Preface

xv

PART ONE: NORMAL HEMATOPOIESES

1. The stem cell	1
Rob E Ploemacher, Elaine A Dzierzak	
2. Stem cell plasticity	13
Balkrishna N Jahagirdar, Catherine MVerfaillie	
3. Cytokine receptors and signal transduction	23
Ivo PTouw, Thamar B van Dijk	
4. Cell cycle regulation	33
N Shaun B Thomas	
5. Transcription factors in hematopoietic differentiation and leukemia	64
Michael A Chapman, Anthony R Green	
6. Cellular aspects of lymphoid differentiation: B cells	83
Claudine Schiff, Michael Fougereau	
7. Cellular aspects of lymphoid differentiation: T and TK cells	92
Anne Cambiaggi, Sophie Ugolini, Eric Vivier	
8. Dendritic cell development	103
Max Schnurr, Eugene Maraskovsky, Jonathan Cebon	
9. Granulomonopoiesis	113
Willem E Fibbe, Rob E Ploemacher	
10. Erythropoiesis	125
Paul-Henri Roméo	
11. Megakaryocyte differentiation and regulation	136
William Vainchenker, Najet Debili, Françoise Wendling	

PART TWO: MECHANISMS OF TRANSFORMATION

12. DNA repair and malignant hematopoiesis	155
Leineke R van Veelan, Roland Kanaar, DC van Gent	
13. Senescence and telomeres	165
Peter M Lansdorp	

14. Angiogenesis and tumor development	172
William T Bellamy	
15. Lymphoproliferations associated with human T-cells leukemia/lymphoma virus type I and type II infection	187
Antoine Gessain, Renaud Mahieux	
16. Immunosuppression: Epstein-Barr virus and other herpesviruses in hematological malignancies	207
Martine Raphaël, Fanny Baran-Marszak, H��l��ne A Poirel	

PART THREE: DEVELOPMENTS IN DIAGNOSIS

17. Acquired genetic changes in myeloid malignancies	218
Cristina Mecucci, Anne Hagemeijer	
18. Cytogenetic and molecular abnormalities in lymphoid malignancies	234
William B Slaytor, Stephen P Hunger	
19. Analysis of clonality using X-chromosome inactivation patterns	243
Rosemary E Gale	
20. Microarray analysis and expression profiling	253
Torsten Haferlach, Wolfgang Kern, Alexander Kohlmann, Susanne Schnittger, Claudia Schoch	
21. Detection of minimal residual disease in lymphoid malignancies	266
Jacques JM van Dongen, Tomasz Szczepanski, VHJ van der Velden, Anton W Langerak	
22. Detection of minimal residual disease in myeloid malignancies	308
Jes��s Fernando San Miguel, Marcos Gonz��lez, Alberto Orfao	

PART FOUR: DEVELOPMENTS IN TREATMENT

23. Drug resistance and its modification in hematological malignancies	326
Jean-Pierre Marie	
24. The theoretical basis of chemotherapy for hematological malignancy	336
Andrew K McMillan, David C Linch	
25. Humoral immunotherapy and the use of monoclonal antibodies	342
Peter T Daniel	
26. T-cell-mediated immunotherapy of cancer	378
Reink Offringa, Rene EM Toes, Maaik�� E Rensing, Marloes LH de Bruijn, Cornelius JM Melief	
27. Interference with signaling pathways in malignant disease	390
Asim Khwaja	
28. Gene transfer in leukemia and related disorders	406
Martin Pul��, Malcolm Brenner	
29. Allogeneic stem cell transplantation	423
Richard J O'Reilly, Esperanza B Papadopoulos, Trudy N Small, Stephen Mackinnon	

PART FIVE: CLINICAL DISEASES

30. Epidemiology	466
J��rgen H Olsen	
31. Lymphoid malignancies in children	482
Raul C Ribeiro, Ching-Hon Pui	
32. Acute lymphoblastic leukemia in adults	500
Dieter Hoelzer, Nicola G��kbuget	

33. Chronic lymphoid leukemias	521
Emilio Montserrat	
34. Multiple myeloma	543
Nikhil C Munshi, Kenneth C Anderson	
35. Hodgkin lymphoma	565
Karolin Behringer, Volker Diehl, Andreas Engert	
36. Non-Hodgkin lymphomas	575
Anton Hagenbeek, Philip M Kluin	
37. Acute myeloid leukemia in children and adolescents	617
Gertjan JL Kaspers, Yaddanapudi Ravindranath	
38. Acute myeloid leukemia in adults	633
Bob Löwenberg, Alan K Burnett	
39. Acute promyelocytic leukemia	657
Laurent Degos	
40. Myelodysplastic syndromes	669
Pierre Fenaux, Claude Gardin	
41. Chronic myeloid leukemia	696
François Guilhot, Lydia Roy	
42. Chronic myeloid disorders, excluding CML	735
Tiziano Barbui, Guido Finazzi, Giovanni Barosi	

PART SIX: LATE EFFECTS OF THERAPY

43. Late effects after treatment for Hodgkin lymphoma	753
Anthony J Swerdlow, Flora E van Leeuwen	
44. Late effects in children treated for acute leukemia	769
Stuart Mucklow, Gill Levitt	
45. Late effects following allogeneic stem cell transplantation	782
Gérard Socié, Lionel Ades	

PART SEVEN: SUPPORTIVE CARE

46. Hematopoietic growth factors	794
Stephen Devereux, Antonio Pagliuca	
47. Management of infectious complications in hematological patients	811
Catherine Cordonnier	

APPENDICES

Appendix I Selected lineage-associated antigens in hematopoietic cells: CD nomenclature	827
Appendix II Concise summary of the cytokines involved in human hematopoiesis	
Index	845

Preface

The hematological malignancies as a whole are the fourth most common form of cancer in men and the third most common in women. By the age of 75 years, nearly 1 in 20 individuals will have developed a hematological malignancy if they have not died of something else beforehand. The importance of the hematological malignancies far exceeds their frequency, however. The repeated accessibility of hematological tissue has facilitated rapid advances in the understanding of the molecular pathogenesis of the hematological malignancies and their diagnostic implications. From a therapeutic perspective, the hematological malignancies have been the test-bed for the development of the principles of therapy, which apply to most other forms of cancer. This includes combination chemotherapy, chemotherapy dose escalation and, most recently, immunochemotherapy and the use of biological therapies.

The first edition of this book emphasized the recent insights into the pathophysiology of the hematological malignancies and focussed on the scientific principles underlying current therapy. This approach has been maintained in the second edition, and it has required considerable revision of some chapters and the addition of new chapters, including stem cell plasticity, DNA repair, senescence and telomeres, angiogenesis and tumor development, microarray analysis, and expression profiling. There has also been a major increase in the emphasis given to late effects of therapy and there are now three chapters devoted to this topic.

Many authors from the first edition have been retained, but numerous new authors have also been recruited to maintain an up-to-date international perspective from experts in their fields.

Figure 4.7 (a) The pRb family. The schemata depicting each member of the pRb family show phosphorylation sites and acetylation sites (in red). The phosphorylation sites that are conserved in p130 and p107 are boxed.¹⁶² The A and B domains (separated by a spacer domain, S) make up the ‘pocket’ that binds proteins with LXCXE motifs. The ‘large pocket’ (domains A, B, and C) binds E2F-DP factors. The C-terminal domain also binds MDM2 and c-ABL. eye is the cyclin-cdk binding site (KXLKXL). Numbers indicate amino acids (N| C terminus), (b) The E2F and DP families. The domains shown allow the E2F and DP proteins to dimerize as E2F-DP heterodimers (DD, comprising leucine zipper (LZ) and marked box (MB) domains), to bind pRb, p130, or p107 ‘pocket proteins’ (pp), to bind E2F-binding sequences in the promoters of genes (DNA binding), and to transactivate (TD) or repress (RD) transcription. E2F1, 2, and 3 have nuclear localization signals (NLS) and E2F4 and 5 have nuclear export signals (NES). Cyclin A binds E2F1, 2, and 3 (eye). The schema is shown with N| C terminus, left to right.

Figure 6.2 The early steps of B-cell differentiation take place in the bone marrow and are antigen-independent. The main discrete steps that lead from the hematopoietic stem cell to the immature B lymphocyte are identified by the successive Ig gene rearrangements, by the presence of intracytoplasmic markers, and by the expression of characteristic markers at the cell surface. The very early stages that go from the stem cell to the early pro-B cell encompass several precursors that are not completely defined to date. TdT, terminal deoxynucleotidyl transferase, responsible for including N diversity; Ψ L, surrogate light chain that combine with the Ig μ chain to form the pre-B receptor; RAG, recombination activating genes, which encode for the recombinase enzyme.

Figure 17.2 Double-color metaphase FISH in a patient with a cryptic *ETV6-ABL1* fusion gene and only a t(8; 12)(p12; p13) translocation on classical cytogenetics. Red signals mark the *ETV6* gene both in the abnormal 12p and in the abnormal 8 derived from the chromosomal translocation. Green signals label the *ABL1* gene in both the normal chromosome 9 and the abnormal 8.

Figure 17.3 AML with extra material in the short arm of chromosome 16 derived from chromosome 1 (arrow), as revealed by multicolor FISH karyotype.

Figure 18.1 Detection of *E2A* translocations in interphase cells via two-color 'split apart' FISH. (a) Schematic depiction of the *E2A* gene on chromosome 19 and location of probes centromeric (green) and telomeric (red) to *E2A*. (b) Interphase FISH of a normal cell shows two fused red/green or yellow signals from the adjacent signals on each chromosome 19 homologue. (c) Interphase FISH of a cell with a t(1; 19)(q23; p13) shows one fused red/green signal from the normal chromosome 19, and single red and green signals from the der(1) and der(19) chromosomes, respectively.

Figure 20.1 Schematic illustration of microarray technology. For DNA oligonucleotide microarrays, one sample is hybridized per experiment. The detection is accomplished by a fluorescent dye, and results in an absolute expression level for each gene. The oligonucleotides are synthesized in situ onto the array surface. For spotted microarrays, the test RNA is co-hybridized with control RNA. Following detection of the signals, the ratio of differentially tagged test and control RNA is calculated.

Figure 20.6 Hierarchical clustering based on U133A expression data of 45 AML samples (columns) comprising the subgroups t(15; 17) ($n=20$), t(8;21) ($n=13$), and inv(16) ($n=12$) versus 36 informative genes represented by 58 U133A chip design probesets (rows). New patient samples, which were not previously hybridized to U95Av2 microarrays are marked by asterisks. The normalized expression value for each gene is coded by color, with the scale shown at the lower left (standard deviation from mean). Red cells represent high expression and green cells low expression. The previously published set of diagnostic markers is given by respective gene symbols.

Figure 20.7 Principal component analysis based on U133A expression data of WHO-classified AML subtypes with recurrent chromosome aberrations and normal bone marrow mononuclear cells from healthy volunteers. Sixty AML samples comprising the color-coded subgroups t(15; 17) ($n=20$), t(8; 21) ($n=13$), inv(16) ($n=12$), and t(11q34)/MLL gene rearrangement-positive samples ($n=15$) can be discriminated accurately, and are different from normal bone marrow nBM ($n=9$).

Figure 25.15 Three-dimensional (3D) structure of a recombinant bispecific single-chain antibody (diabody). An scFv antibody against CD19 was fused by a linker to an scFv against CD3. This diabody construct is highly efficient in activating resting T cells and inducing a CTL response and target cell lysis of CD19⁺ malignant B cells.¹⁵⁸ (a) Backbone of the peptide chain, (b) Rendering of the 3D surface structure. Green, V_H of the anti-GDI 9 scFv; purple, V_L of the anti-GDI 9 scFv; gray, V_H of the anti-CD3 scFv; light blue, V_L of the anti-CD3 scFv; yellow, linker peptide; orange, His tag; darker blue, Flag tag (employed for detection and purification of the recombinant protein).

Figure 28.1 Creation of a replication incompetent retroviral vector with a split packaging cell line. Wild-type retrovirus is shown in inset upper-left corner. Virus is composed of gag/pol and env proteins and a RNA genome. This genome codes for gag/pol and env proteins, hence upon infecting a host cell, all retroviral elements can be generated and virus can replicate. Split packaging line provides coding regions for gag/pol and env elements in trans. Coding region for our transgene (red) is preceded by a packaging signal (blue). Packaging signal has been removed from gag/pol and envelope coding regions. Hence virus is assembled as normal but our transgene replaces usual genome. Upon infecting a cell, our transgene is expressed but no gag/pol or env can be generated, and virus cannot replicate. For replication competent virus to be generated, packaging sequence, gag/pol and env elements would have to coincidentally recombine.

Figure 28.2 Artificial TCR (dimer) and native TCR. Artificial receptor components can be divided into two groups. External section is involved with antigen recognition. This is usually composed of a Single Chain Variable Fragment (ScFv) derived from a monoclonal antibody. This is connected to the internal section of the receptor via a flexible spacer which allows the receptor multiple orientations. The internal section transmits signal. In this figure we show a signaling domain composed of a fusion of signaling portions of CD28 and CD3 ζ . This receptor is capable of transmitting a CD3 ζ signal and CD28 co-stimulatory signal upon antigen recognition. Simplicity of artificial receptor is contrasted to the complexity of the native TCR which requires an aggregate of multiple proteins to transmit a similar signal.

Figure 41.5 Structure of the *ABL* and *BCR* genes, with their exons and introns.

Figure 41.2 Structure of *ABL*, with its domain

Figure 41.3 Structure of *BCR*, with its domain

The stem cell

Rob E Ploemacher and Elaine A Dzierzak

Introduction

The hematopoietic stem cell (HSC) compartment is composed of primitive cells that maintain blood cell production throughout the lifetime of an individual. In the adult, most of the HSC are located in the bone marrow. They are able to migrate in a highly regulated fashion via the bloodstream between the widely dispersed areas of blood cell formation. The HSC compartment is heterogeneous in various aspects, possibly as a result of different mitotic histories of the individual stem cells. It is generally accepted that the majority of HSC have a very low turnover rate and/or extended G_1 cell cycle phase, while potentially possessing considerable capability to both self-renew and differentiate into at least eight hemato-lymphoid lineages. The activation of cycling activity is probably regulated by stochastic mechanisms.^{1,2}

By analogy to the situation in the mouse, the human HSC compartment most likely represents a hierarchy of primitive cells. This is based on their decreasing ability to generate new HSC, decreasing pluripotentiality and proliferative potential, and increasing turnover rate.³⁻⁹ When bone marrow is used for transplantation, its heterogeneity may be reflected in the different time periods that individual stem cell clones contribute to long-term reconstitution of a conditioned host, irrespectively of whether this includes all hematopoietic lineages.¹⁰⁻¹⁵ Because of this heterogeneity, the question may arise as to what one should denote as a 'stem cell'.

Lifetime conservation of stem cell activity

Many research papers have focused on the topic of HSC 'self-maintenance' and the current high expectations of 'ex vivo expansion of HSC'. Moreover, gene therapy for the hematopoietic system is based on the general acceptance of HSC immortality. However, there is no extensive evidence for unlimited HSC self-renewal, and it should be questioned whether such a cell would not endanger the integrity of life because it has qualities of neoplasia. Secondly, immortality could be interpreted in a semantic manner, so that a future of 50 cell divisions meets conditions of virtual self-maintenance. For example, the recent demonstration that lymphomyeloid-repopulating HSC can expand their numbers more than 300-fold following their transplantation into a conditioned recipient is impressive indeed, but this takes a mere 8-10 cell divisions with full self-renewal.¹⁶ Thirdly, a clear distinction should be made between maintenance of an individual stem cell and that of the HSC population as a whole. The well-known cartoon of an individual stem cell that divides and produces two distinct daughter cells—one remaining 'stem cell' and the other committing itself towards differentiation—may not be commonplace. Rather, one should use operational terms that apply to the whole population and characterize the HSC compartment as a cell population with a probability of self-renewal that approaches 0.5. Alternatively, a population can be structured in a way that it uses a (small) number of cells from a reserve compartment, while the largest part is responsible for the daily supply of differentiated progeny. This structure can be recognized in many tissues. There is ample evidence for a metabolically quiescent HSC population with relatively low turnover that harbors a high proliferative potential and probability to give multilineage offspring. Many observations have suggested that in the steady state, only a few stem cell clones at the same time display clonogenic expansion and contribute to daily blood cell production.^{10,11,17-20} In a transplant setting, it has been shown that many different clones contribute to the initial phase of hematopoietic reconstitution. However, within weeks, only a few remain (and some arise in delayed manner) to provide for the body's demand of blood cells over the longer term. In contrast, the work of Harrison and colleagues supports a model wherein HSC function continuously.^{15,21} The ultimate self-renewal capacity of a single HSC is

unknown, but serial transplantation studies in mice and reports on chromosome telomere shortening in human HSC suggest that human HSC self-replication is limited to around 50 cell divisions.²² Extinction of individual clones may then feed back into the quiescent HSC compartment and trigger proliferation of other HSC.

Adult stem cell plasticity

Until recently, HSC have been regarded as being committed, to give rise exclusively to hematopoietic progeny. This concept is now being challenged in a variety of experimental settings, and the available evidence suggests that adult HSC are flexible in their differentiation repertoires and can be reprogrammed, both *in vivo* and *in vitro*. Such observations suggest that under certain conditions HSC are able to produce cells with specialized structural and metabolic features of tissues distinct from the bone marrow, such as liver, gastrointestinal tract, pancreas, kidney, skin, skeletal and heart muscle, brain, or adult endothelium. The reprogramming most likely occurs within the organ to which HSC have been transplanted but would not have migrated to under normal conditions. A further prerequisite would be that the specific site should have extensive damage or a deficiency that attracts and stimulates the grafted or migrating stem cells to reprogram and produce adaptations commensurate with their new location.

To date, many studies suggesting stem cell plasticity have not used highly purified HSC, but rather crude bone marrow cell populations. Therefore, not all findings of plasticity may have to be attributed to HSC, but rather mesenchymal stem cells (MSC) or endothelial precursors could be responsible in part for these findings. Indeed, the scientific community has asked for more stringent proof of stem cell plasticity, such as a clonal approach²³ or sustained functional activity.²⁴ Among the few studies meeting or approaching these criteria is the demonstration that highly purified murine HSC infused into mice with a congenic liver disease (hereditary tyrosinemia type I) contributed not only to the hematopoietic system but to some of the recipient's liver parenchymal cells.²⁵ More recently, Jiang et al²⁶ reported that murine bone marrow-derived cells co-purifying with mesenchymal stem cells differentiate at the single-cell level not only into mesenchymal cells but also into cells with visceral mesoderm, neurectoderm, and endoderm characteristics *in vitro*. On transplantation into a non-irradiated host, these cells—termed multipotent adult progenitor cells (MAPC)—engraft and differentiate into the hematopoietic lineage and in addition into the epithelium of liver, lung, and gut. These MAPC may therefore represent a more primitive precursor of HSC and many other somatic cells.

Ontogeny of the HSC

The origin of the hematopoietic system is within the mesodermal cell layer of the gastrulating embryo. Once the founding cells are generated within the conceptus, it is thought that these cells migrate and colonize the liver during the fetal stage and subsequently migrate and colonize the bone marrow, where they reside throughout the adult stage.²⁷ Using the mouse embryo as a model, the earliest observed hematopoietic cells (primitive erythrocytes) are found within the yolk sac blood islands. Both the hematopoietic cells and closely associated endothelial cells of the yolk sac vasculature are thought to arise from a common mesodermal precursor, the hemangioblast.²⁸ It was recently demonstrated that rigorously selected endothelial cells sorted by flow cytometry from the human yolk sac and embryonic aorta yielded a progeny of myelolymphoid cells in culture, strongly suggesting that HSC may develop directly from endothelium.²⁹ While other hematopoietic cells and progenitors can be detected shortly thereafter, HSC that are the basis of the adult mouse hematopoietic hierarchy and defined by their adult repopulating properties are not found until midgestation.^{30,31} The first and most active embryonic site involved in HSC generation is the aorta-gonad-mesonephros (AGM) region.^{31,32} Extensive studies in many vertebrate species, including mouse and human, strongly support two independent origins of hematopoiesis: an initial wave of transient, embryonic hematopoiesis in the yolk sac and a second wave in which the adult hematopoietic system emerges in the AGM.³³ In the midgestation mouse embryo, the first adult repopulating HSC have been localized to the dorsal aorta³⁴ and are included in the emergent hematopoietic clusters and endothelium along the ventral aortic wall.³⁵ Interestingly, some AGM HSC possess surface characteristics of the endothelial lineage,³⁶ suggesting that some of the cells of the major vasculature are 'hemogenic endothelium' and perhaps act as a specialized type of hemangioblast.³⁷

Human embryos have also been studied for the presence of hematopoietic cells in the AGM region. During the fourth week of human ontogeny, hematopoietic clusters emerge from the vascular endothelium of the aorta and vitelline artery.³⁸ Functional analyses reveal that adult-type, multilineage hematopoietic and presumably adult-repopulating hematopoietic stem cells (some of which exhibit a vascular endothelial phenotype) are present in the aorta and vitelline artery at this time.³⁸ Moreover, such hemogenic endothelial cells have also been found in the human embryonic liver and fetal bone marrow.³⁸ These data, taken together with the observation that the number of HSC in the mouse AGM region increases during *ex vivo* explant culture,³¹ suggest that it may be possible to manipulate

human HSC growth and expansion *in vivo* by inducing HSC from non-hematopoietic precursors (fate determination) and/or by expansion of a single founder HSC (proliferation without differentiation). Hence, further studies into the emergence of the first HSC during ontogeny should lead to the identification of the cells and molecules involved in these processes and may result in novel opportunities to induce and/or expand human HSC from fetal and/or adult sources for blood-related therapies.

Regulation of HSC quiescence and proliferation

It is generally accepted that the bone marrow stromal elements, together with their extracellular matrix molecules, are involved in regulating HSC cycling activity. Many of the cytokines that have been cloned in recent years are actually elaborated and presented by the hematopoietic organ stroma through, for example, membrane-bound glycosaminoglycan species. This local regulation serves to gain specificity and avoid pleiotropic and thus undesired side-effects. In addition, cell adhesion molecules may be directly involved in this regulation, or may contribute to specific interactions between HSC and stromal elements.

