolutely clear, since the figures are derived from patients who enter clinical trials. It is well known that this is the minority of older patients. Poorer outcome with age can be explained in part by the tendency for favorable karyotypes to occur in younger patients while the opposite is true for older patients, but the general medical health of older patients tends to be less robust and therefore they can withstand intensive chemotherapy less well (see below).

Cytogenetics and molecular genetics

Cytogenetic abnormalities are seen in approximately 60% of cases of AML and are highly predictive of response to therapy as well as probability of relapse.^{113–116} The translocations t(8;21), inv16 or t(16;16), and t(15;17) generally carry a relatively favorable prognosis and are more commonly seen among younger patients with AML. The fusion genes of each of these translocations have been identified and can be detected with molecular probes in reverse transcriptase (RT)-PCR. Among patients with these chromosomal abnormalities or the corresponding

Figure 38.1 Survival in MRC AML trials: age 15–59 years.

Table 38.3 Unfavorable prognostic factors for outcome of chemotherapy in adult patients with AML

	Predictive for complete response	Predictive for relapse following response or for overall survival
Young and middle-aged adults (15–60 years)		
Greater age		
Cytogenetics (chromosomes 5 or 7 or complex abnormalities)	+	+
immunophenotype (CD34+)	+	+
Multidrug-resistance phenotype	+	+
High white blood cell count	+	+
Autonomous cell growth in culture	+	+
Elderly (>60 years)		
Greater age	+	–
Abnormal cytogenetics	+	+
Poor performance	+	+
High white blood cell count	+	+
Secondary AML or prior MDS	+	–
The above listed factors have been identified to express negative prognostic value in two or more prospective studies, The following specific favorable cytogenetic abnormalities have been distinguished: t(8;21), inv(16), and t(15;17).		

molecular genetic abnormalities (*AML1-ETO*, *CBF β -MYH11*, and *PML-RAR α*), the response to induction therapy is 80% or greater and for those entering remission the probability of relapse is approximately 30%, resulting in 5-year survival rates of 60–70%. The latter molecular or cytogenetic subsets of AML correlate with cytomorphological categories. For instance, t(8;21) correlates mainly with FAB subtype M2, while inv(16) correlates with FAB M4 with eosinophils. However, the cytogenetics and molecular genetics of a particular case, rather than the FAB subtype, possess the overriding prognostic significance.

In contrast, patients with monosomies of chromosomes 7 (–7) or 5 (–5), 11q23 (*MLL* gene) abnormalities,¹¹⁷ abnormalities of the long arm of chromosome 3 (abn3q), t(6;9), t(9;22), or Philadelphia chromosome and complex cytogenetic abnormalities (four or more different cytogenetic aberrations) generally have a distinctively poor prognosis. Among these individuals (when aged 60 years or younger), the average complete response to induction treatment is 60% with a majority of patients (approximately 80%) relapsing within 2 years, so that the survival rate at 5 years is approximately 15%.^{60,118,119} These cytogenetic and molecular indicators have led to the definition of prognostic groups: favorable risk (favorable molecular genetics or cytogenetics), unfavorable risk (poor-risk cytogenetics), and intermediate risk (all others). Usually, these risk classifications are refined by considering selected additional prognostic determinants that enhance the value of the cytogenetic or molecular distinctions. Risk-scoring systems based upon multiple prognostic factors may permit more precise approximations of prognosis in individual cases. For the sake of practicality, most collaborative groups have restricted the use of these additional risk factors, and only take into account a limited number of covariables with considerable prognostic impact. As an example, the MRC group has considered rapid versus late attainment of complete response (i.e. after cycle 1 versus cycle 2) in their risk score in order to enhance the separation between intermediate-risk and poor-risk patients.¹¹⁹ The Dutch-Belgian HOVON and Swiss SAKK groups have required a white blood cell count of less than $20 \times 10^9/l$ in addition to favorable cytogenetics for the good-risk category (risk of relapse 24% at 5 years).¹²⁰ Another recent study has confirmed the white blood cell index as a prognostic factor in t(8;21) AML.¹²¹

Various studies have suggested that AML with *FLT3* internal tandem duplications (ITD), seen in 15–30% of pediatric and adult patients, predicts for significantly greater risk of relapse and for reduced sur

vival.^{31,34,36,39,43} Other studies with large numbers of patients have not yet unquestionably reproduced the prognostic value of *FLT3* ITD for survival.^{122–124} More recently, it has been suggested that a high mutant/wild-type *FLT3* ratio enhances the predictive power of *FLT3* for survival as well.^{122,125} Interestingly, *FLT3* mutations are mainly seen in the largest category of intermediate-cytogenetic-risk AML. Hence, *FLT3* ITD offer important additional molecular markers to distinguish a new subset of poor-risk AML. Another recurrent D835 point mutation of the *FLT3* receptor, seen in approximately 5–10% of de novo AML, has not yet been convincingly correlated with prognosis.

Mutations of the tumor suppressor gene *TP53* predict negative outcome.¹²⁶ In addition, high levels of *BCL2* and *WT1* expression have also been suggested to define AML with poor risk.¹²⁷ Tandem repeats of the *MLL* gene also appear to confer inferior outcome.¹²⁸ *EVII* is an oncogene overexpressed in AML with translocations of 3q26. *EVII* mRNA overexpression also characterizes AML with poor-risk outcome when associated with 3q26 abnormalities. Recently, it was shown that *EVII* expression in AML in the absence of 3q26 cytogenetic abnormality also predicts notably bad prognosis.¹²⁹ In contrast, *CEBPα* mutations define AML with relatively good risk.^{130,131}

These cases, hidden among the intermediate-cytogenetic-risk subset of AML patients, can now be separated. Each of these molecular defined groups is of relatively small size, confirming the genetic heterogeneity of AML. With the introduction of highthroughput analysis for molecular abnormalities and gene expression profiling, it will probably in the near future be possible to define new classes of AML (Table 38.4). The introduction of expression array chips (Chapter 20) may yield composite mRNA signatures of AML cells with prognostic value.^{205,206} These distinctions, when properly validated, are likely to provide powerful tools for guiding treatment strategies in AML in the future.

Immunophenotyping

There is at present no clear picture as to what contribution immunophenotyping at diagnosis makes to prognosis. Some of the inconsistency of the evidence can be attributed to technical differences, for example methods, antibodies, and thresholds of positivity, as well as the inherent heterogeneity of the disease. There seems to be general agreement that immunological definition is helpful in endorsing the FAB subgroups known to have an impact on prognosis, for example M6, M7 biphenotypic (adverse), M3 (favorable). In general, lack of DR or CD34 expression will be favorable.^{132,133} MDR1/P-glycoprotein (P-gp) positivity (multidrug-resistance phenotype) will be unfavorable.^{133–137}

Initial morphological response to treatment

The appearance of the bone marrow in response to initial treatment is increasingly being recognized in both ALL and AML as predictive of outcome. Failure to substantially clear blasts within a few days of treatment has been taken in some chemotherapy protocols as an indication to give more treatment at that time. When the blast count has not been reduced below 15% after hematopoietic recovery from the first course, the prospect of achieving CR with the next course diminishes, but even for those who do achieve CR, the relapse risk is high compared with those with less than 20% blasts at that point. The conventional definition of CR depends on observing less than 5% blasts in the bone marrow, but in the MRC AML 10 trial there was little difference between patients at less than 5% or between 5% and 15% who subsequently entered CR on long-term survival.¹¹⁹ The morphological response to treatment can identify a subgroup of patients who are failed by present approaches to treatment and need novel approaches. Such patients who receive a transplant also do less well. Dysplasia of all lineages in remission may indicate a pre-existing myelodysplasia, and is thought to have a less good outcome.

Table 38.4 Molecular markers additional to cytogenetics with prognostic significance of remission duration or survival in adult AML

Marker	Frequency	Predictive for relapse	Survival	Ref
<i>TP53</i> mutation	9/200 (4.5%)	—	Unfavorable	126
High <i>BCL2</i> and <i>WT1</i> mRNA expression	35/98 (36%)	Unfavorable	Unfavorable	127
<i>MLL</i> partial tandem duplication	18/221- (8%)	Unfavorable	NS	128
High <i>EVII</i> mRNA expression	32/319(10%)	Unfavorable	Unfavorable	129
<i>CEBPα</i> mutation	15/135(11%)	Favorable	Favorable	130

^a Normal cytogenetics only. NS, not significant.

Other factors

Poor performance score, male sex, high leukemic cell burden (i.e. high white blood cell count or organomegaly) and raised lactate dehydrogenase (LDH) have all been recognized for a long time as being associated with poor treatment outcome (Table 38.3). Markers of chemoresistance, such as Pgp expression^{133–137} and function, as discussed above, are now being more consistently shown to be individual predictors of response. Clearly there is a tendency for functional resistance (which has been associated with Pgp expression), adverse karyotype, and age to be associated in the same patient. However, each has been identified as an individually powerful predictor of outcome. The cells in some cases of AML can be demonstrated to proliferate in a cytokine-free culture system. In a study where patients were stratified into three categories (low, intermediate, and high) based on in vitro proliferative response, differences in outcome were noted.²⁰⁷ The respective CR rates were 68%, 62%, and 39%, while the relapse rates were 51%, 71%, and 89%. This translated into a major difference in survival difference (high 4% versus low 44%). The biological explanation for the heterogeneity of in vitro responses may relate to autonomous generation of growth factors and prevention of apoptotic death.

In summary, there are a number of powerful prognostic factors in AML that have potential as guides towards appropriate treatment, and away from ineffective or inappropriate lines of management. The most important in these respects are patient age (where a division around 60 years can be made), karyotype (which has both a favorable and an unfavorable subgroup), and initial response to treatment (where persisting with similar therapy to what has already been tried is unproductive). Prognostic values used to direct treatment are at present most relevant in younger patients, in whom more treatment options, particularly stem cell transplantation, can be considered.

Minimal residual disease

The genetic abnormalities seen in a significant proportion of cases of AML provide unique markers of minimal residual disease, which in some instances can be detected with molecular methods. Such markers have been used to monitor the disappearance of leukemic cells during treatment and during remission (see also Chapter 22), or to assess their re-emergence following remission. Conventional cytogenetic analysis, FISH, and Southern blot analysis provide relatively insensitive measurements (1 leukemic cell per 10^2 cells). RT-PCR measures transcripts of fusion genes at much greater sensitivity (10^{-3} to 10^{-6}), and more recently real-time PCR has been introduced for quantitative measurements of fusion gene transcripts. As yet, these techniques have been applied mainly to the most common fusion genes: *AML1-ETO* (t(8;21)), *CBFβ-MYH11* (inv(16) and t(16;16)), *BCR-ABL* (t(9;22)), and a few others.

In AML with t(8;21), *AML1-ETO* fusion transcripts have been detected in patients in long-term remission, indicating that their persistence does not necessarily predict relapse.^{138–141} A proportion of the long-term survivors did become negative for such transcripts.¹⁴² More recently, quantitative PCR techniques have permitted individuals at high risk of relapse to be distinguished from those in stable remission.^{143,144} These studies are based upon small series of cases, emphasizing the need for more information regarding the predictive value of quantitative PCR measurements. Studies of real-time PCR are in progress. In AML with inv(16) or t(16;16), *CBFβ-MYH11* transcripts have been followed. There are at least eight variant transcripts. Most studies conducted so far have only assessed the common type A transcript (present in more than 80% of patients with this abnormality) in limited numbers of patients, and therefore cannot provide definite conclusions regarding the clinical value of this marker.^{144–146} Both PCR-positive and PCR-negative cases have been reported among long-term survivors. Studies with quantitative PCR have as yet provided only preliminary (but promising) data.^{147–151} Especially when PCR negativity appears after completion of therapy, it may predict continuous remission.^{147–151} Another significant proportion of patients with AML present with *MLL* gene rearrangements (abn(11q23)).¹⁵² One of many *MLL* abnormalities is the *MLL-AF9* fusion gene in patients with the t(9;11) translocation, but the value of molecular methods for the detection of this genetic abnormality remains uncertain.^{153,154}

Targeted leukemic cell killing

An appealing concept in AML treatment is to direct therapeutic agents specifically to the leukemic cell population while sparing normal hematopoietic progenitors and normal tissue. Antibodies and growth factors conjugated to a cytotoxic agent can be used to deliver drugs to the site of the malignant cell (see also Chapter 25). For instance, the granulocyte-macrophage colony-stimulating factor (GM-CSF)-cholera toxin and the *GM-CSF-Pseudomonas* toxin have shown significant activity against leukemic progenitor cells in colony assays as well as in vivo repopulation assays.^{155,156} The CD33 antigen is a 67 kDa glycoprotein that functions as a sialic acid-dependent adhesion protein. It is expressed on most AML cells, including leukemic clonogenic precursors, but is not expressed on normal pluripotent hematopoietic stem cells. The CD33 antigen is absent

from non-hematopoietic tissue. Because of these properties of selective binding and the fact that upon binding of specific antibody the CD33 antigen is internalized, anti-CD33 antibodies are suitable for delivering cytotoxic agents to leukemic cells.^{157,158,201} Several other interesting immunoconjugates (e.g. anti-CD45 antibodies and G-CSF—toxin conjugates) are under development. Clinical studies with a humanized anti-CD33 antibody conjugated with the chemotherapeutic antitumor antibiotic calicheamicin (gemtuzumab ozogamicin, Mylotarg) show that approximately 30% of cases with AML in relapse may enter complete remission after one or two injections of this agent.^{157,201} Currently, the use of this drug as a single agent is being evaluated in patients of younger age and with newly diagnosed disease. See also Chapter 25.

The targeting of disease alleles (e.g. mutated signaling molecules and transcription factors) remains a promising challenge. The paradigms of retinoic acid therapy in *PML-RAR α* ⁺ leukemia and of imatinib in *BCR-ABL*⁺ leukemia have demonstrated the applicability of this concept. There are many potential targets in AML, and it will be important to target those involved in the multistep leukemogenic cascade on which AML growth continues to depend, and preferably those with a broad range of activity affecting common pathways of development of multiple AML types. Current research is concentrating on a variety of principles. Examples of these include the development of kinase inhibitors (e.g. FLT3 inhibitors),^{159,208} inhibitors of activated RAS processing,¹⁶⁰ and inhibitors of transcription repressors (histone deacetylase inhibitors¹⁶¹) (see also Chapter 27).

Treatment of the patient of older age with AML

AML is seen at all ages, but more than half of patients are aged 60 years or older.^{162,163} Because of demographic changes and the projected increase in the number of elderly people among the total population in the next decade, a significant increase in the incidence of cases of AML is foreseen.¹⁶⁴ Intensified cytotoxic therapy and stem cell transplantation have improved the prognosis of AML in recent years in young and middle-aged adults. However, these modern approaches to therapy have as yet provided little benefit to individuals with AML older than 60 years. Elderly people suffer from AML that in general is resistant to chemotherapy. Furthermore, aged individuals have greater difficulties in tolerating the toxicity and morbidity that accompany intensive chemotherapy.

Should older patients with AML actually be submitted to remission induction chemotherapy, or is it better to refrain from this and offer palliative support to these individuals? A purely supportive approach results in short survival and is associated with frequent hospitalization and a poor quality of life.¹⁶⁵ The prevailing opinion today is that intensive chemotherapy is the treatment of choice for elderly patients suffering from AML—provided they are fit. Remission induction chemotherapy usually involves a combination of the chemotherapeutic agents cytarabine and an anthracycline (daunorubicin or idarubicin) or an anthracenedione (mitoxantrone). Following one or two cycles of chemotherapy, approximately 50% of patients aged 60 years or more enter complete remission. Thus, the elderly population of patients respond significantly less favorably to induction treatment. The inverse relationship between age and CR rate is also apparent from a number of studies that enrolled patients covering a broad range of ages. These results are indicative of a progressive decline in the response to chemotherapy with increasing age. Patients aged 0–39, 40–59, 60–84, and 70–84 years show average response rates of about 78%, 66%, 45%, and 35%, respectively.¹⁶⁶ Independent prognostic factors that express an additional negative impact on the probability of attaining CR are poor performance status of older patients at diagnosis, high blast or white blood cell counts, and abnormal cytogenetics (Table 38.3).^{79,167,168}

Complications and mortality during remission induction therapy in the elderly

Approximately 30% of patients do not enter remission, owing to early death or death during the hypoplastic phase post chemotherapy. Death occurs during hospitalization in spite of supportive care, including antibiotics as well as red blood cell and platelet transfusions. A majority of the deaths among these individuals are due to infections. The greater death rate indicates that elderly individuals are less able to tolerate the consequences of severe infections, including hemodynamic dysfunction and the associated negative effects on cardiac, pulmonary, and renal function.¹⁶⁶ There are also age-related changes that might affect the pharmacokinetics and pharmacodynamics of antineoplastic agents, resulting in more intense or prolonged exposure. Reduced marrow regenerative abilities, the reduced tolerance of other organs to handle the toxic effects of drugs, as well as the reduced elimination and metabolism of drugs might all explain why elderly patients are at increased risk of hematopoietic and other complications from intensive chemotherapy. The incidence of severe infections in elderly patients with AML on induction therapy is approximately 20%.¹⁶⁹ Approximately 10% of patients die during or within the week following completion of chemotherapy.¹⁷⁰ Those who have experienced significant toxicity following the first cycle of chemotherapy are gener

ally prematurely withdrawn from additional efforts of treatment. Thus, the obstacles to offering adequate therapy to older patients with AML are still quite formidable.

Outcome of treatment and prognosis in elderly AML

Patients aged over 60 years, once induced into remission, are usually consolidated with additional cycles of chemotherapy, but rarely with stem cell transplantation or high-dose chemotherapy. Stem cell transplants are currently applied to patients aged 60 years and above only infrequently. Allogeneic transplants employing reduced-intensity conditioning regimens and associated with less organ toxicity are currently in clinical trial^{209–211}. As discussed earlier, it will not be possible to give substantial amounts of intensive treatment anyway. Among patients aged 60 years and older treated with chemotherapy, survival at 2 years has been estimated as approximately 20%^{79,168,169,171} and at 4–5 years as 10% or less.^{79,168,170,171} The median disease-free survival is approximately 9 months^{79,167,168,170} and approximately 30% of patients survive free of leukemia at 2 years. The disease-free survival rate at 4–5 years is about 5–15%.^{79,86,168,170,171} Apparently, only a minor fraction of elderly patients submitted to intensive chemotherapy at the end become long-term survivors (Figure 38.2). These results probably represent an overestimate of the true outcome of elderly individuals with AML. Many patients are not referred to hospital for chemotherapy, or are ineligible for chemotherapy for medical reasons. Taking account of these patients, the overall prognosis of elderly patients with AML is even more dismal than indicated by the results of prospective studies.

One report estimated that only about one-third of elderly patients were selected to enter treatment protocols, and this is confirmed from the UK MRC databases.¹⁷¹ In fact, the variability of patient selection leading to the inclusion of patients with variable risks in individual studies might also explain the differing outcomes of treatment in study reports. In one study of more than 400 cases, an additional 196 patients were identified as not having entered the trial. The most important reasons for exclusion of patients from trial therapy were their old age and poor clinical condition. The median age of non-trial patients (67 years) was significantly greater than that (53 years) of the trial group.

Based on these considerations, it can be estimated that the real 4-year survival rate of elderly patients is 5% or less. Therefore, the choice to treat or not to treat is critical in these individuals. A poor performance status and high white blood cell count and unfavorable cytogenetics at diagnosis have been identified as powerful prognostic factors for survival.^{79,167–169} It makes sense to select patients for induction treatment only if they are in reasonable good clinical condition. Further, it makes sense to continue treatment only if they respond to and tolerate the first cycle of treatment with no major complications. The aim of this prognostic approach is to attempt to avoid treatment that has no benefit.

Randomized studies in AML to enhance hematopoietic recovery after chemotherapy

The rationale for applying hematopoietic growth factors to the treatment of adult patients with AML is mainly twofold.¹⁷² First, the introduction of these factors may hasten hematopoietic regeneration following chemotherapy and thus reduce morbidity and mortality. Second, *in vitro* studies have shown that hematopoietic growth factors might sensitize AML

Figure 38.2 Survival in MRC AML trials: age over 60 years.

cells to chemotherapy, and their coadministration with chemotherapy might enhance the antileukemic efficacy of treatment. The results of a limited number of randomized studies that were concerned with evaluating the role of G-CSF or GM-CSF after completion of chemotherapy have been reported. Several studies have been conducted in previously untreated patients. Some studies were done in patients with relapsed or refractory AML, and included some patients with CML in blast crisis.^{172–174} These studies were all done in a relatively aged population, as the median ages of the patient groups in each of the trials varied between 43 and 71 years. In all studies, the application of G-CSF or GM-CSF after chemotherapy resulted in a reduction of the duration of severe neutropenia, although it varied from 2 to 12 days.

Beneficial effects of G-CSF or GM-CSF treatment on the number of severe infections and the need for antibiotic treatment have been reported. In one of the randomized G-CSF studies,¹⁷⁵ fewer documented infections were observed and patients in the G-CSF arm had fewer days with fever—and fewer days of antibiotic treatment in another study.¹⁷⁶ Application of GM-CSF reduced WHO grade 4–5 infections significantly in one of the three GM-CSF studies.¹⁷⁷ However, a consistent reduction of infection-related morbidity and mortality that would justify the general application of G-CSF or GM-CSF to patients with AML undergoing intensive chemotherapy has not been noted. Thus, the results of currently available studies do not establish a role for G-CSF or GM-CSF in modifying the response to induction chemotherapy or survival. An explanation for the lack of clinical utility could relate to the fact that the enhanced hematopoietic recovery results in a reduction of neutropenia of only a few days following a prolonged period of neutropenia.

Refractory disease

Resistance of AML to chemotherapy is still the major cause of treatment failure in patients of all ages with AML (see also Chapter 23). The proportion of patients showing primary resistance to chemotherapy as the cause of remission induction failure may be estimated as 15% or more. Others may first achieve a CR, but after variable periods of time encounter recurrence of the leukemia. Why should AML in a fraction of individuals be relatively unresponsive to chemotherapy? The answers to this question are still open. M0 cytological FAB subtype, unfavorable cytogenetic abnormalities (e.g. chromosome 5 and 7 abnormalities), MDR1 surface marker expression, *BCL2* positivity, CD34 immunophenotype, and high levels of autonomous proliferation in culture have all been shown to be adverse cellular predictors of treatment outcome. Overexpression of the membrane P-glycoprotein (P-gp) is a typical phenotypic marker of drug resistance. P-gp belongs to a group of phosphorylated glycoproteins first described in hamster ovary cells. The classical form of multidrug resistance (MDR) was established when similar increased P-gp expression was found in a large range of cell lines.¹⁷⁸ Primary or acquired resistance to chemotherapy in patients is also associated with P-gp expression. In addition, there are several other proteins that are responsible for a form of pleiotropic resistance shown in multidrug-resistant cell lines that do not express P-gp, but do express the multidrug resistance-related protein (MRP) or lung resistance related protein/major vault protein (LRP/MVP). Intracellular concentrations at adequate levels of the antileukemic chemotherapeutic agents daunomycin, mitoxantrone, and etoposide are critical for achieving cell kill of leukemia cells. Several cellular escape mechanisms have been defined that counteract chemotherapy cytotoxicity and confer drug resistance. High P-gp expression results in enhanced P-gp pumping activity and reduced intracellular drug concentrations in MDR-positive cells. Since the recognition of MDR as an independent mechanism of drug resistance, attempts have been made to downregulate P-gp or inhibit its function, using oligonucleotides and protein kinase C (PKC) inhibitors such as staurosporine. Another approach to modulating P-gp is to inhibit its interaction with cytostatic drugs by the use of competitor agents. It is currently accepted that various reversal agents can restore drug accumulation by competing with cytostatic drugs for P-gp-binding sites. These agents include calcium channel blockers, calmodulin inhibitors, immunosuppressive agents, quinolines, indole alkaloids, detergents, steroids, and antiestrogens.^{179,180}

There is only limited experience with reversing MDR in AML *in vivo*^{181,182} with mitoxantrone/etoposide, to which cyclosporine was added. Although several responses were noted, the toxicity of this regimen was considerable. In another small study, quinine was used as a reversing agent in refractory AML, and was well tolerated.¹⁸³ Two studies evaluated the cyclosporine analog PSC833 as a modulator of drug resistance and showed more induction deaths but reduced late relapse and mortality.^{184,213} One of the largest studies to date¹⁸⁵ included 226 patients with refractory and/or relapsed AML. They were treated with daunorubicin plus high-dose cytarabine, to which cyclosporine was added in a dose-escalation design. The toxicity of cyclosporine was dose-dependent and included prolongation of myelosuppression, nausea, and hyperbilirubinemia. The plasma levels of daunorubicin were elevated in patients who received a high dose of cyclosporine. The rate of complete remission was not significantly improved in this group, but both overall and relapse-free survival were significantly increased with the cyclosporine. The

results of this study indicate that it is possible to combine a drug-reversal agent such as cyclosporine with combination chemotherapy in AML patients without unacceptable toxicity and with clinical benefit, but additional confirmatory studies are clearly needed.

Modulation of resistance to chemotherapy with hematopoietic growth factors

Cytarabine is one of the most effective cytotoxic agents included in the induction therapy of AML. It is an analog of 2'-deoxycytidine. It is metabolized to Ara-CTP, the active form. Ara-CTP is incorporated into DNA. This results in slowing of elongation of the nucleotide chain and a defect in the ligation of newly synthesized fragments of DNA. Ara-CTP also acts as an inhibitor of DNA polymerase in competition with deoxycytidine triphosphate (dCTP).

Cytarabine cytotoxicity is S-phase-dependent and related to the rate of DNA synthesis. Reasons for treatment failure of AML patients in response to cytarabine may relate to pharmacological resistance of the leukemia (due, for example, to a deletion of deoxycytidine kinase) or kinetic resistance (cells not in S phase may escape cell killing). Enhanced cytotoxicity of cytarabine against AML colony-forming cells (AML-CFU) following incubation of the cells with G-CSF, interleukin-3 (IL-3), or GM-CSF has been demonstrated by various investigators.^{186–188} There is an average threefold increase in the cytotoxicity of cytarabine to AML clonogenic cells in the context of stimulation with GM-CSF (range 2.2- to 229-fold) and IL-3 (range 1.5- to 63.2-fold), corresponding to an additional cell kill at a magnitude of 1–1.5 log on the cytarabine dose-response curve.¹⁸⁹ Costimulation of AML cells with a variety of hematopoietic growth factors in culture enhances the incorporation of Ara-CTP into cellular DNA.¹⁸⁹ GM-CSF may enhance DNA polymerase activity in leukemic cells, and this increased activity is related to augmented cytarabine incorporation and AML cell cytotoxicity.¹⁹⁰ G-CSF or GM-CSF has been applied simultaneously with chemotherapy in order to sensitize leukemic cells to the cytotoxic effects of chemotherapy. At present, results from uncontrolled prospective studies^{191–193} and several randomized studies of relatively small size (and therefore limited statistical power) are available.^{194–197} In two larger studies, GM-CSF was applied both during and after chemotherapy.^{168,198} Although these studies were conducted in patients of older age, thus representing poor-prognosis AML, in one of them G-CSF sensitization improved disease-free survival.¹⁹⁸ In one large phase III study, specially and selectively designed to assess the value of growth factor priming, G-CSF was given concomitantly with chemotherapy only and not continued until neutrophil recovery.²¹² This study was conducted in adults aged 15–60 years with newly diagnosed AML, and showed a reduced relapse rate and better disease-free survival for those treated with G-CSF. The advantage was apparent mainly in patients with AML of intermediate prognosis (according to cytogenetics).²¹² Clearly, the therapeutic concept of growth factor priming in AML deserves further clinical trial.

Novel treatment approaches

The limitations of conventional approaches to treatment using various chemotherapy schedules have been described in this chapter. Intensification of treatment has brought better results in younger patients. This in turn has exposed more clearly the risk factors that are valuable in predicting the risk of relapse and has enabled a degree of targeting of treatment (e.g. transplantation). There still remains the major problem of preventing relapse. Allogeneic stem cell transplantation has consistently been shown to be the best modality to prevent relapse, but it continues to be limited by procedural morbidity and mortality and the need for a matched donor. The time-censoring benefit also applies to the transplanted cohorts, while it does not to chemotherapy schedules. The Holy Grail of capturing the graft-versus-host leukemia effect of allografting will continue to be pursued.

It may be, however, that the limits of conventional intensive chemotherapy have been reached, and there is no doubt that, for many patients, (particularly those with high-risk disease or older patients), novel approaches are needed. Over the next few years, targeted treatment will become available aimed at the molecular lesions and/or their consequences that are thought to play key roles in disease causation (see also Chapter 27). Preliminary studies have been initiated of, for example, farnesyl transferase inhibitors aimed at counteracting the effect of *RAS* mutations and kinase inhibitors abrogating the FLT3 receptor mutations.^{199,208} Several agents are under development, each of which has provided enticing preclinical data. It will, however, take a significant time before such agents are fully assessed. As the molecular mechanisms unfold, so new targeted drugs will become available. These will be aimed at small groups of patients, and this brings the additional challenge of developing clinical trials that are of sufficient size for the usual statistical rigor. It seems likely that novel approaches to trial statistics are also needed. Another potential way to improve the therapeutic ratio of treatment is by immune targeting. The concept of the 'magic bullet' is not new, but clinical opportunities have only arisen relatively recently. In the context of AML, the CD33 antigen has become the focus of attention. It is expressed in 90% of cases of AML, and, as

far as is known, is not expressed on normal tissues. It is expressed on normal hematopoietic precursors, but not stem cells. This is a favorable profile, but might also be a limitation if leukemic stem cells also do not express CD33.

Naked antibodies, whether or not humanized to enable repeated use, have met with little success as single agents.²⁰⁰ However, the coupling of a toxic agent to the antibody is an attractive concept, particularly as the CD33 antigen-antibody complex is rapidly internalized to the cell, thus providing an ideal drug delivery system. Gemtuzumab ozogamicin has been developed as such an agent. This is a humanized anti-CD33 monoclonal antibody that is coupled to the powerful antitumor antibiotic calicheamicin (see the section on targeted leukemic cell killing earlier in this chapter). Early clinical trials demonstrated a favorable side-effect profile and efficacy in that 30% of relapsed patients achieved second remission.^{157,201}

On this basis, the drug received regulatory approval in the USA for the treatment of relapse in patients over 60 years. There are a number of situations in which this agent could find a role. Several studies are using it as a component of an overall treatment plan, either in sequence with courses of chemotherapy or giving it coincidentally with chemotherapy. This latter approach must be introduced with care and with a reduced dose of the immunconjugate, since preliminary studies suggest that coincidental use will result in important hepatotoxicity.²⁰² Careful clinical trials of these new approaches will require patience, but may well open the way to many more directed treatment approaches.

Modern laboratory techniques (see also Chapter 20) such as expression profiling and proteomics promise much in relation to diagnostics, prognostication, treatment choices, and the development of molecularly targeted treatments.^{205,206}

Acute promyelocytic leukemia

Laurent Degos

Introduction

Acute promyelocytic leukemia (APL) was recognized as a distinct subset of acute myeloid leukemia (AML) in the 1950s,¹ distinguished by morphological features categorized as M3 in the French-American-British (FAB) nomenclature,^{2,3} and by an associated coagulopathy with a bleeding diathesis,⁴ often exacerbated by cytotoxic chemotherapy,⁵ leading to a relatively high rate of early mortality, mainly due to intracranial hemorrhage.

APL is relatively uncommon, the frequency being estimated as 10% of acute leukemias. The mean incidence in Europe is about 2–3 cases per million inhabitants per year. In the USA there are up to 800 new cases every year. The frequency seems to be higher in southern Europe (Italy and Spain: 15% of AML) than in central Europe (Germany: 7% of AML). A particularly high incidence of APL is found in Latin America (Mexico), accounting for one-third of AML.⁶ Both sexes are equally vulnerable to APL, and there is a wide range in age at first presentation. However, APL is a rare disease in children.

Definition

APL was initially defined morphologically. In 1977, it was found to be consistently associated with a balanced and reciprocal translocation between the long arms of chromosomes 15 and 17: t(15;17).^{7–9} Ten years later, a collaborative study by Chinese and French groups demonstrated the *in vivo* and *in vitro* effects of all-trans retinoic acid (ATRA; tretinoin) in the differentiation of malignant cells from APL patients. At the same time, the gene encoding the retinoic acid receptor alpha (RAR α) was mapped to chromosome 17q21.¹⁰ Because ATRA was found to be clinically effective in this disease, rearrangements of the *RAR α* gene in the translocation were assumed.¹¹ The break-point of the translocation disrupted the *RAR α* gene on chromosome 17 and a previously unknown gene, initially called *myl*¹² and renamed *PML* (for ProMyelocytic Leukemia),^{13,14} on chromosome 15. The two genes *PML* and *RAR α* are fused, leading to the transcription of a fusion product PML-RAR α that has been found in all patients studied, and is considered as the signature of the disease.^{15–17}

Thus APL is defined not only by morphological and clinical features but also by the specific translocation t(15;17) resulting in the fusion of two genes *PML* and *RAR α* , generating a disease-specific fusion protein that is potentially involved in the carcinogenesis.

Clinical features and laboratory findings

Usually, the first symptoms of APL are consequences of bleeding diathesis. Hemorrhages of the skin and mucosae prompt physicians to perform a hemogram. Sometimes severe hemorrhage (intracranial) leads to early death. Usually, no tumor, bone pain, adenopathy, or spleno- or hepatomegaly are recorded. Patients with APL share many of the symptoms of acute non-lymphocytic leukemia, such as pallor, fatigue, weakness, palpitations, dyspnea on exertion, and fever.

In contrast to other subtypes of leukemia, in the hemogram, the majority of patients (approximately 95%) have a total white blood cell (WBC) count of less than $5 \times 10^9/L$. Marked thrombocytopenia ($<50 \times 10^9/L$) is usually found. The anemia is variable, often related to hemorrhage. However, about 5% of patients, usually those having a variant form called the microgranular form, present with an elevated WBC count of up to $100 \times 10^9/L$.

In the common form, with a low WBC count, few malignant cells are found in the blood, most of them being the bone marrow.

The diagnosis of APL is made morphologically on bone marrow smears. In the bone marrow, the majority of cells are abnormal, having some similarities

with promyelocytes (size of cell, nucleus/cytoplasm ratio, and nuclear aspect). The malignant cells bear numerous large granules and several Auer rods. Bone marrow aspirates are also taken at presentation for cytogenetic evaluation and for reverse transcriptase polymerase chain reaction (RT-PCR) assays in order to detect the t(15;17) translocation and the PML-RAR α mRNA respectively.

A microgranular variant (M3v) of the disease is characterized by a bilobed nucleus and very small granules that are not visible with light microscopy. Patients with M3v have a high WBC count and a poor prognosis (early death and risk of relapse).

Immunophenotyping confirms the myeloid lineage (CD13-CD33) with association in some cases with CD19 and/or CD2 antigens usually found in lymphoid lineages.

Coagulation disorders

The coagulopathy in APL can provoke a life-threatening hemorrhage, which rapidly induces a course in untreated patients. The risk of early mortality necessitates treatment of the patient immediately after diagnosis. The coagulopathy is characterized by severe fibrinopenia and thrombocytopenia. The mechanisms of fibrinopenia result from at least three distinct syndromes due to the release of procoagulant activators, plasminogen activators, and lysozymal neutrophil enzymes from leukemic cells.^{18,19} The procoagulant effect activates thrombin, leading to diffuse intravascular coagulation (DIC). The plasminogen activation induces a primary fibrinogenolysis, whereas the lysozymal neutrophil enzymes (human leukocyte elastase, cathepsin G, and proteinase 3, also called myeloblastin) provoke a leukocyte-mediated proteolysis that cleaves various substrates, including fibrinogen itself and von Willebrand factor. On one hand, the primary fibrinolysis theory is supported by the high level of annexin II detected on APL leukemic cells (and not on other types of leukemic cells); annexin II is a cell surface receptor for plasminogen, as well as for one of its activators, the tissue plasminogen activator, tPA.²⁰ On the other hand, the DIC theory is supported by the presence of tissue factor release by APL cells.²¹ Tissue factor serves to initiate coagulation by an interaction with Factor VII. The relative extent of these mechanisms in APL patients is still debated, and recommendations for the management of hemostatic disorders (heparin, antifibrinolytic drugs, plasma, or nothing) in APL patients treated with chemotherapy, therefore, vary from one group to another.^{22–27} Two parameters are usually evaluated during the treatment: the plasma level of fibrinogen and the number of platelets. In order to follow the DIC, factor V, fibrinogen degradation products, and soluble complexes are serially tested.

The rule for treating patients with APL is to transfuse platelets in order to have more than $50 \times 10^9/L$ permanently during the treatment until complete remission.

A rapid normalization of fibrinogen level is observed in APL patients treated with ATRA; this normalization is related to the disappearance of plasmin-dependent primary fibrinogenolysis (see below) more than to the control of the DIC. Patients treated by ATRA are still susceptible to thrombosis, which is prevented by low molecular weight heparin. Conversely, chemotherapy exacerbates the fibrinopenia and the DIC.

Molecular genetics of APL

As mentioned above, Rowley and colleagues^{7,8} discovered in the mid-1970s that APL was always⁹ associated with a balanced and reciprocal translocation between the long arms of chromosomes 15 and 17: t(15;17)(q23;q21). Two reciprocal fusion transcripts result from this translocation: PML-RAR α which is found in all patients with APL and contains the functional parts of the RAR α and PML genes, and a small RAR α -PML transcript that is detected in only about two-third patients.

RAR α belongs to the retinoid receptors—members of a superfamily of nuclear receptors that act as ligand-dependent transcription factors. Retinoid receptors bind to specific sites in DNA (called RA responsive elements) on the promoter region of some genes and act as transcription factors controlling the expression of target genes. Two families of nuclear retinoid receptors RAR (α , β , and γ) and RXR (α , β , and γ) have been identified.^{28–33} These receptors contain two binding sites: one domain that binds to DNA on the promoting region of a target gene, and another domain that binds to the retinoids that switch on the transcription activity. These receptors have the capacity to dimerize, which markedly increases the DNA-binding affinity and the activation of a target gene. Almost all the domains are present in the PML-RAR α fusion protein: only the first domain of RAR α is missing—this is a domain involved in the activation of the target gene. The natural ligand of RAR is ATRA, while the ligand of RXR is 9-cis retinoic acid,^{34,35} a metabolite and isomer of ATRA. The 9-cis isomer is also able to bind to RAR. Usually heterodimers, made of one RAR and one RXR, bind to DNA on two adjacent responsive elements. The expression of the genes targeted by RAR subtypes α , β , and γ differs in the tissue distribution—for example, RAR γ in the skin. Other types of receptors bind to similar responsive elements on DNA, and also dimerize with RXR, such as vitamin D3 receptors (VD3R), the thyroid hormone receptor (TR) and RXR itself. However, the heterodimers RXR-RXR, VD3R-RXR, TR-RXR and RAR-RXR bind to different target gene promoters according to the number (1 to 5 respectively) of nucleotides inserted between the two DNA-responsive elements.

PML was discovered with the cloning of the translocation t(15;17) and belongs to a family of nine pro-teins that share a ring finger (an atypical zinc finger domain) and another large domain implicated in dim-mer formation.³⁶ All these domains are present in the PML-RAR α fusion product; only a small portion of the molecule is missing.

In fact, the breakpoint on *RAR α* gene is always in the same region (second intron, leaving the A domain outside of the fusion *PLM-RAR α*) while the break-point on *PML* could localized on three different regions leading to three isoforms of PML-RAR α fusion protein: bcr1 the longest, bcr3 the shortest, and less frequently a bcr2 isoform similar to bcr3.

The fusion gene *PML-RAR α* is under the control of the promoter of the *PML* gene.

Immuno staining with anti-PML antibodies has demonstrated that PML is normally localized on discrete subnuclear structure³⁷ previously identified by electron microscopy and called PML nuclear bodies. However, prior to the cloning of *PML*, these structures were identified using a subset of auto-antibodies from patients with primary biliary cirrhosis (PBC).³⁸ Most of these auto-antibodies recognized a molecule called SP100.³⁹ Other proteins (NDP55, SUMO, DaXX, BLM) are also present together with SP100 and PML on these nuclear bodies.⁴⁰ PML nuclear bodies are parts of the nuclear matrix, a biochemically defined scaffold that has been proposed to play an important role in intranuclear biology. PML localization is regulated in the cell cycle (diffuse nuclear fluorescence during S phase and a subsequent reformation of bodies).⁴¹

In APL patients, the nuclear body is disrupted, and the PML molecules as well as PML-RAR α molecules, are spread out in the nucleus and in the cytoplasm³⁷ taking with them normal PML/PML and RXR/RAR molecules through PML and RXR dimerization respectively.

The transforming potential of the fusion-gene products has been tested by cotransfection assays in cell lines. These experiments demonstrated an alteration (repression or overactivation) of transactivation of target genes of retinoic acid receptors.^{13,14} Retinoic acid mediated differentiation of the HL60 cell line is also blocked by the presence of the PML-RAR α fusion product.⁴² The fusion protein seems to block the activity of retinoic acid receptors, mainly in the differentiation of the granulocytic lineage.

In the presence of high concentrations of ATRA, all these abnormalities are reversed. Retinoic acid induced reporter genes blocked by PML-RAR α are activated, and HL60 transfected with *PML-RAR α* can be differentiated in the presence of retinoic acid. The normal allele of *RAR α* (on the non-translocated chromosome 17) is transiently upregulated while *RXR* gene expression is downregulated under ATRA treatment. In a second step, RAR α molecules are cleared. On the other hand, after ATRA treatment, the nuclear body is rebuilt, PML relocalized in 24 hours in vitro and in five days in vivo and PML-RAR degraded.

At the molecular level, it was reported that the fusion protein PML-RAR α inhibits the exchanges of corepressor with coactivators of transcription of *RAR α* target gene. In fact, RAR-RXR dimers are attached to corepressors which are linked to histone deacetylase (HDAC).

Histone deacetylases compact DNA on histone, blocking the transcription process. In presence of retinoic acid, RXR-RAR dimers exchange corepressors to coactivators, which are linked to histone acetylase, decompacting the DNA from histones, allowing by this fact the transcription. High doses of retinoic acid are capable to reverse the inhibition of PML-RAR α in this exchange of corepressor-coactivators.

In conclusion, the fusion protein PML-RAR α on the one hand induces an arrest of differentiation of the granulocytic lineage through an abnormal RAR α , and on the other hand alters the nuclear biology and probably the natural apoptosis through an abnormal PML. ATRA restores these two abnormalities.

Another agent, arsenic (as the trioxide As₂O₃) is also able to induce complete remission by way of differentiation effect (promyelocyte to abnormal myelocyte) and apoptosis. Arsenic targets its effects on the PML moiety of the fusion protein PML-RAR α . Arsenic induces first a relocalization of PML in the nucleus, and on the nuclear bodies, and second, a degradation of PML as well as PML-RAR α inside the nuclear bodies through a sumoylation (due to a link with the SUMO molecule) by the proteasome. Thus, under treatment by arsenic, the PML-RAR α fusion proteins as well as PML molecules are relocalized in the nucleus and rapidly degraded.

Treatment

Results of intensive chemotherapy

Several studies demonstrate the sensitivity of APL to anthracycline treatment.⁵ The complete remission (CR) rate was improved progressively (reaching 80% of patients), due to better management of the coagulopathy and thus to a reduction of the fatal bleeding, using intensive platelet support during the induction phase associated with a potential beneficial role of heparin and/or antifibrinolytic agents.²³⁻²⁵ With consolidation chemotherapy, the median disease-free survival ranges from 11 to 25 months, and approximately 35% of the patients who achieved a CR (25% of patients at diagnosis) could probably be cured of the disease. In contrast to the situation in other acute non-lymphocytic leukemia, cytarabine (cytosine arabinoside; Ara-C) at

standard doses does not appear to be beneficial in combination with anthracyclines.⁴³ High dose of Ara-C could reduce the number of relapses.

Adverse prognostic factors for CR with chemotherapy are greater age, microgranular APL variant, high leukocyte count, and severe coagulopathy at diagnosis; a shorter disease-free survival (relapse rate) was observed in patients with a high leukocyte count at diagnosis.^{22,43–46}

Results obtained with ATRA

Retinoids are able to induce a terminal differentiation of leukemic cell lines, such as HL60 and U937, and of short-term culture APL cells from humans.^{47,48} In 1985, a first informal meeting in Paris, Wang and Degos pointed out the differentiation activity of retinoids on APL cells. In fact, at that time the only available retinoid in Europe, the ethyl ester retinoid (etretinate) was not effective on APL cells.⁴⁷ The differentiation effect on fresh cells is restricted to patients with the APL subtype of non-lymphoblastic leukemia and the sensitivity of the malignant cells depend on the specific derivative, with ATRA being the most efficient drug.⁴⁹

All trans retinoic acid was produced in Shanghai and first used to treat patients there.⁵⁰ Following a second collaborative meeting (French and Chinese) in Shanghai in 1987, the Chinese drug was kindly provided to subsequently treat French patients.⁵¹

Differentiative effect obtained with ATRA alone

Treatment with ATRA (daily dose 45 mg/m²) was proposed for newly diagnosed patients in Shanghai⁵⁰ and for patients in first or subsequent relapse in Paris,⁵¹ with the CR rate reaching 90% in both studies. The clinical features were unusual for a chemotherapy inducing a CR of leukemia. Instead of the initial worsening observed with conventional chemotherapy, coagulopathy (fibrinogenopenia) rapidly improved. No primary resistance, no aplastic phase, no hairless, and few infectious episodes were observed. The most remarkable features was the progressive change of malignant cells in bone marrow, with signs of their terminal differentiation and with Auer rods being sometimes observed in mature cells.⁵¹ The differentiation process was confirmed by serial fluorescence in situ hybridization (FISH) and clonality was demonstrated using X chromosome-linked polymorphism.⁵² Clonal malignant cells carrying the t(15;17) translocation are replaced by polyclonal hematopoiesis. Correction of neutrophils and platelets occurred first, after 1 month of treatment, while low hemoglobin levels and monocytopenia persisted for a few days after treatment, most likely in relation to the inhibitory effect of retinoic acid on BFU-E burst-forming units, erythroid) and CFU-M (colony-forming units, monocyte-macrophage).⁵³

Two major adverse effects: retinoic acid syndrome and secondary resistance

Treatment with ATRA alone showed two adverse effects: one during treatment (retinoic acid syndrome) and one following it (secondary resistance to ATRA). An activation of leukocytes inducing an increase in WBC count is observed during treatment with ATRA alone,⁵¹ and one-third of patients develop fever, dyspnea and even renal failure corresponding to the well described and so-called ATRA syndrome.⁵⁴

The 'ATRA syndrome' corresponding to a leukocyte activation syndrome, combines fever, respiratory distress, weight gain, pleural or pericardial effusions, and, sometimes, renal failure. The incidence of this syndrome is lower in China compared with Europe or America,⁵⁵ and the syndrome is frequently preceded by an increase in WBC counts in peripheral blood. The pathophysiology is not clearly understood and appears to be related to cytokine release by differentiating cells.⁵⁶ Two approaches have been attempted to counteract this syndrome: the *European attitude* is to prevent the syndrome using chemotherapy when WBC counts increase; the *American attitude* is to treat the syndrome with high-dose intravenous corticosteroids. The current consensus is to use chemotherapy in combination with ATRA and to add corticosteroids either from the onset of treatment, if patients have a high WBC count, or when patients show symptoms of ATRA syndrome during treatment.

Following treatment with ATRA alone, patients experience an induction of a secondary resistance to ATRA.

Secondary resistance occurs in all patients treated with ATRA.⁵⁷ Thus, patients receiving ATRA alone achieved CR for only a short time, usually relapsing within 6 months. Patients treated with ATRA become refractory to this treatment for a period of 6–12 months and the acquired resistance is usually reversible after this period. Since all patients acquire a resistance and because that resistance is usually reversible, it appears that a secondary genetic change is not involved in this process, in contrast to the phenomenon occurring in artificial ATRA-resistant cell lines.

The observed resistance is likely to be related to feedback mechanisms aimed at reducing ATRA concentrations in the organism. A significant decrease of ATRA levels in plasma is observed after only a few days of treatment and ATRA remains at lower, sometimes undetectable, levels even if the dose is doubled.⁵⁸ On one hand, ATRA treatment increases the activity of cytochrome P450 implicated in the catabolism of ATRA itself, which reduces the plasma level of the drug,⁵⁸ and on the other, ATRA increases the transcription of the cytoplasmic retinoic acid binding protein II (CRABP II), trapping the ATRA and thereby inducing a reduction of nucleic concentration of the drug.⁵⁹

Other side-effects

Dryness of lips and mucosae are usual, but these can be alleviated by symptomatic treatment. Increase in transaminases and triglycerides and bone pain are common, but they have never required discontinuation of treatment in our experience. Headache, due to intracranial hypertension, is generally moderate in adults but may be severe in children, and associated with signs of pseudotumor cerebri.⁶⁰ Lower ATRA doses (25 mg/m²/day) in children reduce this sideeffect, and this dose seems to be as effective as conventional doses of 45 mg/m²/day.⁶⁰ Monitoring of hemostatic parameters in APL patients treated with ATRA alone shows that primary fibrinogenolysis disappears during the first days of treatment, while DIC and leukocyte-mediated proteolysis seem to persist for the first 2 or 3 weeks of ATRA therapy.^{19,61,62} This could lead to a transient period of hypercoagulability not compensated by fibrinolytic activity, and a few well-documented cases of thromboembolic events in APL patients treated with ATRA have been reported.^{63,64}

ATRA in combination with chemotherapy: a step towards the cure of APL

The occurrence of secondary resistance to ATRA in APL patients led us (French trials) to administer a treatment combining ATRA with intensive chemotherapy.

Non-randomized studies. In the first studies,⁶⁵ 26 newly diagnosed cases of APL, treated with ATRA (45 mg/m²/day) until CR, followed by three courses of chemotherapy (daunorubicin and cytarabine), were compared with an historical control group treated with chemotherapy alone (Figure 39.1). Initial results showed that ATRA followed by chemotherapy dramatically reduces the number of relapses (occurring within 24 months after the onset of the disease). These results have now been largely confirmed.^{66,67}

Randomized trials: ATRA followed by chemotherapy. A European trial (APL 91) comparing three courses of chemotherapy (daunorubicin and cytarabine) to initial ATRA treatment followed by the same chemotherapy in newly diagnosed APL patients was prematurely stopped after 18 months because the event-free survival (EFS) was significantly better in the ATRA group. The analysis at 4 years confirmed the higher actuarial EFS (63% vs. 17%; $p < 0.0004$), mainly due to a reduction in relapse rate (13% vs. 78%; $p < 0.03$).^{68,69} In a 3-year American inter-group study, started in 1992 and closed in 1995, three courses of chemotherapy were compared with ATRA treatment followed by two courses of chemotherapy.⁷⁰ The incidence of relapse was significantly reduced in patients who received ATRA (33% vs. 68% at 3 years; $p < 0.01$).

Figure 39.1 Event-free survival: pilot study (ATRA+ conventional chemotherapy) compared with historical series.

Randomized trials: ATRA given simultaneously with chemotherapy. Initially ATRA was used alone until CR followed by chemotherapy. The European group (APL 93 trial) compared two combination regimens including ATRA and chemotherapy, ATRA being given either prior to chemotherapy or simultaneously with chemotherapy. In the latter combination, ATRA was started 3 days before chemotherapy in order to maintain the beneficial effect on coagulation disorders. Relapses at 2 years are significantly less frequent (6% vs. 16%) when ATRA is given simultaneously to chemotherapy.⁷¹

Treatment after remission

A retrospective Chinese study conducted by the Chinese Cooperative Study Group summarizing 5-year survival probability in 423 APL patients treated with ATRA as induction of remission, followed by ATRA alone or ATRA plus chemotherapy as maintenance therapy, has shown that the alternating use of chemotherapy and ATRA could yield a longer survival time.⁵⁵

Two randomized studies^{70,71} strongly suggest that maintenance treatment with ATRA has a beneficial effect in newly diagnosed APL. The American intergroup trial⁷⁰ compared continuous ATRA treatment as maintenance (45 mg/m²/day) for 1 year with no maintenance. The frequency of relapse was reduced in

patients who received ATRA (10 of 46 vs. 24 of 54 patients). However, liver toxicity limits the use of continuous maintenance with ATRA. Patients who received no ATRA during induction therapy also benefited from ATRA maintenance.

The European APL group (APL 93 trial)⁷¹ randomized patients who achieved CR into groups with no maintenance and maintenance with ATRA 15 days every 3 months, continuous low-dose chemotherapy with 6mercaptopurine and methotrexate (MTX), or both (ATRA and low-dose chemotherapy) for 2 years using a 2×2 factorial design. The frequency of relapse at 2 years was reduced in patients who received ATRA compared with those who did not (13% vs. 25%; $p < 0.002$) and was also reduced in patients who received low-dose chemotherapy compared with those who did not (11% vs. 27%; $p < 0.03$). An additive effect of low-dose chemotherapy and ATRA maintenance therapies was also observed (7% of relapse at 2 years). Furthermore, patients with higher rise of relapse because of high blood cell counts at diagnosis seemed to benefit particularly from both low-dose chemotherapy and ATRA maintenance (10% vs. 30% of relapse rate at 2 years).

Standard treatment. The conclusion of these randomized trials suggests that APL patients should be treated with ATRA and chemotherapy including anthracyclines simultaneously, as induction treatment; two courses of chemotherapy (including anthracyclines or similar drugs), for consolidation; and ATRA in combination with low-dose chemotherapy for 2 years, as maintenance therapy. Under these conditions we can achieve a CR rate over 90% and a relapse rate lower than 10% at 2 years. If few delayed relapses occur, we hope that more than 75% of APL patients will actually be cured.

Prognostic factors

White blood cell count

High WBC counts at diagnosis (more than 5000–10 000 mm³, according to the various group protocols) increase the risk of early mortality and relapses. The M3v hypogranular form is often associated with a high WBC count which increases the risks of leukocyte activation syndrome and relapse. Simultaneous administration of ATRA, chemotherapy with dexamethasone reduces the risk of leukocyte activation syndrome and mortality. In addition maintenance therapy (ATRA plus chemotherapy) reduces the risk of relapse.⁷¹

Age

Patients older than 65 years have a higher risk of early death (17% vs. 6% in younger patients).⁷¹ New treatment combinations, such as the association of ATRA and arsenic trioxide (As₂O₃), which exclude or reduce anthracyclines, have yet to be tested.

Other types of APL

Therapy-related APL (t-APL) has a similar outcome as non t-APL.⁷² Several other translocations including RAR α as a partner are actually registered. Some are sensitive to ATRA, others are not (see Table 39.1). In case of the t(11;17) translocation involving the PLZF-RAR α fusion protein, G-CSF appears to be beneficial when associated with ATRA.⁷³

Immunophenotype. APL blasts have a different immunophenotype from those of other forms of AML. Although, like other AML, APL blasts are positive for GD13 and CD33, they lack HLA-DR antigens and are usually negative for CD34 and CD 7, indicating that they derive from a more mature progenitor cell than other AML cells. Sometimes they also carry lymphocyte markers such as the B-cell marker GD19, or the Tcell marker CD2. This latter marker is mainly found in cases of M3v and in patients with PML-RAR α /bcr3 breakpoint. CD19 seems to be associated with high WBC counts.⁷⁴ The presence or not of CD56 is suspected to affect survival.^{75,76}

Karyotype and molecular biology. Additional karyotype abnormalities do not appear to influence prognosis in APL.^{77,78} The type of PML-RAR α isoform has

Table 39.1 Acute promyelocytic leukemia (APL) and APL-like acute leukemia with a translocation involving RAR α (17q21)

Gene	Location	Name	Function	Sensitive to ATRA (tretinoin)	Reference
PML	15q22	Promyelocytic leukemia	Apoptosis	Yes	
PLZF	11q23	Promyelocytic leukemia zinc finger	Morphogenesis (limbs, skeleton)	No	Chen et al, 1993 ⁹¹
NPM	5q35	Nucleophosmin	Ribosome biogenesis	Yes	Redner et al, 1996 ⁹²
NuMA	11q13	Nuclear mitotic apparatus	Chromatic compaction	Yes	Wells et al, 1997 ⁹³
STAT 5b	17q11	Signal transducer Activ. Transcript.	Transcription factor for EPO, G-CSF, IL2, IL3, IL7	No	Arnould et al, 1999 ⁹⁴

been suggested as a prognostic factor, with bcr1, the longest isoform, giving a better prognostic index.⁷⁹ In a recent clinical trial using ATRA plus chemotherapy as maintenance therapy, the bcr type is no longer considered to be a prognostic factor.⁷¹

Molecular remission is an endpoint for a better survival. However, the definition of molecular remission depends upon the sensitivity of the RT-PCR technique. Quantitative RT-PCR provides threshold value for prognostic estimates after combination chemotherapy/ATRA treatment. Some patients have shown a delayed molecular CR without early relapse (personal observations). A conversion from negative to positive PCR result is consistently associated with subsequent hematological relapse.⁸⁰⁻⁸³

Cellular (in vitro) assay. Sensitivity to ATRA using short-term culture. The sensitivity of the leukemic clone from fresh bone marrow cells to ATRA at diagnosis is an independent criterion of long-term patient outcome, in terms of better EFS, few relapses and better overall survival.⁸⁴ It has been demonstrated previously that primary cultures of blast cells are correlated with CR.⁴⁹ Thus, the efficacy of differentiation therapy in vivo would appear to be correlated with the in vitro sensitivity, in contrast to classical chemotherapy where in vitro experiments cannot predict in vivo results.

Unresolved issues

Management of patients with high WBC at diagnosis

Patients with high WBC at diagnosis are still at high risk of early mortality and of relapse once they have achieved CR. These patients usually have severe coagulopathy at diagnosis and bleeding symptoms, and have an increased incidence of early death with chemotherapy alone. Our results suggest that the

Figure 39.2 Event-free survival according to randomized treatment (APL91 study). Thick line: ATRA plus chemotherapy, 54 patients, 20 events. Thin line: chemotherapy alone, 47 patients, 38 events, $p=0.0001$, log-rank test.

addition of ATRA to chemotherapy, by providing more rapid reversal of coagulopathy, has further improved prognosis.^{85, 86} Furthermore, the addition of intravenous steroids is recommended in these patients as well as low molecular weight heparin. A maintenance therapy (ATRA and low-dose chemotherapy) reduces the incidence of relapses.

The role of bone marrow transplantation

Because more than 75% of patients treated with ATRA, intensive chemotherapy and maintenance therapy have prolonged remissions of their disease, the roles of allogeneic bone marrow transplantation (BMT) in first CR in these patients is not recommended, even if the results of allogeneic BMT seem to be better in APL than in other AML.⁸⁷ Our more recent results, however, suggest that patients presenting with high WBC counts treated by ATRA plus chemotherapy (without maintenance therapy) are still at risk of relapse, and could be candidates for allogeneic BMT. Patients with positive RT-PCR findings for *PML-RARα* rearrangements during follow-up in first CR could also be candidates, when we will have more data on the exact threshold of positivity by quantitative RT-PCR.

Because only limited experience of autologous BMT in APL is available, its place in this disease after ATRA plus chemotherapy is unknown. The fact that, in some cases, APL blasts are negative for CD34 anti-gen⁸⁸ suggests a possible role for autologous BMT using marrow or circulating progenitors collected after CD34⁺ selection.

Usually, allogeneic and autologous BMT are proposed after relapse in APL patients.

Arsenic treatment

Two teams from Harbin (Manchuria, China) reported at the Chinese Society of Hematology (Da Lian,

Figure 39.3 Relapse according to randomized treatment (APL91 study). Thick line: ATRA plus chemotherapy, 49 patients, 15 relapses. Thin line: chemotherapy alone, 38 patients, 24 relapses, $p=0.0001$, log-rank test.

September 1995) the beneficial effect of arsenic (as As_2O_3) given daily at a dose of 10 mg intravenously until complete remission (30–60 days). The first trials started in 1971 and included 60 patients: 30 de novo patients and 30 relapse patients, with 75% and 53% CR respectively. The second team included 72 patients: 30 de novo patients, with 73% achieving CR, 17% partial remission, and 10% resistance; and 42 refractory and relapse patients, with 52% achieving CR, 12% partial remission, and 36% non-response.

Arsenic trioxide has been confirmed to be effective in the treatment of APL mainly by groups of Shanghai (China)⁸⁹ but also in Europe (Paris, France), in USA (New York), and in Japan. In vitro, As_2O_3 exerts a dose-dependent dual effect: it triggers apoptosis at relatively high concentrations (0.5–2.0 $\mu\text{mol/L}$) and induces partial and mild differentiation at low concentrations (0.1–0.5 $\mu\text{mol/L}$). As_2O_3 induces a degradation of the PML-RAR α molecule as well as the wild-type PML. In vivo, As_2O_3 (10 mg intravenous infusion daily) induces a high complete remission rate in patients with both primary and relapsed APL (around 90%). Side-effects, such as skin reaction, gas-trointestinal symptoms, electrocardiographic changes (QT elongation), peripheral neuropathy, and liver dysfunction, are mild-to-moderate in relapsed patients. However, severe hepatic adverse effects have been found in de novo patients (one death and one severe liver failure among 10 de novo patients in the Shanghai Chinese series). Therefore, arsenic is not actually included in front line treatment in de novo APL and is preferentially proposed in consolidation causes. In relapsed patients, after CR obtained using arsenic, the combination of As_2O_3 with chemotherapy as postremission therapy has yielded better survival than treatment with As_2O_3 alone, and subsequently a bone marrow transplantation (allogeneic or autologous) is proposed as an intensification treatment. The in vivo effect of As_2O_3 seems to be related to the

Figure 39.4 Survival according to randomized treatment (APL91 study). Thick line: ATRA plus chemotherapy, 54 patients, 13 deaths. Thin line: chemotherapy alone, 47 patients, 22 deaths, $p=0.013$, log-rank test.

expression of APL specific PML-RAR α oncoprotein. A synergistic effect between As_2O_3 and ATRA has been shown in the APL mouse model.⁹⁰ Besides As_2O_3 , other arsenic compounds such as As_4S_4 also show a therapeutic effect in APL. The toxic effects of arsenic treatment in de novo APL patients restrict its use to multidrug postremission therapy consolidation or as a rescue for relapsed APL patients.

Conclusion

Acute promyelocytic leukemia as a model for malignancies

Acute promyelocytic leukemia⁹⁵ is the first model of a malignant disease treated by differentiation agents. ATRA, in vitro and in vivo, induces a terminal differentiation (followed by natural apoptosis) of malignant cells. Therefore, ATRA is the principal model of a cell modifier in the treatment of malignancies. Other cell modifiers are actually proposed in leukemia, for instance, arsenic for the treatment of APL, and antikinase, which has shown promising results in chronic myeloid leukemia.

Acute promyelocytic leukemia is also the first model of an acquired genetic disease specifically treated by a drug (ATRA). In fact, ATRA is active in APL and not in other leukemias. APL is characterized by the translocation t(15;17) with a fusion of a large part of the *RAR α* gene on chromosome 17 to a part of the promyelocytic leukemia (PML) gene on chromosome 15. A pharmacologic dose of ATRA overcomes the blockage of exchange between corepressors and coactivators of *RAR α* caused by the fusion with the partner *PML*.

In addition, because ATRA is effective in the leukemia-bearing specific chromosome aberration t(15;17) with *PML-RAR α* fusion gene, the treatment of APL with ATRA constitutes the first successful model for gene-targeting therapy.

Acute promyelocytic leukemia gives the opportunity to better understand leukemogenesis. The *PML-RAR α* fusion gene is sufficient to induce leukemia in mice. In fact, *RAR α* is a nuclear receptor acting as a ligand-dependent transcription factor.⁹⁶ *RAR α* binds to DNA on specific responsive elements located in the promoter region of a set of genes. These genes are transcribed when ATRA is present. Several of these genes are involved in the myeloid differentiation. A defect of *RAR α* induces an arrest of myeloid differentiation at the promyelocytic stage. The partner of fusion protein PML is not a DNA-binding protein. PML proteins located on nuclear bodies seem to be involved in apoptotic events of the cell. Thus, a defect of PML proteins could induce long survival and accumulation of the malignant cells. In conclusion, the leukemic process is caused by an arrest of differentiation (*RAR α* defect) and a long survival (*PML* defect).

A new-old drug, arsenic (As_2O_3 and arsenic sulfide) also has a specific activity in APL. In fact, arsenic clears the PML molecule and thus also clears the oncogenic molecule PML-RAR. In vitro, arsenic mainly activates the apoptotic events of APL cells; in vivo, both differentiation and apoptosis are observed.

Two drugs, ATRA and As_2O_3 are now available for the treatment of APL. These drugs have different mechanisms of action—one acts on RAR α the other on PML—that cleans the oncogene molecule and cures the two abnormalities, differentiation arrest and defect of apoptosis. In mice transplanted with cells bearing the PML-RAR α transgene, the induced leukemia is cured by the association of ATRA with As_2O_3 , whereas the use of one of these drugs on its own prolongs survival but does not produce complete cure. The cure of one of the most dramatic leukemias, APL, is now reachable.

Myelodysplastic syndromes

Pierre Fenaux and Claude Gardin

Introduction

Myelodysplastic syndromes (MDSs) are clonal disorders of pluripotent hematopoietic stem cells, of generally unknown etiology, occurring predominantly in the elderly. They are characterized by ineffective hematopoiesis leading to blood cytopenias, a high incidence of progression to acute myeloid leukemia (AML) and overall by a limited response to most available treatments.

Epidemiology

Incidence, age and sex^{1–5}

MDS is a disorder of elderly people, occurring at a median age of about 70 years.^{1–3} Childhood MDS is rare,⁴ relatively often familial and often associated with monosomy 7⁵ in those in that age range. Among adults, only 8–10% of the patients are younger than 50 years at diagnosis.² The incidence of MDS is about 3–5/100 000 per year, reaching 30/100 000 per year in patients aged over 70. The incidence does not seem to have increased over the last 20 years. A male predominance is seen in all series (with a M:F ratio of 1.5:2).

Etiology

The etiology of MDS is generally unknown ('de novo' MDS). However about 20% of MDSs are 'secondary' to exogenous factors—mostly to antineoplastic chemotherapy or radiotherapy, less often to occupational or environmental exposure to various chemicals. Finally genetic predisposition to MDS includes constitutional disorders of childhood³ and possibly genetic polymorphisms for enzymes involved in the detoxification of potential carcinogenic substances.⁶

Exogenous factors

Antineoplastic drugs (therapy-related MDS)^{7,8}

A majority of cases of AML occurring after exposure to antineoplastic drugs are preceded by a phase of MDS. The most frequently incriminated drugs are alkylating agents, especially when used for prolonged periods. Some alkylating agents, such as cyclophosphamide, could induce fewer cases of MDS than others, especially when used in pulsed injections such as in CHOP cycles. Mechlorethamine (used in MOPP protocol) or prolonged use of melphalan, on the contrary, induces more cases of MDS. The nature of the primary tumor seems to have an impact on the incidence of therapy-related MDS, which is for example with chlorambucil less than 1% after CLL, but reaches 10% after polycythemia vera. Likewise, therapy-related MDS after hydroxyurea and pipobroman has only been reported in myeloproliferative disorders.

The epipodophyllotoxin agents etoposide (VP16) and teniposide (VM26) and, to a lesser extent, anthracyclines, have also been incriminated in the development of secondary AML, but these AMLs are generally not preceded by a preleukemic phase of MDS, and carry other genetic abnormalities, mainly balanced translocations involving 11q23, t(8;21), t(15;17), inv 16).^{7,8}

After autologous marrow or stem cell transplantation, especially in lymphoma, an incidence of MDS of 3–5% has been reported.⁹ Some studies have shown that the MDS clone was generally present prior to the conditioning regimen, and was rather due to prior treatment, especially prolonged alkylating agents, than to the conditioning regimen itself. On the other hand, total-body irradiation in the conditioning regimen is also associated with a higher risk of MDS.

Therapy-related MDS usually develops 3–7 years after exposure to chemotherapy and is associated to complete or partial loss of chromosome 7 in more than half of the cases, often with complex cytogenetic abnormalities.

Occupational and environmental exposure to chemicals^{10–14}

Exposure to benzene and its derivatives has clearly been associated with the development of MDS, or AML generally preceded by MDS.^{10,11}

For other compounds, data are less clear. The few case-control studies performed in MDS suggest a higher incidence of MDS not only in persons exposed to petroleum derivatives and exhausts from diesel engines (which contain benzene derivatives among others) but also in persons using insecticides, pesticides and weedkillers.¹⁴ Those findings might possibly explain the higher incidence of MDS observed in agricultural workers and factory workers in some studies. A higher incidence of MDS was also present in smokers or ex-smokers in several experiences.^{13,14} This could be due to the polycyclic aromatic hydrocarbons that are present in tobacco smoke.¹⁴ Evidence for an association between MDS (or AML) and other exposures, including professional exposure to radiation, work in nuclear plants and high magnetic fields, has not been demonstrated.