The molecular mechanisms regulating cycle activity and facilitating undifferentiated proliferation of HSC are not completely understood, and many cytokines have been shown in recent years to synergize in inducing the proliferation of candidate HSC. These factors may, or may not, have growth factor activity when used alone, and their action may therefore be explained by a series of assumptions, including (a) competence acquisition, i.e. they induce $G_0 \rightarrow G_1$ transition in HSC without being able to drive cells through S phase and G_2 to mitosis;³⁹ (b) induction or upregulation of receptor expression for other cytokines that can activate HSC; (c) downregulation of receptors for negative regulators of HSC; or (d) the downstream targets of receptor-ligand complexes, the transcription molecules, act in concert to affect molecular processes that are essential for regulation. Many small molecules have been proposed to be HSC-specific. However, none has reportedly lived up to its promises thus far. The most studied hematopoietic inhibitors are transforming growth factor $\beta 1$ (TGF- $\beta 1$), tumor necrosis factor α (TNF- α), interferon- γ (IFN- γ), and macrophage inflammatory protein 1 α (MIP-1 α). They are considered pleiotropic factors that may have both stimulatory and inhibitory properties on different cell populations. As an example, TGF- $\beta 1$ stimulates monocyte cluster formation but at the same time is the most active inhibitor at the stem cell level.^{40–44}

Cytokines that are effective in the regulation of HSC proliferation—most likely in a redundant or overlapping fashion and often in synergy—are stem cell factor (SCF, a ligand for the c-Kit receptor), Fms-like tyrosine kinase receptor 3 ligand (Flt3-L), thrombopoietin (Tpo, a ligand for c-Mpl), interleukin-6 (IL-6), IL-11, IL-3, leukemia inhibitory factor (LIF), and granulocyte colony-stimulating factor (G-CSF). The sources of these factors vary and can be autocrine, paracrine (e.g. elaborated by stromal cells in the bone marrow environment, or by T cells or monocytes), or endocrine. The above molecules certainly do not act exclusively on HSC proper, and therefore specificity requires local presentation in context with other signals, possibly cell-cell and cell-extracellular matrix contact mediated by cell adhesion molecules (CAM).

In addition to soluble factors elaborated by stromal cells and HSC, there could exist other more intimate levels of regulation of HSC. Rather than exclusively determining HSC sublocalization in the hematopoietic organs, CAM could have direct regulatory effects on HSC. For example, it has been reported that an antibody against LFA-1 inhibits the generation of progenitor cells by a fraction of human HSC in stroma-supported cultures.⁴⁵ Maybe the most well-studied CAM interaction is that of c-Kit and its ligand, SCF.⁴⁶ SCF is expressed on stromal cells in, for example, the bone marrow, the reproductive organs (Sertoli cells in the testis and follicular cells in the ovary), the skin, and the cerebellum, whereas c-Kit is the SCF receptor expressed on immature cells, including HSC, spermatides, oogonia, and melanocytes.^{47–50} Loss of SCF from the stromal cell membrane leads to a pleiotropic phenotype in mice (the Steel phenotype—hence the alternative name for SCF: Steel factor), that includes macrocytic anemia, decreased fertility, and coat color defects. This condition largely develops as a result of a defective stem cell migration during embryogenesis, while the anemia in adult mice cannot be normalized by infusion of the soluble receptor, i.e. SCF. Yet we know that the soluble receptor SCF acts as a survival factor and a growth factor and has potent synergistic activity *in vitro*.

From embryogenesis it has become evident that genuine cell-cell communication may be even more intimate and involves coupling of intracellular compartments of adjacent cells via gap junctions (GJ). The connexin-43 (Cx43) type GJ can be detected immunohistologically in bone marrow and its expression increases 80–100-fold in murine bone marrow during the neonatal period and shortly after cytoreductive treatment of adult mice during the period when active regeneration is beginning.⁵¹ We have recently reported that functional blocking of all GJ intercellular communication (GJIC) between mutual stromal cells, and stromal cells and hematopoietic cells, in LTC and CAFC cultures (see below) substantially inhibits hematopoietic activity. This inhibition could be fully abrogated by restoring GJIC within the first two weeks of culture.⁵² Reintroduction of the

Cx43 gene into Cx43-deficient fetal liver-derived stromal cells was able to restore their diminished intercellular communication as well as their decreased ability to support stem cells in a CAFC culture.⁵³

It cannot be excluded that there exist systemic or endocrine signals that regulate or overrule this complex local signaling network if decisive action is required following, for example, blood loss, infection, or cytoreductive therapy.

Characterization of stem cells

In the last four decades, the description of HSC characteristics has been largely a reflection of the methods, techniques, and hardware that were available to investigators. From these efforts, HSC have emerged as typically small 'blast' cells with a relatively low buoyant density and sedimentation velocity, few and small mitochondria, and a nucleus with several nucleoli and little condensed chromatin. In agreement with these properties, they concentrate in a region of relatively low side and forward light scatter in a flow cytometer. Physical isolation studies using fluorescence-activated cell sorting (FACS) have shown that human HSC express on their surface CD34, c-Kit, IL-6R (brightly), Thy-1, CD45RA and Flt3 (weakly), but not lineage-specific markers, HLA-DR, CD71, CD38, or CD33.

HSC share part of the aforementioned characteristics with other cells, and therefore phenotypical identification and enumeration of HSC is still not truly feasible. In addition, expression of such antigens may depend on the proliferative status of HSC and progenitor cells. A good example of this is the expression of the sialomucin CD34 on progenitor cells, which is extensively used in enumeration, isolation and clinical transplantation of HSC. CD34 is highly expressed on HSC, including cells providing long-term marrow repopulation, and is downregulated as cells differentiate and mature. However, it is not exclusively expressed on hematopoietic progenitor cells but also on vascular endothelial cells^{54,55} and some fibroblasts.^{56,57} It has been shown that human CD34⁻ cells contained within the bone marrow cell population depleted for cells expressing mature lineage antigens (Lin⁻) could induce long-term repopulation and multilineage differentiation in sheep⁵⁸ and murine NOD/SCID⁵⁹ xenograft models. As the transplanted cells produced many CD34⁺ stem cells in these in vivo models and little or no clonogenic (CFU-C) or LTC-IC activity was observed in vitro, there is reason to suggest that Lin⁻CD34⁻ cells represent primitive precursors of CD34⁺ cells. Further studies revealed that HSC from the fetus express CD34 at late stages and continue to express it in neonates and adults, but that this expression decreases with aging.^{60,61} When older recipients were engrafted with neonatal Lin⁻c-Kit⁺CD34⁺ cells, containing all HSC activity, the HSC activity shifted to the Lin⁻c-Kit⁺CD34⁻ bone marrow cell population.⁶⁰ Ogawa et al⁶¹ showed that CD34⁻ stem cells from adult bone marrow stimulated in vivo by 5-fluorouracil (5-FU) injection or in vitro by a combination of IL-11 and SCF became CD34⁺. The activated CD34⁺ stem cells reverted to CD34⁻ when the recipients' marrow achieved steady state. The majority of G-CSF-mobilized HSC also were CD34⁺ and reverted to CD34⁻ under steady-state conditions. These observations therefore strongly suggest that the proliferative activity or activation status of HSC determines expression of CD34 by stem cells from fetal, neonatal, and adult mice, and that CD34⁻ HSC are not more primitive than CD34⁺ cells.

The nucleic acid dye Hoechst 33342, which hardly stains the most quiescent HSC, has been extremely helpful in HSC isolation. Similarly useful has been the vital fluorochrome rhodamine-123 (Rhl23). Rhl23 accumulates in mitochondria and is a substrate of the *MDR1* gene product, the membrane pump P-glycoprotein,^{62,63} which is highly expressed in quiescent HSC. For these reasons, primitive HSC hardly stain with Rhl23,⁶⁴⁻⁶⁷ but within the HSC compartment Rhl23 retention increases dramatically so that the murine day-12 spleen colony-forming cells are among the brightest Rhl23-stained cells in the bone marrow.⁶⁴

Because of their relative quiescence, primitive HSC have been shown to be especially resistant to antimetabolic agents (e.g. hydroxyurea and vincristine) and 5-FU,^{5,8,66} and this property has been exploited to enrich HSC by exclusion of all other cells.⁶⁸ In contrast, the most primitive and in vivo long-term repopulating HSC, as well as CAFC wk5, are extremely sensitive to the alkylating agent busulfan and a number of its derivatives.⁶⁹⁻⁷⁰ It has been long held that HSC in general represented one of the most radiosensitive cell types in the body, with a D_{010} of about 0.75 Gy and no sublethal damage (SLD) repair. This notion has resulted from the circumstance that radiation studies were carried out using the CFU-S day 7-9 assay and animal survival as endpoints. However, current views are more in line with the realization that both these methods are a measure of transient repopulating HSC.^{6,7,64} The recognition of heterogeneity in the HSC compartment and the development of the CAFC assay allowing the estimation of HSC subset frequencies, and thus radiation survival, has led to a more balanced appraisal of the HSC compartment's radiosensitivity. It is the CFU-S day 7/CAFC day 7-10 population that shows high radiation sensitivity and lack of SLD repair.⁷¹⁻⁷³ But, with increasing primitivity, CAFC subsets are far more radioresistant and display high levels of SLD repair, matching that of lung tissue.⁷⁴ All of the above-mentioned characteristics have emerged from studies on HSC from adult donors and may, or may not, apply to HSC from other developmental stages.

Measurement of stem cell activity

Because of their low frequencies and lack of truly distinctive physical characteristics, measurements of HSC rely on functional assays. HSC have been defined as cells that have high proliferation potential, are able to self-renew, and give rise to multipotential lineage development. HSC assays commonly use these characteristics as an endpoint. In vivo, spleen colony formation,⁷⁵ animal survival, competitive repopulation,^{15,21} serial transplantation,^{10,76} and engraftment of mice having a congenital immune suppression,⁷⁷ anemia,^{12,78–79} or polymorphism in an enzyme⁶⁹ or cell surface epitope^{16,80} have been used to detect HSC and their descendants. In vitro, clonogenic potential^{81,82} with particular attention to multipotential or blast colony formation⁸³ and replating efficiency, short-term liquid (delta) cultures,^{84–87} and long-term progenitor cell production on stromal cells^{66,88–92} have been employed.

The effectiveness and reliability of such assays depends on many parameters, including (a) HSC seeding efficiency to a specific hematopoietic organ in vivo, (b) knowledge about, and availability of, growth factor combinations that are required to activate the most quiescent HSC to cycle in vitro, (c) insight into the context in which cytokines should be presented to HSC (e.g. bound to stromal cell surfaces or extracellular matrix molecules), (d) knowledge of inhibitors that maintain quiescence of HSC, and methods to neutralize or counteract their activities, (e) the time required to activate the most quiescent HSC, and (f) stochastic mechanisms operating at the HSC level that determine quiescence/cycling ratio, or commitment to specific differentiation lineages. The latter issue clearly demonstrates the limitation of HSC techniques, in that HSC may not always behave according to their ascribed ability for multipotential differentiation and self-renewal capacity. As has been discussed by Lemischka¹¹ on the basis of extensive transplantation experiments with provirus-marked HSC, analysis of a reconstituted hematopoietic system at a single point in time merely defines a grafted HSC in terms of its minimal differentiation and proliferation potential. Therefore, estimation of HSC self-renewal should preferentially be done by analysis at multiple points in time and transplantation into secondary hosts.

A last matter of concern is the circumstance that human in vitro assays are difficult to validate, so that assumptions have to be made on the basis of single case histories and through extrapolation of the better characterized murine and large animal models.

Stem cell assays

In the course of time, various assays have been claimed to exclusively detect HSC and even allow their enumeration. It should be realized that a genuine assay should (a) allow frequency assessment independently of the accompanying cells in the sample or of the HSC purity, (b) be validated using in vivo endpoints, and (c) permit indisputable identification of these endpoints. There is perhaps no assay that meets these requirements. The first issue touches on the presence or absence of progenitor cells and bystander cells. As an example, although properly stimulated HSC from various sources may form colonies in semisolid media, such colonies would be outnumbered by progenitor-derived colonies by a factor of 5×10^2 – 5×10^5 . These figures are based on the observation that one detects 300–500 colony-forming units in culture (CFU-C) per 10^5 bone marrow cells (BMC), while primitive HSC have been reported to have a frequency of 10–20/ 10^5 BMC, as estimated using LTC-IC week 5 and CAFC week 6 (see below) in stroma-supported long-term cultures,^{66,90} or even $1/10^8$, using repopulation of cytokine-treated NOD/SCID mice as an endpoint.⁹³ In addition, both progenitor cells and accessory cells elaborate cytokines and inhibitors and consequently will affect the outcome of the HSC assay.

The second requirement—one that is underrated and unpopular—is that of proper assay validation. In the past 50 years, it has been proposed that hematopoietic rescue from radiation-inflicted death could be induced by transfusion of body fluids, spleen homogenates, spleen or bone marrow cells, CFU-S (cells that can form hematopoietic nodules in the spleen of an irradiated mouse), or long-term repopulating HSC that have extremely low CFU-S quality. As mentioned above, many types of in vitro methods claim to score ‘stem cell quality’. The proof of such statements depends on the acceptance of a stem cell definition and the ability to sort the target cells to high purity and show that the cells comply with the spirit of such a definition.

Thirdly, the most relevant assays for HSC enumeration are those that have a unique endpoint, which is characteristic for HSC, and thus discriminate HSC from accompanying progenitors in the sample. In practice, this includes all assays that detect long-term (multilineage) activity of HSC in vivo or in vitro.

Long-term cultures

One of these methods is the stroma-dependent long-term culture (LTC) of hematopoietic cells, which is routinely performed in 25 cm² flasks.⁸⁸ LTC measures the capacity of a complement of inoculated cells to generate hematopoietic progenitor cells over a number of weeks, typically 5–8 weeks. Progenitor cells can be detected in the non-adherent cell fraction that is weekly harvested during medium changes, and in the adherent layer that can be harvested by trypsinization. The LTC thus gives an insight in the capacity of a

graft to produce progenitor cells,⁹⁴ while it remains unknown how many HSC and progenitors contribute to it. The latter issue is highly relevant when differences are anticipated in the progenitor cell-generating capacity of HSC, for example on the basis of disease, chemotherapy, or following ex vivo strategies for physical or chemical purging or selection. In order to allow such HSC enumeration, limiting dilution-type miniaturized LTC have been reported that use either CFU-C production (LTC-initiating cells, LTC-IC)⁹⁰ or stroma-associated clone formation (cobblestone area-forming cells, CAFC)^{8,66,95} as an endpoint for frequency calculation.

The CAFC assay is assumed to detect frequencies of the various HSC subsets with 'transient repopulating' and/or 'long-term repopulating' properties and has been developed as an extrapolation from the murine CAFC assay.^{8,9} Extensive studies using physically sorted BMC have allowed regression analysis on the applicability of the murine CAFC assay as an in vitro equivalent of in vivo assays for a series of HSC subsets. These studies have indicated that, both in vivo and in vitro, early developing, short-lived clones are initiated by the transient repopulating spleen colonyforming cells (CFU-S day 12), whereas later-developing and more permanent clones are descendants of more primitive, so-called long-term repopulating, HSC, that induce stable chimerism for more than a year.^{8,9,12-13} There is increasing evidence that the human CAFC assay may also detect transiently and long-term repopulating normal and leukemic stem cell subsets.⁹⁶⁻¹⁰¹ A good correlation has been found between CAFC week 7 and cells that repopulate SCIDhu mouse bone implants 8 weeks post engraftment using human mobilized peripheral blood Thy1⁺CD34⁺Lin⁻ cells.¹⁰² In addition, early detectable CAFC have the characteristics of the more differentiated and transiently repopulating HSC (5-FU-sensitive, CD34^{medium}, CD38^{medium/high}, HLA-DR^{high}), whereas late CAFC meet the phenotype routinely employed for primitive HSC (5-FU-resistant, CD34^{high}, CD38^{negative/medium} HLA-DR^{low/dim}).⁶⁶

Both the flask LTC and the CAFC assay propagate successive clonal amplification of HSC subsets at their own expense.^{103,104} This property renders the CAFC assay useful in assessing the full hematopoietic potential of a marrow specimen in a relatively short period, and in presenting a quantitative cross-section of the heterogeneous stem cell compartment.

Extended stroma-dependent LTC (ELTC; 8–14 weeks) have been described¹⁰⁵ that appear to reveal an even more primitive human HSC population than that detected in regular LTC (5 weeks) and CAFC (6–8 weeks) assays. ELTC-initiating cells (ELTC-IC) differ from LTC-IC in several respects. Firstly, ELTC-IC produce most CFU-C after 60 days, whereas LTC-IC do so before. Currently, it is not clear whether these differences are realistic or merely result from the use of different stromal support layers, cytokine combinations, sera, or the serial replating required for the ELTC. Secondly, in contrast to LTC-IC, which show a high level of gene marking,⁹³⁻¹⁰⁵ only about 1% of ELTC-IC can be transduced. The latter characteristic is reminiscent of the low transduction efficiency of long-term repopulating cells in human clinical gene therapy trials and most large-animal models.^{63,106,109} Finally, ELTC-IC are exclusively found in the CD38⁻ fraction of CD34⁺ cells, as are human SCID-repopulating cells (SRC).⁹³ In contrast, part of LTC-IC and CAFC week 6 are CD38^{medium} (unpublished observations).

SCID mouse assay

The propagation of human hematopoietic progenitors in mice with a severe combined immune deficiency syndrome (SCID) has dramatically extended our insight into the repopulating abilities and frequencies of primitive human HSC.⁷⁷⁻⁹³⁻¹¹⁰⁻¹¹² Grafted human HSC proliferate in SCID mice and differentiate in the murine bone marrow, producing large numbers of LTC-IC, CFU-C, immature CD34⁺Thy1⁺ and CD34⁺CD38⁻ cells, as well as mature myeloid and erythroid cells. Relatively large numbers of lymphoid cells are produced in the bone marrow, and the human engraftment of the murine thymus and spleen is almost exclusively lymphoid. Reported frequencies of the primitive cells that initiate the graft in sublethally irradiated NOD/SCID mice, the SCID-repopulating cells (SRC), are extremely low: there is about 1 human SRC in 10⁶ umbilical cord blood (UCB) cells, 1 in 3×10⁶ mobilized normal BMC and only 1 in 6×10⁶ peripheral blood (PB) cells.^{113,114} These frequencies are far lower than estimated by the LTC-IC and CAFC assays: average CAFC week 8 numbers in all of these specimens are between 1 and 10 per 10⁵ nucleated cells. We have found that these low apparent HSC frequencies result mainly from extremely low seeding efficiencies of the human HSC in these mice. Indeed, of all infused CAFC subtypes, only 1–5% could be retrieved from the whole NOD/SCID bone marrow within 24 hours following lethal conditioning and cell infusion.¹¹⁵ In support of these data were our previous observations in SCID mice, which showed a 5–10-fold higher engraftment with human AML cells following pretreatment of the recipients with macrophage-depleting C1₂MDP liposomes.⁹⁷ In light of these data, the human HSC frequencies are apparently far higher than those of the reported SRC. A correction with a factor 20–100 thus leads to comparable frequencies of SRC and CAFC/LTC-IC. Different growth requirements of these cells may also affect the apparent frequencies in NOD/SCID mice. UCB cells grow spontaneously in SCID mice, but PB and BM stem cells need continuous cytokine support following their transplantation.

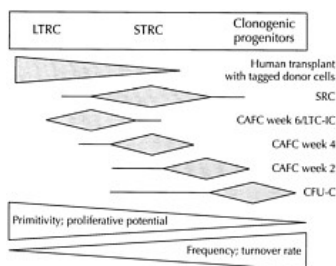

Figure 1.1 Schematic diagram of the hierarchy in the hematopoietic stem/progenitor cell compartment. Functionally defined assays have been ordered here on the basis of the primitivity of the endpoint detected. LTRC (STRC), long-term (short-term) repopulating cells in vivo; SRC, NOD/SCID mouse repopulating cell; CAFC, cobblestone area-forming cell; LTC-IC, long-term culture-initiating cell; CFU-C, colony-forming unit in culture. Note that these populations probably represent a continuous array of stem cell subsets, differing in mitotic history, that are either able to establish stable chimerism in vivo (LTRC), or induce short-term (1–3 months) hematopoietic repopulation (STRC), or merely give rise to size-restricted clones (clonogenic progenitors).

As opposed to LTC-IC, SRC have been reported to show low transfection efficiencies.⁹³ Again, seeding of the SRC in vivo could play a role in this observation. It has been shown that cycling CFU-S show a 50% decreased splenic seeding,¹¹⁶ and a similar loss in seeding and repopulating ability has been demonstrated to be induced by incubations as short as 3 hours.¹¹⁷ As stable gene integration requires cycling of HSC in a transfection protocol, it is conceivable that transfected cells are preferentially sequestered following their in vivo transplantation.

The tentative position of the progenitor subsets, as detected by the assays described here, is shown in Figure 1.1.

Ex vivo expansion of stem cells

The enrichment and in vivo expansion of HSC using a variety of techniques and cytokine cocktails have created novel areas of applied research. The possible therapeutic applications for primitive HSC are many and varied. HSC and progenitor cells have become attractive vehicles for administering certain genes therapeutically, including genes to treat metabolic disorders, inherited immune and hematological diseases, and acquired immune deficiency syndromes. Yet, although experimental data on efficient gene transfer and long-term gene expression in mice have boosted expectations for clinical application of gene therapy, the human data have been extremely disappointing. Low transduction rates of hematopoietic cells, limited lineage expression, and diminishing numbers of transduced cells observed after transplantation have necessitated additional basic research.