Immunological disorders in MDS

The increased incidence of immunological abnormalities in MDS, the favorable response to immunosuppressive drugs in some cases of MDS (see later) and the fact that 10–15% of cases of aplastic anemia (a disorder generally of autoimmune origin) evolve to MDS suggest a pathogenic role of immune effectors in some subsets of MDS.^{15,16} Evolution to MDS, in aplastic anemia, is strongly associated to immunosuppressive treatment (as compared to allogeneic BMT), and possibly to high-dose or prolonged uses of G-CSF.

In addition, a significant association has been observed between MDS and some immunological disorders, including relapsing polychondritis, seronegative arthritis, vasculitis and possibly Crohn's disease.^{17–19}

Genetic predisposition in MDS

A high incidence of antecedent constitutional disorders (about 35%) is seen in childhood MDS.^{20–22} These include Fanconi anemia, Noonan syndrome, Schwachman-Diamond syndrome, Down syndrome, mitochondrial cytopathies and neurofibromatosis. A large proportion of MDS occurring in these situations have monosomy 7.^{3,4,23} In addition, families with several cases of MDS have been reported, both in children and adults.^{24,25} In more than one family, a linkage to the 16q22 region has been suggested, by lodscore analysis.²⁴

Biology of MDS

Cytogenetic abnormalities^{26–36}

Clonal cytogenetic abnormalities in marrow cells are seen in about 50–60% of cases of MDS (Table 40.1).^{26,27} In contrast to some other hematological malignancies, MDSs are not associated with any specific chromosomal abnormality. However, the rare occurrence of translocations and the high incidence of complete or partial chromosomal loss or (less often) chromosomal gain is typical of MDS and distinguishes MDS from AML. The most frequent abnormalities are, in decreasing order, del 5q monosomy 7, trisomy 8, del 20q and loss of the Y chromosome, the latter being clearly a clonal anomaly. Among translocations, unbalanced translocations, leading to loss of chromosomal material are relatively frequent. For example, unbalanced t(5; 17)(p11; p11) and t(7; 17)(p11; p11) translocations lead to 17p deletion. These translocations are more frequent in therapy-related MDS than in de novo MDS.^{7,8,29} Complex cytogenetic findings (i.e. with at least three chromosome abnormalities) are seen in 15–20% of MDS and 50% of therapy-related MDS (Table 40.1).

The fluorescence in situ hybridization (FISH) technique, performed on cytogenetic preparations (metaphase or interphase nuclei) or on bone marrow

Table 40.1 Main cytogenetic abnormalities encountered in MDS

	Approximate incidence (%)	
	De novo MDS	Secondary MDS
Partial chromosomal deletion		
del 5q	20	20
del 20q	3–4	<1
del 7q	1–2	10
del or del 11q	2–3	<1
del or del 12p	1–2	3–4
del 13q	1	<1
Chromosome loss		
Monosomy 7	10–15	50
Loss of Y chromosome	3–4	10
Monosomy 17	3	5–7
Chromosome gain		
Trisomy 8	10–15	10
Trisomy 11	3	1
Trisomy 21	2	1
Translocations		
t(3; 3)(q21; q26)	1–2	3
t(1; 7)(p11; p11)	<1	4–5
t(5; 17)(q11; p11)	1–2	4–5
t(5; 7)(q11; p11)	<1	2
t(5; 12)	<1	<1
Other findings		
iso(17q)	<1	3–4
inv(3)(q12; q26)	<1	3
Complex finding		
(≥ 3 chromosome abnormalities)	15–20	50

slides, appears to be more sensitive than conventional cytogenetic analysis in some situations, especially for the detection of monosomy 7 and trisomy 8.^{30–34} It is useful when low numbers of mitoses are obtained or when only one or two abnormal mitoses are found, questioning the clonality of the anomaly. Multiplex FISH or spectral karyotype (SKY) techniques,³⁴ whereby each chromosome pair is stained by a different color, can be useful in complex karyotypes, where they generally show the involvement of a larger number of chromosomes than expected from conventional studies, and often reveal unsuspected translocations.

The role of cytogenetic findings in the diagnosis of MDS—but more importantly for prognosis—will be stressed later.^{27,35,36}

Molecular abnormalities

Few genes involved in the pathogenesis of MDS have been identified (Table 40.2). This is certainly due in part to the fact that recurring chromosomal translocations are rarely seen in MDS—as translocation break-points indicate precisely the chromosomal regions of interest for the discovery of involved genes.

RAS, NF1, PTPN11 mutations in MDS

Point mutations involving codons 12 or 13 or 61 of members of the RAS gene family (mainly N-RAS, less often K-RAS and rarely H-RAS), leading to an activated RAS protein, constitute the most frequent known molecular anomaly identified in MDS.^{37–40} Incidence of RAS mutations of about 30% in MDS were reported in early series, but that often included patients with advanced MDS. The incidence of RAS mutations at diagnosis in MDS is more likely to be in the range of 10–15%, with a higher incidence in chronic myelomonocytic leukemia (CMML) by comparison with other MDS subgroups. RAS mutations often appear during the course of the disease, as shown by longitudinal studies. Cases of MDS occurring in children with neurofibromatosis are associated with NF1 gene deletions and with a decrease in neurofibromin, the product of NF1 gene.⁴¹ Neurofibromin is active in the RAS pathway, and inactivation of neurofibromin, like RAS gene mutations, leads to RAS activation.⁴² This suggests the importance of a deregulated RAS pathway in the pathogenesis of MDS. This is further substantiated by the fact that RAS mutations often occur in the absence of chromosomal abnormalities, suggesting the involvement of a limited number of genetic defects in pathogenesis. On the other hand, no abnormalities of the NF1 gene have been found in adult MDS.⁴³

Recently, point mutations of the PTPN11 gene, another gene involved in the RAS pathway and encoding for the SHP-2 phosphatase have been described in childhood MDS or AML.⁴⁴ These muta-

Table 40.2 Known molecular abnormalities in MDS

Gene	Type of anomaly	Incidence (%)
P15	Hypermethylation	0–60
RAS (N or K)	Point mutation (codon 12,13 or 61)	10–30
p53	Point mutation + deletion of other allele	5
FMS	Point mutation (codon 969 or rarely 301)	5–10
Flt3	Deletion (ITD) point mutation D835	5–20
AML1	Point mutations	2.7
	Point mutations (tMDS)	>15
PTPN11	Point mutations	10 (children)
NF1	Deletions	5 (children only)
TEL	Fusion to PGDF-R gene (t(5;12) translocation)	<1
MDS1	} Fusion to AML1 gene	<1
EV11		
EV11		

tions differ from the germline mutations present in patients with Noonan syndrome, and are associated with a gain of function of SHP-2. These mutations are frequent (35%) in sporadic juvenile CMML, not associated with Noonan syndrome.

FMS, p53, and AML mutations in MDS

The FMS gene encodes for the macrophage colony-stimulating factor (M-CSF) receptor. It has been reported to be mutated in about 10% of MDS cases, with a predominance in CMML, as for RAS mutations.^{38,45} However, most mutations involve codon 969, a mutation that does not lead to activation of the M-CSF receptor. Some mutations involve codon 301, leading to activation of the receptor, but they only account for 10–15% of FMS gene mutations. The role of FMS mutations in MDS therefore still has to be more precisely established.

p53 gene mutations occur in about 5% of MDS cases.^{46–48} As in other malignancies they predominate in exons 5–8 of the gene, and are generally missense mutations inactivating p53. They can be detected by single-stranded conformation polymorphism (SSCP) analysis of exons 5–8 of the gene, or immunocyto-chemistry on bone marrow slides (which detects p53 overexpression, almost synonymous with p53 missense mutation). p53 mutations are almost exclusively seen in refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-T) and CMML, and are generally associated with deletion of the nonmutated allele, through deletion of chromosome 17p (resulting from t(5;17) or other unbalanced translocations involving 17p, monosomy 17 or, less often, iso 17q).^{47,48} Most MDS cases with p53 mutations have complex cytogenetic abnormalities. It is unknown whether this is secondary to the p53 mutation, since p53 inactivation can lead to chromosomal instability. In the current authors' experience, p53 mutations in MDS (and AML) have always been found at diagnosis and are not acquired during the course of the disease. However, this does imply that they constitute an 'early' event in pathogenesis.

Missense mutations of the AML1 gene, have been identified at low frequency in de novo MDS,⁴⁹ but found in five of 13 patients with therapy-related MDS and six of 13 atomic bomb survivors in Hiroshima, diagnosed with MDS. All mutations but one were dominant-negative AML1 mutations,⁵⁰ as the germline mutations, described in the familial platelet disorder predisposing to AML (FDP/AML).⁵¹

Mutations of flt3, either D835 mutations or internal tandem duplications (ITDs) of the juxtamembrane region, have been described in MDS but their frequency is lower than in AML.^{52,54} and they seem restricted to advanced-stage MDS or MDS having progressed to AML.⁵⁴

Finally, it should be noted that deletion and/or decreased expression of the retinoblastoma gene is very rare in MDS.⁵⁵

p15 hypermethylation^{56–61}

Abnormal hypermethylation of gene promoter regions is a ubiquitous mechanism of reduced gene expression in tumor cells, as are irreversible missense mutations or gene deletions. In MDS, hypermethylation of the p15 gene, a cell cycle inhibitor, has been well studied.^{56,57} Hypermethylation of p15 may be an early event in MDS,⁶⁰ but is also more frequently found (60%) in advanced-stage MDS.⁵⁶ Sequential studies have confirmed the association of abnormal methylation of p15 with clinical progression.⁵⁹

The use of demethylating agents, such as 5-azacytidine or its analog decitabine, have yielded major responses in MDS patients (see later). Reactivation of hypermethylated gene expression, such as p15,⁶¹ is the rationale of the clinical use of demethylating agents, at low dose, although several mechanisms of action of these drugs in the clinical setting (cytotoxicity and differentiation through demethylation) have been demonstrated.

Other well-characterized molecular anomalies in MDS

A few other gene abnormalities have been well characterized in MDS, but they occur in very small subgroups of MDS. They have generally been found in the rare cases of MDS with balanced translocations, molecular analysis of which has led to the discovery of fusion genes between a known gene and a new gene of interest, which could be subsequently cloned.

MDS with t(5; 12)(q31; p13)^{62–64}

A few cases of MDS generally having features of atypical CMML with, in particular, eosinophilia have been reported. Cloning of the translocation breakpoint allowed the identification in 12p13 of TEL gene, a member of the ETS gene family.⁶² In this translocation, the TEL gene was fused to the PDGF receptor gene (PDGF-R) at 5q31, the fusion product having constitutive tyrosine kinase activity. Importantly, the tyrosine kinase inhibitor, imatinib, has in vitro inhibitory activity on the fusion product, and is associated in vivo with a favorable clinical response.⁶³ Other translocations in rare CMML patients involve the fusion of the PDGF-R to other genes than TEL. Some new partners of PDGF-R have been even identified.^{63,64}

MDS with t(3; 21)(q26; q22) or t(1; 3)(p36; q21)⁶⁵

A small number of MDS with t(3; 21), generally occurring after antineoplastic drugs, has been reported. In these cases, the AML1 gene situated in 21q22 is fused

to one of the following genes identified at 3q26: EVI1, MDS1, EAP or both (AML MDS1—EVI1 complex fusion). In patients with high-risk MDS, a t(1; 3) (p36; q21) translocation has also been described. The fusion involves an EVI 1-like gene, named MEL1, and RPN1, a housekeeping gene.

MDS with t(3; 5)(q25; q34)⁶⁶

Patients with MDS and t(3; 5)(q25; q34) have been described. The chimeric fusion gene involves the NPM gene, a regulator of p53, also frequently involved in anaplastic lymphoma subtypes, and a new gene: MLF1. In vitro expression of the fusion gene in cell lines is associated with increased apoptosis.^{67,68}

Unidentified genes: from cytogenetics to molecular biology of specific 'entities' in MDS

In AML, specific morphological-cytogenetic entities such as M2 AML with t(8; 21), M4 eosino AML with inv(16), M3 AML with t(15; 17) have been described. As in AML, specific entities with morphological-cytogenetic characteristics have been identified in MDS, including the '5q syndrome' and 17p deletions with dysgranulopoiesis (see later). In AML, specific gene abnormalities are being found in a growing number of these 'entities'. This search has been more difficult in MDS—to a large extent because translocations, which offer a good opportunity to identify new genes, are so rare in MDS. Because chromosomal deletions are frequent in MDS, the role of inactivation of tumor-suppressor gene(s) situated on deleted chromosomal fragments is strongly suspected in the pathogenesis of MDS. However, discovering new genes whose abnormalities could specifically be involved in MDS in these large chromosomal segments has so far proved difficult, in spite of cytogenetic, FISH and molecular techniques.

In the case of del 5q, the deletion is always interstitial, but of variable extent.^{69–72} Analysis of large numbers of del 5q cases, however, showed two main commonly deleted segments in 5q31 and 5q32, respectively. The next step was to analyze known genes located in this region. However, none of the genes coding for growth factors or growth factor receptors situated in this region were found to be part of the common deleted segment. A third step was to identify new genes in those segments, one allele of which was deleted through del 5q and the other allele inactivated on the remaining chromosome 5 (by deletion or mutation). By positional FISH and molecular biology techniques, several genes, candidate genes, were shown to play a possible role, but no consensus has been reached. In fact, several genes could be involved in the pathogenesis of MDS with del 5q. Another possibility is that loss of one allele of one or several genes could lead to impaired hematopoiesis (haplo-insufficiency).

For other chromosome deletions, including del 20q, monosomy 7 and del 7q, common deleted segments have been identified in 20q11 and 7q31.^{72–76} Several groups are also looking for tumor-suppressor genes; some candidate genes have been identified.

Gene-expression profiles using microarray technique in MDS

Preliminary results of gene-expression profiles using the microarray technique in MDS have been published. Studies were complicated by the heterogeneity of the clonal cells in MDS, and the difficulty in comparing them to normal counterparts. Most groups have studied purified CD34⁺ populations. Among the genes overexpressed in MDS, the DLK1 gene, involved in stem cell and adipocyte differentiation, has been identified by at least two different groups.^{77,78}

Clonality in MDS

The first demonstration that MDSs were clonal disorders came from studies of G6PD isoenzymes in hematopoietic cells, although clonality was already strongly suspected when an abnormal clone was seen by chromosome findings. More recently, X-linked gene polymorphisms have been used to study clonality in female patients.^{79,80} The main genes studied were the PGK, M27 β and HUMARA genes. Their polymorphisms allow these genes to be informative in 50% (PGK gene) or almost all females (M27 β and HUMARA genes).⁸⁰ Although there is still some controversy, it appears that in the majority of MDS cases, only myeloid but not lymphoid cells are part of the neoplastic clone; in some cases, however, B and/or T cells may also be clonal.^{79–81}

Studies combining chromosome analysis (e.g. by FISH) and cell-lineage determination (e.g. by immunophenotype) have been performed both on marrow progenitors and circulating cells. In the former, the Scandinavian group found in MDS with del 5q, the chromosomal abnormality in early CD34⁺, CD38⁻ progenitors.⁸² By contrast, in MDS with +8, this cytogenetic abnormality was not found in CD34⁺, CD38⁻ marrow progenitors.⁸³ Blood studies also showed that, in many cases of MDS, chromosome abnormalities such as monosomy 7 or trisomy 8 were present in only part of the circulating granulocytes.⁸⁴ In a study of MDS with del 20q, circulating granulocytes were shown not to carry the deletion.⁸⁵ All these findings could reflect the persistence of some nonclonal granulopoiesis in MDS in some patients with monosomy 7 or trisomy 8. However, in some well-studied examples, it was demonstrated by X-linked polymorphisms that granulocytes that did not carry the mutation were clonal. Likewise, in one study CD34⁺ and CD38⁻ marrow cells that did not carry +8 behaved as MDS cells.⁸³ This suggests that chromo-

some abnormalities may be late genetic events, in many cases of MDS. In the case of childhood MDS, several findings show that monosomy 7 is a secondary event, and could constitute a 'common final pathway' to different conditions predisposing to MDS.⁵

Immunological abnormalities in MDS

Associations between autoimmune disorders (including Crohn disease, ulcerative colitis, rheumatic disease, glomerulopathy, systemic lupus erythematosus, vasculitis, and seronegative arthritis) and MDS have been reported, especially in CMML.^{17,18} The association may be stronger for relapsing polychondritis (RP).^{18,19} Indeed, in a series of 18 RP cases, five had clinical MDS. In a systematic study of bone marrow samples in seven cases of RP, three had morphological signs of MDS. This suggests a pathophysiological link between the two disorders. MDS could be a consequence of the immune disorder. Alternatively, granulocyte and/or monocyte dysfunction in MDS could lead to impaired disposal of immune complexes and subsequent deposition in small blood vessels, allowing the local activation of inflammatory mediators. Abnormalities of B cells including hypergammaglobulinemia, a higher incidence of monoclonal immunoglobulins and a higher incidence of autoantibodies than in a control age-matched population, are seen in CMML but not in other MDSs.¹⁸ Irrespective of the type of MDS, the number of circulating T cells is generally diminished, and their function is reduced. Recently, several works have shown in MDS a skewed oligoclonal pattern in the T-cell repertoire, with preferential use of some V β chain rearrangements, as seen in immunological disorders.^{86–88} In some MDS patients, circulating clonal large granular T cells are also present.⁸⁹ An inhibition of CFU-GM growth by T cells has also been demonstrated in MDS.⁸⁷ Importantly, response to antithymocyte globulin (ATG) was associated to normalization of the T-cell repertoire and of CFU-GM growth in the presence of T cells. Impaired NK activity and dramatic reduction in the generation of NK cells from CD34+ cells in the presence of IL15 are also found.^{90,91} Monocytes in MDS are derived from the abnormal clone, but only subtle functional impairment is generally seen.

Finally, a higher than expected incidence of lymphoid neoplasms, especially of immunoglobulinsecreting tumors, is seen in MDS.¹⁸

A particular situation where autoimmunity could be implicated is MDS with thrombocytopenia. Indeed, specific auto-antibodies directed against platelets are seen in 20% of MDSs,⁹² and some responses are observed in this situation with therapeutic agents that are active in idiopathic thrombocytopenic purpura (ITP) (danazol steroids, high-dose immunoglobulins). In some of those patients, platelet lifespan was reduced and splenectomy improved platelet counts.^{93,94,95}

The relationship between impaired immunity and clonal proliferation in MDS is therefore still uncertain. In some cases, abnormal lymphoid function could be explained in cases where lymphocytes are part of the abnormal clone. In other more frequent MDS cases, an immune attack on bone marrow progenitors could lead to destruction of most of them and genetic instability of the remaining progenitors.⁹⁶ This could lead to aplastic anemia evolving, after subsequent genetic events, in MDS.¹⁶ Another model gives a major role to monocytes, which in MDS are part of the abnormal clone. Disordered monocyte/macrophage function could lead to persistent immune stimulation, by poor clearance of bacterial antigens, overactive antigen presentation, upregulated cytokine expression or a mixture of all three. This in turn would lead to B-cell hyperplasia, hypergammaglobulinemia, production of auto-antibodies and a greater risk of genetic errors in proliferating B cells, leading to neoplastic changes in some cases. This model could explain why CMML is the MDS subtype with the greatest immune disturbances.

Cellular proliferation, differentiation and death in MDS

Erythropoiesis in MDS

Ferokinetic study of erythropoiesis with ⁵⁹Fe demonstrates in MDS high marrow iron turnover (MIT) but low iron incorporation in erythrocytes, which is a characteristic feature of ineffective erythropoiesis.⁹⁷ A high proliferation of early erythroblasts, about 30% of erythroblasts being in S phase, has also been demonstrated. However, moderately shortened red cell lifespan is also often present in MDS. Finally, with evolution to RAEB and RAEB-T, MIT and percentage of ineffective erythropoiesis fall and a component of quantitative failure of erythropoiesis emerges.⁹⁷

Growth of mature erythroid progenitors (burst-forming units erythroid [BFU-E] and colony-forming units erythroid [CFU-E]) from bone marrow and peripheral blood is suboptimal in most cases of MDS and absent in 30–75% of cases.⁹⁸ Long-term bone marrow cultures show reduced progenitor recovery in MDS patients. Overall, MDS erythroid progenitors appear to have reduced self-renewal capability, reduced capacity to generate BFU-E from blast colonies, and a deficiency of BFU-E relative to CFU-E in most patients.

Growth factors and growth factor receptors in MDS

Because cytopenias in MDS could have been due in part to a lack of growth factors (GFs) or of response to GFs, serum levels of GF were measured and an analysis of GF receptors was performed.⁹⁹ Overall, very few abnormalities were found. In a recent report, expres-

sion of G-CSF receptors at the cell's surface was found to be variable in MDS.¹⁰⁰ Erythropoietin (EPO) concentration is usually appropriate for the degree of anemia, but sometimes low or high. In patients with low levels for the degree of anemia, response to treatment with EPO is often observed.¹⁰¹ No rearrangements or abnormal expression of FMS, IL3 and GM-CSF genes (all situated in 5q) were seen, and no mutation of the c-KIT gene (which encodes for the SCF receptor) was observed.¹⁰²

Apoptosis in MDS

Increased apoptosis (programmed cell death) of myeloid cells would provide an explanation of the ineffective hematopoiesis leading to blood cytopenias observed in MDS, despite normal or increased numbers of bone marrow precursor cells. Quantitative studies in thin-section bone marrow biopsies support this assumption in most cases of MDS, although apoptosis of MDS cells is generally less important in bone marrow aspirates.^{103,104} The importance of apoptosis measured in these studies is variable, from modestly increased to massive.¹⁰⁵ In some studies apoptosis predominates in immature cells, in others in more mature cells (high- vs. light-density cells). The increased tendency of MDS cells to undergo apoptosis can be demonstrated by morphological analysis, showing typical apoptotic features, by ISEL or similar techniques, DNA fragmentation (DNA laddering), or Annexin V labeling.^{106,107}

Increased apoptosis is more important in less advanced stages of MDS, when compared to MDS with higher blast counts,^{106,108,109} the escape of clonal cells from apoptosis could therefore be associated with progression of MDS and transformation.

Mechanisms of increased apoptosis in MDS remain uncertain.^{108,110–112} Activation of cell death receptor signaling, including elevated TNF- α levels, TNF-related apoptosis inducing ligand (TRAIL), Fas and Fas ligand overexpression, are found in MDS bone marrows and/or plasma, especially in low risk patients (RA or RARS).^{113–117} Direct activation of the mitochondrial apoptotic pathway has also been found. Increased ratios between proapoptotic (bad, bax) and antiapoptotic (bcl2, bclXL) molecules of the bcl2 family have been observed in early MDS, whereas this ratio tended to diminish with disease evolution.¹¹³ Some MDS cells appear to be more sensitive to Fas-mediated cytotoxicity, such as MDS cells with trisomy 8 when compared to MDS cells with monosomy 7.¹¹⁸

What triggers the increased apoptosis in MDS is unknown: intrinsic defects of the clonal cells, including mitochondrial dysfunction,¹¹⁹ may predominate in some MDS subtypes such as RARS or alternatively extrinsic apoptotic inducing signals from stromal cells, monocytes or T cells may play a major role in other patients, more likely to respond to anti TNF- α therapeutics or immune suppression.

Diagnosis of MDS¹²⁰

The diagnosis of MDS is, in the majority of cases, relatively easily made by the combined examination of blood and bone marrow aspirate—at least if the latter is examined by an experienced morphologist. Aplastic anemia and some diseases accompanied by marrow dysplasia, including vitamin B₁₂ and/or folate deficiency, exposure to heavy metals, recent cytotoxic therapy, ongoing inflammation (including HIV, and chronic liver disease/alcohol use), should, however be ruled out before concluding that MDS is present. Bone marrow trephine biopsy and karyotype, and less often, other tests may be useful to ascertain diagnosis in difficult cases.

Recently, flow cytometry studies in MDS have been reported, using various myeloid antigens on blast cells and/or more mature myeloid cells. Although these immunophenotypic studies are not yet standardized, they could improve the diagnosis and quantification of dysplasia, and could be of independent prognostic value.^{121–124}

Clinical findings

They are nonspecific and are usually the consequences of cytopenias, including:

- Symptoms of anemia
- Infections due to neutropenia but also to the frequently associated defect in neutrophil function. As in other types of neutropenia, infections are mainly due to Gram-negative bacilli or Gram-positive cocci, and less often to deep fungal infections
- Bleeding due to thrombocytopenia; this is usually seen in patients with very low platelet counts (however, bleeding may also occur in moderately thrombocytopenic patients or even in patients with normal platelets counts, because of thrombocytopathy, with abnormal platelet function).

No organomegaly is generally found in MDS, except in CMML, where splenomegaly is found in onethird of cases, sometimes associated to hepatomegaly. Specific infiltration of other organs is also observed in some cases of CMML—particularly infiltration of serous cavities (leading to pleural, pericardial or less often peritoneal effusions) or infiltration of the skin.

Peripheral blood findings

MDSs are characterized by cytopenias of variable importance, involving one or several myeloid lineages.

Red cells

Anemia is present in about 85% of the cases and is usually macrocytic. The mean corpuscular volume (MCV) rarely exceeds 120 μm^3 , however, contrary to what is frequently observed in megaloblastic anemias. Red cell shape abnormalities are frequent, including elliptocytosis and sometimes schizocytosis, and nucleated red cells can be found in about 10% of cases. Qualitative defects of erythrocytes, reflecting abnormal erythropoiesis, can be observed, including increased Hb F (or less often Hb H), decreased red cell enzyme activities (especially of pyruvate kinase), a paroxysmal nocturnal hemoglobinuria (PNH)-like disorder, and modification of red cell group antigens.

Granulocytes and monocytes

Neutropenia is present in about 50% of the cases at diagnosis, and is often associated to morphological anomalies of neutrophils, including hypogranulation and less often hypolobulation with, in its extreme form pseudo-Pelger-Huet anomaly. Qualitative neutrophil defects include decreased myeloperoxidase, and impaired chemotactic and bactericidal capability, which can potentiate, as described earlier, the risk of infections associated with neutropenia. The proportion of monocytes may be increased, and absolute circulating monocytosis ($>1000/\text{mm}^3$) defines the CMML subtype of MDS.

Platelets

Thrombocytopenia is present at diagnosis in about 30% of cases. Thrombocytosis can be observed, although rarely. Platelets may be abnormally large, and may have poor granulation or large, fused central granulation. Platelet dysfunction, reflected by prolonged bleeding time and decreased aggregation to collagen or adrenaline, and secondary to dysthrombopoiesis, can be observed. It may clinically increase the bleeding tendency.

Lymphocytes

As described earlier, T-cell lymphopenia and abnormal T-cell function can be observed.

Bone marrow aspirate

The bone marrow aspirate is usually normo- or hypercellular, but is sometimes hypocellular, due to marrow fibrosis, poor aspiration, or true hypocellularity.

Myelodysplastic features are a characteristic finding of MDS. The different types of morphological abnormalities of myeloid precursors that can be observed are listed in Table 40.3. Among the most typical changes are megaloblastoid changes in erythroblasts, the presence of ringed sideroblasts (after Prussian blue staining), hypogranulation and hypolobulation of granulocytes, micromegakaryocytes, and large mononuclear megakaryocytes. It is notable that myelodysplastic features do not always involve all three myeloid lineages, and that the megaloblastoid changes observed in erythroblasts in MDS are generally less pronounced than in vitamin B₁₂ or folate deficiency. This characteristic and the hyperlobulation of granulocytes seen in vitamin deficiencies allow strong diagnostic orientation by morphology alone. On the other hand, none of the dysplastic features observed in MDS is specific.

Table 40.3 Myelodysplastic features in MDS

MDS	Bone marrow and/or peripheral blood findings
Dyserythropoiesis	Bone marrow: Multinuclearity Nuclear fragments Megaloblastoid changes Cytoplasmic abnormalities Ringed sideroblasts Peripheral blood; Poikilocytosis Anisocytosis Nucleated red blood cells
Dysgranulopoiesis	Nuclear abnormalities, including: Hypolobulation Ring-shaped nuclei Hypogranulation
Dysmegakaryopoiesis	Micromegakaryocytes Large mononuclear forms Multiple small nuclei

Prussian blue staining for iron should be systematically performed to reveal ringed sideroblasts where iron is stored in (abnormal) mitochondria, giving ring-shaped staining around the nucleus.

An increased percentage of marrow blasts (defined by marrow blasts >5%) is seen in about 50% of MDS, and is very specific of MDS, in the context of myelodysplastic features of the myeloid precursors. Because the percentage of marrow blasts forms the basis of the FAB classification of MDS, it is important to clearly identify marrow blasts and to distinguish them from more mature myeloid cells, especially promyelocytes. For this purpose, the FAB group distinguishes type I blasts, which have no cytoplasmic granules, from type II blasts, which have a few primary azurophilic granules, and are termed 'myeloblasts' by others. The blast percentage used for FAB and by the recent WHO classification should include type I and type II blasts. Marrow blasts of MDS usually have morphological and immunological features of myeloid blasts (CD13⁺, CD14⁺, CD33⁺, peroxidase⁺) but pure lymphoid (TdT⁺, CD19⁺, CD10⁺) and biphenotypic patterns have been noted. They express CD34, a marker of stem cells, more often than blasts of AML. Expression of P-glycoprotein, the product of the multidrug resistance (MDR) gene is found in blast cells of MDS at diagnosis in 50% of the cases of MDS with an excess of marrow blasts (RAEB and RAEB-T), as compared to 20–30% in de novo AML. This higher incidence of P-glycoprotein expression in MDS could explain in part the lower response rate to chemotherapy seen in MDS, in comparison with de novo AML (see later).

Bone marrow biopsy^{125–127}

Because, in many cases, blood examination and bone marrow aspirate are sufficient for a diagnosis of MDS, the current authors feel bone marrow biopsy should not be systematically performed in elderly MDS patients, especially if it does not lead to any treatment modification. However it is obviously important in cases of difficult diagnosis, and it could bring additional prognostic information in some cases.

Bone marrow biopsy obviously assesses bone marrow cellularity better than bone marrow aspirate in MDS. Normal or increased cellularity is seen in 85–90% of cases, but authentic hypocellularity can be observed in 10–15% of cases (hypocellular MDS). Provided that care is taken to fix and process the specimen properly, myelodysplastic features can be analyzed very well in marrow biopsies, and for many authors this method is superior to marrow aspirate for the analysis of dysmegakaryopoiesis.

Marrow biopsy can also allow the detection of clusters of immature granulocytes in the intertrabecular region, away from their normal sites along the osseous surface, termed abnormal localization of immature precursors (ALIP).^{125–127} ALIP has been linked to an increase of intracellular vascular endothelial growth factor (VEGF) with coexpression of one of its receptors, flt1, suggesting autocrine cytokine interaction, in patients with CMML, but also in other types of advanced MDS.¹²⁶ The presence of ALIP, even when it coexists with a normal percentage of blasts on bone marrow aspirates, might predict a poor outcome.^{125,127} However, it may be difficult to distinguish true ALIP from clusters of early erythroblasts or megakaryocytes.¹²⁷

Finally, biopsy is needed to assess fibrosis in MDS. A mild degree of reticulin fibrosis has been reported in up to 50% of patients with MDS, but only 15–20% show a significant increase in reticulin fibers, and collagen formation is rarely seen.

Other tests for diagnosis

Apart from tests aimed at ruling out differential diagnoses, other tests are rarely indicated.

Bone marrow karyotype

This allows the diagnosis of MDS in difficult cases, with moderate cytopenias and/or myelodysplastic features, by showing a clonal abnormality typical of MDS, especially monosomy 7, trisomy 8, del 5q or del 20q. When the number of mitoses obtained is low, FISH analysis of those chromosomes may also be useful to demonstrate the anomaly.

Bone marrow progenitor cultures^{99,128}

Colony-forming unit granulocyte-macrophage (CFUGM) growth is characteristic of MDS when the number of colonies is diminished and small aggregates (clusters) predominate. A marked decrease of BFU-E and CFU-E is almost always observed in MDS.

*Magnetic resonance imaging*¹²⁹

A few studies have shown that magnetic resonance imaging (MRI) of the spine or femur gave atypical marrow patterns in MDS that could be differentiated from those observed in aplasia. MRI could therefore be useful in some cases of difficult diagnosis.

Isotopic studies

Normal platelet lifespan study using ¹¹¹In-labeled platelets may be useful to demonstrate MDS and rule out autoimmune destruction in cases with isolated thrombocytopenia.

Isotopic study of erythropoiesis can sometimes be useful, by demonstrating ineffective erythropoiesis, which is typical of MDS.⁹⁸

Differential diagnosis¹³⁰

Megaloblastic anemias, due to vitamin B₁₂ and/or folate deficiency should always be ruled out, by measuring serum and erythrocyte levels of those compounds.

When an excess of marrow blasts is present, diagnosis of MDS is generally easy, the only question being the border with AML, which is defined by a percentage of marrow blasts greater than 30% in the French-American-British (FAB) classification and 20% in the World Health Organization (WHO) classification.

In cases with numerous ringed sideroblasts, other sideroblastic anemias (due to alcohol abuse, lead poisoning, copper deficiency or, very rarely, congenital sideroblastic anemias) can be ruled out relatively easily.

Chronic blood monocytosis is almost diagnostic of CMML, but causes of transient monocytosis should be eliminated.

In cytopenias without excess of marrow blasts, ringed sideroblasts and blood monocytosis, MDS is a diagnosis of exclusion. In particular, one should exclude several causes of myelodysplastic features of marrow precursors:

- Vitamin B₁₂ and folate deficiency
- Recent cytotoxic therapy
- Inflammation, including viral infections and particularly human immunodeficiency virus (HIV) infection, which can lead to myelodysplastic features in the bone marrow, probably resulting from infection of myeloid cells, nutritional factors, autoimmunity and drug effects
- Chronic liver disease and alcohol use.

Aplastic anemia should be ruled out in hypocellular MDS.

In MDS with isolated neutropenia or thrombocytopenia, other causes of neutropenia and peripheral thrombocytopenia should be excluded.

Classification of MDS

FAB Classification¹³¹

The FAB classification of MDS, proposed in 1982, has been widely adapted by hematologists for almost 20 years (Table 40.4). It is based on a small number of variables (blood and marrow blasts, ringed sideroblasts and blood monocytes) and is easy to apply, although discordances between groups have arisen, due to a large extent to the interpretation of the blast category on marrow smears. Some authors, for example, until recently did not categorize type II blasts among the blasts' cell population, but counted them as promyelocytes.

RAEB and RAEB-T

RAEB and RAEB-T account for about 30% and 10% of MDSs, respectively. Pancytopenia is usually present. Cytogenetic abnormalities, present in 60% of cases, are often of the unfavorable type (monosomy 7, trisomy 8, complex findings). About one-half of the patients progress to AML, and survival is short, with a median survival of about 9 months for RAEB-T and 15 months for RAEB.

Refractory anemia with ringed sideroblasts

Refractory anemia with RARS constitutes about 10% of MDS. The median age is older than in other MDSs

Table 40.4 FAB classification of MDS⁶⁵

FAB type*	Frequency [†]			
	Circulating blasts (%)	Marrow blasts (%)	Ringed sideroblasts (%)	Blood monocytes (×10 ⁹ /l)
RA	<1	<5	<u>≥15</u>	<1
RARS	<1	<5		<1
RAEB	<5	<u>5–20</u>	Variable	<1
RAEB-T	>5	21–30 or Auer rods	Variable	<1
CMML	<5	>30 [‡]	Variable	<u>≥1</u>

*RA; refractory anemia; RARS; refractory anemia with ringed sideroblasts; RAEB: refractory anemia with excess blasts; RAEB-T; refractory anemia with excess blasts in transformation; CMML: chronic myelomonocytic leukemia,
[†]Underlining indicates the important feature of some subtypes; [‡]Some authors classify patients with features of CMML but 21–30% blasts or >5% circulating blasts among RAEB-T.

(with the exception of CMML). Anemia is usually not associated with neutropenia or thrombocytopenia, and, in contrast, thrombocytosis is seen in 25–30% of cases. Cytogenetic abnormalities are less frequent than in RAEB and RAEB-T and, when present, are generally not unfavorable. Progression to AML occurs in only 10% of cases, and survival ranges between 5 and 10 years. The main complication of RARS is repetitive anemia, requiring frequent RBC transfusions, which expose the patient to the long-term risk of iron overload.

Chronic myelomonocytic leukemia

Chronic myelomonocytic leukemia (CMML), like RARS, occurs at an older age than most MDSs, and has a more significant male predominance than other MDSs. It has characteristics of both MDS and myeloproliferative disorders (MPDs). Characteristics of MPD result from the granulocytic and monocytic proliferation, which tends to increase during the disease evolution, leading to high leukocyte counts and immature circulating granulocytes, in addition to monocytosis, splenomegaly and sometimes visceral involvement (particularly of the skin and serous cavities). Some authors have attempted to make a distinction between ‘myelodysplastic’ CMML, with no hyperleukocytosis and no organomegaly from ‘myeloproliferative’ CMML, with hyperleukocytosis and frequent splenomegaly. However, the former often evolves to the latter and the disorder should be seen as a continuum rather than as composed of clear-cut entities. About 25% of CMMLs progress to AML, and median survival is about 2.5 years.

Refractory anemia or refractory cytopenias

This group is a diagnosis of exclusion among MDS, characterized by negative findings (no excess of marrow blasts, no blood monocytosis, no significant numbers of ringed sideroblasts). Although it is termed ‘refractory anemia’ (RA), this group is relatively heterogeneous: it also includes patients with pancytopenia, and patients without anemia but with neutropenia and/or thrombocytopenia. Therefore the term ‘refractory cytopenia(s)’ would appear preferable to ‘refractory anemia’. About 20% of patients included in this group progress to AML, and median survival ranges from 4–6 years.

WHO classification of MDS¹³²

Published in 1999, the WHO classification is largely inspired from the FAB classification, but with several important modifications (Table 40.5):

- RAEB-T no longer exists, and MDS with marrow blasts from 20–30% are classified in AML.
- RA and RARS are divided each into two groups, based on the absence or presence of myelodysplastic features in the granulocytic and

Table 40.5 WHO classification of myeloid neoplasms relevant to MDS according to the WHO classification, 1999

Myelodysplastic/myeloproliferative diseases
Chronic myelomonocytic leukemia
Atypical chronic myelogenous leukemia
Juvenile myelomonocytic leukemia
Myelodysplastic syndromes
Refractory anemia
With ringed sideroblasts
Without ringed sideroblasts
Refractory cytopenia (myelodysplastic syndrome)
with multilineage dysplasia
Refractory anemia (myelodysplastic syndrome) with
excess blasts
5q-syndrome
Myelodysplastic syndrome, unclassifiable
Acute myeloid leukemias*
AML with multi lineage dysplasia
With prior myelodysplastic syndrome
AML and myelodysplastic syndromes! therapy related
Alkylating agent related
(Epipodophyllotoxin related (some may be lymphoid)**)
*de novo AMLs are not included in this table,
**are generally not preceded by MDS

megakaryocytic lineage. When they are absent and MDS features are confined to the erythrocytic lineage, they are classified as having ‘pure refractory anemia’ (PRA) and ‘pure refractory sideroblastic anemia’ (PSA); when they are present, patients are classified as having ‘refractory cytopenias with multilineage dysplasia’ (RCMD) and ‘refractory sideroblastic cytopenias with multilineage dysplasia’ (RSMD).

- CMMLs are reclassified into a group of ‘myeloproliferative/myelodysplastic disorders’ or MPSs.
- The ‘5q- syndrome’ (i.e. MDS with isolated del 5q) is classified separately.
- RAEBs are divided in RAEB 1 (with fewer than 10% marrow blasts) and RAEB 2 (with 10% blasts or greater).

Discussion has arisen after publication of those WHO proposals. In particular, there can be some interobserver variability in differentiating PRA from RCMD, and PSA from RSMD, as this differentiation is only based on morphological criteria. Furthermore, many patients with marrow blasts between 20–30% blasts can remain stable for months, and it is difficult to classify them among AMLs. Also, many CMMLs, at least at diagnosis, have limited features of MPD (high WBC counts, splenomegaly etc.) and never acquire them or acquire them after prolonged evolution. On the other hand, the prognostic value of multilineage dysplasia, in RA and RAS (according to FAB classification) has

been shown.^{133,134} Likewise, for RAEB, the cut-off point of 10% for marrow blasts appears to have important prognostic value. It has also been shown that RAEB-T had almost similar response to chemotherapy as AML, at least after adjustment on other features (especially cytogenetics).

Atypical forms of MDS¹³¹

Most MDS cases can be classified according to FAB or WHO criteria. However, several types of MDS, with relatively specific features, were recognized after the FAB classification was proposed.

MDS with myelofibrosis¹³⁵

These probably include about 5% of MDSs, and are more frequently seen in therapy-related MDS. They can only be recognized well by marrow biopsy, which generally shows prominent dysmegakaryopoiesis. They can be distinguished from agnogenic myeloid metaplasia by the absence of splenomegaly, the absence of teardrop-shaped RBCs and the absence of leukoerythroblastosis, and from acute megakaryoblastic leukemia by the absence or small percentages of blasts of megakaryocytic origin.

Hypocellular MDS¹³¹

These include cases with bone marrow cellularity below 30% (or below 20% in patients older than 60 years) and represent about 10% of de novo MDS, but are more frequent in therapy-related MDS. They are often associated to chromosome abnormalities, especially to monosomy 7, which helps distinguish them from aplastic anemia (AA). However, the borderline between hypoplastic MDS and AA may not always be clear-cut, as suggested for example by the therapeutic response to antilymphocyte globulin in well-documented cases of hypoplastic MDS.

MDS with erythroblastopenia¹³¹

In some cases of MDS, anemia may be associated with erythroblastopenia on marrow samples, confirmed by ferrokinetic studies of erythropoiesis. When other lineages are not involved, these cases should be distinguished from erythroblastopenia of autoimmune origin, particularly associated to thymoma. del 5q is often observed in MDS with erythroblastopenia.

MDS with features of MPD

As seen earlier, CMMLs often have features of MPD. Another disorder at the MDS/MPD interface is 'atypical CMML', characterized in the blood by moderate hyperleukocytosis, granulocytic dysplasia with a moderate number of immature granulocytes, usually between 3% and 10% of monocytes, no basophilia, no Philadelphia (Ph1) chromosome and no BCR rearrangement.

Finally, thrombocytosis is observed in some MDS, especially in RARS, and in MDS with 3q21, 3q26 abnormalities, del 5q or less often del 20q. Some cases of RARS or RA with del 20q can evolve to a typical MPD with myelofibrosis.¹³⁶

Specific morphological-cytogenetic 'entities' in MDS

As mentioned earlier, the identification of morphological-cytogenetic subgroups in AML such as M2 with t(8; 21), M3 with t(15; 17) and M4 eosino with inv(16) has allowed the discovery of specific cancer genes, which in at least one case (M3 with t(15; 17)) is indicative of a response to a specific form of treatment. A few similar entities have also been identified in MDS, although no specific gene abnormality has as yet been identified in most of them, as seen earlier.

5q- (del 5q) syndrome⁶⁹

del 5q may be associated with other chromosomal abnormalities or with an important excess of marrow blasts, and in those cases no typical features are generally seen. However, isolated del 5q in patients with RA (or RAEB) generally has very typical features, and can be recognized before cytogenetic results: most cases occur in elderly females, who have severe anemia, prominent macrocytosis, erythroblastopenia, normal leukocyte counts, thrombocytosis, and typical hypolobulated megakaryocytes in the bone marrow. The 5q deletion generally involves bands 5q13 to 5q33, progression to AML is rare, and survival is prolonged.

MDS with 17p deletion¹³⁷

MDS with 17p deletion have characteristics of RAEB or RAEB-T, and are often therapy related. They generally have a specific type of dysgranulopoiesis, with small granulocytes having prominent pseudo-Pelger-Hiiet anomaly and cytoplasmic vacuoles, an association almost never seen in the current authors' experience in MDS or AML without 17p deletion. In three-quarters of cases, those patients have mutation of the nondeleted p53 allele (since the p53 gene is situated in 17p13 and one p53 allele is deleted in patients with 17p deletion). Although p53 inactivation may play an important role, it is suspected that other genes are involved in the pathogenesis of this syndrome.

MDS with t(3; 3)(q21; q26) or inv(3)(q21; q26)¹³⁸

These are typically RAEB or RAEB-T, often therapy related, with thrombocytosis and micromegakaryocytes in the bone marrow. The gene(s) involved in these MDS variants are not yet identified, but the EVI1 and/or MDS1/EVI genes, located in 3q26, are inappropriately expressed after these rearrangements.

Other entities

Two of these, namely MDS with t(5; 12) and MDS with t(3; 21) are very rare, but their analysis has led to the discovery of new genes whose disruption seems to play a role in pathogenesis, as seen earlier.

No other chromosomal abnormality is associated with specific hematological features in MDS.

Childhood MDS^{4,5,20–22}

Childhood MDSs are rare, accounting for about 2–3% of all MDSs. In about 35% of the cases, they occur in a background of constitutional abnormalities, including Down syndrome, Fanconi anemia, Noonan syndrome, mitochondrial cytopathies, neurofibromatosis and Schwachman-Diamond syndrome. They occur mainly in young children and are often not classifiable in the FAB or adult WHO classifications.

Recently, a modified WHO classification of childhood MDS has been proposed (Table 40.6).⁴ Besides juvenile chronic myeloid leukemia (JMML) and transient myeloproliferations or AML associated with Down syndrome, de novo MDSs are split into refractory cytopenias (RCs), RAEB and RAEB-T. Therapy-related or secondary JMMLs are separately recognized (see Table 40.6).

The most frequent entity in childhood MDS is JMML, which has many features in common with adult CMML, including hepatosplenomegaly, high leukocyte counts and monocytosis. It is also characterized by frequent elevation of Hb F. In mitochondrial cytopathies, the FAB type of MDS is usually RARS. The most frequent chromosomal abnormality in childhood MDS, including JCML, is monosomy 7, present in about 40% of cases. Point mutations of ras, PTPN11 or mutations of NF1 are present in the majority of these patients, and appear to be mutually exclusive. Interestingly, these gene mutations all lead to activation of the RAS pathway in leukemic cells.

Table 40.6 Diagnostic categories of myelodysplastic and diseases in (Hasle et al, 2003)

I Myelodysplastic/myeloproliferative diseases
Juvenile myelomonocytic leukemia (JMML)
Chronic myelomonocytic leukemia (CMML) (secondary only)
BCR-ABL negative chronic myelogenous leukemia (Ph-CML)
II Down syndrome (DS) disease
Transient abnormal myelopoiesis (TAM)
Myeloid leukemia of DS
III Myelodysplastic syndromes
Refractory cytopenia (RC)
PB blasts <2% and BM blasts <5%
Refractory anemia with excess blasts (RAEB)
PB blasts 2–19% and BM blasts 5–19%
Refractory anemia with excess blasts in transformation (RAEB-T)
BM blasts 20–29%

In JMML, spontaneous colony-forming unit granulocyte-macrophage (CFU-GM) growth, which appears to be due to hypersensitivity of CFU-GM to GM-CSF, has been observed.⁵ Because GM-CSF is particularly produced by monocytes, this phenomenon could be involved in the myeloid proliferation, through an autocrine mechanism.

On the whole, childhood MDSs have a poor prognosis. Chemotherapy, in particular gives limited results and allogeneic bone marrow transplantation (BMT) should be proposed whenever possible. Its results, as for other hematological malignancies, are somewhat better in childhood than in adult MDS.

Prognostic factors in MDS^{36,138–142}

Although a large number of prognostic factors have been reported in MDS, a small number of them are generally sufficient in clinical practice. The most important factors are the percentage of marrow blasts, the number and extent of blood cytopenias and cytogenetic data; these factors can be grouped together in prognostic 'scores', mainly the International Prognostic scoring³⁷ (see Table 40.7).

Prognostic factors

These include prognostic factors for survival, but also for progression to AML.

Survival

Female sex and lower age are associated to more prolonged survival. However when the death rate in MDS is adjusted to that of a sex- and age-matched population (standard mortality ratio), it appears that MDS per se is not less aggressive in females and younger patients, and that their better survival rate is related to a lower incidence of death from other causes.¹⁴²

Bone marrow blast percentage is certainly the most important prognostic factor, and is inversely proportional to survival. The number and extent of cytopenias also has major prognostic value, independent of that of marrow blasts. The FAB classification, largely based on marrow and circulating blasts, therefore has strong prognostic value, with RAEB and RAEB-T having short survival, RA and RARS relatively prolonged survival, and CMML an intermediate outcome. The

WHO classification further refines prognosis, with RCMD and RSMD having significantly poorer prognosis than PRA and PSA, RAEB 2 than RAEB 1 and the 5q-syndrome having a more favorable outcome.

Apart from bone marrow blasts and cytopenias, the only factor having clearly shown independent prognostic value is cytogenetic analysis. Three main prognostic groups can be identified by cytogenetics.^{26,27,35} Complex cytogenetic abnormalities have a very poor prognosis, with survival rarely exceeding a few months; monosomy 7 also has a poor prognosis, although usually yields a longer survival when isolated. Isolated del 5q and probably isolated del 20q and loss of Y chromosome (although this is more disputed⁷⁶) are a favorable subgroup with prolonged survival; patients with normal karyotype or with other single abnormalities have an intermediate prognosis.

Other parameters have been associated with a short survival, including ALIP,^{125–127,143} importance of myelodysplastic features on marrow analysis (included in the WHO classification), CD34 expression by marrow blasts,^{122,123} serum lactate dehydrogenase (LDH) levels,¹⁴⁴ results of marrow progenitor cultures,¹²⁸ presence of RAS^{37,38} and p53 mutations,^{38,145} and P-glycoprotein expression by marrow blasts.¹⁴⁶ Hyperexpression of WT1 has also been shown to be of prognostic value in some studies, although not shown to be independent of other widely known prognostic variables such as blast counts or IPSS score.¹⁴⁷

Progression to AML

Prognostic factors for progression to AML are generally similar to those associated with survival, in particular increased bone marrow blast percentage and the presence of complex cytogenetic rearrangements, which are associated with very high rates of progression to AML.

Prognostic factors in treated patients

Most prognostic factors have been established in cohorts of MDS that received supportive care only. Other prognostic factors could appear with the application of specific treatments. For example, P-glycoprotein expression, which was an unfavorable factor in cases with MDS who received intensive chemotherapy, had no prognostic value on results of treatment with low-dose cytosine arabinoside (Ara C) in the current authors' experience.¹⁴⁶ Likewise, RAEB-T, according to the FAB classification, was the best prognostic subgroup in patients who received intensive chemotherapy, in contrast to patients treated by supportive care only.¹⁴⁸ Prognostic factors associated with response to ATG or G-CSF-Epo will be discussed later.

On the other hand, 'unfavorable' karyotypes are associated with a poor response to all available treatments, including intensive or low-dose chemotherapy, growth factors and immunosuppressive drugs, although it has been suggested that response to decitabine, a hypomethylating agent, could be independent of cytogenetic features.

Prognostic scores in MDS^{36,37,139–142}

These are based on parameters that have demonstrated prognostic value by multivariate analysis, and their purpose is to provide useful guidelines to the clinician for the choice of a therapeutic approach. Several prognostic scores for survival and progression to AML mainly based on bone marrow blasts, number

Table 40.7 International Prognostic Scoring System (IPSS) for myelodysplastic syndrome (MDS)

Prognostic variable	Survival and AML Evolution Score Value				
	0	0.5	1	1.5	2
Marrow blasts (%)	<5	10		11–20	20–30

Int-1	0.5–1				
Int-2	1.5–2				
High	>2.5				

AML: acute myeloid leukemia. *Good: normal, Y, del(5q), del(20q); Poor: complex (three abnormalities) or chromosome seven abnormalities; Intermediate: other abnormalities. †Neutrophils <1800/μL, hemoglobin <10 g/dL, platelets <100 000/μL.

of cytopenias and cytogenetic features have been designed, mainly the International Prognostic Scoring System (IPSS), adapted after meetings of major groups involved in MDS (summarized in Table 40.7). It has been suggested that a few other factors could be of value and yield additional prognostic value independent of the IPSS. They include in particular the presence of RAS or p53 mutations,¹⁴⁵ and immune phenotypes of blast and myeloid cells,¹²⁴ shown to be a predictor independent of the IPSS score in one recent study. Ongoing studies using microarrays will most likely be powerful tools to uncover new biologically relevant predictors of survival or response to various therapies.

Treatment of MDS

Overall, it remains disappointing. The only really potentially curative treatment available so far is allogeneic stem cell transplantation, which can, however, only be performed in a small proportion of patients, given the usual age of MDS cases, although the advent of nonmyeloablative regimens may increase this proportion. Other treatments include chemotherapy, demethylating agents, growth factors, other agents aimed at reducing apoptosis, immunosuppressive drugs and new targeted treatment such as farnesyl transferase inhibitors. Supportive care remains an important component of the treatment.

Response criteria in MDS

Because, in MDS, treatment generally cannot eradicate the disease but can at best improve cytopenias, response criteria used in clinical trials in MDS have been recently adapted to take into account all types of responses. Response criteria proposed by an International Working Group (IWG)¹⁴⁹ are summarized in Table 40.8. They include, as for AML, CR and PR, but also take into account 'hematological improvement' (HI) of one or several lineages. They also encourage the use of quality-of-life parameters in evaluating results of therapies.

Allogeneic stem cell transplantation (SCT)^{150–156}

Most reported series concern allogeneic SCT with standard conditioning regimens, bone marrow stem cells and from familial donors. Combination of published literature showed that about 40% of the patients were alive in first long-term remission, 30% relapsed and 30% died from the procedure. The high incidence of transplant-related mortality, by comparison to allogeneic SCT in other blood malignancies, is probably due to the age of the transplanted patients, a high proportion of cases being older than 40 and to the fact that those retrospective series often included a large proportion of patients allografted some 10–15 years ago. Relapses occurred mainly in patients with an excess of marrow blasts and in patients with cytogenetic abnormalities. In order to prevent them, some authors advocated the use of intensive anthracycline—Ara C chemotherapy before allogeneic BMT in RAEB and RAEB-T. This hypothesis is being investigated in randomized trials. Another approach has been to reinforce the conditioning regimen. This does indeed lead to lower relapse rates—but also to higher transplant-related mortality. A last approach to reduce the relapse rate is the use of peripheral stem cells, which in a recent experience was shown to reduce the relapse rate post-transplant, with only moderate increase in chronic GVHD incidence, and survival improvement, by comparison to historical controls using bone marrow stem cells.

Several experiences of allogeneic SCT using a non-myeloablative regimen, aimed at reducing toxicity, have been reported, although with limited followup.¹⁵⁶ The mortality rate during the first years of follow-up is about 25%, but it is too early to evaluate the incidence of relapse after the procedure. As the GVL effect induced by nonmyeloablative allo SCT can probably be effective on a small tumor burden, it is suggested that, in patients with increased marrow blast percentage, nonmyeloablative allo SCT should be preceded by chemotherapy in order to reduce the leukemic burden. Nonmyeloablative allo SCT appears especially suitable for patients older than 50, i.e. the great majority of MDS patients.

Large reports of unrelated-donor marrow transplantation in patients with MDS have also been published. The 2-year disease-free survival, relapse and transplant-related mortality were of about 25%, 25% and 45%.⁸⁸ As for other hematological malignancies, results have however improved over the last years due to better donor-recipient HLA matching with molecular biology techniques.

Intensive chemotherapy with or without autologous stem cell transplantation

Large series of MDS treated with intensive chemotherapy, in MDS phase or after progression to AML, have been published in the last few years.^{157–164} They clearly show that the complete remission (CR) rates obtained are lower than in de novo AML, and range between 40% and 60%. Furthermore, median CR duration is only about 1 year and fewer than 10–15% of patients have prolonged remission.

On the other hand, several of those studies have shown that some subgroups of patients, including patients younger than 60, patients with RAEB-T at diagnosis and patients with normal karyotype had better results with intensive chemotherapy and that their survival rates could be prolonged with this approach, although probably only a small proportion

Table 40.8 Measurement of response/treatment effect in MDS (International Working Group)

<p>Altering disease natural history</p> <p>1. Complete remission (CR)</p> <p>• <i>Bone marrow evaluation:</i></p> <p>Repeat bone marrow showing less than 5% myeloblasts with normal maturation of all cell lines, with no evidence for dysplasia*. Erythroid response (HI-E)</p> <p><i>Major response:</i> For patients with pretreatment hemoglobin less than 11 g/dL, greater than 2 g/dL increase in hemoglobin; for RBC transfusion-dependent patients, transfusion independence.</p> <p><i>Minor response:</i> For patients with pretreatment hemoglobin less than 11 g/dL, 1–2 g/dL increase in hemoglobin; for RBC transfusion-dependent patients, 50% decrease in transfusion requirements.</p> <p>2. Platelet response (HI-P)</p> <p><i>Major response:</i> For patients with a pretreatment platelet count less than 100 000/mm³, an absolute increase of 30 000/mm³ or more; for platelet transfusion-dependent patients, stabilization of platelet counts and platelet transfusion independence.</p> <p><i>Minor response:</i> For patients with a pretreatment platelet count less than 100 000/mm³, a 50% or more increase in platelet count with a net increase greater than 10 000/mm³ but less than 30 000/mm³.</p> <p>3. Neutrophil response (HI-N)</p> <p><i>Major response:</i> For absolute neutrophil count (ANC) less than 1500/mm³ before therapy, at least a 100% increase, or an absolute increase of more than 500/mm³, whichever is greater.</p> <p><i>Minor response:</i> For ANC less than 1500/mm³ before therapy, ANC increase of at least 100%, but absolute increase less than 500/mm³.</p> <p>4. Progression/relapse after HI: One or more of the</p> <p>a 50% or greater decrement from maximum response levels in granulocytes or platelets, a reduction in hemoglobin concentration by at least 2 g/dL, or transfusion dependence.</p> <p>For a designated response (CR, PR, HI), all relevant response criteria must be noted on at least 2 successive determinations at least 1 week apart after an appropriate period following therapy (e.g. 1 month or longer).</p> <p>*The presence of mild megakaryoblastoid changes may be permitted if they are thought to be consistent with treatment effect. However, persistence of pretreatment abnormalities (e.g. pseudo-Pelger-Huet cells, ringed sideroblasts, dysplastic megakaryocytes) are not consistent with CR. †In some circumstances, protocol therapy may require the initiation of further treatment (e.g. consolidation, maintenance) before the 2-month period. Such patients can be included in the response category into which they fit at the time the therapy is started. ‡ In the absence of another explanation such as acute infection, gastrointestinal bleeding, hemolysis, and so on.</p>
--

could be cured.^{148,160} By contrast, the presence of an abnormal, or worse a complex karyotype, p53 mutation and of P-glycoprotein expression predicts poor response to chemotherapy and long-term outcomes.^{146,165,166}

Although several drugs (including fludarabine and topotecan) have been tested for induction treatment in combination to Ara C, generally at high dose, it appears that anthracyclin high-dose Ara C combinations (especially with idarubicin) remain the most effective induction regimens.^{159,164} G-CSF and GM-CSF can significantly reduce the duration of aplasia after intensive chemotherapy. This effect is important to consider because the duration of aplasia after chemotherapy is longer in MDS than in de novo AML, and addition of G or GM-CSF could also reduce the incidence of deaths due to myelosuppression. However, their overall impact on CR rate and survival is unproven.^{161,163} The current authors results suggest that agents reverting MDR gene expression, such as quinine, can increase the CR rate in P-glycoprotein-positive cases but they will have to be confirmed.¹⁶²

In order to prevent relapse, several groups performed autologous bone marrow transplantation (ABMT) or peripheral stem cell transplantation (AP SCT) after achievement of CR. The fact that, in a majority of MDS patients, lymphocytes do not appear to be part of the clone suggests the persistence of normal nonclonal hematopoietic cells that could reconstitute hematopoiesis after myeloablative treatment. Furthermore, it has been shown that circulating progenitors obtained after mobilization with chemotherapy and growth factors MDSs in hematological remission after chemotherapy were polyclonal,¹⁶⁷ although those findings rest on limited numbers of cases. More than 400 autografted MDS cases have been reported so far.^{168–170} Hematological reconstitution does not seem to differ from that observed in AML, and is shorter after AP SCT than ABMT.^{169,170} However, the incidence of post-transplant relapse is high, and it is uncertain whether this approach will cure a significantly greater fraction of MDS patients, than intensive chemotherapy alone.¹⁷⁰ An ongoing trial compares intensive post-remission chemotherapy and autologous transplantation in CR.

Low-dose chemotherapy and demethylating agents

Low-dose chemotherapy has been initially advocated in MDS on the basis of potentially ‘differentiating’ effects. The most frequently used drug has been low-dose Ara C (3–10 mg/m²/12 h during 2–3 weeks),^{171,172} while a few studies have used other drugs including hexamethylene bisacetamide (HMBA).¹⁷³ It is in fact unclear whether these drugs have a differentiating effect; in the case of Ara C (at least at 10 mg/m²/12 h), a cytotoxic effect is obvious and pancytopenia is generally observed.

Response rates are usually in the range of 30–40%, about one-half being CR and one-half partial responses (PRs). Myelotoxicity is important, however, at Ara C 10 mg/m²/12 h,¹⁷¹ and regimens combining low-dose Ara C and G or GM-CSF do not seem superior to low-dose Ara C alone in terms of response and survival.¹⁷² Most responses to low-dose Ara C do not exceed 12–18 months. A higher response rate to low-dose Ara C has been reported in patients with normal karyotype. Although, in a randomized trial, treatment with low-dose Ara C showed no superiority over supportive care only;¹⁷¹ this treatment is probably beneficial to some MDS patients.

Two pyrimidine analogs other than cytarabine have also been used at low dose in MDS, i.e. 5 azacytidine and 3’5’ deoxyazacytidine (decitabine). In vitro and in vivo data strongly suggest that, at least in part they may be active through gene demethylation. As seen earlier, hypermethylation of genes such as p15, leading to its inactivation, appear to be a major pathogenetic mechanism of progression of MDS and demethylation could restore their tumor-suppressive effect. Response rates of 50–60% have been reported with both 5 azacytidine and decitabine, with approximately 20% showing a complete response.^{174–176} Furthermore, in a randomized study, treatment with 5 azacytidine was associated with significantly longer time to evolution to AML and improved quality of life and, a trend for improved survival^{174,175} as compared to supportive care alone, despite the crossover of most patients allocated to supportive care. Following these studies, the use of 5azacytidine in the treatment of MDS has been approved by the American FDA.¹⁷⁷

Growth factors

Erythropoietin

Erythropoietin (Epo), even at a very high dose (150 U/kg three times a week subcutaneously) can improve transfusion requirements in only about 25% of cases. However, in patients whose transfusion requirements are less than two red blood cell (RBC) units per month, and who have a serum Epo level of less than 200–500 U/ml, however, the response rate reaches 40–45%.¹⁰¹ For responders, drug doses and/or frequency may be reduced, according to tolerance. For nonresponders to Epo alone after 4–6 weeks, the addition of G-CSF or GM-CSF to EPO increases the overall response rate to 40% and to at least 70% in patients with low serum Epo levels, limited transfusion requirement, or RARS.^{178–183}

Trials are ongoing with darbepoetin, a modified form of Epo, with a 3-fold longer half-life.

Granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor

G-CSF and GM-CSF can correct neutropenia in about 75% of cases of MDS, using conventional doses of

5 µg/kg/d, and there is no evidence that they increase the incidence of progression to AML.¹⁸⁴ However no study has shown that growth factors, by potentially reducing the risk of infection, could improve survival.

Furthermore, G-CSF and GM-CSF are expensive treatments, especially if they have to be applied for prolonged periods in patients where, as in MDS, neutropenia is chronic. It has been shown that lowdose G-CSF or GM-CSF (i.e. 0.25–0.5 µg/kg/d) are almost as efficient as conventional doses in correcting neutropenia.¹⁸⁵

In addition to improving neutropenia, granulocytic growth factors improve granulocytic function. Their stimulating effect on granulopoiesis seems to exert itself on both clonal and nonclonal hematopoiesis in MDS.

Growth factors for megakaryocytic lineage

No trials of thrombopoietin, the specific platelet growth factor, or of its truncated form M-GDF, have been reported in MDS. Other growth factors with thrombopoietic (although nonspecific) activity have been used in MDS. Some platelet responses have been reported with IL3 and IL6, but with relatively important toxicity. More recently, platelet responses have been observed with IL11, but also with important toxicity.¹⁸⁶ The latter could be reduced with lower doses of IL11, which can still increase platelet counts.

Finally, no experience of treatment of MDS with growth factors active at the multipotent stem cell level, including stem cell factor or FLT3 ligand has been reported.

Immunosuppressive drugs

Initial case reports of responses to ATG and/or cyclosporine A (CsA) in hypoplastic forms of MDS, have led to phase II trials of ATG or CsA in MDS patients, all RBC transfusion dependent. CsA alone, despite an early encouraging report, seems to have limited efficacy. ATG, with or without CsA, can yield major erythroid responses, or even trilineage responses in about 35% of the patients, in several ATG trials.^{187–189} Responses are more frequent in patients with RA. Of interest, patients with RA and normal or increased cellularity can obtain a meaningful response to ATG. Responses are durable, estimated to be 75% at 2 years in the largest cohort reported to date.¹⁸⁷

Prognostic factors of response, initially identified by the NIH investigators were: younger age, low blast count, normal cytogenetics, presence of other cytopenias, presence of a PNH clone or DR2/15 subtype, and duration of previous RBC transfusion dependence. In a multivariate analysis of an expanded cohort of MDS patients treated with ATG and/or CsA at the NIH, DR2/15, age and shorter duration of previous RBC dependence, were the only significant prognostic factors of response to immunosuppressive therapy.^{187,190}

The combined use of ATG and CsA in MDS was not associated with a higher response rate when compared to ATG alone, in the NIH studies.¹⁹⁰

Other drugs in MDS

Many drugs have been proposed in MDS over the last 20 years, based on their potential mechanism of action, or sometimes empirically.

Interferon- α , IL-2 and vitamin D derivatives have shown very limited efficacy, if any, in MDS.¹⁹¹ Retinoids alone appear to improve cytopenias in limited numbers of patients,¹⁹² but a preliminary report suggests they could have synergistic activity with EPO.¹⁹³

Danazol and other androgens also appear to significantly improve thrombocytopenia in about one-third of MDS patients with no major excess of blasts. Their mechanism of action is uncertain but probably includes stimulation of megakaryopoiesis.^{194,195} Lowdose melphalan can also yield responses, including CRs, in one-third of 'high-risk' patients.¹⁹⁶

More recently, drugs supposedly active through their antiapoptotic or antiangiogenic activity have been used in MDS. Thalidomide has both antiangiogenic and antiapoptotic activity, the latter through its antiTNF properties. Cytopenias are improved in about one-third of MDS patients, mainly those without excess of marrow blasts, but many patients stop treatment due to side-effects (constipation, fatigue, sleepiness), which are often prominent in this elderly population.^{197,198} Therefore trials using lower thalidomide daily doses (200–300 mg) have been started. Thalidomide derivatives with fewer side-effects are in development. Promising early results, using the thalidomide analog CC 5013 have been reported with higher response rates, including a high incidence of complete responses in RA or 5q- patients.¹⁹⁹ An anti-VEGF antibody, bevacizumab is currently under study in phase II trials.²⁰⁰ Other treatments aimed at reducing TNF- α levels in MDS, using soluble TNF- α , anti TNF- α have been tested in a few patients, some of whom improved their cytopenias.^{201–203}

Amifostine is capable of reducing increased apoptosis of MDS precursors but, after a first favorable experience where it was shown to improve cytopenias in about two-thirds of the patients,²⁰⁴ subsequent results have generally been more disappointing.²⁰⁵ Other drugs being currently investigated included arsenic trioxide, which gives significant responses in 25–30% of the patients,^{206,207} and farnesyl transferase inhibitors (FTIs). The latter have been designed to inhibit proteins such as activated ras, but probably also inhibit other proteins involved

in the pathogenesis of MDS, such as the MAP kinase pathway.²⁰⁸ They are active in about one-third of the patients, and CR has been reported, including in RAEB and RAEB-T. CMML may be particularly sensitive to FTIs.²⁰⁹ Furthermore, presence of ras mutations does not appear to be a prognostic factor of response to FTIs. Arsenic trioxide can also improve cytopenias in 20 to 25% of both low risk and high risk MDS. Its mechanisms of action includes triggering of apoptosis (in high risk MDS), differentiation induction and angiogenesis inhibition (in low risk MDS).