With the increasing information on the number, quality, and characteristics of HSC in umbilical cord and placental blood, this material has been found to be efficacious as an alternative source of HSC for transplantation in children.¹¹⁸ Transplants with UCB have utilized about 10-fold smaller numbers of nucleated cells than comparable transplants with BMC. However, it is held that UCB contains a greater proportion of progenitors than BM and that their proliferative capacity as determined by colony replating, stroma-supported growth in LTC, and SCID mouse engraftment is high.^{93,112,119–121} These data suggest that a single UCB collection should suffice for repopulation of the hematopoietic system of an adult. Such transplants in adults have shown long postgrafting intervals to platelet and neutrophil recovery. Although this could have resulted from the transfusion of too few primitive HSC, an alternative explanation could be merely that the number of transient repopulating HSC and progenitors is limited in UCB grafts. These observations therefore present a rationale for the growing number of studies in which ex vivo ‘expansion’ of true HSC and transient repopulating progenitor cells is investigated. Although impressive increases in CD34⁺ cells and progenitor cells have been reported, there have been limited reports on net increases in the LTC-IC and CAFC week 6–8 content of cultures initiated with BM stem cells or mobilized stem cells from leukapheresis products (PBSC).^{101–122–125} Thus, while modest numerical HSC expansion seems possible in short-term liquid cultures, we have documented a concomitant dramatic loss of the ability of individual HSC to generate progeny if the cells are propagated in the absence of stromal cell layers and Flt3-L.^{101,126–128}

It remains unclear why various investigators report different successes in expanding HSC even though often similar cytokine species and concentrations are included and culture periods are comparable. Such cultures generally contain IL-3, SCF, and IL-6, and in addition often a variety of cytokines such as G-CSF granulocyte-macrophage CSF (GM-CSF), and erythropoietin. Likely, undefined factors, including serum batches and medium ingredients, may have profound effects on the results. In addition, the roles of stromal cells, or stroma-conditioned media, and the design of the ex vivo culture vessel (static versus flowthrough reactors), have been demonstrated to be of importance.

More recently, it has been reported that umbilical cord stem cells capable of repopulating NOD/SCID mice could be 2–4-fold expanded in 4-day liquid cultures.¹²⁹ In 10–12-week cultures, up to a 1000-fold expansion of human stem cells measured as CAFC week 6 was observed on stromal cell lines generated from murine midgestational AGM regions^{130,131} in the presence of at least exogenous Tpo.¹³² An extraordinary finding has been that HSC from umbilical cord and placental blood can be maintained and expanded for over 20 weeks ex vivo, with a total calculated 200 000-fold numerical expansion of LTC-IC if they were exposed only to Flt3-L and Tpo.¹³³ During that extended culture period, the HSC still maintained the capacity to differentiate into various lineages, including the B- and T-lymphocytic lineages. However, at present, there is insufficient reproducible evidence that a net increase in long-term in vivo repopulating HSC can be achieved by short-term bulk culture of a graft. Such evidence should come from the demonstration that ex vivo expanded stem cells still possess their long-term in vivo repopulating ability in immune-deficient mice or, better, in a human transplantation setting. In addition, we do not know how ex vivo propagation will affect the behavior of HSC in the recipient, including their post-transplantation homing to hematopoietic organs or in the aging process. The identification of more primitive precursors of hematopoietic stem cells²⁶ that proliferate extensively ex vivo without obvious senescence or loss of differentiation potential holds promise for an ideal source of stem cells for clinical use.

2 Stem cell plasticity

Balkrishna N Jahagirdar and Catherine M Verfaillie

Introduction

For many years, it was thought that embryonic stem (ES) cells were the only pluripotent cells¹ and that somatic stem cells found in postnatal life have a differentiation potential that is limited to a single organ system, as the result of a number of specification and commitment steps during development. For instance, hematopoietic stem cells (HSC), which are part of the splanchnic mesoderm, differentiate² to the myeloid and lymphoid hematopoietic lineages, but not cell types outside of the hematopoietic system, in the mesoderm or other germ layers. However, several recent reports have challenged this concept: at least 30 reports have suggested that the stem cells residing in one postnatal organ can differentiate to cells of an entirely different organ system and can therefore cross lineage and even germ layer boundaries.³ This phenomenon of presumed wider differentiation potential of postnatal stem cells has been termed 'stem cell plasticity'. Although this greater potential has caused significant excitement in the scientific and non-scientific community, the reports have also been viewed with skepticism. This arises from several factors, including the low levels of trans differentiation observed, the fact that some studies could not be repeated, and most of all the fact that this phenomenon would contradict the dogma that somatic stem cells have been lineage-primed and committed early during development. Several theories have been proposed to explain the apparent plasticity of postnatal stem cells, most of which can be supported with scientific observations. In this chapter, we will first review the criteria that are used to characterize stem cells and that thus should be used to characterize the plasticity of stem cells, discuss the evidence for stem cell plasticity, and then review potential mechanisms that may explain this plasticity.

The concept of the stem cell

Stem cells are defined by their biological function (Figure 2.1). Stem cells are undifferentiated cells that self-renew,² which is critical for maintaining the stem cell pool. Stem cells differentiate to give rise to, in general, at least two mature functional progeny cells, and this occurs in a clonal manner, i.e. a single stem cell should differentiate into two or more different cell types. In addition, a stem cell should be capable of replacing a damaged organ or tissue for the lifetime of the recipient. Some would argue that stem cells should also be capable of functionally integrating into non-damaged tissues.³

A fertilized egg is considered a totipotent stem cell, as it gives rise to both intra- and extra-embryonic cells.

Figure 2.1 Definition of a stem cell. Stem cells are defined by their biologic function. They are undifferentiated cells that (1) self-renew, which is critical for maintaining the stem cell pool and (2) differentiate to give rise to, in general, at least two mature functional progeny cells. The stem cell differentiation occurs in a clonal manner, i.e. a single stem cell should differentiate into two or more different cell types. In addition, a stem cell should be capable of replacing a damaged organ or tissue for the lifetime of the recipient.

The inner cell mass of the pre-implantation embryo is considered pluripotent, as these cells give rise to all somatic stem cells, progenitors, and mature cells, as well as germ cells, but not the trophoblast. When removed from the blastocyst and cultured *ex vivo*, cells from the inner cell mass are termed embryonic stem (ES) cells. ES cells were first described for the mouse, and more recently for non-human primates and humans.^{4–8} ES cells spontaneously differentiate into embryoid bodies, which contain cells of the ectodermal, mesodermal, and endodermal lineages. When injected under the skin, in muscle, or under the kidney capsule, ES cells will create teratomas that again contain differentiated cells from all three germ layers. Finally, when injected into a developing blastocyst, ES cells contribute to all tissues of all three germinal layers as well as the gametes. ES cells have proven to be a powerful tool for understanding the normal development and pathogenesis of several diseases. Because ES cells differentiate into relatively homogeneous populations of differentiated ectodermal, mesodermal, and endodermal cells^{9–17} under specific inductive *ex vivo* culture conditions, they have great therapeutic potential. However, their embryonic origin has raised several ethical concerns.

In postnatal life, stem cells maintain the integrity and function of organ systems by replacing the cells that are lost due to normal wear and tear, apoptosis, or injury. Stem cells have been identified in several postnatal organs. Despite extensive investigations, the phenotype of most somatic stem cells remains ill defined, with no single phenotypic marker unique to any stem cell. Many stem cells efflux Hoechst 33342 dye, due to presence of the ABC transporter, BCRP1,¹⁸ and distinctly form a ‘side population’ (SP) on fluorescence-activated cell sorter (FACS) analysis.^{19,20} However, the SP phenotype is not unique to stem cells and is also shared by malignant and multidrug-resistant cells, as well as more mature cells such as natural killer (NK) cells. Several laboratories have used the SP phenotype to isolate stem cells, as described below. Other markers found on stem cells include CD34, AC133, c-Kit, Sea1, and Thy-1.^{21–24} However, not all stem cells are positive, and cells other than stem cells also express these markers. Therefore, identification of stem cells requires functional assays, to demonstrate their self-renewal potential and clonal multilineage differentiation potential.

Hematopoietic stem cells

HSC are by far the best-characterized postnatal stem cells, with extensive *in vitro* and *in vivo* data. They can be found in the SP population.^{19–20} They are (at least in humans), CD34⁺ and AC133⁺, do not express lineage commitment markers, and express Sea1 (mouse),^{21–25} low levels of Thy-1, and c-Kit. HSC provide a constant supply of hematopoietic cells in normal individuals. Several studies have elegantly shown that a single murine HSC can repopulate the myeloid and lymphoid lineages following transplantation, and can rescue animals²⁶ from lethal irradiation. In humans, single-cell transplantation is not possible. However, retroviral marking studies have shown that a single human HSC can contribute to all hematopoietic lineages after transplantation.²⁷

Neural stem cells

The discovery of neural stem cells (NSC) in adults was initially unexpected, as it was thought that in postnatal life, nervous tissue could not be repaired. However, more recently, stem cells for the central nervous system (CNS) have been identified in postnatal brain, including the olfactory bulb and the peri ventricular zone.^{28–29} A recent study has shown that NSC can be purified from neurogenic areas of human brain using antibodies against the stem cell antigen AC133.²³ Rodent and human NSC can be expanded *ex vivo* for many population doublings when cultured as neurospheres. Single NSC differentiate *in vitro* and *in vivo* into neurons, astrocytes, and oligodendrocytes, and migrate *in vivo* to specific sites of damage.³⁰ Likewise, stem cells for the peripheral nervous system have been found in the spinal cord.³¹

Mesenchymal stem cells

In bone marrow (BM)^{32–36} and also fat tissue,³⁷ mesenchymal stem cell (MSC) have been identified, which differentiate into osteoblasts, chondroblasts, adipocytes, fibroblasts, and skeletal muscle. MSC do not express classical stem cell antigens such as CD34 and AC133.^{35,36} It is not known whether they purify in the SP fraction of fat or BM cells. MSC can be culture-expanded for several passages without losing their differentiation potential. Ring cloning studies have suggested that such differentiated progeny is indeed derived from single MSC.³⁵

Epithelial stem cells

‘Oval cells’ that reside in the canals of Herring are thought to be the stem cells for hepatocytes and biliary epithelial cells. Oval cells can be found in the CD34⁺, c-Kit⁺, and Thy-1⁺ fraction of liver cells.^{38,39} It is not known whether they can be selected based on an SP phenotype. In response to liver injuries, oval cells proliferate and eventually differentiate into liver and biliary epithelial cells.³⁸ When cultured *ex vivo*, oval cells can be induced to differentiate into these two cell types.^{40–41} Because terminally differentiated hepatocytes have extensive proliferative potential, they are usually responsible for liver regeneration.⁴² The exact role of oval cells in liver regeneration is unclear at present, except under those circumstances where mature hepatocytes are incapable of mounting a proliferative response.^{43–44}

The constantly shed epithelium of the skin is replaced by epithelial stem cells present in the bulge zone of the follicular epithelium, which give rise to skin epithelium as well as to hair and other skin appendages.⁴⁵ Stem cells for the different types of epithelial cells lining the gastric, duodenal, jejunal, ileal, and colonic epithelia have been identified,⁴⁶ residing in the crypts.

Muscle progenitor cells

Satellite cells are thought to be the progenitors for skeletal myoblasts. Satellite cells are mononuclear cells present under the basal lamina that surrounds multinucleated skeletal muscle fibers.⁴⁷ They form myotubes in vitro and contribute to skeletal muscle fibers in response to muscle damage in vivo.⁴⁷ In contrast to the cell types described above, satellite cells only give rise to a single mature progeny cell, and are therefore not 'classical' stem cells.

Other stem/progenitor cells

Angioblasts are progenitors for endothelial cells. Like satellite cells, angioblasts do not fulfill all criteria for a stem cell, as differentiation to endothelium only has been described. Angioblasts can be found in the CD34⁺ and AC133⁺ fraction of blood and BM.^{48–50} Stem cells have also been identified for many other tissues, including the retina, the cornea, and the skin, even though the phenotype of the latter cells is less well defined.

Evidence for stem cell plasticity

The traditionally held view of stem cell differentiation—linear and irreversible lineage restriction—is challenged by several recent reports, which suggest that stem cells residing in one postnatal organ can differentiate into cells of an entirely different organ system and therefore have much wider differentiation potential—or are much more plastic—than previously thought (Figure 2.2). Since the initial report of in vivo myogenic differentiation of BM-derived cells by Ferrari et al,⁵¹ over 50 studies claiming stem cell plasticity have been published.

The majority of studies have identified donor-derived non-hematopoietic cells, based on identification of the Y chromosome in recipients of sex-mismatched BM transplants, whereas others have demonstrated plasticity based on transgenic expression of LacZ or enhanced green fluorescent protein (eGFP) in the donor cells. Few studies have shown that lineage switch occurs even in the absence of tissue damage, whereas most studies showed lineage switch in animals with injury to a specific organ. These studies vary widely in the criteria used to define and select stem cells as well as in the details of the experimental

Figure 2.2 Stem cell plasticity. Several recent reports suggest that stem cells residing in one postnatal organ can give rise to cells from an entirely different organ. This phenomenon of apparent wider potential of the adult stem cells is called 'stem cell plasticity'. Persistence of pluripotent stem cells in postnatal organs, somatic cell fusion, and dedifferentiation and transdifferentiation of organ-specific stem cells have all been proposed as mechanisms underlying this phenomenon.

designs. In the following section, we will discuss a selection of representative studies.

Plasticity of BM-derived stem cells

BM is an attractive source of stem cells for several reasons. First, large numbers of BM cells can be harvested without harming the donor and with relative established procedure in the mouse, which is often ease. Second, BM transplantation (BMT) is a well-the first experimental animal, as well as in humans. Third, BM-derived cells may have 'natural' access to the circulation and therefore may be able to correct damage to a 'distant organ'.

For decades, it has been known that BM contains HSC. More recent studies have shown that BM contains MSC and angioblasts. Recent stem cell plasticity studies have suggested that BM may also contain cells that differentiate in vitro and/or in vivo in other cell types of endodermal and ectodermal origin.

Skeletal muscle from BM-derived cells

The growth and regeneration of skeletal muscle fibers in postnatal life is considered to be the function of satellite cells.⁴⁷ However, the number of resident satellite cells in the adult muscle is significantly lower than the number of committed myogenic precursors that populate the muscle tissue after muscle injury. Migration of myogenic precursors from the adjacent fibers, or recruitment of resident non-myogenic cells, such as fibroblasts and MSC, have been proposed to explain this paradox. Ferrari et al,⁵¹ for the first time, demonstrated that BM-derived cells

contribute to skeletal muscle myogenesis following muscle injury. Following cardiotoxin-induced tibialis anterior muscle damage in *scid/bg* mice (which lack T- and B-lymphocyte and NK-cell function), unfractionated BM from *C57/MlacZ* transgenic mice (which express nuclear β -galactosidase enzyme under the control of the muscle-specific myosin light-chain promoter) was injected into the damaged muscle. Alternatively, tibialis anterior muscles of *scid/bg* mice that had stable hematopoietic engraftment following BMT from *C57/MlacZ* mice were chemically damaged. In both sets of recipient animals, donor BM-derived cells formed immature centrally nucleated and mature peripherally nucleated myofibers in the damaged muscle. BM-derived myogenesis occurred 7–10 days later than satellite cell-derived myogenesis, suggesting that the satellite cells may represent a committed muscle progenitor, whereas cells in BM may precede the satellite cells in ontogeny. However, the investigators did not show that BM-derived cells contributed to the satellite cell pool. The population of BM cells that does not adhere to plastic had less in vivo myogenic potential than plastic-adherent cells. It is therefore possible that the myogenic cell is derived from MSC, which are plastic-adherent, and not from HSC, which are not plastic-adherent. The exact phenotype of the myogenic cell in BM was not defined. In addition, the investigators did not demonstrate that BM-derived myocytes displayed normal muscle function.

Gussoni et al.⁵² intravenously injected 2000–5000 BM-derived SP cells from male *C57/MlacZ* mice into lethally irradiated female *mdx* mice, a model of Duchenne muscular dystrophy. Aside from hematopoietic recovery from donor origin, they also showed the presence of up to 4% LacZ-positive, dystrophin-positive muscle fibers at 12 weeks post transplant in the tibialis anterior muscle, with 10–30% of these containing Y-chromosome-positive donor nuclei. The phenotype of the SP cells is Sca1⁺c-Kit⁺Lin⁻CD45⁺CD34⁻, consistent with an HSC phenotype. In another set of experiments, these investigators injected *C57/MlacZ* skeletal muscle-derived SP cells into lethally irradiated *mdx* mice and showed that the muscle-derived SP cells reconstitute hematopoiesis and contribute to skeletal myogenesis. Unlike BM-derived SP cells, the muscle-derived SP cells were Sca1⁺c-Kit⁻Lin^{+/}-CD45⁻, suggesting that the stem cell population derived from these two organs may be distinct but shares the SP phenotype. However, as was shown in subsequent studies by McKinney-Freeman et al.⁵³ and Kawada et al.,⁵⁴ it cannot be ruled out that hematopoietic engraftment was due to HSC present in muscle. Two additional points regarding this study merit consideration. First, a proportion of myocytes from the *mdx* mouse are known to spontaneously revert to synthesize dystrophin and the immunohistochemical methods do not distinguish between donor-derived and native *mdx* dystrophin. Hence, identification of donor-derived myocytes based on dystrophin expression in the *mdx* model may overestimate the number of donor-derived cells. In the *mdx4cv* mouse model, which has almost no spontaneous synthesis of dystrophin, donor-BM-derived cells contributed to a maximum of 1% skeletal muscle fibers.⁵⁵ Second, donor-derived cells formed maximally 4% myocytes at 12 weeks post transplantation. The low level of donor-derived myogenesis seen in this study may not be expected to functionally correct the myopathy, although muscle function was not formally assessed here.

These studies thus suggest that BM contains myogenic progenitors, which may have an MSC or an HSC phenotype. Whether the same cell gives rise to myoblasts and hematopoietic cells, or myoblasts and other mesenchymal cell types—a prerequisite for ‘stem cell plasticity’—is not known. From a therapeutic standpoint, the current level of BM-derived myogenesis is probably not sufficient to correct myopathy. Here, it should be stressed that in the *mdx* mouse model the native myogenic precursors regenerate muscle throughout life. Hence, the low degree of donor-derived myogenesis in the *mdx* mouse model could be explained by the lack of selective growth advantage to the donor over the native myogenic precursors.⁵⁶ However, in Duchenne muscular dystrophy patients, where the degenerating muscles undergo fibrosis, it is possible that the donor-derived myogenic precursors may have a selective growth advantage and progressively replace the diseased muscle with functional muscle fibers.⁵⁷ Future studies are expected to address this issue.

Myocardium from BM-derived cells

Until recently, it was believed that adult cardiomyocytes do not replicate.⁵⁸ Following coronary artery occlusion, cardiomyocytes undergo ischemic necrosis, which eventually heals with fibrosis and often results in ventricular failure, although this notion has recently been challenged.⁵⁹ The high prevalence of cardiomyopathy from ischemic and non-ischemic causes has led several investigators to search for noncardiac sources of stem cells that can regenerate cardiomyocytes and revert ventricular dysfunction. Orlic et al.⁶⁰ for the first time, demonstrated that c-Kit⁺Lin⁻ BM mononuclear cells may generate cells with cardiomyoblast features when injected in the peri-infarct myocardium. They demonstrated that about 50% of regenerating cardiomyocytes in the female heart were donor-derived male cells with cardiomyocyte, vascular smooth muscle cell, and endothelial phenotype. This translated into improvement by 36% of left ventricular (LV) diastolic function—the LV end-diastolic pressure in the study animals. c-Kit⁻ BM cells did not contribute to the regenerating myocardium. Although the c-Kit⁺Lin⁻ cell population

contains HSC, it is not known whether a single cell gives rise to hematopoietic progeny and cells with cardiac myocyte characteristics. HSC express c-Kit on their cell membrane.⁶¹ It is thought that membrane-bound stem cell factor (SCF, Steel factor, c-Kit ligand) mediates the migration of HSC and other primitive cells to their target organs.⁶¹ Because SCF and granulocyte colony-stimulating factor (G-CSF) mobilize c-Kit⁺ BM cells into the circulation,⁶² Orlic et al⁶³ also treated mice with SCF and G-CSF between 5 days before and 3 days after experimental induction of acute LV myocardial infarction. The cytokine-treated animals showed significant improvement in ventricular hemodynamics and mortality at 28 days (approximately 80% survival in treated versus approximately 20% in control animals), which could be attributed to increased cardiomyocyte, endothelium, and vascular smooth muscle regeneration. However, whether the mobilized BM cells contributed to the regeneration or the cytokines had a direct effect on the area of infarction could not be determined by this study.

Jackson et al⁶⁴ transplanted BM-derived SP cells into lethally irradiated murine hosts. After hematopoiesis was re-established, a LV infarct was induced by coronary artery occlusion for 50 minutes. Donor-derived cardiomyocytes (0.02–0.3%) could be detected, even though the frequency was significantly lower than what was reported by Orlic et al, after in situ delivery of BM cells or mobilization with SCF and G-CSF. The degree of chimerism seen in the study by Jackson et al is unlikely to be of functional importance, even though this was not directly tested.