In 'proliferative' CMML with hyperleukocytosis, and sometimes splenomegaly or visceral involvement, the most frequently used cytotoxic drugs used are hydroxyurea and 6-mercaptopurine. Although preliminary reports suggested that (VP16) gave better response rates than those two drugs, especially in cases of visceral involvement, this was not confirmed in a randomized study in advanced CMML, where hydroxyurea gave both higher response rates and more prolonged survival than VP16.²¹⁰

Finally, and importantly, reports show favorable response to imatinib in the rare cases of CMML with t(5;12) translocation⁶³ with TEL-PDGF-R rearrangement further stressing the importance of cytogenetic analysis in MDS. On the other hand, imatinib appears to be ineffective in CMML without t(5;12), including with those with other 12p abnormalities.

Supportive care in MDS

Supportive care remains a major component in the management of MDS.

Repeated RBC cell transfusions expose patients to the risk of iron overload, which, as in thalassaemias, can be efficiently prevented in patients who require frequent transfusions by prolonged subcutaneous infusions of desferrioxamine during several nights every week. Two reports strongly suggest that slow direct subcutaneous injections of desferrioxamine (0.5–1 g) once or twice daily are as effective in MDS as prolonged subcutaneous infusion with similar daily dosage.²¹¹ The oral chelator L1 appears somewhat less effective than desferrioxamine. Other oral iron chelators are currently tested in MDS, including the ICL 670 agent.

Platelet transfusions can be useful in the case of severe bleeding episodes. Broad-spectrum antibiotics should be administered for all infectious episodes in neutropenic cases.

Therapeutic strategy in MDS

There is no clear consensus over the therapeutic strategy in MDS in many situations, given the limited number of efficient available treatments in these disorders. The therapeutic strategy is generally based on age, IPSS (and/or bone marrow blasts infiltration) and donor availability for an allograft. The current authors have summarized in Figure 40.1 the approach currently used by the French MDS group. In patients aged less than 50–55 years with an HLA-identical family donor, who constitute fewer than 5% of MDS cases, allogeneic BMT is certainly the best treatment. However, it should probably not be performed in MDS with low or int1 IPSS until progression occurs.²¹² When decided, the current authors suggest that it should not be preceded by intensive chemotherapy except in patients who present with a high marrow blast percentage (especially RAEB2 and RAEB-T) and do not have an unfavorable karyotype (i.e. patients who have a good chance to achieve CR with chemotherapy). The source of stem cells (marrow or peripheral stem cells) is also a matter of debate but currently available data favors the use of peripheral blood stem cells in patients with an excess of marrow blasts, who remain at high risk of relapse. In patients aged between 55 and 65, allogeneic BMT using nonmyeloablative regimens is currently under study. This approach has not yet demonstrated to be curative in MDS but, as seen earlier, preliminary results are encouraging.

In other patients, the current authors suggest the following attitude, also based on age, FAB or WHO classification, and/or IPSS.

In patients with low or int1 IPSS (or if karyotype is not available, marrow blasts <10%)

No treatment is useful in the absence of symptoms. Supportive care (transfusions, antibiotics) should be administered whenever required. In case of anemia, requiring transfusions, a trial of EPO±G-CSF is warranted, if baseline serum EPO level is low (<500 U/l). Treating with epo ± G-CSF may also be discussed in patients with anemia not requiring transfusions as it may, by correcting anemia, improve the quality of life. In case of failure of epo+G-CSF, subcutaneous desferrioxamine should be proposed, as soon as ferritinemia rises above 1500–2000 ng/ml and/or important hepatic or cardiac iron infiltration occurs. Investigational drugs (ATG, thalidomide, and other drugs) can then be proposed. ATG may be especially indicated early in the disease, when several cytopenias or a small PNH clone are present, or if the patient is HLA DR2/15. CC5013 may be particularly indicated in patients with 5q- syndrome.

In the case of repeated infections in severely neutropenic cases, low-dose G-CSF or GM-CSF can be envisaged, at least during infectious episodes and if a neutrophil response is observed, in combination with antibiotics. In patients with platelets below $50\text{--}60 \times 10^9/l$ or in the presence of bleeding symptoms, the

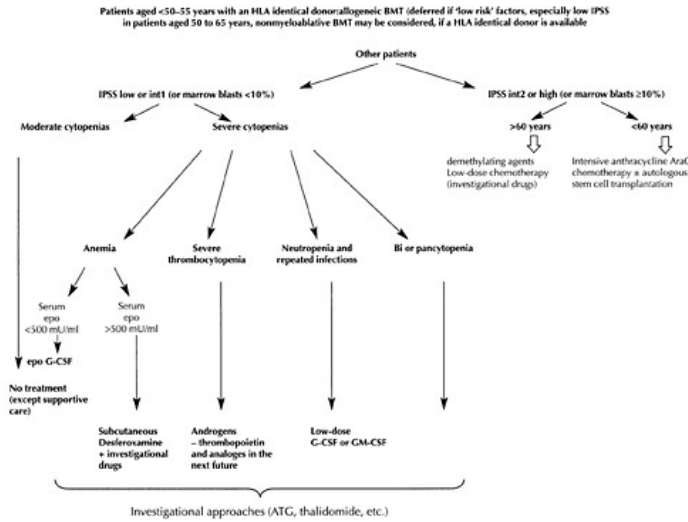

Figure 40.1 Proposed therapeutic strategy in MDS.

current authors suggest a trial of danazol at a daily dose of 600–800 mg for at least 3 months. Trials with thrombopoietin or IL11 should be starting. In case of severe neutropenia, anemia or thrombocytopenia not responding to those approaches, or in case of bi- or tricytopenia, investigational approaches should be tried.

In patients with int2 or high IPSS (or if karyotype is not available marrow blasts >10%)

Some kind of treatment aimed at reducing the blastic proliferation is required. In patients aged less than 60 years, capable of receiving intensive chemotherapy, the current authors suggest an anthracycline-Ara C course, followed, in the case of CR achievement, by consolidation chemotherapy and possibly autologous peripheral blood SCT. In older patients, several multicenter trials with demethylating agents are starting; low-dose Ara C, with or without growth factors can be efficient in some patients, especially with normal karyotype. Preliminary results with FTIs are also encouraging.

Conclusion

MDS are frequent disorders of the elderly whose pathophysiology remains poorly known. However, knowledge of the role of alkylating agents in the etiology of MDS has already led to a reduction in their prolonged use, and this should translate into fewer cases of therapy-related MDS. Better knowledge of other occupational and environmental factors could also lead to preventive measures.

Further improvement in understanding the mechanisms of ineffective hematopoiesis should lead to the design of new therapeutic approaches that, for instance, could reduce apoptosis.

In cases with a major excess of blasts, the major goal, as in AML, remains the eradication of blast cells.

As in AML, progress will probably be also achieved by overcoming drug resistance, the possibility of separating nonclonal from clonal cells for autologous stem cell transplantation, and improvements in allogeneic stem cell transplantation procedures.

Chronic myeloid leukemia

François Guilhot and Lydia Roy

Introduction

Chronic myeloid leukemia (CML) is a hematopoietic stem cell disease characterized by neoplastic proliferation of hematopoietic stem cells and their progeny within the bone marrow and in extramedullary hematopoietic sites. This leukemic disease was classified in the group of myeloproliferative disorders, which also include polycythemia vera, agnogenic myeloid metaplasia, and essential thrombocythemia.¹ CML was then distinguished from other myeloproliferative diseases by the presence in the hematopoietic stem cells of a reciprocal translocation between chromosomes 9 and 22 in over 90% of patients. The first description of the marker was given by Nowell and Hungerford,² who reported in 1960 two cases with an apparent loss of the long arm of chromosome 21 or 22. This abnormality was confirmed and designated the Philadelphia (Ph) chromosome.^{3–5} Later, with the availability of more sensitive banding techniques, the Ph chromosome was identified as a modified chromosome 22 and part of a reciprocal translocation.^{6,7} As the result of this translocation, a new chimeric tyrosine-specific protein kinase gene is generated. This new gene is a fusion of the cellular oncogene, *ABL*, located on chromosome 9, with a segment of chromosome 22, designated the breakpoint cluster region *BCR*^{8–11}

The Philadelphia chromosome was the first example of a specific cytogenetic abnormality consistently associated with a human cancer. Although approximately 10% of patients are Ph⁻, it is generally accepted that, at a molecular level, the fusion gene is invariably found in CML. The expansion of the myeloid compartment explains the main clinical and biological features of the disease. In the early stage of the disease, this expansion can easily be controlled by standard chemotherapy. However, the disease will inexorably progress from this early indolent chronic stage to a more aggressive accelerated stage and will finally terminate in blast crisis. The modern approach to the treatment of patients with CML in chronic phase includes the use of imatinib and interferon- α (alone or in combination), allogeneic bone marrow transplantation or autografting, each option being undertaken with the aim of re-establishing normal hematopoiesis.

Etiology and epidemiology

The reason why the Philadelphia translocation occurs is still unknown. The most frequent environmental agent associated with CML is exposure to ionizing radiation. Since 1950, a cohort of 120 000 atomic bomb survivors from Japan and their controls have represented an important source of information regarding radiation leukemogenesis. Most of the radiation to which these people were exposed was relatively low-energy γ radiation. The earliest cases of radiation-induced leukemia occurred 3–4 years following exposure, with the peak incidence 4 years later. People who were less than 15 years old at the time of exposure had the highest risk of radiation-induced leukemia. The radiation effect disappeared 15 years following exposure for all age groups.^{12–14} An increased risk of 4.61 for CML has been recorded in patients with ankylosing spondylitis treated with spinal irradiation.¹⁵ The relative risk for CML was also increased in women treated with X-rays for cervical carcinoma.¹⁶ Diagnostic X-ray exposure has been associated with an increased occurrence of CML.¹⁷ A similar observation was reported for patients receiving intravenous thorium dioxide for diagnostic X-ray contrast studies.¹⁸ In contrast to the high incidence of therapy-related myelodysplastic syndrome and acute myeloid leukemia, therapy-related CML is less frequent. CML has been described after treatment for Hodgkin disease^{19,20} or after high-dose chemotherapy with subsequent autologous stem cell transplantation.^{21,22}

In vitro, high-dose ionizing irradiation of hematopoietic cell lines can induce the formation of the *BCR-ABL* fusion gene with corresponding mRNA

transcripts.^{23,24} Although ionizing radiation is a physical mutagen known to induce DNA double-strand breaks, little is known of the molecular mechanisms by which it generates leukemia-specific fusion genes.

In several large studies, no relationship was found between benzene exposure and CML.^{25,26} In general, no chemical or petrochemical products have been recognized as factors that could increase the occurrence of CML.

There is no evidence of a genetic predisposition although multiple occurrence of CML in a family has been reported.²⁷

Chromosomal polymorphism studies in Ph⁺ leukemic patients and their parents have suggested that the chromosome 22 involved in the t(9; 22) translocation is of maternal origin, whereas the chromosome 9 is preferentially of paternal origin. This indicated that parental imprinting could be involved in the formation of the fusion gene.²⁸ However, additional studies demonstrated that in leukocytes from normal individuals, both the paternal and maternal copies of the *ABL* gene are expressed at similar levels, and that there is no random allelic exclusion of *ABL* at the level of single hematopoietic progenitor cells.^{29,30} Other reports showed that the *BCR* gene is not imprinted either.^{31–32} Moreover, using Southern blot analysis and two intragenic polymorphisms located in the major breakpoint cluster region (M-bcr), the *BCR* gene was shown to be of paternal origin in three CML patients.³³

It has been claimed that the *BCR-ABL* products are the prime cause of Ph⁺ leukemia. However, epidemiological data suggest that at least two stem cell mutations are necessary for the generation of CML chronic phase.³⁴

There is no strong evidence for a significant association between HLA antigens and CML, although an increased frequency of HLA-CW3 and -CW4 has been found in CML patients.³⁵

CML accounts for 7–20% of all leukemias, with an incidence estimated at between 1 and 2 per 100 000 persons.^{36,37} Although the incidence increases with age, CML occurs in all age groups, with presentation being most common among those aged 40–60 years.³⁸ However, less than 10% of cases occur in patients under 20 years of age. The median age at diagnosis is 55–60 years. There is a small predisposition to CML in men, with a male-to-female ratio of 1.4–2.2:1. The clinical course is similar in males and females,³⁹ and CML is slightly more common in Whites and Blacks than in other races.

Pathogenesis

The *BCR-ABL* gene and its variants

The *BCR-ABL* gene is a consequence of the Ph translocation and occurs in a primitive hematopoietic stem cell. The breaks in chromosomes 9 and 22 transpose the proto-oncogene *ABL* (*c-ABL*) from its normal location on chromosome 9 to a new position on chromosome 22 (Figure 41.1). The *ABL* gene is the cellular homolog of a transforming element (*v-abl*) of the Abelson murine leukemia virus, and its 5' end is oriented towards the centromere at band q34.⁹ *ABL* has two alternative first exons, 1b and 1a, separated by 175 kb, and 10 other exons, which are more closely spaced.⁴⁰ The *ABL* locus thus spans 230 kb. The *ABL* gene is transcribed into two mRNA of either 6 or 7 kb. This gene encodes a 145 kDa tyrosine kinase.⁴⁰ Exon 11 encodes the nuclear localization signals and the actin-binding and DNA-binding domains of the ABL protein^{41–43} (Figure 41.2. See color plate).

The *BCR* gene is located on chromosome 22, band q11; the locus spans 134kb and encompasses 23 exons. The first intron, between exons 1 and 2, is described as the minor breakpoint cluster region (m-bcr), which contains chromosomal breakpoints found in acute lymphoblastic leukemia (ALL). The other breakpoints have been shown to occur in introns 13 and 14 in a region referred to as the major breakpoint cluster region (M-bcr).^{44,45} The *BCR* gene is transcribed into two mRNA of either 4.5 or 6.7 kb. The gene encodes a 160 kDa serine/threonine kinase that phosphorylates several protein substrates⁴⁶ (Figure 41.3. See color plate).

Both *BCR* and *ABL* are expressed ubiquitously,^{47,48} and their normal cellular functions have been investigated using null mutant mice. *ABL-null* mice have thymic and splenic atrophy with a reduction in developing B- and T-cell progenitor compartments,^{49,50} which may indicate a role for the ABL protein in progression in pre-B cells. *BCR-null* mice develop septic

Figure 41.1 Schematic diagram of chromosomes 9 and 22. The *ABL* from chromosome 9 is transposed to chromosome 22, and the terminal portion of chromosome 22 is transposed to the long arm of chromosome 9.

Figure 41.2 Structure of *ABL*, with its domains. (See Plate 8)

Figure 4.13 Structure of *ABL*, with its domains. (See Plate 8)

shock, with a defect in neutrophil function that suggests a role for the BCR protein in the normal myeloid lineage.⁵¹

In the *ABL* gene, breakpoints can occur anywhere at the 5' end of the gene upstream of the first exon 1b, between exons 1b and 1a, between 1a and a2, and in intron 2. In the *BCR* gene, breakpoints are found in three areas (Table 41.1; Figures 41.4 and 41.5, see Plate 8). In the vast majority of patients, the breakpoints are clustered in the *M-bcr* region, which spans 5.8 kb with the five exons, 12, ..., 16, previously termed b1, ..., b5. In this region, the position of the breakpoints vary

Figure 41.4 Structure of the four *BCR-ABL* mRNA transcripts.

Figure 41.5 Structure of the *ABL* and *BCR* genes, with their exons and introns. (See Plate 8)

and may generate fusion transcripts with a b2a2 or a b3a2 junction. Such transcripts encode a p210 fusion protein

m-bcr is located upstream of *M-bcr*, between the two alternative exons e2' and e2. The *BCR-ABL* mRNA molecule resulting from a breakpoint within this region contains the e1a2 junction and is translated into a smaller 190 kDa BCR-ABL fusion protein.⁴⁰

The third region is the most 3' cluster region, and is termed the micro breakpoint cluster region (μ -*bcr*). Breakpoints in this region result in *BCR-ABL* tran-

Table 41.1 The Three regions of the *BCR* gene

Site and location of the breaks within <i>BCR</i>	5', between exons e1'	A 5.8 kb region between e13 and e15	3'
Size of transcript(s)	7 kb	8.5 kb	
Type of junction (s)	e1a2	e13a2 (b2a2) e14a2 (b3a2)	e1 9a2 (c3a2)
Protein	p190 ^{BCR-ABL}	p210 ^{BCR-ABL}	p230 ^{BCR-ABL}

scripts with an e19a2 junction (previously termed c3a2). This *BCR-ABL* hybrid gene is the largest and is responsible for the production of a p230 protein with tyrosine kinase activity.⁵²

The vast majority of the Ph⁺ CML patients have a p210-encoding *BCR-ABL* gene exhibiting mRNA transcripts with a b3a2 or b2a2 junction and sometimes both b3a2 and b2a2 (5–10% of cases). Several studies have attempted to correlate the position of the breakpoint within the *M-bcr* region and the duration of survival or the frequency of lymphoid blast crisis.^{53,54} However, no such correlation was found when large series of patients were considered.⁵⁵ It has been claimed that a possible link may exist between the type of *BCR-ABL* fusion transcript and platelet count. Some groups reported that patients with 3'*M-bcr* breakpoints had significantly higher numbers of platelets,⁵⁶ although this was not confirmed by two other studies.⁵⁷ However, it is possible to select a subgroup of patients in whom the b3a2 transcript is associated with a higher platelet count.⁵⁸ Hematologic disorders associated with the production of the p190^{BCR-ABL} protein are usually of ALL type, but very rare cases of CML and AML may have a similar molecular rearrangement. The various cases of CML with the production of the p230^{BCR-ABL} protein are considered as less aggressive myeloproliferative disorders and are now described as chronic neutrophilic leukemia.

The role of *BCR-ABL* in leukemic stem cell dysfunction

CML is characterized by genetic mutation that deregulates cell growth and its distribution. There are several mechanisms that may explain the myeloid expansion in CML: more rapid proliferation of leukemic cells, increased self-renewal of the progenitor, prolonged lifespan of leukemic leukocytes, and reduction of the cell death by apoptosis.

Various *in vitro* studies have been used to demonstrate the mitogenetic effect of *BCR-ABL*. When the *BCR-ABL* gene is transfected into hematopoietic cell lines, they become grow factor-independent with an increased proliferative capacity. The mitogenetic ability of *BCR-ABL* is mediated through activation of Ras, Raf, and MAPK leading to increased levels of c-Myc and c-Fos and subsequent increased gene transcription. When these BCR-ABL-containing cells are treated with antisense oligonucleotides against the *ras* or *raf* genes, the *BCR-ABL*-induced growth factor independence is abrogated. Most of these *in vitro* studies suggest that *BCR-ABL* acts as a mitogen by activating Ras and Myc.^{59–61}

The myeloid expansion of leukemic cells is not explained by more rapid proliferation of these cells. Several kinetic studies performed during chronic phase have suggested that the leukemic precursors have lower mitotic indices, a smaller fraction of cells in DNA synthesis, longer generation times, and longer transit times in the maturation compartment compared with normal precursors.^{62,63} When the leukocyte count is decreased by chemotherapy, these proliferative parameters return to normal. There is no evidence that cytokines that regulate cell growth either positively or negatively are overproduced in the microenvironment.⁶⁴ Thus, the proliferation of CML progenitors could be related to defects in the adhesive interaction that regulates the growth of normal hematopoietic progenitors. Several studies have suggested that adhesive interactions between CML cells and the marrow microenvironment are defective. This defect may, in part, explain the proliferation of hematopoietic progenitors.⁶⁵

BCR-ABL mutants have been used to identify the *BCR-ABL* domains required for the transforming activity. In order to determine the possible role of the BCR-ABL oncoprotein SH3 domain, the properties of a BCR-ABL SH3 deletion mutant (Δ SH3 BCR-ABL) constitutively expressed in murine hematopoietic cells have been studied. Δ SH3 BCR-ABL can activate BCR-ABL-dependent downstream effector molecules (Ras, PI3K, MAPK, JNK, Myc, Jun, STATs, and Bcl-2). Leukemic growth from cells expressing Δ SH3 BCR-ABL was significantly delayed in SCID (severe combined immuno-deficient) mice compared with that of cells expressing the wild-type protein. *In vitro* as well *in vivo*, Δ SH3 BCR-ABL-expressing cells showed a decreased interaction with collagen IV- and laminin-coated plates and a reduced capacity to invade the stroma. Such results suggest that the SH3 domain of BCR-ABL is important for *in vitro* transformation of hematopoietic cells and essential for full leukemogenic potential *in vivo*.⁶⁶

Another mechanism by which myeloid expansion can be explained is a decreased cell death rate. Apoptotic cell death is dysregulated by *BCR-ABL*. This has been demonstrated *in vitro* using cell lines transfected with *BCR-ABL*: such cells are protected from apoptosis. An interaction between p210^{BCR-ABL} and Bcl-2 has also been suggested: in cells transfected with *BCR-ABL* the removal of Bcl-2 with antisense oligonucleotides to the *bcl-2* gene abrogates the transforming ability of *BCR-ABL*.⁶⁷

The CML blast crisis K562 cell line, which expresses p210^{BCR-ABL}, is resistant to antileukemic drug-induced apoptosis and overexpresses the antiapoptotic Bcl-x_L but not Bcl-2.⁶⁸ Studies have indicated that a variety of apoptotic stimuli cause the pre-apoptotic mitochondrial release of cytochrome *c* into the cytosol. This release mediates the cleavage and activity of caspase-3, which is involved in the execution of apoptosis. BCR-ABL exerts its antiapoptotic effect upstream to the cleavage and activation of caspase-3. More precisely, BCR-ABL blocks apoptosis by preventing the cytosolic accumulation of cytochrome *c* and by inhibiting the activation of caspase-3.⁶⁹ Thus, altered adhesion to stroma cells and the extracellular

matrix constitutively active mitogenetic signaling, reduced apoptosis, and proteasome-mediated degradation of ABL-inhibitory proteins are the four major mechanisms implicated in malignant transformation by *BCR-ABL*.

It is accepted that CML involves a pluripotent stem cell, which explains the presence of the Ph chromosome in the precursors of the myeloid, monocytic, lymphoid, and megakaryocytic lineages.⁷⁰ The clonal origin of the disease has also been suggested in the past by the demonstration of a presence of a single glucose-6-phosphate dehydrogenase isoenzyme in the erythroid, myeloid, and megakaryocytic compartments but not in fibroblasts in women with CML who are heterozygotes for isoenzymes A and B.⁷¹ The same conclusion came from studies using DNA hybridation-methylation analysis of heterozygotic women with restriction fragment length polymorphisms (RFLP) at the X-linked locus for hypoxanthine phosphoribosyltransferase.⁷²

The role of the *BCR-ABL* oncogene has been examined using transformed cells in murine models. The introduction into the germline of *p189^{BCR-ABL}* cDNA is responsible for B-cell ALL. The same experiment using *p210^{BCR-ABL}* cDNA transcriptionally regulated by a metallothionein promoter led to the development of late-onset AML, T-cell ALL, or T-lymphoblastic lymphoma.⁷³

The transplantation of mouse marrow cells transduced with *BCR-ABL* cDNA into syngeneic animals induces a CML-like disease within a few months after transplant. When secondary transplants are reformed with marrow obtained from animals that developed a CML-like disorder more than 6 months after transplant, a fraction of secondary recipients develop a form of AML or ALL.^{74–76} More recently, reproducible and sustained engraftment of SCID mice with intravenously transplanted chronic phase cells has been obtained using large numbers of cells from patients with high white blood cell count and high-dose irradiation for the conditioning regimen.⁷⁷ Using this model, it has been demonstrated that Ph[–] and Ph⁺ cells coexist and that Ph[–] progenitors engraft preferentially. By comparison with the SCID model, engraftment of NOD (non-obese diabetic) SCID mice with multiple types of normal and leukemic human cells is higher and can be achieved with lower numbers of CD34⁺ cell-enriched populations.⁷⁸

Clinical and biological features of the disease

Symptoms and physical examination of the chronic phase

At the beginning, CML is asymptomatic, although patients are now being diagnosed earlier in the course of the disease. In several countries, general practitioners routinely perform leukocyte and platelet measurements, which may explain a higher frequency of incidental diagnosis (20–40% of cases). Patients with symptoms have a gradual onset of fatigue, anorexia, weight loss, and sweats.⁷⁹ Left upper quadrant discomfort and early satiety attributable to splenomegaly are less frequent. In a series of 430 patients,⁸⁰ fatigue was the most frequent symptom (33%), followed by bleeding (21%), weight loss (21%), and splenic discomfort (18%). Less than 10% of the patients had bone pain, infection, or headache. The frequency of signs or symptoms of increased tumor burden has decreased. Rare patients may have manifestations of leukostasis or symptoms related to hyperuricemia: stupor, priapism, tinnitus, cerebrovascular accidents, or acute gouty arthritis. Other infrequent symptoms include splenic infarction and perisplenitis, or acute febrile neutrophilic dermatosis (Sweet syndrome).

Physical examination is frequently normal because of earlier diagnosis. Splenomegaly is the predominant sign, present in 50–70% of cases. The size of the spleen may be an indication of chronic phase duration and is also greater in patients with history of fatigue and sweats.⁸⁰ Because spleen size is an important prognostic factor, the length of the spleen below the costal margin should be determined precisely. Hepatomegaly and lymphadenopathy are less common in chronic phase CML. Sternal tenderness is sometimes noted in the lower portion.

Laboratory findings

Elevated leukocytosis, anemia, and thrombocytosis are common features. The hematocrit is decreased in most patients, with a normal reticulocyte count. Some cases of erythrocytosis or erythroid aplasia have been reported. The white blood cell count (WBC) is usually above $25 \times 10^9/l$ and half of the patients have total WBC over $100 \times 10^9/l$. The WBC differential shows granulocytes at all stages of development from blasts to mature granulocytes, which are normal in appearance. The blast prevalence is about 5%, with a range from 0% to 14%; promyelocytes, myelocytes, and metamyelocytes account for about 45%, and segmented neutrophils about 35% of total leukocytes. Basophils are usually elevated between 5% and 15%. This elevation in basophil count, which is always present when the total leukocyte count is over $10 \times 10^9/l$, is an important sign in the preliminary differential diagnosis. Eosinophils are also elevated, but to a lesser degree. The total lymphocyte count is increased as the result of an expansion of T lymphocytes, whereas natural killer (NK)-cell activity is defective in CML.^{81,82} An absolute monocytosis is usual. The platelet count is elevated in about 50% of patients, and some may have a count above $1000 \times 10^9/l$. A low platelet count is occasionally seen in CML at diagnosis, and may be a sign of accelerated

or blastic phase. It is generally considered a sign of poor prognosis. Platelet function is frequently abnormal, but is not associated with exaggerated bleeding. A decrease in the second wave of epinephrin (adrenaline)-induced platelet aggregation is the most common abnormality, and is associated with a deficiency of adenine nucleotides in the storage pool.⁸³ Some patients have wide cyclic variations of all cells derived from myeloid stem cells, including reticulocytes and platelets, with a periodicity of 50–70 days.⁸⁴

The bone marrow is markedly hypercellular, with a cellularity of 75–90%, fat being reduced. Granulopoiesis is dominant, with a myeloid-to-erythroid ratio of between 10:1 and 30:1, rather than the normal 2:1–5:1. Basophils and eosinophils are increased in proportion to their increase in the blood. Megakaryocytic hyperplasia is usual, with dysplastic changes in all cell lines. Some rare patients will have lipid-laden macrophages resembling Gaucher cells or sea-blue histiocytes. There is no deficiency of glucocerebrosidase in CML, but the normal cellular glucocerebrosidase activity is not high enough to degrade the increased glucocerebrosidase load associated with markedly increased cell turnover. Melofibrosis is not usually present in early chronic phase. However, fibrosis may occur during the course of the disease; the rapid development of myelofibrosis is generally considered a poor prognostic feature.⁸⁵

The Ph chromosome is present in the marrow and nucleated blood cells of 90–95% of patients with typical features of CML. In the remaining patients, molecular studies have revealed the presence of the translocation. This chromosomal abnormality can be found in all blood cell lineages (erythroblasts, granulocytes, monocytes, megakaryocytes, B cells, and macrophage precursors). Stimulated T cells may display the Ph translocation, but skin and marrow fibroblasts do not. The Ph chromosome is a shorter chromosome 22 (22q-) resulting from the reciprocal translocation t(9; 22) in which the distal end of chromosome 22 is exchanged for a small portion of the long arm of chromosome 9 (9q+). The breakpoints in chromosomes 9 and 22 are at bands q34 and q11, respectively. Using high-resolution cytogenetic analysis, the translocation has been precisely defined as t(9;22)(2)(q34.1; q11.2).

Variant Ph chromosome translocations occur in 5–12% of patients. These translocations are ‘simple variant’ when they involve chromosomes 22 and a chromosome other than 9 and ‘complex variant’ when they involve chromosomes 9 and 22 and one or more other chromosomes.⁸⁶ In rare cases, the 22q- is not detected by microscopic examination. This situation has been described as a ‘masked Ph chromosome’.⁸⁷ In a large review of 327 variant Ph translocations reported in the literature, no significant difference was found in survival between patients with standard, simple, or complex Ph translocations.⁸⁸

Cytogenetic analysis usually displays the t(9; 22) in 100% of mitoses. However, about 5–10% of patients have evidence of normal diploid cells at diagnosis. This finding is associated with a better prognosis.⁸⁹ Also, these patients may have favorable prognostic features, with a lower WBC, no spleen enlargement, and no symptoms at presentation. They may also have better cytogenetic responses with interferon- α and a longer survival.⁹⁰ Additional cytogenetic abnormalities at the time of diagnosis have been associated with a poor outcome.^{91,92} In one large series of patients, the median survival of patients with additional cytogenetic abnormalities was 28 months versus 41 months for those without abnormalities.⁹¹ However, such additional abnormalities are uncommon in chronic phase, whereas they are more frequent during accelerated and blastic phases. In Ph- patients, using restriction enzymes and molecular probes for the breakpoint cluster region, a Southern blot analysis will detect rearrangement of fragments, leading to the conclusion that all cases of CML have an abnormal long arm of chromosome 22. Such Ph-, *BCR*⁺ CML patients can express the p210^{BCR-ABL} tyrosine kinase and have a clinical course identical to that of Ph⁺ CML patients.⁹³

Leukocyte alkaline phosphatase (LAP) activity is usually reduced in all patients at diagnosis.⁹⁴ The activity increases towards or to normal in cases of infection or inflammation, and also when the leukocyte count is normal after chemotherapy. LAP activity is restored after infusion of leukocytes into leukopenic patients, suggesting an effect of regulators or factors extrinsic to the neutrophils.⁹⁵ Although low LAP activity is a classical feature of CML at diagnosis, it is not specific. It may be seen in idiopathic myelofibrosis, congenital hypophosphatasia, and paroxysmal nocturnal hemoglobinuria.

Increased production of uric acid with hyperuricemia and hyperuricosuria is usual in untreated patients. Because initial therapy leads to rapid cell destruction, excretion of the additional purine load may produce urinary tract blockage or urate nephropathy. Formation of urate stones is common in CML, and patients with latent gout may develop uric acid nephropathy or acute gouty arthritis. Patients with CML have an increased serum level of vitamin B₁₂ up to 10 times normal levels, whereas transcobalamin II, the physiological B₁₂ carrier, is not increased. This biological feature is not specific, since a high vitamin B₁₂ level may occur in the case of any increase in the number of neutrophilic granulocytes. The serum lactic dehydrogenase level (LDH) is elevated. It is possible to observe pseudohyperkalemia due to the release of potassium from white cells during clotting, and false hypoxemia or pseudohypoglycemia from in vitro utilization of oxygen or glucose by leukocytes.

Clinical and biologic characteristics of advanced phases

After an indolent phase lasting 2–6 years when patients are treated with conventional chemotherapy, the disease changes to a more aggressive phase. This accelerated phase or metamorphosis is characterized by an increase in tumor burden and a poor response to therapy. After 1–1.5 years, this accelerated phase is followed by the blastic phase, which results in the patient's death within 3–6 months. Different definitions of the accelerated and blastic phases have been established based on the occurrence of several different clinical and biological features (Table 41.2).^{96,97}

Accelerated phase

Several features may suggest progression from chronic to accelerated phase, including fever without infection, bone pain, weight loss, night sweats, and splenic enlargement unresponsive to previously successful chemotherapy. Anemia may worsen, with an uncontrolled increase in WBC. The proportion of blasts and/or basophils may increase in the blood and marrow. A decrease in the platelet count to below $100 \times 10^9/l$ is usual. Some marked dysplastic changes may occur in the major cell lineages, with reticulin and collagen fibrosis. The presence of additional cytogenetic abnormalities is common. Three additional abnormalities are frequently observed: trisomy 8, duplication of the Ph chromosome, and iso(17q). A higher incidence of these changes has been reported after treatment with busulfan compared with hydroxyurea.⁹⁸ The death rate during this phase is between 20% and 25%. Accelerated phase is, however, a loosely defined condition. Clinically, it may be suspected in the presence of progressive splenomegaly,

Table 41.2 Signs of accelerated and blastic phases of CML

Accelerated phase
Persisting progressive splenomegaly
Increasing WBC resistant to treatment
Increasing marrow fibrosis
Additional cytogenetic abnormalities
Anemia or thrombocytopenia (platelets $<100 \times 10^9/l$) unrelated to therapy
Marked thrombocytosis
Fever not otherwise explained
Peripheral basophils $\geq 20\%$
Peripheral blasts plus promyelocytes $\geq 30\%$
Peripheral blasts $\geq 15\%$
Elastic phase
Peripheral blasts $\geq 20\%$
Bone marrow blasts $\geq 30\%$
Extramedullary blastic infiltrates

splenic pain, fever, or night sweats. However, approximately 20% of patients are asymptomatic when the diagnosis of accelerated phase is made on the basis of peripheral blood counts or bone marrow findings.⁹⁷

The clinical significance of cytogenetic clonal evolution (i.e. the appearance of new cytogenetic abnormalities in addition to the Ph chromosome) as a manifestation of accelerated phase is more controversial and probably not uniform. In a study of 264 patients with clonal evolution, the median survival from the onset of clonal evolution was 19 months.⁹⁷ However, multivariate analysis identified four groups of patients with clearly differing outcomes. The 'good' group included 37 patients with no chromosome 17 abnormality, a percentage of metaphases with clonal evolution below 16% and a time to clonal evolution of less than 25 months, with a median survival of 54 months. In contrast, the median survivals of the two 'worst' groups were 6 months (27 patients with chromosome 17 abnormality and 34% or more abnormal metaphases) and 7 months (22 patients with other features of accelerated phase and 16% or more abnormal metaphases). The median survival of the 'intermediate' group ranged from 13 to 24 months.

There is no consensus definition of the accelerated phase, and the existing definitions are not always precise. Several authors have proposed various classifications,^{80,100–103} which have been developed empirically (Table 41.3).

However, the Houston criteria have been defined using multivariate prognostic factor analysis. Kantarjian et al.⁹⁷ followed up 357 patients with newly diagnosed CML treated between 1965 and 1984 with hydroxyurea or busulfan (n=206), intensive chemotherapy (n=97), or more recently with interferon- α (n=54). The prognostic value of features of accelerated phase (as reported in the prior literature) was assessed for survival and time to blast crisis.

In a multivariate analysis, five factors were found to be independently associated with poor survival: cytogenetic evolution, peripheral blasts 15% or more, peripheral basophils 20% or more, peripheral blasts and promyelocytes 30% or more, and thrombocytopenia (platelets $<100 \times 10^9/l$).¹⁰⁵ Each of these factors was associated with a median survival below 18 months (7, 9, 17, 5, and 16 months, respectively). The corresponding median time to blast crisis ranged from 2 to 15 months (Table 41.4).

Altogether, it appears from an examination of these diagnostic criteria that patients classified as in accelerated phase in the Sokal or IBMTR systems^{92–104} may still be classified as being in chronic phase in the Houston system. Furthermore, whereas the occurrence of chloromas qualifies for an accelerated phase in the IBMTR system, it is more commonly considered as evidence of progression to blast crisis.

Table 41.3 Definitions of accelerated phase CML

MD Anderson Cancer Center⁹⁷	Sokal⁹²	IBMTR¹⁰⁶
PB blasts $\geq 15\%$	PB or BM blasts $\geq 5\%$	PB or BM blasts $\geq 10\%$
PB blasts+promyelocytes $\geq 30\%$	–	PB or BM blasts+promyelocytes $\geq 20\%$
PB basophils $\geq 20\%$	PB basophils $\geq 20\%$	PB basophils+eosinophils $\geq 20\%$
Platelets $\leq 100 \times 10^9/l$ unrelated to therapy	Thrombopenia unrelated to therapy	Thrombocytopenia unresponsive to BU or HU therapy
Cytogenetic karyotypic evolution	Cytogenetic karyotypic evolution	Cytogenetic karyotypic evolution
	Platelets $\geq 1000 \times 10^9/l$ despite adequate therapy	Persistent thrombocytosis
	Marrow collagen fibrosis	Myelofibrosis
	Anemia unrelated to therapy	Anemia unresponsive to BU or HU therapy
	Progressive splenomegaly	Progressive splenomegaly
	Leukocyte doubling time < 5 days	Rapid doubling time of leukocytes < 5 days
	Frequent Pelger-Huet-like neutrophils; nucleated erythrocytes; megakaryocyte nuclear fragments	Leukocyte count difficult to control with BU or HU therapy
	Fever not otherwise explained	Development of chloromas

IBMTR, International Bone Marrow Transplant Registry; PB, peripheral blood; BM, bone marrow; BU, busulfan; HU, hydroxyurea.

Table 41.4 Houston staging system for CML

Phase	Clinical characteristics	Stage	Definition
Chronic	Age ≥ 60 years Spleen ≥ 10 cm	1	0 or 1 characteristic
	Blasts $\geq 3\%$ in blood or $\geq 5\%$ in marrow Basophils $\geq 7\%$ in blood or $\geq 3\%$ in marrow	2	2 characteristics
	Platelets $\geq 700 \times 10^9/l$	3	≥ 3 characteristics
Accelerated	Cytogenetic clonal evolution Platelets $< 100 \times 10^9/l$	4	≥ 1 characteristic defines accelerated phase

However, it is also noteworthy that all patients who qualify for accelerated phase in the Houston system will also qualify in the other systems. Taking the example of the threshold used for peripheral blood blasts ($\geq 15\%$), the Houston system probably define a group of patients with a more advanced stage of the disease, as compared with the Sokal ($\geq 5\%$) and IBMTR ($\geq 10\%$) systems.

In conclusion, whereas the Houston criteria are likely to identify a population of patients with a more advanced disease (i.e. closer to progression to blast crisis), the other systems may be used for an earlier identification of signs of progression. However, it must be emphasized that both the Sokal and IBMTR systems lack precision in the definition of some criteria such as ‘progressive splenomegaly’, ‘anemia or thrombocytopenia’, or ‘persistent thrombosis’. All of these differences must be carefully taken into account when comparing reports from different studies.

Blastic phase

Blast crisis is usually defined by the appearance of 30% or more blasts in the peripheral blood or the bone marrow.^{102,106} However, alternative definitions have been proposed, such as the presence of more than 15% or 20% blasts, or more than 30% or 50% of blasts plus promyelocytes in the peripheral blood or the bone marrow, respectively.^{107,108} In particular, a clinical advisory committee of international hematologists and oncologists has reached a consensus to define AML as a disease presenting at least 20% of blast cells in the bone marrow. The specific impact of

this new threshold on the interpretation of the results of previously published studies using the usual threshold of 30% bone marrow blasts remains to be determined. Nevertheless, this new cut-off should be considered for the definition of acute phase of CML in future trials.¹⁰⁸

The blastic phase usually results in the patient's death within 3–6 months. It may occur after a period of accelerated phase or arise directly from the chronic phase, the latter in 20–25% of patients. In some cases, extramedullary blastic tumors may precede marrow involvement. Thus, these tumors are sometimes considered to be the first manifestation of metamorphosis. These leukemic infiltrates appear in the lymph nodes, breast, or gastrointestinal or genitourinary tracts. Most of the patients with extramedullary manifestations will develop acute leukemia with marrow and blood involvement within a few months. A combination of morphology, histochemistry, monoclonal antibodies specific for lymphoid or myeloid cells, and cytogenetic and molecular analysis must be used in order to classify the blast cells. Lymphoblasts, like myeloid blasts, are Ph⁺.^{107,109}

The blastic phase is myeloid in about 50% of cases—usually myeloblastic or myelomonocytic. Promyelocytic, eosinophilic, or basophilic blast crises have also been described. Some cases are undifferentiated (15–25%), classified as erythroblastic, or occasionally as megakaryoblastic.^{107,109} In these latter cases, myelofibrosis is not unusual and monoclonal antiplatelet antibodies (e.g. antiplatelet glycoprotein antibodies) are useful to identify the proliferation. The blastic phase is lymphoid in 25% of case, the B phenotype being predominant, although rare patients have blasts with a T-lymphocyte phenotype. In vitro studies may occasionally show a biphenotypic blast crisis with cells having myeloid and lymphoid markers. The presence of additional chromosome abnormalities is frequent at this stage of the disease. The principal additional abnormalities are duplication of the Ph chromosome and iso(17q) or trisomy 8. These changes occur frequently, being noted in 62–86% of patients. Other chromosome abnormalities have also been noted.

Forms of the disease and atypical presentation

In some patients (10–15%), symptoms and signs of leukostasis are present at diagnosis, with extreme leukocytosis exceeding $500 \times 10^9/l$. Hyperviscosity of the blood and infiltration of tissues may explain priapism, visual difficulty with retinal bleeding, and mental confusion due to cerebral hypoxia.¹¹⁰ Hyperleukocytosis is more prevalent in children with Ph⁺ CML. Other cases may mimic polycythemia vera, idiopathic myelofibrosis, or primary thrombocythemia.¹¹¹ Skeletal lesions are uncommon (between 3% and 10%) and may represent ectopic areas of myeloid metaplasia or the first sign of blastic phase.¹¹²

Coexistence or sequential development of CML with other proliferative disorders has been described. CML has been diagnosed after treatment including radiotherapy and/or chemotherapy for Hodgkin's disease or non-Hodgkin lymphoma.¹¹³ Patients may have concurrent lymphoproliferative malignancies (chronic lymphocytic leukemia, CLL) or myeloma or Waldenström's macroglobulinemia. In some cases, it has been clearly established that two independent clonal disorders are present.^{114–116}

Ph⁺ adult-type CML may occur in children, but is rare under the age of 5 years. CML in children has the typical manifestation and course of the adult disorder. However they may present with higher total leukocyte counts with leukostatic symptoms.

Chronic neutrophilic leukemia is a rare form of proliferative disorder, which can now be classified as a molecular variant of CML. A few well documented cases with Ph⁺ leukemia have been reported in association with a *p230^{BCR-ABL}* gene. The course of the disease seems to be much more benign than that of typical CML. Patients may complain of anorexia and weakness; otherwise, the disease is discovered after a routine blood test. The spleen is frequently less prominent and lymphadenopathy is infrequent. The patients have lower WBC and a low proportion of circulating immature granulocytes, anemia is less severe, and blastic transformation occurs much later, if at all. Some of these cases have shown a marked thrombocytosis, with platelet counts between $762 \times 10^9/l$ and $1442 \times 10^9/l$.^{117–119}

Ph⁻ CML is a heterogenous group of disorders. Patients who are Ph⁻ but BCR⁺ have a clinical course similar to those with Ph⁺ CML: these patients should receive the same therapeutic options.¹²⁰ A subgroup of patients are Ph⁻ and BCR⁻. They present with higher WBC, neutrophilia, and basophilia, and occasionally with splenic enlargement and bone marrow hyper-cellularity. The natural history of these patients is characterized by increasing leukemia burden, with leukocytosis, organomegaly, extramedullary infiltrates, and bone marrow failure without excess of blasts.¹²¹ However, some of these patients may have similar clinical and biological features of chronic myelomonocytic leukemia (CMML).¹²² A few cases of AML (2–3%) have the Ph translocation. These may represent an early blast crisis of CML. These patients have marked spleen and liver enlargement, normal platelet counts, basophilia, and a breakpoint within the M-bcr region, with production of the usual 210 tyrosine kinase.¹²³ Their prognosis is very poor. However, some patients enter remission by converting to chronic phase CML. About 5% of children with ALL and 20% of adults with ALL have the Ph chromosome in their blast cells.¹²⁴ In children, the

prognosis is worse than that of those without the translocation, although the clinical and biological features are similar to those of classic ALL. However, these patients may have higher WBC, a more frequent L2 blast cell morphology, and a high incidence of pre-B CALLA+ disease.¹²⁵ Remission rates and median survivals are lower in adults with Ph⁺ ALL.

Prognosis

Since the 1970s, several studies have been conducted in order to set up prognostic models. Such models have been used to categorize patients into risk groups.^{91,126–130} At the time of diagnosis, most of these models (Table 41.5) have selected several variables associated with the duration of chronic phase, such as age, spleen size, race, hemoglobin level, WBC, and platelet count.

Using these variables, patients usually segregate into three risk groups with significantly different survival times. Good-risk patients have a median survival of 50–60 months, intermediate-risk a survival of 39 months, and high-risk a survival of 25–32 months. A subsequent model has been proposed including five prognostic variables (Table 41.6), patients being distributed into four categories (the fourth category corresponding to patients with accelerated phase). The median survivals of patients were 56, 45, 30 and 30 months, respectively.¹⁰⁵ For a long time, these prognostic models were used for the evaluation of therapeutic trials, and they also played an important role in deciding the timing of bone marrow transplantation.

One of the most popular prognostic systems is that proposed by Sokal et al¹³⁰ in 1984 and subsequently called the ‘Sokal model’. This widely used model was derived on a cohort of 813 patients treated with chemotherapy. It is based on the calculation of a

Table 41.5 Prognostic variables in CML

- Age
- Race
- Spleen size
- Liver size
- Hemoglobin level
- WBC
- Platelet count
- Nucleated red blood cells in peripheral blood
- Percentage of blasts in peripheral blood or bone marrow
- Percentage of basophils in peripheral blood or bone marrow
- Percentage of promyelocytes plus myelocytes in peripheral blood
- Percentage of eosinophils in peripheral blood

score, taking into account simple clinical parameters such as age, spleen size, platelet counts, and the percentage of blasts in the peripheral blood (Table 41.7). Patients are then distributed into three risk groups: low-risk (score <0.8), high-risk (score >1.2), and intermediate-risk. This model, developed in a large cohort of patients treated essentially with chemotherapy, was highly efficient in predicting long-term survival. However, these staging systems were based on series of patients treated with chemotherapy (mainly hydroxyurea or busulfan), and there have been concerns that they may not be fully applicable with interferon-based therapies.

Until recently, the modern approach to the treatment of patients with CML included the use of interferon- α (IFN- α) alone or in combination with cytarabine (cytosine arabinoside, Ara-C), allogeneic bone marrow transplantation from related as well as unrelated donors, and autologous stem cell transplantation. Most of the prognostic models are not applicable to these new therapeutic strategies. For example, several trials comparing IFN- α versus busulfan or IFN- α versus hydroxyurea.^{100,131,132} and a single-arm trial with IFN- α 173 did not find any association of the Sokal index with survival. Most of the patients treated with IFN- α achieved a complete hematological remission (60–80%). In addition, treatment with IFN- α induces cytogenetic responses that are complete in some patients. Several trials have demonstrated that achieving major (i.e. < 35% Ph⁺ residual cells) or complete cytogenetic responses significantly improved survival.^{134,135} Some studies have not found an association between achievement of major or complete responses and survival—probably because the number of responders was too small.^{132,133} However, using a multivariate analysis including major cytogenetic response as a time-dependent variable, the achievement of such a response was independently associated with prolonged survival. Therefore, the achievement of a cytogenetic response might be the most important prognostic feature for patients with CML treated with IFN- α alone or in combination with cytarabine.¹³⁶

A survival improvement has also been demonstrated in patients who achieved sustained cytogenetic responses compared with those with transient responses.¹³⁷ Also, the patients who achieved rapid hematologic responses had a higher probability of cytogenetic responses. Patients with a complete hematologic response within 3 months had a major cytogenetic response rate of 82%, compared with 29% in those who were resistant at that time.¹³⁸ Other predictive factors of the cytogenetic response could be lymphokine-activated killer (LAK) cytotoxicity level and the occurrence of autoimmune complications.^{139,140}

More recently, a new prognostic scoring system adapted to IFN- α -treated patients has been

Table 41.6 Prognostic models for patients with CML

developed.¹⁴¹ This model utilizes age, spleen size, blast count, platelet count, eosinophil count, and basophil count (Table 41.7). Among 908 patients included in 14 studies involving 12 institutions, three distinct risk groups were identified, with median survival times of 98 months, 65 months, and 42 months. This meta-analysis has been updated, with 1400 patients being followed for up to 12.5 years, and showing median survival times of 100, 69 months and 45 months for low-, intermediate-, and high-risk groups.¹⁴² The distribution of patients was 42%, 45%, and 13% in the low-, intermediate-, and high-risk categories. This score, usually referred to as either the ‘Hasford score’ or the ‘Euro score’, has been used in clinical trials only recently. The merits of one prognostic model over the other remain unclear, and both the Sokal and the Euro systems are now widely used.

The decision whether to offer an individual patient the option of treatment by allogeneic stem cell transplantation (allo-SCT) must be based in part on an assessment of the probability of success using the best available stem cell donor. Gratwohl et al¹⁴³ have defined five principal prognostic factors for survival after allo-SCT on the basis of data submitted to the European Group for Blood and Marrow

Table 41.7 Sokal and Hasford prognostic scoring systems for CML

Transplantation (Table 41.8). They allocated a score of 0, 1, or 2 to each of the five factors in accordance with the degree to which the influence of that factor was favorable or unfavorable for a particular patient. Thus, for each factor in a given transplant procedure, a patient's total score could be 0 (most favorable) or 2 (least favorable). The aggregate prognostic score calculated in this way correlated well with actual survival (Table 41.9). This approach is extremely useful

Table 41.8 Risk score for individual transplant procedures in CML as established by the European Group for Blood and Marrow Transplantation

for helping a clinician to make recommendations and the patient to decide whether or not to undergo alloSCT. It must be conceded, however, that many of the factors to be considered in such decision-making are 'empirical'. There is a complete absence of prospective studies addressing the results of allo-SCT in CML—a point stressed in the report from the American Society of Hematology Committee on Practice Guidelines.¹⁴⁴

The presence of deletions adjacent to the translocation breakpoints on the derivative chromosome 9 has been described in 10–15% of patients with CML. These deletions span the translocation breakpoint, often involve both chromosome 9 and 22 sequences, are large (sometimes measuring many megabases), and occur at the same time as the formation of the Ph translocation. They are associated with an extremely poor prognosis, with those patients who carry them having shorter length of chronic phase, earlier disease transformation, and shorter survival. Also, in a direct comparison, deletion status was a far more powerful prognostic indicator than either the commonly used Sokal or Hasford scores.¹⁴⁵

The recent approval in the USA and Europe of imatinib represents the latest improvement of the treatment of patients with CML. It will likely change the current clinical treatment pathway, as clinical trial results have been positive.¹⁴⁶ Advances in the treatment of CML, as well as progress in supportive care, have significantly impacted the natural history of the disease and its prognosis. Historically, the median survival for patients with CML was 3 years, with a 5-year survival rate of less than 20%. Today, patients with chronic phase disease have a median survival of 5–7 years and 50–60% of patients are alive at 5 years, with more than 30% being alive at 10 years. Because

various and highly divergent treatment options are available for patients with CML, it is becoming ever more important to determine the effect of baseline characteristics on the efficacy of a given therapy. Imatinib has only recently been introduced for the treatment of CML patients. Thus it seems too early to use a define prognostic model for imatinib-treated patients.

Treatment

Treatment of the chronic phase of the disease

Some two decades ago, the treatment of a patient with chronic phase CML was virtually restricted to the use of standard chemotherapy such as busulfan or hydroxyurea. These drugs have the ability to control the signs and symptoms of the disease. However, progression to blastic phase was constant. At that time, a combination of antileukemic drugs was used, unfortunately without success, and finally the patient died within a few months after a median survival of the disease of 3–6 years. For many years, the prognosis of patients with CML was poor. The expected median survival was 3 years, and less than 20% of patients were alive at 5 years. However, prognosis has improved because of earlier diagnosis, improved antileukemic therapy, and better supportive care. Currently, many therapeutic options are offered for the treatment of chronic phase, such as IFN- α -based regimens, homoharringtonine, stem cell transplantation, and, recently, imatinib, a very promising tyrosine kinase inhibitor.

Chemotherapy

Busulfan, introduced in 1953, became in 1968 the treatment of choice when the results of the UK Medical Research Council (MRC) randomized trial comparing radiotherapy with busulfan demonstrated the superiority of the drug.¹⁴⁷ Although busulfan produces good control of blood cells for a long period, it does not alter the course of the disease. Also, it has potential side-effects, which may be serious. The prolonged use of busulfan has been associated with adrenal insufficiency, pulmonary fibrosis, skin pigmentation, and marrow fibrosis. Prolonged aplasia can occur, which may be a major cause of death. However, survival has sometimes been prolonged in such cases. Other drugs, including thioguanine, melphalan, dibromomannitol, chlorambucil, 6-mercaptopurine, and cyclophosphamide, were not considered to be more active compared with busulfan. Hydroxyurea was introduced later (in 1972), and has been extensively used.¹⁴⁸ Hematologic relapse is usual if hydroxyurea is stopped. Thus, the drug must be administered continuously. Although hydroxyurea and busulfan can both control the hematological manifestations of CML, hydroxyurea proved to be superior. In a prospective trial, patients who received hydroxyurea had a significantly longer median survival (56 months versus 44 months) compared with those who were treated with busulfan.¹⁴⁹ These findings have been confirmed in a meta-analysis of 812 patients enrolled in three randomized trials.¹⁵⁰

Because of its *in vitro* activity, cytarabine was tested *in vivo* as a single agent for the treatment of patients with CML in chronic phase. Treatment of two patients in chronic phase with low-dose cytarabine resulted in a significant reduction of Ph⁺ metaphases.¹⁵¹ The cytarabine was administered by subcutaneous infusion at a dose rate of 20 mg/m²/day, with the aim of inducing and maintaining a granulocyte count of less than 2000/ μ l for at least 10 days. It was administered for 17–31 days, either continuously or with interruptions of 2–7 days because of hematological toxicity or side-effects. Cytogenetic analyses were performed 4–9 days after the end of the cytarabine infusion. After two or three successive cycles, Ph⁺ metaphases decreased from 100% to 2 of 27 and 3 of 26 metaphases in patients 1 and 2, respectively. In contrast, subsequent intensive chemotherapy with high-dose hydroxyurea in a dosage sufficient to maintain granulocytopenia and normal serum vitamin B₁₂ levels reduced the Ph positivity to only 46% and 72%, respectively. Thus, it was concluded that a selective antileukemic effect has been seen with cytarabine but not with hydroxyurea. Also, it was assumed that cytarabine exhibits significant antileukemic selectivity, while hydroxyurea is a non-specific inhibitor of granulopoiesis. Similar antileukemic activity of cytarabine was observed in five patients in chronic phase.¹⁵²

Homoharringtonine (HHT), a plant alkaloid, is one of a group of cephalotoxin esters isolated in 1969. It has long been recognized as an antitumor agent in Chinese folk medicine. Preclinical studies indicated good antitumor activity in murine P388 lymphocytic leukemia and L-615 leukemia. Several phase I-II studies documented some degree of antileukemia activity in refractory AML. The use of HHT in CML was first reported by Chinese teams. Of 15 patients in chronic phase, 9 achieved a hematological remission with a dose of HHT of 5–7 mg/day for 7–10 days.¹⁵³ However, no cytogenetic evaluation was reported. The most important antileukemia activity of HHT is inhibition of protein synthesis. However, induction of apoptosis has also been demonstrated. *In vitro*, HHT is able to induce a dose-dependent cell growth inhibition. It exerts a synergistic effect with IFN- α , cytarabine, and IFN- α + cytarabine in inhibiting CML hematopoietic progenitors. Such *in vitro* synergism is the rationale for clinical trials using the three agents.¹⁵⁴

HHT has been used as a low-dose continuous infusion of 2.5 mg/m² daily for 14 days for induction, then for 7 days every month, in patients with late chronic

phase CML. It induced a complete hematologic remission in two-thirds of patients (more than 50% of whom had shown resistance to IFN- α) and a cytogenetic response in one-third (half of which were major responses).¹⁵⁵ HHT was then given for 6 cycles as remission induction, followed by IFN- α maintenance to patients with early chronic phase CML. The complete hematologic response rate was 92% and the cytogenetic response rate was 68%.¹⁵⁶

Interferons

Interferons are cellular glycoproteins with antiproliferative, antiviral, and immunoregulatory properties. They are produced by various cell types in response to viral infection. Both IFN- α and IFN- β are acid-stable, bind to the same receptors, and are produced primarily by leukocytes and fibroblasts, respectively. In contrast, IFN- γ is an acid-labile, structurally distinct molecule that binds to a different receptor, and is produced mainly by T lymphocytes. IFN- α , the molecule used in CML, initially prepared from human leukocytes, is now essentially produced by recombinant techniques.

IFN- α has the potential to control progression in the chronic phase and was the first non-myelotoxic drug to be shown to cause a marked reduction in Ph positivity in some patients. The use of IFN- α in CML was first evaluated by the Houston group some 15 years ago. They first used human IFN- α in 51 patients in chronic phase treated with doses of 3–9 MIU daily. IFN- α resulted in satisfactory control of the disease in 36 patients (71%), with normalization of peripheral blood counts and a gradual decrease in bone marrow cellularity. Of greatest interest was the finding that serial cytogenetic studies showed a reduction in the percentage of Ph⁺ cells in 20 of the 36 patients in whom satisfactory control was established. The Ph suppression lasted in 7 patients for more than 39–62 months.¹⁵⁷

The responses to IFN- α among these patients required the development of standardized criteria for complete hematologic response (CHR) and cytogenetic responses (Table 41.10).

Following the first reports from the Houston group, several small phase II studies were published (Table 41.11). Using recombinant IFN- α 2a, 2b, 2c, several studies from single-institution or cooperative groups have subsequently confirmed the efficacy of IFN- α in CML.^{133,158–163} The dose of 5 MIU/m² daily has been used at the MD Anderson Cancer Center, Houston for the treatment of 274 patients with early chronic phase CML.¹⁵⁸ Of these 80% achieved CHR and 58% had a cytogenetic response (26% complete and 38% major). The median survival was 89 months. Achieving a cytogenetic response after 12 months of therapy was associated with a statistically longer survival. At 5 years, the survival rates were 90% for complete, 88%

Table 41.10 Hematologic and cytogenetic Houston response criteria for CML

None	100

for partial response, and 76% for minor cytogenetic responses.

The relationship of the response to the dose and schedule of the treatment with IFN- α , as well as the duration of chronic phase and survival, were then the subjects of several randomized studies (Table 41.12).^{100,131,132,135,164}

In the German CML study, IFN- α was superior to busulfan therapy, but it did not demonstrate a survival advantage after hydroxyurea.¹³² In the UK trial, major responses have been associated with IFN- α doses between 2 and 6 MIU daily, and responsiveness did not appear to be associated with higher doses.¹³¹ In the Japanese trial, the predicted 5-year survival rates were 54% and 32% for the IFN- α and busulfan arms, respectively.¹⁰⁰

A survival advantage was also demonstrated in the Italian study, with a 6-year survival rate of 50% with IFN- α compared with 29% with chemotherapy.¹³⁵ However, in the Benelux study, the benefits of a better hematologic and cytogenetic response after IFN- α did not translate in a longer survival for the IFN- α -treated patients.¹⁶⁴

Studies of combinations of IFN- α and chemotherapy were conducted in order to attempt to achieve CHR or cytogenetic responses in IFN- α -resistant patients. It was also assumed that a higher cytogenetic response rate might be achieved by increasing myelosuppression with a combination of myelotoxic drugs. In a pilot study, 24 patients received hydroxyurea 50 mg/kg/day and IFN- α 2a at a starting dose of 5 MIU/m²/day. Courses of low-dose cytarabine were given to 11 patients at a dose of 10–20 mg/m²/day for 10–15 days per month.¹⁶⁵ A CHR was obtained in 18 patients, 8 achieving a major cytogenetic response. A rapid cytogenetic improvement was recorded in 6 out of 11 patients receiving low-dose cytarabine, with a complete Ph chromosome suppression in 4.

Table 41.11 Phase II studies with IFN- α in CML

Subsequently, two French multicenter trials were conducted in order to study the potential benefit of a combination of IFN- α with low-dose cytarabine as front-line treatment.^{136,166} In the second of these, the CML91 study, the dose of cytarabine was increased to 20 mg/m²/day, the monthly courses being started within 2 weeks after randomization.¹³⁶ The trial enrolled 810 patients, and 721 were studied: 360 randomly assigned to the IFN- α /cytarabine group and 361 to the IFN- α group. An update of this trial shows that the probability of having a major cytogenetic response at 24 months was significantly higher in the IFN- α /cytarabine group ($p=0.006$). Also, the patients in the IFN- α /cytarabine group survived significantly longer than those in the IFN- α group ($p=0.02$). At 3 years, the estimated survival rates were 85.7% and 79.1% for the IFN- α /cytarabine and IFN- α groups, respectively (Figure 41.6). In this trial, a relationship was also noted between cytogenetic response and survival.

The Italian Cooperative Study Group on CML conducted a similar randomized trial. In this, 540 evaluable patients were randomized, 275 being assigned to IFN- α plus cytarabine and 265 to IFN- α alone. At 12 months, the combination resulted in a higher cytogenetic response rate (41% versus 34%) and a higher major cytogenetic response rate (17% versus 9%; $p=0.01$). Survival was also, improved with the combination, the difference being significant only for patients with low-risk disease ($p=0.01$).¹⁶⁷ Other groups have reported similar observation of a potential benefit of IFN- α therapy combined with low-dose cytarabine.¹⁶⁸⁻¹⁷¹

Cytarabine ocfosfate (YNK01), an oral formulation of cytarabine, has been tested in combination with IFN- α by several groups.¹⁷²⁻¹⁷⁴ In the Italian and French trials, the study design was the same: IFN- α 5 MIU/m² daily and YNK01 600 mg daily, 14 days per month. The response rate was higher in the Italian study, with a major cytogenetic response rate at 12 months of 28%, whereas it was 16% in the French study. Doses of YNK01 were too high, and lower doses such as 200 mg daily should be tested in the future.

Patients' compliance with prolonged treatment with IFN- α in CML is an important factor for achieving

Figure 41.6 Survival by cytogenetic response at 24 months in the CML91 study: (a) IFN- α ; (b) IFN- α /cytarabine. Landmark analysis ($p < 10^{-4}$).

clinical benefit. In some studies, the antitumor efficacy appears to be related to higher-dose schedules of daily IFN- α therapy. Similarly, trials in CML suggest that an increased area under the curve (AUC), and associated prolonged tumor exposure to IFN- α , may be important in mediating the antileukemic effects. Therapy with IFN- α is cumbersome, and is associated with significant side-effects requiring dose reductions and temporary or permanent treatment interruptions in 10–50% of patients.

Polyethylene glycol (PEG) is a linear, hydrophobic, uncharged, flexible polymer available in a variety of molecular weights. A semisynthetic formulation protein—polymer conjugate of IFN- α 2b) was developed by attaching a single PEG 12 kDa molecule to the amino groups of selected lysine residues in the IFN- α 2b molecule or the N-terminal amino acid. Twenty-seven adults with Ph⁺ CML in chronic or accelerated phases, in whom IFN- α treatment has failed, were included in a phase I study.¹⁷⁵ PEG IFN- α 2b was given as a weekly subcutaneous injection starting at 0.75 μ g/kg weekly and escalating to 1.5, 3, 4.5, 6, 7.5, and 9.0 μ g/kg. The maximum tolerated dose was defined at 7.5–9 μ g/kg; dose-limiting toxicities included severe fatigue, neurotoxicity, liver function abnormalities, and myelosuppression. The proposed phase II dose of PEG IFN- α 2b was 6 μ g/kg weekly. Among 19 patients with active disease, 7 (37%) achieved CHR; 2 (11%) had a cytogenetic response (complete).

A randomized study of PEG IFN- α 2a versus IFN- α 2a suggested a superiority of the pegylated form, with a higher response rate.¹⁷⁶ However, these results were not confirmed with PEG-IFN- α 2b.¹⁷⁷

There is accumulated evidence from randomized controlled trials that, compared with busulfan or hydroxyurea, IFN- α improves survival in chronic phase patients with favorable features: no or minimal prior treatment, relatively normal hemoglobin levels and platelet counts, less than 10% blasts in the blood, and especially beginning treatment within 6 months of diagnosis when IFN- α is coupled with other agents such as hydroxyurea or cytarabine.

Results of clinical trials with imatinib

Through our understanding of signaling pathways regulating cellular growth, the cell cycle, and programmed cell death (apoptosis), numerous targets for anticancer agents have emerged. In this setting, the *BCR-ABL* rearrangement possesses many characteristics of an ideal therapeutic target. BCR—ABL functions as a constitutively activated tyrosine kinase, and mutagenic analysis has shown that this activity is essential for the transforming function of the protein. Consequently, an inhibitor of the BCR-ABL kinase would be predicted to be an effective and selective therapeutic agent for CML. Tyrosine kinases catalyze the transfer of phosphate from adenosine triphosphate (ATP) to tyrosine residues on substrate proteins. Because all protein kinases use ATP as a phosphate donor, it was thought that inhibitors of ATP binding would lack sufficient target specificity to be clinically useful. However, this turned out not to be the case, and a lead compound of the 2-phenylaminopyrimidine class rapidly emerged. One series of compounds, optimized against the platelet-derived growth factor receptor (PDGFR), showed equipotent activity against the ABL tyrosine kinase, of these, imatinib (imatinib mesylate, STI571, Gleevec/Glivec) emerged as a major compound for the treatment of CML. In vitro preclinical studies of imatinib showed specific inhibition of the proliferation of myeloid cell lines containing BCR-ABL. Colony-forming assays from CML patients showed a marked decrease (92–98%) in the number of BCR-ABL colonies, with little toxicity to normal stem cells. Further experiments showed that both p185^{BCR/ABL} and p210^{BCR/ABL}-expressing cells were sensitive to imatinib and that dose-dependent inhibition of tumor growth was seen in animals inoculated with BCR-ABL-expressing cells.^{178,179} Based on the efficacy of imatinib in these preclinical models and an acceptable animal toxicology profile, phase I and II trials were initiated, followed by a large phase III trial.

The first phase I/II trial included 83 patients in whom treatment with IFN- α had failed or who could not tolerate the drug.¹⁸⁰ Of these, 37 had hematologic resistance or relapse, 33 had cytogenetic resistance or

relapse, and 13 could not tolerate IFN- α . The median duration of the therapy with IFN- α was 8.5 months (range 1 week—8.5 years). Nineteen patients had findings suggestive of accelerated disease. The median duration of treatment with imatinib was 310 days (range 17–607 days). Half of the patients assigned to receive daily doses of 25, 50, or 85 mg of imatinib were subsequently removed from the study within 2 months because of elevated white cell or platelet counts requiring therapy, which was not permitted by the protocol.

A subsequent phase II study enrolled 532 patients from December 1999 to May 2000.¹⁸¹ After a central review of the data, the diagnosis of chronic phase CML was confirmed in 454 patients (85%). This diagnosis could not be confirmed for 78 (15%) patients, either because they had characteristics of accelerated (17 patients) or blastic (12 patients) phase or because of missing data (49 patients). Patients were eligible for this study if they were 18 years or older and had Ph⁺ CML in chronic phase that had failed prior IFN- α therapy according to one of the following criteria: hematologic failures were defined either as hematologic resistance (failure to achieve a CHR following at least 6 months of IFN- α treatment) or as relapse after achieving CHR, with WBC increased to 20×10^9 /or more, while receiving IFN- α . In both cases, hydroxyurea was allowed for up to 50% of the IFN- α treatment duration. Cytogenetic failures were defined either as cytogenetic resistance ($\geq 65\%$ Ph positivity after at least 1 year of interferon) or as relapse from a major cytogenetic response (an increase in the percentage of Ph⁺ metaphases by at least 30%, or an increase to $\geq 65\%$). Intolerance of IFN- α was defined as any non-hematologic toxicity of grade 3 or more (as defined by NCI Common Toxicity Criteria) persisting for more than 1 month with IFN- α given at 25 MILJ/week or higher.

In this single-arm multicenter phase II trial, patients received imatinib 400 mg orally daily. Dose escalation to 400 mg twice daily was permitted in patients who did not achieve a CHR after 3 months of treatment, whose disease relapsed within 3 months of a CHR, or who did not achieve a major cytogenetic response after 12 months of therapy. Imatinib induced major cytogenetic responses in 60% of the 454 patients with confirmed chronic phase CML and CHR in 95%. After a median follow-up of 18 months, CML had not progressed to the accelerated or blastic phases in an estimated 89% of patients, and 95% of the patients were alive. Grade 3 or 4 non-hematologic toxic effects were infrequent, and hematologic toxic effects were manageable. Only 2% of patients discontinued treatment because of drug-related adverse events, and no treatment-related deaths occurred (Table 41.13).

In order to demonstrate the benefit of imatinib compared with other IFN- α -based regimens, it was decided to set up a large international study. This study (IRIS: International Randomized Study of IFN+ Ara-C vs STI571) was carried out in newly diagnosed patients with CML in chronic phase to compare the efficacy, safety, and tolerability of imatinib administered as monotherapy with that of standard treatment with IFN- α +cytarabine as the first-line treatment of the disease. The objective of the trial was to determine the progression-free survival in adult patients with newly diagnosed previously untreated Ph⁺ CML in chronic phase randomized to receive either imatinib as a single agent or a combination of IFN- α and cytarabine. The aim of the trial was also to assess the rates and durations of CHR and major cytogenetic responses as well as the quality of life and overall survival.¹⁸²

In the imatinib arm, patients were treated with 400 mg/day. This dose was recommended for chronic phase patients following the results of the phase I and II studies. In the IFN- α arm, patients were treated with a target dose of IFN- α of 5 MIU/m²/day subcutaneously in combination with subcutaneous cytarabine 20 mg/m²/day for 10 days a month. Because of the high level of efficacy seen with imatinib given as second-line therapy in patients with chronic phase CML failing prior IFN- α therapy in the preceding phase II study 0110, patients showing lack of response (lack of CHR at 6 months, increasing WBC, no major cytogenetic response at 24 months), loss of response (loss of CHR or major cytogenetic response), or severe intolerance to treatment were allowed to cross over to the alternative treatment arm (Figure 41.7).

This multicenter phase III study included 1106 adult patients, 553 in each arm. The baseline characteristics of these patients were well balanced between the two arms and there were no differences between the two arms with regard to the distribution into the three sub-categories of risk using a scoring system such as the Sokal score or the Euro score.

The median time from randomization to start of treatment was 3 days in both groups, ranging from 0 to 41 days in the imatinib arm and from 0 to 79 days in the IFN- α /cytarabine arm. After a median follow-up of 19 months, the estimated rate of a major cytogenetic response (0–35% of cells in metaphase positive for the Ph chromosome) at 18 months was 87.1% (95% confidence interval (CI) 84.1–90.0%) in the imatinib group and 34.7% (95% CI, 29.3–40.0%) in the group given IFN- α plus cytarabine ($p < 0.001$). The estimated complete cytogenetic response rates were 76.2% (95% CI 72.5–79.9%) and 14.5% (95% CI 10.5–18.5%), respectively ($p < 0.001$). At 18 months, the estimated rate of freedom from progression to accelerated phase or blast crisis CML was 96.7% in the imatinib group and 91.5% in the combination-therapy group ($p < 0.001$) (Table 41.14).

^c Myeloid blast crisis.

^d Sustained response (≥ 4 weeks).

Discontinuation of first-line therapy was more frequent in the group of patients randomized to IFN- α , the most frequent reason for discontinuation being withdrawal of consent (13%). Importantly, in the USA, the rates of discontinuation of IFN- α due to withdrawal of consent, protocol violation, administrative problems, or loss of follow-up increased sharply around the time imatinib was introduced into the US market for the treatment of chronic phase patients failing prior IFN-therapy (May 2001). A similar pattern could not be observed outside the USA.

Further analysis using the Kaplan-Meier method has been performed, in which patients who crossed over or discontinued for reasons other than progression were censored. Using this approach, the estimated rate of CHR at 12 months in the imatinib arm was minimally affected (95.9%), whereas it increased to 66.5% in the IFN- α arm (p<0.001). Of interest, the rate of CHR to second-line imatinib for the 218 patients who crossed over was 83.5%, i.e. very similar to the reported rate of 88% in the phase II study 0110. Even when CHR was analyzed under the intention-to-treat

Response	Imatinib (n=553)	IFN- α -cytarabine (n=553)	p
CHR	95.3	55.5	<0.001
MCR	85.2	22.1	<0.001
CCR	73.8	8.5	<0.001

CHR, complete hematologic response; MCR, major cytogenetic response; CCR, complete cytogenetic response.

(ITT) principle, the rate of CHR in the imatinib arm (94.6%) remained significantly higher than in the IFN- α arm (76.5%; $p<0.001$).

In patients who had a complete cytogenetic response, levels of *BCR-ABL* transcripts after 12 months of treatment had fallen by at least 3 log in 57% of those in the imatinib group and 24% of those in the group given IFN- α plus cytarabine ($p=0.003$).¹⁸³ On the basis of the complete cytogenetic response rates of 68% in the imatinib group and 7% in the group given IFN- α plus cytarabine at 12 months, an estimated 39% of all patients treated with imatinib but only 2% of all those given IFN- α plus cytarabine had a reduction in *BCR-ABL* transcripts levels of at least 3 log ($p<0.001$). For patients who had a complete cytogenetic response and a reduction in transcript levels of at least 3 log at 12 months, the probability of remaining progression-free was 100% at 24 months, as compared with 95% for such patients with a reduction of less than 3 log and 85% for patients who were not in complete cytogenetic remission at 12 months ($p<0.001$) (Figure 41.8).

Figure 41.8 Progression-free survival in the IRIS trial (vertical bars indicate censored observations).

Patients completed cancer-specific quality-of-life (QoL) (FACT-BRM) and utility (EQ-5D) questionnaires at baseline and during treatment ($n=1049$). The primary QoL endpoint was the Trial Outcome Index (TOI, a measure of physical function and well-being). Secondary endpoints included Social/Family Well-Being (SFWB), Emotional Well-Being (EWB), and the utility score. Primary analyses were ITT, with secondary analyses accounting for crossover. Multivariate mixed effects growth curve models and logistic and linear regression models were used. Patients on IFN- α plus cytarabine experienced a large decline in the TOI, while those on imatinib maintained their baseline level. Mean treatment arm differences at each visit were significant ($p<0.001$) and clinically relevant in favor of imatinib. Mean SFWB, EWB, and utility scores were also significantly better on imatinib. Patients who crossed over to imatinib experienced a large increase in TOI, and there were significant ($p<0.001$) differences between patients who did and did not cross over in favor of imatinib.¹⁸⁴ Tolerability of imatinib was good, serious adverse experiences being more frequent with IFN- α plus cytarabine (Tables 41.15 and 41.16).

Stem cell transplantation

Allogeneic bone marrow transplantation (BMT) was first proposed for refractory leukemia and then for CML. The first results were published by the Seattle group, who demonstrated that, using an effective conditioning regimen, BMT could cure patients. The best BMT results are obtained using human leukocyte antigen (HLA)-matched sibling donors. However, unrelated BMT has improved recently.¹⁸⁵ Most patients are now transplanted in chronic phase (71%). Also, the proportion of patients who are offered BMT is higher. A study of 10 countries in Europe, North America, Australia, and New Zealand suggests that about 35% of persons with CML under the age of 55 years receive BMT.¹⁸⁶

The best results are obtained when the transplant is performed during chronic phase and within the first year after diagnosis. Among 3409 recipients of HLA-identical transplants performed between 1989 and 1995 and reported to the International Bone Marrow Transplant Registry (IBMTR), the 3-year actuarial probabilities of relapse were 16% for 2753 patients transplanted in first chronic phase, 36% for 490 in accelerated phase, and 61% for 166 in blast phase. The 3-year probabilities of leukemia-free survival (LFS) were 59%, 37%, and 17%, respectively. Patients relapsing after an HLA-identical sibling transplant for CML often survive for long periods with conventional treatment. Many achieve durable remissions with donor lymphocyte infusions and some have successful second BMTs. Consequently, 3-year survival rates after transplants are higher than LFS rates: 66% in chronic phase, 44% in accelerated

phase, and 19% in blastic phase. In general, relatively few deaths after HLA-identical sibling transplants for chronic phase CML result from leukemia, particularly if the transplants are not T-cell-depleted. Most deaths are from transplant-related complications such as regimen-related toxicity, graft-versus-host disease (GVHD), and infection. An IBMTR study of HLA-identical sibling transplants for CML in first chronic phase performed between 1985 and 1990 identified prior treatment with hydroxyurea rather than busulfan and a short interval between diagnosis and transplant (less than 1 versus at least 1 year) as favorable prognostic factors. The 3-year probabilities of survival were 67% for patients treated with hydroxyurea and receiving transplant within 1 year of diagnosis, 59% for those treated with hydroxyurea and receiving transplant later, 54% for patients treated with busulfan and receiving transplant after 1 year after

diagnosis, and 45% for those treated with busulfan and receiving transplant later.^{187–189} A comparison was performed between a cohort of 548 patients of HLA-identical sibling transplants reported to the IMBTR and 196 patients receiving hydroxyurea ($n=121$) or IFN- α ($n=75$) in the German trial.¹⁹⁰ For the first 18 months after diagnosis, mortality was higher in the transplant than in the non-transplant cohort. From 18 to 56 months, mortality was similar, and after 56 months, mortality was lower in the transplant cohort.

Only 35% of patients with CML under the age of 55 years actually undergo an allogeneic transplant, primarily due to the lack of an appropriate tissue-compatible related donor. Alternative progenitor cell sources such as cord blood, mismatched related transplants, and matched unrelated donor transplants have been extensively explored as treatment options for patients with CML. CML is the most common indication for unrelated donor transplants, representing 35% of all unrelated donor transplants performed in the USA. With the increasing number and size of volunteer donor registries, the median time for identification of a suitable donor has decreased from 6.9 months to 5.5 months; however, only one of four searches actually culminates in transplantation. The results of the largest series of unrelated donor transplantation for CML are summarized in Table 41.17.^{185,191–193}

Acute GVHD and infectious complications remain the most important causes of morbidity and mortality of unrelated donor transplantation. The single most important prognostic factor for the development of acute GVHD is the degree of histocompatibility. Serologic typing underestimates the degree of mismatching in a large proportion of donor-recipient pairs. Modern molecular techniques have demonstrated that molecular mismatches in serologically matched donor-recipient pairs are common and correlate with transplant outcomes. In the Seattle study, young patients with CML (age <50 years) who receive a fully molecular matched unrelated donor and are transplanted within 1 year of diagnosis have an estimated 5-year survival rate of 74%, indistinguishable from recipients of fully matched sibling donor transplants.

The approach to patients with CML who lack an HLA-identical sibling donor has become increasingly complex. On the one hand, the availability of non-transplant strategies that can effectively achieve cyto-genetic remission, such as imatinib, offers the possibility of long-term disease control for some patients without allogeneic transplantation. On the other hand, the increasing size and number of volunteer donor registries as well as improvements in tissue typing and supportive care have improved the outcomes of unrelated donor transplantation. The current challenge for physicians and patients is how to incorporate these strategies into the approach to each individual case and how to decide who should undergo unrelated donor transplantation as primary therapy or as salvage therapy for their disease. Transplant and non-transplant options should be viewed as complementary strategies in the treatment of CML, the goal being to obtain complete cytogenetic remissions in as many patients as possible with the minimum toxicity necessary for each patient.

One of the major causes of treatment failure is relapse, which occurs in 10–30% of patients who received unmanipulated donor marrow cells, but is considerably

Table 41.17 Results of representative studies of unrelated donor transplantation for CML

Ref	n	Median age (years)	% survival	% GVHD II-IV	% GVHD III-IV	% relapse
191	1423	35	37 (3 yr)	43	33	8
192	115	33	46 (3 yr)	–	24	23
185	196	35	57 (5 yr)	77	35	10
193	27	32	52 (3 yr)	39	8	9

more frequent in those who received marrow stem cells that have been depleted of T cells in an effort to minimize or eliminate GVHD. Patients who relapse may be treated with IFN- α 194 or by infusion of lymphocytes harvested from the original stem cell donor. The use of such donor lymphocyte infusions (DLI) was first reported in 1990, and many subsequent studies have confirmed their efficacy.^{195,196} The benefit of the salvage treatment of post-transplant relapse with DLI can be estimated using a new definition of leukemia-free survival called 'current leukemia-free survival (CLFS)', which is defined as survival without evidence of leukemia at the time of the most recent assessment. Using this new statistical methodology, the 5-year estimate of conventional LFS was 36% in a cohort of 189 patients, but was 49% using the CLFS approach.¹⁹⁷ However, DLI are still associated with a high rate of acute and chronic GVHD. Current research is exploring the value of DLI, IFN- α , or imatinib in patients relapsing after BMT. Other approaches include new pretransplantation conditioning using non-myeloablative regimen.

High-dose chemotherapy followed by autologous stem cell infusion has also been considered as a therapeutic option that could improve survival.

Large prospective trials have recruited patients in order to address the question of whether autografting prolongs survival (Table 41.18). The observation that a substantial number of benign progenitors coexist with their malignant counterparts during early chronic phase provides the theoretical basis for the design of autologous transplantation trials. It is known that CML patients receiving high-dose chemotherapy or busulfan recover after a period of aplasia with predominantly Ph⁻ hematopoiesis that is transient or occasionally long-lasting.¹⁹⁸ In several prospective trials, a significant proportion of patients treated with IFN- α achieved complete cytogenetic responses with restoration of Ph⁻ hematopoiesis and prolongation of survival. In addition, it has been shown that Ph⁻ progenitor cells can be successfully mobilized after high-dose chemotherapy with or without growth factor support.¹⁹⁸⁻²⁰⁵ In vitro data support the notion that Ph⁻ cells are present in the bone marrow. It has been demonstrated that granulocyte-macrophage colony forming unit (CFU-GM) colonies from CML patients could be partially Ph-negative.²⁰⁶

Ex vivo culture of CML marrow in Dexter-type long-term bone marrow culture produces increasing numbers of Ph⁻ hematopoietic cells.^{207,208} Benign progenitors have also been selected on the basis of cell surface phenotype and have been shown to be polyclonal on the basis of the methylation pattern of the human androgen receptor gene located on the X chromosomes.²⁰⁹ These observations support the hypothesis that Ph⁻ hematopoietic cells are present in a significant proportion of patients with CML and that they are probably not part of the leukemic population.²¹⁰ These benign progenitors are suitable for reconstitution of hematopoiesis after high-dose chemotherapy and can be recovered from the marrow or peripheral blood in selected CML patients.

New approaches to select out benign progenitors from blood and marrow have been developed. However, the number of benign progenitors available for separation is often limited. There is also evidence that reduction of both normal and leukemic cells to low levels favors regeneration of normal stem cells, at

Table 41.18 Results of autografting for CML

least in the short term. Thus, the sources of cells that have been used for autologous transplantation are unmanipulated peripheral blood stem cells (PBSC), or bone marrow cells, or in vitro manipulated cells, or mobilized PBSC following various regimens of chemotherapy, cytokines, and growth factors.

Autologous stem cell transplantations were performed first on CML patients with blastic transformation.^{211,212} Subsequently, autografting has been used in chronic phase patients.^{213,214} A retrospective analysis of the European Blood and Marrow Transplantation Registry (EBMTR) was performed on 174 patients who had undergone stem cell transplantation during their chronic phase²¹⁵ (and J Reiffers, personal communication, 2000). Patients received different conditioning regimens and most of them were treated with IFN- α after transplantation. The actuarial percentage of patients surviving at 5 years was $68.4\% \pm 11\%$, and was significantly higher for those who achieved a cytogenetic response.

McGlave et al²¹⁶ conducted an overview analysis of 200 patients autografted for CML with purged or unpurged marrow or PBSC at eight different transplant centers. At the time of publication, the survival time of 142 patients with chronic phase CML was not reached. However, as the data have matured, the outcome does not appear to be so good.

The crucial point is that these transplants are performed with leukemic stem cells included because the cryopreserved product is not manipulated. It has been demonstrated that progenitors released from the marrow into the circulation during the earliest stages of hematopoietic reconstitution following high-dose chemotherapy appear to be in part Ph-. Because these progenitors seem to have the capacity to reconstitute hematopoiesis, some groups have attempted to select these cells for the purpose of autografting.²¹⁷

Treatment of accelerated phase

In patients with accelerated phase CML, good hema-tologic control can be generally obtained by increasing the dose of IFN- α or hydroxyurea. However, the overall survival usually remains short, ranging from 8 to 18 months.¹⁰²

In a cohort of 357 patients treated at the MD Anderson Cancer Center, Houston between 1965 and 1984, in which the majority of patients were managed with hydroxyurea, busulfan, or single-agent INF- α , the median survival after the onset of accelerated phase features was less than 18 months.⁹⁷ In a study of 20 patients treated with a combination of IFN- α and low-dose cytarabine (16 of whom had clonal evolution as the only evidence of accelerated phase), the CHR rate was 50%, and four patients (20%) achieved a partial or minor cytogenetic response. However, these responses were generally transient. The 3-year survival rate for the 16 patients with clonal evolution was 74%. In contrast, it was only 22% for patients with accelerated phase features other than clonal evolution (4 from the present study and 9 from historical control series).¹⁶⁸

Only two studies have evaluated the outcome of cohorts of more than 15 patients with accelerated phase CML treated with chemotherapy. In a study of 17 patients treated with decitabine, 9 (53%) achieved a response, with a median duration of 9 months. Six patients returned to chronic phase, two achieved a partial response, and one had a 'hematologic improvement' only, but no patients achieved a CHR. The median survival was 14 months, with a 2-year survival rate of 28%.²¹⁸ In another study of 24 patients treated with a combination of daunorubicin and high-dose cytarabine, 6 (25%) achieved a CHR and 4 (17%) returned to chronic phase. Five patients achieved a transient cytogenetic response. The median survival was 8 months, and the probability of survival at 18 months was 30%.²¹⁹

Altogether, it appears that with chemotherapy and/or IFN- α , up to 50% of patients may achieve a response. However, these responses are usually short-lived, CHR are uncommon, and cytogenetic responses anecdotal. As consistently reported in these studies, the overall survival of patients with accelerated phase remains below 18 months.

The results of allogeneic BMT in patients with accelerated phase are intermediate between the results reported in patients with chronic phase or blast crisis. As with chemotherapy, the results may be significantly influenced by the criteria used to define accelerated phase CML. For example, in a study of 251 BMT patients from the Hammersmith Hospital in London, the proportion of patients transplanted in accelerated phase was 11% using the institution's criteria and 79% using the IBMTR criteria.⁸⁰ In a study by Clift et al,¹⁰¹ 58 patients with accelerated phase (using criteria similar to the Sokal and IBMTR criteria) were transplanted at a single institution with HLA-matched sibling bone marrow donors. At 4-years, the overall and relapse-free survival rates were 49% and 43%, respectively. However, the rate of death not related to relapse was high, with 29 (50%) patients who died because of various complications of BMT (acute respiratory distress syndrome or other respiratory failures, cytomegalovirus infection, veno-occlusive disease, bacterial or fungal infection, or GVHD). Interestingly, the 4-year relapse rate was low, at 12%. In a multivariate analysis, factors associated with an improved survival were a young age (<38 years) and cytogenetic clonal evolution as the only manifestation of accelerated phase. The 4-year probability of survival for the 16 patients transplanted within 1 year of the diagnosis of CML and with cytogenetic clonal evolution as the only manifestation of

accelerated phase was 74%. In contrast, the 4-year probability of survival for the 31 patients who were categorized as accelerated phase for reasons other than cytogenetic abnormalities was only 34%.

Data are also available from BMT registries. In one report of 1480 transplants from the EBMTR, 206 patients were grafted while in accelerated phase.²²⁰ The 5-year LFS rate was only 22%. This low rate can be explained by a high relapse rate (42% at 2 years) and a high death rate. As in the study mentioned above, the transplant-related mortality rate was high: 47% at 2 years and 51% at 5 years. Similarly, in a report from the IBMTR, the 4-year LFS rate for the 408 patients transplanted in accelerated phase was 25%²²¹ (Figure 41.9). Among 3409 recipients of HLA-identical sibling transplants performed between 1989 and 1995, the 3-year actuarial relapse rate was 36% (30–42%) for 490 patients in accelerated phase. The 3-year LPS probability was 37% (35–39%). Patients relapsing after HLA-identical sibling transplant for CML often survive for long periods with conventional treatment. Many achieve durable remissions with DLI, and some have successful second BMT. Consequently, 3-year survival rates after transplants are somewhat higher than LFS rates: 44% (39–49%).²²²

Imatinib

Imatinib has been tested on patients in accelerated phase in several phase I and II trials. In the first phase I study, imatinib showed relevant activity in a subset of patients with accelerated phase.¹⁸⁰ Of the 83 patients enrolled in this study, 19 had had findings suggestive of accelerated phase, and they responded favorably to the drug at a daily dose of 300 mg or higher. Therefore, a large phase II trial was conducted in order to confirm its observed activity and favorable safety profile.²²³ The study was an open-label, non-randomized, multicenter, phase II trial designed to evaluate the clinical efficacy of imatinib as determined by the rate of sustained hematologic response.

Figure 41.9 Leukemia-free survival (LFS) after allogeneic bone marrow transplantation for CML: dotted lines, HLA-identical siblings; full line, matched unrelated donors. (Taken from International Bone Marrow Transplant Registry: 1990–1995)

Initially, enrolled patients received a daily dose of 400 mg. Following the availability of phase I dose-escalation data demonstrating the safety of prolonged treatment with higher doses, this initial daily dose was increased to 600 mg. For patients who had a relapse, dose escalation to a maximum of 400 mg twice daily was permitted. A total of 235 patients were enrolled in the study, of whom 181 had a confirmed diagnosis of accelerated phase.

Imatinib induced a hematologic response in 82% of the patients and sustained hematologic responses lasting at least 4 weeks in 69% (complete in 34%). The rate of major cytogenetic response was 24% (complete in 17%). Estimated 12-month progression-free and overall survival rates were 59% and 74%, respectively (see Table 41.13). In comparison, doses of 600 mg/day led to more cytogenetic responses (28% compared with 16%) and to longer duration of response (79% compared with 57% at 12 months) and time to disease progression (67% compared with 44% at 12 months), with no clinically relevant toxicity. A clear relationship between survival and cytogenetic response was observed using a landmark analysis at 3 months. Of 83 patients with an evaluation of cytogenetic response at 3 months after start of therapy, 20 (24%) had a major cytogenetic response at that time, and none of these 20 patients had died at the time of analysis. Of the 63 evaluated patients without major cytogenetic response after 3 months, 14 (22%) had died.

In multivariate analysis, the factors most strongly predictive of longer time to disease progression were hemoglobin levels of 100 g/l or higher and a starting dose of 600 mg. Female sex was marginally predictive in this analysis. In subgroup logistic regression analyses excluding patients without data for blasts in bone marrow or additional chromosomal abnormalities, neither variable added further to the prediction of hematologic response in multivariate analyses ($p > 0.10$). Further analyses indicated that varying the cutoff values used to define patient subgroups had little effect on most prognostic factors. Platelet counts below $40 \times 10^9/l$ were independently predictive of a shorter time to disease progression in exploratory analyses, but the reliability of this result was limited by the small number of patients in this subgroup. The use of different cutoff values for hemoglobin (< 110 g/l) and blasts in peripheral blood ($< 5\%$) led to the elimination of male/female sex as a marginal prognostic factor in the final multivariate model, and to the inclusion of high platelet counts and low blast counts in peripheral blood as predictive of longer time to disease progression. In further exploratory multivariate analyses, a hemoglobin level of 100 g/l or higher was the sole factor significantly predictive for higher rates of sustained hematologic response. Exploratory multivariate analyses of prognostic factors for overall survival were limited by the small

Figure 41.10 Overall survival of CML patients in accelerated phase and treated with imatinib (vertical bars indicate censored observations).

number of patients who had died, but results identified three factors as predictive of longer survival: a starting dose of 600 mg, $WBC < 30 \times 10^9/l$, and absence of splenomegaly (Figure 41.10).

The toxicity of imatinib in this trial was generally similar to that observed in a previous phase I study at comparable doses. The most frequently reported events were nausea, edema, vomiting, diarrhea, and muscle cramps. Grade 1 or 2 edema, dermatitis, vomiting, muscle cramps, myalgia, arthralgia, and weight increase/fluid retention were generally more frequent in the 600 mg dose group than for patients treated with imatinib at 400 mg per day, but the incidences of other grade 1 or 2 reactions, and of all grade 3 and 4 reactions, were similar in both dose groups. Routine laboratory tests revealed infrequent development of grade 3 abnormalities in aspartate aminotransferase (AST) (2% of patients), alanine aminotransferase (ALT) (3%), and bilirubin (2%) during treatment.

A comparison of the results of this study with historical reports suggests that imatinib may bring substantially increased efficacy to the treatment of patients in accelerated phase CML, compared with current alternative chemotherapy and biologic therapy. Among patients in the 600 mg dose group, the overall and complete hematologic response rates of 71% and 37%, respectively, compare favorably with the range of approximately 20–60% overall response rates in similar patients treated with single-agent therapies, IFN- α and low-dose cytarabine, or hydroxyurea and 6-mercaptopurine. The induction of major cytogenetic responses in 28% of patients treated with imatinib is encouraging, since fewer than 5% of patients with CML in accelerated phase achieve cytogenetic response with alternative therapies. The 12-month progression-free and overall survival rates of 67% and 78%, respectively, also compare favorably with the more transient responses observed with other therapies (Figure 41.11).

Treatment of acute phase

High dose chemotherapy

Patients with blast crisis are usually treated with combination chemotherapy regimens commonly

Figure 41.11 Overall survival of patients in accelerated phase treated with imatinib by cytogenetic response at 3 months: landmark analysis (vertical bars indicate censored observations).

used in the treatment of acute myeloid or lymphoid leukemias, as appropriate. The drugs most often used are anthracyclins and cytarabine. However, only a limited number of studies have reported on the results of treatment of patients with blast crisis only. The information provided by these studies is limited as these reports are all small-scale phase I or II studies or single-institution series. Nevertheless, the response to chemotherapy is in the range of 22–65%.^{109,224–231}

Responses are usually reported as complete response, partial response, return to chronic phase, or 'hematologic improvement'. Whereas the criteria for complete response are usually consistent, requiring the disappearance of blasts from the peripheral blood and the bone marrow and a complete recovery of peripheral blood counts, the criteria for partial response, return to chronic phase, or hematologic improvement vary greatly from study to study. Response criteria for blastic CML based on morphology and on cytogenetic or molecular markers have been proposed.¹⁰⁶ Improvement of marrow morphology defines either a complete (<5% blasts plus promyelocytes) or partial (5–15% blasts plus promyelocytes) response, but cytogenetic abnormalities are still present. Complete remission requires a loss of clonal progression. Disappearance of the Ph⁺ cell population defines cytogenetic remission and polymerase chain reaction (PCR) negativity for *Bcr-Abl* rearrangement refers to biologic remission of CML. Less than 10% of patients are reported to achieve CHR.²³² In the largest series published to date, with 296 patients, lymphoid blast crisis appears to be more responsive to chemotherapy (with a 49% rate of complete response when treatment is given as first 'salvage', as compared with 19% and 12% for patients with myeloid and undifferentiated phenotypes).¹⁰⁹ Transient reductions in the proportion of Ph⁺ cells are rarely reported.^{225,230,232}

These responses are, however, invariably short-lived, with a median duration ranging from 1 to 8 months.^{107,224,228–230,232,233} Overall, the survival of these patients is poor, averaging 3–6 months. Consistent with the suggestion that patients with a lymphoid phenotype may be more responsive to chemotherapy, in a large study of 296 patients from the Houston group, the median survivals were 3 and 9 months in patients with myeloid and lymphoid blast crisis, respectively.¹⁰⁹ Although the survival of responding patients remains short, responders had a significant prolongation of survival. For example, in one study,²³¹ patients who responded had a median survival of 231 days, whereas it was 73 days for the non-responders ($p=0.008$). A retrospective analysis of prognostic factors was conducted in 90 patients in blast crisis.²³⁴ The response to therapy was significantly better in lymphoid blast crisis and in patients without clonal evolution. In a multivariate analysis containing all significant variables of the univariate analysis, two parameters retained their prognostic significance: response to therapy and trisomy 8.

The toxicity of these combination chemotherapy regimens is typical of those used in the treatment of acute leukemias, and requires inpatient hospitalization. Common non-hematologic adverse events include nausea, vomiting, mucositis, and diarrhea. Myelosuppression is usual, and febrile neutropenias were reported in 80–94% of patients in one study with 162 patients.²³² In a series of 48 patients treated with a combination of daunorubicin and cytarabine, the median number of days with an absolute neutrophil count (ANC) below $0.5 \times 10^9/l$ was 28 (range 10–48), and the number of days with a profound thrombocytopenia below $30 \times 10^9/l$ was 19 (range 2–55).²¹⁹ In the study by Sacchi et al,²⁷² 5 out of the 90 patients who were treated with multiagent combination chemotherapy had early deaths that may be attributable to toxicity.

Stem cell transplantation

BMT is usually performed only in patients with a good performance status, below 50 years of age, and with a suitable bone marrow donor. The outcome of patients receiving an allogeneic BMT while in overt blast crisis is very poor.¹⁹¹ This poor outcome is usually related to a very high rate of transplant-related mortality and to a high rate of relapse. In a report of 1480 patients transplanted for CML from the EBMTR, 59 transplants were performed during blast crisis.²²⁰ The transplant-related mortality rate was 62%, and the LFS rate at 2 years was only 17%. No patients were alive at 5 years of follow-up. These results are consistent with another report from the IBMTR of 1685 patients transplanted for CML.²²¹ In this report, 113 patients were transplanted in blast crisis, and their LFS rate was approximately 15% at 2 years. Among 3049 patients who received an HLA-identical stem cell transplant between 1989 and 1995 and were reported to the IBMTR, 166 were in blastic phase. The 3-year LFS probability was 17% (10–24%), the 3-year actuarial probability of relapse was 61% (50–72%), and the 3-year survival rate was 19% (12–26%).²²² In a single-center study of 115 patients evaluating a preparative regimen with busulfan and cyclophosphamide but without total body irradiation, 27 patients were transplanted in blast crisis, and these patients had a relapse rate of 27% at 2 years. Furthermore, the presence of blast crisis at the time of transplant was identified as an independent negative prognostic factor for relapse and death in a multi-variate analysis.²³⁵

The outcome of BMT performed with matched unrelated donors appears to be equally poor. In a report from the National Marrow Donor Program, the 2-year disease-free survival rate of 101 patients (out of 1423 with CML) transplanted while in blast crisis was

approximately 10%.²³⁶ In this report, in multivariate analyses, transplantation in advanced stage CML was significantly associated with a higher risk of graft failure, acute grade III/IV and chronic GVHD, leukemia relapse, and death.

High-dose chemotherapy followed by autologous stem cell transplantation has been used in order to restore a second chronic phase. Bone marrow or PBSC from these patients were cryopreserved during their chronic phase. Once the blast crisis was evident, the cells were infused following high-dose chemotherapy with or without total body irradiation. Although chronic phase CML could be reestablished in most patients, it was usually short-lived, with recurrence of advanced disease and death occurring within 6 months to 1 year. In a few patients, cytogenetic responses were observed following transplantation, with a prolongation of survival.^{237–239} McGlave et al²¹⁶ compiled the results of 200 consecutive autologous transplants performed with purged or unpurged bone marrow or PBSC grafts at eight different transplant centers in Europe and North America between 1984 and 1992. For patients transplanted in blastic phase, the median survival time was 4.1 months.

Imatinib

A first phase I study included 58 patients with blastic phase CML and relapsed or refractory Ph⁺ ALL treated with a daily dose of 300–1000 mg imatinib.^{240,241} The overall rates of response among patients with myeloblastic crisis and lymphoblastic crisis were 55% and 77%, respectively. Almost 80% of patients had a reduction of at least 50% in peripheral blasts, usually within the first week after the initiation of treatment. Of the subgroup of 38 patients who were receiving imatinib for myeloblastic crisis, 17 (45%) had a partial hematologic response (defined by a reduction in the marrow blast count to 15% or less) and 4 (11%) a complete response (<5% marrow blasts, neutrophils $>1 \times 10^9/l$, and platelets $>100 \times 10^9/l$). Three patients had a major cytogenetic response. Most responses were transient, but 7 patients (18%) remained in complete or partial remission for 3–12 months during treatment. The results for 10 patients with CML in lymphoblastic transformation and 10 with Ph⁺ ALL were similar. Of these 20 patients, 10 had a partial hematologic response and 4 a complete response. Two patients had a major cytogenetic response. Nevertheless, all patients who had a response relapsed within 4 months. Side-effects in patients who received imatinib for advanced leukemia were similar to those in patients with chronic-phase CML. Serious adverse events possibly due to imatinib occurred in 13 patients, usually at doses of 800–1000 mg/day. Only 3 patients had a febrile neutropenia, and no deaths were related to the use of the drug. Following these encouraging results, a large phase II trial was initiated in order to confirm the initial promising results of the phase I study.²⁴²

Male or female patients were eligible for inclusion in this study if they were at least 18 years of age and had Ph⁺ CML in myeloid blast crisis. The study was mainly designed to evaluate treatment in patients with newly diagnosed blast crisis, defined as patients who had not received specific therapy for advanced CML (either in blast crisis or in accelerated phase), with the exception of IFN- α and palliative therapy with hydroxyurea, or low-dose cytosine arabinoside (<30 mg/m² every 12–24 hours administered daily). However, enrollment was also open to patients who had received prior therapy for advanced CML, in order to allow a preliminary investigation of imatinib in a heavily pretreated population. Initially, the enrolled patients received treatment with orally administered imatinib at daily doses of 400 mg. Following the availability of phase I dose-escalation data demonstrating the safety of prolonged treatment with higher doses, this initial daily dose was increased by protocol amendment to 600 mg. For patients who relapsed, dose escalation (initially to 600 mg daily, and increased by protocol amendment to 400 mg twice daily) was permitted at the discretion of the investigator. Dose escalation was also permitted for patients who did not achieve hematologic response after at least 1 month of therapy. A total of 260 CML patients were enrolled in this phase II trial, of whom 229 had a confirmed diagnosis of CML in blast crisis. Of the 260 patients enrolled, 37 (14%) started therapy with imatinib at daily doses of 400 mg, which was the highest dose adequately tested for safety at the time of their enrollment. The remaining 223 (86%) patients started treatment at a daily dose of 600 mg, based on phase I data available after the start of this study, demonstrating that treatment with this higher dose was feasible and possibly associated with greater activity. At the time of data analysis, the median duration of treatment for all enrolled patients in the 400 and 600 mg dose groups was 3.7 months (25–75% quartiles: 1.5–7.6 months) and 4.0 months (25–75% quartiles: 1.9–9.3 months), respectively; 21% of the patients were treated for more than 1 year. The median actual dose intensities were 400 and 600 mg/day, as planned. About 50% of the patients in both dose groups reduced or interrupted treatment at least once, but 58% in the 400 mg dose group and 40% of the patients started with 600 mg had their dose escalated to 600 and 800 mg, respectively, at least once during the study. Of the 260 patients enrolled, 220 (85%) patients withdrew from treatment. The primary reasons for withdrawal were disease progression or unsatisfactory therapeutic effect for 151 (58%) patients, adverse events or laboratory test results for 23 (9%) patients, death during therapy for 24 (9%) patients, initiation of BMT for

14 (5%) patients, protocol violations for 3 (1%) patients, and withdrawal of consent for 5 (2%) patients.

After 1 month, more than 80% of the patients with available values had a blast count less than 15% in peripheral blood. Of the 229 patients, 119 (52%) had reductions in blast counts in peripheral blood and bone marrow features corresponding to hematologic response on at least one occasion; 35 (15%) patients had a CHR, 55 (24%) had a CHR or marrow response, and 64 (28%) met the criteria for return to chronic phase (RTC). Sustained hematologic responses, lasting at least 4 weeks, were reported for 31% of patients, including 8% of patients with CHR or 12% with either a CHR or a marrow response, and 18% with RTC. Responses usually occurred soon after the start of treatment: of the 70 patients with a sustained hematologic response, 45 (64%) achieved their first response within 1 month after starting imatinib therapy, corresponding to the first scheduled evaluation of response, and a further 15 (21%) responded within 2 months. In three patients, hematologic response was achieved only after their dose was escalated (one from 400 to 600 mg, and two from 600 to 800 mg). In a multivariate analysis, four factors were independently predictive of a higher likelihood of sustained hematologic response: initial dose of imatinib (34% with a dose of 600 mg and 9% with 400 mg), hemoglobin level of 100 g/l, or more, a platelet count of $100 \times 10^9/l$ or more, and blood blasts less than 50%.

Major cytogenetic responses were reported for 37 (16%) patients, of which 7% were complete. Major, minor, or minimal cytogenetic response was reported in 71 (31%) patients. The median time to major cytogenetic response was approximately 3 months, corresponding to the first assessment of response in most patients. The initial dose of imatinib had a strong effect on response: major cytogenetic responses were reported for 18% of patients treated with 600 mg/day, and for 6% with 400 mg/day. The Kaplan-Meier estimated median survival was 6.9 months (95% CI 5.7–8.7 months), and the estimated survival rate was 43% (9.5% CI 36–49%) at 9 months, 32% (25–38%) at 12 months, and 20% (15–27%) at 18 months. These estimates remained the same when survival data were included for the 10 patients who discontinued therapy to undergo BMT (4 of these 10 patients were still alive at the time of analysis). The estimated median survival was 7.5 months for previously untreated patients, and 5.6 months for patients who had received treatment for advanced CML (Figure 41.12).

Ongoing and planned trials

Imatinib in combination with other antileukemic agents

The rationale for the combination of imatinib with cytarabine is based on several observations. Cytarabine has well-described modest activity as a single agent in CML. In combination with IFN- α , it has been shown to significantly improve the rate of cytogenetic responses and survival in CML patients. Imatinib has shown significant activity in CML in all studies to date. In vitro studies examining the effects of imatinib plus cytarabine using CML cell lines and colony-forming assays of CML patient samples have shown synergistic antiproliferative effects of this combination.^{243–246}

However, a concern with any single agent administered chronically is that resistant clones may emerge. Recent in vitro data suggest that cytarabine shows particular enhanced cytotoxic efficacy against potential imatinib-resistant CML cell lines. More recently, resistance has been associated, in some patients, with a single amino acid substitution in a threonine residue of the ABL kinase domain.²⁴⁷ The majority of CML patients respond to imatinib. Relapse, however, is known to occur in a subset of patients, particularly those with advanced phase. While, to date, the relapse rate in the chronic phase is approximately

Figure 41.12 (a) Overall survival of CML patients, (b) Overall survival of imatinib-treated by hematologic response. (Vertical bars indicate censored observations.)

15%, nearly 100% of advanced phase cases relapse despite continuation of imatinib at higher doses. When sensitive methods are used, BCR-ABL kinase domain mutations appear to be detectable in the majority of CML patients with acquired resistance to imatinib. A minority of patients exhibit genomic amplification of apparently non-mutated *BCR-ABL*. While it is possible that other mechanisms of resistance are contributing, future efforts to address imatinib resistance effectively must overcome the activity of BCR—ABL kinase domain mutants. The rapid rate of acquired resistance in the majority of advanced phase patients, coupled with the ability to occasionally detect kinase domain mutations prior to therapy, is supportive of a model in which mutant BCR-ABL isoforms exist at a variable rate prior to therapy.^{248–251} Thus, new strategies using combination therapies are currently being explored.

A phase I study of the combination of imatinib plus low-dose cytarabine was initiated in CML chronic phase patients who failed IFN- α .²⁵² In this study, 22 patients were enrolled into four cohorts. Imatinib was given daily and cytarabine was administered on days 14–28, with cycles being repeated every 28 days.

In this study, the maximally tolerated dose was 400 mg of imatinib daily with 20 mg/m² of cytarabine given for 2 out of every 4 weeks. Myelosuppression at the highest dose level necessitated dose reductions in all patients such that no patient remained on treatment with 600 mg plus 20 mg/m² of cytarabine. Other toxicities that were more common with the combination as compared with imatinib alone included nausea (77% grade 1/2 and 14% Grade 3/4), diarrhea (36% grade 1/2), fluid retention (73% grade 1/2), and skin rashes (45% grade 1/2 and 9% grade 3/4). Grade 3/4 fatigue and elevations in aminotransferases were seen in 2 of 22 (9%) patients. With a median duration of follow-up of 300 days, the CHR rate was 86% and the major cytogenetic response rate was 32%. This compares favorably with the results reported in phase I and II studies of imatinib alone.

The CML French Group has recently conducted a phase II study to determine the safety and tolerability of a combination of imatinib and cytarabine. Other endpoints were rates and duration of major and complete cytogenetic responses at 6 and 12 months, 6-months CHR rate, level of molecular residual disease in patients in complete cytologic remission, and overall survival.^{253,254} Treatment was administered on 28-day cycles for 12 months. Patients received a continuous administration of imatinib orally at a dose of 400 mg daily. Cytarabine was given on days 14–28 of each cycle at an initial dose of 20 mg/m²/day via sub-cutaneous injection, hydroxyurea being stopped at least 7 days before Imatinib. Thirty newly diagnosed CML patients in chronic phase (20 males and 10 females, median age 48 years, range 22–81 years) were recruited by 14 French centers. Adverse events were frequently observed, with grade 3 or 4 hematologic toxicities and non-hematologic toxicities in 53% (n=16) and 33% (n=10) of patients, respectively. However, the CHR and complete cytologic response rates compared favorably with those previously obtained with imatinib alone. The cumulative incidence of complete cytologic response at 12 months was 83%, and at 6 months 100% of the patients achieved CHR. It was concluded that the combination was safe and promising, given the high response rate.

As imatinib and IFN- α are the two most active non-transplant therapies available for CML patients, this combination is an obvious choice for testing. In vitro data demonstrate additive or synergistic antiproliferative effects of the combination of imatinib with IFN- α using *BCR-ABL*⁺ cell lines and in colony-forming assays using CML patient samples.^{243,244} Based on these data, two phase I/II pilot studies with this combination are in progress—one using regular IFN- α and the other pegylated (PEG) IFN- α . By December 2001, 49 patients with chronic phase CML had been entered into PISCES (PEGIntron and Imatinib Combination Evaluation Study), with a median age 52.5 years, and of whom 32 were newly diagnosed (<6 months since diagnosis). After 6 months of treatment, the major cytogenetic response rate was 73.3% (n=22) overall and 82.4% (n=14) in the newly diagnosed patients (with complete responses is 36.7% and 41.2%, respectively). Of the 22 patients achieving a major cytogenetic response, 59% were taking 200 mg imatinib plus 0.25 μ g/kg/wk PEG IFN- α (n=8), 200 mg imatinib plus 0.5 μ g/kg/wk PEG IFN- α (n=4), or 400 mg imatinib plus 0.5 μ g/kg/wk PEG IFN- α (n=1). All patients (n=35) achieved a CHR. Of 49 patients, 30 patients suffered grade 3/4 neutropenia within the first month on study while taking 400 mg imatinib plus 0.5 μ g/kg/wk PEG IFN- α . Grade 1/2 adverse events were common; flu-like symptoms/fatigue (40.8%), increased liver aminotransferases (transient) (36.7%), edema (34.7%), on headache (28.6%). Grade 3/4 adverse events were rare, with febrile neutropenia and joint/muscle pain being experienced by 6.1%.²⁵⁵ Additional studies are also evaluating the feasibility of administering imatinib before or after BMT.

SPiRiT study

The only known curative therapy for CML is allogeneic BMT, but the risks of this procedure are considerable and it is only available to a minority of patients with CML. Imatinib has produced remarkable results in the treatment of CML, although comparative data on long-term survival are not yet available.

In the light of recent evidence, patients and doctors increasingly consider imatinib to be the standard of care for newly diagnosed patients with CML. The

SPIRIT study is setting out to establish whether combining imatinib with other drugs or increasing the dose to 600 mg daily can improve survival when compared with imatinib 400 mg daily. It is a crucial long-term study attempting to improve the prognosis for patients with CML. SPIRIT is a phase III, multi-center, open-label, prospective randomized trial comparing imatinib alone versus imatinib plus cytarabine versus imatinib plus IFN- α in patients with chronic phase CML. Patients must be newly diagnosed (<6 months) and have been treated with only hydroxy-urea and/or anagrelide.

It is expected that 3000 patients will be entered into the study, initially from the UK (MRC), USA (SWOG, ECOG, and CALGB), and France (FIϕLMC). Additional countries may join later.

Practical aspects of treatment

For young patients, the best treatment is still a matter of uncertainty—essentially because a stem cell transplant can be offered as first-line treatment. However, the transplant-related mortality should be considered and balanced with other treatments, such as imatinib.

The first step after a diagnosis of CML is to calculate risk factors. The two prognostic scoring systems—the Sokal and Euro scores—were validated for patients treated with standard chemotherapy or IFN- α -based regimens. Because a recent update of the IRIS study has suggested that patients treated with imatinib may respond differently according to the Sokal risk scoring System, this score could be used in the context of imatinib therapy. However, for young patients who are suitable for stem cell transplantation, the Gratwohl score is the appropriate scoring system.

Tolerance appears to be poor in the elderly, especially in terms of possible neurologic and psychiatric side-effects, such as depression. Although there is no firm evidence supporting this conclusion, caution is recommended. While no drugs have been identified to limit the side-effects of IFN- α , an effort has been made to modify IFN- α itself to make its administration easier and to minimize side-effects. The pegylation of IFN- α provides a pharmacokinetic profile that allows for weekly injections and is expected to limit toxicity, efficacy being equal.

Although therapy with imatinib is generally well tolerated, it is not devoid of side-effects. Particularly common side-effects include myelosuppression, nausea, vomiting, edema, muscle cramps, arthralgias, diarrhea, and skin rashes. Elevated aminotransferases are observed less frequently, but occasionally necessitate discontinuance of therapy.

Myelosuppression is particularly common in CML patients treated with imatinib. In a phase II trial in chronic phase patients who had failed IFN- α , the protocol mandated interruption of therapy with imatinib for grade 3 myelosuppression. Using these guidelines, 25% of patients experienced grade 3 neutropenia (ANC $<1 \times 10^9/l$) and 16% developed grade 3 thrombocytopenia (platelets $<50 \times 10^9/l$). In addition, 8% of patients developed grade 4 neutropenia (ANC $<0.5 \times 10^9/l$). In advanced phase patients (accelerated and blastic phases), owing to the more life-threatening nature of the disease, treatment was not interrupted except for prolonged myelosuppression, and accordingly a higher percentage of patients developed grade 3 and 4 neutropenia and thrombocytopenia. In CML patients in blast crisis, almost 50% of patients developed grade 4 neutropenia. A number of deaths have been attributed to imatinib-induced myelosuppression, almost all of which were seen in advanced phase disease.²⁵⁶

Although myelosuppression can occur at any time during imatinib therapy, it generally occurs within the first 2–4 weeks in blastic phase patients, although slightly later in chronic and accelerated phase patients. Factors associated with myelosuppression besides advanced disease may include prior myelosuppression from IFN- α therapy or prior therapy with busulfan. The risk of developing myelosuppression may depend on the amount of residual normal hematopoiesis, and this may be negatively correlated with the above factors.

In CML patients in chronic phase, the recommended starting dose of imatinib is 400 mg. The complete blood count should be monitored weekly for the first month. Thereafter, the frequency of blood count monitoring depends on the stability and level of the blood count. Thus, if a patient's ANC falls to less than $1.5 \times 10^9/l$ and/or the platelet count to less than $100 \times 10^9/l$, the CBC should be monitored weekly. If blood counts are higher than these levels, monitoring can be reduced to every 2 weeks until 12 weeks of treatment is reached, and, depending on the stability of the counts, the frequency of monitoring can be lengthened to monthly. For patients with advanced phase CML, a starting dose of 600 mg of imatinib is recommended. The CBC should be monitored at least weekly, or more often, depending on the clinical situation. Higher doses of imatinib are currently being explored with the aim that higher doses may reinduce hematologic response or improve the cytogenetic resistance to standard-dose imatinib.^{257–259}

Imatinib is generally well tolerated, and the most common side-effects are mild and can be managed easily. However, therapy requires frequent and careful monitoring, particularly for myelosuppression, fluid retention, and hepatotoxicity, which are occasionally severe.

It has been estimated that in patients with overt clinical leukemia (at diagnosis or relapse), the total tumor burden represents approximately 10^{12} malignant cells

or more. When clinical remission is achieved ('hematologic response'), the number of remaining leukemic cells may be as high as 10^{10} – 10^{11} . Therefore, the achievement of a hematologic response represents only one step in a continuum in the actual response to therapy. For this reason, the potential value of estimating the level of minimal residual disease (MRD), or the amount of persisting leukemic cells was recognized as early as the start of the 1980s.

Up to now, for patients achieving a CHR, the only tool that was routinely available was monitoring the cytogenetic response using standard karyotyping methods. The clinical value of achieving a cytogenetic response with IFN- α therapy has been strongly established, as discussed above. However, cytogenetic analysis is limited by the low number of cells analyzed (usually 20–30) and its consequent low sensitivity of about 5%, the need for dividing cells (excluding potential Ph⁺ 'quiescent' cells or cells with a low proliferative potential), and the need for invasive bone marrow aspirates. On the other hand, cytogenetic analysis is the only method that allows the detection of additional chromosomal abnormalities ('clonal evolution'), which is considered by some investigators to be suggestive of disease acceleration.

For these reasons, a number of techniques have been developed over the last 15 years to better monitor MRD, particularly in patients after BMT. Fluorescence in situ hybridization (FISH) reverse transcriptase PCR (RT-PCR), and quantitative PCR are the usual techniques for monitoring MDR.

Chromosome banding analysis is still the gold standard for the diagnosis and monitoring of CML. This technique is able to detect chromosomal abnormalities in addition to the Ph chromosome that may impact the outcome of the patients. However, the sensitivity of chromosome analysis is too low in good responders to detect residual disease. Hypermetaphase FISH (HM-FISH) is a new method that combines a modified preparation of metaphases with FISH. Recent data have confirmed the high sensitivity of this test compared with chromosome banding. Nested RT-PCR is more sensitive than HM-FISH, and is the method of choice for the detection of MRD after allogeneic BMT.

Chronic myeloid disorders excluding CML

Tiziano Barbui, Guido Finazzi, and Giovanni Barosi

Introduction

Chronic myeloproliferative disorders (MPD) are clonal diseases originating in a pluripotential hematopoietic stem cell. The clonal expansion results in increased and abnormal hematopoiesis and produces a group of interrelated syndromes, classified according to the predominant phenotypic expression of the myeloproliferative clone. Excluding chronic myeloid leukemia (CML), which is characterized by peculiar biological and clinical features and is described in Chapter 41, MPD include polycythemia vera (PV), essential thrombocythemia (ET), and myelofibrosis with myeloid metaplasia (MMM). Due to the underlying defect, which involves a common hematopoietic precursor cell, 'hybrid' phenotypes may be discovered at diagnosis and transitions among the syndromes may occur during the course of the disease. Nevertheless, the clinical course and management of the various syndromes is different, and this makes it essential to adopt clearly defined diagnostic criteria. In this chapter, we will briefly review the pathophysiological background, diagnostic approach, and natural history of MPD other than CML with the aim of offering the necessary background for up-to-date treatment.

Polycythemia vera

Pathophysiology

PV is an MPD characterized by generalized marrow hyperplasia with prevalent overproduction of the erythroid cell line that is independent of the physiological growth factor erythropoietin (EPO). This is manifested *in vitro* by 'spontaneous' colony formation in the absence of exogenous EPO. The molecular bases for these alterations are being actively studied, but still remain poorly understood.^{1,2} An interesting finding from the molecular cloning of the EPO receptor (EPOR) made it possible to formulate the hypothesis that PV is caused by a mutation of the *EPOR* gene. Actually, at least two different mutations of *EPOR* have been found in cases of congenital polycythemia,^{3,4} but the search for these mutations has failed to reveal any abnormality in the majority of patients with familial erythrocytosis² or with PV.⁵

There are data showing that erythroid progenitors are hypersensitive to other growth factors, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin-3 (IL-3),⁶ insulin-like growth factor I (IGF-I),⁷ and thrombopoietin (TPO).⁸ This observation would seem to fit better with a more generalized intracellular defect (e.g. a shared signaling pathway) than with a selective receptorial defect. Moliterno et al reported that platelets from patients with PV displayed impaired tyrosine phosphorylation in response to TPO stimulation, whereas the response to thrombin remained intact.⁹ The inability to transduce the TPO signal was due to a dramatic reduction or a complete absence of the TPO receptor, c-Mpl, in 34 of 34 PV patients. However, it is at present not clear how a loss of c-Mpl expression could contribute to the growth factor hypersensitivity of PV cells.

Interestingly, PV erythroid precursor cells express the anti-apoptotic protein Bcl-x_L to a much higher proportion than normal precursor cells.¹⁰ In addition, in PV, more mature cells, which normally show no BclX_L expression, still express high levels of the protein. Hematopoietic growth factors, such as IGF-I, act in part by suppressing apoptosis.¹¹ Thus, the observed growth factor hypersensitivity of PV cells could result from an intrinsic protection from apoptosis, thereby requiring less protection through growth factor stimulation.

Of particular interest is the cloning of PRV-1, a novel member of the uPAR receptor superfamily, which is overexpressed in granulocytes from patients with PV, but is not detectable in normal control granulocytes.¹² Moreover, PRV-1 is not expressed in granulocytes from patients with secondary erythrocytosis, whereas a more heterogeneous pattern was observed in patients with ET. Although PRV-1 is not expressed in

resting granulocytes from normal controls, stimulation of these cells with granulocyte colony-stimulating factor (G-CSF) induces PRV-1 expression. Further studies are ongoing to establish whether this novel hematopoietic receptor may be useful in the differential diagnosis of PV and whether it may play a role in the pathophysiology of this MPD.

Even though pathognomonic chromosomal abnormalities have not been described so far, a deletion of the long arm of chromosome 20 can be found in 10–15% of patients with PV at diagnosis.¹³ This abnormality does not seem to be restricted to this MPD phenotype, but is also present in patients with myelofibrosis or myelodysplastic syndromes. The fact that the 20q deletion is encountered in a spectrum of MPD suggests that this cytogenetic abnormality may mark the site of a tumor suppressor gene, or genes, possibly involved in the regulation of normal multipotent hematopoietic progenitors.¹⁴

Diagnostic criteria

Several criteria have been used to establish a diagnosis of PV, with an elevated red blood cell mass (RCM) being the most important conventional parameter for distinguishing between true and apparent polycythemia. Secondary causes have to be ruled out by using previously formulated guidelines and algorithms. The Polycythemia Vera Study Group (PVSG) criteria¹⁵ (Table 42.1) were initially formulated to enrol a uniform patient population with overt PV for studies on therapeutic intervention. Consequently, if these stringent criteria are adopted, patients in the initial stages of the disease may be excluded from this diagnosis. For such individuals, the new and more specific techniques include cytogenetic studies, endogenous colony formation and serum EPO assay.¹⁶ A revision of the PVSG criteria that takes into account these latter findings has been recently proposed by Pearson et al¹⁷ (Table 42.2) and is based on the following considerations:

Table 42.1 Polycythemia Vera Study Group diagnostic criteria for polycythemia vera¹⁵

A1. Raised red cell mass: Male >36 ml/kg Female >32 ml/kg	B1. Thrombocytosis: platelet count >400×10 ⁹ /l
A2. Normal arterial oxygen saturation >92%	B2. Leukocytosis >12×10 ⁹ /l (no fever or infection)
A3. Splenomegaly	B3. Raised neutrophil alkaline phosphatase (score >100) or raised vitamin B ₁₂ (>900 ng/l) or raised unsaturated vitamin B ₁₂ -binding capacity (>2200 ng/l)
Diagnosis of polycythemia vera is acceptable if the following combinations are present: A1+A2+A3 or A1+A2+any two from category B	

- The PVSG criteria included documenting a raised RCM based on normal ranges expressed in terms of milliliters per kilogram total body weight. This method is considered inappropriate for obese individuals, since adipose tissue is relatively avascular and does not contribute proportionally to the blood volume. In these cases, the presence of an absolute polycythemia in the initial phases can go undetected using the PVSG criteria. A more precise method of RCM measurement might be the use of formulae based on height and weight.¹⁸ The proposed normal range for each prediction is +25% of the mean value, which includes 98% and 99% of normal males and females, respectively. Therefore, patients with a RCM more than 25% above their mean normal predicted value should be regarded as fulfilling the criterion of increased RCM.
- Cytogenetic abnormalities were not part of the list of PVSG criteria, but can now be identified in up to 20% of PV patients at diagnosis.¹³ The most common changes are trisomies 1, 8, and 9, and deletions of 13q and 20q. The presence of karyotypic defects does not appear to affect prognosis,¹⁹ but could be regarded as a major diagnostic criterion of PV; however, it should be borne in mind that an abnormal karyotype (e.g. a balanced translocation) can be found in less than 1% of phenotypically normal individuals.
- Patients with PV, but not those with secondary erythrocytosis, are able to generate spontaneous erythroid colonies without the addition of EPO to the culture medium. The EPO endogenous

Table 42.2 modified criteria for the diagnosis of polycythemia vera¹⁷

A1. Raised red cell mass (>25% above mean normal predicted value)	81. Thrombocytosis: is: platelet count $>400 \times 10^9/l$
A2. Absence of causes of secondary polycythemia	B2. Neutrophil leukocytosis (neutrophil count $>10 \times 10^9/l$)
A3. Palpable splenomegaly	B3. Splenomegaly on isotope or ultrasound scanning
A4. Clonality marker (e.g. abnormal marrow karyotype)	B4. Characteristic BFU-E growth or reduced serum erythropoietin
Diagnosis of polycythemia vera is acceptable if the following combinations are present: A1+A2+A3 or A4 or A1+A2+any two from category B	

colonies (EEC) assay can now be considered reliable and reproducible,²⁰ but it still remains a complex and time-consuming test that is not readily available in most laboratories. Besides PV, EEC can also be observed in patients with apparently idiopathic thrombocythemia²¹ and in some cases of CML or erythroleukemia.²² The current role of the EEC assay in the diagnostic strategy of PV is to recognize incomplete or unusual presentations of the disease, for example in patients with rare sites of thrombosis who do not fulfill conventionally established criteria for a PV diagnosis.

- In vivo and in vitro bioassays, radio immunoassays (RIA), enzyme-linked immunoassays (ELISA), and immunoradiometric assays (IRMA) have been applied to measure serum EPO levels. These immunological techniques are specific, sensitive, reproducible, and easy to perform, and published studies show that normal individuals have values ranging from 6 to 32 IU/l. At diagnosis of PV, serum EPO levels are reduced or in the lower normal range, whereas normal or raised amounts are found in secondary polycythemia.^{23,24} For this reason, EPO determination has been used in the differential diagnosis of PV, but the wide overlapping of results between PV and normal or secondary polycythemia patients limits the diagnostic value of this test, which at best should be considered among the minor criteria for PV diagnosis.

The modified criteria for diagnosis of PV represent a proposal that has the merit of summarizing the current state of knowledge in this field, and should also allow recognition of patients with an early disease presentation. Nevertheless, unusual cases with difficult-to-interpret clinical and laboratory characteristics still represent a diagnostic problem. If asymptomatic, these patients should be followed carefully and unnecessary therapeutic interventions avoided; if they present with serious symptoms, decisions about treatment should be made on the risk/benefit principle.

Epidemiology and natural history

PV is a rare disease, the yearly incidence in Western Europe and the USA being approximately 5–16 cases per 1 million population.²⁵ The incidence was found to be higher in Jews and lower among Blacks and in Japan. However, these figures are probably underestimates in view of the difficulty in recognizing patients in the early stage of disease when only conventional criteria for diagnosis are applied.

PV usually appears during middle age and is slightly more prevalent in males. In a study carried out by the Gruppo Italiano Studio Policitemia (GISP),²⁶ the median age at diagnosis was 60 years in men and 62 years in women and the ratio of men to women was 1.2:1. Only a small number of PV patients have been reported in childhood, and these cases deserve careful investigation for the possible diagnosis of familial polycythemia, a rare but distinct nosological entity.²⁷

PV has a natural history of slow progression into subsequent clinical and hematological phases. Its onset may be insidious, and symptoms may precede an overt diagnosis by years. During this 'developmental phase', patients may be asymptomatic or may present thrombotic complications, which are observed in up to 14% of cases before diagnosis of PV. In up to 20% of patients, thrombosis is the presenting symptom of disease; cerebral ischemia accounted for 70% of arterial thromboses at diagnosis in our study, and was as prevalent as myocardial infarction (30%) before diagnosis of PV.²³ These findings emphasize the importance of early diagnosis, and call for the implementation and validation of the new techniques discussed above. The 'polycythemic phase', clearly defined by conventional diagnostic criteria, may be either asymptomatic or characterized by thrombotic

events of variable severity that also depend on the concomitant presence of other risk factors for vascular disease. Bleeding complications are less frequent than thrombosis, and are thought to account for 15–30% of cases. The ‘spent phase’ is the final stage, characterized by anemia, leukopenia, thrombocytopenia, and a leuko-erythroblastic peripheral blood picture. This transformation can be observed in up to 20% of PV patients after an average interval of 10 years from diagnosis, and its outcome is very poor, since no effective treatment is available. An attempt to improve prognosis was carried out in a small series of patients with transformed PV who underwent allogeneic bone marrow transplantation. Even though the results seem promising, this procedure should be considered only in selected young patients.²⁸

Current treatments for PV have dramatically improved the natural history of patients in the pretransformed stages. Thus, the median life-expectancy has increased from 6–18 months in untreated patients to over 10 years in those receiving cytoreduction and antithrombotic drugs. Unfortunately, we now have to deal with complications chiefly related to the cytotoxic therapy, which are among the leading causes of death in these patients. The impact of the therapeutic guidelines provided by the PVSG on the natural history of PV has been investigated by the GISP in a retrospective cohort study of 1213 patients in Italy through an analysis of overall survival and incidence of thrombotic and neoplastic complications.²⁶ The cumulative median duration of survival exceeded 15 years, with an overall mortality rate of 2.94 deaths/100 patients per year. The age- and sex-standardized mortality rate was 1.7 times greater than that of the general Italian population. This finding contrasts with a previous study suggesting that expected survival in PV patients did not differ from the survival of a control sample.²⁹ The most frequent causes of death were thrombosis (30% of cases) and cancer (15% of patients with acute leukemia and 15% with other cancers). These complications were analyzed in detail (Tables 42.3 and 42.4). The overall rate of fatal and non-fatal thrombotic events was 3.4 per 100 patients per year. The incidence of thrombosis increased significantly with age (<40 years, 1.8%; 40–57 years, 2.8%; 60–69 years, 4.0%; >70 years, 5.1% per year; $p<0.001$) and with a history of thrombosis (24.6% versus 17.3%; $p=0.001$), confirming previous data from the PVSG.¹⁵ The risk of death for patients who had previously received radiophosphorus or alkylating or non-alkylating myelosuppressive agents was four times greater than that of those who had received phlebotomy or other pharmacological treatments (6.7% versus 1.6%; $p=0.06$). Thus, cytoreduction favorably affects the incidence of thrombotic events, but this treatment may be associated with an increased risk of secondary neoplasm. A reevaluation of the best approach with available drugs is therefore needed to improve the therapeutic profile.

Table 42.3 Fatal and non-fatal thrombotic events ($n=254$) during follow-up in 1213 patients with polycythemia vera

Type of complication	No. of non-fatal events ^a	No. of fatal events ^a
Arterial thrombosis	101 (50.5)	44 (81.5)
Myocardial infarction	28 (14.0)	27 (50.0)

Total	200 (100)	54 (100)

^a percentages in parentheses.

Therapy

At present, there is no known treatment that eradicates the abnormal clone. Consequently, therapy is aimed at reducing the incidence of vascular complications and limiting the progress of the myeloproliferative process. Available information for therapeutic recommendations in PV derives from a very limited number of randomized clinical trials and from a series of prospective and retrospective studies that have described the natural history of PV patients and indirectly evaluated the effect of different strategies on the main outcomes of the disease.³⁰ For practical purposes, we will discuss the results of strategies intended to reduce RCM and myeloid hyperplasia

Table 42.4 Causes of death in 192 patients with polycythemia vera

Cause of death	No. of patients ^a
Cardiovascular	70 (36.4)
Arterial thrombosis	46 (24.0)
Myocardial infarction	14 (7.3)
Sudden death	15 (7.8)
Ischemic stroke	17 (8.8)
Venous thromboembolism	10 (5.2)
Cerebral sinus thrombosis	2 (1.0)

^a Percentages in parentheses.

(‘cytoreductive’ therapy) separately from those aimed at reducing the risk of thrombosis through the use of antithrombotic drugs.

Cytoreduction

In the first study by the PVSG (the 01 trial),¹⁵ 431 patients were randomized to one of the following treatments: (a) phlebotomy alone; (b) phosphorus-32 ³²P plus phlebotomy, and (c) chlorambucil plus phlebotomy. Patients treated with phlebotomy alone had an excess mortality within the first 2–4 years, principally due to thrombotic complications. In contrast, those randomized in the two myelosuppression arms of the study suffered from an increased rate of acute leukemia and other malignancies (non-Hodgkin lymphomas (NHL) and neoplasms of the gastrointestinal tract and skin), while the spent phase, with myelofibrosis and myeloid metaplasia, had virtually identical incidence in the three arms. Overall, the median survival was 8.9 years for patients receiving chlorambucil, 11.8 years for those receiving ³²P, and 13.9 years for those undergoing phlebotomy only. The conclusion of this study was that myelosuppression could reduce the incidence of thrombosis and that chlorambucil had to be replaced by a new agent.

The search for a non-mutagenic myelosuppressive agent led the PVSG to investigate hydroxyurea (HU). This antimetabolite prevents DNA synthesis by inhibiting the enzyme ribonucleoside reductase. Because of its non-alkylating mechanism of action, it has been assumed that it would not be leukemogenic or carcinogenic in patients with PV. The PVSG experience with HU in PV was subsequently updated.³¹ Fifty-one patients were followed for a median and a maximum of 8.6 and 15.3 years, respectively. The incidence of acute leukemia, myelofibrosis, and death were compared with the incidence in 134 patients treated with phlebotomy only in the PVSG-01 protocol. There were no statistically significant differences in any of the three parameters, although the HU group showed a tendency to more acute leukemias (9.8% versus 3.7%), less myelofibrosis (7.8% versus 12.7%), and fewer total deaths (39.2% versus 55.2%).

In a randomized clinical trial carried out in France, 292 PV patients aged below 65 years were given HU or pipobroman and were followed from 1980 until 1997.³² Pipobroman is a bromide derivative of piperazine with a chemical structure related to that of the alkylating agents but whose mechanism of action also involves metabolic competition with pyrimidine bases. No significant differences between the two groups were observed in overall survival, rate of thrombotic complications, and incidence of secondary leukemia (about 5% at the 10th year and 10% at the 13th year). A significant increase in risk of progression to myelofibrosis was seen in the patients treated with HU (26 cases) compared with those treated with pipobroman (3 cases).

Another important issue regards patients who become resistant or develop significant side-effects while taking HU. Various studies, mainly in ET, showed that substituting either alkylating agents or ³²P for HU greatly increases the incidence of leukemic transformation.^{33–35} Thus, some anxiety remains about the leukemogenic potential of HU, and this has prompted trials with other agents thought to be less toxic, such as interferon- α or anagrelide (described later in this chapter under ET).

Recombinant interferon- α (IFN- α) is an active agent in PV with antiproliferative activity that is virtually devoid of mutagenic risk.³⁶ The rationale for the use of this drug includes its myelosuppressive activity and its ability to antagonize the action of platelet-derived growth factor (PDGF), a product of megakaryopoiesis that initiates fibre-blast proliferation. This observation would suggest that IFN- α could, theoretically, modify the natural history of PV and reduce or delay the development of myelofibrosis. IFN- α has been evalu

ated in some phase II studies.³⁷ The overall results indicate that RCM can be controlled within 6–12 months in up to 70% of cases, as seen by a reduction in the need for phlebotomy. In addition, IFN- α can reverse the associated splenomegaly, leukocytosis, and thrombocytosis in the majority of patients, and is particularly effective for the treatment of generalized pruritus. Side-effects are often a major problem with this drug, causing therapy withdrawal in approximately one-third of patients. Signs of chronic IFN- α toxicity include weakness, myalgia, weight and hair loss, severe depression, and gastrointestinal and cardiovascular toxicity.

These new drugs are of particular interest for the treatment of younger patients with PV, since their prolonged use could theoretically be devoid of leukemogenic risk. However, it should be emphasized that to date the demonstration of their efficacy is based only on secondary endpoints, such as reduction of RCM and platelet count. Their capacity to prevent vascular complications and secondary malignancies and, in turn, to improve the survival of PV patients remains to be established in appropriate clinical trials.

Antithrombotic therapy

The use of aspirin or other antiplatelet agents in patients with PV and other MPD remains controversial, and the decision rests primarily on the clinical picture.³⁰ In fact, laboratory tests of platelet function (e.g. bleeding time and platelet aggregation studies), which have been generally unreliable in predicting the risk of bleeding and thrombosis,³⁸ are of little help.

Aspirin is generally recommended in PV patients who have had recurrent thrombotic complications, particularly those with digital or cerebrovascular occlusive syndromes. On the other hand, the risk of serious bleeding with aspirin use may be elevated in patients with prior histories of bleeding problems, especially of the gastrointestinal tract. Uncertainty reigns for those patients without a clear-cut prior history of bleeding or thrombosis, for whom the benefits and risks of aspirin or related drugs have not yet been evaluated.