Endothelium from BM-derived cells

Vasculogenesis and angiogenesis are the mechanisms responsible for the development of blood vessels. Vasculogenesis refers to in situ differentiation and growth of blood vessels from mesodermal-derived hemangioblasts that give rise to the heart and the first primitive vascular plexus inside the embryo and in its surrounding membranes, as the yolk sac circulation.⁶⁵ Angiogenesis is responsible for the remodeling and expansion of this network. The most important positive regulators of Vasculogenesis and angiogenesis are vascular endothelial growth factor (VEGF) and its receptors fetal liver kinase 1 (Flk1) and Fms-like tyrosine kinase (Flt1), the angiopoietin/tie system, and the ephrin-B/Eph-B system.⁶⁵ In postnatal life, angiogenesis is essential for a variety of physiological processes, such as female reproduction, wound healing, and neovascularization of ischemic tissue. Until recently, it was thought that blood vessel formation in postnatal life was entirely the process of angiogenesis and not Vasculogenesis. However, recent studies have suggested that endothelial stem cells may persist into adult life and contribute to neoangiogenesis, so that the neoangiogenesis in the adult may be at least in part from Vasculogenesis.^{66–68} Precursors of endothelial cells, angioblasts, have been isolated from BM and peripheral blood.^{66–69} Lin et al⁶⁹ showed that in recipients of sex-mismatched BMT who had 100% donor hematopoietic engraftment, most of the circulating endothelial cells (CEC) isolated from fresh blood had recipient genotype. In contrast, blood-outgrowth endothelial cells (BOEC), thought to represent angioblasts, were mostly of donor genotype. The recipient-genotype endothelial cells expanded only about 20-fold over this period, whereas donor-genotype endothelial cells expanded about 1000-fold. These data suggest that most CEC in fresh blood originate from vessel walls and have limited growth capability and that BOEC is mostly derived from transplantable marrow-derived cells. Because these cells had more delayed outgrowth but a greater proliferative rate, they were likely to be derived from circulating angioblasts.⁶⁹ Lyden et al⁶⁷ showed that BM-derived angioblasts are responsible for tumor angiogenesis. These investigators used angiogenic-defective, tumor-resistant Id-mutant mice to show that transplantation of wild-type BM or VEGF-mobilized stem cells restores tumor angiogenesis and growth. Donor-derived circulating endothelial precursors were detected throughout the tumor neovasculature.⁶⁷ Although the exact phenotype of angioblasts is not completely known, they are CD34⁺, VE-cadherin⁺, AC133⁺, and Flk1⁺. Reyes et al⁶⁸ have shown that rare multipotent cells in human and murine postnatal BM, called multipotent adult progenitor cells (MAPC) exist that are CD34⁺, VE-cadherin⁺, AC133⁺, and Flk1⁺. When cultured with VEGF, MAPC differentiate into CD34⁺VE-cadherin⁺Flk1⁺ cells—a phenotype that would be expected for angioblasts, and ultimately differentiate into mature functional endothelial cells that contribute to tumor and wound-healing angiogenesis in vivo.⁶⁸ MAPC may be the putative progenitor for angioblasts. Given these studies, it is not surprising that unfractionated BM mononuclear cells can give rise to endothelium when implanted into non-hematopoietic tissue, such as infarcted myocardium.^{60,63,64}

Neural cells from BM-derived cells

Developmentally, neurons are derived from the embryonic neuroectoderm, whereas glial cells can be derived from either myeloid cells (microglia) or NSC (astroglia and oligodendrocytes). Recent studies have suggested that BM can give rise to cells with neuronal markers in vivo. Eglitis et al⁷⁰ were the first to show that BM-derived cells can give rise to both microglia and macroglia in the brains of adult mice. Since then, Mezey et al and Brazelton et al have found Y-chromosome-containing NeuN⁺ cells in the brains of female mice that received BM from male donors after lethal irradiation⁷¹ and in newborn PU.1 murine recipients.⁷² Whether a single cell gave rise to neuron-like cells and HSC was not addressed. In addition, full characterization of BM-derived neuron-like cells and

glia-like cells in terms of their integration into host tissue (e.g. ability to form synapses) and function in vivo is lacking at this point. Several groups have now shown that BM MSC and MAPC can differentiate in vitro into cells that have morphological and phenotypic markers of neurons, astrocytes and oligodendrocytes.^{73,74} Again, functional characterization of the neuron-like progeny has yet to be done.

Liver from BM-derived cells

Initial experiments testing hepatocyte regeneration from BM-derived cells involved transplantation of male BM into myeloablated female recipients and demonstrating the presence of donor-derived cells, containing a Y chromosome, by fluorescence in situ hybridization (FISH) and bearing hepatocyte antigens in the recipient's liver.⁷⁵⁻⁷⁸ As will be discussed below, these results could be explained by the coexistence of hepatocyte progenitors and HSC within BM.⁷⁹

The strongest evidence for generation of hepatocytes from BM-derived HSC comes from Lagasse et al.⁸⁰ These investigators systemically infused as few as 50 c-Kit⁺Thy^{low}Lin⁻Sca1⁺ (KTLS) cells derived from the BM of *lacZ* transgenic mice into lethally irradiated FAH^{-/-} mice (fumarylacetoacetate hydroxylase mutant mice—a model of hereditary tyrosinemia). FAH^{-/-} mice die from hepatic failure, unless they are fed NTBC, a substance that blocks the production of fumaryl acetoacetate, which is a substrate for FAH. The recipient animals were maintained on an interrupted course of NTBC for 7 months. The interruptions in NTBC were designed to give a selective growth advantage to the donor cells. After 7 months, when the NTBC was completely stopped, the KTLS cell-transplanted animals survived, and had donor-cell-derived clusters of hepatocytes and marked improvement in biochemical markers of hepatocyte function, indicating that the donor-KTLS cell-derived hepatocytes were functional. Neither study has shown that a single HSC could also differentiate into hepatocytes.

Plasticity of NSC

After transplantation of genetically labeled NSC into irradiated mice, NSC differentiated into myeloid, lymphoid, and early progenitor cells,⁸¹ indicating that adult NSC can adopt a hematopoietic fate in vivo. However, a more recent study indicated that such a phenomenon may be rare.⁸² Clarke et al⁸³ injected adult mouse brain-derived NSC into the amniotic cavity of early chick embryos and found that the NSC contributed to the formation of tissues from all the germ layers. However, in this study no embryos were allowed to be born.

Plasticity of skeletal muscle-derived cells

Jackson et al⁸⁴ initially reported that postnatal skeletal muscle-derived cells can adopt a hematopoietic fate and rescue a lethally irradiated host. However, subsequently using Ly5.1/5.2 mismatch transplant, Kawada et al⁸⁴ have shown that the cells with hematopoietic potential that reside in the skeletal muscle are hematopoietic stem cells. A more recent study by McKinney-Freeman et al⁵³ also demonstrated that the cell in skeletal muscle that contributes to hematopoietic recovery is CD45⁺, indicating that HSC lodge in muscle.

Pitfalls in plasticity studies

Several factors merit consideration when evaluating studies regarding changes in stem cell fate. First, as true stem cell plasticity should be defined as a single tissue-committed stem cell being capable of differentiating into that tissue and a second unrelated tissue, studies using unselected populations of cells (e.g. unfractionated BM) are difficult to interpret. Indeed, as will be discussed below, most tissues are heterogeneous and may contain multiple stem cells. Even within a population of cells that is selected based on the expression of certain markers, there may be heterogeneity. Therefore, true plasticity can only be defined by transplanting a single cell⁷⁸ or by retroviral marking.^{74,85}

Second, acquisition of a different fate by the stem cell is mostly based on the detection of a donor marker in the cells that express markers of the differentiated cell. Several difficulties may occur in interpreting results. A common method used to identify the donor origin of cells is demonstration of a Y chromosome by FISH in male-female transplantation studies. A false impression of colocalization of the Y chromosome in the cell that expresses a tissue-specific cytoplasmic or cell membrane marker can be created by overlap of the nucleus from an adjacent cell, such as a circulating hematopoietic cell. Somewhat less problematic is the use of transgenically expressed tracers, even though this too may lead to a false impression of engraftment and differentiation. Optimally, the tracer should be activated by a tissue-specific promoter, as this then demonstrates engraftment and activation of a tissue-specific genetic program.⁵²

Third, the mere presence of one or two markers consistent with differentiation into a lineage different from the lineage of origin does not suffice to demonstrate true lineage switch. There should be functional characterization of the new lineage. Most studies to date, with a few exceptions,^{68,74,80,85} have fallen short in demonstrating functional 'plasticity'.

Potential mechanisms underlying stem cell plasticity

Why, then, should cells residing in one postnatal organ acquire the fate of cells from another organ?

Several theories have been proposed to explain the plasticity of postnatal stem cells.

Multiple tissue-specific stem cells are present in different organs

HSC exit the BM space, circulate in the peripheral blood, and 'home' in on different organs—a concept used clinically in peripheral blood transplantations.⁸⁶ Recent studies have also shown that HSC reside within muscle,^{53–54} and that such muscle HSC can contribute to the hematopoietic system when transplanted in lethally irradiated animals. Aside from HSC, BM contains MSC and endothelial progenitors. More recently, a study has shown that BM may also contain cells with characteristics of oval cells, the progenitors for hepatic and biliary epithelial cells.⁷⁹ Thus, liver regeneration following BMT could be the results of infusion of hepatic oval cells present in the BM sample.

Plasticity is the result of fusion of the donor cell with resident cells in an organ

It has long been known that cellular fusion can change the fate of a cell, as heterokaryon studies were already performed early in the 20th century and a number of studies have shown that cell fate can be changed upon heterokaryon formation. These studies have shown that cytoplasm of one cell has factors that induce a new fate upon the cell with which it fuses.⁸⁷ That this may occur in stem cell studies was suggested in two recent studies documenting that coculture of adult tissue cells with ES cells leads to cell fusion and imposition of the ES fate on the fused, tetraploid resulting cell. Terada et al⁸⁸ cocultured murine BM cells with ES cells and Ying et al performed similar studies with fetal and adult murine NSC murine fetal or adult NSC.⁸⁹ Both groups demonstrated that such coculture yields what appeared initially to be 'transdifferentiated' BM cells or NSC that had acquired ES characteristics. The apparent switch was caused by fusion of an ES cell with $1/10^5$ – $1/10^6$ BM cells or NSC, yielding cells with ES characteristics that were tetraploid. The authors of these papers pointed out correctly that this mechanism may underlie at least some of the apparent 'plasticity', even though studies were only done using ES/adult cell coculture, and were only done in vitro.

Cells undergo dedifferentiation and redifferentiation

'Dolly' the sheep has taught us that genetic information of a cell can be reprogrammed, and that somatic cells can dedifferentiate into pluripotent cells.⁹⁰ Even before Dolly, it was known from studies in amphibians such as *Urodeles*, which can regenerate whole limbs, that differentiated somatic cells can dedifferentiate and generate multiple cell types required for regeneration of whole body parts. The mechanisms underlying this dedifferentiation are not totally understood, although the homeobox gene *Msx1*, expressed in the regenerating blastema, appears to play an important role. It has been demonstrated that overexpression of this homeobox gene in myotubes derived from the C2C12 cell line causes myotubes to regress into multiple mononuclear cells, which now proliferate and gain the ability to differentiate not only into myoblasts but also into osteoblasts, chondrocytes, and adipocytes.⁹¹ Other examples of possible dedifferentiation include the capability of oligodendrocyte progenitors from the optical nerve, maintained in serum-free and low-density culture conditions, to acquire what appear to be NSC characteristics,⁹² pancreatic epithelium to acquire a hepatic phenotype,⁹³ and hepatocytes to acquire a pancreatic fate.^{94–95}

True multi/pluripotent stem cells persist

Finally, there is mounting evidence that cells with greater multipotency may persist beyond gastrulation. Suzuki et al⁹⁶ isolated what appears to be an endodermal stem cell from murine fetal liver at e14. They demonstrated that a $VLA6^+c\text{-Met}^+CD34^-Thyl^-c\text{-Kit}^-$ cell can be purified by FACS and culture-expanded, and that upon transplantation into postnatal animals it differentiates not only into liver and biliary epithelial cells but also into epithelium of the pancreas and the gastrointestinal tract. As discussed above, muscle can generate hematopoietic cells. Although two groups have now shown that this is at least in part due to resident HSC in muscle, there is also evidence from mouse genetics that a progenitor may exist in muscle that can differentiate into either muscle or hematopoietic cells—a process governed by the transcription factor Pax7.⁹⁷ Finally, Jiang et al⁷⁴ showed that cells copurifying with MSC can differentiate into most, if not all, somatic cell types. As these cells are maintained in culture, the verdict is open as to whether this represents resident multipotent cells or dedifferentiation of MSC in vitro. These studies suggest therefore that cells that precede the known somatic stem cells may persist, and, depending on the milieu, differentiate into cells different than the organ of origin.

Conclusions and future directions

The traditionally held view of stem cell differentiation is that of linear and irreversible lineage restriction. Several recent reports have suggested that stem cells residing in one postnatal organ can differentiate into cells of an entirely different organ system and therefore have much wider differentiation potential—or are much more plastic—than was previously

thought. Although such greater potential has caused significant excitement in the scientific and non-scientific community, the reports have also been viewed with skepticism. This arises from several factors, including the low levels of trans differentiation observed, the fact that some studies could not be repeated, and most of all the fact that this phenomenon would contradict the dogma that somatic stem cells have been lineage-primed and committed early during development. Future studies are expected to explore the molecular mechanisms underlying stem cell fate change, and to use them to optimize the number of derived differentiated cells. If a substantial number of cells of therapeutic interest can indeed be derived from an alternative organ source, especially from an autologous source, and these cells can be used to improve the function of a diseased organ, this will bring about a revolution in the medical field.

Cytokine receptors and signal transduction

Ivo PTouw and Thamar B van Dijk

Introduction

marrow microenvironment and by soluble polypeptide complex network of signals, provided by the bone marrow growth factors or cytokines, tightly regulates the balance between proliferation, differentiation, and survival of hematopoietic precursor cells. Hematopoietic cytokines include colony-stimulating factors (CSFs), erythropoietin (EPO), thrombopoietin (TPO), stem cell factor (SCF), Flt3 ligand, and certain interleukins (ILs). Cytokines exert their function by binding to their cognate transmembrane receptors on the surface of target cells. Some receptors, like those for granulocyte CSF (G-CSF-R), EPO (EPO-R), and TPO (TPO-R, also known as Mpl), form homodimeric or -oligomeric complexes. Many other receptor systems, however, are heteromers composed of two or three different receptor subunits. Notably, these heteromeric receptors may share subunits. Examples of such common receptor subunits are the γ chain shared by a number of IL-Rs, the gp130 shared by, for example, IL-6R and IL-11R, and the β common chain shared by IL-3R, IL-5R, and GM-CSF-R (Figure 3.1).¹⁻²

The interaction between growth factors and their receptors causes either the oligomerization of receptor components or a conformational change of preexisting receptor dimers.^{3,4} This subsequently results in the activation of intracellular protein tyrosine kinase activity and the generation of intracellular signals.⁵ Two major groups of tyrosine kinase-linked receptors can be distinguished that act in this way: the cytokine receptor superfamily introduced above, which associate with intracellular tyrosine kinases, and the receptor tyrosine kinases (RTKs), which have an intrinsic tyrosine kinase activity. The receptor for macrophage CSF (M-CSF-R, also referred to as c-Fms or CSF-1R), FLT3 (Fms-like tyrosine kinase receptor), and the receptor for SCF (SCF-R, also known as c-Kit) belong to this latter category of RTKs.⁶ As we will see later, transforming mutations contributing to malignant transformation of hematopoietic cells occur most frequently in this group of receptors. These mutations induce growth factor-independent multimerization, affect autoinhibitory regions, or directly affect the tyrosine kinase domain itself. Invariably, these defects lead to uncontrolled and increased tyrosine kinase activity. Activating mutations in the receptors of the cytokine receptor superfamily are less prominent, probably because these receptors do not contain an intrinsic tyrosine kinase domain.⁷ However, several hematopoietic disorders have been associated with mutations that alter the signaling

Figure 3.1 Homodimeric and heteromeric composition of class I cytokine receptors. The four cysteines and WSXWS motif are characteristic of this receptor superfamily. Heteromeric receptors within different clusters may share common receptor subunits (see text).

function of these receptors in a qualitative and/or quantitative manner. In this chapter, we will first summarize the major features of normal cytokine signal transduction and its subsequent downregulation. Then we will discuss some of the consequences of receptor abnormalities and the resulting signaling defects for the pathogenesis of hematological diseases, including leukemia.

Cytokine receptor signaling

The JAK-STAT pathway

As explained above, the first intracellular event in cytokine-mediated signal transduction is the initiation of tyrosine kinase activity. Cytokine receptors lack intrinsic tyrosine kinase activity and rely for their function on cytoplasmic tyrosine kinases, in particular of the Janus kinase (JAK) family (Figure 3.2a). The JAK family comprises four mammalian members: JAKs 1–3 and TYK2. Upon their activation via transphosphorylation on tyrosines, JAKs phosphorylate the tyrosine residues in the intracellular domain of the receptor. The phosphorylated tyrosines in both the receptor and JAKs then provide docking sites for signaling proteins with an Src-homology 2 (SH2) domain. The STAT (signal transducer and activator of transcription) proteins form a major group of signaling molecules activated in this way (Figure 3.2a). Once phosphorylated on specific tyrosine residues, STATs dimerize or oligomerize and translocate to the nucleus, where they bind to specific DNA sequences (TTCN₂₋₄GAA) in promoter regions, thereby regulating transcription of cytokine-responsive genes.⁸⁻¹⁰ Seven mammalian STAT proteins have been identified (STATs 1–6, STAT5A, and STAT5B). Studies in STAT knockout mice have shown that STATs 1, 2, 4, and 6 have specialized functions: STATs 1 and 2 are crucial in the antiviral response induced by interferons;¹¹⁻¹³ STATs 4 and 6 are exclusively activated by IL12 and IL-4 respectively and therefore play decisive roles in T helper cell (Th1/Th2) development.¹⁴⁻¹⁷ In contrast, STATs 3 and 5 are activated by multiple receptors and play a more general role in controlling the cell cycle by regulation of the expression, for example, *c-myc*, *p21*, *p27*, and *cyclin D1* and cell survival by regulation of, for example, *bcl-x_L*.^{18,19}

It becomes increasingly clear that uncontrolled activity of JAKs and STATs may contribute to malignant transformation of hematopoietic cells. This is most directly exemplified by the cases of human leukemia with chromosomal translocations resulting in oncogenic fusion proteins comprising JAK2 (TEL-JAK2) or STAT5 (STAT5B-RARoc).²⁰⁻²³ Additional evidence comes from studies showing that constitutively active mutants of STATs 3 and 5 are transforming in a variety of models, whereas dominant-negative STAT5 can block the transforming activity of the TEL-JAK2 oncoprotein.^{24,25} Finally, the observation that STATs 3 and 5 are often constitutively phosphorylated in leukemia, lymphoma, multiple myeloma as well as in various solid tumors further supports the notion that abnormal activation of these STAT proteins can contribute to tumor cell growth.

Other signaling pathways

The JAK-STAT pathway is the most direct and potentially most selective route to the regulation of gene

Figure 3.2 Schematic representations of (a) JAK-STAT and Ras and (b) PI3K/PKB signaling pathways, the latter involving recruitment of signaling molecules with pleckstrin homology (PH) domains to the cell membrane through binding to phosphoinositides (PIP₃).

expression, since the SH2-containing target recruited to the receptor complex is the transcription factor itself. Other signals from cytokine receptors take a more tortuous path to the nucleus, providing more opportunity for crosstalk and branching. For example, there are several distinct mechanisms for the activation of the Ras signaling pathway, which may differentially involve the adapter proteins She (Figure 3.2a) and docking proteins such as Gab, and IRS (Figure 3.2b). Via binding of an additional adapter protein, Grb2, the nucleotide exchange factor son-of-sevenless (Sos) is recruited, leading to activation of the Ras protein. Ras, in its turn, stimulates the Raf, MEK, and subsequently the MAPK (mitogen-activated protein kinase) protein serine/threonine kinases. Finally, the MAPKs Erk1 and Erk2, JNK, and p38 regulate transcription by phosphorylating several transcription factor complexes involved in controlling the cell cycle, cell survival, and differentiation.²⁶⁻²⁷ Other examples of signaling substrates activated in this more complex manner include tyrosine kinases of the Src and Tec families, phospholipid kinases, and phospholipases (PLCy).²⁸

Another important signaling cascade is initiated via recruitment of p85, the SH2-containing regulatory subunit of phosphatidylinositol 3'-kinase (PI3K). This lipid kinase catalyzes the generation of phosphatidylinositol 3,4,5-trisphosphate (PI-3,4,5-P₃, or PIP₃ for short), which serves as a docking site for proteins with a pleckstrin homology (PH) domain, for instance the docking proteins Gab and IRS, the serine/threonine kinases PDK1 and PDK2 and protein kinase B (PKB/c-Akt) (Figure 3.2b). Apart from its regulatory function in cellular metabolism, by phosphorylating glycogen synthase kinase 3 (GSK3) and phosphofructokinase 2 (PFK2), and protein synthesis, by phosphorylating 4E-binding protein 1 (4E-BP1) and p70S6-kinase, activated PKB plays a major role in controlling cellular survival and growth. PKB directly phosphorylates the Bcl-2 family member Bad and caspase-9, thereby inhibiting their pro-apoptotic activities. Furthermore, PKB negatively regulates the expression of the cell cycle inhibitors p27 and p130 and the pro-apoptotic factor Bim. This involves inhibition of the activity of the Forkhead transcription factors Foxo1, Foxo3A, and Foxo4 through phosphorylation of these proteins, leading to their retention in the cytoplasm²⁹⁻³¹ (Figure 3.2b).

It should be noted that the above description of signaling mechanisms is simplified and far from complete. It is particularly important to realize that, rather than acting in linear pathways, signaling proteins are increasingly seen to form interactive networks at almost every step of the signaling process. As a consequence, activation of distinct signaling routes often converges on a set of target genes.

Mechanisms that switch off receptor activation

Continuous activation of receptors would eventually lead to uncontrolled responses of the target cells. Therefore, different feedback mechanisms exist to ensure that cytokine receptors act transiently. These mechanisms, depicted in Figure 3.3, include (1) dephosphorylation of phosphotyrosines and PIP₃ by phosphatases or inactivation of Ras-like proteins by GTPase accelerating proteins (GAPs), (2) masking phosphotyrosines by CIS/SOCS proteins, and (3) internalization and degradation of receptor complexes.