The first trial in this field was carried out by the PVSG.³⁹ They randomized 163 PV subjects to be treated with ³²P or phlebotomy associated with aspirin 900 mg/day plus dipyridamole. After a median follow-up of 1.6 years, six bleeding episodes (mostly gastrointestinal) and seven thrombotic events were observed in the group assigned to antiplatelet therapy, while two thromboses and no bleeding episodes were observed in the other group. For this reason, the study was discontinued and the authors concluded that antiplatelet agents were both ineffective and potentially dangerous in PV patients. However, neither the excess of thrombosis nor that of bleeding was statistically significant, due to the low number of subjects recruited in the trial, and either mere chance or even a moderate imbalance between groups could have been responsible for the results. In addition, the excess of gastrointestinal bleeding was most likely related to the high dose of aspirin used in that study.

A new avenue for exploring the role of aspirin in preventing thrombosis in PV patients would be to decrease the dosage, since lower aspirin doses (30–250 mg/day) are thought to be at least as effective as higher ones and to be better tolerated.⁴⁰ With this in mind, the GISP completed a pilot study aimed at assessing the safety of low-dose aspirin (40 mg/day) in PV patients; 326 patients were considered and criteria for exclusion were clear indications (e.g. previous arterial thrombosis) for or against (e.g. gastrointestinal bleeding) aspirin. Thus, 112 (34%) patients were included and randomized to low-dose aspirin or placebo and were followed for more than 12 months. In this pilot study, no differences in sideeffects or adverse events were apparent, showing the feasibility of a large-scale evaluation of low-dose aspirin in PV patients.⁴¹

Current therapeutic recommendations and future directions

As a general rule, recommendations about the care of an individual patient outside the rigid criteria of clinical trials should derive from the best available evidence combined with clinical experience and practice. As briefly reviewed above, a sound scientific basis for making therapeutic decisions in PV patients is very limited due to the paucity of randomized clinical trials, and this causes uncertainty for the clinician when he or she must select the best available treatment for an individual patient.⁴²

The possible leukemogenicity associated with the prolonged use of cytotoxic therapy suggests differentiating treatment primarily according to age.¹⁵ In patients aged under 50 years, phlebotomy alone should be the choice, with the goal of maintaining the hematocrit below 46%. In patients over 70 years old, myelosuppressive therapy is indicated, and ³²P is probably the best therapeutic option. In patients between the ages of 50 and 70 years, there is room for individualization. The administration of HU seems to be justified in the case of frequent phlebotomies or when a previous history of thrombotic events confers a high probability of recurrence. The addition of lowdose aspirin or related drugs should always be considered in the case of cerebrovascular, coronary, or peripheral arterial ischemia.³⁰ Warfarin should be preferred in patients with recurrent venous thrombosis, even though a protective role for antiplatelet drugs cannot be excluded even in vascular occlusions of the venous tree.^{43,44} These guidelines are shared by the majority of experts in this field,^{25,45,46} but should be

followed with caution in the light of a series of relevant considerations.

First, there are methodological limits to the PVSG-01 trial¹⁵ that represents the cornerstone of the above recommendations. For instance, it was reported that 69 out of 156 patients died in the ³²P group (44%) and 43 out of 132 (32%) died in the group allocated to phlebotomy. Since this difference was not statistically significant, the PVSG conclusion was that survival was the same in the two groups. However, the 28% relative reduction in mortality is not trivial, and one might wonder whether phlebotomy prolongs survival with respect to myelosuppression and whether the trial had the statistical power necessary to detect this potential advantage.⁴⁷

Second, since the major problem with phlebotomy is patient acceptance of this procedure, one could argue about the actual feasibility of this treatment. This was assessed in a cohort of 75 patients randomized to receive only phlebotomy in the context of the PVSG-01 protocol by Najean et al,⁴⁸ who reported that phlebotomy had to be stopped after 9 years in almost all patients. The main reasons for this poor compliance were patient refusal, an increase in platelet count, or the development of cardiovascular problems. It is obvious that this observation weakens the conclusions reached in the phlebotomy arm of the PVSG-01 study.

Third, despite concerns about potential leukemogenicity, HU remains the myelosuppressive drug of choice. Unfortunately, at present, no other drugs have shown convincing evidence of efficacy on hard clinical endpoints, such as major thrombosis or survival. We advocate the organization of clinical trials aimed at assessing the role of the new drugs IFN- α or anagrelide in those patients most likely to be exposed to cytoreductive drugs for a long period, such as younger individuals, or in those who become resistant to HU.

Finally, a scientific answer about the efficacy and safety of low-dose aspirin in PV is expected from a large-scale, placebo-controlled clinical trial that is currently ongoing (European Collaboration on Low-Dose Aspirin—the ECLAP study). Until this trial has been completed, we recommend using aspirin in microvascular disturbances of PV, such as erythromelalgia, and in patients with a clear history of arterial thrombosis. This drug might be the cause of severe gastrointestinal bleeding in those individuals with previous episodes of bleeding, and should be considered with great caution in such cases.

Essential thrombocythemia

Pathophysiology

ET is a chronic myeloproliferative disorder characterized by sustained elevation of the platelet count, bone marrow hyperplasia, excessive proliferation of megakaryocytes, and a high incidence of thromboembolic complications. It has generally been assumed that ET is a clonal disease state. This was first demonstrated by Fialkow et al,⁴⁹ using the X-linked glucose-6-phosphate dehydrogenase (G6PD) locus as a cell marker for clonality. However, more recent studies using X-linked gene techniques such as the HUMARA polymorphism assay⁵⁰ showed a much more heterogeneous picture. In an elegant study of 46 patients classified as having ET on the basis of the PVSG diagnostic criteria,⁵¹ HUMARA analysis and other X-chromosomal inactivation assays revealed polyclonal hematopoiesis in 13 patients (28%), clonal hematopoiesis in 10 (22%), and an uninterpretable pattern in 23 patients (50%).⁵² Patients with a polyclonal pattern had fewer thrombotic complications in comparison with those with monoclonal hematopoiesis. Others have confirmed this clinical correlation,⁵³ although the retrospective analysis and the small number of patients hitherto evaluated preclude any definite conclusions. These studies have raised serious doubts on the previous understanding of ET as a universally clonal disorder, and emphasize the considerable heterogeneity of this disease.⁵⁴

The concept of ‘polyclonal’ ET suggests that persistent thrombocytosis may be due to elevation of thrombopoietin (TPO) or other thrombopoietic cytokines. However, serum TPO levels in ET are usually normal or only slightly elevated.⁵⁵ Furthermore, circulating TPO levels in ET are not significantly different from those in reactive thrombocytosis.⁵⁶ Similarly, mutations in either the *TPO* gene⁵⁷ or its receptor (*c-mpl*)⁵⁸ have not been identified in patients with sporadic ET. In contrast, some familial forms of thrombocytosis are associated with dominant mutations of the *TPO* gene (5'-untranslated regions of the *TPO* mRNA involving a donor splice site) that result in enhanced TPO production.^{59–61} Several possibilities have been put forward to explain the ‘inappropriately’ normal or elevated TPO levels in ET. These include ineffective TPO clearance because of markedly reduced c-Mpl expression in platelets and megakaryocytes,⁶² increased bone marrow stromal production of TPO,⁶³ and increased rate of TPO catabolism.⁶⁴ The clinical relevance of increased circulating TPO concentration and/or reduced c-Mpl expression is uncertain.⁶⁵ In a recent study in patients with ET, a weak heterogeneous expression pattern of c-Mpl in megakaryocytes correlated with thrombotic risk,⁶⁶ but this finding remains to be confirmed.

Diagnostic criteria

The criteria generally accepted for the diagnosis of ET are those suggested by the PVSG⁵¹ and subsequently updated.³³ They are mainly ‘exclusion’ criteria, developed to rule out other MPD with variable degrees of

thrombocytosis, as well as reactive thrombocytosis secondary to chronic inflammatory diseases, malignancy, splenectomy, and iron deficiency. Several investigators have tried to improve the diagnostic criteria for ET by identifying positive markers of the disease. These include spontaneous megakaryocyte or erythroid colony formation, abnormal cytogenetics, and bone marrow histology.

Spontaneous colony formation

The presence of spontaneous erythroid colony growth and/or colony formation of megakaryocyte progenitors is a strong indicator of ET. The diagnostic value of this test seems to be better when cultures containing plasma or serum are used. Spontaneous colony formation from bone marrow megakaryocyte progenitors was investigated in 24 patients with ET and 20 with reactive thrombocytosis using an in vitro assay containing 30% plasma.⁶⁷ Virtually all ET patients, but none of those with reactive thrombocytosis showed spontaneous bone marrow megakaryocyte colonyforming units (CFU-Meg). However, another study⁶⁸ demonstrated that a serum-free culture technique, combined with sensitive positive identification of CFU-Meg-derived cells, failed to discriminate between ET and reactive thrombocytosis.

Cytogenetics

Non-stimulated metaphases obtained from marrow aspirates should be examined for cytogenetic abnormalities. Karyotypic analysis is primarily important in order to exclude the presence of the Philadelphia (Ph) chromosome, the genotypic hallmark of chronic myeloid leukemia (CML). There is some controversy over the proper classification of thrombocytosis associated with the Ph chromosome or its molecular equivalent, the *BCR-ABL* fusion gene.⁶⁹ However, most authors agree that such cases are not clearly distinguishable from CML and should be provisionally classified as CML.⁶⁵ Definite cytogenetic abnormalities are rare in Ph- ET, being observed in only 5% of patients at diagnosis. Karyotypic abnormalities generally arise upon transformation of ET to acute leukemia.¹³ Deletions or elongations of the short arms of chromosomes 1, 2, 5, 17, 20, and 21 are the most frequent defects.¹³ For the majority of these karyotypic abnormalities, the gene or genes responsible for the clinical phenotype in ET are not yet known.

Bone marrow histology

It has been suggested that ET can be positively diagnosed by careful, quantitative examination of the bone marrow biopsy.^{70,71} Typical clustering of enlarged megakaryocytes with multilobulated nuclei has been advocated to represent the hallmark feature of the disease. The histological background of hematopoiesis in ET features a discrete pattern of minimal or no prominence of erythropoiesis, no change in granulopoiesis, almost no fibrosis, and a reduction of stainable iron. A detailed evaluation of bone marrow features may also help to distinguish 'true' ET from the initial stages of idiopathic myelofibrosis⁷¹ or myelodysplasia.⁷⁰ 'Early' myelofibrosis is characterized by increasing cellularity with prominent neutrophil granulopoiesis, borderline to slight reticulin fibrosis, and pronounced abnormalities of megakaryocyte differentiation, including hyperchromasia and marked nuclear-cytoplasmic deviation. Notably, patients with these morphological features frequently develop an overt myelofibrosis and have a significantly worse life-expectancy. However, an experienced observer and a well-standardized procedure are required to diagnose ET by examination of the bone marrow biopsy. This is one of the major limits of the diagnostic classifications of ET based on bone marrow histology.

In summary, positive assays for establishing the presence of ET are promising but still insufficiently standardized to be recommended for diagnostic use in all patients. Despite current limitations, this is an expanding field and it is likely that in due course these tests will complement or substitute the timehonoured PVSG criteria.

Prognostic factors for bleeding and thrombosis

The search for factors possibly associated with an increased risk of hemostatic complications in ET patients has formed the object of several studies (reviewed in reference 72). However, one limitation on the available information is that these studies are almost always retrospective and the data are generated by evaluation of a relatively small number of patients. This may explain the wide range in hemorrhage (13–63%) and thrombosis (8–84%) observed in cases reported in the literature.

Bleeding

Risk factors predicting major bleeding and thrombosis were specifically looked for in a cohort study of 100 consecutive patients with ET diagnosed between 1978 and 1988 in our department at the Ospedali Riuniti, Bergamo, Italy and subsequently checked at least every 2 months.⁷³ The patients received busulfan when platelets exceeded $1000 \times 10^9/l$ and/or when a major thrombotic or hemorrhagic event occurred. Only four major bleeding episodes requiring hospital admission or blood transfusion (gastrointestinal tract and knee hemarthrosis) were registered (0.33%/ patient-year (pt-yr)) in that study. Due to the low incidence of major hemorrhagic complications, any prognostic evaluation would be uncertain. In addition, there was no correlation between the broad array of specific structural, biochemical, and metabolic platelet defects and bleeding.³⁸ Thus, platelet

functional tests are not considered good indicators for predicting the hemostatic disturbances in ET. In some particular cases, such as those with platelet counts above $1500 \times 10^9/l$, a decrease in high-molecularweight multimers of von Willebrand factor may be detected and this might be associated with bleeding symptoms.⁷⁴

Thrombosis

At variance with a low incidence of major bleeding, 20 thrombotic episodes (17 arterial and 3 venous) were observed (6.6%/pt-yr) in our study.⁷³ When the incidence of thrombosis was analyzed in individuals at different ages, a rate of 1.7%/pt-yr was found in patients younger than 40 years, versus 6.3%/pt-yr in those aged between 40 and 60 and 15.1%/pt-yr in subjects aged over 60 ($p < 0.001$ versus patients older than 40). The rate of thrombosis also increased progressively in relation to previous history of vascular occlusive episodes (from 3.4–31.4%/pt-yr), despite the fact that all these patients were treated with cytoreductive drugs (Table 42.5). Thus, a category of ET patients at increased risk for thrombosis was identified, namely those over 60 years old or with a history of thrombotic events.

Clinical course of untreated, lower-risk ET patients

Withholding chemotherapy could be justifiable in asymptomatic ET patients under 60 years of age with a platelet count below $1500 \times 10^9/l$, due to their lower risk of developing major bleeding or thrombotic events.

The natural history of untreated, 'lower-risk' ET patients was evaluated in a prospective, controlled study.⁷⁵ In this study, 65 ET patients aged below 60 years, with no history of thrombosis or major bleeding and a platelet count below $1500 \times 10^9/l$ were compared with 65 age- and sex-matched normal controls. Patients were not treated with cytoreductive therapy until the occurrence of major clinical events. After a median follow-up of 4.1 years, the incidence of thrombosis in patients and controls was 1.91 and 1.5%/pt-year, respectively. The age- and sex-adjusted risk rate ratio was 1.43 (95% confidence interval 0.37–5.4). No major bleeding was observed. This study indicates that the thrombotic risk of young, asymptomatic ET patients is not significantly increased compared with the normal population. These findings have been confirmed in another Italian cohort of 28 patients under 40 years of age followed for a median of 4 years.⁷⁶ However, it should be recognized that the number of patients included in these studies is relatively small and further data from large, currently ongoing clinical trials are warranted.

Table 42.5 Risk factors for thrombosis in 100 patients with essential thrombocythemia

Risk factor	Relative risk ^a	<i>P</i>
Age (years) ^b	3.9 (0.7–21.5)	NS
40–60	103(2.1–51.5)	<0.001
>60		
Previous thrombosis	13.0 (4.1–41.5)	<0.0005
Smoking	0.9	NS
Hyperlipidemia	0.5	NS
Hypertension	0.95	NS

^a 95% confidence intervals in parentheses.
^b Reference category: age <40 years.

Thrombotic deaths have been reported occasionally in young ET patients,⁷⁷ but in general they seem very rare in 'lower-risk' subjects and there are no data showing that fatalities can be prevented by starting cytoreductive drugs early. This point should be considered in the risk/benefit evaluation of cytotoxic, potentially leukemogenic, drugs.

Management of high-risk ET patients: benefits and risks

Hydroxyurea

HU has emerged as the treatment of choice in patients with ET because of its convenience in use, its efficacy, and its low acute toxicity.⁷⁸ The drug is given at an initial dose of 15–20 mg/kg/day, with adjustments to maintain maximal reduction of platelet values without excessive lowering of white blood cell (WBC) counts. Continuous treatment with HU has been shown to reduce the platelet count to below $500 \times 10^9/l$ within 8 weeks in 80% of patients. Hematopoietic damage leading to leukopenia and megaloblastic anemia is the major short-term toxic effect of HU. Leukopenia is dose-related and quickly reversible if the drug is discontinued. Withdrawal is followed by a rebound of platelet counts, so that continuous treatment is necessary.

Lowering the platelet count by HU is associated with significant improvements in acute ischemic or hemorrhagic symptoms. In a randomized clinical trial, we demonstrated the efficacy of HU in preventing thrombosis in ET patients aged over 60 and/or with a history of previous thrombosis.⁷⁸ This trial randomized 114 (35 males and 79 females, median age 68, range 40–85; median platelet count $788 \times 10^9/l$, range 533 – $1240 \times 10^9/l$) to long-term treatment with HU ($n=56$) or no cytoreductive treatment ($n=58$). During a median follow-up of 27 months, two thromboses (one stroke and one myocardial infarction) were recorded in the HU-treated group (1.6%/pt-yr) versus 14 (one stroke, five transient ischemic attacks, five peripheral arterial occlusions, one deep vein thrombosis, and

two superficial thrombophlebitis) in the controls (10.7%/pt-yr; $p=0.003$).

It is not known whether ET patients have an inherent tendency to develop acute leukemia. A review of the literature from 1981 to 1994⁷⁹ identified a total of 40 Ph-ET cases transformed into acute leukemia after a mean time from presentation of 6.5 years. Two major factors appeared to facilitate blastic transformation: cytogenetic abnormalities⁸⁰ and cytotoxic treatments.^{33–35} The role of cytotoxic drugs in enhancing the risk of developing hematological complications is one of the major issues currently under discussion in the question of using chemotherapy for ET. HU, as a non-alkylating agent, was initially thought to be nonmutagenic; however, long-term follow-up studies of HU-treated patients with PV and ET revealed that some cases did develop acute leukemia.³⁴ These reports cast doubts on the innocence of HU in the process of leukemogenicity. Even when used as a single agent in the treatment of PV and ET, the expected rate of acute leukemia is 5–10% and this fatal complication is encountered 4–8 years after the start of treatment. The rate of malignant events might be enhanced in patients given multiple cytotoxic drugs with different mechanisms of action (antimetabolites and alkylating agents).^{33,35}

When balancing benefits and risks, one can conclude that there is convincing evidence for giving HU to ET patients at high risk for major thrombotic complications. In contrast, the risk of acute leukemia associated with the use of HU is more difficult to accept in young low-risk individuals. In these cases, thrombosis is expected to occur in 4–5% patients yearly, with only occasional fatal events, and there are no available data on the effectiveness of HU in reducing this rate. The place of new drugs in the management of ET will essentially depend on whether they can be proven to be equally effective and less leukemogenic than HU.

Anagrelide

The efficacy of anagrelide in ET has been assessed in non-comparative clinical studies.⁸¹ Response was defined as a platelet count under 500 or $600 \times 10^9/l$ or a 50% drop in platelet count. A response rate of 60–93% was reported, irrespectively of age, sex, spleen size, bleeding time, clinical symptoms, or prior treatment. The average dose required to control the platelet count was 2–2.5 mg/day and in most cases the median time for response was 3–4 weeks, although delayed responses up to 24 months were described. Patients refractory to HU responded to anagrelide in 68% of cases. Continuous therapy is required because the platelet count rebounds in a few days after withdrawal of the drug. The most common adverse side-effects of anagrelide are palpitations and tachycardia related to a vasodilative and positive inotropic effect. Transient neurological (headache and dizziness) or gastrointestinal (nausea and diarrhea) complications have also been reported. Sudden death was observed in two patients given anagrelide: one death was related to a pulmonary infiltrate and the other to congestive heart failure. Therefore, anagrelide should be used with caution in patients with a history of heart disease.

The long-term efficacy and safety of anagrelide have been analyzed in 37 consecutive young patients with ET (median age 40 years, range 18–49 years) followed in a single institution for a median follow-up period of 10.7 years (range 5.2–13.7 years).⁸² The overall response rate was approximately 90% and the reduction of platelet count was sustained in more than 80% of patients. Four patients (11%) discontinued treatment because of toxicity. Most importantly, thrombotic complications while on therapy occurred in seven patients (19%) and major bleeding complications in six (16%). None of the patients developed acute leukemia. Thus, long-term therapy with anagrelide appears to be relatively well-tolerated, but thrombohemorrhagic complications continue to occur despite the control of thrombocytosis.

Interferon- α

IFN- α is able to reduce the platelet count in patients with ET. With an average dose of about 3 MIU daily, the response rate was about 90%. During maintenance, the IFN- α dose could be tapered, but if IFN- α is suspended, the platelet count rebounds in the majority of patients. Long-term IFN- α treatment is limited by side-effects (see the discussion of therapy of PV above) and the mode of administration. A revision of 273 patients published in the literature⁸³ showed that IFN- α therapy had to be interrupted in 206 cases (75%). The most common reasons for withdrawal were IFN- α -related side-effects in 55% of cases and patient refusal or loss to follow-up in the other 20%. Thus far, no leukemogenic effects have been observed. As already mentioned for PV, these new drugs are promising cytoreductive agents, but further studies are required to identify their place in the therapy of MPD.

Anti-aggregation therapy

The use of aspirin is widely accepted in ET patients with microvascular disturbances such as erythromelalgia or transient neurological and ocular ischemias.⁸⁴ For these patients, in the absence of contraindications and/or side-effects, the administration of aspirin at a dose of 100–300 mg/day is generally continued indefinitely, since its withdrawal is often associated with relapses of the clinical manifestations. The use of aspirin in ET patients with a history of arterial thrombosis is also becoming a widely accepted practice.⁸⁵ In the absence of clinical trials,

this recommendation is largely based on the assumption that secondary prevention with aspirin is associated with a risk reduction comparable to that achievable in other clinical settings.⁴⁰ However, the enhanced risk of bleeding in ET patients should be appreciated and in each case the risk must be weighed against possible benefits. There is no evidence that other anti-aggregation agents are equally effective or that their addition to aspirin provides further benefit.

Current therapeutic recommendations and future directions

Convincing evidence is emerging in the literature that the treatment of ET patients should be based primarily on the expected risk of major thrombotic complications. Young asymptomatic subjects with platelet counts in the range of $600\text{--}1500 \times 10^9/l$ are at lower risk and can be followed untreated. Nevertheless, it should be emphasized that major thrombotic events can also occur in a small percentage of these 'lowerrisk' cases. Future studies should be directed toward identifying other parameters useful for predicting the vascular risk in this particular subset of patients. Furthermore, the risk/benefit ratio of low-dose aspirin in the primary prevention of thrombosis should be tested in appropriate clinical trials.

As far as 'higher-risk' patients are concerned, HU (plus aspirin in the case of ischemia and/or thrombosis) is the treatment of choice because its efficacy in preventing thrombotic complications has been clearly proven. However, the long-term leukemogenicity of this drug, as well as that of other effective cytoreductive agents such as busulfan and pipobroman, remains a major concern. Anagrelide and IFN- α could overcome this worry, but their efficacy has been hitherto demonstrated only in lowering the platelet count, and clinical studies aimed at documenting a clinical benefit as well in ET are urgently needed.

Myelofibrosis with myeloid metaplasia

MMM is characterized by bone marrow fibrosis and neo-angiogenesis, immature myeloid and erythroid cells in the peripheral blood, anisopoikilocytosis with teardrop erythrocytes, and progressive splenomegaly due to myeloid metaplasia.

Cellular and molecular pathogenesis

The clonal nature of MMM could be inferred from variable but not random patterns of chromosomal abnormalities and by isoenzyme expression for G6PD, mutations of the *ras* gene family, and restriction fragment X-chromosome DNA polymorphisms.⁸⁶ Clonality invariably involves erythroblasts, mega karyocytes, granulocytes, monocytes, and B lymphocytes, indicating that the disorder stems from a pluripotent progenitor.

Bone marrow fibrosis derives from fibroblastic proliferation and increased deposition of connective tissue proteins (collagens, non-collagenous glycoproteins, and basement membrane components). Proliferation of fibroblasts is a secondary event, because fibroblasts do not derive from a totipotent hematopoietic stem cell and because they display no intrinsic alteration.

Humoral factors released from the proliferating myeloid cells and responsible for increased collagen synthesis by bone marrow fibroblasts include platelet-derived growth factor (PDGF), fibroblast growth factors (FGF), platelet factor 4 (PF4), transforming growth factor β (TGF- β), and β -thromboglobulin. TGF- β release is thought to be pivotal, in that it induces the transcription of most of the observed connective tissue proteins.

Abnormalities of packaging and secretion of PDGF, PF4, and TGF- β in megakaryocytes and platelets⁸⁷ link megakaryocytes to the pathogenesis of myelofibrosis. The proliferating bone marrow population of monocytes-macrophages has been implicated by the observation that it is responsible for adhesion-mediated overproduction of two fibrogenic cytokines, IL-1 and TGF- β .⁸⁸

Neo-angiogenesis is an integral component of the bone marrow stromal reaction in MMM. The hypothesis is that the bone marrow microenvironment in MMM hosts excess angiogenic cytokines.⁸⁹ In fact, increased serum levels of vascular endothelial growth factor (VEGF) in most patients with MMM were demonstrated,⁹⁰ and morphometric studies documented increased bone marrow vascularity. According to studies of microvessel density in bone marrow sections, MMM exhibits the most pronounced angiogenesis among MPD.⁹¹ Since the extent of marrow angiogenesis correlates with hematopoietic cellularity and megakaryocyte clumping, neo-angiogenesis could be an integral part of the myeloproliferation in MMM.

The biological and molecular mechanisms responsible for the clonal proliferation in MMM are presently unknown. The characteristic exuberant *in vitro* 'spontaneous' growth of progenitor cells in the absence of exogenous growth factors classifies MMM as an autocrine-driven disease. A number of growth factor pathways have been investigated and a variety of anomalies detected; however, most of them are common to other MPD and affect a limited number of the cases investigated, suggesting that they are acquired abnormalities in the evolution of the neoplastic clone.

Elevated expression of the stem cell factor (SCF) receptor (c-Kit) and deregulation of the basic FGF (bFGF) pathway in circulating stem cells could

provide the reason of the proliferative advantage to the affected clone in the disease. When compared with normal CD34⁺ progenitors, the expression of bFGF is significantly increased in MMM patients' CD34⁺ cells, and the density of bFGF type I and type II receptors is significantly augmented.⁹² This increased bFGF expression is contrasted by a decreased expression of the receptor for TGF- β , a negative regulator of hematopoiesis.⁹²

A truly autonomous megakaryocyte development occurs in MMM, which results neither from mutations or deletions in the coding region of the TPO receptor (*c-mpl*) nor from autocrine stimulation by TPO.⁹³ Reduced surface expression of the c-Mpl in MMM platelets has been reported, being due to a specific, incompletely processed form of platelet c-Mpl. The defect is associated with a failure to activate the kinase signaling system, with subsequent loss of phosphorylation of the proteins involved in signal transduction, JAK2 and STAT5.⁹

Among recurrent chromosomal abnormalities, deletion of 13q is one of the most frequent, suggesting deletion in a tumor suppressor locus.⁹⁴

Myeloid metaplasia results from extramedullary diffusion of the neoplastic myeloid clone. The evidence that high numbers of CD34⁺ hematopoietic stem cells circulate in the bloodstream in patients with MMM has favored a model according which hemopoietic stem cells relocate from bone marrow to extramedullary hematopoietic macroenvironment.⁹⁵

Clinical features and diagnosis

MMM is a rare disease, with an annual incidence of about 0.5 per 100 000. A slight male preponderance is usually reported and the median age at diagnosis ranges from 54 to 62 years. It has been described in children, and rarely may be familial.

Considerable variability is detected in the hematological features of the disease.^{96–99} More than 50% of patients are anemic at diagnosis, and 25% have severe anemia (hemoglobin (Hb) <8 g/dl). Normocytic anemia is the rule. Mechanisms of anemia include aregenerative, hemodilutional, hemolytic, folate deficiency and iron deficiency. The reticulocyte count is increased in 50% of patients, but ineffective reticulocytosis is present in many cases. In 15% of cases, a polycythemia is manifest, and if the RCM is measured, the percentage of patients with erythrocytosis is still higher.

Circulating erythroblasts range from 0% to 20% at diagnosis and they may constitute more than half of the nucleated cells in peripheral blood after splenectomy. WBC are increased in approximately half of the cases, and in more than 30% circulating blast cells are observed from the diagnosis. Elevated levels of plasma lactate dehydrogenase (LDH) correlate significantly with WBC counts. Thirty-seven percent of cases present thrombocytopenia at diagnosis, while thrombocytosis is present in 13%. Thrombocytopenia is usually multifactorial in cause, due to both marrow failure and hypersplenism. Serious bleeding complicates MMM in approximately 16% of patients. This may be due to qualitative platelet dysfunctions, inapparent or manifest disseminated intravascular coagulation, or thrombocytopenia.

Fever, weight loss, nocturnal sweating, pruritus, and bone pain are the constitutional symptoms that accompany 40% of patients at diagnosis or during the course of the disease. Immune disorders with the presence of autoimmune phenomena have been reported. Cutaneous vasculitis, dermatitis resembling Sweet syndrome, and pyoderma gangrenosum have been described. Plasma soluble IL-2 receptor levels were significantly elevated, suggesting T-cell activation.¹⁰⁰

Splenomegaly is the cardinal symptom of myeloid metaplasia. It occurs in 97–100% of patients at diagnosis, and is massive in about 10% of them. The liver enlargement is due to extramedullary hematopoiesis, which is associated with increased values of plasma alkaline phosphatase. A variety of symptoms may be due to myeloid metaplasia: intestinal hemorrhage, focal seizures, pulmonary failure, ascites, hematuria, spinal cord compression, testicular enlargement, and papular nodules of the skin.

Bone marrow histological pictures range from highly cellular with fewer fat cells and focal increase of reticulin stroma to absence of normal hematopoiesis with a dense or loose network of reticulin and collagenous fibers. Documentation of histological progression during the course of the disease is scanty, and on sequential studies a relatively constant pattern has been seen throughout the disease.¹⁰¹ Bony changes that appear radiologically as sclerosis are characteristically seen in half of the patients. The axial skeleton is most frequently involved and osteolytic lesions occur rarely. Increased levels of circulating procollagen III peptide correlate with the extent of fibrosis and the degree of disease activity.

If analyzed singly, there is no one diagnostic finding that can be considered absolutely specific for MMM. Moreover, in MMM, the characteristic lineage proliferation that allows other MPD to be categorized with simple diagnostic criteria is lacking. Thus the PVSG originally identified diagnostic criteria of MMM in: myelofibrosis involving more than one-third of the sectional area of bone marrow biopsy, a leukoerythroblastic blood picture, splenomegaly and absence of the well established diagnostic criteria for the other CMPD (i.e. absence of increased red cell mass or Philadelphia chromosome), with systemic disorders excluded.¹⁰²

More recently, Thiele et al¹⁰³ established a set of relevant criteria for the diagnosis of MMM with special regard to its early stages. The authors combined accepted clinical characteristics at diagnosis with corresponding histomorphological findings (the Cologne criteria), in the belief that bone marrow histology is an invaluable aid when attempting to define the different subtypes of MPDs. Megakaryocytes mark MMM by their characteristic bizarre shape with plump lobulation of nuclei and disturbances of nuclear cytoplasmic maturation that create a dysplastic appearance (Table 42.6). These criteria have been accepted in the WHO classification of MMM.¹⁰⁴

The Italian Cooperative Group on Myeloproliferative Disorders¹⁰⁵ developed a definition of MMM using the evidence and a consensus methodology. This definition of the disease is shown in Table 42.7.

Table 42.6 The Cologne criteria for the diagnosis and staging of myelofibrosis with myeloid metaplasia (idiopathic myelofibrosis, IMF)

A. No preceding or allied other subtype of myeloproliferative disorder or myelodysplastic Syndrome	F. Histopathology; Granulocytic plus megakaryocytic myeloproliferation with large, multilobulated nuclei containing megakaryocytes that show abnormal clustering and definitive maturation defects and:
B. Splenomegaly (on palpation or >11 cm on ultrasound)	1. No reticulin fibrosis
C. Thrombocytopenia (platelet count $\geq 500 \times 10^9/l$)	2. Slight reticulin fibrosis
D. Anemia (Hb < 12g/dl)	3. Marked increase (density) in reticulin fibers or collagen fibrosis (and)
E. Definite leuko-erythroblastic blood picture	4. Osteosclerosis (endophytic bone formation)
Diagnosis and classification of IMF is acceptable if the following combinations are present:	
Stage 1. A+B+C+F ₁ is consistent with a hypercellular (prefibrotic) stage clinically simulating essential thrombocythemia	
Stage 2. A+B+C+D+F ₂ is consistent with early IMF	
Stage 3. A+B+D+F ₃ is consistent with manifest IMF	
Stage 4. A+B+D+E+F ₃₊₄ is consistent with advanced IMF complicated by osteosclerosis (osteomyelosclerosis)	

Table 42.7 The Italian criteria for the diagnosis of myelofibrosis with myeloid metaplasia

Necessary criteria	
A. Diffuse bone marrow fibrosis	B. Absence of Philadelphia chromosome or <i>BCR-ABL</i> rearrangement in peripheral blood cells
Optional criteria	
1. Splenomegaly of any grade	4. Presence of circulating erythroblasts
2. Anisopoikilocytosis with teardrop erythrocytes	5. Presence of clusters of megakaryoblasts and anomalous megakaryocytes in bone marrow sections
3. Presence of circulating immature myeloid cells	6. Myeloid metaplasia
Diagnosis of MMM is acceptable if the following combinations are present:	
● The two necessary criteria plus any two optional criteria when splenomegaly is present	
● The two necessary criteria plus any four optional criteria when splenomegaly is absent	

Prognosis

The course of the disease is highly variable. One-quarter of patients are asymptomatic at diagnosis. Forty percent have progressive splenomegaly with worsening of anemia. A wide variety of complications and associated medical problems emerge during followup, including infections, heart failure, and cerebrovascular accidents.

The Median survival time from diagnosis ranges from 3.5 to 5.5 years, and most patients die from infections, hemorrhages, or evolution to acute leukemia. Between 5% and 30% of deaths are due to blastic transformation of the disease, with granulocytic, granulomonocytic, or megakaryocytic type blasts. Predictors of bad prognosis are severe anemia, a large number of immature myeloid cells in peripheral blood, and a clinical picture of erythroid failure. Increased angiogenesis correlates significantly with increased spleen size and has been found to be a significant and independent risk factor for overall survival.⁹¹

Dupriez et al¹⁰⁶ proposed a score (the LILLE scoring system) that was able to identify three distinct prognostic groups (Table 42.8). In the low-risk group (Hb

Table 42.8 The LILLE spring system for; predicting survival in myelofibrosis with myeloid metaplasia

Adverse prognostic factors		
Hb <10 g/dl		
WBC <4 or >30×10 ⁹ /L		
Scoring system (number of adverse prognostic factors).		
No. of factors	Risk group	Median survival (months)
0	Low	93
1	intermediate	26
2	High	13

>10 g/dl and WBC between 4×10⁹/l and 30×10⁹/l), patients had a median survival of 93 months, whereas those in the intermediate-risk (Hb <10 g/dl or WBC < 4×10⁹/l or >30×10⁹/l) and high-risk (Hb <10 g/dl and WBC <4×10⁹/l or >30×10⁹/l) groups had median survivals of 26 and 13 months, respectively. A previously reported subgroup analysis of patients allowed Morel et al¹⁰⁷ to document that the disease was less frequently aggressive based on the LILLE score in patients younger than 55 years.

More recently, in a European collaboration study on 121 patients aged 55 years or less,¹⁰⁸ the median survival was 128 months, i.e. more than twice that reported in recent comprehensive series of MMM patients. Anemia, the presence of constitutional symptoms, and circulating blasts were the three presenting features associated with survival. These prognostic factors allowed separation of low-risk and high-risk groups among young patients. The former, with none or only one poor prognostic factor, included three-quarters of patients and had a median survival of more than 14 years, whereas the latter, with two or three poor prognostic factors, contained one-quarter of the patients, with a median survival of less than 3 years.

Therapy

At present, ablation of the abnormal hematopoietic clone with high-dose chemotherapy and allogeneic stem cell transplantation (SCT) is the only chance to achieve a cure in MMM. A report of a collaborative study including 55 patients (39 males and 16 females) evaluated the results of allogeneic SCT in patients with MMM on a larger scale.¹⁰⁹ An HLA-matched related donor was used in most cases, whereas in 6 cases the graft was harvested from HLA-mismatched related or three-loci-matched unrelated donors. Hematopoietic recovery was reached in 50 out of the 55 patients. Factors associated with a shorter time to reach the neutrophil engraftment endpoint (an absolute neutrophil count (ANC) of at least 0.5×10⁹/l) were splenectomy, absence of grade III myelofibrosis, and a high number of nucleated cells infused. Splenectomy and the absence of grade III myelofibrosis were also factors associated with a shorter time to achieve the platelet recovery endpoint (a platelet count of 50×10⁹/l). Out of 55 patients, 5 (9.1%) died early after SCT of primary graft failure, secondary graft failure, or transplantation-related complications. Among the 50 evaluable patients, 22 had grade 0–I, 15 grade II, and 13 grade III–IV acute graft-versus-heart disease (GVHD). Among 44 evaluable patients, 27 experienced chronic GVHD. Nineteen patients achieved complete histo-hematological remission. Resolution of myelofibrosis occurred between 21 days and 23 months after transplant. Seven patients showed evidence of relapse, which occurred at a median time of 12 months.

Overall, 43.6% of patients died, the causes of death being infections, chronic GVHD, acute GVHD, disease progression, solid organ failure, lymphoproliferative disorders, and graft failure. The Kaplan-Meier estimate of survival at 5 years was 49%, with a 57% survival rate for patients receiving an unmanipulated HLA-matched related graft (*n*=44). Hemoglobin greater than 10 g/dl at the time of transplant and the absence of grade III myelofibrosis were significantly associated with a better outcome.

No medical therapy has proven to have an effect on overall patient survival, and the therapeutic strategies are mainly aimed at maintaining quality of life. Patients with an intact quality of life and with no threatening erythrocytosis or thrombocytosis do not need any treatment.

Anemia deserves therapeutical consideration when it is symptomatic or progressively worsening. Aregenerative anemia responds to androgens (oxymetholone, fluoxymesterolone, methandrosthenolone, testosterone enanthate, and danazol) in approximately 30–40% of cases.¹¹⁰ Studies on the use of recombinant human erythropoietin (rHuEPO) in MMM have been reviewed in a total of 32 patients.¹¹¹ Overall, 53% of them responded to rHuEPO treatment, but the vast majority of responders were not transfusion-dependent and the doses required to achieve response varied from 300 to 1500 U/kg per week. Factors predicting response include serum erythropoietin level below 123 mU/ml, female gender, and none or mild transfusion requirement. In some patients, aggravation of splenomegaly due to stimulation of extramedullary erythropoiesis led to withdrawal of the drug.

An elevated platelet count (>600×10⁹/l), as after splenectomy, represents a major risk factor for thrombosis and hemorrhage. Therefore, patients with a

number of platelets greater than $600 \times 10^9/l$ have to be treated. HU is the drug of first choice. The recommended starting dose is 1500 mg/day, and 500 mg/day as maintenance. The possible carcinogenic potential of HU becomes important in young people (<45 years old), who have the longest life expectancy. In these cases (INF- α) is a valuable alternative to cytostatic therapy.¹¹² Hematological responses have been seen in 50% of patients—usually those with a hyperproliferative type of disease. A reasonable starting dose is 5 MIU subcutaneously three to five times per week. Long-term control can be obtained with a well-tolerated lower dose.

With the aim of taking advantage mainly of its antiangiogenic effect, and thus improving the microenvironment and hematopoietic cell maturation in the bone marrow and extramedullary sites, trials have determined the effect of thalidomide in patients with MMM. In a pooled analysis, updated data on 62 individual patients from five phase II trials were reported.¹¹³ Overall, using a standard dose of thalidomide (i.e. starting with no less than 100 mg/day), 29% of patients with moderate to severe anemia showed an increase in hemoglobin or a reduction/abolition of blood transfusion requirements, 38% with moderate to severe thrombocytopenia had an increase in platelet count, and 41% with high-grade splenomegaly demonstrated a measurable reduction in spleen size. Major disease severity and high degrees of splenomegaly before therapy predicted response with a probability of 61.9%. However, 18% of the patients had a ‘myeloproliferative reaction’ with leukocytosis and/or thrombocytosis. Sixty-six percent of patients discontinued the drug before 6 months of treatment due to intolerance.

A progressively enlarging painful spleen with severe anemia and/or thrombocytopenia requires a choice between splenectomy and medical treatment. The decision depends on the trade-off between the risk of and the benefits from the operation, and at present no clear guidelines can be provided to help resolve this dilemma. Single-institution experiences in Italy¹¹⁴ and the USA¹¹⁵ (71 patients and 223 patients, respectively) showed 8.4–9% mortality and 31–39.3% morbidity rates. New hemorrhagic or thrombotic complications occurred in 16.9% of surviving patients, and were predicted by an age less than 50 years, a normal to high platelet count ($>200 \times 10^9/l$), and huge splenomegaly (>16 cm from the costal margin). There was a substantial improvement in anemia in 45% and 52% of patients at 3 months and 1 year, respectively, which was predicted by severe anemia, low platelet count ($<100 \times 10^9/l$), or normal to high WBC count ($>4 \times 10^9/l$). Postsurgical thrombocytosis of over $600 \times 10^9/l$ or over $1000 \times 10^9/l$ was observed in 20.2% and 5.8% of patients, respectively, and was predicted by a platelet count greater than $50 \times 10^9/l$. Massive liver enlargement occurred in 24% of patients. An increased frequency of symptomatic or asymptomatic portal or splenic venous thrombosis warrants routine surveillance imaging with ultrasonography.

In a paper on 549 patients with primary MMM collected in a collaborative study group comprising 13 large hospitals in Italy,¹¹⁶ splenectomy was reported to be an independent risk factor for blast transformation. The cumulative incidence of blast transformation was 27% in non-splenectomized patients and 55% in splenectomized patients 12 years after diagnosis. The overall median survival was 2.0 years (range 0–12.9) from the time of splenectomy.

Late effects after treatment for Hodgkin lymphoma

Anthony J Swerdlow and Flora E van Leeuwen

Introduction

As described elsewhere in this book (Chapter 35), the treatment of Hodgkin lymphoma (HL) has become extraordinarily successful over the last 40 years. One of the penalties of this success, however, has been the growing importance of late effects of treatment. The balance of early and late effects is especially critical in early-stage patients and after long follow-up. For instance, in stage I and II patients treated at Stanford during 1962–95, the cumulative probability of death from causes other than HL exceeded that due to the disease itself beyond about 12 years.¹ Beyond 20 years, indeed, mortality is virtually entirely due to causes other than HL.²

Some of the deaths occurring in long-term follow-up, of course, represent the mortality to be expected in any group of people as they grow older. Many, however, do not. In particular, patients with HL suffer large excesses of morbidity and mortality from second cancers and from cardiovascular disease (Table 43.1); this chapter concentrates on these major endpoints. In addition, treatment can have long-term effects on the lung, thyroid, bone and soft tissue, gastrointestinal system, urinary tract, immune system and infection, and on fertility. These have lesser effects on mortality, however, and are not reviewed here.

Second malignancies

Overall risk of second malignancy

Since the first reports of increased risk of second cancer in HL patients in the early 1970s,^{5,6} nearly all major treatment centers have evaluated this risk in their patients. An excess of acute myeloid leukemia (AML) in chemotherapy-treated patients and an increased risk of solid tumors in radiotherapy-treated patients have been reported consistently in the literature.^{7,8} The overall risk of selected second malignancies compared with the general population is given in Table 43.2, on the basis of results from two recent large studies, one from the UK⁹ and one from a joint study in the USA, Canada, Scandinavia, and the Netherlands.¹⁰

The largest relative risk (10- to 15-fold) is observed for leukemia (with an even greater risk for AML: 22-fold),

Table 43.1 Major causes of excess mortality in Hodgkin lymphoma (HL): selected large cohort studies

AER, absolute excess risk=excess number of cases per 10 000 patients per year.
^a Not specified, but maximum follow-up was approximately 35 years.

followed by a 6- to 14-fold increased risk for non-Hodgkin lymphoma (NHL), and 4- to 10-fold excesses for connective tissue, bone, and thyroid cancers. Moderately increased risks (2- to 4-fold) are observed for a number of solid tumors, such as cancers of the lung, stomach, esophagus, colon, breast, mouth and pharynx, and cervix, and melanoma. Because leukemia and NHL are diseases with a low incidence in the general population, even a high relative risk compared with the population may translate into a low cumulative (actuarial) risk. As shown in Figure 43.1, for the entire follow-up period the cumulative risk of solid tumors far exceeds that of leukemia or NHL. The absolute excess risk is the best measure to judge which subsequent tumors contribute most to the second cancer burden. Table 43.2 shows that, compared with the general population, HL patients in general experience an excess of about 45 malignancies per 10000 person-years of observation, although, as discussed later, this varies with age at treatment and other factors. Solid tumors account for the majority of excess cancers (approximately 30 per 10000 patients per year), with lung cancer contributing 10–12 excess cases per 10000 person-years. Leukemia and NHL each account for about 8–9 cases per 10000 person-years.

Temporal patterns of risk of second malignancy vary by tumor site, as illustrated in Table 43.3. In most studies, an increased risk of leukemia is observed as early as 2–4 years following initiation of chemotherapy, with peak occurrence between 5 and 9 years, and decreasing risks thereafter.^{9–15} In studies with large numbers of long-term survivors, significantly increased relative risks are still observed for 15 years after first treatment.^{9,10,13,15} The relative risk of NHL is already greatly increased in the first 5 years after treatment. In some studies, the risk remains rather constant over time,^{10,12,16} whereas others report that risk increases with time since treatment.^{13,17} The relative risk of solid tumors is minimally elevated in the 1- to 4-year follow-up period, and increases steadily with increasing follow-up time from 5 years since first treatment.^{9,10,12,13,15–18} For some tumor sites (breast and thyroid), the excess risk does not become apparent until after 10 or even 15 years of observation. In studies that include data on 20-year survivors, the relative risk of solid tumors continued to increase through the 15- to 20-year follow-up period.^{9,10,13–16–18–20} Only two recent studies have reported on the time course of risk 20 or more years after treatment.^{10,15} In the international population-based study by Dores et al,¹⁰ a downturn in the relative risk for all solid tumors com-

Figure 43.1 BNLI cohort: 20-year cumulative risks of second primary cancer, by age at first treatment.⁹

bined was observed after 25 years of follow-up, with relative risks of 3.0 and 1.8 among patients in the 20- to 24-year interval and 25-year survivors, respectively (Table 43.3). A Dutch study in patients diagnosed with HL before the age of 40 years reported a relative risk for solid tumors of 5.3 among 25-year survivors, compared with a relative risk of 8.8 in the 20- to 24-year interval.¹⁵ This suggests that the relative risk may decrease in very long-term survivors.

In accordance with the patterns of relative risks of leukemia, NHL, and solid tumors with time since first treatment, the absolute excess risks in long-term survivors differ greatly from those observed in the entire patient population. Table 43.3 clearly shows that the *absolute excess risks* of solid malignancies increase at a much steeper rate than the *relative risks*, due to the fact that, with longer follow-up, patients grow older and their background rate of cancer rises strongly.

n, number of patients entering interval; O/E, observed/expected; 95% CI, 95% confidence interval; AER, absolute excess risk= excess number of cases per 10000 patients per year.

Related to this phenomenon, the absolute excess risk amounts to about 100 excess cancer cases per 10000 20-year survivors per year, as compared with 45/10000/year in all patients (Table 43.2). Based on estimates from the study by Dores et al,¹⁰ solid cancers contribute by far the most to the absolute excess risk in 20-year survivors, with 92 excess cases per 10000 patients per year, followed by NHL (8/10000/year), and AML (2/10000/year). In females, breast cancer accounts for most of the absolute excess risk of solid tumors in 20-year survivors (42/10000/year) (Table 43.3).¹⁰ Lung cancer accounts for 17 excess cases per 10 000 patients per year in 20-year survivors of both sexes combined.

Leukemia

For a number of second malignancies, the association with treatment factors has been investigated in detail. Leukemia following HL is certainly the most studied malignancy induced by treatment, and extensive knowledge of its risk factors has emerged.⁸ Radiotherapy alone is associated with very little or no increased risk of leukemia,^{9,12,17,18,21} while alkylating agent chemotherapy is linked with a greatly elevated risk. Several studies have compared the leukemogenicity of different chemotherapy regimens. The risk of AML rises sharply with an increasing number of MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) or MOPP-like cycles.^{11,21} The risk associated with 10–12 MOPP cycles appears to be approximately three to five times higher than that following 6 MOPP cycles.^{11,21} Since the 1980s, MOPP-only chemotherapy has been gradually replaced by ABV(D) (doxorubicin, bleomycin, vinblastine, and dacarbazine)-containing regimens in many centers. There are only a few reports on the occurrence of AML following ABV(D) alone. Patients treated with ABVD in the Milan Cancer Institute, where this regimen was designed, were shown to have a significantly lower risk of AML than MOPP-treated patients (15-year cumulative risks of 0.7% and 9.5%, respectively).²² Another study showed that HL patients treated with MOPP/ABV(D)-containing regimens in the 1980s had substantially lower risk of AML/myelodysplastic syndrome (MDS) than patients treated in the 1970s with MOPP alone (10-year cumulative risks of 2.1% and 6.4%, respectively; $p=0.07$).¹³ The German—Austrian Pediatric Hodgkin's Disease Group observed a low risk of AML (1.1% at 15 years) following regimens that contained relatively low doses of procarbazine, doxorubicin, and cyclophosphamide, without mechlorethamine.²³

An important question is whether radiotherapy adds to the risk of leukemia associated with chemotherapy. Evidence that combined-modality treatment results in greater risk than chemotherapy alone is provided by several reports,^{18,22,24} whereas other large series indicate that the risk of AML after combined treatment is comparable to that after chemotherapy alone.^{9,11–14,17,21,25} These inconsistent results may be due partly to differences in treatment regimens between studies, but also to lack of adjustment for type and amount of chemotherapy in some reports. The interaction between radiotherapy and chemotherapy was evaluated most rigorously in the large case-control study by Kaldor et al,¹¹ which included 163 cases of leukemia following HL. When examining the combined effects of radiation dose to the active bone marrow and the number of mechlorethamine-procarbazine-containing cycles, it was found that for each category of radiation dose (<10, 10–20, >20 Gy to the marrow), the risk of leukemia clearly increased with the number of chemotherapy cycles. In contrast, among patients with a given number of chemotherapy cycles, risk of leukemia did not consistently increase with higher radiation dose. Taken together, the preponderance of available data does not support the hypothesis that the combination of chemotherapy and radiotherapy confers a higher risk of leukemia than chemotherapy alone.

Intensification of therapy with autologous stem cell transplantation (ASCT) support is increasingly being used for relapsing lymphoma patients. Relatively high actuarial risks (4–15% at 5 years) of AML and MDS have been observed after ASCT for HL. Evidence suggests that much of the risk is related to intensive pretransplant chemotherapy.^{26–29}

The influence of host-related factors such as age on the risk of leukemia in HL survivors has been examined in a number of studies and has been reviewed elsewhere.⁸ The reported higher *cumulative* risk of AML in older HL patients compared with younger ones mainly reflects the higher baseline incidence of the disease in older persons. In the few studies that have analyzed the *relative* risk of leukemia by age, based on comparisons with general population expectations, either no differences between age groups were observed^{15–17} or the relative risk of AML was significantly greater at younger ages than at older.^{90–11} The risk of AML in relation to treatment-associated acute and chronic bone marrow toxicity has been examined in only one study to date.²¹ Significantly increased risks of leukemia were found among patients who developed thrombocytopenia, either in response to initial therapy or during follow-up. After adjustment for the type and amount of chemotherapy, patients who showed a decrease in platelet counts of 70% or more after initial treatment had an approximately fivefold higher risk of developing leukemia than patients who showed a decrease of 50% or less. Severe acute thrombocytopenia may indicate greater bioavailability of cytotoxic drugs, which would be likely to contribute to the development of leukemia.

Non-Hodgkin lymphoma

The literature consistently reports an increased risk of NHL following HL, but the causes of the excess risk are not well understood.⁸ As increased risks of NHL occur in immunosuppressed patients, such as transplant recipients,³⁰ and as HL may be accompanied by immunosuppression,³¹ several investigators have argued that the elevated risk of NHL may be attributed to HL itself rather than to its treatment. This view is supported by several studies in which risk did not vary appreciably between treatments.^{9,12,16,17} However, in other studies, the risk of NHL was found to be lowest among patients treated with radiotherapy alone, and highest among patients who received intensive combined-modality treatment, both initially and for relapse.^{13,18,32–34} The inconsistent results regarding the relation with treatment may be partly attributed to diagnostic misclassification, ie misdiagnosis of the primary tumor as HL while it represented NHL according to modern lymphoma classification schemes.^{8,34} In only very few studies were diagnostic pathology slides of the second NHL and original HL reviewed in order to avoid such misclassification, however, and these did not give consistent results.^{12,13,34} Although transformation to NHL may be part of the natural history of some types of HL, the role of intensive combined-modality treatment and its associated immunosuppression, and of the inherent immune deficiency associated with HL, should be explored further.

Solid malignancies

Role of radiation

Elevated risks of solid cancers following HL have generally been attributed to radiotherapy.^{8,10,12–20,35} Excesses of melanoma, however, are more likely to be related to immunosuppression accompanying HL or its treatment, because elevated risks appear as early as in the 1- to 4-year follow-up interval.^{9,36} Emergence of an increased risk of cervical cancer 10 years after the diagnosis of HL may also be related to defects in cellular immunity that may facilitate the progression of human papillomavirus-related neoplasia.³⁷ The other sites for which excess solid cancers have been reported (lung, breast, gastrointestinal tract, thyroid, bone, and connective tissue) are those for which elevated risks have also been described in other radiation-exposed cohorts.^{38–40} Two case-control studies have examined lung cancer risk in relation to the radiation dose to the affected lung area, as well as the modifying effect of the patient's smoking habits.^{41,42} In both studies, it was observed that the risk of lung cancer rose significantly with increasing radiation dose. In the largest study, which included 222 lung cancer patients and 444 matched controls, the relative risk (RR) was 7.2 (95% confidence interval (CI) 2.2–28) for patients who received 40 Gy or more (to the relevant lung area) compared with those who received no radiation.⁴² In the Dutch study, the increase in risk of lung cancer with increasing radiation dose was significantly greater among patients who smoked after diagnosis of HL than among those who refrained from smoking.⁴¹ Travis and collaborators⁴² observed that the increased relative risks from smoking appeared to multiply the elevated risks from radiation. Both studies imply that there are large absolute excess risks for lung cancer among irradiated patients who smoke.

The strongly elevated risk of breast cancer following radiotherapy for HL has become a major concern for female survivors.^{10,15,43–47} A case-control study of breast cancer after HL in the Netherlands investigated the effects of radiation dose, chemotherapy, and reproductive factors.⁴⁸ The study included 48 patients who developed breast cancer 5 or more years after treatment for HL and 175 matched controls. The radiation dose to the area of the breast where the case's tumor had developed was estimated for each case-control set. The risk of breast cancer increased significantly with increasing radiation dose ($p_{\text{trend}}=0.01$), with an RR of 4.5 (95% CI 1.3–16.0) for patients who received 38.5 Gy or more, as compared with those who received less than 4 Gy. Patients who received chemotherapy and radiotherapy had significantly decreased risk compared with those treated with radiation alone (RR 0.45; $p=0.009$). For patients who never received chemotherapy, the risk of breast cancer increased more strongly with increasing radiation dose (RR 12.7 for patients receiving 38.5 Gy or more) than among patients also treated with chemotherapy. The substantial risk reduction associated with chemotherapy was attributable to its effect on menopausal age. Reaching menopause before age 36 (25% of the controls) was associated with a strongly reduced risk of breast cancer (RR 0.06; 95% CI 0.01–0.45). These results suggest that ovarian hormones are a crucial factor in promoting tumorigenesis once radiation has produced an initiating event.

Role of chemotherapy

A very important question is whether chemotherapy for HL can also induce solid cancers, and, if so, at which sites. Several studies have indeed observed that chemotherapy significantly increased the risk of solid malignancy, in particular lung cancer.^{9,12,49} The British National Lymphoma Investigation cohort study of 5519 patients⁹ showed a significantly elevated risk of lung cancer following chemotherapy alone, with the RR (3.3; 95% CI 2.2–4.7) compared with the general population being of similar magnitude to that observed in patients treated with either radiotherapy (RR 2.9; 95% CI 1.9–4.1) or mixed-modality treatment (RR 4.3; 95% CI 2.9–6.2). Two large case-control studies have investigated the separate and joint roles of chemotherapy, radiation, and smoking in detail.^{42,50} In both reports, there was a clear

trend of increasing lung cancer risk with greater number of cycles of alkylating agent chemotherapy ($p_{\text{trend}} < 0.001$)⁴² or MOPP chemotherapy ($p_{\text{trend}} = 0.0750$ and $p_{\text{trend}} = 0.001$)⁴²). In the largest study, in which individual radiation dosimetry was performed, the risk of lung cancer after treatment with alkylating agents and radiation together was as expected if individual excess relative risks were summed, with RRs of 4.2 (95% CI 2.1–8.8) for patients with alkylating agents alone, 5.9 (95% CI 2.7–13.5) for patients with radiotherapy alone (>5 Gy), and 8.0 (95% CI 3.6–18.5) for those with combined-modality treatment, compared with patients who received no alkylating agents and had a radiation dose of 5 Gy or less.⁴² Among patients treated with MOPP chemotherapy, the risk of lung cancer rose with increasing cumulative dose of either mechlorethamine or procarbazine.⁴² Both agents are carcinogenic to rodent lungs,⁵¹ and mustard gas, from which mechlorethamine was originally derived, is also known to cause lung cancer in humans⁵²—although of course after presumed inhalation in that circumstance. As was observed for the joint effects of smoking and radiotherapy, the risks from smoking appeared at least to multiply the risks from alkylating agent chemotherapy.^{42,50} Smoking remains the major cause of lung cancer in patients treated for HL, as is evident from the observation that only 7 out of 222 cases included in the study by Travis and colleagues⁴² occurred in patients who had never smoked.

In several series,^{14,15,17,18,21} no increased risk of solid malignancy overall was observed following chemotherapy alone. However, the expected number of solid tumors 10 or more years after chemotherapy alone was less than two in nearly all negative studies, so a moderate increase in risk could not be excluded. If chemotherapy affects the risk of solid tumors, one might expect that patients receiving combined-modality treatment would have a greater relative risk than patients treated solely with radiotherapy, although this would depend on whether doses were comparable. Only one study to date has reported a significantly greater risk for solid cancers overall following chemo- and radiotherapy compared with irradiation alone,¹⁶ whereas no such difference has been found in the majority of investigations.^{1,12,14,17,18,21} For gastrointestinal tract cancers, however, larger risks were observed after combined-modality treatment than after irradiation alone.^{9,15,20}

The inconsistent results reported with regard to the influence of chemotherapy on the risk of solid tumors may be partly related to the fact that most studies considered all solid tumors combined, whereas chemotherapy may differentially affect the risk of tumors at disparate sites. A recent study from the Netherlands Cancer Institute demonstrated that the addition of salvage chemotherapy to initial radiotherapy, as compared with initial irradiation alone, did not influence the risk of solid cancers overall, but significantly increased the risk of solid tumors other than breast cancer (RR 9.4, versus 4.7 for initial irradiation alone).¹⁵ Conversely, patients who received salvage chemotherapy were found to experience significantly lower risks of breast cancer than patients treated with radiotherapy alone (RRs 2.8 and 7.6, respectively), probably related to premature ovarian failure due to intensive chemotherapy¹⁵ (see also above).

Effect of age at treatment

Several studies have shown that the relative risk of solid cancers increases strongly with decreasing age at first treatment.^{9,10,15,20} The effect of age is most notable for breast cancer, with the risk increasing dramatically with younger age at first irradiation down to 10–14 years, but not younger. In a Dutch study, 15-year survivors who had radiation treatment before 20 years of age had an 18-fold increased risk of breast cancer; women irradiated at ages 20–29 had a 6-fold increased risk; and a small, non-significant increase was observed for women irradiated at age 30 or older (RR 1.7).¹⁵ A similar trend, with even larger relative risks, was reported from Stanford University.¹⁹ An approximately 100-fold increased risk of breast cancer has been observed after treatment at ages less than 16, with relative risks ranging from 17 to 458.^{14,16,19,53} This huge variation in estimated risk is not surprising in view of the large differences between series in important variables such as the proportion of patients irradiated and the duration and completeness of follow-up. Generally, surveys with more complete follow-up have found lower relative risks of breast cancer^{9,10,15,53,54} than those in which completeness of follow-up was less satisfactory or was not addressed.^{14,16,55} Incomplete follow-up may lead to overestimation of the risk of second malignancy if patients who remain well lose contact with clinical follow-up, while those with second cancers come to attention because of this. The very high *actuarial* risks reported in two US studies (34% at 25 years after first treatment for women treated at ages under 20⁵⁵ and 35% at 40 years of age for those treated at ages under 16¹⁴) may well be exaggerated estimates, not only because of losses to follow-up but also because the actuarial method is less appropriate when including events that occur at follow-up intervals later than those at which data for most of the patients were censored.⁴³ In the Dutch study with (nearly) complete follow-up, the 25-year actuarial risk of breast cancer amounted to 16%, both for women first treated before age 20 and at ages 20–30.¹⁵

Several studies have demonstrated that age at treatment for HL is also a crucial determinant of increased relative risks for solid malignancies other than breast cancer.^{9,10,15,20} Dores and colleagues¹⁰ reported that the relative risk of lung cancer decreased from a 5.5-fold

increase (compared with the general population) for patients diagnosed before age 21 to a 1.5-fold increase for patients diagnosed at age 61 or above. In the UK study, the relative risks for lung cancer decreased from 20-fold among those diagnosed before age 25 to 2.2-fold for patients diagnosed at age 55 or above (Table 43.4). Table 43.4 demonstrates that a significantly greater relative risk with younger age at diagnosis of HL is also observed for digestive tract cancers^{9,10,15,20} and for cancers of the thyroid, bone and soft tissue.^{9,10} Despite the very high *relative risks* at younger ages, the *absolute excess* risks for all solid cancers except breast cancer are greater for those diagnosed at older ages, related to the much higher background rate of cancer among elderly patients.^{9,10}

The strongly increased relative risks of solid tumors in patients treated for HL at a young age only become manifest after an extended follow-up period. This might point to a prolonged induction period, but it might also in principle relate to the attained age of the patients. Only three recent studies have distinguished the separate contributions of age at first treatment and attained age.^{10,15,37} The relative risk of solid tumors was greatest among patients treated at a young age (≤ 20 years), but the largest relative risk emerged *before* the patients attained the age range at which solid tumors normally occur. Among patients first treated at age 20 or younger, in the largest study to date, the relative risk of developing a solid tumor at ages 40–59 was significantly lower than the relative risk of solid tumor development before age 40 (RR 2.3 versus RR 10.5).^{10,37} Table 43.5 shows that for breast cancer, the diminution in relative risk with increasing age is even more dramatic. Metayer et al³⁷ found that among female patients first treated at ages 17–20, the relative risk of developing breast cancer before age 30 was 84-fold increased, while the risk of breast cancer development after age 40 was only 4-fold elevated. It is notable that a similar finding has been reported with regard to the risk of breast cancer among atomic bomb survivors in Japan.⁵⁶

Conclusions

In conclusion, the occurrence of treatment-related second cancers is a major problem in survivors of HL. The substantial increase in risk of solid tumors with time since diagnosis of HL necessitates careful, long-term medical surveillance of all patients. The greatly increased risk of NHL throughout follow-up demonstrates the importance of performing biopsies in recurrent HL. As the absolute excess risk of lung cancer is much greater among smokers than non-smokers, physicians should make a special effort to dissuade HL patients from smoking even before treatment starts. Women treated with mantle field irradiation before the age of 30 are at greatly increased risk of breast cancer. In many centers, from 8 years after irradiation, the follow-up program of these women now includes yearly breast palpation and mammography. Also, the importance of regular breast examinations is explained to survivors, and they are taught (monthly) breast self-examination. It should be emphasized, however, that the efficacy of these measures in this specific population has not been demonstrated. There is a strong need for research to evaluate the efficacy of programs aimed at reduction of breast cancer mortality in these high-risk women. Physicians should also be alert to the raised risk of gastrointestinal cancers in patients who have received para-aortic and pelvic radiation fields. Thorough examination of gastrointestinal complaints is indicated. Chemotherapy also appears to increase the risk of solid malignancies, in particular lung cancer. An important question to be answered in future research is whether modern chemotherapy regimens (ABV) also contribute to the risk of solid tumors, and if so, which cytotoxic drugs are responsible for the excess risk. One of the most devastating second malignancies to occur among patients cured of HL remains chemotherapy-related leukemia. As the poor prognosis of this complication cannot be changed by early diagnosis, it is promising that the risk of leukemia decreased dramatically with the introduction of ABV-based regimens in the 1980s. Hopefully, current treatment protocols that limit the dose and fields of radiotherapy will similarly reduce the late risk of solid cancers.

Cardiovascular disease

Aside from second malignancies, cardiovascular disease is the most common cause of excess morbidity and mortality among long-term survivors of HL. The information available on the relation of cardiovascular disease to HL treatment is less extensive and detailed, however, than that for second malignancies. In general, also, the quality of epidemiological data available is poorer, and as a consequence the results are more difficult to interpret.

Two methodological points need especially to be borne in mind when considering the literature. First, because cardiovascular disease is such a common cause of morbidity and mortality in adults in Western countries, findings that substantial numbers of cardiovascular events, abnormalities, or deaths occur after treatment for HL does not in itself implicate the HL treatment as the cause; one needs to compare the numbers of events/deaths occurring with those to be expected in the general population of the same age and sex as the patients at the same calendar period, to conclude whether treatment has led to an increased risk. Unfortunately, much of the literature has not provided such 'expected' data, so that it is difficult to know to what extent the observed morbidity or mortality is in excess. This is particularly the case for incidence, because data on incidence of cardiovascular diseases such as pericarditis are scarce. Unlike the discussion of second malignancy, however, we have included such results in this chapter, *faute de mieux*.

A second methodological point, again unlike for second cancers, is that ascertainment of many cardiovascular endpoints, in particular subclinical disease, requires procedures that are beyond those needed for clinical care or treatment and are often invasive. As a consequence, usually only a modest proportion of eligible subjects undergo these procedures. There is therefore scope for selection bias in the subjects included, especially for long-term follow-up studies.

There have been three major potential cardiovascular late effects of HL treatment that have been of concern: the cardiac effects of radiation exposure to the heart, the cardiac effects of treatment with anthracyclines, and the potential ill-effects of carotid exposure to radiation.

Cardiac effects of radiotherapy

Cardiac damage from chest radiotherapy is the most thoroughly investigated late cardiovascular effect of HL treatment. Electrocardiographic abnormalities are frequent (25% of patients or more) in many studies, but not all,^{57,58} especially where radiation fields have been anterior or anteriorly weighted. In addition, however, mediastinal radiotherapy has been associated with a range of heart diseases, including acute and chronic constrictive pericarditis, valvular heart disease, ischemic heart disease, and myocardial infarction.

Pericarditis

Pericarditis may be acute, occurring months or years after treatment, or chronic constrictive. The risk of pericarditis has been shown to increase with radiation dose⁵⁹⁻⁶¹ and with dose per fraction.⁶¹ Subcarinal blocking can greatly decrease the incidence of pericarditis.⁶⁰ The risks of pericarditis have been greater when anterior field weighting was greatest, and

radiation techniques were then modified to reduce the dose of radiation to the heart. In a French series of 499 patients treated during 1971–84 with mediastinal radiotherapy, mainly about 40 Gy, with anterior and posterior beams equally weighted, the 10-year cumulative incidence of pericarditis was 9.5%, whereas no cases of pericarditis occurred among 138 patients who did not receive mediastinal radiotherapy ($p < 0.005$).⁶¹ In a US series, carditis occurred within a year in 6.6% of 318 patients treated before 1970 with mediastinal radiotherapy, mainly 44 Gy.⁵⁹ In 590 patients treated during 1969–84 at Harvard with at least full mantle radiotherapy around 40 Gy, equally from anterior and posterior fields, however, and who were followed for at least 2 years (unless dying), pericarditis occurred in only 2.2%.⁶² No comparison was made with expected numbers in the general population (see the introduction to this section).

Heart valve injury

It is clear that radiation can cause heart valve injury in a substantial proportion of patients. In a study of 116 patients in Norway given mediastinal irradiation at ages under 50 years and examined by echocardiography 5–13 years later, aortic and/or mitral valvular regurgitation was found in 24% of patients. The prevalence was significantly greater in females (46%) than in males (16%),⁶³ and the lesions were more frequent and severe than expected from normal reference groups.⁶⁴ Age, period of follow-up, radiation dose, and chemotherapy were not found to be significant risk factors, however. In Zurich, echocardiography on 144 patients who had been treated with mediastinal irradiation for HL during 1964–92 showed that 29% had valvular thickening, although there was functional disturbance in only 3%.⁶⁵ The cumulative incidence of valvular thickening increased from 8% at 10 years after irradiation to 45% at 20 years. Furthermore, in patients who had echocardiography repeated 1–6 years after an initial such examination, 8% who were initially normal had developed valvular thickening at the second investigation and 37% of those whose valves were initially abnormal had deteriorated.

Valvular injury can lead to death, but is not a major cause—in a large HL cohort at Stanford, 7 out of 617 deaths were due to valvular heart disease or complications of valve replacement (expected number not stated).⁶⁶

Myocardial infarction and cardiac death

Myocardial infarction is an important late effect of mediastinal radiotherapy. The cumulative incidence of myocardial infarction in a French cohort receiving mediastinal irradiation, generally mantle, was 3.9% at 10 years,⁶¹ while in a European Organization for Research and Treatment of Cancer (EORTC) cohort who had received mantle radiotherapy, it was 2.4% at 10 years and 4.6% at 15 years.⁶⁷ In Swiss patients who had received mediastinal radiotherapy, the cumulative risk of ischemic events, sudden death, and congestive heart failure was 14% at 20 years.⁶⁵ In 145 patients treated with mantle irradiation at the MD Anderson Cancer Center, cumulative rates of cardiac complications (coronary artery disease, valvular stenosis, arrhythmia, and pericarditis) were 13% at 10 years and 35% at 20 years.⁶⁸

In patients treated at ages under 21 years, mainly with mantle radiotherapy, the cumulative risk of myocardial infarction was 8.1% at 22 years.⁵⁸ The expected figures for the general population were not given in the above studies, however (see the introduction to this section).

Table 43.6 shows the relative risks of mortality from myocardial infarction and from cardiac death more broadly, in cohorts of patients most or all of whom were treated with mediastinal radiotherapy. The studies are highly heterogeneous with regard to age and sex distribution, dose distribution, duration of follow-up, calendar periods, and outcome, so it is unsurprising that the risks found vary, but in general relative risks for adults are around 3–10, and are far greater for child/adolescent-treated cohorts (>20) than for all-age or adult cohorts. Absolute excess risks appear more similar between these groups, however, suggesting that the effect of radiation on risk may be closer to additive than multiplicative. This is also suggested by the one apparent outlier in the adult results: the relative risk from Mexico (where one would expect background rates to be low) is much greater than elsewhere, but the absolute excess risk is similar.

Sex. The relative risk of myocardial infarction or cardiac death has usually been found to be somewhat greater in men than in women,^{65,66,71,75} although not always,^{2,70} whereas absolute excess risks have been several times greater in men.^{2,66,75} The more marked sex difference for absolute excess risks than for relative risks reflects higher background rates in men. For other cardiac disease mortality, relative risks have been similar between the sexes, but absolute excess risks have been greater in men.⁶⁶

Age at treatment. As noted earlier, studies of patients treated as children and adolescents compared with those of patients treated as adults suggest much larger relative risks (but more similar absolute excess risks) for the former than the latter (Table 43.6). This is also true for comparisons within cohorts.^{66,71,76}

Within adult ages, in a large cohort from Stanford,⁶⁶ relative risks of death due to myocardial infarction, and due to other cardiac diseases, decreased sharply with increasing age at irradiation, while absolute excess risks increased with age. A large Dutch cohort

of patients aged 40 or younger at treatment showed similar effects for non-cerebrovascular cardiovascular disease.² EORTC data also indicate decreasing cardiac mortality with increasing age, dichotomizing the analysis at age 40.^{61–69} In a large North American cohort, however, Boivin and colleagues⁷⁰ found greatest relative risks of death due to myocardial infarction after mediastinal irradiation at ages 60 and above, and in patients treated under age 40 and at ages 40–59 fairly similar to each other.

Relative risks of both myocardial infarction and other cardiac disease have been found to decrease with increasing attained adult age.^{2,62,66,75}

Calendar period. The introduction of blocking should have diminished the rate of cardiac mortality in patients treated in subsequent years, but the evidence on this is not entirely consistent. At Stanford, in a large all-age cohort, the relative risk of death from cardiac diseases other than myocardial infarction decreased from 5.3 to 1.4 when left ventricular and subcarinal blocking were introduced (subsequently, there was also a reduction in fraction size and other modifications), but the relative risk of death from myocardial infarction barely changed (3.7 for patients treated before 1972 and 3.4 for those treated subsequently).⁶⁶ The authors suggested that this may have been because the blocking may not have shielded critical proximal coronary arteries. In patients treated under age 21 at Stanford, the risks of cardiac disease mortality overall, and of myocardial infarction specifically, were also similar for those treated before and after blocking was introduced,⁵⁸ and in the Netherlands, for patients treated under age 40, treatment-specific relative risks did not diminish with the introduction of shielding.² Boivin and colleagues,⁷⁰ however, found a relative risk of 6.3(1.7–23.2) for myocardial infarction mortality in patients treated during 1940–66, when radiotherapy tended to be orthovoltage with anterior or predominantly anterior techniques, compared with 2.0(0.7–5.2) for those treated in 1967–85, when megavoltage machines and improved techniques were used.

Dose of radiation. Investigation of the risk of cardiac death in relation to the dose of radiation has been limited by a lack of variation in dosage, because most patients treated with mantle radiotherapy have received around 40 Gy. In 2232 patients treated at Stanford, there was a relative risk of 2.6(0.4–8.7) for those receiving 30 Gy or less to the mediastinum, and 3.5(2.7–4.3) for those receiving more than this⁵⁸—however, relatively few patients received the lower doses, with a correspondingly wide confidence interval. Cosset and colleagues,⁶¹ in a follow-up of 637 French patients, stated that no ‘dose-effect’ could be detected for the incidence of myocardial infarction in relation to radiotherapy, but did not present risk data. In Sweden, the risk of mortality due to ischaemic heart disease was found to rise with an increasing dose to a larger volume fraction, but the statistical significance was not tested.⁷⁷

Duration since treatment. Risks of cardiac mortality rise in the early years after mediastinal radiotherapy, and remain elevated for 20 years or more, although the literature is not consistent on when the peak relative risk is reached. At Stanford, for patients treated in 1960–90,⁶⁶ the relative risk of death due to myocardial infarction was significantly raised even 0–4 years after initial treatment (RR 2.0(1.1–3.3)), and increased significantly and approximately progressively through 20 or more years after treatment. The absolute excess risks rose even more steeply. A similar pattern was present for other cardiac disease deaths. It should be noted, however, that the patients with longer follow-up were those treated during earlier calendar periods, when the radiation techniques gave less protection against myocardial damage. At Harvard, for patients treated in 1969–97, the relative risk of cardiac mortality was again raised in the first 5 years of follow-up and did not diminish even 20 and more years after first treatment.⁴ Absolute excess risks of cardiac mortality rose steeply in long follow-up periods. In patients treated under age 21, risks of both myocardial infarction and other cardiac diseases have remained greatly elevated beyond 20 years of followup.⁵⁸ In a study in the Netherlands with exceptionally long follow-up, the peak of both relative and absolute excess risk of non-cerebrovascular cardiovascular disease mortality occurred at 20–24 years after treatment, and, based on modest numbers, there was a decrease thereafter.

Cosset and colleagues,⁶⁷ however, stated that in EORTC data, standardised mortality ratios for cardiac failure reached a peak 3–11 years after treatment, although data were not presented. North American data⁷⁰ also gave some suggestion of a similar pattern for myocardial infarction deaths.

Interaction with other risk factors. An important question is whether the effect of radiotherapy interacts with that of other risk factors for myocardial infarction. Data are limited and inconclusive. Glanzmann and colleagues⁶⁵ found that the risk of ischemic heart disease after mediastinal radiotherapy was greater in patients with cardiovascular risk factors in addition to radiotherapy than in those without, but this conclusion was based on small numbers and the difference between the groups was not significant. At Rochester, NY, the cardiovascular risk factor prevalence was greater in patients with cardiac events after radiotherapy than in the general population, but it was not stated how this compared with other radiotherapy-treated HL patients.⁷¹ Boivin and colleagues⁷⁰ found inconsistent results on whether the risk of death due to myocardial infarction after mediastinal radiotherapy was greater in patients with certain

other cardiovascular risk factors, and Hancock and colleagues⁶⁶ noted that 53% of 49 patients in their cohort who died of myocardial infarction after mediastinal irradiation and for whom smoking data were held were ever-smokers, compared with 47% of the cohort overall. It remains unclear, and needs investigation, how the increased risks from radiation interact with those from other cardiovascular risk factors—for instance, if they are additive or multiplicative.

Chemotherapy with anthracyclines

Cardiac effects of anthracyclines in cancer patients generally

A second potential source of long-term cardiac damage from treatment for HL is treatment with anthracyclines, notably doxorubicin. Doxorubicin can lead to an acute toxic cardiomyopathy, which has a peak onset at 1–3 months after cessation of treatment. Longer-term follow-up of such patients, however, has shown that there are also chronic cardiac complications.

Much of the evidence for this comes from studies following up children who were treated with anthracyclines for a range of childhood malignancies, mainly or entirely not HL. Abnormalities have been found in a high proportion of children, with the prevalence and/or severity greater in those with higher dose rates and higher cumulative doses and increasing with longer follow-up; and there is conflicting evidence on whether the prevalence and/or severity is greater with younger age of childhood treatment. Thus, Lipshultz and colleagues⁷⁸ performed echocardiograms on 120 patients (50% of those eligible) who had been treated at a median age of about 7 years with 244–550 mg/m² of doxorubicin, and found that all had echocardiographic abnormalities at follow-up 2 or more years after the end of treatment and 12 (10%) had congestive heart failure a year or more after treatment. Similarly, Steinherz and colleagues⁷⁹ evaluated by electrocardiograph 4–20 years after anthracycline treatment 201 patients treated at ages 2–23 years with 200–1275 mg/m² anthracycline (51 also with mediastinal radiotherapy), and found that 23% had abnormal cardiac function and 9 developed cardiac failure and dysrhythmia, of whom 3 died suddenly. Among 607 Dutch children treated with anthracyclines, clinical heart failure not attributable to other known causes was found in 2% after 2 years and 5% after 15 years, with a cumulative dose-response effect and 4 deaths from this complication.⁸⁰ Another large cohort study noted 6 deaths from doxorubicin-induced cardiomyopathy 5 or more years after childhood treatment.⁸¹

Few studies have furnished comparisons with expectations. Pihkala and colleagues⁸² compared left ventricular contractility on echocardiogram at a median of 4 years after the end of treatment in children treated with anthracyclines and those not so treated. The prevalence of abnormality was greater in those receiving both anthracyclines and chest radiation (50% of 26 patients) or doxorubicin alone (32% of 53 patients) than in those treated with chest radiotherapy alone (8% of 12 patients) or in healthy children plus newly diagnosed untreated cancer patients (3% of 38 subjects). A greater cumulative dose of anthracycline was associated with decreased contractility ($p < 0.05$). Green and colleagues,⁸³ in follow-up beyond 15 years of 474 patients treated for cancer at ages under 20, found that the relative risk of cardiac death in males was significantly associated with doxorubicin treatment in a univariate ($p = 0.0015$, $n = 5$) but not a multivariate analysis, while no cardiac deaths occurred in females.

In adults, anthracyclines can lead to late cardiac deaths, but the risk remains unqualified. Moreb and Oblon⁸⁴ noted that among a series of 19 adult cancer patients (none with HL) with anthracycline-induced heart failure, 7 died within weeks, but 4 more who had made a clinical recovery from their heart failure had a fatal relapse of it later during an intercurrent illness.

Effect in patients with HL

Doxorubicin is commonly used in HL treatment—notably since the introduction of the ABVD regimen in 1973. Information on the effects of anthracyclines on cardiac disease in HL patients has been very limited, however. Large cohort studies have found no significant raised risk of mortality due to myocardial infarction or to coronary artery disease in relation to chemotherapy overall,^{58,66,70} but they have not analyzed risks specifically in relation to anthracycline treatment.

In 39 children and adolescents treated with six cycles of A-COPP (doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) plus involved-field radiotherapy (IFR), probably followed for 6–14 years, Sullivan and colleagues⁸⁵ noted 1 death from cardiopathy, 1 case of late cardiac toxicity, plus 1 cardiac abnormality under treatment, whereas among 45 similar patients treated with MOPP and bleomycin plus IFR, no such episodes of toxicity occurred.

In patients treated as adults, several studies have assessed cardiac function in groups of about 20–40 patients treated with ABVD plus radiotherapy (\pm MOPP) 6 months to several years earlier, and have not found frequent serious abnormalities.^{86–89} Because the assessments were for the subset of subjects who had survived and were willing to be tested, however, these represent a potentially biased evaluation of cardiac effects. Lund and colleagues⁶⁴ analyzed indices of myocardial function in relation to cumulative dose of

doxorubicin in about 40 mainly adult patients and stated that there was ‘no significant dose-response’, but presented no data. Avilés and colleagues⁹⁰ investigated cardiac function at rest in adults 5–8 years after treatment with at least six cycles of chemotherapy but no mediastinal radiotherapy, and found an abnormal left ventricular ejection fraction (LVEF) in 40% of 45 patients treated with doxorubicin (ABVD), 31% of 51 treated with epirubicin (EVBD), and 42% of 40 treated with mitoxantrone (MVBD). It is unclear what proportion of the general population, or of other HL patients, would have been deemed abnormal on the basis of the same criteria. In Berlin pericardial thickening was found 2–10 years after treatment in 27% of 18 adult HL patients treated with COPP/ABVD without mediastinal irradiation and 45% of 31 treated with this chemotherapy plus mediastinal irradiation.⁹¹ There was valvular thickening in 43% of the overall group of patients, but no significant difference in cardiac flow velocity between treated patients and controls.

With regard to major morbidity in adults, Avilés and colleagues,⁷³ in follow-up of 2980 patients with HL, stated that anthracycline treatment was ‘associated’ with cardiac events (occurrence of myocardial infarction, congestive heart failure, or LVEF abnormalities—mainly the first two categories, and including 27 deaths), but no denominator-based analyses of risk were presented.

Cerebrovascular disease

Case reports have suggested that carotid artery disease and stroke might be late consequences of neck irradiation, and a cohort study of cancer (but not HL) patients treated with radiotherapy to the neck found a significantly raised incidence of stroke.⁹² Evidence on cerebrovascular disease incidence or mortality in HL patients in relation to radiation treatment is scant, however. Elerding and colleagues,⁹³ in a cohort study of 910 patients who had survived at least 5 years after cervical irradiation for HL, NHL, or head and neck neoplasms (mainly the latter), found an incidence of stroke 66% (but not significantly) greater than expected for age, sex, and race, but the comparability of the expected data source is unclear. In 77 of the HL patients who underwent oculoplethysmography (but these were probably well under 50% of those approached to participate), 16% had significant stenosis of the carotid/ophthalmic artery system (and 10% had carotid symptoms)—twice the frequency in a group of 25 age- and sex-similar patients referred to the authors’ laboratory for evaluation of cardiovascular symptoms.⁹³ In a cohort of HL patients in the Netherlands almost all treated with radiotherapy—although this may not have been to the neck, a significantly raised relative risk of cerebrovascular accident mortality was found (3.3(1.1–7.8)).²

Conclusions

Mediastinal radiotherapy can cause a range of cardiac ill-effects, including pericarditis, valvular damage, ischemic heart disease, and myocardial infarction. Treatment strategies have been altered over time in order to try to reduce the risks of these ill effects, but the extent to which this has been achieved has not been well documented. There is extensive evidence that doxorubicin in high cumulative doses can cause cardiac damage in children, and data showing long-term cardiac mortality—although the risks of the latter have not been well quantified and the evidence is largely not from HL patients per se. There is a need for large cohort studies focused on the question of whether doxorubicin treatment for HL affects the risk of late mortality from cardiac disease, and whether the effects of mediastinal radiotherapy interact with any effects of doxorubicin. The possible effect of cervical irradiation on risks of stroke incidence and mortality also needs clarification.

While it would seem reasonable to reduce radiation doses to the heart within constraints of therapeutic needs, and to monitor and minimize cardiovascular risk factors in patients who have been treated with mediastinal radiotherapy, the evidence to show to what extent this will actually reduce cardiovascular disease and mortality risks is partial and inconclusive. There is a need for large-scale studies of long-term cardiovascular mortality and major morbidity in relation to the therapeutic modalities discussed above.

Acknowledgments

We thank Mrs Margaret Snigorska for secretarial help.

Late effects in children treated for acute leukemia

Stuart Mucklow and Gill Levitt

Introduction

A majority of pediatric patients who present with acute leukemia in a developed country will achieve long-term disease-free survival following intensive chemotherapy. Major developments of treatment regimens for pediatric leukemias have taken place over the last 30 years, validated through data obtained from large multicenter randomized clinical trials. Significant gains in rates of disease-free survival for successive cohorts of children with acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) have been achieved over this period (Figure 44.1). Advances in diagnostic techniques and disease classification, application of risk-stratified approaches to treatment, developments in combination chemotherapy therapies, and improvements in supportive care have all contributed to this survival benefit. Although further chemotherapy or allogeneic stem cell transplantation (alloSCT) can be successful in relapsed disease, most of the long-term survivors of pediatric leukemia are individuals who remain in first complete remission.¹

However, the modalities used in the treatment of leukemia are associated with significant acute and long-term toxicities at therapeutic doses.^{2,3} In children, dysfunction may arise either due to direct organ damage or through an impairment of the growth or maturation of an organ system. Toxicities are cumulative, so exposures to therapeutic agents that are accrued through retreatment of relapsed patients tend to be associated with greater organ damage.

An important aim of clinical trials of pediatric leukemia treatment is to seek to establish an optimal balance between the likelihood of achieving long-term disease remission through effective treatment, and minimizing treatment-associated morbidity in the disease-free survivors. Long-term follow-up is important to identify treatment-related morbidity, which may not appear until many years after the completion of therapy, and to assess its adverse impact on survivors' quality of life. This should be an important consideration in the process of reviewing and further developing treatment regimens for pediatric leukemia.

We believe that the correct setting for follow-up of child survivors of leukemia is in a dedicated age-specific 'long-term follow-up clinic'.^{4,5} Here, surveillance for treatment-related morbidity can be part of a global assessment of the health and development of these individuals, in a supportive multidisciplinary environment that also addresses health promotion issues.

Figure 44.1 Overall survival rates of children treated for acute lymphoblastic leukemia in successive UK MRC trials. Courtesy of S Richards and G Buck, MRC Clinical Trials Service Unit, University of Oxford, UK.

An essential basis for appropriate follow-up is an accurate end-of-treatment summary that clearly itemizes the relevant therapeutic exposures with potential toxicity. In this context, the original histological diagnosis is of less direct relevance. However, it can provide a useful means of categorization when a cohort of children who are being followed up in a long-term follow-up clinic have been treated according to a particular regimen and have accrued similar exposures. Debate continues over whether regular follow-up in a hospital-based clinic is necessary for all individuals who have been treated for leukemia in childhood, and the duration for which such follow-up remains appropriate.

The discussion of late effects of treatment for childhood leukemia in this chapter concentrates on four areas: cardiotoxicity, effects on growth and other endocrine dysfunction, cognitive and neuropsychological sequelae, and the increased risk of second primary neoplasms. This chapter is intended to complement the other chapters in this book on late effects associated with the treatment of Hodgkin lymphoma (HL) and alloSCT (Chapters 43 and 45). Our choice of areas that we consider to be clinically important is based on the selection of predominantly retrospective clinical studies of cohorts of survivors of childhood leukemia that have provided valuable data relating treatment modalities and long-term outcome. However, they are by no means the only ones that should be considered in the long-term follow-up of such individuals.^{6–9} Systems that may be affected by therapeutic exposures to radiotherapy, chemotherapeutic or antimicrobial agents, or opportunistic infections are listed in detail in recent follow-up guidelines developed by the Children's Oncology Group.¹⁰

Cardiotoxicity

Anthracycline drugs constitute an effective component of contemporary combination chemotherapy protocols for the treatment of AML and ALL in children. However, their use is limited by dose-related cardiotoxicity due to focal myocyte death and replacement fibrosis, which can result in acute or late cardiac dysfunction. Growth hormone insufficiency and obesity, which may also be consequences of childhood leukemia treatment, are additional independent risk factors for cardiac dysfunction in survivors. Two recent systematic reviews^{11,12} have provided overviews of the risk factors for and incidence of heart failure and subclinical cardiotoxicity in survivors of childhood cancer who received anthracycline treatment.

An increased risk of cardiac dysfunction and ischemic heart disease following mantle irradiation that includes the heart, particularly with doses above 30 Gy, has been found following treatment for HL,^{13,14} but no increased incidence of cardiac dysfunction has been demonstrated in ALL survivors who received craniospinal irradiation in addition to chemotherapy.

The cumulative total dose of anthracycline is the most important parameter associated with early cardiomyopathy and symptomatic heart failure.¹⁵ An increased incidence of heart failure in children has been demonstrated with a cumulative exposure of more than 300 mg/m² of doxorubicin, while the rate increases rapidly above 450 mg/m².¹⁶ Cumulative anthracycline exposure was also the most important factor identified in the retrospective analysis of children who had received chemotherapy on Pediatric Oncology Group protocols: a dose of more than 550 mg/m² increased the relative risk of congestive heart failure in this series reported by Krischer et al.¹⁷ Other treatment factors included a maximum single anthracycline dose of over 50 mg/m², treatment with amsacrine, trisomy 21, female sex, and the ethnic origin of the child. Delivery of low or moderate anthracycline doses through continuous infusion rather than as a bolus does not appear to be cardioprotective in children.^{18,19}

Cumulative anthracycline dose is also the strongest independent risk factor for developing late-stage cardiac dysfunction.^{20–22} These late cardiotoxic effects of anthracycline exposure were identified initially through long-term surveillance of pediatric cancer survivors who had been treated in the late 1970s and received relatively high cumulative anthracycline doses. For example, the children described by Goorin et al²³ had been treated with between 390 and 450 mg/m² of doxorubicin.

Evidence of early cardiac dysfunction related to anthracycline treatment is also an important indicator of increased risk for developing late cardiac failure or asymptomatic dysfunction on echocardiography. A cross-sectional study of relapse-free ALL survivors,²⁰ who had been treated with cumulative doses of between 230 and 550 mg/m² of doxorubicin, found echocardiographic abnormalities of cardiac function in almost two-thirds of the patients at a median follow-up time of 6 years from remission. Of the children in this cohort, 11 (10%) had required treatment for acute congestive heart failure, and 5 of these suffered a recurrence, with 2 proceeding to cardiac transplant. Lipshulz et al²¹ presented data that suggested an increasing prevalence of cardiac abnormalities with length of follow-up in ALL survivors, and more severe abnormalities were found in this study in female subjects.

The UK Medical Research Council (MRC) UKALL X Pilot and UKALL X clinical trials^{24,25} were conducted in the 1980s to assess the value of intensification treatment in pediatric ALL. Patients were treated on a common treatment protocol with a cumulative total dose of 90, 180, or 270 mg/m² of daunorubicin,

delivered through bolus infusions. Three samples, based on these doses, of 40 relapse-free patients from the combined trial cohorts, who were treated at a single institution, have been studied prospectively for more than a decade, and provided valuable data on long-term cardiotoxicity from exposure to lower cumulative anthracycline doses.^{26,27}

Although all of the ALL survivors in the study were asymptomatic at the time of assessment, 23% were found to have echocardiographic abnormalities of cardiac function at a mean of 6 years post treatment, while 15% had abnormalities at 10 years.^{26,27} In most individuals, the abnormality was increased left ventricular end-systolic wall stress, while a minority of the subjects also had a significant reduction in cardiac contractility. No association was found between cumulative dose, female sex, or age at presentation and the likelihood of an echocardiographic abnormality within this range of cumulative doses (90–270 mg/m² daunorubicin). Where deterioration was demonstrated in cardiac performance between the first and second assessments, this was more likely to be found in children who had received a cumulative dose of more than 240 mg/m². Significant improvements in functional echocardiographic parameters tended to be restricted to subjects who had received lower exposures. There was one sudden death—in a 16-year-old boy who had previously been shown to have mild echocardiographic abnormalities. Extensive myocardial fibrosis was found at autopsy. All other members of these sample cohorts remained asymptomatic.

Regular cardiac monitoring during and after anthracycline treatment is recommended practice.^{5,8,10,28} However, Lipschultz et al²⁹ reviewed the evidence base for the Children's Cancer Study Group (CCSG) practice guidelines²⁸ and have disputed the value of echocardiographic screening, using chamber dimensions and fractional shortening as measures of left ventricular function, in reliably detecting early signs of anthracycline-related cardiotoxicity, or in providing prognostically relevant data with respect to long-term cardiac performance. More invasive tests, such as dobutamine stress testing, can increase the sensitivity of echocardiography, and may be appropriate for assessment in situations such as pregnancy or competitive sports.^{5,30}

Angiotensin-converting enzyme (ACE) inhibitors have been used to treat anthracycline-related cardiac dysfunction in survivors of childhood leukemia with short-term improvement in echocardiographic cardiac function,³¹ although the clinical benefit has been questioned.³² The long-term benefit of ACE inhibitor treatment for such individuals is under investigation in a prospective clinical trial.³³

A liposomal formulation of daunorubicin, Dauno-Xome, may offer equivalent efficacy with lower rates of acute or long-term cardiotoxicity and is under evaluation. Co-administration of dexrazoxane (ICRF-187) with an anthracycline has been shown to reduce the risk of acute cardiotoxicity,³⁴ but its effectiveness in avoiding late cardiac dysfunction has not been established.

Endocrine dysfunction

Endocrine disturbances are present in up to 40% of childhood cancer survivors.³⁵ For survivors of childhood acute leukemia, the areas where late effects of treatment are particularly important are growth, obesity, skeletal changes, progression through puberty, and fertility. The deficits and adverse long-term outcomes that may be present depend on the nature and cumulative dose of the cytotoxic agents that were administered, and the dose and fields used for radiotherapy. They also relate to the age and developmental stage that the individual had reached at the time of treatment. A higher incidence of endocrine deficit is detected in studies where provocative testing is used as the investigational tool, rather than measurement of physiological parameters.

Growth

Modern protocols for the treatment of childhood ALL do not use routine cranial or craniospinal irradiation to provide central nervous system (CNS)-directed therapy. Impaired growth is seen in some survivors after treatment with chemotherapy alone,^{36–39} but the final height achieved is generally within the normal adult range. Growth hormone (GH) deficiency on laboratory testing is not found as frequently in these individuals as in survivors from earlier cohorts who received treatment for ALL that included low-dose cranial or craniospinal irradiation (18–24 Gy), where GH deficiency can be demonstrated in up to 50%.^{40–45}

Some studies report a dose dependence of the deficit in GH production after 18 or 24 Gy cranial irradiation shown by GH stimulation testing,^{40,44,46} but this relationship has not been observed by others.^{47,48} In some individuals, the GH deficit was shown to evolve during the follow-up period,^{42,45,49} and it may not become manifest until puberty, when the peak amplitude and periodicity of GH secretion may be adversely affected.⁵⁰

Studies of long-term ALL survivors have also shown that spontaneous GH secretion over 24 hours is reduced both before and during puberty,^{41,46,48,50} but a direct relationship between the mean 24-hour GH level and height or growth velocity has not been demonstrated.^{41,51,52} Low-dose cranial irradiation may result in precocious puberty in girls,^{53–56} but no effect on puberty has been demonstrated in boys. Precocious puberty may compound the effect of GH

deficiency by reducing the time taken to reach final height.

Decreased final height relative to centile height at diagnosis has been demonstrated in several longitudinal and cross-sectional cohort studies of ALL survivors who received prophylactic low-dose cranial irradiation.^{37,38,52,55,57–61} Davies et al⁶⁰ demonstrated that the short stature was disproportionate in their cohort of child survivors of ALL, who had relatively shorter backs than legs. Nevertheless, a majority still achieve an acceptable final height that lies within the normal adult range, and GH therapy^{54,62} is not often required. However, survivors who require further cranial irradiation after a course of irradiation as primary CNS-directed therapy are often more severely affected.^{40,63}

Secretion of GH is the most sensitive to disruption following low-dose cranial irradiation, and this does not commonly lead to a deficit in the production of other anterior pituitary hormones.⁴⁵ For example, a long-term follow-up study assessing thyroid hormone secretion found that prophylactic cranial irradiation for childhood ALL did not affect subsequent thyroidstimulating hormone (TSH) secretion from the anterior pituitary in response to stimulation with exogenous thyroid-releasing hormone (TRH).⁶⁴ Lowdose craniospinal irradiation may lead to some direct thyroid damage, but the long-term risk of hypothyroidism after such treatment appears to be relatively low.

Obesity

Survivors of childhood ALL show increased rates of obesity at all ages following treatment.^{59,61,65–71} Effects on the timing of normal changes in body mass parameters, which influence adult obesity risk, are observed in young children following treatment for ALL.⁷³ Obesity may be a consequence of corticosteroid therapy or low-dose cranial irradiation, and may develop through treatment-related disturbances of the GH and leptin systems. Chronic changes in metabolic status could be exacerbated by the physical inactivity and reduced energy expenditure that have been documented in long-term survivors.^{74,75}

The majority of long-term follow-up studies that have assessed obesity in survivors of childhood ALL have shown females to be at increased risk relative to male survivors.^{67,70,71} However, some studies have not reproduced this observation.^{66,69} Cranial irradiation has also been identified as a risk factor for weight gain or adiposity in most,^{67,69,71} but not all,^{66,73} reports. For example, Sklar et al⁶⁹ undertook a retrospective analysis of the body mass index (BMI) standard deviation (z) score, corrected for sex and height, from measurements recorded at diagnosis, at the end of treatment, and at the attainment of final adult height in 126 survivors treated for childhood ALL. They found that a significant increase in the mean BMI of the group treated with cranial radiotherapy could be observed at the completion of ALL treatment, and persisted to the completion of growth. Of the patients in this group, 40% were overweight when they attained their final height. No increase in BMI was seen for the group who had not been treated with cranial irradiation, and no association with cumulative corticosteroid dose, age at diagnosis, or sex was demonstrated in this study.

The largest retrospective cross-sectional study in this area to date, comprising almost 300 individuals, was based on cohorts drawn from the UK ALL X/XI clinical trials,⁶⁷ and compared survivors who had and had not received cranial irradiation. Both males and females treated with chemotherapy alone showed increased BMI z scores at more than 4 years from diagnosis. In individuals who had been treated with cranial irradiation, an increased BMI z score at final height was associated with female sex but not with age at diagnosis. Severe obesity (BMI z score >3) was only seen in females, with a prevalence of 8%.

Skeletal changes

Osteopenia and osteoporosis are increased in incidence in survivors of childhood ALL.^{76–82} The critical period for bone mineralization extends from childhood into early adulthood, with peak bone mineral density (BMD) reached by about age 25 years, and this process can be severely affected by treatment for acute leukemia in childhood.⁸³ Peak bone mass is the strongest predictor for risk of osteoporotic fracture in later life.

Changes in bone mineralization may be multifactorial:^{83,84} causes may include craniospinal or cranial irradiation,^{76,77,81,86} treatment with methotrexate^{80,81,86} and corticosteroids,⁸⁷ deficiencies of hormones, including sex hormones and GH, nutritional deficiency during treatment, and reduced physical activity and biomechanical loading of the skeleton during and after treatment.⁸⁰ Most studies use dual-energy X-ray absorptiometry (DEXA) to assess BMD.⁸⁴

Among ALL survivors, male sex and prophylactic cranial irradiation are risk factors for a reduced BMD, while age and pubertal status at treatment were not found to be associated with osteoporotic change.^{81,82} However, a smaller study of a cohort of older children (mean age 16 years) treated for ALL with high-dose dexamethasone and methotrexate, but not cranial irradiation, found no long-term effect on BMD in either sex.⁸⁸ Children proceeding to bone marrow transplantation (BMT) may be more severely affected.^{89,90}

Gonadal function and fertility

In survivors of childhood acute leukemia, irradiation of the gonads and the cumulative dose of alkylating

agents are the treatment modalities that have the greatest impacts on subsequent gonadal function and fertility in both sexes.^{91,92}

Gonadal function in males is affected by relatively low doses of direct testicular irradiation.^{92–96} The germinal epithelium appears to be exquisitely sensitive. Radiation doses less than 0.1 Gy can produce temporary oligospermia or azoospermia, while permanent azoospermia occurs with a dose above 2 Gy. Leydig cell damage following external radiation doses above 2 Gy can be detected biochemically through elevated luteinizing hormone (LH) levels, although testosterone levels are still maintained in many cases at this dose. With doses above 20 Gy, irreversible Leydig cell failure occurs in prepubertal boys, while older boys and adults can in some cases tolerate doses up to 30 Gy without loss of testosterone secretion.⁹² Direct irradiation of the testes with a dose of 12 Gy to treat testicular involvement with leukemia has been shown to result in reduced testicular volume (<10 ml), permanent azoospermia, and elevated follicle-stimulating hormone (FSH) and reduced serum inhibin B levels, but testosterone replacement therapy is often not required.^{91,97}

The effects are most marked in boys treated for ALL with testicular involvement or relapse who receive direct testicular irradiation,^{94,97} and in those who proceed to high-dose therapy and BMT with total body irradiation (TBI) conditioning. There is also a risk of gonadal damage in males treated with craniospinal irradiation, due to scatter. In the cohort of ALL survivors investigated by Sklar et al⁹⁸ with FSH and testicular volume measurements, 55% of those who had been treated with craniospinal irradiation and 12 Gy direct testicular irradiation showed testicular failure; 13% who had received craniospinal irradiation alone were also affected, while none of the individuals treated with identical chemotherapy plus prophylactic cranial irradiation had signs of testicular failure.⁹⁸

Cyclophosphamide and other alkylating agents damage the germinal epithelium of the testes, resulting in oligospermia or azoospermia and elevated FSH levels. At higher doses, Leydig cells may also be affected, leading to elevated LH levels, but testosterone levels often remain normal following primary chemotherapy for acute leukemia and most boys undergo normal progression through puberty.^{91,92,99,100} However, spontaneous progression through puberty does not guarantee future fertility.

The degree of permanent damage to gonadal function is related to the cumulative dose of alkylating agents received: testicular failure and infertility is almost universal after exposure to more than 25 g/m² of cyclophosphamide, while normal function and fertility have been reported to be preserved in most males when the cumulative cyclophosphamide dose remains below 3.5 g/m².^{101,102} It has been suggested that prepubertal boys have a lower rate of testicular failure than adults at equivalent doses of cyclophosphamide. This may be based upon the finding of normal gonadotropin levels in prepubertal males despite gonadal damage, which is revealed in an elevation of LH and FSH levels as the child enters puberty. Kenney et al¹⁰² found no effect of pubertal status in their cohort treated with high-dose cyclophosphamide.

Radiation damage to the ovaries due to scatter from low-dose craniospinal irradiation has been demonstrated in a significant proportion of female survivors of childhood ALL who received a dose of 10–15 Gy.¹⁰³ Direct abdominal irradiation is associated with a high rate of primary gonadal failure in survivors.¹⁰⁴ In a study of female ALL survivors in which ovarian function was assessed through measurement of FSH and LH levels, Hamre et al¹⁰⁵ found elevated levels indicating ovarian failure in 93% of individuals who had been treated with abdominal irradiation. Elevated levels were measured in 49% and 9% after identical chemotherapy and craniospinal or cranial irradiation, respectively. TBI with a single dose of 10 Gy causes ovarian failure in prepubertal girls,^{63–106} but ovarian function can be preserved or can recover in many females with fractionated TBI to a cumulative dose of 12 Gy.^{107,108}

With alkylating agent exposure in females, the cumulative dose again determines the risk of subsequent primary gonadal dysfunction. The combination chemotherapy treatments used for primary treatment of childhood leukemia do not often affect ovarian function or fertility.¹⁰³ The age at which the exposure occurs is important, and the ovaries of prepubertal girls appear to be relatively resistant to cytotoxic chemotherapy, probably due to the higher number of follicles that are present. Accelerated loss of follicles and cortical fibrosis have been observed directly in the ovaries of 10 girls following treatment for ALL.¹⁰⁹

Fertility

The majority of ALL survivors are fertile, and female survivors can have successful pregnancies.^{110–113} Cryopreservation of semen from young postpubertal males is effective from the age of 14 years,^{114,115} but gonadal tissue is not preserved from prepubertal males according to current recommended practice.

Although chemotherapy and irradiation could potentially damage DNA in germ cells, no excess risk for congenital malformations in the children of cancer survivors has been found.^{110,116–120} To date, there has been no evidence of an excess risk of cancer being transmitted to the children of survivors of childhood leukemia, after exclusion of individuals suffering from familial cancer syndromes.^{110,121}

Cognitive and neuropsychological sequelae

There is considerable (although at times conflicting), evidence of impairment in cognitive or psychosocial functioning of survivors of childhood leukemia, although the methodology and evidence are of variable quality. Cognitive and psychosocial parameters are methodologically complex to assess, and changes may be multifactorial in etiology: the underlying disease itself, a direct effect of the modalities of treatment that were received, and the adverse impact of the experience of treatment for childhood leukemia on the individual and the family may all contribute to cognitive and psychosocial morbidity.

Cranial irradiation has been associated with long-term impairments in cognitive functioning and educational achievement in a number of studies of long-term survivors of childhood ALL. Cognitive deficits and neuropsychological morbidity are particularly severe in patients who received CNS irradiation with their primary course of treatment and subsequently require retreatment for CNS relapse or as part of TBI conditioning for alloSCT.¹²² In contrast, intrathecal methotrexate does not appear to lead to a subsequent decrement in intelligence quotient (IQ) score in survivors¹²³ or in other areas of cognitive functioning.¹²⁴

A meta-analysis of 30 earlier studies of cognitive function in long-term ALL survivors¹²⁵ concluded that individuals who had been treated with low-dose cranial or craniospinal irradiation showed a significant reduction in IQ relative to various control groups. This effect of CNS irradiation appeared to be inversely related to the individual's age at the time of exposure, and was more marked in females. Subsequent studies have generally supported these conclusions,^{126–132} although it has not been established whether the IQ decrement remains stable with time.

The range of cognitive and educational deficits that have been described for survivors of childhood ALL who received CNS irradiation is wide. They include difficulties with attention or concentration, processing speed and abstract reasoning, short-term memory-dependent functions, and acquisition of language and numerical skills.^{128,130,132–145}

For example, in a cohort of ALL survivors who were assessed in comparison with both sibling controls and survivors of childhood solid tumors,^{135,140} persistent significant cognitive deficits were identified in the ALL survivors, who had received cranial irradiation with 18 or 24 Gy. No dose dependence was established. In a follow-up study, a memory deficit in tasks requiring strategic planning behavior was shown for the ALL group.¹⁴² In another ALL cohort,¹³² a significant reduction in cognitive and educational ability was found relative to solid tumor survivors and normal control subjects, with more severe deficits in tasks requiring language function, such as verbal IQ, reading, and spelling. Here, there was a trend towards a worse outcome following irradiation with a dose of 24 Gy compared to 18 Gy, with treatment given at a younger age. No sex differences in outcome were observed here, in contrast to other studies, where females have been found to be more severely affected than males.^{131,146}

However, many of the relevant studies that consider these effects retrospectively assess relatively few subjects derived from cohorts of ALL survivors under long-term follow-up at single institutions, and compare them variously with siblings, parallel groups of relapse-free survivors of other childhood cancers, or controls drawn from the normal population. There are further methodological differences in ascertainment and analysis that make comparison of individual studies problematical. There is also considerable variation in the duration of relapse-free survival at followup. Prospective analyses of the long-term intellectual, cognitive, and educational achievements of survivors of childhood acute leukemia are rare. Such data would prove invaluable in determining the relative contributions of the leukemia and the adverse experience of being treated for a pediatric malignancy from the direct morbidity attributable to the various CNS-directed therapies used in contemporary treatment protocols for childhood ALL.

Valuable studies have also been undertaken on the psychosocial functioning of long-term survivors of childhood leukemia and other pediatric malignancies, with outcomes assessed against parameters such as social, educational, or occupational status, although the methodological considerations detailed above also apply to most of these studies. These may contribute to the inconsistent portrait of long-term psychosocial impairment reported by different groups for survivors of childhood leukemia.

Some studies report few psychological problems in relapse-free survivors of childhood leukemia and other malignancies,^{147–151} and document normal social, academic, and vocational functioning relative to control groups.^{152–155} In contrast, others report a higher prevalence of psychological distress, negative mood, poor coping skills, and poor body self-image,^{156–161} and find greater deficits in social competence, increased behavioral problems, and poorer educational achievement in survivors of childhood cancer.^{162–165} Cancer survivors are less likely to be married than individuals in the general population.¹⁶⁶

Studies of the prevalence of psychiatric morbidity in survivors of childhood leukemia, including a recent population-based survey from Denmark, have not found an excess in this group.^{159,167,168}

Neurological changes

Structural changes in the brains of survivors of childhood leukemia may be seen in individuals treated with methotrexate or cranial irradiation.¹⁶⁹ Some subtle changes can be detected with sensitive imaging techniques, but may not be associated with any demonstrable functional impairment.

Several relatively small magnetic resonance (MR) studies have imaged the brains of survivors of childhood ALL treated with prophylactic cranial irradiation,^{170–175} in which individuals were assessed up to 12 years from diagnosis. Various structural abnormalities were reported in some of the survivors, including periventricular white matter changes, cerebral atrophy, and calcification, but these findings were not accompanied by cognitive or neuropsychiatric assessments, and their significance is unclear. Cerebral atrophy may be a consequence of diffuse white matter injury resulting from cerebral irradiation.^{169,175} In the MR angiography component of the study by Laitt et al,¹⁷³ changes in two subjects suggested the possibility of a radiation-induced large-vessel vasculopathy, although this is believed to be very rare with low-dose irradiation for CNS-directed therapy in ALL treatment.

Intrathecal methotrexate, which shows equivalent efficacy in preventing CNS relapse and has consequently replaced irradiation for CNS-directed therapy in contemporary treatment regimens for low-risk ALL patients, has also been found to produce cerebral white matter abnormalities on MR imaging.¹⁷⁶ Again, the clinical significance of these data has not been established. The neurotoxic effects of chemotherapeutic agents have been reviewed by Anderson et al,¹⁴³ Demopoulos and DeAngelis,¹⁷⁷ and Reddy and Witek.¹⁷⁸

Second malignancy

Survivors of childhood acute leukemia grow up with a lifelong increased risk of developing a second malignant neoplasm, but long-term follow-up of relapse-free survivors of ALL suggests that the cumulative incidence in this group is less than 4% at 20 years from diagnosis.^{179–183} Histologically and clinically aggressive second neoplasms may present within the first few years of remission from ALL. Not all series include low-grade neoplasms such as basal cell carcinomas, which show a marked increase in incidence over longer follow-up periods.¹⁸³ Population-based studies may be more powerful than surveys based on a cohort from a single center.

There is a strong association between exposure to cranial or craniospinal irradiation in treatment for childhood ALL and an excess of second malignant neoplasms.^{181,183–189} Many of the neoplasms reported in these series were solid tumors, frequently meningiomas, arising in or adjacent to radiotherapy fields. Asymptomatic meningiomas and other cerebral neoplasms have also been found in small MR imaging studies,^{172,173} where the subjects were assessed at a median interval of more than 15 years from diagnosis. The thyroid gland is particularly radiosensitive, and may be at risk due to scatter in individuals who were treated with craniospinal irradiation, or who received TBI.¹⁹⁰

Data have recently been presented by Pui et al¹⁸³ for the large cohort of patients treated in clinical trials at St Jude Children's Research Hospital between 1962 and 1992, who had achieved at least 10 years of event-free survival following remission induction and had been followed up for a median of over 18 years. These data demonstrate a significantly increased cumulative incidence of second neoplasms among individuals who had received low-dose cranial or craniospinal irradiation, of 4%, 7%, and 20% after 20, 25, or 30 years of event-free survival, respectively. Fellow survivors who were not treated with radiation had an incidence of less than 1% after 30 years from remission. Pui et al¹⁸³ reported that a majority of the second neoplasms diagnosed in irradiated individuals in this cohort were relatively benign or low-grade neoplasms, such as meningiomas and basal cell carcinomas, and this group had a non-significant small excess in mortality relative to the general population.

Registry-based case-control studies have provided an opportunity to investigate associations between exposures during childhood treatment for acute leukemia and the incidence of second malignant neoplasms in areas where registry data approach comprehensiveness. Klein et al¹⁹¹ included survivors of AML and ALL in their case-control analysis of data from the German Childhood Cancer Registry. They were able to show a trend towards an increased incidence of second malignant neoplasms with radiotherapy, and established a dose-related excess risk for treatment with cyclophosphamide or other alkylating agents and mercaptopurine. No clear dose-response relationships were found in this study for methotrexate, cytarabine, or the topoisomerase II inhibitor etoposide. The association between secondary leukemia, often with a chromosomal translocation involving the *MLL* gene, and previous exposure to a topoisomerase II inhibitor has been established and risk estimates have been obtained in other studies.^{192–194}

Conclusions

In this chapter, we have provided an overview of four clinically important areas where there has been valuable research into subsequent adverse 'late effects' resulting from primary treatment of childhood leukemia. The selection of studies discussed above

are necessarily of survivors who received historical rather than contemporary treatment for leukemia. Almost all are retrospective. One of the considerable strengths in this field has been the willingness of patients and clinicians to participate in meaningful large-scale clinical trials of childhood leukemia treatment, and some of the current clinical trial protocols now include long-term prospective studies of various late effects. Such data should prove valuable in confirming the results of previous investigators in this field, and will contribute to the further development of validated primary treatment regimens and the design of appropriate long-term follow-up systems for survivors.

Various models for long-term follow-up of childhood cancer survivors have been proposed,^{4,8–10} and it is unlikely that any one can satisfy the needs of every individual in the context of disparate healthcare systems.

Nevertheless, we feel that a tiered model has considerable merit, and support the proposal for long-term follow-up of survivors of childhood cancer from the Late Effects Group of the UK CCSG⁴ and developed by the Scottish Intercollegiate Guidelines Network (SIGN) authors as part of their practice guidelines.⁵ In this model, most individuals who receive contemporary primary leukemia treatment could receive lifelong follow-up through annual or biennial assessments in an appropriately skilled primary care or specialist nurse-led setting, and be referred to a hospital-based multidisciplinary unit for specific treatment-related problems. However, the SIGN authors concede that the evidence base for this model has not yet been established. Other authors challenge whether lifelong follow-up is appropriate.¹⁹⁵

Since childhood leukemia is relatively ‘curable’, and survivors can potentially enjoy a full lifespan, it is for this group, perhaps more than for any other group treated for hematological malignancy, that the ‘weighting’ that should be given to adverse late effects in selecting appropriate primary treatment is most important. We await with eager anticipation further high-quality data on late effects of childhood leukemia treatment upon which to consider modifications to current clinical practice.

Late effects following allogeneic stem cell transplantation

G rard Soci  and Lionel Ades

Introduction

Over the past two decades, large numbers of patients have survived for years after hematopoietic stem cell transplantation (SCT). Immediate survival as well as prevention of relapse are no longer the sole interest for long-term survivors. Thus, studies on late effects after SCT is a major concern in the 21st century. Malignant diseases are of particular clinical concern, as more patients survive the early phase after transplantation and remain free of their original disease.^{1,2} They are closely related to the preparative regimens used before transplantation. These malignant complications have been previously reviewed³ and recently updated.⁴ Non-malignant late effects are heterogeneous delayed complications of multifactorial etiology. Although often not life-threatening, they may impair the quality of life of long-term survivors.⁵ This chapter will cover both malignant and non-malignant late effects.

Malignant complications

Secondary malignancies are a well recognized complication in patients with Hodgkin lymphoma (HL) or non-Hodgkin lymphoma (NHL) treated with chemotherapy or combined-modality treatment (see Chapter 43). However, it was only in the early 1990s that the risk of secondary malignant diseases was described after allogeneic SCT. Experiments in murine models in the 1960s and 1970s, and in rhesus monkeys, and dogs in the 1970s and 1980s, showed a significant increase in the incidence of malignancies relative to controls in animals irradiated with lethal doses of total body irradiation (TBI) and infused with allogeneic marrow cells. Thus, it should not be surprising that new malignancies occur in patients after allogeneic hematopoietic SCT where one or several of these risk factors are present.

According to the Seattle group, it has been usual to divide the problem of secondary malignancies following hematopoietic SCT into three groups: leukemia, lymphoma, and solid tumors. Chronologically, lymphoma, leukemia, and solid tumors have a typical time course: most lymphomas occur within the first months of transplant, while solid tumors and leukemia are mostly diagnosed years after transplant.

Post-transplant lymphoproliferative disorders and lymphomas

Most cases of post-transplant lymphoproliferative disorders (PTLD) are best classified as B-cell PTLD rather than NHL. In addition, lymphomas with clinical and biological characteristics typical of NHL or HL as seen in non-transplanted patients have occurred following SCT.

B-cell PTLD

B-cell PTLD are clinically and morphologically heterogeneous; they are usually associated with T-cell dysfunction and the presence of Epstein-Barr virus (EBV). The mean interval from transplantation to the development of B-cell PTLD lies between 5 and 6 months, with most cases being diagnosed within 3 months. The diagnostic criteria may differ from one study to another. For example, a non-lethal 'infectious mononucleosis-like' syndrome may resolve spontaneously, and acute-onset extensive disease may be diagnosed only at autopsy. In the largest series, involving 18014 patients, PTLD developed in 78 recipients, with 64 cases occurring less than a year after transplantation.⁶ The cumulative incidence of PTLD was $1.0 \pm 0.3\%$ at 10 years. The incidence was highest 1–5 months post transplant (120 cases/10000/year), followed by a steep decline to less than 5/10000/year among 1 year-plus survivors.

The most frequent presenting findings of PTLD are fever and organomegaly. As with other lymphoproliferative

disorders developing in the context of immunodeficiency patients, extrahematopoietic organ involvement, including lungs, kidneys, and the central nervous system (CNS), is frequent. The differential diagnosis should include PTLD a priori in high-risk situations. Today, the use of quantitative polymerase chain reaction (PCR) of EBV DNA has dramatically changed diagnostic criteria. Using EBV viral load, patients are now frequently diagnosed with 'PTLD'+ while they present only isolated fever with (or even without) low tumor burden and a monoclonal gammaglobulin. This became important in the late 1990s after the development of powerful therapeutic tools. It soon appeared that early diagnosis can be established and the effect of therapy can now be monitored by quantitative PCR of the EBV DNA.

PTLD occurring after allogeneic SCT are almost always of donor origin, and associated with EBV genomic DNA integration. Biopsies reveal monomorphic or polymorphic, diffuse large-cell lymphoma of B-cell origin. PTLD after SCT are pathologically similar to the polymorphic PTLD described in solid organ transplant recipients, but as many as half of the cases after SCT show aggressive features of immunoblastic lymphoma.⁷ Also, in contrast to PTLD after organ transplantation, most B-cell PTLD occurring after SCT are oligo- or monoclonal.⁷⁻¹¹ PTLD express the full array of latent EBV antigens, including EBNA1, 2, 3, 4, 5, and 6, and LMP1.^{7,12-16}

B-cell PTLD were the first post-transplant malignancies for which risk factors were identified^{6,7,17-20} (Table 45.1). The largest study included 18 014 patients.⁶ In multivariate analyses, the risk of early-onset PTLD (<1 year) was strongly associated with unrelated or HLA-mismatched related donors, T-cell depletion of donor marrow, and the use of antithymocyte globulin or an anti-CD3 monoclonal antibody. Methods of T-cell depletion that selectively targeted T cells or T and natural killer (NK) cells were associated with markedly higher risks of PTLD than methods that removed both T and B cells, such as the alemtuzumab monoclonal antibody or elutriation.

B-cell PTLD develop because of a combination of depressed EBV-specific cellular immunity and the inherent transforming capacities of EBV. The virus persists as a latent infection in certain epithelial cells, where reactivation and replication may occur intermittently, and in B lymphocytes.²¹ Among the 80-100 EBV-encoded proteins, latent membrane protein 1 (LMP1) plays an essential role in B-cell immortalization. Deletions near the 3' end of the *LMP1* gene have been reported in some EBV-related lymphoproliferative disorders.^{22,23} Infection of B cells by EBV also induces high levels of interleukin-1 (IL-1), IL-5, IL-6, IL-10, CD23, and tumor necrosis factor (TNF). Deficiencies in EBV-specific cellular immunity contribute to EBV-PTLD susceptibility.²⁴⁻²⁶ Adoptive transfer of EBV-specific cytotoxic T lymphocytes offers effective therapy for B-cell PTLD.²⁷

The diagnosis of PTLD in the 2000's has changed dramatically since the introduction of effective and highly sensitive techniques to measure EBV load and to estimate early EBV-specific immune reconstitution after allogeneic SCT.²⁸ Truly quantitative PCR techniques allow frequent monitoring of the DNA load to predict the development of PTLD. After allogeneic SCT, the utility of such monitoring was confirmed by the Rotterdam group.^{29,30} Finally EBV-specific T lymphocytes can now be monitored through the tetramer technology, which allows the detection of minute numbers of antigen-specific T cells.³¹ The relative frequencies of T cells specific for different EBV peptides in transplant recipients closely reflect those of their respective donors. Investigation of patients at monthly intervals following unmanipulated allogeneic peripheral blood (PB) SCT demonstrated that the frequency of EBV-specific T cells correlates with the number of EBV genome copies in the peripheral blood and that expansion of EBV-specific T-cell populations occurs even in the setting of immunosuppressive therapy. In contrast, patients undergoing T-cell-depleted or unrelated cord blood transplantation have undetectable EBV-specific T cells, even in the presence of Epstein-Barr viremia. Thus, the

protective shield provided by EBV-specific CD8⁺ T cells seems to be rapidly established following unmanipulated matched sibling allogeneic PBSCT.

Complete regression of B-cell PTLD has been reported in 40% of patients following reduction or discontinuation of immunosuppressive drugs, particularly in renal transplant recipients. Immunosuppression is intrinsic to marrow transplantation, and discontinuation of immunosuppression is likely to result in flares of graft-versus-host disease (GVHD) and a further delay in recovery of T-cell-mediated immunity. EBV-transformed B cells contain a circular viral DNA that is not susceptible to inhibition with thymidine kinase (TK) inhibitors. Nevertheless, anecdotal reports suggest tumor regression with either acyclovir or ganciclovir therapy. Chemotherapy and irradiation generally have not proven useful. The use of monoclonal antibodies to treat PTLD was first reported by the Necker group in Paris.^{32–34} However, the anti-CD21 and anti-CD24 antibodies used in these studies are no longer available for clinical use. Most recently, efficacy of the anti-CD20 monoclonal antibody rituximab in the treatment of PTLD after SCT has been reported, and rituximab seems to be highly effective in this setting^{35,36} (Hôpital St Louis, unpublished data). In 1994, Papadopoulos and co-workers first reported the therapeutic efficacy of the infusion of donor leukocytes in five patients who developed a B-cell PTLD following T-cell-depleted allogeneic marrow transplantation. Subsequently, Rooney et al²⁷ reported on the use of gene-marked EBV-specific T lymphocytes to control or prevent B-cell PTLD in 10 patients. The St Jude group described the prophylactic use of EBV-specific T-cell clones in 25 patients, none of whom developed PTLD.³⁷ The use of EBV-specific cytotoxic T lymphocytes (CTL) still requires high-level biotechnology laboratories to provide EBV-specific CTL clones. The most readily available and most efficacious treatment seems to be rituximab, but this still needs further studies with larger numbers of patients before it can be considered as the gold standard treatment for allogeneic SCT recipients.

Late-onset lymphomas

Some cases of late-occurring lymphomas have been reported in the literature (reviewed in reference 4). These cases presented like ordinary NHL. Among more than 18 000 patients, 14 late-onset NHL were reported.⁶ The only risk factor identified for late-onset PTLD was extensive chronic GVHD. Eight patients were diagnosed with HL.³⁸ HL differed from PTLD in its later onset (>2.5 years), lack of established risk factors, and relatively good prognosis.

Solid tumors

Observations in animal models suggested that posttransplant solid tumors occurred with considerable delay (median 8–11.5 years). Extrapolation to humans with a longer expected lifespan would suggest that solid tumors might develop a decade or more after transplantation. This appears to be borne out by the actual data,^{3,39,40} since the median elapsed time from SCT to solid tumors lies between 5 and 6 years.

The largest series reporting solid tumors after SCT are summarized in Table 45.2.^{17,41,42} In a collaborative study, Curtis et al² analyzed results in 19 220 patients. There were 80 solid tumors for an observed/expected (O/E) ratio of 2.7 ($p < 0.001$). In patients surviving at least 10 years after transplantation, the risk was increased eightfold. The cumulative incidence of tumors was 2.2% at 10 years and 6.7% at 15 years. The risk was increased significantly for melanoma (O/E 5.0), cancers of the buccal cavity (11.1), liver (7.5), CNS (7.6), thyroid (6.6), bone (13.4), and connective tissue (8.0). The risk was highest for the youngest patients. Most striking was the link of squamous cell carcinoma with chronic GVHD and male gender. The underlying diagnosis was important insofar as the risk of solid tumors was higher for patients with leukemia and lower in patients with lymphoma or aplastic anemia. The risk associated with total body irradiation (TBI) declined if irradiation was given with a fractionation regimen but increased with the total cumulative dose administered. This analysis strongly suggests that reduced doses of TBI, the omission of limited-field irradiation, and the prevention of GVHD (in particular chronic GVHD) should reduce the risk of post-transplant solid tumors. Finally, since in this first study relatively few patients surviving more than 10 years post SCT were included, we have continued surveillance of these and other SCT survivors to determine whether the risk of solid tumors changed beyond 10 years after transplantation.⁴³ The preliminary results of this survey can be summarized as follows. New cancers were sought in 28884 allogeneic SCT recipients. The cumulative incidence of invasive solid cancers for all patients was 5.0% at 15 years and 8.1% at 20 years. Compared with a matched general population, transplant recipients were at significantly higher risk of developing new invasive solid cancers (161 observed second cancers; O/E=2.3). The risk increased with time since transplantation; the O/E ratio was 4.8 among 10-year survivors. A new finding in this study, not seen in previous reports, is a significantly increased risk of breast cancer among 10-year survivors. These data indicate that SCT survivors face increasing risks of solid cancers with time after transplantation, supporting the need for lifelong surveillance. The main points concerning solid tumors are highlighted in Table 45.3.

Myelodysplastic syndrome and acute leukemia

Already in the early 1970s, Thomas et al⁴⁴ reported on two patients with acute lymphoblastic leukemia

Table 45.2 Incidence and risk factors of solid tumors after SCT

	Witherspoon et al ¹⁰¹	Deeg et al ⁴²	Bhatia et al ¹⁸	Curtis et al ²	Socié et al ¹⁰²

Table 45.3 Post-SCT solid tumors: main current points

- Cancer incidence continues to increase with prolonged follow-up, with no evidence of any plateau phase
- Irradiation is the strongest risk factor, but while chemotherapy alone must be used in patients with aplastic anemia, other diseases may need irradiation. Furthermore, recent data do suggest that solid cancers can occur after non-radiation-based conditioning regimens
- Chronic GVHD and/or its treatment is strongly associated with the occurrence of squamous cell carcinoma (SCC)
- Ongoing studies try to identify cancer-specific risk factors
- Biological data are needed to study oncogenetic process in SCT recipients.
- Most patients who underwent allogeneic SCT had received substantial amounts of chemotherapy and radiation before transplant. The role of those pretransplant treatments on the occurrence of solid tumors clearly needs evaluation
- How to treat patients with second solid tumors after SCT? There are very few data to answer this critical and practical question. In our experience, patients with SCC of the head and neck have a bad prognosis with conventional therapy. With this exception, patients with solid tumors can generally be treated safely with conventional treatment

(ALL) who developed leukemia in donor cells. Several similar cases were subsequently reported from other institutions (reviewed in reference 3). The mechanisms that lead to leukemia in previously healthy transplanted cells are not clear. More recent studies have employed variable-number tandem repeat (VNTR) analysis to determine the origin of cells in patients post transplant.⁴⁵

Conclusions

Second malignancies after allogeneic SCT have emerged as a significant complication. The development of highly immunosuppressive but non-myeloablative conditioning before transplantation from HLA-identical sibling and unrelated donors makes it likely that the incidence of PTLD will rise in these patients. The incidence rate of solid tumors shows an

alarming slope, with increasing incidence with increased follow-up. For solid tumors, the only practical approach is to closely follow long-term survivors on an (at least) annual basis to allow early diagnosis and treatment.

Non-malignant late effects

Chronic GVHD and associated immunodeficiency are the major causes of late complications following allogeneic SCT. Chronic GVHD is the prime cause of transplant-related mortality late after marrow grafting. This complication—by far the main one of allogeneic SCT—is reviewed in reference 46. In a large study the 5-year probability of transplant-related mortality following discharge home was 22% in patients with and 6% in patients without chronic GVHD.⁴⁷ Despite conventional and new therapies for the treatment of chronic GVHD, this syndrome continues to account for significant morbidity and mortality after allogeneic SCT. With the expanded use of allogeneic PBSCT using matched unrelated as well as mismatched related donors, there is an increased incidence of chronic GVHD that poses a new clinical challenge.^{46,48,49} Although improvements have been made in the prevention of acute GVHD, these advances have not resulted in a concomitant decrease in the incidence of chronic GVHD.⁴⁶ This sustained incidence of chronic GVHD is likely related to changes in clinical SCT practice.

Whereas the prophylactic use of multiagent immunosuppression has reduced the incidence and severity of acute GVHD, the incidence of chronic GVHD remains unchanged. The incidence of chronic GVHD after sibling-matched related, unrelated, and PBSCT lies in the ranges 27–50%, 42–72%, and 54–57%, respectively.⁵⁰ Factors that increase the risk of development of chronic GVHD include increased donor and recipient ages, prior acute GVHD, the use of alloimmune female donors, the type of GVHD prophylaxis, and a history of recipient herpes virus infection.

As will be summarized in this chapter, chronic GVHD and/or its treatment with glucocorticoids is the major risk factor leading to late non-malignant complications after allogeneic SCT. The other main risk factor for many non-malignant late complications is irradiation.

Late infections and immune deficiency

Immune reconstitution plays a pivotal role in the long-term consequences of allogeneic SCT, not only because an immune defect is related to infectious morbidity post transplant, but also because it may influence the risk of relapse and the development of secondary malignancies after SCT. Several studies have characterized the immune reconstitution in the few months following allogeneic SCT, but data on large numbers of patients regarding long-term immune reconstitution are scarce.^{51–54} A large number of variables related to patient or transplant characteristics, such as age of recipients, stem cell engineering, type and duration of disease, and conditioning regimen, may influence the recovery of immunity after SCT. Other post-transplant variables—in particular chronic GVHD and the consequent administration of immunosuppressive drugs—also have an impact. Chronic GVHD is the leading factor affecting immune reconstitution of CD4⁺ and CD8⁺ T cells and of B cells. Donor source (marrow versus peripheral blood), unrelated versus sibling transplant, and the degree of histocompatibility between donor and recipient also affect the pace of immune reconstitution. Low B-cell count, inverted CD4⁺/CD8⁺ ratio, and decreased IgA level are risk factors associated with late infections. Recent immunological methods such as repertoire analysis and the presence of recent thymic emigrants are currently being evaluated as tools to investigate immune reconstitution after SCT.⁵⁴

Late bacterial and viral infections have been reviewed extensively, and guidelines for preventing these opportunistic infections after SCT have been proposed in a document published under the auspices of the US Centers for Disease Control (CDC), the Infectious Disease Society of America (IDSA), and the American Society of Blood and Marrow Transplantation (ASBMT).⁵⁵ Susceptibility to encapsulated bacteria (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*) has been well documented, especially in patients with current or previous chronic GVHD. Late (>2 years) fungal or cytomegalovirus (CMV) diseases are rare, and almost invariably occur in patients with ongoing immune suppression for GVHD. Varicella zoster infections are, on the contrary, extremely frequent (even in patients without GVHD), but usually occur within months post SCT after discontinuation of acyclovir prophylaxis. Finally, among parasitic infections, late *Pneumocystis carinii* pneumonia (PCP) and *Toxoplasma gondii* infections usually occur in patients receiving active therapy for chronic GVHD.

Late ocular effects

Microvascular retinopathy

Ischemic retinopathy, including cottonwool spots and optic disk edema, is the most frequent complication of the posterior ocular segment following transplantation.⁵⁶ Microvascular retinopathy is observed only after allogeneic transplantation, in patients conditioned with TBI and receiving cyclosporine for GVHD prophylaxis. Ocular lesions appear during the first 6 months after transplantation. Visual acuity

decreases in most patients, but recovers in all patients with a follow-up of at least 12 months on withdrawal of cyclosporine.⁵⁷

Cataract

Cataract formation, particularly posterior subcapsular cataracts, has been recognized in transplant recipients as one of most frequent late complications of TBI. Single-dose TBI of 10 Gy or more causes cataract formation in all patients. Fractionation of the dose was attempted to reduce the side-effects on tissues and particularly on the lens.^{58–60} The estimated incidence of cataract lies between 80% after single-dose TBI and 20% in non-irradiated recipients.⁶¹ The only treatment for cataract is to surgically remove the opacified lens from the eye to restore transparency of the visual axis. Today, cataract surgery is less risky and improves visual acuity in 95% of eyes without preexisting ocular comorbidity.

Kerato conjunctivitis sicca syndrome

This complication is usually part of the more general sicca syndrome with xerostomia, vaginitis, and dryness of the skin.⁶² All of these manifestations are closely related to chronic GVHD, which may lead in its most extensive forms to a Sjögren-like syndrome. The ocular manifestations include reduced tear flow, keratoconjunctivitis sicca, sterile conjunctivitis, corneal epithelial defects, and corneal ulceration. The incidence, time course, and risk factors associated with late-onset keratoconjunctivitis sicca syndrome after transplantation was evaluated in a retrospective cohort study of the European Group for Blood and Marrow Transplantation (EBMT) Working Party on Late Effects.⁶³ Of the 248 patients, 48 (19%), with a minimum follow-up of 5 years, developed a keratoconjunctivitis sicca syndrome between 3 and 127 months (median 13.8 months) after transplantation. The probability of developing keratoconjunctivitis sicca syndrome at 15 years was 38% for patients with and 10% for those without chronic GVHD. Factors associated with an increased risk of late-onset keratoconjunctivitis are chronic GVHD, female sex, age older than 20 years, single-dose irradiation for pretransplant preparation, and methotrexate for prevention of GVHD.

Pulmonary late effects

Significant late toxicity involving both the airways and the lungs affects at least 15–40% of patients after SCT. Clinical syndromes are not well defined or definable because of overlapping of pathogenetic mechanisms and/or because they represent a continuum rather than a distinct disorder. Sensitivity to cytotoxic agents and irradiation, infections, and immune-mediated lung injury associated with GVHD are the most prominent among the multiple factors that contribute to late respiratory complications.⁶⁴ Respiratory abnormalities are a consequence of scarring and thickening of the interstitial space, leading to interference with gas exchange and respiratory dynamics. Impaired growth of both lung and chest can be an additional factor in children. Immune-mediated injury due to GVHD can play an important role in damaging the small airways.

Chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease can be evident in up to 20% of long-term survivors after SCT.^{65–67} Airflow obstruction can be an indirect consequence of chronic GVHD (aspiration secondary to esophageal GVHD, sinobronchial sicca syndrome, abnormal mucociliary transport, and recurrent infections due to immunosuppression) or can be due to direct immune-mediated damage to the airway by donor T lymphocytes and cytokines. Mortality is high among these patients, particularly those with an earlier onset and rapid decline of FEV₁ (forced expiratory volume in 1 second). Symptoms consist of non-productive cough, wheezing, and dyspnea; the chest radiograph is normal in most cases. High-resolution computed tomography (CT) may show abnormalities similar to those reported in patients with bronchiolitis obliterans. Symptomatic relief can be obtained in some patients with bronchodilators; however, in most cases, obstructive abnormalities are not changed by this treatment. Patients with low IgG and IgA levels should receive immunoglobulin to prevent infections, which may further damage the airways. Immunosuppressive therapy leads to improvements in less than 50% of cases, probably because the damage has already become irreversible or because other pathogenetic factors still persist. Asymptomatic patients with abnormal pulmonary function tests (PFT) should be closely monitored for the development of respiratory symptoms—early recognition of airflow obstruction allows the initiation of treatment at a potentially reversible stage.