Phosphatases and GAPs

Inherent to the fact that the JAK tyrosine kinases are crucial for the cytokine response is that protein tyrosine phosphatases (PTPases) can downmodulate receptor function. Currently, SHP-1 and, to a lesser extent, SHP-2 and CD45 are examples of PTPases whose inhibitory effects on the JAK-STAT pathway have been demonstrated.³²⁻³⁴ SHP-1, also known as hematopoietic cell phosphatase (HCP), binds to phosphorylated tyrosine residues of the receptors via its SH2 domains. Such a direct interaction of SHP-1 with receptor proteins has been demonstrated for the common β chain of the IL-3/IL-5/GM-CSF receptors, the EPO-R, and c-Kit.³⁵ The importance of this mechanism is supported by the phenotype of motheaten mice, which lack Shp-1. These mice suffer from a disease characterized by autoimmunity and inflammation.³⁶ In addition, a human hematological condition, benign

Figure 3.3 Major mechanisms involved in 'switch-off' of receptor signaling.

erythrocytosis, has been linked to a reduced ability of a cytokine receptor to recruit SHP-1 (see below).

Analogous to phosphotyrosine regulation, dephosphorylation of PIP₃ is crucial to silence PI3K signaling. SHIP (SH2-containing inositol-5-phosphatase) is recruited to a number of cytokine receptor complexes and converts PI-3, 4, 5-P₃ to phosphatidylinositol 3, 4-bisphosphate (PI-3, 4-P₂). SHIP^{-/-} mice display a chronic progressive hyperplasia of myeloid cells, associated with increased PKB phosphorylation and reduced apoptosis.³⁷ The tumor suppressor PTEN (phosphatase and tensin homolog deleted on chromosome 10) dephosphorylates the 3 position of both PI-3, 4, 5-P₃ and PI-3, 4-P₂, and is therefore a more complete antagonist of PI3K than SHIP. Strikingly, many cell lines and cells from solid tumors show deletions or mutations in the *PTEN locus*, suggesting an important role of this protein in normal growth control. PTEN^{-/-} cells have an extremely high phospho-PKB level, associated with increased survival and proliferation.³⁸

As will be explained in more detail in Chapter 27, proteins of the Ras family are inactivated by a group of enzymes that accelerate the GTPase activity of these proteins, thereby reverting the GTP-bound (active) state of Ras-like proteins to their inactive GDP-bound state. These RasGAP proteins can be recruited into the receptor complexes, for example, via interaction with docking proteins such as Dok (Figure 3.3).

CIS/SOCS/JAB/SSI proteins

Shortly after the cytokine inducible SH2-containing protein CIS (cytokine-inducible substrate) was cloned in 1995, it turned out to be the prototype of a new family of proteins with negative regulatory functions in cytokine receptor signaling.³⁹ The CIS family comprises eight members that bear the alternative names SOCS (suppressor of cytokine signaling), JAB (JAKbinding protein), and SSI (STAT-induced STAT inhibitor). The principle mode of action of these proteins is that the SH2 domains block critical phosphotyrosines in either receptors or JAKs. CIS is a direct target of STAT5, while SOCS1 and SOCS3 are STAT1, 3-responsive genes. Upon induction, they bind to the phosphorylated EPO-R, the common β chain of the IL-3/IL-5/GM-CSF receptors (CIS), or the G-CSF-R (SOCS3) and thereby prevent recruitment and activation of other signaling molecules. The SH2 domain of SOCS1/JAB1, on the other hand, specifically binds to phosphorylated Y1007 in the activation loop of JAK2 and is thought to prevent the access of substrates and/or ATP to the catalytic pocket of JAK2.^{40,41}

Internalization and degradation of receptor complexes

After activation, receptors are rapidly internalized into (early) endosomes. The mechanisms involved in the internalization of cytokine receptors are still poorly characterized. For intrinsic tyrosine kinase receptors, a major mechanism controlling receptor endocytosis has been unveiled.^{42,43} An important step in this process is the recruitment of the oncoprotein Cbl, again via a phosphotyrosine-SH2 domain interaction. Cbl attracts a complex that contains the Cblinteracting protein CIN85 and endophilin. The latter protein is probably involved in the invagination and scission of the vesicle. Furthermore, Cbl recruits an enzymatic machinery that covalently tags receptor, adapter, and/or signaling proteins with ubiquitin, a peptide of 76 amino acids. The level of ubiquitination then serves as a signal for lysosomal degradation or for recycling to the cell surface.⁴⁴ Although this is still controversial, the CIS/SOCS proteins are also thought to recruit a ubiquitin ligase complex via their 'SOCS box', a conserved region in the C terminus. In this situation, the JAKs are supposedly the main target for polyubiquitination.⁴⁵

Involvement of cytokine receptor mutations in hematological disease

The first evidence for the involvement of cytokine receptors in hematological disorders was obtained in mouse models, in which it was shown that mutations in the genes encoding receptors for EPO and GM-CSF were causally involved in the development of erythroid and myeloid leukemia, respectively.^{7,46} In addition, after the cloning and structural characterization of the members of the cytokine receptor family, it was readily recognized that the transforming gene of the myeloproliferative leukemia virus (MPLV) coded for a truncated form of a cytokine receptor, which was later identified as the receptor for thrombopoietin (TPO).⁴⁷ These mutations resulted in growth factor-independent activation of the receptors, leading to uncontrolled cell proliferation. Although comparable mutations in the EPO, GM-CSF, and TPO receptors have not been detected in human leukemia, there are several other examples of mutations in cytokine receptor genes involved in human hematological diseases. These mutations appear to affect specific signaling functions of the involved receptor complexes.

Severe combined immunodeficiency (SCID)

While the underlying molecular defects of SCID, a condition characterized by the almost complete absence of functional B and T lymphocytes, are heterogeneous, at least three types have been identified that are caused by defects in the signaling function of interleukin receptors. For instance, in X-SCID, the affected gene located on Xq13.1 encodes the common interleukin receptor γ chain, required for the formation of, for example, functional receptor com

plexes for IL-2, IL-7 and IL-15, the major cytokines involved in B- and T-cell development^{48–50} (Figure 3.1). The essential contribution of this common γ receptor chain to signaling is its unique ability to recruit JAK3 kinase into the receptor complexes. It is not surprising, therefore, that individuals lacking functional JAK3 suffer from clinical symptoms that are identical to X-SCID.^{51–52} Individuals with mutations disrupting the function of the IL-7R α chain also suffer from SCID, although with slightly distinct clinical features, due to the fact that natural killer (NK) cells are still formed in these patients.⁵³ X-SCID is the first human disease that has been successfully corrected with gene therapy. The basis of this success lies in the fact that the genetically corrected lymphoid cells have a proliferative advantage over the noncorrected cells.^{54,55} Unfortunately, a recent follow-up of these cases revealed that two patients developed T-cell malignancies.^{55a}

Benign erythrocytosis

Benign erythrocytosis is characterized by enhanced EPO sensitivity of erythroid progenitors and an absolute increase in red cell mass. Similar to SCID, the underlying disease mechanisms are diverse and only partly understood. Familial erythrocytosis with autosomal dominant inheritance is a specific form of benign erythrocytosis that has been associated with mutations in the gene encoding the EPO receptor (EPO-R).⁵⁶ Among different families, frameshift mutations and point mutations in the *EPO-R* gene have been reported, which all lead to truncations of the receptor C terminus.^{57–61} Tyr 449, the principle docking site for SHP-1, is invariably deleted due to this truncation. In view of the fact that SHP-1-deficient mice (*motheaten; me^v/me^v*) demonstrate an increased sensitivity to EPO, it is now generally believed that the failure of truncated EPO-R to recruit SHP-1, leading to reduced downregulation of JAK2 kinase activity, is the principle underlying signaling defect. Thus far, not a single case of benign familial erythrocytosis with truncated EPO-R has been reported to progress towards (erythroid) leukemia, suggesting that this defect does not confer a strong predisposition to neoplastic transformation. A mouse model has been developed in which a mutant human *EPO-R* gene derived from one of the affected families was introduced by homologous recombination.⁶² These mice show the expected EPO hyperresponsiveness and erythrocytosis and thus provide a good model to further investigate the molecular and cellular pathology of the disease.

Congenital amegakaryocytic thrombocytopenia (CAMT)

CAMT is a rare disease presenting with isolated thrombocytopenia and a severe paucity of megakaryocytes in the bone marrow. Often, a more generalized cytopenia develops in later childhood. Several cases of CAMT have been reported with frameshift or nonsense mutations in the *c-mpl* gene that disrupt the expression of a functional TPO-R.^{63–66} Because TPO is the main regulator of thrombocytopoiesis and has also been demonstrated to be an important factor in early hematopoiesis, *c-mpl* mutations are being considered the single cause of both the thrombocytopenia and the progression into pancytopenia seen in patients with CAMT.

Severe congenital neutropenia (SCN)

SCN is characterized by the almost complete absence of peripheral neutrophils due to a myeloid maturation block in the bone marrow. The disease presents with a variable genetic background and comprises both familial and sporadic cases. While the cellular mechanism(s) involved in the pathogenesis of SCN are still unknown, recent studies have implicated mutations in the gene encoding neutrophil elastase as a major underlying genetic defect in SCN.⁶⁷ The disease management of SCN, characterized in the pre-growth factor therapy era by a high mortality due to opportunistic bacterial infections, has improved dramatically upon the introduction of G-CSF in the clinic, with over 90% of the patients responding favorably to G-CSF treatment.⁶⁸

Along with the prolonged lifetime expectancy, a predisposition to develop myelodysplastic syndrome (MDS) and/or acute myeloid leukemia (AML) was unmasked in a subgroup of patients.⁶⁹ Progression of SCN to MDS/AML correlates strongly with the presence of acquired mutations in a critical stretch in the coding region of the *G-CSF-R* gene, resulting in C-terminal truncations of the G-CSF-R protein. Typically, clones harboring such mutations can already be detected in the neutropenic phase of the disease in approximately 20% of cases. In some cases, affected myeloid cells descend from minority clones, originally making up only 1–2% of the myeloid progenitor cell compartment. However, clones harboring *G-CSFR* mutations become overt in more than 80% of the SCN cases upon progression to MDS and AML, suggesting that truncated forms of G-CSF-R commonly contribute to the expansion of the (pre-)leukemic clones that arise in SCN. Studies in knock-in mouse models with equivalent targeted mutations have established that the truncated G-CSF-R confers a hyperproliferative response of myeloid progenitor cells to G-CSF.^{70,71} The truncated G-CSF-R displays multiple defects that can be linked to its perturbed signaling properties. These abnormalities include defective receptor internalization, increased and sustained activation of STAT5 and PI3K/PKB and the loss of specific docking sites for the negative regulators SOCS3 and SHIP.^{72–77}

Kit mutations in AML and mastocytosis

Kit is a receptor tyrosine kinase encoded by the *c-kit* gene, the cellular homolog of the viral oncogene *vkit*.^{78,79} Different cell types, including hematopoietic precursor cells, mast cells, melanocytes, germ cells, and the interstitial cells of Cajal, express c-Kit. Together with Flt3 and the receptors for M-CSF and platelet-derived growth factor (PDGF), c-Kit belongs to the type III family of RTKs. These receptors have five immunoglobulin-like repeats in the extracellular domain, a single transmembrane region, and a cytoplasmic kinase domain that is interrupted by a kinase insert sequence.⁶ In normal situations, the kinase activity of c-Kit is tightly regulated by its ligand, stem cell factor (SCF; also called Steel factor, mast cell growth factor, and c-Kit ligand). Ligand binding induces receptor oligomerization and subsequent auto/transphosphorylation, followed by recruitment and activation of cytoplasmic target proteins, such as members of the MAPK and PI3K pathways, Src tyrosine kinases, and several docking proteins.⁸⁰

Activating mutations

c-Kit has been implicated in the pathophysiology of a wide variety of human malignancies. These include solid tumors—gastrointestinal stromal tumors (GIST), germ cell tumors, small cell lung, ovarian, and breast carcinomas, neuroblastoma, and melanoma—as well as mastocytosis/mast cell leukemia, sinonasal NK/Tcell lymphoma (SNK/TCL), and AML. Autocrine and/or paracrine stimulation of c-Kit appear to be important for the proliferation of several tumors, but the acquisition of activating mutations is the main cause of aberrant Kit activity in blood cell progenitors.⁸¹

Mutations associated with human disease have been identified in several different exons of the *c-kit* gene (Figure 3.4). Although the functional significance of some mutations remains to be determined, two different mechanisms of receptor activation can be distinguished. ‘Enzymatic pocket’-type mutations, represented by codon 816 substitutions (D816V, D816Y, D816F), affect the activation loop at the entrance to the enzymatic pocket (exon 17). The D816V mutation characteristic of mastocytosis results in a higher specific activity and an almost 10-fold increase in ATP affinity.⁸² Furthermore, changes in substrate specificity have been reported for codon 816 mutants: (1) STATs 1 and 3 are strongly and constitutively activated, whereas activation of these STATs in normal cKit signaling is moderate or absent, depending on the cell type studied, (2) the PI3K pathway is constitutively activated, while activation of the MAPK pathway still requires stimulation with SCF.^{83,84}

‘Regulatory’ mutations do not affect the enzymatic site, but alter regions of the protein that are crucial for the regulation of kinase activity. For example, an α -helix in the intracellular juxtamembrane domain (exon 11) suppresses autoactivation, by sterically blocking the activation loop and/or by functioning as an antidimerization domain.^{85,86} Small in-frame deletions/insertions or point mutations in this sequence release this inhibitory regulation, resulting in SCF-independent activation.

The distinction between enzymatic and regulatory mutations has major therapeutic implications. To date, most of the small-molecule compounds that have been developed to target tyrosine kinases exhibit their inhibitory effect by binding to the enzymatic site of the kinase. For example, SU9529 and imatinib (STI571) bind to the catalytic site of c-Kit, thereby inhibiting the activity of the wild-type protein. The enzymatic mutations often alter the structure in such a way that the drug no longer obstructs the function of the enzymatic site. This accounts for the fact that these compounds have no effect on the codon 816 mutants of c-Kit, but still inhibit the regulatory c-Kit mutant V560G, which contains a nonmutated kinase domain. These observations have opened new avenues for the development of therapeutic compounds with specific affinity to the mutated enzymatic pocket.^{81,87} Furthermore, several new inhibitors have been identified (e.g. SU4984 and SU6577), that

Figure 3.4 *c-kit* mutations in human disease.

block the activity of wild-type c-Kit, as well as enzymatic and regulatory mutants.

Mastocytosis and acute myeloid leukemia

SCF is essential for mast cell development. Mutations of codon 816 (most commonly D816V) of *c-kit* are found in neoplastic mast cells in essentially all cases of adult sporadic mastocytosis.⁸⁸ As noted above, imatinib does not inhibit the kinase activity of the D816V mutant and would not be predicted to be useful in the treatment of mastocytosis patients with this mutation. Mast cell lines expressing codon 816 mutants are killed when they are cultured in the presence of the compounds SU4984 or SU6577.⁸⁹ This indicates that the mutations in *c-kit* are indeed a cause of mastocytosis and that these inhibitors may be clinically useful in treating diseases associated with codon 816 mutations.

In contrast to blast cells in acute lymphoblastic leukemia (ALL), cell surface expression of c-Kit is observed in the neoplastic cells of approximately 80% of AML patients, with a greater prevalence in the MO and the MI subtypes than in the M5 subtype.^{90,91} Other observations that suggest that c-Kit may be involved in the pathogenesis of AML are (1) the addition of SCF results in the proliferation of some human leukemic cell lines and AML blasts and (2) in a proportion of AML cases, c-Kit phosphorylation was observed in the absence of exogenous SCF, implicating an autocrine loop and/or activating *c-kit* mutations.⁸¹ Recent reports have indeed identified two major classes of *c-kit* mutations in AML. Surprisingly, mutations were only found in patients with core binding factor (CBF) leukemias. The first type of *c-kit* mutation is again the codon 816 substitution, found in 6 of 15 patients with t(8;21) or inv(16).⁹² The other class of *c-kit* mutation is the loss or replacement of D419 (exon 8). This type of mutation was found in one-third of cases of AML with the inv(16) karyotype, giving an overall incidence of around 2% in AML.⁹³ The reason for the association between a translocation of CBF and mutations of *c-kit* is unclear. Also, the functional significance of the codon 419 mutations has not yet been determined. When the D418 mutation is indeed activating, it is most likely a regulatory type mutation. If this proves correct, inhibitors that act on wild-type c-Kit are expected to block the kinase activity of Kit D418 as well.

FLT3 mutations in human AML

Flt3 is by far the most frequently affected receptor in human AML. Mutations in the *FLT3* gene are found in approximately 30% of AML patients and occur in all FAB types and cytogenetic subgroups. Most often, the mutations are small internal tandem duplications (ITD) in the juxtamembrane (JM) domain of the receptor. Similar to the JM mutations in the c-Kit receptor, the *FLT3* JM length mutations affect the kinase autoinhibitory function of the JM domain, resulting in constitutive activation of *FLT3* kinase. Alternatively, but less frequently, mutations affect a critical Asp residue in the activating loop, equivalent to the D816 mutations in c-Kit described above. It has now been firmly established that *FLT3* mutations are indicative of a poor prognosis in AML, independent of other risk parameters, such as specific cytogenetic abnormalities. It is plausible, therefore, that *FLT3* mutations confer a more 'aggressive' phenotype on AML cells, which makes *FLT3* important for the development of kinase inhibitors, along the same lines as the development of imatinib. The significance of *FLT3* mutations in leukemia and their impact on diagnosis/prognosis and therapy development has recently been reviewed⁹⁴⁻⁹⁵ and is discussed in more detail in Chapter 38.

4 Cell cycle regulation

N Shaun B Thomas

Introduction

Cells of all hematopoietic lineages are derived from a small number of stem cells in the bone marrow. On a population basis, when stem cells divide, it is thought that one of the daughter cells remains as a stem cell (self-renewal) while the other proliferates many times and differentiates to produce a fully functional end-stage cell¹ (see Chapter 1). For an individual stem cell, the decision to self-renew or to differentiate along a particular lineage may be stochastic, but the probability of committing to a particular lineage is changed by extrinsic (growth) factors (reviewed in references 2 and 3, and see Chapter 46) which are needed for survival and stimulate cell proliferation. The correct numbers of mature hematopoietic and non-hematopoietic cells of each lineage are produced by a balance between cell division, programmed cell death (apoptosis),⁴ replicative senescence, and differentiation governed by the appropriate growth factors. A schema depicting these cell fates during normal hematopoiesis is shown in Figure 4.1 (a).

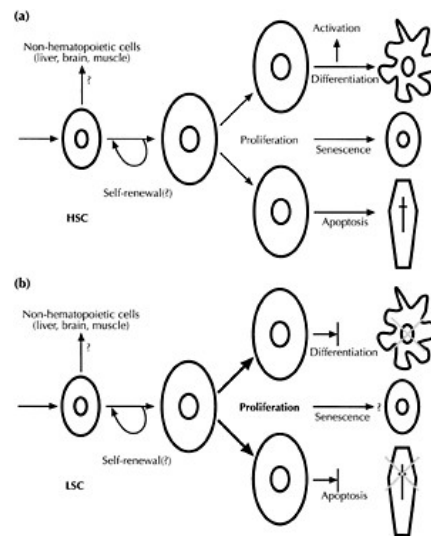

Figure 4.1 (a) A schema of normal hematopoiesis, highlighting the main processes that govern the fates of hematopoietic cells. The most primitive cells are on the left and mature cells on the right. (HSC, hematopoietic stem cell.) (b) A schema of abnormal hematopoiesis in a patient with leukemia. (LSC, leukemic stem cell.)

Over the past 20 years, many of the basic molecular mechanisms within cells that control each of these processes have been identified. Furthermore, we are beginning to understand how activation of individual molecular mechanisms can have different consequences depending on which other molecular pathways are also activated in the cell. At a given moment in time, a cell has ‘molecular circuitry’ that interprets the input signal of, for example, *ras* activation, the readout of which may be to cause cell proliferation or to induce replicative senescence. Such complexities enable any given cell to react appropriately and to ensure the production of the correct numbers of mature hematopoietic cells of the appropriate lineage.

In this chapter, I will review what is known about proteins that are involved in regulating cell division, but I will also highlight where they have also been shown to affect other processes such as apoptosis or differentiation. Many of the genes involved in cell proliferation are commonly mutated, deleted, or deregulated in a variety of different malignancies. This, together with inhibition of apoptosis and an aberrant differentiation program, may be sufficient to alter a stem cell so that its progeny predominate and cause leukemia (Figure 4.1b).

This chapter covers what we know about the control of cell division during the mitotic cell cycle. Many of the basic molecular mechanisms are conserved in different cell types and sometimes between organisms that are separated by millions of years of evolution. However, wherever possible, I will concentrate on studies that have been carried out with human hematopoietic cells. The chapter is divided into four sections. The first will cover the principal phases of the cell cycle and where the control points lie. The second reviews those proteins that regulate the cell cycle, concentrating on the cyclin-dependent kinases. The substrates of these kinases will be discussed in the third section, and finally, in the fourth section, I will review what we know about abnormalities in these proteins in hematological malignancies.

Cell division

In order for a cell to proliferate, an orderly series of processes must be carried out whereby DNA is duplicated and the chromosomes are then segregated accurately to each daughter cell. These processes occur during S (DNA synthesis) phase and mitosis respectively. The mechanisms involved in DNA synthesis and mitosis will not be discussed in this chapter, but there are a number of reviews that cover these topics in detail.^{5–8} Although the molecular processes that occur during S and M phases are tightly controlled, responses to extracellular stimuli or to DNA damage that lead to a pause in the cell cycle normally occur during two ‘gap’ phases, called G_1 and G_2 . These phases precede S phase and M phase respectively (Figure 4.2a). The net result is that when a cell has progressed through all four phases, two genetically identical daughter cells are produced from one original cell.

Certain cells, such as $CD34^+Lin^-$ stem/early progenitor cells or non-activated peripheral blood T cells are in a quiescent state termed G_0 (Figure 4.2a).⁹ These are non-dividing cells that will enter the cell cycle ($G_0 \rightarrow$ early G_1 (G_{1A})) and divide in response to mitogenic growth factors. For example, human T cells require CD3/CD28 costimulation for >2–5 hours to cause them to enter G_{1A} , otherwise they remain in G_0 .¹⁰ A cell that is in G_0 will take longer to enter S phase than a proliferating cell that is in G_{1A} . In addition, cells in G_0 lack many of the proteins that are necessary for S phase to occur. Examples of proteins that are not present in G_0 are Cdc6 and the minichromosome maintenance proteins Mcm2 to Mcm7. The Cdc6 and MCM proteins collectively bind DNA at specific sites that define where DNA replication will originate. Binding of these proteins ‘licenses’ DNA replication at those sites.¹¹ Enzymes required for DNA synthesis are also not present in G_0 , including thymidine kinase, ribonucleotide reductase, and DNA polymerase- α . These proteins are induced as cells progress from G_{1A} to late G_1 (G_{1B}).

Figure 4.2 (a) The main phases of the mitotic cell cycle. (R, restriction point; CP, $G_0 \rightarrow G_1$ commitment point.)

Figure 4.2 (b) Quiescence (G₀). Members of the INK4 and Cip/Kip families of cdk inhibitors prevent the activation of cdk6, cdk4, and cdk2 and maintain cells in a quiescent state. See Figure 4.5 for more details. (A—B indicates that protein A inhibits protein B.) (c) Proliferation. Resorting of cdk-CK1 complexes and down regulation of INK4 and Cip/Kip proteins allows the cdks to be activated by the relevant cyclins. These phosphorylate and inactivate the pRb and p130 proteins and allow cells to progress from G₀ through G₁ into S phase, (d) pRb, p130, and E2F6 inhibit E2F-dependent transcription. pRb and p130 proteins bind the E2F.DP1 proteins shown and inhibit their activation in G₀ or G_{1A}. E2F6.DP1 binds to E2F sites in the promoters of several genes in G₀ and prevents their activation. See Figure 4.9 for more detail.

Cell size and protein and RNA content also increase markedly as cells progress through G_1 .^{9,12} Entry into the cell cycle and the cellular growth cycle are normally coordinated,⁹ and cell size continues to increase as cells progress through the remainder of the cell cycle. This is necessary since cells must ultimately divide to produce two daughter cells that maintain the same characteristic size. Shortening the time taken for a cell to traverse a cell cycle phase such as G_1 without also increasing biosynthetic rates to increase cell size would result in smaller cells. Mutations that in vitro reduce the time taken to progress through a given cell cycle phase will not necessarily increase the rate of cell proliferation, as the time taken to traverse through other phases of the cell cycle may be increased to maintain cell size. Homeostatic mechanisms exist to maintain a given cell type at a characteristic size, although the sensing mechanisms in higher eukaryotic cells are poorly understood.¹³

Cell proliferation is controlled at a number of different stages: first, to determine when cells should enter the cell cycle ($G_0 \parallel G_1 \parallel S$ phase), secondly in proliferating cells ($M \parallel G_1 \parallel S \parallel G_2$), for example to ensure that mitosis follows S phase, and thirdly to control exit from the cell cycle ($M \parallel G_1 \parallel G_0$) without inducing apoptosis. For T cells, entry into the cell cycle is regulated by progression through the $G_0 \parallel G_1$ commitment point (CP).¹⁰ This is the point beyond which costimulation via the T-cell receptor (CD3) and CD28 are no longer required for progression into G_{1A} . There is then a point in G_{1B} called the restriction point (R) beyond which cells become committed to entering S phase (Figure 4.2a) (reviewed in references 9 and 14). The restriction point was defined using fibroblasts, and if these cells are deprived of mitogenic growth factors before R, they will not divide, whereas deprivation after this point (i.e. in G_{1C}) has no effect on progression into S phase.

During active proliferation, the cell cycle in progress can be arrested during either G_1 or G_2 if, for example, DNA has to be repaired. Arrest can also occur when a susceptible cell is exposed to negative growth factors such as interferon- α (IFN- α) or transforming growth factor β (TGF- β) that cause cells to exit the cell cycle. However, in the absence either of survival factors or of negative growth factors, growth factor deprivation will trigger some hematopoietic cells to undergo apoptosis.

It is also crucial to maintain the order in which individual cell cycle phases are carried out. Failure to maintain the temporal order between DNA replication and mitosis, i.e. $G_1 \parallel S \parallel G_2 \parallel M \parallel G_1$, results in a change in ploidy. This can occur if cell cycle control mechanisms go awry, for example if the *cdc2* gene is deleted experimentally.¹⁵ There are natural situations in which mitosis and cell division do not follow S phase, resulting in the formation of polyploid cells but with no increase in cell number. For example, megakaryocytes are polyploid and one cell can contain hundreds of copies of each chromosome. Experiments that established the basic principles of feedback control governing cell cycle S and M phases include cell fusion experiments of cells in different cell cycle phases,¹⁶⁻¹⁷ and the genes involved are reviewed in references 9, 18, and 19.

Proteins that regulate the cell cycle

There are certain key proteins within a cell that play a crucial role in responding to a mitogenic stimulus. Cells are maintained in a non-dividing state by members of the INK4 and Cip/Kip families of cyclin-dependent kinase inhibitor (CKI) proteins (Figure 4.2b). Activation of mitogenic signaling pathways in a quiescent cell lead to re-sorting of CKI-cdk-cyclin complexes and activation of cdk4 by D-type cyclins. Some cells also contain cdk6, which is also activated by the D-type cyclins. These kinases then phosphorylate proteins such as the members of the retinoblastoma family (Figure 4.2c). The retinoblastoma protein (pRb), together with its relative, p130, bind E2F transcription factors in non-dividing cells and repress the activity of E2F-responsive genes by recruiting chromatin-remodeling proteins, such as histone deacetylases (HDAC) (Figure 4.2d). This occurs when pRb and p130 are in a hypophosphorylated state. When pRb and p130 are fully (hyper-)phosphorylated during G_1 by cdk6-cyclin D, cdk4-cyclin D, and cdk2-cyclin E, they release E2F factors to activate the transcription of a number of different genes that encode proteins required for cells to enter S phase. The E2F family members E2F1 to E2F5 are regulated in this way. However, there is a sixth E2F protein that does not act in the same way as the others. The factor composed of E2F6-DP1 does not bind pRb or p130 but acts as a transcriptional repressor itself when cells are in G_0 (Figure 4.2d). In addition to repressing E2F-regulated genes, this factor also inhibits the activities of genes that are activated by c-Myc. Certain cdk6 are also needed once cells are cycling to coordinate the intricate mechanisms involved in mitosis. The role played by each of these proteins is discussed in detail below, beginning with the cdk6.

Cyclin-dependent kinases

Identification of cell division cycle (*cdc*) yeast mutants by Leland Hartwell, *cdc2* by Paul Nurse, and cyclins by Tim Hunt formed the basis for their shared 2001 Nobel Prize in Medicine (for further details, see the website²⁰). These studies provide excellent examples where the power of yeast genetics and

biochemical studies of appropriate, simpler eukaryotic organisms have identified evolutionarily conserved mechanisms that also operate in mammalian cells.

The cyclin-dependent kinases (cdks) are a family of serine/threonine kinases that in general control the transitions between successive phases of the cell cycle in eukaryotic cells. Each is the catalytic subunit of a kinase that is activated, as their name suggests, by binding to a cyclin regulatory subunit (reviewed in reference 21). The *cdc2* gene from the budding yeast *Schizosaccharomyces pombe*²² encodes a protein, p34^{cdc2} that is activated by cyclin B and is crucial for regulating mitosis.^{5,6,18,23} p34^{cdc2} is also important in yeast for ensuring that cells only enter into M phase on completion of the previous S phase.^{18,19,22,24,25} If this mitotic kinase is active then the cell is identified as being in G₂ and proceeds to M phase. If it is inactive then the cells are redirected into G₁ and undergo S phase.

The function of p34^{cdc2} in mitosis has been conserved through millions of years of evolution. This was shown by using the human *CDC2* cDNA to functionally replace the yeast *cdc2* gene.²⁶ However, care should be taken in extrapolating specific details between species. For example, p34^{cdc2} has additional roles in higher eukaryotic cells. It can induce apoptosis in terminally differentiated cells but inhibits apoptosis via the survivin pathway during mitosis.²⁷ Furthermore, whereas the yeast *S.pombe* only needs one cdk, to date 11 kinases homologous to *CDC2* have been identified and cloned from mammalian cells (*cdc2* (cdk1) and *cdk2*-*cdk11*).^{28–34} There is evidence that *cdks* 7–10 regulate transcription and that *cdk11* regulates translation and may also be involved in apoptosis. However, the functions of *cdks* 1–6 have been studied in most detail and their roles in mammalian cells are discussed below.

Cyclins were originally identified as two proteins (A and B), which were synthesized and degraded in a cyclical fashion during the cell cycle of the surf clam *Spissula* and sea urchin eggs.^{35–37} At least 15 cyclins have since been identified in mammalian cells, but not all are synthesized and degraded in this manner.²¹ The cyclins do, however, contain a consensus sequence of 100 amino acids, known as the ‘cyclin box’, which is required for binding the cdk partner.

The mitotic cyclins A, B1, B2, and B3 accumulate during S and G₂ phases and are destroyed at a discrete point in mitosis.²⁰ Degradation requires a small sequence motif (the destruction box) near the N terminus and involves the ubiquitin-dependent proteolytic machinery. Cyclins C, D1, D2, D3, and E accumulate during entry into G₁ from G₀, and so they are called G₁ cyclins (reviewed in reference 38). These G₁ cyclins are short-lived proteins, and a sequence, Pro-Glu-Ser-Thr (PEST), within their C terminus is correlated with their rapid turnover, also probably via a ubiquitin-mediated pathway.³⁹

The gene encoding cyclin D1 (*CCND1*) is induced via the ras, Raf, MAPK pathway in some cell types^{40,41} and this provides a direct link between growth factor signal transduction (detailed in Chapter 3) and entry into the cell cycle. All three of the D-type cyclins initiate activation of cdk(s) required for progression through G₁ into S phase (reviewed in reference 42). They associate primarily with *cdk4* and *cdk6* but can also bind *cdk5*.^{38,43} Cdk6 activity is detected prior to *cdk4* kinase activity in T lymphocytes^{10,44,45} and both kinases are involved in early cell cycle events during the G₀ → G₁ transition. Indeed, suppression of *cdk6* by the INK4 protein p18^{INK4C} controls the proliferation of murine T cells.⁴⁶ Furthermore, inhibition of *cdk6/4*-cyclin D2 by introducing p16^{INK4A} during the first 5 hours of anti-CD3/CD28 stimulation maintains human T cells in G₀.¹⁰ In vivo, cyclin D3 is required for the production of CD4⁺CD8⁺ double-positive T cells. Thymocytes from *cyclin D3*^{-/-} mice fail to proliferate during the DN-3 to DN-4 transition that is required for the maturation of CD4⁻CD8⁻ to CD4⁺CD8⁺ cells.^{47,48} Interestingly, *cdk6*, but not *cdk4* or *cdk2*, also has a role in cell differentiation. Downregulation of *cdk6* is required for erythroid differentiation of a mouse erythroleukemia (MEL) cell model and the *CDK6* gene is regulated at least in part by the transcription factor PU.1.^{49,50}

In parallel with cyclin association, phosphorylation and dephosphorylation reactions are required for *cdks* to become active (reviewed in reference 51) (Figure 4.3). For example, although cyclin B accumulates and associates with p34^{cdc2} (*cdk1*) during S and G₂/M phases, this complex does not become active until the onset of mitosis. This is because *cdk1* is inhibited by phosphorylation of threonine 14 (T¹⁴) and tyrosine 15 (Y¹⁵). The crystal structure of *cdk2* in active and inactive forms has been solved and the roles of phosphorylation in controlling access to the active site have been determined (reviewed in reference 52). The inhibitory phosphates must be removed in order for the *cdk*-cyclin complex to become active. This is carried out by *cdc25C*, which is a member of the *cdc25* family of dual-specificity phosphatases (reviewed in reference 51). Furthermore, as an added level of regulation, T¹⁶¹ must be phosphorylated by a kinase, which is a complex of *cdk7*-cyclin H and a p32 protein (reviewed in reference 53). Dephosphorylation of T¹⁶¹ occurs at the end of mitosis once the cyclin has been degraded.

Another member of the *cdc25* family, *cdc25A*, forms complexes with the Raf1 kinase in somatic mammalian cells, and Raf1 activates the *cdc25A* phosphatase in vitro.⁵⁴ Thus, this interaction provides another link between mitogenic signal transduction and the cell cycle machinery. As is the case for *cdk1*,

Figure 4.3 Cdk activation. The cdk's are activated by cyclins and by phosphorylation and dephosphorylation of specific amino acids. (Y tyrosine; T, threonine.)

both cdk4 and cdk2 are phosphorylated on Y¹⁵, which is a target for cdc25A phosphatase activity. If cdc25A is a substrate in vivo for Raf1 then cdk-cyclin complexes could be activated in G₁ in response to growth factors and their activity would then depend only on the balance between relevant cyclins, cdk's, and cdk inhibitors (see below). Therefore, withdrawal of growth factors in G₁ preceding the restriction point could abort the cell cycle via rapid inactivation of cdc25A and depletion of cyclin D.

Cdk2-cyclin E is active during late G₁ and early S phase and is a good candidate for controlling entry into S phase, once cells have passed the restriction point in late G₁.⁵⁵ It also has a role in centrosome duplication during mitosis.⁵⁶ The abundance of cyclin E in the cell has to be regulated within tight limits—too little and cells arrest in G₁, whereas too much causes premature entry into S phase and genomic instability (see the section below on abnormalities in malignant cells).

Both c-Myc and Ras pathways can activate cdk2-cyclin E.⁵⁷ Activation of cdk2-cyclin E occurs in two steps: the first, induced by c-Myc, involves the release of cdk2-cyclin E from a high-molecular-weight complex, and the second, induced by growth factors, requires cdc25 phosphatase activity⁵⁸ (discussed below). However, cdk2-cyclin E is maintained in an inactive state by the cdk inhibitor p27^{Kip1} (see the next subsection). Initial activation of cdk2-cyclin E phosphorylates p27^{Kip1} and causes its degradation via the ubiquitin pathway (Figure 4.4). This process activates more and more cdk2-cyclin E, which peaks in late G₁, allowing cells to enter S phase. It is thought that cdk2 controls its own activity by phosphorylating cyclin E at threonines 62 and 380. An F-box protein hCdc4 (or Fbw7) binds cyclin E when it is phosphorylated at these positions. hCdc4/Fbw7 is an adaptor protein that also binds a ubiquitin ligase complex called SCF (made up of Skp1, Cul1, Rbx1, and E2 proteins). The amount of cyclin E, and hence cdk2 activity, is then reduced by ubiquitination and degradation of cyclin E by the 26S proteasome (Figure 4.4). The papers that delineated these mechanisms provide excellent examples of the power of genetic screens in model organisms—yeast and fruitflies—to isolate genes whose products carry out similar functions in human cells (reviewed in references 59 and 60).

In spite of such intricate control, genes that encode cdk2 or cyclins E1 and E2 (*CCNE1* and *CCNE2*) are not required for cell proliferation and development in the mouse.^{61–64} However, cdk2-cyclin E1/E2 is needed for germ cell development and meiosis. Also, loss of cdk2 affects the timing of S phase, suggesting that cdk2 has a regulatory role in progression through the mitotic cell cycle. Data from a cell-free system suggest that cdk2-cyclin E and cdk2-cyclin A indeed have distinct roles during DNA replication complex assembly and activation. Cdk2-cyclin E stimulates replication complex assembly, making nuclei isolated from cells in G₁ competent to replicate DNA. Cdk2-cyclin A then activates DNA synthesis by pre-existing replication complexes and inhibits assembly of new complexes, thereby preventing reinitiation of DNA replication until the next cell cycle.⁶⁵

Cdk2-cyclin A associates with proliferating cell nuclear antigen (PCNA, a cofactor of DNA polymerase δ), as cells enter S phase from G₁.³⁸ Similarly, cdk5 binds PCNA, and so both cdk2 and cdk5 may be involved in DNA synthesis. On the other hand, cdk5 has been detected in terminally differentiated neuronal cells that are incapable of dividing. In non-neuronal cells, cdk5 plays a role in replicative senescence by repressing Rac1 activity and blocking actin polymerization.⁶⁶ Cdk5 also phosphorylates proteins called dephosphins that are necessary for synaptic vesicle endocytosis.⁶⁷ In hematopoiesis, cdk5 has a role in monocyte differentiation. The cdk5 activator p35^{Nck5a} is expressed in monocytes but not in granulocytes or lymphocytes. Activation of cdk5 in HL60 cells causes an increase of markers of monocyte differentiation, such as CD14 and non-specific esterase.⁶⁸

Transfection experiments with dominant-negative mutants have shown that cdk3 as well as cdk2 are required for progression through G₁.⁶⁹ In addition to inhibiting cell cycle progression, dominant-negative cdc2 (cdk1), cdk2, or cdk3 also suppressed apoptosis

Figure 4.4 Regulation of cdk2. Cdk2 is activated by cyclin E and inhibited by p27^{Kip1}. Both cyclin E and p27^{Kip1} are regulated by ubiquitination and 26S proteasome-mediated degradation. Phosphorylation of p27^{Kip1} by cdk2-cyclin E at T¹⁸⁷ causes it to be recognized by Skp2 and ubiquitinated by the E2 ligase of the Skp1 complex. Similarly, phosphorylation of cyclin E by cdk2 at T⁶² and T³⁸⁰ causes binding of hCdc4 and ubiquitination by the Skp1 complex. Ubiquitinated p27^{Kip1} and cyclin E are degraded by the 26S proteasome.

triggered either by staurosporine or tumor necrosis factor α (TNF- α).⁷⁰ Cdk3 is activated by cyclin C, promotes pRb-dependent exit from G₀,^{71,72} and contributes to the activation of a component of the E2F transcription factor family⁷³ (the E2F family is reviewed in detail in the section below on substrates of the cdk).

Cyclin-dependent kinase inhibitors

During G₁, cdk are activated by G₁ cyclins and inhibited by specific cdk inhibitors (reviewed in reference 74). The cyclin kinase inhibitors (CKI) identified in mammalian cells are proteins that associate either with a cdk or a cyclin-cdk complex and by their association can inhibit kinase activity, leading to cell cycle arrest (Figure 4.5). The CKIs are divided into two groups based both on sequence similarities and on their target proteins. The first group are the inhibitors of cyclin-dependent kinase 4 (INK4). These proteins—p16^{INK4A}, p15^{INK4B}, p18^{INK4C}, and p19^{INK4D}—all have 32-amino-acid ankyrin motifs, inhibit cdk4 and cdk6 specifically, and are potential tumor suppressors. The second group comprises the p21^{Cip1}, p27^{Kip1}, and p57^{Kip2} proteins, which have homologies in their N-terminal cdk-inter acting domain and C-terminal nuclear localization sequence. These are general cdk inhibitors, but they may also be required for activating cdk4-cyclin D (discussed below).

The earliest CKI to be discovered was p16^{INK4A} (encoded by the *CDKN2A* gene; also known as *MTS1* and *Cdk4i*). This protein binds to cdk4 and cdk6, thereby inhibiting their interaction with D-type cyclins.⁷⁵ The crystal structure shows that p16^{INK4A} distorts the cyclin-binding site of cdk6 and promotes ATP binding.⁷⁶ Inhibition by p16^{INK4A} prevents cdk phosphorylation of the retinoblastoma protein (pRb) (see the section below on substrates of the cdk), halting cell cycle progression from G₁ into S phase.^{51,77} In contrast, loss of p16^{INK4A} function (see the section below on abnormalities in malignant cells) may result in unscheduled cdk activity, leading to phosphorylation and inactivation of pRb. This in turn can lead to dysregulated progression into the cell cycle^{78,79} and may affect other processes such as differentiation and apoptosis (see the section on cdk substrates). p16^{INK4A} expression is high in senescent cells, but it also peaks during S phase, which suggests that it may be required at the G₁/S transition to inhibit cdk4 and cdk6 when their activity is no longer necessary.