Obliterative bronchiolitis (OB) has been reported in 2–14% of allogeneic SCT recipients, with a mortality rate of 50%. It is strongly associated with chronic GVHD and a low level of immunoglobulin. GVHD is most likely responsible for the initial mucosal injury to the small airways,⁶⁸ with further damage being caused by repeated infections. The initial symptoms often resemble those of recurrent upper respiratory tract infections, and then persistent cough, wheezing, inspiratory rales and dyspnea appear. PFT gradually deteriorate, with severe and non-reversible obstructive abnormalities. Chest radiographs and CT reveal hyperinflation with or without infiltrates and vascular attenuation; however, radiological findings do not correlate with lung function. It is not clear to what extent combined immunosuppressive treatment can be effective in the treatment of this disease, which

typically does not respond to conventional treatment with steroids.

Late liver complications

When faced with a patient with liver dysfunction after SCT, it must be borne in mind that more than one cause of liver disease—of viral and/or non-viral origin—may coexist. The pattern of viral serology is often atypical, and, moreover, besides the most important hepatotropic viruses, other agents, such as herpesviruses (including CMV), adenoviruses, and EBV, may also be implicated, sometimes causing a life-threatening fulminant hepatitis, due to their cytopathic effect.⁶⁹ Useful tools for differential diagnosis are timing post transplant, the type of clinical and biochemical deterioration, previous evidence of liver complication (including veno-occlusive disease), acute or chronic GVHD, and infection. Histological examination can be very helpful in discriminating between acute exacerbation of a viral hepatitis or an acute onset of chronic GVHD.

Based on serum ferritin levels, a diagnosis of iron overload is made in up to 88% of long-term survivors of SCT.⁷⁰ Iron deposition begins before SCT, and other causes of iron accumulation (e.g. prolonged dyserythropoiesis and increased iron absorption) contribute to iron overload. Hepatic iron overload may worsen the natural course of chronic hepatitis, especially hepatitis C.⁷¹ Iron overload spontaneously decreases in the years following SCT.

Late complications of bone and joints

Avascular necrosis of bone

The main reports on avascular necrosis (AVN) are summarized in Table 45.4.^{72–75} Pain is usually the first sign, and often early diagnosis cannot be made by standard radiography, while magnetic resonance imaging (MRI) already shows extensive necrosis. While the hip is the most frequent location (in over 80% of cases, with bilateral involvement in over 60%), other locations have been described, including the knee (10% of patients with AVN). Symptomatic relief of pain and orthopedic measures to decrease the pressure on the joint can be helpful, but most adult patients with advanced damage will need surgery.^{76,77} Studies on risk factors for AVN have clearly identified steroids (both total dose and duration) as the strongest risk factor. Thus, avoiding unnecessary low-dose steroids for months in non-active chronic GVHD is probably a good way to prevent AVN. The other important risk factor is TBI (with the highest risk being for 10 Gy single dose or >12 Gy fractionated), as demonstrated elegantly in a Seattle case-control study.⁷⁵

Osteoporosis

Transplantation-associated osteoporosis is a wellknown side-effect of solid organ transplantation, but data for SCT are still few (reviewed in reference 78 and 79). SCT can induce bone loss and osteoporosis because of direct toxic effects of radiation therapy, chemotherapy, and gonadal and pituitary hormone secretion. The incidence and course of bone mineral density (BMD) abnormalities following SCT was studied in a series of 104 patients.⁸⁰ The cumulative dose and number of days of glucocorticoid therapy and the number of days of cyclosporine or tacrolimus therapy showed significant associations with loss of bone density. Non-traumatic fractures occurred in 10.6% of patients. In a prospective study from the Hôpital St Louis, 105 asymptomatic patients had BMD measurement 12–18 months post transplant.⁸¹ By multivariate analysis, including also as cofactors hormonal replacement (in women) and peripheral gonadal deficiency in both sexes, only steroid treatment for chronic GVHD was associated with decreased BMD.

Table 45.4 Avascular necrosis of bone following SCT

Ref	Incidence (%)	Time to necrosis (months) ^a	Median age at diagnosis (years)	Risk factors
72	10.4	12 (1–62)		19 GVHD/steroids
73	8.1	13.2 (4–58)		16 GVHD/steroids Aplastic anemia ALL
74	4.3	22(2–132)		16 GVHD/steroids Male gender
75	4.5	26.3		Irradiation Steroid dose

GVHD, graft-versus-host disease; ALL, acute lymphoblastic leukemia.
^aRange in parentheses.

Endocrine function after SCT

Thyroid

Between 7% and 15.5% of patients will develop post-SCT subclinical hypothyroidism, a condition where slightly-high serum thyroid-stimulating hormone (TSH) and normal free thyroxine levels are found.⁸² This condition is an early finding after transplantation. It has not yet been clarified whether patients who develop subclinical hypothyroidism should be treated with L-thyroxine, since the majority of these cases are mild, compensated, and resolve spontaneously.⁸³ Furthermore, treatment with L-thyroxine might induce early osteoporosis, especially if given to those women after SCT with gonadal failure who are already at risk for developing osteoporosis due to sex hormone deficiency. The great majority of overt hypothyroidism after SCT is due to a primary lesion to the thyroid gland. Secondary hypothyroidism, caused by pituitary damage, is rare in patients after SCT, but is frequently observed in brain tumor patients who receive high doses of cranial irradiation. Hypothyroidism is usually diagnosed after a median period of 50 months from transplant. The frequency of hypothyroidism requiring L-thyroxine replacement therapy is highly variable,^{84,85} and depends to a large extent on the type of pretransplant conditioning applied.^{61,84–87} Treatment with L-thyroxine is indicated in all cases with frank hypothyroidism (elevated TSH with low free thyroxine blood levels). An emerging condition of thyroid dysfunction in transplanted patients is that due to an autoimmune thyroiditis, presumably transferred by the affected donor cells.⁸⁸

Growth

Linear growth is an intricate process that depends on a number of factors, such as genetic (i.e. mid parental height), nutritional, hormonal, and psychological. Children who undergo SCT form an extremely heterogeneous group. Pretransplant conditioning differs significantly with regard to the modality of irradiation and of chemotherapy. In addition, GVHD and its treatment, especially steroids used for long periods, might also induce growth failure in childhood.^{89–92} Growth deficiency is found in some patients who underwent SCT during childhood. The mean loss of height (as estimated by the standard deviation score SDS) is estimated to be of approximately 1 height-SDS (equivalent to 6 cm) compared with both the mean height at the time of transplant and the mean genetic height. A cohort study on 181 children conducted by the Late-Effect Working Party (LEWP) of the EBMT showed that 143 (79%) reached 'normal' adult height.⁹³ Growth deficiency is more pronounced in children transplanted at younger age (before 10 years old) and in those who received irradiation.⁹⁴ The reduction in growth observed in the irradiated group may be explained by the direct effect of radiation on the gonads, by damage to the thyroid gland, and/or by damage to the bone epiphyses.

Puberty and gonadal failure

Gonadal failure (both testicular and ovarian) is a common long-term consequence of prior chemotherapy and intensive pretransplant conditioning. The major cause of gonadal damage, which will eventually result in hypergonadotropic hypogonadism, is irradiation.⁹⁵ Similar damage can be also caused by busulfan, which is often used in children because of its minor effect on growth.

In males, the testicular germinal epithelium (Sertoli cells), where spermatogenesis occurs, is more vulnerable to radio- and chemotherapy compared with the testicular Leydig cell component involved in sex hormone (testosterone) secretion. Therefore, reduced or absence spermatogenesis, increased follicle-stimulating hormone (FSH) serum levels, and elevated luteinizing hormone (LH) levels, with (usually) normal testosterone, are commonly observed in most patients. The great majority of these patients will therefore not require testosterone replacement treatment to guarantee sexual activity, libido, erection, and ejaculation.

In females, the ovaries are more vulnerable to radiation and chemotherapy compared with the testes, and hypergonadotropic hypogonadism is almost the rule. The age at transplant is of great importance, since the younger the patient, the better will be the chances for gonadal recovery. In fact, ovarian failure in adult women is usually irreversible, while in prepubertal girls, although uncommon, there is still a greater possibility for subsequent spontaneous recovery and achievement of spontaneous menarche. Fractionation of irradiation reduces the impact on the ovaries.^{90,96} With the increasing utilization of non-irradiation-based protocols in pediatric pretransplant conditioning, it has become clear that the majority of girls of any age at transplant develop ovarian failure.⁹⁷

The majority of females will need sex hormone replacement therapy (SHRT), both for the induction of pubertal process in girls who received a transplant during childhood and for maintaining menstrual cycles and bone turnover and mineralization in adult women. In girls who were transplanted during childhood and who are without spontaneous onset of puberty, and who show clinical and hormonal signs of gonadal failure, estrogen treatment should be started at age 12–13 years in order to achieve increased breast size, uterus volume, and pubertal growth spurt. After 1–2 years of continuous estrogen treatment in gradually increasing doses, when the breast shape is satisfactory, combined cyclic estrogen-progesterone treatment is introduced to achieve menses and to reduce the risk of osteoporosis. SHRT can be

interrupted once every 2–3 years, for a period of 6 months, to evaluate the possible spontaneous recovery of ovarian activity, which can occur in a minority of women. SHRT should be reconsidered in those patients who develop amenorrhea and high gonadotropin levels during the interruption period.

Infertility is common following SCT, but conception is possible both for male and for female recipients. Return of gonadal function following cyclophosphamide conditioning for aplastic anemia is well documented.⁹⁸ In patients with malignant diseases, recovery of gonadal function occurs in 10–14% of the women, although the incidence of pregnancy is less than 3%.^{98,99} In men, recovery of gonadal function has been reported in less than 20% of patients, and the use of increasing doses of TBI may be associated with considerably lower recovery.⁹⁸ Parenting following the administration of TBI is a rare event in men.^{98,99} Busulfan plus cyclophosphamide (BuCy) is also associated with a high incidence of gonadal failure in women, and there have been no pregnancies reported with the use of BuCy for patients with leukemia.^{98,99} In men, this conditioning regimen appears to be associated with the return of gonadal function in approximately 17% of cases, which is similar to the recovery after TBI conditioning for malignancy. Few patients have subsequently fathered children naturally; however, 20 patients were identified by the EBMT LEWP99 and 2 patients out of a series of 46 men receiving TBI from Seattle.⁹⁸ Pregnancies have also been reported after high-dose melphalan plus cyclophosphamide conditioning for allogeneic SCT.¹⁰⁰ Post-transplant management should routinely include symptomatic and biochemical monitoring of gonadal function. While the patient should be prepared for infertility, the possible need for contraception soon after SCT must also be emphasized, particularly in women who resume menstruation or in patients who do not wish to become parents. Distressing vasomotor symptoms may commence acutely post SCT, but may be prevented by initiating hormone replacement therapy.

Conclusions

Allogeneic SCT has been able to cure thousands of patients with otherwise-lethal diseases. In this century, we move to an aim that is not only to cure patients but also to provide them with as few late complications as possible and to give them the best quality of life that we can. The two main risk factors (conditioning and chronic GVHD) were, until recently, deemed to be poorly amenable to modifications. However, new hope in reduced-intensity conditioning and new immunosuppressive drugs has shed new light in the field, and opens the door for a curable procedure with, hopefully, few late effects.

Hematopoietic growth factors

Stephen Devereux and Antonio Pagliuca

Introduction

Over the last 20 years, numerous growth factors with activity on the hematopoietic system have been discovered. Although a considerable number were tested in phase I and II clinical trials, only granulocyte and granulocyte—macrophage colony-stimulating factors (G-CSF and GM-CSF), interleukin-11 (IL-11), and erythropoietin (EPO) have been licensed for clinical use. Growth factors with multilineage effects, such as IL-3 and IL-1 in the main proved too toxic, whilst others such as thrombopoietin (TPO) failed to produce sufficient clinical benefit to justify full development or had unexpected side-effects.¹ It is now some years since a new growth factor with major clinical potential was discovered, and the emphasis has instead been on the modification of existing agents to improve their pharmacokinetic properties.

The data supporting the clinical use of G-CSF and EPO are similarly now relatively mature, and although questions remain to be answered, it is unlikely that many of these will be addressed by further randomized trials. The evaluation of growth factor studies is notoriously difficult, and evidence-based guidelines have been produced by a number of bodies to assist with decision-making in this area. This chapter will review the biology and indications for the use of currently available factors, concentrating mainly on EPO and G-CSF, since these are the most widely used.

Erythropoietin

Biology of EPO

The existence of a soluble regulator of red cell development was postulated at the start of the last century² and confirmed in the 1950s by animal cross-circulation experiments³ and by studies on the plasma of anemic rabbits.⁴ The renal origin of EPO was demonstrated soon afterwards,⁵ and it is now known that in adult humans EPO is secreted almost exclusively by renal cortical fibroblasts in response to tissue hypoxia.⁶

The cloning of the EPO cDNA was reported in 1985,^{7,8} allowing the production of recombinant material, characterization of its *in vitro* and *in vivo* properties, and investigation of clinical applications. Recombinant human (rh)EPO has been reported to contain tetraacidic structures whilst native serum EPO has only mono-, di-, and triacidic oligosaccharides.⁹ The two forms of rhEPO used clinically differ somewhat in their glycosylation pattern, with more basic sugars, more non-sialylated N-glycans, and higher *in vivo*: *in vitro* activity ratio in EPO- β compared with EPO- α .¹⁰

The effects of EPO on erythropoiesis include an expansion of the number of erythroid precursors and an increased rate of reticulocyte release. EPO has no major effects on erythroid cell cycle length or the number of mitotic divisions, and inhibition of progenitor apoptosis appears to be the major effect at the cellular level.¹¹ EPO receptor (EPOR) knockout mice fail to produce mature red blood cells,¹² although a few very early erythroid cells are seen, suggesting that the commitment to the erythroid lineage is EPO-independent. EPOR density increases between the erythroid burst-forming and colony-forming (BFU-E and CFU-E) compartments, which are dependent on EPO for survival.

Although the most important physiological effects of EPO are on erythropoiesis, EPOR have also been found in a number of other tissues including brain, ovary, oviduct, uterus, testis, and developing gastrointestinal (GI) mucosa and vasculature. In the embryonal forebrain, EPO stimulates the proliferation of neuronal progenitor cells,¹³ and a protective effect in ischemic brain injury in rats has also been reported.¹⁴ EPO also influences GI vascular growth in the neonatal rat, leading to the suggestion that EPO present in breast milk may be important in the normal

development of this tissue¹⁵ or that it might act as a growth factor in gastric cancer.¹⁶ The precise biological and clinical significance of these intriguing observations remains to be determined.

Clinical use of EPO

EPO has been used to augment erythropoiesis in situations of absolute or relative deficiency or in an effort to overcome bone marrow insensitivity. Therapy with EPO is now an important component of the supportive care of patients with end-stage renal failure; however, this is outside the scope of the present chapter and will not be discussed further. Cancer-associated anemia is more complex and the place of EPO in its management has yet to be fully defined. Contributory factors include bone marrow infiltration, myelosuppressive chemotherapy, anemia of chronic disease, iron, folate, or vitamin B₁₂ deficiency, as well as blood loss and hemolysis.¹⁷ In addition, a study that compared EPO levels in iron deficiency and malignant disease showed that levels were lower for a given hemoglobin (Hb) value in the patients with cancer, suggesting that production may be impaired in these individuals.¹⁸

There are wide variations in the use of EPO in cancer-related anemia across and within different healthcare systems that relate to uncertainty over its cost-effectiveness. Concerns over the safety of blood products, their increasing cost, and the shrinking donor pool, along with quality of life (QoL) considerations and commercial pressures, have, however, resulted in a year-on-year increase in EPO use in this situation. The evidence supporting this is reviewed below.

Evaluation of clinical trials with EPO

The endpoints of clinical trial of EPO therapy have included increment in Hb level, the effect on the requirement for blood transfusion as well as QoL. Evaluation of these trials is often problematic; for example, it is important to know whether factors such as hematinic deficiency are equally addressed in treatment and control groups and that there are clear triggers for blood transfusion that are equally adhered to. QoL assessment raises particular difficulties, since although appropriate questionnaires have been devised, whether patients participate in this aspect of the study might depend on how well they are feeling—thus biasing the result in favor of improved QoL. In addition, although many studies are double-blinded, patients are often not blinded to their Hb result, thus further confounding QoL assessment. A detailed discussion of the methodological aspects of these studies is provided in the American Societies of Hematology (ASH) and Clinical Oncology (ASCO) guidelines.¹⁹

Use of EPO for anemia primarily due to hematological disease

Myelodysplastic syndromes

The myelodysplastic syndromes (MDS) are acquired clonal disorders of the bone marrow characterized by bone marrow failure and a predisposition to develop acute myeloid leukemia (AML). Patients with less than 10% myeloblasts in the bone marrow at presentation have a relatively low risk of leukemic transformation, and up to 80% of these individuals will become dependent on red cell transfusion. In the new World Health Organization classification, such patients would be categorized as having refractory anemia (RA), RA with ringed sideroblast (RARS) with or without multilineage dysplasia, and RA with an excess (5–10%) of bone marrow blasts (RAEB-1).²⁰ Although such patients may have a relatively good prognosis, anemia is a major problem, leading to reduced QoL. Excessive apoptosis²¹ and impaired erythroid colony growth²² are frequent observations in bone marrow from low-risk MDS patients, and are thought to contribute to the anemia. The finding that the addition of higher concentrations of EPO and other growth factors^{23,24} to in vitro cultures can reduce apoptosis led a number of groups to investigate whether this is also the case in vivo.

EPO. A randomized controlled trial of EPO at a dose of 150 iu/kg/day in 87 patients with low-risk MDS showed a complete or partial responses in the subgroup with RA.²⁵ A baseline EPO level of less than 200 iu/l predicted response, and the best outcome was observed in those patients who were untransfused prior to study entry. Two meta-analyses covering trials of EPO alone until late 1994 (205 patients from 17 trials and 115 patients from 11 trials) demonstrated response rates of 16% and 23.5%, respectively.²⁶ Longer-term follow-up shows that in some cases these responses can be maintained for a number of years.²⁷ No data on QoL is available from the published studies, although extrapolation from other studies suggests that it may be improved.

EPO and G-CSF. A number of non-randomized uncontrolled studies have suggested that the combination of G-CSF and EPO might be superior to EPO alone. A trial that randomized patients to receive either G-CSF followed by G-CSF plus EPO or EPO followed by the same combination showed an overall response rate of 38%, with more responses in the group with RARS. A scoring system based on the serum EPO level and transfusion requirement has been devised to predict the response to EPO plus G-CSF.²⁸ This has been validated in two non-randomized uncontrolled studies.^{29,30} In the very best group of patients, a response rate of 61% accompanied by an improvement in QoL was reported. The ASH/ASCO guidelines concluded that a trial of 8 weeks of EPO in patients with low-risk MDS and a serum EPO level

below 200 iu/l would be appropriate on the evidence available.¹⁹ There are no randomized trials comparing EPO plus G-CSF with either EPO alone or best supportive care; however, uncontrolled studies look promising. There is a need for randomized trials incorporating QoL analysis to address this issue.

Aplastic anemia

There is no convincing evidence that EPO has any place in the management of aplastic anemia (AA), and its use is not recommended.³¹ This is in line with the observation that serum EPO levels are very high in AA³² whilst the number of progenitors that are able to respond is very low.³³ EPO has also been used in combination with G-CSF in the treatment of AA. In a study in which patients were randomized to receive either G-CSF or G-CSF plus 200 or 400 iu/kg EPO, some response was observed at the higher dose; however, this was confined to those with non-severe disease and lower baseline EPO levels.³⁴

Stem cell transplantation

The results of clinical studies of EPO administration after autologous (auto) or allogeneic (allo) hematopoietic stem cell transplantation (HSCT) are in keeping with the observed changes in endogenous serum EPO level. In the early post-transplant period, a consistent increase in EPO level has been reported in both auto- and alloHSCT patients.^{35–41} This is followed by a period in which EPO levels are inappropriately low in allograft patients whilst levels are mainly appropriate for the degree of anemia in autologous transplant recipients. Cyclosporine (cyclosporin A) is known to inhibit EPO secretion,⁴² but graft-versus-host disease (GVHD) and cytomegalovirus (CMV) may also contribute to this phenomenon.^{36,40,43,44}

In keeping with these observations, EPO administration has no effect on indices of red cell production or transfusion requirement after autoHSCT. As predicted from the data on serum levels, the effect of EPO administration in the allogeneic setting is most marked later in the post-transplant period when the relative deficiency is greatest. Although an effect of EPO on the reticulocyte count has been consistently observed in the early post-transplant period, this has required doses of 1000 iu/kg/week and the impact on red cell transfusion requirement has been variable in randomized controlled trials.^{45–47} In contrast, EPO administration later in the post-transplant period at a dose of 500 iu/kg/week produced a major response in over 90% of patients;⁴⁸ however, there have been no randomized controlled trials to confirm this finding.

Other hematological malignancies

A number of studies have been performed in anemic patients with chronic lymphocytic leukemia (CLL), multiple myeloma, and non-Hodgkin lymphoma (NHL).^{49–52} All of the studies included patients who were also receiving chemotherapy, and compared the outcome of EPO therapy with conventional support with blood transfusion. EPO therapy was associated with an improvement in Hb level and a reduction in transfusion requirement that was especially evident in those patients with low endogenous EPO levels and good bone marrow function as evidenced by a normal platelet count. Based on the quality of the evidence, the ASH/ASCO guidelines recommend therapy of the underlying disorder in the first instance, with EPO being reserved for those who do not respond according to the guidance in chemotherapy-associated anemia.

Use of EPO for chemotherapy-induced anemia

There is evidence from a number of randomized clinical trials that EPO administration is effective at increasing Hb level and reducing the requirement for blood transfusion in patients with a Hb of 10 g/dl or lower who are receiving chemotherapy for malignant disease.^{53–58} It is also likely that this leads to symptomatic improvement; however, due to the methodological difficulties in assessing QoL outlined above, the evidence for this is less convincing. For patients with a baseline Hb level between 10 and 12 g/dl, the evidence supporting the use of EPO is also less strong. Any potential benefit of raising the Hb in this situation must relate to improvement in QoL, since few clinicians would transfuse such a patient. A recent study that assessed QoL at different Hb levels in cancer patients revealed a nonlinear relationship between the two over the range 8–14 g/dl, with the maximum benefit at 12 g/dl, suggesting that use of EPO in patients with a Hb level above 10 g/dl may be warranted.⁵⁹ The ASH/ASCO guidelines on EPO use are summarized in Table 46.1.

Use of EPO in transfusion medicine

There are a number of possible applications of EPO therapy in blood transfusion medicine. In the main, these center around the avoidance of transfusion in patients scheduled for surgery. A variety of strategies have been proposed, including raising the preoperative Hb level to facilitate preoperative autologous blood donation or acute normovolemic hemodilution (in which autologous blood is deposited, with saline replacement immediately preoperatively) or simply to give the patient a higher baseline Hb. Appropriate iron supplementation is important in this situation if the maximum erythropoietic response is to be achieved. The contribution of EPO to transfusion medicine has recently been reviewed.^{60,61}

Side-effects of EPO

EPO is remarkably free of side-effects in patients with hematological malignancies, since the very rapid

Table 46.1 Indications for the use of erythropoietin (EPO)^a

1. Chemotherapy-induced anemia where Hb \leq 10 g/dl
2. Chemotherapy-induced anemia where the Hb $>$ 10 g/l but falling. Depends on clinical circumstances
3. EPO starting dose 150 iu/kg, 3 \times weekly s.c. for 4 weeks. Consider increase to 300 iu/kg for 4–8 weeks in non-responders. Alternative regimen of 40 000 iu/week may be effective, but there is less evidence for this
4. If there is no response after 6–8 weeks, discontinue. Investigate for tumor progression plus iron deficiency
5. Titrate EPO dose to maintain Hb at around 12 g/dl
6. Measure serum iron, total iron-binding capacity, transferrin saturation, or ferritin at baseline and at intervals during therapy
7. There is some evidence to support EPO use in low-risk myelodysplasia in the absence of chemotherapy. Evidence in other disorders such as myeloma, lymphoma, and chronic lymphocytic leukemia is less convincing if patients are not receiving chemotherapy
8. Anemia associated with myeloma, lymphoma, and CLL should initially be treated with chemotherapy and corticosteroids. If there is no response in Hb, consider supplementing with EPO

^a Summary of the main points in the ASH/ASCO guidelines,¹⁹ which state that in all circumstances blood transfusion would be an acceptable alternative.

rises in Hb that may lead to hypertension in patients with renal failure do not occur. Similarly, thromboembolic events such as clotted arteriovenous shunts, pulmonary embolism, and myocardial infarction, which have been consistently reported in renal failure patients, have been less of a feature in hematological malignancies. A recent study in patients with cervical cancer undergoing combination chemotherapy did, however, show that EPO therapy was associated with a higher risk of venous thrombosis.⁶² Possible reasons for the observed increased risk of thromboembolism during EPO therapy include changes in blood viscosity,⁶³ transient thrombocytosis, and direct effects on the vascular endothelium resulting in increased expression of tissue factor.⁶⁴

A recently described adverse event of EPO therapy has been the development of neutralizing antibodies to EPO in a small number of renal failure patients treated with EPO- α over the last few years.⁶⁵ This has resulted in pure red cell aplasia (PRCA) due to cross-reactivity of the antibody with native EPO; in most cases, this has responded to EPO withdrawal and immunosuppression. So far, there have been no cases of EPO-associated PRCA outside of renal medicine; however, there is no reason in principle why this might not happen, and it has led some physicians to avoid starting new patients on EPO- α .

Newer agents derived from EPO

The relatively inconvenient schedule of thrice-weekly subcutaneous injection has led to the development of agents with modified pharmacokinetic properties. The first of these is darbepoietin- α , a hypersialated glycoform of EPO- α whose circulating half-life is prolonged because of reduced clearance by hepatic galactose receptors.⁶⁶ A randomized clinical trial in patients with chronic renal failure showed that a once or alternate weekly schedule of darbepoietin gives a similar response to thrice-weekly or weekly dosing with conventional EPO.⁶⁷ Randomized clinical trials in cancer patients have shown darbepoietin to be well tolerated and active on a weekly schedule.^{68–70} A pegylated form of EPO is also in clinical trials and appears to have similar pharmacokinetics.⁷¹ The place of these newer agents remains to be determined, and there will inevitably be a trade-off between cost and patient convenience, especially when generic EPO becomes available.

G-CSF and GM-CSF

Biology of G-CSF and GM-CSF

The colony-stimulating factors (CSFs) are a family of glycoproteins, initially identified using cell culture assays developed in the 1960s,⁷² that control the survival, proliferation differentiation, and functional activity of myeloid cells. Cloning of the cDNAs for granulocyte CSF (G-CSF)^{73,74} and granulocyte-macrophage CSF (GM-CSF)⁷⁵ in the mid 1980s allowed characterization of the biological properties of these molecules, and clinical trials with recombinant materials followed soon afterwards.

The physiological role of these factors was elucidated by gene deletion studies in mice and measurements of the levels of the factors during cytopenia. Mice with a disruption of the gene for either G-CSF⁷⁶ or its receptor⁷⁷ are neutropenic and cannot respond to infection. In contrast, mice with a similar disruption of GM-CSF signaling are hematologically normal and instead suffer from pulmonary alveolar proteinosis.^{78–80} During neutropenia and infection in humans, G-CSF levels rise whilst GM-CSF levels remain unchanged.⁸¹ These observations suggest that whilst G-CSF is important for both steady-state and stress hematopoiesis, GM-CSF is not.

G-CSF acts at all stages of neutrophil development⁸² and causes the release of progenitors and mature neutrophils from bone marrow stores. Functional attributes such as phagocytic activity, killing of microorganisms, and antibody-dependent cell-

mediated cytotoxicity (ADCC) are enhanced by G-CSF.^{83,84} GM-CSF has similar effects on neutrophil, macrophage, and eosinophil production⁸⁵ and function. The differentiation of dendritic cells (DC) from CD34⁺ progenitors⁸⁶ and monocytes⁸⁷ is also induced by GM-CSF, whilst G-CSF mobilizes DC that cause T-helper type 2 (Th2) polarization of lymphocytes into the peripheral blood.⁸⁸

Commercially available forms of G-CSF include filgrastim, a non-glycosylated *Escherichia coli*-derived recombinant protein, and lenograstim, a glycosylated form of G-CSF produced in Chinese hamster ovary cell lines.⁸⁹ An N-terminal mutated form of lenograstim, known as nartogastim, is also available commercially, but few data are available.^{90,91} A long-acting filgrastim called pegfilgrastim will be discussed separately below.^{92,93} Currently, only a non-glycosylated *E. coli*-derived preparation of recombinant GM-CSF (molgramostim) is available. There are potential differences in pharmacokinetics, potency, and immunogenicity of the various preparations; however, so far these do not appear to be clinically important and the preparations will therefore be considered together.

Clinical use of G-CSF and GM-CSF: indications and evaluation of studies

Since the introduction of G-CSF and GM-CSF in the early 1990s, numerous studies have sought to define their place in hematological oncology. The specific aims have been:

- The prevention of neutropenic sepsis following conventional chemotherapy, thereby reducing treatment-associated mortality, morbidity, and the attendant cost, and improving QoL. Practically, this entails:
 - primary prophylaxis in which all patients are treated;
 - secondary prophylaxis, when only high-risk patients are treated (e.g. those who had an episode of neutropenic sepsis during a previous cycle of chemotherapy);
 - interventional therapy, when a growth factor is used as an adjunct to antibiotics in patients with established neutropenic sepsis.
- To accelerate hematopoietic reconstitution after auto- or alloHSCT.
- To induce proliferation of leukemic cells and increase sensitivity to chemotherapy.
- To facilitate the harvesting of peripheral blood stem cells and mature neutrophils.

The evaluation of clinical trials of growth factor support has been notoriously difficult and several points are worth bearing in mind. The duration of neutropenia is a valuable hard endpoint that is reported in all studies; however, unless it leads to a reduction in morbidity or mortality, its only clinical relevance is as

Table 46.2 Summary of indications for granulocyte and granulocyte-macrophage colony-stimulating factors (G-CSF and GM-CSF)

Indication	Recommendation
Primary prophylaxis	Use if the expected risk of febrile neutropenia is greater than 40%
Secondary prophylaxis	Use when there is good evidence that treatment delay or dose reduction would compromise outcome
Established neutropenia	Use only in high-risk patients
Stem cell transplantation	CSFs are indicated following autologous and allogeneic hematopoietic stem cell transplantation
Progenitor mobilization	CSFs are indicated for progenitor mobilization
Neutrophil collection	Possible use. Clinical trials are required

a reassurance to the clinician. The risk of death after chemotherapy is now so low after even the most intensive regimens that it has not been possible to demonstrate a survival benefit in patients treated with G-CSF or GM-CSF. Rates of infection are also difficult to assess accurately, and alternative endpoints such as ‘days of febrile neutropenia’ (FN) are completely dependent on the duration of neutropenia, which will always favor the growth factor-treated group. QoL and cost-effectiveness analyses are also complex and difficult to evaluate. A frequent flaw in pharmaco-economic studies, for example, is the fact that clinical trials are often performed in large centers, where costs may be quite different from the smaller centers in which the majority of patients are treated.

To address these difficulties, a number of well-researched guidelines, position papers, and Cochrane reviews of growth factor use have been published, and these are summarized below along with evidence supporting the use of these factors in particular disorders.^{94–101} Guidance on the clinical use of CSFs is summarized in Tables 46.2 and 46.3. Although much of what can be said about G-CSF is also applicable to GM-CSF, the former is much more widely used, mainly because of its superior safety profile.

Prophylactic and therapeutic use of G-CSF and GM-CSF

Primary prophylaxis

At present, the routine use of G-CSF as primary prophylaxis in previously untreated patients undergoing

Table 46.3 Use of G-CSF and GM-CSF in specific disorders

Disorder	Ref	Result	Recommendation
Acute myeloid leukemia (AML) induction	190–200	Reduced duration of neutropenia and/ or hospital stay. Some studies show increased CR rate, OS, or DFS	Possible use if appropriate to reduce inpatient stay and antibiotic and antifungal costs
AML consolidation	193,201	Reduced neutropenia and antibiotic use	Recommended
AML sensitization	196–199, 202–207	Generally a limited effect. One study showed an increased CR rate; another reduced relapse and improved OS	Not recommended. Clinical trial only
Acute lymphoblastic leukemia induction	208–213		Recommended
Myelodysplastic syndrome	28,214–218		Possible use with chemotherapy or episodic infection. Chronic use not recommended
Congenital neutropenia	84,219–221		Recommended. Caution over leukemia risk in long-term use
Aplastic anemia	222–224		Not recommended. Clinical trial only
Non-Hodgkin lymphoma	225–231		Possible use if risk of infection is greater than 40%
Hodgkin lymphoma	232,233		Possible use

CR, complete remission; OS, overall survival; DFS, disease-free survival.

induction chemotherapy is not recommended, since the proportion of patients who might benefit is small compared with the cost and inconvenience of G-CSF administration.⁹⁵ Moreover, it is possible that CSFs themselves may induce fever that may be interpreted as FN, leading to inappropriate use of empiric antibiotics. A pharmaco-economic analysis suggested that primary prophylaxis is worthwhile when the risk of FN exceeds 40%,¹⁰² for example in patients with AIDS-related NHL or during dose-escalated treatment schedules for lymphoma. This has been incorporated into some guidelines, although there is so far no evidence for clinical benefit.^{95,96} It has been suggested that if current US estimates of hospitalization costs and indirect ‘societal’ costs such as loss of productivity, and out-of-pocket patient expenses are included, routine primary prophylaxis is warranted if the risk of FN is 18% or greater.¹⁰³

Recent efforts have focused on risk-adapted strategies that might be used to target growth factor prophylaxis to patients who are at greatest risk, especially the elderly. A retrospective study of patients with NHL showed that serum albumin, lactate dehydrogenase (LDH), and presence of bone marrow involvement may be used to predict the risk of FN.¹⁰⁴ Elderly patients are also at particular risk of FN and may warrant growth factor prophylaxis. If predisposing factors such as these can be defined and validated then they may provide the basis for more appropriate decisions about primary prophylaxis in individual patients.¹⁰⁵

Secondary prophylaxis

There is no published evidence of a survival advantage for patients treated in this way; however, as the alternative is usually treatment delay and since acceleration of treatment has been shown to be beneficial in lymphoma,¹⁰⁶ it seems reasonable to extrapolate a role for CSFs in this situation.^{96,107}

Treatment of established neutropenia

It is necessary to distinguish in this context between afebrile and febrile neutropenic patients. One randomized trial showed no clinical benefit for the routine use of CSFs in afebrile neutropenic patients,¹⁰⁸ whilst in febrile patients, the results of nine randomized trials were variable, with the expected reduction in the duration of neutropenia but different effects on clinical outcome and cost.^{109–117} G-CSF is not currently recommended in this situation unless there are particular high risk factors such as neutropenia (absolute neutrophil count (ANC) $<0.1 \times 10^9/l$), hypotension, multiorgan failure, invasive fungal infection, or an elderly patient.

Use of G-CSF and GM-CSF in specific disorders

Many studies have now been conducted to investigate the potential benefits of G-CSF and to a lesser extent GM-CSF in specific disorders. The data and key recommendations from these mainly randomized studies are summarized in Table 46.3.

Use of G-CSF and GM-CSF for mobilization of peripheral blood progenitor cells

A marked rise in the number of circulating progenitor cells in the blood during recovery from myelosuppressive chemotherapy was first described by Richman and colleagues in 1976.¹¹⁸ The clinical exploitation of this finding was, however, limited by the number of leukaphereses required to yield sufficient cells. Both G-CSF and GM-CSF also mobilize progenitor cells into the peripheral blood,^{119,120} particularly when given after myelosuppressive chemotherapy, and autologous G-CSF mobilized peripheral blood progenitor cells (PBPC) are now routinely used to support high-dose chemotherapy.

A randomized study comparing transplants using autologous bone marrow and mobilized PBPC showed accelerated neutrophil and platelet recovery, fewer platelet transfusions, and less hospitalization in the PBPC group.¹²¹ A randomized comparison between GM-CSF- and G-CSF-mobilized autologous PBPC in patients with Hodgkin lymphoma (HL)¹²² showed no difference in outcome; however, superior tolerability has resulted in the almost exclusive use of the latter. Accelerated neutrophil and platelet recovery has also been reported with allogeneic PBPC.^{123,124} The higher T-cell dose found in PBPC harvests has been associated with an increased risk of GVHD in some studies but not others, and this is still under investigation.

Use of G-CSF for neutrophil mobilization

Neutrophils collected by steady-state apheresis of normal donors fell out of favor for the treatment of neutropenic sepsis as they had little clinical impact. More recently, however, several groups have begun to administer G-CSF, with or without dexamethasone, to mobilize peripheral blood neutrophils.^{125–127} G-CSF (600 µg subcutaneously) and dexamethasone (8 mg orally) given 12 hours before standard leukapheresis routinely results in the collection of approximately 80×10^9 granulocytes. This number of cells is sufficient to increase the neutrophil count of a severely neutropenic patient to normal and restore the recipient's ability to develop a neutrophil response in tissues. Several trials are ongoing to establish the clinical benefit of this new approach to supportive care for neutropenic patients.

Use of G-CSF and GM-CSF in stem cell transplantation

Autologous PBPC transplantation

Most randomized trials employing CSFs after high-dose chemotherapy and autologous PBPC transplantation (PBPC-T) have shown them to be valuable in terms of significantly shortening the duration of neutropenia and hospitalization^{128–131} and possibly reducing costs.^{121,128,132} In a UK study, for example, the clinical benefits of G-CSF started at day +5 after autologous PBPC-T were shown to be associated with a mean cost saving of £1816 per patient, even taking into account the cost of the G-CSF.¹²⁸ One placebo-controlled trial showed no benefit for therapy with GM-CSF following transplantation of GM-CSF-mobilized PBPC, with significantly fewer febrile days with the placebo.¹³³

The optimal timing of CSF administration after autologous PBPC-T is still under investigation. Two randomized studies demonstrated no significant differences in efficacy between early or delayed G-CSF (day +1 versus day +7,¹³⁴ and day 0 versus day +3 versus day +5¹³⁵), but both reported cost savings with the delayed treatment.^{133,135} On the other hand, a non-randomized study showed significant benefits for early compared with delayed G-CSF (day +1 versus day +4) with regard to neutrophil recovery, length of hospital stay, and duration of non-prophylactic antibiotic use, together with an 11% reduction in costs.¹³⁶

Autologous and allogeneic BMT

There are fewer data on the role of CSFs following bone marrow transplantation (BMT), but those that are available are positive. In a randomized trial of G-CSF (0, 10, or 30 µg/kg/day) in 54 patients with HL or NHL undergoing autologous BMT, G-CSF treatment was well tolerated and associated with significant reductions in the duration of neutropenia (by up to 16 days) and days with FN (by up to 5 days).¹³⁷ There were no significant differences between the two doses of G-CSF in this study. In a non-randomized trial in 81 patients undergoing allogeneic BMT, G-CSF started on day +1 post transplant was found to result in a significantly decreased time to engraftment and time from marrow infusion to discharge, together with significantly lower median costs (a \$3400 difference).¹³⁸ In a further randomized study, G-CSF compared with placebo following alloHSCT significantly shortened the time to neutrophil regeneration.¹³⁹

Pegfilgrastim

G-CSF has a short half-life necessitating daily administration. Recently, pegfilgrastim, a bioengineered form of filgrastim, was created by covalently binding a 20 kDa polyethylene glycol (PEG) molecule to the N-terminal methionine residue of filgrastim.¹⁴⁰ This modification reduces renal clearance and results in a sustained duration of action. The predominant route of elimination of pegfilgrastim is through binding to G-CSFR on neutrophils and their precursors, so that clearance is directly related to the ANC, and serum levels remain elevated during neutropenia and decrease as the ANC rises.

Pegfilgrastim is administered as a single subcutaneous injection per cycle of chemotherapy. Clinical trials in hematological and non-hematological malignancies have shown it to have similar efficacy to filgrastim in decreasing the incidence of febrile neutropenia following chemotherapy. The safety profile and tolerability of pegfilgrastim are similar to those of the parent molecule,^{141–147} and it has now been licensed to reduce the duration of neutropenia and the incidence of febrile neutropenia following chemotherapy for malignant disease (chronic myeloid leukemia (CML) and MDS excluded). The once-per-cycle dosing is of benefit to the patient and carers, and may improve compliance and QoL. The cost and benefits of single-dose pegfilgrastim will need to be compared closely with daily G-CSF before it can be recommended for routine use.

Interleukin-11

IL-11 is a member of the IL-6 hematopoietic growth factor family, with *in vitro* and *in vivo* effects on megakaryocytopoiesis¹⁴⁸ and synergy with factors acting on other lineages.¹⁴⁹ In mice, *in vivo* administration results in elevated platelet counts,¹⁵⁰ and there is acceleration of platelet recovery after both chemotherapy and BMT.¹⁵¹ Multilineage effects are also evident in these systems, with acceleration of neutrophil and reticulocyte recovery. In addition to its effects on the hematopoietic system, IL-11 has a protective effect in models of chemotherapy-induced gastrointestinal mucosal damage.¹⁵² Studies in IL-11 deficient mice have shown that it is required for the maintenance of female fertility and has no essential role in hematopoiesis.^{153,154}

A number of phase I and II clinical trials with IL-11 (oprelvekin) have been reported, leading to its approval by the US Food and Drug Administration (FDA) for the prevention of chemotherapy-induced thrombocytopenia in non-myeloid malignancies. The first of these was a dose-finding study in which IL-11 was given to women with advanced breast cancer before and after combination chemotherapy.¹⁵⁵ The maximum tolerated dose was 75 µg/kg, with dose-limiting fatigue, arthralgia, and myalgia above this level in all patients. A dose-independent reduction in hematocrit (mean 20%), possibly due to the previously observed expansion in plasma volume,¹⁵⁶ was noted. Although there was an increase in acute phase proteins, the fever and capillary leak syndrome observed with some of the other pleiotropic cytokines did not occur. Dose-related increases in platelet count were seen when IL-11 was given alone, and at higher dose levels the severity of thrombocytopenia in the first two cycles of chemotherapy was reduced.

Further phase I/II studies in a variety of tumors confirmed the modest effect of IL-11 on platelet (and sometimes neutrophil) recovery after chemotherapy,^{157,158} and a randomized study in which placebo or IL-11 was given to patients who required platelet transfusion after the first course of myelotoxic therapy showed a significant reduction in the frequency of platelet transfusion in the second cycle. IL-11 was reportedly well tolerated, with side-effects similar to those previously seen; however, atrial arrhythmias (7 fibrillation and 1 flutter) developed in 8 out of 55 patients receiving IL-11 but in none of the controls. These effects were thought to be due to plasma volume changes, and it was suggested that they might be prevented by diuretic treatment. The effects of IL-11 on the gastrointestinal tract have led to trials in inflammatory bowel disease and as a protective agent following chemotherapy. A subset of patients with active Crohn's disease showed improvement in a randomized clinical trial.¹⁵⁹ Based on encouraging data in a murine study,¹⁶⁰ a small randomized study of IL-11 in the prevention of mucositis and GVHD was performed; however, no beneficial effect was shown.¹⁶¹ A pharmaco-economic study of IL-11 as secondary prophylaxis of thrombocytopenia in solid tumor patients receiving chemotherapy showed that although some platelet transfusions were prevented, the costs were significantly higher than for conventional supportive care.¹⁶²

Thrombopoietin

The identification of the cDNA for thrombopoietin (TPO) was reported by five different groups in 1994, a decade after the original colony-stimulating factors.¹⁶³ There is good evidence that TPO is the principal regulator of platelet production, since TPO levels rise during thrombocytopenia¹⁶⁴ and transgenic mice with disruption of either the *TPO* gene or its receptor *c-mpl* are constitutionally thrombocytopenic.^{165–167} TPO deficiency in knockout mice can be largely corrected by liver transplantation,¹⁶⁸ and in humans there is a correlation between the platelet count and TPO level prior to liver transplantation,¹⁶⁹ suggesting that this organ is the most important physiological source of TPO. Factors other than TPO must be involved in the control of platelet production, since although TPO-deficient mice are thrombocytopenic, some platelets are produced and there is no spontaneous bleeding.

In vitro studies confirmed that TPO induces megakaryocyte differentiation, and synergistic effects with other factors on earlier progenitors were also observed. The multilineage effects of TPO were confirmed by the finding that in addition to a reduction in megakaryocytic progenitors, TPO- or *c-Mpl*-deficient mice also have significantly reduced numbers of early erythroid and myeloid cells.^{165,166} Unlike G-CSF and GM-CSF, TPO has relatively minor effects on the function of mature cells, and although there is *in vitro*

priming of platelet aggregation to some agonists,¹⁷⁰ TPO itself has no effect on platelet aggregation.

Preclinical and clinical trials of TPO have been conducted both with a full-length glycosylated recombinant molecule (rTPO) synthesized in mammalian cells and with a non-glycosylated truncated *E. coli*-derived variant with a polyethylene glycol moiety (megakaryocyte growth and differentiation factor, PEG-rMGDF). Although biochemically distinct, these preparations have a similar receptor affinity and in vivo half-life.¹⁷¹ In healthy primates, TPO increased the platelet count and the ploidy of bone marrow megakaryocytes.¹⁷² These effects take several days to occur, presumably because TPO acts on earlier progenitors and not mature cells. Studies in animals treated with chemotherapy or radiation^{173–176} showed that TPO reduced the degree of thrombocytopenia, leukopenia, and anemia.

Clinical trials in humans have mainly used the PEG-rMGDF preparation. When given to patients with advanced malignancies prior to chemotherapy, a dose-dependent increase in platelet count was observed, without evidence of any effect on platelet function,¹⁷⁷ and similar findings were subsequently reported in normal platelet donors.¹⁷⁸ A number of randomized clinical trials subsequently showed that in the context of intensive but non-ablative chemotherapy, TPO induces an earlier and often less marked platelet nadir.^{177,179–181} In some studies, the need for platelet transfusion was reduced, but this was confined to the early cycles of therapy. In contrast to animal studies, there was no effect on the recovery of other lineages. Following more intensive chemotherapy and HSCT, no significant effect of TPO on the duration of thrombocytopenia or need for platelet transfusion has been reported.^{182–184}

TPO has also been studied as an adjunct to PBPC mobilization and in platelet apheresis from normal donors. In a large randomized study, the addition of TPO to G-CSF improved the yield of CD34⁺ cells obtained and reduced the number of patients who failed to mobilize over 2×10⁶ CD34⁺ cells/kg.¹⁸⁵ When administered 10–14 days prior to platelet apheresis in normal donors, TPO improved the yield and reduced the number of transfusions required compared with standard collections.^{178,186}

An unexpected adverse effect of PEG-rMGDF administration was the development of neutralizing anti-TPO antibodies associated with thrombocytopenia and in some cases neutropenia and anemia.^{1,187} The highest frequency (8.9%) was observed in normal donors given three subcutaneous doses of PEG-rMGDF, although antibody formation also occurred at a lower rate in chemotherapy and HSCT patients. It is not known whether truncation, pegylation, lack of glycosylation, or route of administration of the agent were the primary cause of this phenomenon, which resulted in the suspension of clinical trials in 1998. The relatively modest efficacy observed in clinical trials combined with this severe side-effect have meant that no form of TPO has yet been licensed for clinical use. Alternative thrombopoietic agents such as peptide¹⁸⁸ and chemical¹⁸⁹ mimetics have been described and may prove clinically useful in the future.

Management of infectious complications in hematological patients

Catherine Cordonnier

Introduction

Hematological malignancy is a field where significant progress has been made in therapeutic possibilities and prognosis. Some patients who would previously have succumbed can now aspire to a cure and a return to a normal, or almost normal, quality of life. However, these results are obtained with treatments that have side-effects and that increase the risk of opportunistic infections. This means that infections, which are already an inherent risk in some hematological diseases, are even more frequent when treatments increase immune deficiency.

A physician who individually decides a treatment for a patient must be aware of the infectious complications that may threaten that patient, and must know if special prophylactic measures are needed, and how to manage the patient if a complication occurs. On another level of decision, therapeutic groups who design a new protocol for a malignancy should always have data on the infectious complications, such as morbidity or mortality factors. Chemotherapy A may give similar results to chemotherapy B in disease-free survival. However, if patients die mainly from relapse in arm A and mainly from infection in arm B, an approach to prevention of the infections could improve the results for arm B. Therapy can also change the predisposition of a hematological disease for a particular infection. A good example is the association of hairy cell leukemia and legionellosis, which although common some 15 years ago, has almost disappeared since interferon- α has greatly improved the prognosis of the disease.

Finally, understanding the mechanisms predisposing to each kind of infection in each setting is the best way to propose a prophylactic policy. In that way, experimental models and in vitro data are valuable. However, many patients have multiple risk factors for infections (e.g. neutropenia and steroids), and this may make individual analysis difficult. Analysis of each case, taking simple parameters into account, should help in deciding a suitable diagnostic and therapeutic approach.

The different factors that predispose to infections

Host factors related to disease or treatment

The factors that predispose the 'compromised' host to infection are not completely understood. However, lessons drawn from clinical observations and from in vitro data and experimental models allow the proposition of reasonable hypotheses on the association of some infections and risk factors, and also on the specific mechanisms of predisposition. It is usual to consider three categories of compromising factors: neutropenia, cellular immune dysfunction, and humoral immune dysfunction.

Neutropenia

Over 30 years ago, Bodey et al¹ showed that infection is related to the absolute level of circulating neutrophils (PMN), especially when granulocytes fall below $0.5 \times 10^9/l$. However, today, 'high-risk' neutropenia refers to patients with $PMN < 0.1 \times 10^9/l$.

Neutropenia may be due to the primary disease (e.g. in acute leukemia) or to treatment. Most neutropenias are due to chemotherapy and are dose-related. More rarely, functional deficiencies of granulocytic functions, such as chemotaxis, phagocytosis, or microbial killing, may predispose to the same kind of complications. These functional deficiencies may be associated with quantitative deficiencies, as in some myelodysplastic syndromes (MDS).

Neutropenia predisposes to the occurrence of bacterial infection, and to the severity of infection if

untreated. The first source of infection during neutropenia is the gut. Bacterial translocation through the gut barrier in the setting of neutropenia explains most bacteremias of gut origin.² This is the rationale for gut decontamination in severe and prolonged neutropenia. The strains that are most often found in this setting are enterobacteria, and more rarely *Pseudomonas* spp.; however, any strain colonizing the gut may be a source. Systemic bacterial infections may also come from any infected site. Any latent focus may, in the case of neutropenia, become symptomatic and life-threatening.

Neutropenia is also the main predisposing factor, with steroid administration, for fungal infections. Although reported, the occurrence of fungal infection during short-term neutropenia is extremely rare, and this is the basis for reserving antifungal prophylactic measures to, and developing pre-emptive antifungal strategies for, patients who are expected to have at least 10 days of neutropenia. Additionally, prolonged neutropenia consecutive to chemotherapy in hematological diseases is often associated with functional and quantitative deficiencies of the alveolar macrophage populations, which may be an additional factor in pulmonary fungal infections, mainly due to *Aspergillus*.

Humoral immune deficiency

Because of the role of antibodies in opsonization, global hypogammaglobulinemia or specific deficiencies in classes or subclasses predispose to bacterial infections, and especially to infections with encapsulated bacteria, such as *Streptococcus pneumoniae* or *Haemophilus influenzae*. This may be encountered in particular in myeloma, other dysglobulinemias, chronic lymphocytic leukemia (CLL), and bone marrow transplantation (BMT).

Cellular immune deficiency

This category involves the most complicated features of immune deficiencies. These deficiencies are more specific in certain diseases such as lymphomas, but are mostly induced by treatment, such as steroids, fludarabine or BMT/peripheral blood stem cell transplant (PBSCT) conditioning. The complexity of cellular immune function, the number of cells involved, the interactions between them, and the role of cytokines engaged in the infectious process probably explain the long list of potential pathogens in patients with cellular deficiencies. Most of these pathogens are infective through reactivation (i.e. *Toxoplasma gondii* or cytomegalovirus (CMV)), although others are newly acquired and responsible for primary infections. Most of them have an intracellular development, and include *Salmonella*, *Listeria*, mycobacteria, and *Legionella* for the bacteria, mainly *Pneumocystis carinii*, *Cryptococcus neoformans*, and coccidioidomycosis for fungi, and *T. gondii*, *Strongyloides stercoralis*, and *Cryptosporidium* for protozoa.

Other host factors

Any obstruction of natural orifices may lead to or favor infection. This may be the cause in lymphomas when mediastinal nodes are responsible for tracheobronchial obstruction. Moreover, any procedure leading to cutaneous or mucosal barrier disruption offers an opportunity for bacteria and fungi to colonize and then to infect the host. Long-term venous catheters have become routine practice, and are major sources for staphylococcal bacteremia and fungemia.³⁻⁵ Also, certain treatments require bladder catheterization.

Environmental factors

The natural or iatrogenic predisposition of hematological patients to infectious pathogens may favor the acquisition both of nosocomial and of community infections. However, because the periods of highest risk usually follow therapies given during hospitalization, most infections occur in the hospital and should be considered nosocomial. Some pathogens, such as *Aspergillus*, may, however, be acquired outside or inside the hospital. After allogeneic stem cell transplantation, it has been shown that there are two waves of onset of *Aspergillus* infection in this population, one during the neutropenic phase and acquired in the hospital, and a second one later, during the second or third month post transplant, this one being acquired either in or outside the hospital.^{6,7}

Nosocomial infections

Hematological patients are subjected to multiple sources of pathogens through food, beverages, air, invasive procedures, and contact with staff. The potential role of food and beverages in the acquisition of enterobacteria, *Salmonella*, and *Pseudomonas* spp. has been documented.⁸ This justifies regular quality-control procedures and makes it logical to use cooked food for high-risk patients, especially those with prolonged neutropenia and those receiving gut decontamination.

Although the environment is a reservoir for microorganisms, most nosocomial infections require a human vector.⁹ Because of multiple patient contacts, hospital care workers are the second potential source of pathogens and the obligatory intermediary between patients, especially for methicillin-resistant staphylococci and for gram-negative nosocomial strains. Handwashing and simple measures of hygiene remain the most logical and economical procedures to avoid the transmission of most nosocomial bacterial and candidal infections.

In any hospitalized high-risk patient, colonization with bacterial and fungal pathogens usually precedes

infection. Multiple routine microbiological samples (nose, ears, gingivae, axillae, etc.) are not generally helpful in predicting infection. Stool and, to a lesser degree, urine cultures are more useful in routine practice in neutropenic patients to isolate *Pseudomonas* spp., *Klebsiella*, or *Staphylococcus aureus*.² Colonization by bacteria, especially when resistant, should be taken into account in choosing empiric antibiotic therapy in cases of subsequent infections, and can lead to prophylactic measures of isolation to avoid dissemination to other patients. Colonization by *Candida* does not have the same predictive value, depending on the *Candida* sp.: this predictive value is usually poor for *C. albicans* and high for other species, such as *C. tropicalis* or *glabrata*.^{10,11}

Other infections are airborne. The most important in hematological patients is aspergillosis, which can occur at any time and in any hospital. There are climatic and geographical variations in its incidence, and epidemics may be triggered by construction work, which increases the number of spores in suspension in the air.¹² This is also probably the mechanism of acquisition for more unusual filamentous airborne infections such as mucormycosis. Most cases occur after airway colonization or sinusitis. Although specific risk factors, such as neutropenia of long duration and steroid therapy, have been well established, hematologists should always maintain a high level of suspicion regarding this possibility and be aware that aspergillosis is difficult to diagnose and difficult to treat.

Community-acquired infections

The distinction between nosocomial and community infections is to some extent artificial, since some pathogens may be acquired in both ways. This is the case for *Aspergillus*, especially in case of chronic graft-versus-host disease (GVHD).⁷ *Legionella* spp. may be acquired through contaminated water and so may be also of concern to both in- and outpatients. In the same way, a patient susceptible to the acquisition of varicella zoster virus (VZV) may be in contact with infected persons both in and out of hospital. However, some pathogens are predominantly associated with community infections. This is the case for hypogammaglobulinemic patients, who are predisposed to *S. pneumoniae* and *H. influenzae* infections, but this risk will remain while the patient is hospitalized.

Febrile neutropenia

Since the demonstration of the relationship between neutropenia and infection,¹ and the initial study showing that febrile neutropenia must be urgently and empirically treated with broad-spectrum antibiotics,^{13,14} numerous epidemiological and therapeutic studies have been published. However, despite progressive modifications in the epidemiology of bacterial strains responsible for febrile neutropenia, little has changed in the general principles of first-intention therapy in this setting, except for a better recognition of low-risk patients, which allows a reduction in the antibiotic regimens of these patients whenever possible.

Epidemiology of infections during neutropenia

As a result of multiple factors, including the increasing use of indwelling catheters and prophylactic measures that modify the incidence of some infections, the epidemiology of bacterial pathogens in neutropenic patients has changed. While 25 years ago, gram-negative bacteria were predominant, gram-positive bacteria now represent the most frequently isolated pathogens.^{15,16} It is known that only 30–40% of febrile neutropenic patients have a microbiologically documented infection (MDI). This documentation comes in 85–90% of the cases from positive blood cultures. The documentation from other sites is rarer.

Among these 30–40% of patients with MDI, two-thirds will be gram-positive and one-third gram-negative. Coagulase-negative staphylococci are the most frequent pathogens isolated and, despite the lack of strong data supporting the rule, it is routine, at least in therapeutic trials, to consider that two positive blood cultures are necessary to consider these staphylococci responsible for the infection. Streptococci, especially oral strains, have become more frequent over the last 15 years. The main risk factors for oral streptococcal bacteremia in the setting of neutropenia have been studied in retrospective^{17,18} and prospective studies,¹⁹ and have been found to be profound neutropenia ($<0.1 \times 10^9/l$), presence of mucositis, prophylaxis with quinolone or cotrimoxazole or gut decontamination, anti-H₂ drugs, and high-dose cytarabine. Previous administration of antibiotics decreases the risk. The mortality rate from gram-negative bacteremia was reported to be similar to that from gram-positive bacteremia,²⁰ while that from streptococcal bacteremia appears to be slightly higher.¹⁸ Strict anaerobes are very rare in neutropenic patients, and their occurrence is usually associated with severe buccopharyngeal mucositis or perineal cellulitis. Although *Pseudomonas* infections are found in less than 5% of patients during their first febrile neutropenic episode, their incidence increases with the duration of aplasia.

Although not restricted to the setting of neutropenia, candidiasis and aspergillosis are usual complications arising in bone marrow-suppressed patients, and have to be listed in the diagnostic possibilities complicating neutropenia, especially if it is of long duration. The incidence of candidemia depends on multiple factors, including underlying disease, therapy, degree of colonization, and antifungal

prophylaxis.^{11,20} What is clear, however, is that the *Candida* spp. isolated nowadays in hematological patients are not the same as 15 years ago. *C. albicans* has become less frequent, while an increasing number of cases due to *non-albicans* species, such as *C. tropicalis*, *C. glabrata*, *C. krusei* and *C. lusitaniae*, have been reported.^{22,23}

Management of febrile patients during aplasia

Febrile neutropenic patients must be treated emergently and empirically. One should not wait for results of cultures or procedures that may never reveal the likely source. This dogma is the cornerstone of management, and is based on the following points:

1. Bacterial infections in neutropenic patients may kill the patient rapidly if antibiotics are not started very quickly after the occurrence of fever. This strategy, combined with the use of more and more potent antibiotics, has been mainly responsible for the dramatic decline in mortality rates during aplasia, especially from gram-negative bacteremia.
2. The antibiotic regimen must offer an optimal coverage of the more frequently isolated strains, and also of the most dangerous. For this reason, it is strongly recommended in high-risk patients to give a synergistic combination of broad-spectrum antibiotics active against the more frequent enterobacteria (*Escherichia coli*, *Klebsiella pneumoniae*, and *Serratia*) and *Pseudomonas aeruginosa*. Some aspects of this approach can now be questioned, since the antibiotics and the epidemiology are different from 20 years ago, but the general principles of this rationale have to be kept in mind.
3. Foci in neutropenic patients are less obvious than in any other septic condition, probably because the inflammatory process is minimal in neutropenia.²⁴ The absence of a visible focus does not mean that the patient is not infected, and should not delay or change the initiation of antibiotics. On the other hand, it has been shown that some foci, such as pneumonia, cellulitis, or intraabdominal infections, have a major impact on the prognosis of a bacteremic episode occurring during neutropenia, especially in terms of survival to aplasia.²⁵

Initial clinical evaluation

Each febrile neutropenic patient must be carefully evaluated by a very complete clinical examination before starting antibiotics:

- because the severity of the septic process may require additional measures (e.g. haemodynamic monitoring or oxygen);
- because the presence of certain clinical foci associated with particular pathogens may be important for the therapeutic choice of first intention;
- because the decision to change the antibiotic treatment during aplasia will be based on the evolution of the initial manifestations of infection during treatment.

The multinational Association for Supportive Care in Cancer (MASCC) has proposed a scoring system in order to identify high-risk febrile neutropenic patients²⁶ (Table 47.1). More than 1000 patients were prospectively studied at presentation of febrile neutropenia to predict low-risk of fever resolution without serious medical complication development. Almost two-thirds of these patients were hematology patients. A score of 21 or higher identifies low-risk patients with a positive predictive value of 91%, a specificity of 68%, and a sensitivity of 71% (Table 47.1).

The findings of the clinical examination should be precisely recorded and the patient reevaluated at least daily.

Minimal microbiological examinations

Neutropenic patients (PMN < 0.5 × 10⁹/l), or patients who are expected to be at that count in the next 48 hours because of recent chemotherapy, should have at least two blood cultures from two different sites and a microbiological sample from any clinical focus, if easily accessible, as soon as they become febrile, so that the antibiotics may be started as soon as possible in the next few hours following the onset of fever.¹⁴

Table 47.1 Scoring system proposed by the Multinational Association for Supportive Care in Cancer (MASCC) to identify low-risk febrile neutropenic cancer patients²⁶

Characteristic	Weight
Burden of illness: no or mild symptoms ^a	5
No hypotension	5
No chronic obstructive pulmonary disease	4
Solid tumor or no previous fungal infection	4
No dehydration	3
Burden of illness: moderate symptoms ^a	3
Outpatient status	3
Age <60 years	2
The maximal theoretical score is 26. A risk-index score of 21 or more identifies low-risk patients with a predictive value of 91%, a specificity of 68%, and a sensitivity of 71%.	
^a Points attributed to the variable 'burdens of illness' are not cumulative.	

Hypothermia and hypotension represent an even more unfavorable situation, since these patients often evolve rapidly to septic shock and have to be treated without waiting.

Empiric therapy for first intention

The first-intention empiric therapy has to consider at least

- the general rule of broad-spectrum antibiotic treatment, including the possibility of synergistic effects between two drugs in the more at-risk patients;
- the risk status of the patient;
- the most common strains isolated in the particular setting;
- the epidemiology of the ward in the case of nosocomial infection;
- the presence of special foci that may add other microbiological possibilities to the list of pathogens usually found;
- the risk of adverse effects from the drug(s).

Ideally, the choice should also preserve the epidemiology of the ward by avoiding the empiric use of antibiotics able to induce a significant risk of multidrug resistance and superinfections.

A broad-spectrum antibiotic treatment is an antibiotic or a combination of antibiotics that are active against the most frequently isolated gram-negative and gram-positive strains. Beta-lactams are actually the sole class of antibiotics satisfying all the criteria cited above.¹⁴ Most of them, except aztreonam, are active against both gram-positive and gram-negative strains. However, because of differences in activity and, to a lesser degree, in safety, all are not equal, and the choice should be determined both on their respective biological activities and on the results of clinical trials.

Moreover, it is usual to consider at least two groups of patients—mainly according to the duration and depth of neutropenia, but also other risk factors as those identified in the MASCC score²⁶ (Table 47.1). The first group (standard-risk or low-risk patients: PMN < $0.5 \times 10^9/l$ for less than 5 days) are usually those who received sequential chemotherapy, often as outpatients, such as low- or intermediate-grade lymphoma patients. This population is very similar to solid tumor patients. They often have community infection, so that the fear of a multiresistant pathogen is low, since they did not receive previous systemic prophylaxis before or were not colonized with hospital strains.

The second group includes usually those already hospitalized when fever occurs, such as acute leukemia patients in the induction or consolidation phases of treatment, or stem cell transplant patients. They have neutropenia that lasts for more than 10 days, and frequently reach a nadir PMN < $0.1 \times 10^9/l$. In Europe, these patients often receive prophylactic gut decontamination, including at least colimycin and an aminoglycoside. Because of special risk factors and therapeutic approaches, the epidemiology of these patients is often different from that of the first group: they have more streptococci, more coagulase-negative staphylococci, and sometimes more multiresistant gram-negative hospital strains than the first group.

For the low-risk group, two options are recommended:¹⁴ either the oral administration of ciprofloxacin plus amoxicillin-clavulanic acid, or the intravenous administration of a beta-lactam. Monotherapy with an intravenous beta-lactam is the standard in hematology patients, because the benefit from the addition of an aminoglycoside in this population is not clearly supported by clinical trials. Although intravenous antibiotic therapy was until recently the standard, two large randomized trials have shown that in a low-risk inpatient population with short-term neutropenia and no initial morbidity or complication, the oral association of amoxicillin/clavunamic acid and ciprofloxacin has the same efficacy as an intravenous cephalosporin.^{27,28} It should be emphasized that the term 'low-risk patients' should not let one forget that these patients may die from an uncontrolled infectious process, especially when the hematological disease is not controlled—even if they are treated without delay. They require very careful management in the first hours and days of treatment. It is likely that in the future such patients will be managed as outpatients, as has been done in clinical trials for patients with solid tumors.^{14,29}

For the other groups (standard or high-risk patients), and for reasons of toxicity and cost, efforts are also being made to restrict the use of combinations, and if possible to replace them with monotherapy. It is clear, however, that the choice of monotherapy should restrict the choice of the drug to very potent ones, active on *Pseudomonas* spp. and on most multi-resistant gram-negative bacteria. Three options are possible:¹⁴

1. In the absence of first-line glycopeptide indication, either monotherapy with, for example, ceftazidime,¹⁵ cefepime,³⁰ imipenem, or the newer meropenem, which was found to be as effective as the ceftazidime-amikacin combination in high-risk patients.²⁰ Piperacillin-tazobactam is an other alternative, which was shown to be more active than ceftazidime plus amikacin in a large trial.¹⁶
2. A combination of a beta-lactam and an aminoglycoside. It is true that there are now antibiotics that, even without the addition of an aminoglycoside, have bactericidal activities comparable to or better than those obtained 10–15 years ago only with combinations. Therefore, the combination

beta-lactam-aminoglycoside is becoming more and more restricted to high-risk patients, such as where there is suspicion of *Pseudomonas* sp. infections, or to clinically documented infections with severe foci. Those teams who add to the beta-lactam an aminoglycoside usually stop it at 48 hours if blood cultures are negative or if a pathogen is isolated that is resistant to aminoglycosides. It is clear, however, that patients with enterobacterial or *Pseudomonas* bacteremia benefit from the administration of a long course (7 days) of aminoglycoside, both in terms of efficacy and of superinfections.³¹

3. When there is suspicion of gram-positive infections, such as patients colonized with penicillinor cephalosporin-resistant pneumococci or methicillin-resistant *S. aureus* (MRSA), patients with clinically suspected severe catheter-related infections, patients with severe mucositis, or patients receiving high-dose cytarabine or quinolone prophylaxis, a glycopeptide (usually vancomycin) is recommended as first-line therapy, in combination with a broad-spectrum beta-lactam, with or without an aminoglycoside. However, the glycopeptide should be stopped after 48–72 hours in the absence of documentation of gram-positive infection.

Even in large cohorts of patients, it is very difficult to demonstrate that the difference in any microbiological activity between any two of these drugs has any clinical consequences as determined by response rates in neutropenic patients. All of these drugs have very similar clinical efficacy, and the choice should be based on the epidemiology in a given center and the potential risk of selection of resistant mutants, especially when monotherapy is chosen.

The routine empiric addition of glycopeptides to initial therapy is more controversial. It has been clearly demonstrated to be unnecessary in terms of time to defervescence and survival from aplasia when compared with delayed administration at day 3 in the case of persistent fever or documented methicillin-resistant gram-positive infection. This applies to both vancomycin and teicoplanin.^{32–34} However, their empiric use may be justified in centers with a high incidence of MRSA, or in the case of suspicion of beta-lactam-resistant gram-positive infection. The problems that have already been encountered with vancomycin-resistant enterococci (VRE) could be encountered in the near future with coagulase-negative staphylococci. That possibility could have major implications, and physicians on hematological wards should be more and more restrictive with the empiric use of glycopeptides.

The addition of an antibiotic active against strict anaerobes (e.g. imipenem, clindamycin or metronidazole) is needed in patients with severe buccopharyngeal or perineal cellulitis or in any case of perianal or perirectal infection. In the case of ulcerative mucositis suggestive of herpes simplex infection, the administration of acyclovir is also needed, especially in high-risk patients (acute leukemia or BMT/PBSC), if possible after a virological or cytological documentation.