The p19^{ARF} protein in mice, p14^{ARF} in humans (reviewed in reference 80), is encoded by the same DNA locus as p16^{INK4A}. The p19/14^{ARF} protein is produced from an alternative reading frame, which spans exons 2 and 3 of *CDKN2A*⁸¹ (Figure 4.6a). Therefore, the p16^{INK4A} and p19/14^{ARF} proteins are not homologous and p19/14^{ARF} can induce cell cycle arrest without directly inhibiting any of the known cdk.⁷⁴

Figure 4.5 Cdk inhibitor proteins. There are two classes of cdk inhibitors, which act in different ways. The INK4 proteins bind and inhibit cdk4 and cdk6 subunits. The Cip/Kip proteins bind and inhibit the cdk6-cyclin D, cdk4-cyclin E, and cdk2-cyclin E/A complexes. However, the Cip/Kip proteins may also be required for formation of active cdk complexes.

p19/14^{ARF} is induced by mitogenic stimuli, including E1A, c-Myc, activated Ras, v-Abl, and E2F1. The *p19/14^{ARF}* protein then binds MDM2/HDM2 and sequesters it in the nucleolus where it cannot bind p53.⁸² MDM2/HDM2 has E3 ubiquitin ligase activity and causes p53 degradation.⁸³ Inhibition of MDM2/HDM2 by *p19/p14^{ARF}* stabilizes p53, leading to growth arrest or apoptosis. Interestingly, *p19^{ARF}* also binds E2F1, 2, and 3, targets them to the nucleolus, and causes their degradation in a proteasome-dependent manner.⁸⁴ Therefore, *p19/14^{ARF}* can cause cell cycle arrest by more than one mechanism. This is shown schematically in Figure 4.6(b).

p15^{INK4B} (encoded by *CDKN2B*; also known as *MTS*) is highly homologous to *p16^{INK4A}* (82% protein sequence identity), and the *CDKN2B* gene exists alongside *CDKN2A* on chromosome 9p21. Like *p16^{INK4A}*, *p15^{INK4B}* binds and inhibits only cdk6 and cdk4, and growth inhibition by TGF- β is mediated in part by the induction of *p15^{INK4B}*. For example, culturing CD34⁺ long-term culture-initiating cells (LTC-IC) with a neutralizing antibody to TGF- β causes downregulation of *p15^{INK4B}*. When *p27^{Kip1}* is also depleted by antisense methods, this causes the proliferation of pluripotent hematopoietic progenitor cells that can be retrovirally transduced and engrafted long term in immunocompromised mice.⁸⁵ Such data implicate *p15^{INK4B}* and *p27^{Kip1}* in maintaining human hematopoietic stem/ long-term pluripotent progenitor cells in a quiescent state. In mice, in contrast, *p21^{Cip1}* is implicated in maintaining stem cells in a quiescent state⁸⁶ and *p27^{Kip1}* regulates the quiescence of early progenitor cells.⁸⁷ *p15^{INK4B}* can also bind other proteins such as NF- κ B via ankyrin-binding motifs towards the N terminus, and this may be important for inhibiting cell proliferation independent of the pRb pathway.⁸⁸ The role of *p15^{INK4B}* in hematopoiesis is important, as illustrated by the fact that the *CDKN2B* gene is silenced by promoter hypermethylation in a high percentage of patients with late-stage MDS or AML (see the section on abnormalities in malignant cells). *p18^{INK4C}* (encoded by *CDKN2C*; also known as *Ink6A*) and *p19^{INK4D}* (encoded by *CDKN2D/Ink6B*) share some homology with *p16^{INK4A}* (~40%) and inhibit both cdk4 and cdk6.^{51,74} *p18^{INK4C}*, but not *p19^{INK4D}*, is implicated in the cell cycle arrest that occurs during myogenic differentiation.⁸⁹ Furthermore, *p18^{INK4C}* preferentially binds cdk6 in murine T cells, and deleting the *CDKN2C* gene causes T-cell proliferation in response to CD3 that does not require CD28 costimulation.⁴⁶ In addition, deletion of *CDKN2C* increases the self-renewal capacity of hematopoietic stem cells.⁹⁰

p21^{Cip1} was discovered in several laboratories using different approaches and is encoded by the *CDKN1A* gene (also known as *WAF1*, *Pic1* and *SDI1⁹¹*). In whole cells, DNA damage induces the production of p53, which in turn activates the transcription of *CDKN1A*, leading to transient cell cycle arrest by inhibiting cdk activity. *p21^{Cip1}* can inhibit cell proliferation by two independent mechanisms: cdk inhibition is mediated by sequences towards the N terminus of *p21^{Cip1}*, but *p21^{Cip1}* also binds proliferating cell nuclear antigen (PCNA) via a sequence at its C terminus, thereby inhibiting PCNA-dependent DNA replication.⁹² The importance of these mechanisms is highlighted by the fact that inhibition of *p21^{Cip1}* by the human papillomavirus (HPV-16) E7 protein uncouples differentiation and proliferation in keratinocytes.^{93,94}

Although *p21^{Cip1}* is a general cyclin-dependent kinase inhibitor, it has greater selectivity for cdk2, 3, 4 and 6.⁹⁵ In normal fibroblasts, inactive cdk2s exist predominantly in *p21^{Cip1}*-PCNA-cyclin-cdk quarternary complexes and the active kinases exist in cyclin-cdk binary states. The modes of action of members of the two groups of cdk inhibitors have been compared by binding assays in vitro: *p21^{Cip1}* (and *p27^{Kip1}*—see below) bind to cyclins even in the absence of the relevant cdk, whereas *p15^{INK4B}* and *p16^{INK4A}* bind cdk4 and cdk6 in the absence of cyclins⁷⁵ (Figure 4.5). Thus, the inhibitors differ in that *p15^{INK4B}* and *p16^{INK4A}* interfere with the formation of cyclin D-dependent kinase complexes, whereas *p21^{Cip1}* and *p27^{Kip1}* inhibit by binding

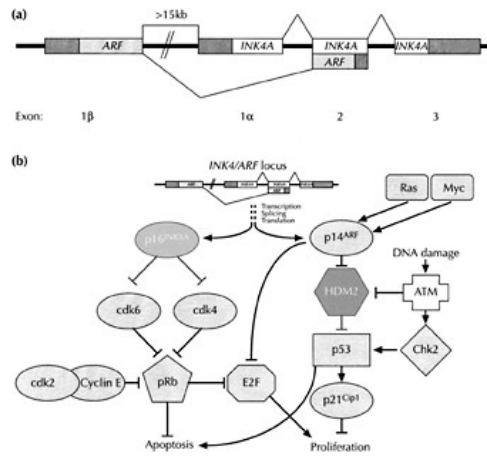

Figure 4.6 (a) The *INK4A/ARF* locus. The *INK4A* and *ARF* proteins are encoded by the same locus. They only use exon 2 in common but the reading frames are different. Therefore, $p14^{ARF}$ and $p16^{INK4A}$ proteins do not share amino acid sequences in common. (b) The *INK4A/ARF* locus encodes proteins that regulate both the p53 and pRb pathways. $p16^{INK4A}$ inhibits cdk4 and cdk6 and so prevents the phosphorylation and inactivation of pRb. This in turn inhibits proliferation and apoptosis. $p14^{ARF}$ binds HDM2 (the human homolog of mouse MDM2) and causes its degradation. This in turn allows the activation of p53, which can inhibit proliferation by inducing $p21^{Cip1}$ and causes apoptosis.

to cyclin-cdk complexes. Cdks can exist in both active and inactive states in complexes containing $p21^{Cip1}$, and the stoichiometry of the complexes is important for determining whether the cdk is active.

$p27^{Kip1}$ is homologous to $p21^{Cip1}$, binds to cyclin E-cdk2, cyclin A-cdk2, and cyclin D-cdk4, and inhibits the activity of these kinases in vitro in a stoichiometric manner.⁷⁴ It also inhibits cdk2, cdk4, and cdk6 by preventing their phosphorylation. In whole cells, $p27^{Kip1}$ inhibits cdk2-cyclin E more effectively than cdk4-cyclin D^{96,97} and arrests cells in G_1 . $p27^{Kip1}$ is probably involved in a number of mechanisms that cause cell cycle arrest in G_1 since its abundance in the cell is elevated following treatment of cells with TGF- β , cAMP, drugs such as tamoxifen, rapamycin, and lovastatin, through cell-cell contact, and during differentiation (reviewed in references 98 and 99). However, the level of mRNA encoding $p27^{Kip1}$ does not change markedly under any of these circumstances. Rather, $p27^{Kip1}$ is predominantly regulated by degradation via the ubiquitin pathway.¹⁰⁰ $p27^{Kip1}$ ubiquitinating activity is more pronounced in cycling cells than in quiescent cells; hence, $p27^{Kip1}$ is more abundant during quiescence. However, $p27^{Kip1}$ can also be regulated by transcriptional¹⁰¹ and translational¹⁰² mechanisms.

Degradation of $p27^{Kip1}$ is regulated by phosphorylation. It is phosphorylated on serine 10 by human kinase interacting stathmin (hKIS).¹⁰³ Phosphorylation at $p27^{Kip1}(S^{10})$ occurs in G_0/G_a after mitogen stimulation and causes $p27^{Kip1}$ to be exported from the nucleus to the cytoplasm in association with CRM1.¹⁰⁴ $p27^{Kip1}$ can be degraded during G_1 ,¹⁰⁵ although the mechanisms involved have yet to be elucidated. $p27^{Kip1}$ is also phosphorylated in the nucleus by cdk2-cyclin E/A at threonine 187 during S and G_2 phases of the cell cycle. This allows binding of the Skp2-E3 ubiquitin protein ligase SCF and leads to degradation of $p27^{Kip1}$ by the proteasome (reviewed in reference 106). These mechanisms cause $p27^{Kip1}$ degradation during transition of cells into the cell cycle (Figure 4.4), but also allow $p27^{Kip1}$ levels to be regulated during S and G_2 .¹⁰⁷ The latter may be important for inhibiting cell proliferation, as elevating $p27^{Kip1}$ would then cause cell cycle arrest when they next entered G_1 . Thus, protein degradation can either inhibit or activate cdk activity: cdk activity is inhibited by ubiquitin-mediated cyclin degradation and can also be activated by ubiquitin-mediated $p27^{Kip1}$ degradation.

The mechanisms of action of $p27^{Kip1}$ are complex and there is conflicting evidence as to whether $p27^{Kip1}$ (or $p21^{Cip1}$) is required for the formation of stable and active cdk4-cyclin D.^{108–110} In non-dividing cells, nuclear $p27^{Kip1}$ binds cdk-cyclin complexes through its N terminus and in particular it prevents cdk2-cyclin E activation. Mitogenic stimulation causes the formation and activation of cdk6-cyclin D and cdk4-cyclin D complexes in early to mid G_1 . This

causes resorting of cdk-cyclin-CKI complexes, so that some of the p27^{Kip1} binds and stabilizes cdk4-cyclin D, allowing activation of cdk2-cyclin E in late G₁ and phosphorylation and degradation of the remaining p27^{Kip1}. Mitogen stimulation also causes p27^{Kip1} to be exported from the nucleus to the cytoplasm by stathmin/CRM1. Cytoplasmic p27^{Kip1} can then bind RhoA and regulate cell migration.¹¹¹

p57^{Kip2} is another p21^{Cip1} and p27^{Kip1} homolog, although with a more restricted tissue expression pattern. Its function as a candidate tumor suppressor gene^{112,113} is discussed in the section on abnormalities in malignant cells.

Substrates of the cyclindependent kinases

During mitosis, many changes occur in the nucleus, including chromatin condensation, reduction of DNA transcription, inhibition of membrane and vesicular traffic, reorganization of microtubules to form the mitotic spindle apparatus, breakdown of the nuclear envelope, and rearrangement of the actomyosin cytoskeleton for cell rounding and cytokinesis. Many of these changes are regulated by cdk1-cyclin B (reviewed in references 21 and 23). The consensus site that is phosphorylated by cdk1-cyclinB is (K/R)^S/_T-P-X-K and about 200 potential substrates have been identified that are involved in each of these processes.^{51,114} The substrate specificity of each cdk is dependent on its expression in the correct cell cycle phase and in the right place in the cell. For example cdk2-cyclin A cannot phosphorylate substrates in early or mid G₁, since cyclin A is only synthesized at the G₁/S border. Cyclin B1 translocates to the nucleus at the start of mitosis and cyclin B2 associates with the Golgi, implying that they must cause the phosphorylation of different substrates in each location.

The cdk substrate in G₁ that has been studied in most detail is the protein encoded by the *RB1* gene, pRb.¹¹⁵ pRb is a nuclear phosphoprotein, which is involved in regulating progression through G₁ into S phase (reviewed in references 42, 51, and 115). The human protein can be phosphorylated on 15 different sites, all of which are serines or threonines (Figure 4.7a, see Plate 1). This occurs progressively as quiescent cells progress through G₁, and pRb is present in a hyperphosphorylated form by the time cells reach the G₁/S border. The pRb protein may be inactive when it is completely dephosphorylated in quiescent cells and becomes active when phosphorylated at a few sites by cdk6- or cdk4-cyclin D (so-called hypophosphorylated form) as cells progress into G₁.¹¹⁶ The hypophosphorylated form of pRb binds E2F transcription factors and thereby represses genes encoding proteins that are required for cell cycle progression (see below). Hyperphosphorylation inactivates pRb, allowing cells to enter S phase.

pRb is also acetylated by p300/CBP as cells enter the cell cycle, in response to differentiation signals (e.g. U937 cells plus phorbol ester (PMA)) or in the presence of adenovirus E1A.¹¹⁷ Acetylation of pRb occurs at lysines 873 and 874, and acetylation of these residues reduces pRb phosphorylation. Thus, acetylation or phosphorylation are two ways of regulating pRb so that the same molecule can potentially operate in different pathways. Acetylation of pRb enhances its ability to bind the MDM2 protein, which indicate that this post-translational modification may also be involved in regulating protein-protein interaction. This may be important in light of the fact that pRb can form a trimeric complex with p53 and MDM2 that is involved in apoptosis.¹¹⁸

The pRb protein binds many other proteins and over a hundred have been described.^{119,120} Some of the inter-actions are based on yeast two-hybrid screens and in vitro biochemical binding ('pull-down') assays. However, several have been analyzed in more detail, and these are involved in a number of cellular processes. Some are involved in entry into the cell cycle, while others are important in apoptosis, differentiation, and replicative senescence (Figure 4.8). Space constraints preclude a description of most of these proteins and discussion of the processes that they regulate. However, some are described below and the reader is directed to references 119 and 120 for further references.

Data on the timing of cyclin-ckd activation would suggest that pRb may be phosphorylated by a succession of cdk's that are activated at different times during G₁; for example, cdk6- and cdk4-cyclin D in early/mid G₁, followed by cdk2-cyclin E in late G₁ (reviewed in reference 51). Based on sequences around the sites that are phosphorylated in pRb, the consensus sequences that are phosphorylated by cdk2-cyclin E and cdk4-cyclin D have been determined as S/_T-P-X-K/R for cdk2 and either P-L-S/_T-P-X-K/R/H or P-L-S/_T-P-I-P-K/R/H for cdk4.¹²¹ Phosphorylation-site specificity may be mediated by cyclins; for example, D-type cyclins are nuclear during G₁, bind pRb, and target cdk4 to carry out phosphorylation (reviewed in reference 122). pRb is hyperphosphorylated by the time cells reach the G₁/S border, which allows progression from late G₁ into S phase (reviewed in reference 42). During continuous proliferation of hematopoietic cells, pRb becomes transiently dephosphorylated to several partially phosphorylated forms in early G₁ and is hyperphosphorylated from late G₁ through the remainder of the cell cycle.¹²³ Experiments in which individual pRb phosphorylation sites were mutated and these mutants expressed in fibroblast or osteosarcoma cell lines showed that phosphorylation of pRb at specific

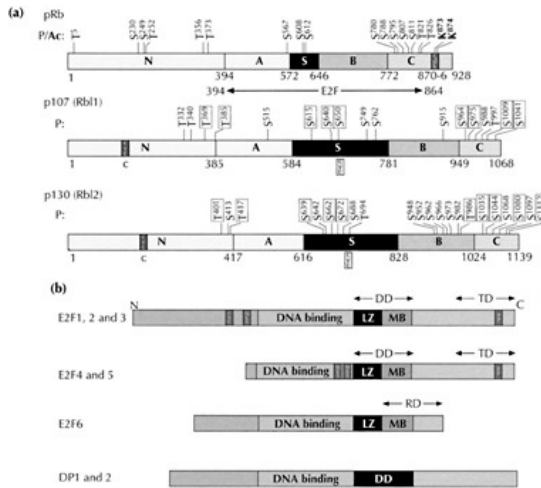

Figure 4.7 (a) The pRb family. The schema depicting each member of the pRb family show phosphorylation sites in yellow and acetylation sites in red. The phosphorylation sites that are conserved in p130 and p107 are boxed.¹⁶² The A and B domains (separated by a spacer domain, S) make up the ‘pocket’ that binds proteins with LXCXE motifs. The ‘large pocket’ (domains A, B, and C) binds E2F-DP factors. The C-terminal domain also binds MDM2 and c-ABL. cyc is the cyclin-cdk binding site (KXLKXL). Numbers indicate amino acids (N] C terminus), (b) The E2F and DP families. The domains shown allow the E2F and DP proteins to dimerize as E2F-DP heterodimers (DD, comprising leucine zipper (LZ) and marked *box* (MB) domains), to bind pRb, p130, or p107 ‘pocket proteins’ (pp), to bind E2F-binding sequences in the promoters of genes (DMA binding), and to transactivate (TD) or repress (RD) transcription. E2F1, 2, and 3 have nuclear localization signals (NLS) and E2F4 and 5 have nuclear export signals (NES). Cyclin A binds E2F1, 2, and 3 (cyc). The schema is shown with N] C terminus, left to right. See Plate 1.

Figure 4.8 pRb regulates a number of cellular processes. The pRb protein is directly involved in inhibiting (–) cell cycle progression, apoptosis, and senescence, and induces (|) differentiation. It does so by binding to the proteins shown. Inhibition of E2F1 prevents induction of the proapoptotic proteins p19^{ARF}, p73, and Apaf1.

sites is also necessary for the completion of S phase as well as the transition through G₁.^{124,125}

Hypophosphorylated pRb prevents cell cycle progression in part by binding E2F transcription factors through the so-called pRb 'pocket' domain and represses their activities. Conversely, hyperphosphorylation of pRb releases E2Fs to activate transcription of genes encoding proteins that are required for DNA synthesis (e.g. DHFR, TK, and DNA Pol α) as well as for regulating the cell cycle (e.g. cdk1 and cyclin A) (reviewed in reference 126). pRb can also bind a number of other cellular proteins, such as MDM2-p53,¹²⁷ c-Jun, ATF-2, Sp1, Elf-1, C/EBP, PU.1, c-ABL, and PML (reviewed in references 119, 120, and 128–130). PML, which is crucial in the pathogenesis of acute promyelocytic leukemia,¹³¹ is important for the proliferation and differentiation of hematopoietic precursors to erythroid or granulocytic lineages and also has a role later in erythropoiesis.^{129,130,132} Phosphorylation of pRb at S⁷⁸⁰ is required to prevent E2F binding, S⁸⁰⁷ and S⁸¹¹ phosphorylation inhibits binding to c-Abl but not to E2F, whereas phosphorylation at T⁸²⁶ and T⁸²¹ inhibits binding to proteins that contain an LXCXE motif, such as the transcription factor Elf-1, as well as virally encoded E7 and Lg T-antigen proteins.^{124,125,133} The phosphorylation site(s) that regulate binding to the myriad of other proteins have not yet been characterized.

Site-specific phosphorylation can regulate binding to specific cellular proteins and, by implication, must be important for controlling a variety of different cellular functions. For example, pRb represses apoptosis (reviewed in references 134 and 135), which is mediated in part through its interaction with MDM2-p53.¹²⁷ Cleavage of pRb towards its C terminus by caspase-3 is thought to inhibit its anti-apoptotic function.¹³⁶ When the caspase site was mutated in mice such that pRb could no longer be cleaved, this rendered certain tissues resistant to apoptosis triggered via the tumor necrosis factor α (TNF- α) receptor, but did not protect against apoptosis induced by DNA damage.¹³⁷ pRb also controls muscle, adipocyte, and neuronal differentiation through interacting with specific proteins expressed in these cells, such as MyoD and C/EBP (reviewed in reference 138). Binding to E2F is not necessary for pRb to activate myogenic differentiation or muscle-specific transcription, so the functions of pRb in regulating proliferation and differentiation are separable.¹³⁹ Downregulation of pRb with antisense oligodeoxynucleotides increased the number of CFU-E and BFU-E colonies produced from cord blood CD34⁺ cells in vitro in the presence of interleukin-3 (IL-3) and erythropoietin (EPO), suggesting that pRb may control the proliferation of erythroid cells.¹⁴⁰ Similar experiments with CD34⁺ cells cultured with Flt3 ligand and IL-3 show that pRb is required for monocytic differentiation.¹⁴¹ In addition, abnormalities of pRb are frequent in myeloid leukaemias (reviewed in reference 142) and maybe prognostic of poor survival^{143,144} (discussed in the next section). The *RBI*^{-/-} mice die at embryonal day 14.5 with neuronal abnormalities, defects in the terminal stages of erythroid differentiation, and unscheduled cell proliferation and apoptosis.^{145–149} These observations were thought to support a direct role for pRb in cellular proliferation, apoptosis, and differentiation in vivo. However, ablation of the *RBI* gene also led to excessive proliferation of trophoblast cells and disruption of placental architecture. This was accompanied by decreased vascularization and reduced placental transport function. Furthermore, a wild-type placenta rescued the neurological and erythroid abnormalities thought to be responsible for the embryonic lethality of *RBI*^{-/-} animals, but the rescued animals died at birth with severe skeletal muscle defects.^{150,151} These data show that pRb has cell-autonomous as well as non-cellautonomous roles in development.

In addition to having roles in proliferation, differentiation, and apoptosis, pRb is also thought to be involved in replicative senescence.¹⁵² The cdk inhibitor proteins p16^{INK4A} and p21^{Cip1} are elevated in senescent cells and such cells contain hypophosphorylated pRb. However, the downstream mechanisms are not understood, although it seems that the role of pRb in inducing replicative senescence is independent of its ability to bind E2F or PML.¹⁵³ The pRb pathway also has a role in regulating telomerase activity. Expression of full-length pRb but not pRb mutants downregulates telomerase activity.¹⁵⁴ Furthermore, expression of p16^{INK4A} or p15^{INK4B} can inhibit telomerase activity¹⁵⁵ and the E2F1 transcription factor inhibits the *hTERT* gene.¹⁵⁶ However, mice deficient for *RBI* did not have elongated telomeres, but combined pRb family knockouts (*RBI*^{-/-}*p107*^{-/-} or *RBI*^{-/-}*p107*^{-/-}*p130*^{-/-}) did.¹⁵⁷ Thus, although the full picture has yet to emerge, the connections between the pRb family and telomerase activity are important for cellular senescence, and may contribute to the development of cancers in which the pRb pathway is abnormal.

The pRb protein shares regions of homology with two other proteins, p107 and p130 (Rb-like proteins 1 and 2: Rb1 and Rb2). Like pRb, they are phosphoproteins that have consensus sites for phosphorylation by cdks. In particular, 22 different serines and threonines are phosphorylated in p130¹⁵⁸ (Figure 4.7a, see color plate). The p130 protein can be separated into at least four forms by one-dimensional polyacrylamide gel electrophoresis. It is present in two distinct forms (forms 1 and 2) in non-dividing cells, and these forms bind proteins such as E2F transcription factors.^{159,160} Fully phosphorylated p130 (form 3) is present in actively dividing cells, albeit at lower levels. This form of the protein does not bind E2F4 but does bind E2F1.¹⁶¹ Twelve of the phosphorylation sites in p130

are not necessary for repressing E2F activity,¹⁵⁸ but it is not clear what other regulatory roles they fulfill. The p107 protein can also be phosphorylated on multiple sites. Seventeen different serine and threonine sites have been identified¹⁶² (Figure 4.7a), and some of these are phosphorylated in whole cells by cyclin D1-cdk4.¹⁶³ For each member of the pRb family, there are many different possible phosphorylated forms that could be present in a cell. We know that certain phosphorylation sites in pRb and p130 are required to regulate E2F activity, but it is not known how the vast number of other proteins that bind members of the pRb family are regulated. No doubt, proteome analyses and investigation by protein : protein interaction screens (see e.g. reference 164) will shed light on the complexity of the cellular mechanisms that are controlled by particular forms of each of these proteins.