Because mycotic infections are not usually early complications of the first febrile episode of aplasia, empiric antifungal treatment is rarely warranted in first-line therapy, except in high-risk patients with particular presentations. These include those with colonization due to a *non-albicans Candida* sp. (which is also unusual at the beginning of aplasia in previously untreated patients) or a history of *Candida* septicemia or aspergillosis during a previous aplastic phase.

Reconsidering therapy during aplasia

In clinical trials, it has been routinely recommended to evaluate patients on day 3 of antibiotics and to reconsider the treatment then. However, in most recent clinical trials in high-risk patients, roughly 50% of the patients did not defervesce before day 5, even if no antibiotic change was made until the end of aplasia, suggesting that day 3 is perhaps too early to observe a defervescence even in favorable cases.

However, it is clear that, whatever the requirements of therapeutic trials, these patients must be routinely evaluated daily, because the occurrence of a new focus, or the deterioration of the clinical condition, may justify earlier therapeutic changes.

If an MDI has been found, the choice of strategy will depend on the susceptibility of the isolated strain(s), always keeping in mind the necessity of a broad-spectrum treatment. If glycopeptides had been given initially and are found to be unnecessary because a gram-negative strain only has been documented, the glycopeptide should be stopped.

In most cases, microbiological samples are negative. If the patient has defervesced and is clinically stable or better, then the same regimen must be continued until the end of aplasia, and the aminoglycoside, if initially given, may be stopped at day 3.³¹ In low-risk adult patients who have defervesced between days 3 and 5, and without microbiological documentation, the intravenous regimen may be changed to oral ciprofloxacin plus amoxicillin-clavulanic acid. In other cases, several strategies may be adopted, none of which can really be recommended more than another.

1. The first is to change the beta-lactam or the beta-lactam-aminoglycoside combination to a more potent treatment. However, if the initial treatment was already very broad, the benefit of changing such a treatment is unclear when given empirically in the absence of a new

clinical focus guiding the choice, and most teams will continue to perform periodic sampling for microbiological documentation before making changes.

2. The second is to empirically add a glycopeptide to the initial combination, which was routine practice in high-risk patients in Europe until recently. However, a trial by the International Antimicrobial Therapy Cooperative Group of the European Organization for Research and Treatment of Cancer (EORTC-IATCG) shows that patients do not benefit from the addition of vancomycin to tazocillin when they have only unexplained fever, with no microbiological documentation of gram-positive infection.³⁵
3. The third option, which may be combined with the first two, is to add an antifungal drug. It has been shown that adding intravenous amphotericin B (0.5–1 mg/kg/day) in patients remaining febrile despite 5–7 days of broad-spectrum antibiotics could be beneficial for those with severe and persistent neutropenia.^{36,37} However, because the standard antifungal, deoxycholate amphotericin B, is highly toxic, this approach has been evaluated using other antifungal drugs, especially with intravenous azole compounds and the various forms of liposomal amphotericin B.^{38–42} Among azoles, fluconazole has been found to have comparable efficacy to amphotericin B in the empiric indication.⁴⁰ However, due to its lack of efficacy on mold infections, it is not widely used. Itraconazole⁴¹ and voriconazole⁴² have both been compared with amphotericin B in its deoxycholate form⁴¹ or its liposomal formulation.⁴² Although the methodology of these trials have been widely debated, it can be concluded from both that azoles have comparable efficacy to amphotericin B, with fewer adverse events, especially less renal failure with azoles than with polyenes. Due to its broad spectrum and its safety profile, liposomal amphotericin B is recommended for empiric treatment of persistent febrile neutropenia in high-risk patients—those who have renal failure of any cause before first-line antibiotic therapy, those who develop renal failure under deoxycholate amphotericin B, or those who concomitantly receive other nephrotoxic drugs, especially the allogeneic stem cell transplant population who receive cyclosporine.

The place of growth factors

Both granulocyte colony-stimulating factor (G-CSF) and granulocyte—macrophage colony-stimulating factor (GM-CSF) diminish the duration of neutropenia and fever, and generally the length of hospital stay (see Chapter 46). However, few randomized trials have been performed on the treatment of febrile neutropenia. Although no trial has clearly shown that the administration of growth factors, begun after the occurrence of the fever, decreases the mortality of aplasia, it seems logical to give one of them each time a documented infection is life-threatening, when the prognosis depends on the duration of neutropenia, and when the spontaneous recovery from neutropenia is not expected for several days.^{43–45} Theoretically, GM-CSF should be preferable to G-CSF in cases of fungal infection because of its activity on the monocyte-macrophage system, although there are no clinical data to support this.

Infections according to the site of infection

Pneumonia

Pneumonia occurring in an immunocompromised host represents a major dilemma for the clinician.⁴⁶ First, the lung is by far the most common site of infection. Second, the chest X-ray may be normal, especially in neutropenic patients, despite a pulmonary infection.²⁴ Third, even without neutropenia, the main problem is whether to risk invasive procedures to have a reasonable chance of finding the etiological agent while weighing the risks of the morbidity and mortality of the procedure.

In hematological patients, pneumonia may be very difficult to diagnose (Table 47.2). Sputum culture is rarely useful in determining the true etiology of the pneumonia, and presents the risk of identifying an agent that is not finally responsible for the pneumonia. Therefore sputum is not recommended, except to look for strains that do not normally inhabit the oropharynx, such as *Legionella*, mycobacteria, and certain fungi.

The standard for diagnosis is bronchoscopic sampling with bronchoalveolar lavage (BAL): in neutropenic patients, this procedure should be considered urgently and specimens sent as described below. Empiric antibiotics against the likely organisms must be started without delay. Consideration should be given to the likelihood of fungus in patients with prolonged neutropenia and on steroid therapy. In non-neutropenic patients who are clinically stable and not asplenic or severely immunocompromised, one may sometimes be able to await the results of laboratory investigations before initiating treatment. In all patients with pneumonia, it is crucial to consider the following:

- the type of immune deficiency, underlying disease and previous treatments;
- the recent environment of the patient and exposure to nosocomial or any community-transmissible disease;
- clinical and radiological pattern and rapidity of evolution;

- association of pneumonia with other infectious lesions (especially skin and brain).

The possibility of non-infectious processes (fluid overload, alveolar hemorrhage, pulmonary embolism, or tumor) should be considered rapidly. Non-invasive procedures should be performed, depending on the clinical setting: blood cultures, microbiological samples of any easily accessible focus (skin, cerebrospinal fluid), and a first set of serologies (*Legionella* and mycoplasmas) and antigenemia (*Aspergillus*, *Candida*, and CMV). Then, one should consider fibroscopy with BAL. A routine BAL protocol should include:

Table 47.2 Main etiologies of pneumonia in hematological patients

Etiology	Pathogens	Relationship to neutropenia	Main population at risk
Infectious	Bacteria		
	• <i>Streptococcus pneumoniae</i> and <i>Haemophilus influenzae</i>	–	Allo BMT/PBSCT, myeloma, splenectomized patients,
	• Other gram-positive bacteria	+	Ig deficiencies
	• Other gram-negative bacteria	+/-	
	• Mycobacteria	–	
	• <i>Nocardia</i>	+/-	
	• <i>Legionella pneumophila ila</i>	–	Hairy cell leukemia
	Fungi		
	• <i>Aspergillus</i> and mucorales	+	Acute leukemia, high-grade NHL and alloBMT/PBSCT
	• <i>Candida</i> spp.	+	Acute leukemia
	• <i>Cryptococcus</i>	–	CLL
	• <i>Pneumocystis jirovecii (carinii)</i>	–	Acute leukemia, high-grade NHL, alloBMT/PBSCT, any patient receiving steroids for more than 4 weeks
	Viruses		
	• Herpes simplex virus (HSV)	+/-	
	• Varicella zoster virus (VZV)	–	Children, CLL, BMT/PBSCT
• Cytomegalovirus (CMV)	–	AlloBMT/PBSCT	
• Adenovirus and respiratory syncytial virus (RSV)	–	BMT/PBSCT	
Protozoa			
• <i>Toxoplasma gondii</i>	–	Seropositive alloBMT/PBSCT recipient, HL	
Helminths			
• <i>Strongyloides des stercoralis</i>	–	Patients originally from endemic countries	
Non-infectious			
Vascular and embolic complications	• Alveolar hemorrhage • Pulmonary embolism • Intrathoracic bleeding post procedure • Pulmonary veno-occlusive disease		
Inflammatory and/or immune diseases	• Hypersensitivity drug reaction • Radiation pneumonitis • Idiopathic interstitial pneumonia • Bronchiolitis obliterans		
Others	• Fluid overload • Pulmonary edema • Alveolar proteinosis • Leukoagglutinin reaction		

(allo) BMT/PBSCT, (allogeneic) bone marrow/peripheral blood stem cell transplantation; Ig, immunoglobulin; NHL, non-Hodgkin lymphoma; CLL, chronic lymphocytic leukemia; HL, Hodgkin lymphoma.

- total and differential cell counts on cytocentrifuge preparations using May—Grünwald-Giemsa (MGG) stain;
- a cell pellet obtained by centrifugation and cytocentrifugation, stained by MGG, Papanicolaou, Perls—Prussian blue,⁴⁷ and Gomori-Crocott methods, and examined for cytological evidence of viral, fungal, and parasitic infections and for the detection of siderophages.

A sample of fluid should be reserved for bacteriological, viral, and fungal cultures. Aspiration rather than BAL fluid should be examined for *Legionella pneumophila* by direct immunofluorescence and cultures. The choice of viruses to be detected by immunological assay should be determined with the laboratory according to the clinical setting. Some populations are at high risk of viral pneumonia, such as allogeneic BMT/PBSCT patients, and the panel of viruses to seek in these cases must include at least herpes simplex virus (HSV) and CMV, and adenovirus and respiratory viruses (influenza, parainfluenza virus, and respiratory syncytial virus (RSV)). However, in most patients who are less immunosuppressed, where the probability of the virus is low, given the cost of the procedure and the absence of effective treatment in most cases, the systematic use of a large panel of antiviral antibodies on first assessment is probably not justified, based on the data in the literature up to now. In the same way, periodic acid-Schiff (PAS) staining on BAL fluid is mandatory if there is a suspicion of alveolar proteinosis,⁴⁸ but its systematic use cannot be yet recommended in all hematological patients. A protected bacteriological sample should be considered with BAL—at least each time the patient has not been on broad-spectrum antibiotics and the clinical pattern is consistent with a bacterial pneumonia. This sample may be obtained either by protected specimen brush or by plugged telescoping catheter,⁴⁹ and processed by quantitative culture techniques. These samples should be considered positive if they show over 10^3 cfu/ml.

Empiric treatment should then be discussed, especially in the case of acute occurrence of pneumonia. In hematological patients, BAL will give the diagnosis in approximately two-thirds of patients.^{50,51} However, in one-third, the etiology of the pneumonia will not be revealed through BAL, because, despite identification of a pathogen, there is no diagnostic criterion clearly established in that case with that tool (e.g. *Candida* pneumonia), or because the cause or the responsible pathogen is difficult to reach (e.g. peripheral lesions), or because the alveolar lesions are non-specific.

In cases where bronchoscopy does not yield the diagnosis, other procedures may be considered, such as a second BAL, and/or a transbronchial biopsy (TBB), or transthoracic needle puncture under computed tomography (CT) scan in the case of peripheral dense lesions. The final decision between lung biopsy (through open or video-assisted thoracoscopy) or empiric treatment against the most likely organisms should be made between at least the hematologist and the lung specialist after consideration of the risk of the surgical procedure, the iatrogenic risk of each empiric treatment and the consequences, for the whole management of the patient, of not having a definite diagnosis for the pneumonia. Lung biopsy is more helpful in a prolonged clinical course, and in nodular or cavitory patterns, than in acute and/or non-nodular diseases, and also more helpful in hematological than in solid tumor patients.^{52,53}

Dermatological manifestations

Skin is both the first line of defense against the environment and also a warning system for the diagnosis of infectious complications in immunocompromised hosts, both through systemic and local development. We shall not discuss here the obvious importance of preserving its integrity and of keeping the skin as clean as possible to avoid colonization and infection by this route.

Numerous types of cutaneous infectious manifestations may be observed in hematological patients. They may occur from hematogenous diffusion or from local infection. They are sometimes the sole visible and accessible manifestation of the infectious process, and so have to be investigated carefully. Biopsies should be performed urgently and processed for both histological and microbiological examinations. The most frequent pathogens and their usual manifestations are listed in Table 47.3. However, not all of them are attributable to direct invasion of the skin by the pathogen, but may also be the consequence of immune or non-specific inflammatory reactions.

Central nervous system infections

Few data are available in the literature on the incidence of central nervous system (CNS) infections in hematological patients. It is likely that this incidence is lower than 3%.⁵⁴ However, though infrequent, the diagnosis of these cases is always quite difficult when the cerebrospinal fluid (CSF) examination is not immediately helpful or the CSF cannot be sampled because of a contraindication to lumbar puncture, and when CNS involvement is not associated with another more accessible focus.

In non-neutropenic patients, and especially in patients with cellular immune deficiencies such as lymphomas, the most frequent infections are due to *Listeria monocytogenes*, which causes meningitis or meningo-encephalitis, with or without cerebritis. Where this is a possibility, once the CSF has been

Table 47.3 Most frequent dermatological infectious manifestations observed in hematological patients

Pathogen	Main types of lesion
Bacteria	
• Streptococci, staphylococci	Erysipelas, rash, abscess, cellulitis
• Enterobacteria, <i>Pseudomonas</i>	Nodules, vesicles, ecthyma gangrenosum, cellulitis
• Strict anaerobes	Cellulitis, gangrene
• <i>Nocardia</i>	Abscess, cellulitis
• <i>Legionella</i>	Abscess, cellulitis, panniculitis
• Mycobacteria	Nodules, papules, abscess, panniculitis
Fungi	
• <i>Candida</i>	Macules, nodules, papules, cellulitis
• <i>Aspergillus</i> and mucorales	Abscess, cellulitis, macules, hemorrhagic nodules, pustules
Viruses	
• Herpesviruses	Vesicles, bullae, rash, papules, perineal ulcers
• Parvovirus B19, others	Rash, vesiculopustules
• Papillomavirus	Extensive warts, condylomata
Parasites	
• <i>Strongyloides stercoralis</i>	Papules
• Crusted (Norwegian) scabies	Crusted erythematous lesions

examined in the laboratory, empiric treatment with intravenous ampicillin (200 mg/kg/day), with or without an aminoglycoside, should be begun urgently. Patients with meningitis and who have been splenectomized or those with hypogammaglobulinemia should be considered at high risk of *S. pneumoniae*, *H. influenzae* and *N. meningitidis* infection. *Nocardia asteroides* may be responsible for brain abscess, but may also involve subcutaneous tissues, liver, and lungs.⁵⁴ Toxoplasmosis has been mainly reported in Hodgkin lymphoma and, more recently, after allogeneic BMT, where non-invasive procedures such as blood polymerase chain reaction (PCR) may be useful.^{55,56} The viruses that affect hematological patients, especially herpes viruses, may be responsible for meningitis or meningoencephalitis.

In neutropenic patients, fungi, especially *Aspergillus*, are the most frequent pathogens involved in neurological processes, and are usually—but not always—associated with pulmonary involvement, while *Candida* abscesses are more often associated with fungemia.⁵⁷ The incidence of neurological involvement during invasive candidiasis in hematological patients has been reported to be about 10%.⁵⁸ Bacteria causing meningitis during aplasia are usually those encountered in other kinds of infections in neutropenic patients, such as *E. coli*, *P. aeruginosa*, and streptococci. One should emphasize that in cases of meningitis occurring in profoundly neutropenic patients, the inflammatory reaction in the CSF is usually poor and the number of cells in the CSF may be very low or even normal.

The approach to a patient suspected of having CNS infection must be very cautious. Some of these CNS infections are easily identified by routine examination of CSF. Routine bedside ophthalmological examinations should be performed. They may be very useful in detecting signs of toxoplasmosis or *Candida* infections. However, these are uncommon, and it is very important to consider the likely causes according to the clinical presentation and the pattern of immune deficiency, and then to discuss with the laboratory what kind of additional techniques should be employed on an individual basis. For example, the diagnosis of cryptococcal meningitis should combine an Indian ink preparation and serological methods. CT scan and magnetic resonance imaging (MRI) can detect asymptomatic lesions, and these are especially helpful in making an etiological diagnosis by showing the localization and pattern and localizations of involvement. When the CSF is normal or non-contributory despite the use of specific procedures, and where there is no accessible focus due to the same pathogen, empiric treatment should be balanced with invasive procedures and, especially if lesions are visible on CT scan or MRI, with brain biopsy. The advantages and risks of the procedure should be weighed carefully. If the clinical status of the patient and the risk/benefit ratio of the procedure permit, everything should be done to optimize the processing of the samples in the pathology, microbiology, and mycology

laboratories according to a written protocol established prior to the procedure.

Diagnosis and treatment of fungal infections

Fungal infections have become the main infectious concern of hematologists in all populations of patients experiencing prolonged neutropenic phases. The incidence and mortality of fungal infections increase significantly over years, especially in stem cell transplant patients.^{59,60} The incidence of *Aspergillus* infection varies greatly according mainly to the underlying disease and the therapeutic approach to the disease, but is roughly estimated at around 4–8% by episode of aplasia in Europe in patients receiving induction or consolidation phases of chemotherapy, and at up to 20–25% in adult allogeneic stem cell transplant recipients from an unrelated donor.⁶⁰ It is the principle infectious cause of death following allogeneic stem cell transplantation. The lung is the main target organ. A non-specific pulmonary focus or thoracic pain usually reveal the disease. Due to the low diagnostic yield of fibroscopy for the early diagnosis of *Aspergillus*, new diagnostic tests have been developed. These include detection of *Aspergillus* galactomannan by an enzyme-linked immunosorbent assay (ELISA). Early results show good sensitivity during neutropenia and after stem cell transplantation, but the test has a false-positive rate of 10–15%.⁶¹ Nucleic acid detection is also currently being explored.^{62,63} However, due to the lack of standardization, and to discrepancies between antigenemia and PCR results,⁶⁴ there is currently no consensus on the use of these new tests in clinical practice, and, despite its limitations, galactomannan is currently the most reliable test in neutropenic patients for the early diagnosis of *Aspergillus* infections. A CT scan may also help in the early diagnosis of *Aspergillus*, and has been shown to improve the prognosis of the disease⁶⁵ in neutropenic patients, where a halo sign can be seen on lung CT scan at the very early phase of development of the disease. The addition of such approaches, and the development of additional, more sensitive, diagnostic tests should finally decrease the mortality of the disease. However, for now, the recommendation is to consider the possibility of *Aspergillus* infection in any patient at risk (i.e. those with neutropenia of more than 10 days duration, especially in cases of concomitant steroid therapy), and to give antifungals active against *Aspergillus* until the suspicion has been confirmed. In a large prospective trial of first-line treatment,⁶⁶ voriconazole has been shown to improve the survival at 12 weeks in patients with *Aspergillus* infection, compared with amphotericin B. There is no randomized study of voriconazole versus liposomal amphotericin B. However, the latter has shown similar efficacy to voriconazole in previous trials versus conventional amphotericin B, and is therefore another option for first-line treatment. Micafungin has been shown to be efficacious in salvage treatment of aspergillosis.⁶⁷ Prospective trials are running to study the effect of echinocandins in combination either with amphotericin B compounds or with azoles.

Candida infections have also been increasing in frequency, and are now more and more often due to non-*albicans Candida* spp.²³ A rare manifestation of *Candida* infection is hepatosplenic candidiasis, which is usually misdiagnosed during the neutropenic phase, and is mostly diagnosed after the patient has recovered a normal granulocyte count. The early signs are fever and an increase in phosphatases.

A major progress in clinical research in this field has come with the publication of a consensus text from the EORTC-IFICG and the MSG for definitions of invasive fungal infections in cancer patients.⁶⁸

Special considerations for allogeneic BMT/PBSCT recipients

Allogeneic BMT/PBSCT offers a unique model of gradual immune reconstitution, and illustrate perfectly the relationship between the type of immune deficiency and infection by specific pathogens. This is also a setting where the impact of therapy may erase the importance of the underlying disease. It is usual to assume that after allogeneic BMT/PBSCT, immunodepression is often so profound that the post-transplant infectious complications are roughly the same whatever the previous underlying disease.

The description of the three classical phases of immune reconstitution has been the subject of a large literature describing how the donor cells are able to proliferate, mature, and differentiate in the recipient until they are capable of attaining the full functions of immune cells.⁶⁹ However, it is known most patients with severe GVHD will never regain normal immune function. After allogeneic BMT/PBSCT, it is usually considered that the sequence of infections may be classified into three periods (Table 47.4).⁷⁰

1. The first is the conditioning period and the aplastic phase until neutrophil recovery from the donated marrow. This phase is characterized by neutropenia and thrombocytopenia, and the infectious complications of BMT/PBSCT patients are not very different at this time from those encountered in other profoundly neutropenic patients such as acute leukemia patients, except that the conditioning regimen (especially total body irradiation (TBI)) usually induces more

Table 47.4 Main pathogens responsible for infectious complications after allogeneic geno-identical bone marrow or peripheral blood stem cell transplantation

	First phase (from conditioning regimen to the end of the 1st month)	Second phase (2nd–4th month)	Third phase (5th month and after)
Bacteria	Gram-positive: • Oral streptococci • Coagulase-negative staphylococci Gram-negative enterobacteria	Nosocomial bacteria for patients staying in the unit because of graft-versus-host disease or rejection (<i>Pseudomonas aeruginosa</i> , enterococci, etc.)	<i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> Unusually: • <i>Nocardia</i> • Mycobacteria • <i>Legionella</i> • <i>Listeria monocytogenes</i>
Fungi	<i>Candida</i> spp. <i>Aspergillus</i> spp.	<i>Aspergillus</i> spp. <i>Pneumocystis carinii</i>	Fungi are observed only in severely immunosuppressed patients
Viruses	Herpes simplex virus 1 and 2 (HSV1 and HSV2)	Cytomegalovirus, human herpesvirus 6 (HHV6) Varicella zoster virus Epstein-Barr virus (EBV) Adenovirus	Varicella zoster virus (VZV) Adenovirus Respiratory viruses
Parasites		Toxoplasmosis	Toxoplasmosis

severe mucosal damage than chemotherapy given outside this setting. It has also been found that allogeneic BMT/PBSCT patients have a higher risk of aspergillosis than other hematological patients, even though it is also known that the aplastic phase of BMT/PBSCT is not the sole period at risk, since many cases have occurred during the second or third month of the graft when steroids are being administered.

- The second phase corresponds to the period from initial marrow engraftment to at least the third or fourth month, and is characterized by cell-mediated immune deficiency with decreased number and function of specific and non-specific cytotoxic cells. CMV infection, which is mainly due to reactivation, was the most disquieting problem in this setting until improved therapy and the routine practice of early diagnosis through PCR or antigenemia and of preemptive therapy, which finally decreased the mortality due to CMV disease. Other viral diseases, less frequent than CMV, have been described during this phase, especially those due to adenovirus and enteric and respiratory viruses. The occurrence and severity of GVHD is the main factor delaying immune recovery and favoring infections. Although most investigations have focused on lymphocytic reconstitution, it is known that these patients also have phagocytic deficiencies of both neutrophils and macrophages, responsible for defects in bactericidal and fungicidal activities that may sometimes last for more than a year.
- The third phase, beginning after the fourth month, is considered to be the late posttransplantation period. Here again, immune reconstitution is mainly influenced by the presence and severity of chronic GVHD. Most patients have immunoglobulin deficiency, particularly of IgG2, which is responsible for a decrease in the response to polysaccharide antigens. Mainly in this way, patients are threatened with encapsulated bacteria (e.g. *S. pneumoniae* and *H. influenzae*), which should be considered particularly in cases of pneumonia occurring after 3 months and should be treated urgently. In the absence of chronic GVHD, this deficiency will often be transient and will resolve over time. In other cases, it may persist indefinitely. However, even in these cases, active immunization may be beneficial, especially with conjugate vaccines.⁷¹

Although immune reconstitution after geno-identical allogeneic BMT/PBSCT is well known, it must be noted that each time a new approach in BMT/PBSCT is undertaken, new infectious complications can be observed. Mismatched transplants, for example, or phenotypically identical transplants, are followed by more severe and protracted immune deficiency, and the best prophylactic and therapeutic approaches to these patients for infection have not been yet determined, since the characterization of immune reconstitution in these patients is currently poorly understood.

Table 47.5 Main anti-infectious prophylactic measures for nosocomial infections that should be proposed in hematology departments

Pathogen	Main sources of acquisition	Prophylactic measure	Medical prophylaxis
Bacteria		Total protective environment (debated)	Gut decontamination (debated)
• <i>Pseudomonas</i> spp. • Gram-negative strains • <i>Salmonella</i> spp.	Food Staff	Regular quality control of food and beverages Education of patients and staff Isolation of colonized or infected patients Labeling of colonized or infected patients	
• <i>Staphylococcus aureus</i>	Nasal portage Staff-patient contact Cutaneous colonization	Isolation of patient if methicillin-resistant	Mupirocin for nasal portage (debated)
• Coagulase-negative staphylococci	Intravenous catheters	Handwashing Written procedures for care of central lines Periodic removal (every 2-3 days) of peripheral intravenous lines if possible	None demonstrated to be efficacious
Fungi			
• <i>Candida</i> spp.	Food Staff Central intravenous lines Plastic devices (urinary, etc.)	Food quality control Handwashing Written procedures for care of central lines Use urinary catheter only if essential, and manage according to written protocols	Antifungals (polyenes or azoles) through oral or systemic route
• <i>Aspergillus</i> spp.	Air Increased risk in construction	HEPA filters (laminar-airflow rooms, units at positive pressure) Staff education about air circulation Room cleaning	Debated or not demonstrated: • Local amphotericin B (sprays, aerosols) • Systemic antifungals active against <i>Aspergillus</i>
• <i>Pneumocystis carinii</i>	Reactivation? Interhuman transmission?	Isolation of patients infected (debated)	Trimethoprim-sulfamethoxazole Pentamidine isethionate aerosols
Viruses			
• Cytomegalovirus (CMV)	Reactivation +++ Blood transfusions containing leukocytes Marrow graft from a seropositive donor	Blood products from seronegative donors or leukocyte-depleted products Selection of a CMV-seronegative donor for BMT if possible	Established: preemptive therapy Antivirals active against CMV: value not established for systematic prophylaxis in BMT/PB SCT
• Varicella zoster virus (VZV)	Reactivation for zoster Reinfection from infected persons for varicella	Patient and staff education to avoid direct contacts with infected persons Isolation of infected patients in the hematology ward	Active immunization during complete remission for children with acute lymphoblastic leukemia Passive immunization by IVIG during the first 48 h after contact in patients at risk Acyclovir (not established as prophylaxis)
• Respiratory syncytial virus (RSV), adenovirus	Air Saliva	Isolation of patients infected Exclusion of infected staff members	Ribavirin (not established) IVIG (not established)
Parasite			
<i>Strongyloides stercoralis</i>	Reactivation	Isolation of infected patients	Thiabendazole or mebendazole

Prophylactic measures

The main reason for having an in-depth knowledge of the infectious complications of a hematological disease is to be able to employ an individually based prophylactic approach. Much has been achieved in the understanding of risk factors for infection and consequently in the protection of these patients from the most common infectious risks. Among the measures summarized in Table 47.5, some are simply obvious and logical proposals for the organization of care in hematology wards to decrease infections, and especially the nosocomial risk, while others have been shown to be effective in controlled trials.

Conclusions

Most treatments used in hematology are intensive and given in repeated cycles. Obviously, the morbidity and mortality due to infection in a given hematological disease are influenced by the therapy and its effect on the underlying disease, and also by the specific mechanisms of immune dysfunction induced and by the necessity for the use of foreign devices. Although the role of infection as a cause of death is difficult to assess in cases of refractory disease, it is more common to die from infection than from the disease. It is therefore mandatory that the hematologists who understand the malignancy also understand the specific infections, the need to follow a prophylactic approach, and the need to be aware of the urgency of treating certain infections.

Chromosomal abnormalities

Summary of specific translocations found in myeloid malignancies, and involved genes (Table 17.12)

Structural alterations in chromosomes in ALL (Table 31.2)

FAB classification

Cytological criteria for the diagnosis of AML: the FAB classification (Table 38.1)

Appendix I: Selected lineage-associated antigens in hematopoietic cells: CD nomenclature*

B cells			
Antigen	Distribution	Structure	Function and comments
CD5	Subset of mature B cells, mature ^l cells, thymocytes	67 kDa transmembrane protein	Unknown function in B cells, but CD5 ⁺ B cells (B-1) cells are implicated in autoimmune disease. Co-stimulates T-cells
CD9	Early B cells, activated B cells, activated T cells, platelets, eosinophils, basophils and endothelial cells	22–27 kDa tetraspan protein that can form complexes with CD63, CD81 and CD82	Platelet activation and aggregation; pre-B-cell adhesion; possible role in signaling mediated by interaction with GTP-binding proteins
CD10 (CALLA)	Widely expressed, including early T- and B-cell precursors, neutrophils, fibroblasts, and epithelial cells	100 kDa integral membrane protein	Zinc metalloprotease. May act to limit activity of fMLP and peptide hormones. Possible role in B-cell development
CD19	All B cells and B-cell precursors, FDC	95 kDa protein of Ig superfamily	Regulation of B-cell activation and proliferation, Part of signal transduction complex that includes CD81, CD21 and, Leu-13
CD20	All mature B cells, and pre-B cells, but not plasma cells	33–37 kDa tetraspan protein: overall structure similar to 'channel-forming' proteins	Can generate intracellular Ca ²⁺ signal. May be involved in regulation of B-cell activation and proliferation. Used in treatment of B-cell NHL
CD21 (CR2R)	Mature slg ⁺ B cells (lost on activation), FDC, subset of normal thymocytes	145 kDa transmembrane protein	Receptor for C3d and EBV. Involved in B-cell activation as part of signalling complex that includes CD19, CD81 and Leu-13. Binds CD23 and is implicated in regulation of IgE production

*Adapted from *Immunology Today*, Vol 18, *Immune Receptor Supplement*, 2nd edn (Ager A, Callard R, Ezine S, eds), 1997, with permission from Elsevier Science. The reader is referred to this publication for a more complete listing.

Antigen	Distribution	Structure	Function and comments
CD22	Surface expression on mature B cells, cytoplasmic expression in late pro- and early pre-B cells Lost prior to plasma cell stage	a form (130 kDa) has five extracellular Ig-like domains; β form (140 kDa) has seven Ig-like domains	Mediates adhesion to erythrocytes T cells, B cells, monocytes and neutrophils. Probably limits B-cell receptor signaling
CD23 (Fc ϵ RII)	Fc ϵ RIIa form expressed on mature B cells and monocytes, Fc ϵ RIIb on monocytes, IL-4-activated macrophages, eosinophils, platelets, DC and FDC	45 kDa type II membrane protein	Low-affinity IgE receptor with a role in IgE regulation. Binds CD21 and has role in B-cell activation, and may also prevent apoptosis of germinal-center B cells
CD24	Expressed throughout B-cell development. Decreased on activation and lost on plasma cells. Expressed on immature thymocytes and activated T cells. Also found on mature granulocytes and a variety of epithelial cells	35–70 kDa GPI-linked sialoglycoprotein	Crosslinking can induce a rise in intracellular Ca ²⁺ in mature B cells. May play a role in regulation of B-cell growth and antibody production, Co-stimulatory molecule for T-cell growth
CD25	See under T cells		
CD32	Fc γ RIIB form present on B cells, Fc γ RII A and C forms expressed on neutrophils; all forms are found on monocytes Fc γ RII proteins are also on Langerhans cells and some endothelial cells	40 kDa. The different isoforms are encoded by three closely related genes: A, B, and C	Low-affinity receptor for aggregated IgG. Mediates endocytosis, activation of secretion and cytotoxicity. Binding to Fc γ RII on B cells can deliver a negative signal
CD38	See under! cells		

Antigen	Distribution	Structure	Function and comments
CD40	Normal and neoplastic B cells, FDC, IDC, endothelial cells, thymic epithelium, macrophages, basal epithelia	48–50 kDa transmembrane protein of the TNF superfamily	Binds CD40L (CD154) on activated T cells. Key signal for B-cell activation, proliferation and differentiation, formation of germinal centres, isotype switching, rescue from apoptosis, and differentiation into memory or plasma cells
CD74	B cells, activated T cells, monocytes, activated endothelial and epithelial cells	33, 35, and 41 kDa isoforms	Intracellular sorting of MHC class II molecules, Associates with α and β chains of MHC class II
CDw75	Mature slg ⁺ B cells, small subset of blood T cells and erythrocytes	Carbohydrate NeuAc α 2,6 Gal β 1,4 GlcNac core epitope	Ligand for CD22, mediates B-B interactions
CD79 (a and P)	All B cells. Expressed early during B-cell ontogeny—probably before expression of cytoplasmic μ , and still present in cytoplasm of plasma cells	33 kDa (CD79 α) and 39 kDa (CD79 β) transmembrane proteins	CD79 forms non-covalent association with slg and is important for B-cell receptor signal transduction. CD79 may also mediate transport of IgM to cell surface
CD85	Mature circulating B cells, many B-cell malignancies, especially hairy-cell leukemias (HCL), monocytes	Unknown	Unknown. Has diagnostic value for HCL
CD95 (Fas, Apo-1)	See under T cells		
CD122 (IL-2R β , IL-15R β)	See under T cells		

Antigen	Distribution	Structure	Function and comments
CD124 (IL-4R, gp140)	Mature B and T cells, hematopoietic precursors, fibroblasts, epithelial and endothelial cells.	130–150 kDa transmembrane protein. Associates with 64 kDa γ_c (CD132) to form higher-affinity IL-4 receptor complex. Also associates with IL-13 R α to form the IL-13R complex	Activates B cells, causing increased expression of surface CD23 and IgM. Switch factor involved in IgE regulation. Stimulates proliferative activity in pre-activated B and T cells. Induces differentiation of Th2 cells and stimulates development of CTL
CDw125 (IL-5R α)	See under myeloid cells		
CD126 (IL-6R α)	Highly promiscuous. Activated B cells, plasma cells T cells, monocytes, epithelial cells, fibroblasts, hepatocytes, and neural cells	80 kDa transmembrane protein that associates with gp130 (CDw130) to form high-affinity IL-6R	Promotes growth of myelomas, B-cell hybridomas, activated and EBV-transformed B cells and T-cell lines. Synergistic factor for early hematopoietic progenitor cells, Mediates acute-phase response of hepatic cells
CD127 (IL-7 α)	Thymocytes, T-cell and B-cell progenitors, mature T cells, monocytes, some lymphoid and myeloid cell lines	68 kDa transmembrane protein that associates with 64 kDa γ_c (CD132) to form high-affinity IL-7R	Stimulates proliferation of pro- and pre-B cells, thymocytes and mature T cells, and induces monocyte activation
CD130 (gp130)	Widespread on hematopoietic cells and many other cell types	130–140 kDa type I membrane glycoprotein	Signaling chain for receptors for oncostatin M, IL-6, IL-11, LIF, CNTF and cardiotropin
CD132 (IL-2R γ , γ_c)	B cells, cells, NK cells, monocytes, macrophages, neutrophils	65–70 kDa. Subunit of IL-2R, IL-4R, IL-7R, IL-9R and IL-15R	Signaling component of receptors for IL-2R, IL-4R, IL-7R, IL-9R, IL-15R

T cells			
Antigen	Distribution	Structure	Function and comments
CD1	Cortical thymocytes	50–55 kDa heavy chain associated with a light chain of 12 kDa (β -m). Different isotypes exist: CD1a, b, c, d, and e	Peptide presentation (CD1d). Lipid presentation (CD1b). Interacts with CD4-CD8-T cells
CD2	Thymocytes, mature! cells, some NK cells	55–60 kDa transmembrane glycoprotein. Binds CD58. Physically associated with CD3 ϵ and ζ chains	Adhesion: CTL to target cells, T cells to endothelium, and monocytes and thymocytes to TEC. Signal transductions: T-cell activation. Interaction with tubulin and regulation of energy
CD3	All T cells	Three chains; γ (25–28 kDa), δ (21 kDa), ϵ (20 kDa) associated with ζ (16 kDa) and η (22 kDa) by disulfide bridges and with the T-cell receptor $\alpha\beta$ chains	T-cell activation and function
CD4	Thymocytes, Th cells, monocytes	60 kDa transmembrane protein of Ig superfamily. Interacts with p56 ^{lck}	Helper activity, co-receptor with the TCR and signalling in association with p56 ^{lck} ; adhesion (stabilizes TCR-MHC class II interaction)
CD5	See under B cells		
CD7	Fetal liver stem/progenitor cells, thymocytes, mature T cells	40 kDa transmembrane glycoprotein	Signal transduction
CD8	Thymocytes, CTL, IEL (CD8 $\alpha\alpha$), some DC	Disulfide-linked dimer $\alpha\beta$ or $\alpha\alpha$ of 34 kDa each. The short cytoplasmic tail interacts with p56 ^{lck} (a chain only)	Maturation and positive selection of MHC class I restricted CTL. Stabilizes TCR-MHC class I interaction
CD10	See under B cells		
CD24	See under B cells		

Antigen	Distribution	Structure	Function and comments
CD25 (IL-2R α)	Some thymocytes, and activated T cells, pre-B cells, NK cells and monocytes	55 kDa chain (low-affinity receptor). Binds IL-2 with low affinity. Associates with IL-2R β and γ chains to form the high-affinity receptor	Induces activation and proliferation of T cells, B cells, thymocytes, NK cells, and macrophages
CD28	T cells, plasma cells	44 kDa homodimeric glycoprotein	Co-stimulatory molecule initiating signal transduction; events distinct from those initiated by TCR
CD30	Activated T and B cells, Hodgkin's and Reed-Sternberg cells	105 kDa membrane-bound glycoprotein of the TNF superfamily	Transduction of a death signal. Useful in diagnosis of Hodgkin disease and anaplastic large-cell lymphoma (ALCL)
CD38	Early B cells and T cells, including thymocytes and pre-B cells. NK and DC precursors. Activated B and T cells, germinal-center B cells, plasma cells. Early but not most-primitive, myeloid stem cells	45 kDa transmembrane protein	Probably gives a proliferative signal to T and B cells, and is involved in adhesion. Extracellular domain has ADP ribosyl cyclase activity
CD43 (leukosialin)	T cells, induced on activated CD4 ⁺ T cells, pre-B cells	115 kDa sialylated mucin-like molecule	Role in T-cell proliferation, co-stimulation and adhesion, Role in HPC proliferation, apoptosis, and cell-cell interaction
CD44	B and T cells, monocytes, neutrophils, epithelial cells, glial cells, fibroblasts and myocytes. Variant isoforms expressed widely and differentially in human tissues	85 kDa hematopoietic form, CD44H lacks alternative exons. 110–250 kDa variant forms, vCD44, result from alternative splicing of 10 exons. V3 exon contains motifs for heparin and chondroitin sulfate addition	CD44H binds hyaluronic acid. Ligands for vCD44 unknown. Cell-cell and cell-ECM adhesion, T- and NK-cell activation, Can mediate lymphocyte rolling on endothelial cells, cell migration, and support of hematopoietic differentiation, Role for vCD44 in DC migration. Binding and presentation of chemokines and growth factors via proteoglycan forms

Antigen	Distribution	Structure	Function and comments
CD45 (leukocyte common antigen)	All hematopoietic cells except nucleated red cells—high levels on lymphocytes. CD45RO isoform expressed on naive T cells and CD45RA on memory T cells	Transmembrane glycoprotein of variable size (180–220 kDa). Different isoforms generated by alternative splicing	Protein tyrosine phosphatase. Role in thymocyte development, selection and TCR-mediated signal transduction. Can induce cell death under some circumstances
CD56 (NCAM)	T cells, NK cells	200–220 kDa glycoprotein of Ig superfamily	Induces killer activity and MHC non-restricted cytotoxicity
CD57 (HNK-1)	Mature T cells, and CD16 ⁺ NK cells	110 kDa glycoprotein.	Mediates MHC non-restricted cytotoxicity after activation. Has low NK-cell activity
CD90 (Thy-1)	T-cell lineage, hematopoietic stem cells, and some progenitor cells and pre-B cells	25–35 kDa membrane protein involved in transmembrane signaling via CD45 and p56 ^{lck}	Role in lymphocyte recirculation, adherence, T-cell activation, cellular recognition
CD95 (Fas, Apo-1)	Thymocytes, mature T cells, activated lymphocytes	36–45 kDa transmembrane protein of TNFR superfamily	Induces apoptosis signal when triggered by FasL or anti-Fas Ab. Role in clonal deletion of peripheral T cells and activation-induced cell death of mature cells.
CD122 (IL-2R β , IL-15R β)	B cells, cells, NK cells, monocytes, macrophages	70–75 kDa transmembrane glycoprotein	Signaling subunit of IL-2R and IL-15R. Associates with CD25 and CD132 (γ_c) to form high-affinity IL-2R, and with IL-15R α and CD132 to form high-affinity IL-15R
CD124	See under B cells		
CD127	See under B cells		

Myeloid/monocyte			
Antigen	Distribution	Structure	Function and comments
CD10	See under B cells		
CD11a	Widespread on hematopoietic cells, lymphocytes, monocytes, macrophages, neutrophils, and eosinophils	180 kDa α subunit (CD11 a; α_L), which non-covalently associates with 95 kDa (CD18; β_2) subunit to form LFA-1	Mediates leukocyte adhesion to endothelium via ICAM-1 and ICAM-2 during migration and inflammation; homotypic and heterotypic adhesion between T cells, B cells and monocytes; neutrophil homotypic aggregation via ICAM-3
CD11b	Monocytes, macrophages, NK cells, neutrophils	170 kDa α subunit (CD11 b; α_M), which associates with the β_2 subunit to form MAC-1/CR3	Mediates adhesion of monocytes and neutrophils to vascular endothelium via ICAM-1, fibrinogen and subsequent extravasation via ICAM-1. Opsonization of complement-coated particles by macrophages via iC3b
CD11c	Monocytes, macrophages, NK cells, neutrophils, activated lymphocytes	150 kDa α subunit (CD11 b; α_X), which non-covalently associates with the β_2 subunit to form CR4	Binds fibrinogen and iC3b. Mediates adhesion of monocytes and granulocytes to inflamed endothelium. Phagocytic receptor. Involved in T-cell aggregation
CD13	Granulocytes, monocytes and their precursors; endothelial cells, renal epithelial cells, bone marrow stromal cells, osteoclasts, subset of large granular lymphocytes	150 kDa integral membrane protein expressed on the cell surface as a homodimer	Aminopeptidase N. Receptor for coronavirus and involved in interaction with cytomegalovirus
CD14	Monocytes and granulocytes	55 kDa <i>N</i> -glycosylated CPI-anchored glycoprotein; 48 kDa soluble form	Membrane-bound form is a high-affinity receptor for LPS-LBP complexes on granulocytes, monocytes and macrophages. Soluble form also binds IPS, and is required for LPS-induced activation of endothelial cells

Antigen	Distribution	Structure	Function and comments
CD15 (Lewis X)	Monocytes, granulocytes and their precursors; Langerhans cells. Many cancer cells	Carbohydrate antigen with a terminal structure of Gal β 1,4 (Fuc α 1,3) GlcNAc β 1,3 Gal β 1,R	Possible ligand for selectins
CD16 (Fc γ RIII)	NK cells, granulocytes, macrophages, subset of T cells	50–65 kDa glycoprotein of the Ig superfamily	Low-affinity IgG receptor, main receptor for ADCC; activation of cytotoxicity, cytokine production, and receptor expression
CD18	Lymphocytes, monocytes, neutrophils, and eosinophils	95 kDa β 2 subunit non-covalently associated with an α subunit (e.g. CD11a)	See under CD11a, CD11b and CD11c
CD23	See under B cells		
CD31 (PECAM-1)	Monocytes, platelets, neutrophils, naive T cells, NK cells, endothelial cells (lateral surfaces)	130 kDa integral membrane glycoprotein of the Ig superfamily. Multiple isoforms produced by alternative splicing	Homophilic (CD31-CD31) and heterophilic (CD31- α v β 3 integrin) adhesion. Implicated in transendothelial migration of monocytes, neutrophils, NK cells and activated T cells
CD32	See under B cells		
CD33	Monocytes, macrophages granulocytes, myeloid progenitor cells	67 kDa glycoprotein expressed as a homodimer	Not known
CD34	Hematopoietic stem/ progenitor cells. Widespread distribution on vascular endothelium	90 kDa glycosylated protein; nature of glycosylation depends on the site of expression.	Mediates L-selectin-independent binding of leukocytes to high endothelial venules and L-selectin-independent binding of hematopoietic stem cells to stromal elements of bone marrow

Antigen	Distribution	Structure	Function and comments
CD35 (CR1)	Neutrophils, monocytes, eosinophils, B cells, subset of T cells, erythrocytes, FDC, glomerular podocytes and some astrocytes	Single-chain glycoprotein of variable length depending on allotype: 190 kDa (A), 220 kDa (B), 160 kDa (C), 250 kDa (D)	Receptor for C3b or C4b. Mediates adherence of C4b/C3b-coated particles prior to phagocytosis. Major role in removing and processing immune complexes of facilitating their localization to lymphoid follicles
CD36	Monocytes, macrophages, platelets, microvascular endothelial cells, DC, mammary endothelial cells	88 kDa single-chain glycoprotein	Receptor for thrombospondin; scavenger receptor for oxidized LDL; recognition and phagocytosis of apoptotic cells; cell adhesion molecule in platelet adhesion and aggregation, platelet-monocyte and platelet-tumor cell interactions
CD64 (Fc γ R1)	Monocytes, macrophages, blood DC, activated neutrophils, early myeloid-lineage cells	72 kDa transmembrane glycoprotein encoded by three related genes	High-affinity receptor for monomeric IgG promoting phagocytosis, ADCC, superoxide and cytokine release in macrophage activation
CD66a	Granulocytes and epithelial cells	140–180 kDa transmembrane heavily <i>N</i> -glycosylated glycoprotein	Capable of homophilic and heterophilic adhesion, E-selectin binding. Role in signaling and regulates adhesion activity of β 2 integrins in neutrophils
CD66b	Granulocytes	95–100 kDa GPI-anchored glycoprotein	Uncertain, but capable of heterophilic adhesion and transmembrane signaling; capable of activating neutrophils
CD66c	Granulocytes and epithelial cells	90 kDa GPI-anchored glycoprotein, heavily <i>N</i> -glycosylated	Unclear, but capable of homophilic and heterophilic adhesion, E-selectin binding, galectin binding; capable of activating neutrophils
CD66d	Granulocytes	35 kDa heavily <i>N</i> -glycosylated transmembrane glycoprotein	Unclear, but capable of activating neutrophils
CD71 (transferrin receptor)	Macrophages and proliferating cells, including hematopoietic progenitor cells—high levels on erythroid progenitors	95 kDa disulfide-linked homodimeric transmembrane molecule	Receptor for transferrin; important in iron metabolism and cell growth

Antigen	Distribution	Structure	Function and comments
CD87 (uPAR)	Activated monocytes, neutrophils, activated T cells, NK cells, vascular endothelial cells, fibroblasts, smooth muscle cells, keratinocytes, placental trophoblasts, hepatocytes. Wide variety of tumor cells	35–59 kDa heavily glycosylated GPI-anchored glycoprotein	Cellular receptor for pro-uPA and uPA; implicated in the process of inflammatory cell invasion and tumor cell metastasis; binds to vitronectin; may contribute to integrin-dependent adherence and chemotaxis
CD114 (G-CSFR)	Granulocytes, monocytes granulocyte precursors, trophoblast cells	130 kDa single-chain transmembrane glycoprotein	Receptor for G-CSF
CD115 (M-CSFR, c-Fms)	Monocytes, macrophages, and their progenitors. Osteoclasts, trophoblasts, and certain carcinomas	150 kDa transmembrane glycoprotein	Receptor for M-CSF
CD116 (CMCSFR α)	Myeloid progenitors and precursors. Macrophages, neutrophils, eosinophils, DC	80 kDa type I transmembrane glycoprotein; associated with CDw131	Binds GM-CSF with low affinity when expressed alone. Binds GM-CSF with high affinity when co-expressed with β_c (CDw131)
CD117 (SCFR, c-Kit)	Hematopoietic stem and progenitor cells, tissue mast cells, early thymocytes	145–150 kDa transmembrane glycoprotein	Growth factor receptor that binds SCF (c-Kit ligand)
CDw119 (IFN- γ R α)	Macrophages and most leukocytes	95 kDa transmembrane glycoprotein which associates with the IFN- γ RII(β chain)	IFN- γ receptor α chain, which transduces IFN- γ -dependent signals

Antigen	Distribution	Structure	Function and comments
CD120a (TNFR1)	Some granulocytes, FDC and endothelial cells; soluble type I (30 kDa form) released from activated granulocytes and monocytes	55 kDa transmembrane molecule	Receptor for TNF; mediates antitumor effects; induces and primes inflammatory response; upregulates leukocyte adhesion molecules and MHC class I
CD120b (TNFR2)	Monocytes and macrophages; soluble form released from activated granulocytes and monocytes	75 kDa transmembrane molecule	Receptor for TNF; functions similarly to TNFR type I (CD120a)
CD121a (IL-1 R)	Macrophages and virtually all leukocytes	75–85 kDa single-chain transmembrane molecule	Binds biologically active IL-1 α and β , and the biologically inactive IL-1ra
CDw123 (IL-3R α)	Most myeloid cells and their progenitors, lymphocytes, neutrophils, eosinophils	70 kDa transmembrane protein	Binds IL-3 with low affinity when expressed alone. Binds IL-3 with high affinity when co-expressed with β_c (CDw131)
CDw125 (IL-5R α)	Eosinophils and B cells	60 kDa transmembrane protein with homology to a chains of IL-3R and GM-CSFR	Binds IL-5 with low affinity when expressed alone. Binds IL-5 with high affinity when co-expressed with β_c (CDw131). Stimulates growth and differentiation of eosinophils B cells (mouse)
CD126 (IL-6R α)	See under B cells		

Antigen	Distribution	Structure	Function and comments
CDw128 (IL-8R)	Neutrophils, monocytes, subset of NK cells, astrocytes, microglia CD8+ T cells	Two variants: IL-8RA, 44–59 kDa glycoprotein; IL-8RB, 67–70 kDa glycoprotein. Both contain seven transmembrane domains	IL-8RA binds IL-8; IL-8RB binds IL-8, gro, NAP-2 and ENA78. Critical regulators of IL-8-mediated neutrophil chemotaxis and activation
CD130 (gp130)	See under B cells		
CDw131 (β_c)	Most myeloid cells, including early progenitors, early B cells	120–140 kDa transmembrane protein	Functions as a β subunit that associates with the α subunits of IL-3R (CDw123), IL-5R (CDw125) and GM-CSFR (CD116)
CD135 (Flt-3)	Multipotential myelomonocytic and primitive B-cell progenitors	130 kDa receptor of the tyrosine kinase family	Growth factor receptor for early hematopoietic progenitors
CD141 (thrombomodulin)	Monocytes, neutrophils, endothelial cells, platelets, megakaryocytes, keratinocytes, smooth muscle cells, synovial lining cells	75 kDa single-chain membrane glycoprotein	Cofactor for thrombin-mediated activation of protein C
CD142 (tissue factor, thromboplastin)	Activated monocytes, vascular endothelial cells and fibroblasts; epidermal keratinocytes, glomerular epithelial cells and stromal cells	45–47 kDa single-chain transmembrane glycoprotein	Procoagulant molecule that binds factor VIIa and zymogen factor VII. It is the major initiator of clotting in normal haemostasis
CD153	Activated macrophages, neutrophils, activated T cells and B cells	75 kDa transmembrane glycoprotein of the TNF superfamily	CD30 ligand. Physiological role unclear

Antigen	Distribution	Structure	Function and comments
CD156 (ADAM 8)	Neutrophils and monocytes	69 kDa transmembrane protein	Disintegrin and metalloproteinase. May be involved in leukocyte extravasation
CD164	Monocytes, bone marrow stromal cells. Normal and neoplastic epithelial cells	80 kDa integral membrane glycoprotein expressed as a homodimer	Possibly mediates adhesion between bone marrow stromal cells and hematopoietic progenitor cells
<p><i>Acronyms:</i> ADCC, antibody-dependent cellular cytotoxicity; CKR-SF, cytokine receptor superfamily; CNTF, ciliary neurotrophic factor; CTL, cytotoxic T lymphocyte; DC, dendritic cell; EBV, Epstein-Barr virus; ECM, extracellular matrix; FDC, follicular dendritic cell; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; GPI, glycosyl-phosphatidylinositol; HPC, hematopoietic precursor cell; ICAM, intercellular adhesion molecule; IDC, interdigitating dendritic cell; IEL, intraepithelial lymphocyte; IFN, interferon; IL, interleukin; LBP, lipopolysaccharide-binding protein; LDL, low-density lipoprotein; LIF, leukemia inhibitory factor; IPS, lipopolysaccharide; M-CSF, macrophage colony-stimulating factor; NK, natural killer; SCF, stem cell factor; TCR, T-cell receptor; TEC, thymic epithelial cell; Th, T helper; TNF, tumor necrosis factor.</p>			

Appendix II: Concise summary of the cytokines involved in human hematopoiesis

Cytokine*	Cellular source in hematopoietic tissues†	Main target cells‡, §	Chromosomal location
IL-1	End, F, T, B, NK, Mo, Mf	SC ⁺ , PC ⁺ , B ⁺ , T ⁺ , Mo ⁺	2q12–21
IL-2	T	T ⁺ , B ⁺ , NK ⁺ , Mo, Mf	4q26–27
IL-3	T, Ma, Eo	SC ⁺ , PC ⁺ , E ⁺ , G ⁺ , Meg ⁺ , PL ⁺	5q23–31
IL-4	T, Ma, PC, F, G		5q31
IL-5	Ma, T, Eo, PC	Eo ⁺	5q23–31
IL-6	End, F, T, B, Mo, Mf, PC	SC ⁺ , PC ⁺	7p21–14
IL-7	F	B ⁺ , T ⁺	8q12–13
IL-8	End, F, T, B, Mo, G	Ne ⁺ , Ba ⁺ , T ⁺	4q 12–21
IL-9	T	T ⁺ , Ma ⁺ , E ⁺	5q31.1
IL-10	T	T ^{+/–} , Mo [–] , NK [–] , B ⁺ , Ma ⁺	1q31–q32
IL-11	End, F	SC ⁺ , PC ⁺ , Meg, Mf	19q13.3–1 3.4
IL-12	B, Mo, Mf	SC ⁺ , PC ⁺ , T ⁺ , NK ⁺	19p13.1 and 1p31.2
IL-13	T	Mo [–] , B ⁺	5q31
IL-14	T	B ^{–/+}	–
IL-15	Mo, G, T, B	T ⁺	4q25–35
IL-16	Ma	T ⁺	–
M-CSF	End, F, T, Mo	Mo ⁺ , Mf ⁺	5q33.1
G-CSF	End, F, Mo, Mf	SC ⁺ , PC ⁺ , G ⁺	17q21–22
GM-CSF	F, End, T, Mf, G	G ⁺ , Mo ⁺ , Mf ⁺	5q21–32
Flt-3L	F	SC ⁺ , PC ⁺ , Mo ⁺	–
EPO	Mf	E ⁺ , Meg ⁺	7pter–q22
TPO	F	SC ⁺ , PC ⁺ , Meg ⁺ , E ⁺	3q26–27
bFGF	End, Mo	Mf ⁺ , End+ SC ⁺ , PC ⁺	4q25–q27
IFN-γ	T, NK	T ⁺ , B ⁺ , Mf ⁺ , NK ⁺ , End ⁺ , F ⁺ , SC ⁺ , PC	12q24.1
LIF	F, T, Mo, G	SC ⁺ , Mf ⁺ , Pl ⁺	22q14

Cytokine*	Cellular source in hematopoietic tissues†	Main target cells‡, §	Chromosomal location
MIP-1 α	T, B, Ne, Mf	Mf ⁺ , PC ⁻ , B ⁺ , Eo ⁺	17q11–21
OSM	T, Mo	SC	22q12
SCF	F	SC ⁺ , PC ⁺ , E ⁺ , G ⁺ , Pl ⁺	12q22–24
TNF- α	F, B, T, Mo, Mf	M ⁻ , PC	6p21.3
TGF- β 1	End, F, Lymf, Mo, G, PC, Mf, Pl	SC ⁻ , PC ⁻ , Mc ⁺	19q13
<p>* <i>Cytokine acronyms:</i> IL, interleukin; CSF, colony-stimulating factor; Flt-3L, ligand for stem cell tyrosine kinase 1 (STK-1, gene symbol <i>Flt-3</i>); EPO, erythropoietin; TPO, thrombopoietin; bFGF, basic fibroblast growth factor; IFN, interferon; LIF, leukemia inhibitory factor; MIP, macrophage inflammatory protein; OSM, oncostatin M; SCF, stem cell factor (c-Kit ligand, Steel factor); TNF, tumor necrosis factor; TGF, transforming growth factor.</p> <p>† <i>Cellular sources and activities:</i> B, B lymphocyte; Ba, basophil; E, erythrocytic; End, endothelium; Eo, eosinophil; F, stromal fibroblastic cells; G, granulocytic; Lymf, lymphoid; Ma, mast cells; Meg, megakaryocytic; Mf, macrophage; Mo, monocytic; Ne, neutrophil; NK, natural killer cells; PC, progenitor cells; Pl, platelet; SC, stem cells; T, T lymphocyte.</p> <p>‡ Activities on target cells represent a diversity of effects, including stimulation or inhibition of survival, proliferation, differentiation, cycle induction, activation, maturation, cytokine production or elaboration, chemotaxis, and antitumor effects.</p>

 cystathionine beta-synthase (CBS), Down syndrome 623
 cytarabine
 +cyclophosphamide, induction therapy in ALL 507
 +daunorubicin+etoposide, CALGB trial 332
 bone marrow transplantation 427
 chronic myeloid leukemia 708, 710
 cytotoxicity 648
 drug resistance 330, 332
 high dose cytarabine (HDAC) 507, 508
 metabolism 648
 cytarabine ocfosfate (YNK01) 710
 cytogenetics
 detection of MRD, sensitivity 268
 lymphoid malignancies 234–42
 recurrent mutations 240
 cytokine inducible substrate (CIS) family 26
 cytokine-mediated signal transduction 23–32
 cytokine receptor mutations, involvement in
 hematological disease 26
 flt3 mutations in human AML 29
 Jak-Stat pathway 24
 Kit mutations in AML and mastocytosis 27–9
 activating mutations 28–9
 PI3K 25
 PKB 25
 Ras signaling pathway 25
 switching off receptor activation 25–7
 benign erythrocytosis 27
 CIS/SOCS/JAB/SSI proteins 26
 congenital amegakaryocytic thrombocytopenia (CAMT) 27, 145
 internalization and degradation of receptor complexes 26
 phosphatases and GAPs 25–6
 receptor mutations in hematological disease 26
 severe combined immunodeficiency (SCID) 26–7
 severe congenital neutropenia (SCN) 27
 cytokines
 expanding dendritic cell numbers 106
 immunotherapy of cancer 379–80
 inhibiting dendritic cell differentiation 106–7
 signaling cascades, multiple myeloma 547–8
 sources, targets and locations 842–3
 T-cell mediated immunotherapy of cancer 379–80
 cytomegalovirus, post BMT 432–3
 cytopenias
 refractory anemias 679
 unexplained, diagnosis of leukemia/lymphoma 287
 cytoreduction regimens
 alkylating agents 435
 polycythemia vera 739–40
 pre-BMT 425
 cytosine arabinoside *see* cytarabine
 cytotoxic drugs, gene transfer 413–14
 cytotoxic T-cells (CTLs) 92–3, 411
 DNR-transduced 413
 vs NK cells 93
 targeting to tumor cells 364–7
 D-trisomy, leukemia risk 474
 DAB(389)IL2 354, 370
 daclizumab (anti-TAC), GVHD 369, 370
 danazol, in MDS 686
 darbepoietin-alpha 685, 797

data mining
 microarrays 254–6
 principal component analysis (PCA) 255, 258

daunombicin
 +cytarabine, AML 620–1
 +doxorubicin, ALL 507
 DaunoXome cardiac effects 771
 liposomal 627

DCTER regimen 620–1
 induction chemotherapy 437

DEC205 105

decitabine 672, 685

dedifferentiation and redifferentiation, stem cells 19

DEK/CAN 72, 221, 223, 318–19

deletions 240
 9q, CML 260
 11q23
 AML 618
 CLL, FISH 260
 del(7)–7, MDS 229, 319
 in MDS 670
 TAL1 282–3

dendritic cells (DC) 103–24
 clinical perspectives 109–10
 development from hematopoietic precursors 103–7
 cytokines expanding DC numbers *in vivo* 106
 cytokines inhibiting DC differentiation 106–7
 DC derived from CD34⁺ hematopoietic progenitors 104
 DC differentiation from multipotential thymic precursors 106
 DC origins and differentiation pathways 103–4
 expression of surface molecules 105
 human DC populations 104
 Langerhans cells and dermal DC 105–6
 monocyte-derived DC 104
 peripheral blood DC 105

maturation and functional development 107–9
 antigen uptake regulation, processing and presentation 108
 induction of tolerance 109
 migratory function regulation 108
 signals inducing maturation 107–8
 T cell activation 108

optimal antigen presentation 381–2
 protein pulsed 382–4
 vaccination 363–4
 vaccine 109

 depletion for BMT 429–30
 GVHD 369–70, 429–30
 myeloablation regimens 425
 non-identical related and HLA-compatible unrelated grafts 447–9
 T cells transduced with *HSV-tk* 413
 development 93–8
 schema 94
 in thymus 96
 differentiation into effector T cells 98
 donor infusions 430–1
 expansion, transduction by chimeric receptor 412
 gene marking, gene transfer 415–16
 gene transfer
 modification to improve survival 412–13
 tumor evasion mechanisms 412–13
 immune response, suppression by Abs 369–71
 immunomagnetic adsorption 361–2, 430
 leukemia-reactive 432
 mature 98–101
 targeting to tumor cells, bifunctional antibodies 364–7
 transduced with *HSV-tk*, post T-cell depletion 413
 transfer of *in vitro* expanded tumor-reactive T cells 384–5
 tumor-specific responses 364–6
see also NK cells

T-cell activation-associated antigen (TAC), CD25 (IL-2R) 346, 369, 370
 T-cell acute lymphoblastic leukemia (T-ALL) 269–71
 classification 501
 expression of TdT 269
 Ig/TCR rearrangements 278–9
 junctional regions, rearranged Ig/TCR genes, PCR analyses 278–9
 MLL-ENL fusion 489
 MRD detection 277
 treatment, results 512–13

T-cell chronic leukemias
 MRD detection 272–3
see also T-cell prolymphocytic leukemia (T-cell PL)

T-cell immunity 378
 dendritic cell vaccine 109

T-cell lymphoblastic lymphomas (T-LBL) 269–71, 287, 590–1
 TdT expression 271

T-cell lymphomas 590–4
 anaplastic large cell lymphoma (ALCL) 486, 494, 591–2
 angio-immunoblastic lymphoma (AIL) 591
 cutaneous T-cell lymphomas 593
 intestinal T-cell lymphoma 592–3
 lymphoblastic lymphomas (T-LBL) 269–71, 287, 590–1
 lymphomatoid papulosis (LP) 593–4
 mycosis fungoides (MF) 593
 nasal-type T/NK-cell lymphoma 592
 peripheral T-cell lymphomas not otherwise specified 593
 Sezary syndrome 593
 T-lymphoblastic lymphoma/T-ALL 590–1

T-cell malignancies
 MRD detection 281
 translocations 234

T-cell mediated immunotherapy 378–89
 cytokines 379–80
 dendritic cells, optimal antigen presentation 381–2
 genetically engineered molecularly defined vaccines 382–5
 peptide-based vaccines for induction of antitumor T-cell immunity 380–1
 transfer of *in vitro* expanded tumor-reactive T cells 384–5

T-cell prolymphocytic leukemia (T-cell PL) 534–5
 diagnosis/treatment 535
 immunology, cytogenetics and molecular features 523

T-cell receptors 94–101
 artificial, gene transfer 412
 chimeric 412
 gene rearrangements 97, 158
 immunoreceptor tyrosine-based activation motif (ITAM) 412
 mature T cell malignancies, PCR analyses 281
 PCR analyses in minimal residual disease detection 273–81
 pre-TCR/CD3 complex 95
 rearrangements, in lymphoid malignancies 266, 273–81
 TCRbetaV families 272–3

TAC *see* T-cell activation-associated antigen tacrolimus, GVHD 429, 434

TAL-1, deletions 282–3

TAL-2 72

TaqMan, real-time quantitative PCR 284–6

TAR syndrome 146

Tax, in leukemogenesis 189–91, 198

Tax oncoprotein 397

Tax responsive elements (TREs) 189

TCR *see* T-cell receptor genes;
 T-cell receptors

TCRalpha, *TCRgamma*
 estimation of potential primary repertoire 274
 PCR analysis 281

TCRbeta V families 272–3

TEL 72, 75–6

TEL-AML1
 APL 241
 precursor B-cell ALL 282
 prognosis in infant ALL 289

TEL-JAK2 394

TEL-PDGFR, CMM1 390, 393–4

TEL-RUNX1 221–3, 259

telomeres 165–71
 checkpoint 167
 length analysis, flow FISH 169
 maintenance pathways 166–7
 and replicative senescence 167–9
 structure and function 165–6

teniposide (VM26) 669

terminal deoxynucleotidyl transferase (TdT)
 B-cell precursor marker 269–70
 coexpression with CD 13/CD3 3 314
 CSF samples, prognosis of CNS leukemia 287
 T-ALL 269
 T-LBL 271

testicular failure/relapse, acute lymphoblastic leukemia in children 494, 773

thalidomide
 anti-angiogenesis 178
 GVHD 429
 MDS 686
 mechanism of action 557
 multiple myeloma 556–8

thalidomide analogs (ImiDs) 178

thioguanine, AML 620, 638

thrombocytopenia, essential (ET) 145

thrombocytopenia
 congenital amegakaryocytic (CAMT) 27, 145
¹¹¹In-platelets 677
 Paris-Trousseau 145
 X-linked 145

thrombopoietin (TPO) 141–2, 396, 801–2
 in essential thrombocythemia 741
 megakaryocytopoiesis 145
 recombinant, clinical potential 146–7
 regulation of myelopoiesis 117
 rTPO 802
 sources, targets and locations 842
 stimulation, and impaired tyrosine phosphorylation 735

Thy-1 834

thymic T-cell ALL, classification 501

thymidine kinase (TK), E2F transcription factor family 46

thymus activation-regulated chemokine (TARC) 195

thymus-derived malignancies, TdT-associated 281

thyroid effects
 BMT 789
 radiotherapy 772

TIF2 221

tissue typing, PCR 424

TLR 105

TLS 72

TNF-related apoptosis inducing ligand (TRAIL) 675

tolerance to ‘self’
 dendritic cells 109
 peripheral tolerance 109

topoisomerase inhibitors, translocations 318

tositumomab, radiolabeled 348, 358

total body irradiation (TBI)
 pre-BMT 425, 434–5
 MM 556

TP53 mutations 240, 634, 643

TRAIL (TNF-related apoptosis inducing ligand) 675

trans-acting factors
 erythroid-specific genes 130–2
 for erythropoiesis 129–30
 and growth factors 132
 list 131

transcription factors 64–82
 differentiation of B cells 84

transcription factors, in leukemia 70–7
 C/EBPalpha disruption 75
 fusion protein generation 73
 genes influencing chromatin structure 76–7
 genetic changes 70
 leukemogenic alterations targeting steps in signaling pathways 73
 leukemogenic rearrangements 76–7
 normal protein, dysregulated expression 73
 target cells for transformation 70–1

target genes
 activation 71–2
 list 72
 therapeutic significance 77
 translocations involving 21q22 and inversion (16) 73–5
 tyrosine kinase and RAS signaling pathways 75–6

transcription factors, normal hematopoiesis 64–70, 65–7
 chromatin structure 68
 homologous recombination studies 65–8
 knockout studies 65
 lineage-specific gene expression 64–5
 motifs 65
 specific lineages 67–8
 stem cells, lineage commitment and plasticity 68–70

transcriptional activational domain (TAD) 234

transferrin receptor 837

transforming growth factor-beta 144, 414
 sources, targets and locations 843
 tumor secretion 413
 type II receptor, dominant-negative (DNR) 414

transient myeloproliferative disorder (TMD) 618

translocation examples 234–5, 238–40
 breakpoints 281–2
 lymphoid malignancies 238–40
 myelodysplastic syndrome 670
 myeloid malignancies 218–19
 myeloma cells 545–6
 PCR targets for MDR detection 282
 RT-PCR 316
 t(1; 19) (q23; p13): *E2A-PBX1* 238, 239
 t(1; 22) (p13; q13) 224
 t(2; 3) (p23; q26) 226