Hypophosphorylated pRb binds members of the E2F transcription factor family (reviewed in reference 165), and p130 and p107 function in a similar way (Figure 4.2d) (reviewed in reference 166). E2F was named for the factor that regulated the transcription of the *E2* gene of adenovirus. The nomenclature for E2F factors and their protein components can be a little confusing. Each member of the E2F transcription factor family is composed of a heterodimer of an E2F protein (E2F1 to E2F5 are known to bind the pRb family) together with a member of the DP (dimerization partner) family (DP1 and DP2) (Figure 4.7b) (reviewed in reference 167). Different members of the pRb family have some specificity for binding different E2Fs: E2F1, 2, and 3 bind pRb rather than p107, whereas E2F4 and 5 bind p130 and p107 in preference to pRb⁵¹ (Figure 4.2d). The functional consequences are that E2F1 overexpression preferentially overcomes cell cycle arrest by pRb, and E2F4/DP1 overcomes arrest caused by p130. Thus, the balance between particular E2Fs and pRb or p130 is important in determining whether a cell proliferates or remains quiescent. The major E2F complex in primary, CD34⁺ hematopoietic progenitor cells,¹⁶⁸ quiescent primary T cells,^{160,169} B cells, and monocytes is composed of E2F4-DP1 bound to p130.¹⁷⁰ In cycling cells, E2F4 either binds both pRb and p107 or p107 alone.¹⁷¹ It has been suggested that the presence of the p130-E2F4-DP1 complex defines the non-dividing state,¹⁷² as this complex is not present in proliferating cells. However, E2F6 was identified after these studies were done, and it may also play a role in regulating E2F activity during quiescence.¹⁷³

E2F6 has a truncated C terminus compared with other E2F proteins (Figure 4.7b), and cannot bind pRb, p130, or p107. It also lacks a transcription activation domain, and so does not induce E2F-regulated genes. E2F6-DP1 binds to the promoter of a target gene when cells are in G₀ and represses transcription by the assembly of a complex of proteins that alters chromatin structure. This complex contains histone methyltransferase (HMTase) activity that methylates lysine 9 of histone H3. There are two methyltransferases, NG36/G9A and a newly described Eu-HMTase 1. The roles of histone methylation and other post-translational modifications are reviewed in reference 174. The complex also contains the transcriptional repressor protein HP1 γ and polycomb group (PcG)-related proteins (RING1, RING2, MBLR, h-1(3)mbt-like protein, and YAF2). As depicted in Figure 4.9(a) and reviewed in reference 175, E2F6-DP1 binds to the E2F site in the promoter of genes such as *E2F1*, *c-myc*, *cdc25A*, and *TK* (thymidine kinase) in quiescent cells. The histone methyl-transferases present in the complex methylate lysine 9 of histone H3 and allow binding of HP1 γ . This protein, together with PcG proteins, then cause long-term repression of the chromatin structure, and hence gene activity, at that site. However, the E2F6 complex also contains the Max and Mga proteins and is able to bind to Myc sites in the promoters of target genes. This is important, as this complex therefore has the ability to bind to more than one DNA-binding site. Many E2F and c-Myc-regulated genes are involved in cell proliferation, and it is important that they be repressed effectively on a long-term basis in quiescent cells. Several genes encoding proteins such as E2F1, *cdc2*, cyclin E, Mcm7, and TK have both E2F and Myc sites in their promoters, and the complex may occupy both sites in these genes. This study was carried out with fibroblasts that were contact-inhibited and serum-starved. It is not yet known whether such mechanisms also repress gene transcription long-term in quiescent hematopoietic cells.

Chromatin immunoprecipitation studies have been used to determine which proteins bind to specific sites in the promoters of E2F-regulated genes. Such experiments showed that E2F sites in the promoters of several genes are occupied by the E2F6-DP1 complex when cells are in G₀.¹⁷³ Complexes containing E2Fs 1 to 4 occupy these sites when cells are in G₁. Therefore, it is thought that pRb and p130 take over from E2F6-DP1 and regulate E2F-dependent transcription as cells enter and progress through G₁. p130, pRb, and p107 bind individual E2Fs at different stages during entry into the first cell cycle (see reference 171 and references therein), so in theory transcription controlled by specific E2Fs could be repressed at different times. Furthermore, expression of E2F1, 2, or 3 alone, or E2F4 in combination with DP-1, causes quiescent cell lines to progress through G₁ into S phase.^{176,177} Different genes can be induced preferentially by different E2Fs.^{172,178} For example, *DHFR* and *TK* are induced by transfecting E2F2, *CCNA2*, and *CDC2* by both E2F1 and 2 and *CDK2* by E2F3.¹⁷² Thus, activation of specific E2Fs at particular times during G₁ may orchestrate the timely activation of individual genes with specific E2F-binding sites in their promoters as cells progress through G₁ and into S phase.

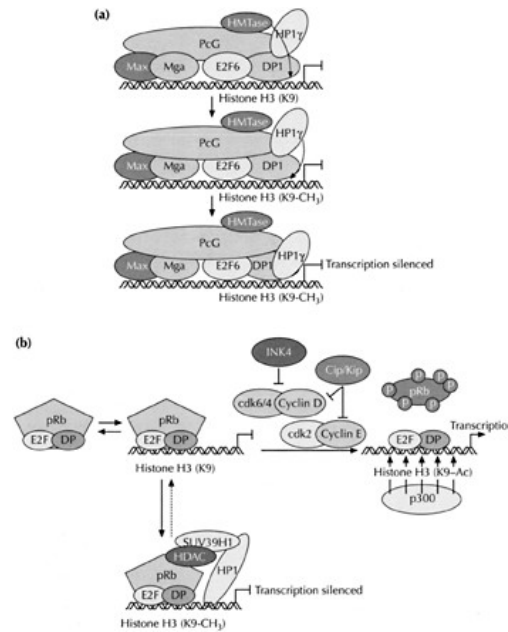

Figure 4.9 (a) Inhibition of transcription by E2F6. The E2F6-DP1 heterodimer binds to E2F sites in genes such as thymidine kinase (770) and recruits a complex of proteins that lead to gene inactivation. The complex contains several polycomb group-related proteins (PcG) as well as two histone methyltransferases (HMTase). The latter methylate lysine 9 (K9) of histone H3, and this allows the HP1y transcriptional repressor to silence transcription. The complex also contains Max and Mga proteins that direct binding to Myc and T-box DNA-binding sites. (b) Inhibition of E2F activity by pRb. Hypophosphorylated pRb binds E2F-DP proteins that direct binding to E2F sites in the promoters of genes such as TK and DMA POLA. Lysine 9 (K9) of histone H3 is deacetylated by histone deacetylases (HDACs) recruited by pRb, and transcription is inhibited. Deacetylation of histone H3 K9 allows methylation by SUV39H1 and binding by the transcriptional repressor protein HP1. Gene activation involves hyperphosphorylation of pRb by cdk6/4-cyclin D and cdk2-cyclin E, which releases pRb from E2F-DP and allows acetylation of histone H3 K9 by p300.

The p130 and pRb proteins also repress gene activity, which causes cells to exit the cell cycle. This occurs by a mechanism that is similar to E2F6-DP1. p130 or pRb bound to the appropriate E2F-DP heterodimer forms a complex containing histone deacetylase (HDAC).^{179,180} This in turn alters chromatin conformation and represses gene activity. Indeed, deacetylation at a specific nucleosome of the CCNE1 gene (encoding cyclin E) may be sufficient to repress its transcription.¹⁸¹ However, histones can also be replaced in chromatin rather than necessarily being methylated or acetylated.¹⁸² In addition to HDACs, pRb binds a histone methyltransferase (SUV39H1) that methylates lysine 9 of histone H3¹⁸³ and targets binding of the repressor HP1¹⁸⁴ (Figure 4.9b). In essence, members of the pRb family act as adaptor proteins that

bring together specific combinations of proteins. Therefore, binding of individual E2F-DP combinations by different pRb family members may target these repressor complexes to the promoters of specific groups of genes. This provides a mechanism for turning the transcription of these genes off at specific times during exit from the cell cycle. Understanding such detail is very important, as there are pRb abnormalities or abnormalities in proteins such as p16^{INK4A} that regulate the pRb pathway in a number of malignancies, including leukemias (see the next section).

Cells driven to proliferate by experimental over-expression of E2F1 die later by apoptosis; however, this is not necessarily true for E2F2 or E2F3.¹⁸⁵ This has led to the suggestion that E2F1 but not E2F2 or E2F3 specifically induces genes that trigger apoptosis and that a proliferating cell is therefore primed for apoptosis unless rescued by the presence of antiapoptotic proteins, such as pRb¹⁸⁶ or p53.¹⁷⁷ Indeed, overproducing E2F1 in cells containing a temperature-sensitive p53 protein causes apoptosis at the permissive but not at the non-permissive temperature.^{187,188} It is important to note that *E2F1*^{-/-} mice have an excess of mature T cells due to a defect in thymocyte apoptosis. The phenotype of the *E2F1*^{-/-} mice is, however, complex (reviewed in reference 189), and suggests that E2F1 can act both as a tumor suppressor and as an oncogene under different circumstances.

E2F1 is a phosphoprotein that can be phosphorylated in vitro only by certain cdk: cdk1-cyclin A > cdk2-cyclin A or cdk1-cyclin B > cdk2-cyclin E, and not at all by cdk4-cyclin D1.⁵¹ Cyclin A is only present from the G₁/S border onwards, and the timing of cdk activation by cyclin A correlates with the timing of E2F1 phosphorylation, which occurs during S phase. It is likely that E2F1 phosphorylation during S phase switches off its transcriptional activation, thereby downregulating certain E2F-dependent genes that were activated at the G₁/S border when the unphosphorylated E2F was released from repression by pRb. Indeed, there is a checkpoint during S phase that requires E2F1 phosphorylation by cyclin A-cdk. Cells in which this occurs progress through S phase, and if this is disrupted then the cells die by apoptosis.¹⁹⁰ Thus, this mechanism links transcription, DNA replication, and cell cycle progression. Although E2F1 can be phosphorylated by cdk2-cyclin A in the absence of pRb or p107, p107 may provide a link between the cdk and E2F1, which could regulate the timing or specificity of the phosphorylation. In contrast to E2F1, E2F4 is phosphorylated on many different sites and the hyperphosphorylated form is predominant in human quiescent primary CD34⁺ progenitor cells.¹⁶⁸ This form is lost as cells progress through G₁, and this may be required for activation of E2F4. In addition to being phosphorylated, 'free' E2F1, 2, and 3 that are not bound to pRb, p130, or p107 can also be acetylated.^{191,192} Acetylation occurs by CBP/p300-associated P/CAF, and causes increased DNA-binding ability, activation potential, and protein half-life.

The pRb protein regulates transcription of specific genes through suppressing E2F activity, as described above. pRb also regulates rRNA transcription via RNA Pol I and tRNA and 5S rRNA transcription via Pol III. Thus pRb regulates the activity of all three classes of RNA polymerases (reviewed in reference 193). However, suppression of cell proliferation by p107 and pRb are not the same. There are two domains in p107, either of which will prevent proliferation.¹⁹⁴ One domain binds E2F and also HDAC1, and so in this respect the mechanism of growth inhibition may be similar to that of pRb. The second growth-inhibitory domain of p107 binds cdk2-cyclin A or cdk2-cyclin E and this domain does not have a counterpart in pRb. pRb and p107 may also differ in that the c-Myc protein, which is important in driving proliferation, is inhibited by binding to p107.¹⁹⁵ The structure and functions of p130 and p107 proteins are reviewed in reference 196.

From what has been described above, it is clear that regulation of cell cycle entry is complex and involves a coordinated series of phosphorylations of key cell cycle proteins and the activation of a number of genes. Cell cycle exit is also a complicated process, and this is illustrated by the way in which IFN- α causes cell cycle arrest. IFN- α was thought to exert its antiproliferative effect in part via the pRb pathway.¹⁹⁷⁻²⁰⁰ However, the cytostatic effect of IFN- α may be mediated by a more complicated series of mechanisms that lead to orderly cell cycle arrest rather than triggering apoptosis. We know about some of the processes involved. Cdk activity is decreased,²⁰⁰⁻²⁰⁴ which may be due in part to decreases in cdc25A and cyclins D3, E, and H, and an increase in p18^{INK4C}, in Daudi B cells,^{203,205} and induction of the cdk inhibitors p15^{INK4B}, p16^{INK4A}, p21^{Cip1}, and p27^{Kip1} in other cell types.²⁰⁶⁻²⁰⁹ The initial phosphorylation of pRb during G_{1A} is prevented¹⁹⁸ and free E2F binding to DNA is reduced.^{210,211} The latter may in part be due to the induction of the gene 200 cluster (*Irfi 200* genes), in particular the p202²¹² and p204²¹³ proteins that bind directly to pRb. IFN- α also causes depletion of the c-Myc protein^{200,211,214} by transcriptional and post-transcriptional mechanisms,²¹¹ mediated by the double-stranded RNA-activated kinase PKR,²¹⁵ and also causes downregulation of the Oct-1 and Oct-2 transcription factors.²¹⁶ Thus, entry into and exit from the cell cycle are complex, orderly processes that involve cdk, the pRb family, and proteins (e.g. the E2Fs), with which they interact. It is not surprising, therefore, that abnormalities in many of these proteins occur in a range of malignancies.

Abnormalities in malignant cells

Introduction

Carcinogenesis is thought to be a multistep process involving changes in the expression or abnormalities in the function of proteins encoded by a number of genes within the same cell (reviewed in references 217–219). Such abnormalities affect the balance between cell proliferation, apoptosis, and differentiation, and in hematopoietic malignancies this leads to an expansion of the malignant clone (Figure 4.1b). In at least some malignancies, such as acute myeloid leukemia (AML), this is aided in turn by immune suppression. This is caused in part by inhibition of the proliferation and activity of normal cells by cells of the malignant clone (see reference 220 and references therein). Deregulation of or inactivating mutations in cell cycle proteins contribute to the malignant phenotype. However, as illustrated in the previous section, aberrant expression of a gene that causes cells to proliferate when they should not may lead to apoptosis rather than uncontrolled cell proliferation. Therefore, it is envisaged that abnormalities in numerous genes are needed to deregulate cell proliferation and also to bypass controls that would normally trigger apoptosis, differentiation, or senescence (reviewed in reference 221). The need for multiple mutations to deregulate proliferation without apoptosis is illustrated by the fact that proliferation and apoptosis occur in *RB1*^{-/-} mouse lens cells but comparable cells lacking both *RB1* and *TP53* genes do not undergo apoptosis.²²² Thus, it is not surprising that there are abnormalities in p53 as well as pRb in a large number of different tumors. Many other tumors have mutations, which affect proteins that are necessary for pRb and p53 function. The pRb and p53 proteins are also key targets for inactivation by DNA tumor viruses, including adenovirus (E1A and E1B proteins), simian virus (SV) 40 (large T antigen), and human papillomavirus (HPV E6 and E7 proteins) (reviewed in reference 223).

Studies have been carried out to determine the minimum number of abnormalities that are necessary to cause a cell to become transformed. The classic assay for cooperating oncogenes is the NIH-3T3-transformation assay.²²⁴ However, as NIH-3T3 cells have an unknown number of genetic abnormalities, this assay does not define the minimum number of genetic ‘hits’ needed. The assay simply defines the number of additional oncogenes that are required to cause anchorage-independent growth in soft agar and tumors in nude mice. Many studies have investigated combinations of oncogenes that transform mouse cells, and transgenic models of various malignancies have been established.²²⁵ Similarly, gene knockout, knock-in, and conditional knockout studies have established that certain genes predispose mice to specific malignancies. As an example, the need for cyclins D1 and D2 in cancers caused by aberrant expression of *myc*, *ras*, *neu* and *wnt-1* is discussed in reference 226. Experiments have also been conducted in which gene expression or protein function can be switched on or off at will. These studies investigated the requirement for proteins such as c-Myc and p53 in the establishment and, importantly, in the maintenance of cancers (reviewed in reference 227).

The studies described above relate to mouse models of carcinogenesis. However, mice and humans are not the same, and there are differences in the way the cells respond to genetic abnormalities in both species.²²⁸ Put simply, genes that transform cells in mice do not necessarily do so in humans, and so the implications of such studies for human diseases have to be treated with caution. Studies have investigated whether deregulation of the controls exerted by a combination of pathways, namely Ras, pRb, p53, and telomerase, are sufficient to transform human cells.^{229,230} The aim was to produce an immortal human cell that could survive without growth factors and did not need to be anchored to a solid support in order to proliferate. This was achieved in the first study²²⁹ using human embryonic kidney and early-passage normal human fibroblast cells. SV40 large T antigen was introduced to abrogate the functions of both p53 and pRb, and the telomerase catalytic subunit (hTERT) was used to prevent telomere shortening, and the cells were also transfected with an activated ras gene (H-rasV12). Introduction of H-rasV12 alone caused replicative senescence, which was shown previously for murine cells.²³¹ This is now known to be dependent on p53: caused by acetylation of p53, induction of PML, and formation of PML-p53-CBP chromosomal complexes.²³² hTERT and large T antigen caused immortalization, but only the combination of hTERT, large T antigen, and H-rasV12 allowed growth in soft agar and tumors in nude mice. However, in a second study²³⁰ using the same fibroblast line, abrogation of p53 and pRb this time with human papillomavirus 16 E6 and E7 proteins, together with hTERT and H-rasV12, was not sufficient to cause growth in soft agar. There are two possible explanations for differences between these studies. First, it is known that large T antigen affects other proteins in addition to pRb and p53,²³³ and so other pathways, such as those involving protein phosphatase 2A, may also be involved in transformation;²³⁴ or, secondly, that the order in which the pathways are deregulated is important. In the first paper, a plasmid expressing large T antigen was transfected first, whereas in the second study, cells expressing hTERT were used. However, notwithstanding the differences in outcomes, there is proof of the principle that human cells can be transformed with a limited number of well-defined molecules. This was confirmed by studies on breast²³⁵ and airway epithelial cells.²³⁶ Such studies beg the question whether

Figure 4.10 Abnormalities of cell cycle proteins in leukemias. A number of abnormalities in the expression or activities of components of the CKI/cdk/pRb pathway exist in different leukemias. Some of these are illustrated, together with the leukemias in which they are found. The effects of such abnormalities are dependent on the context of abnormalities in other genes such as *ras* and *TP53*, as discussed in the text. (Me*CDKN2B*: hypermethylation of the *p15^{INK4B}* gene; ~~*CDKN2A*~~: deletion in the *CDKN2A* gene; ↑ or ↓: upregulation or downregulation of the protein.)

similar mechanisms that inactivate those pathways are important in the development of a variety of cancers, including leukemias and whether such studies relate to the formation of human cancers in vivo.

This section of the chapter will discuss how over-expression, absence, or mutations of key cell cycle proteins, normally involved in G_1 phase of the cell cycle, can result in bypassing control points, which would otherwise induce cell cycle arrest, apoptosis, senescence, or differentiation (Figure 4.1b). I will concentrate on the CKI-cdk-pRb-E2F pathway (Figure 4.2b-d), and the key abnormalities in these molecules in leukemias are summarized in Figure 4.10. At the beginning of this chapter, I alluded to the fact that the molecular circuitry of cells can be important for determining the way in which an abnormal protein acts, and this has been highlighted by recent studies described above (reviewed in reference 237). Therefore, where possible, I will describe what is known of the action of a particular abnormality in the context of other abnormalities that are known to exist in the disease. More generally, there are several excellent reviews of the ways in which cell cycle deregulation contributes to cancer.^{238–243} They contain more detail and bibliography than can be covered here.

pRb, p130, and p107

Abnormalities in the *RB1* gene²⁴⁴ are responsible for the childhood tumor retinoblastoma.²⁴⁵ In many other malignancies, *RB1* mutations and deletions¹¹⁵ are likely to be involved in disease progression. This is true of the invasive phase of bladder cancer and non-small cell lung cancer and in high-grade sarcomas with poor prognosis. pRb is also involved in hematological malignancies (reviewed in references 246–248). Loss of pRb is common in acute lymphoblastic leukemia (ALL), but abnormalities in either pRb or p53 have no prognostic significance.²⁴⁹ In Hodgkin lymphoma, 16% of patients had loss of pRb and high expression correlated with better survival.^{250,251} Abnormalities in the pRb protein also occur in 20–55% of cases of AML, and in three of four studies this was prognostic of poor remission or survival (reviewed in references 246 and 252). In some cases, pRb may control the proliferation of AML blasts by regulating the *IL-6* gene, and absence of pRb in these cells or suppression of pRb production in vitro with antisense oligodeoxynucleotides causes increased proliferation.^{253,254} No mutations, deletions, or promoter hypermethylation of *RB1* have been reported in AML, and no *RB1* mutations have been detected in myelodysplastic syndromes (MDS).²⁵⁵ However, *RB1* mutations do occur in chronic myeloid leukemia (CML) during accelerated phase and blast crisis, but these may not be the crucial events responsible for CML progression (reviewed in reference 246). In addition, many other genes that regulate pRb have been implicated in carcinogenesis, including the D-type cyclins and the cdk inhibitors, discussed below.

Some abnormalities have also been reported for p130 and p107, although these have not been studied as extensively as pRb. The nuclear localization signal of p130 was mutated in T-ALL and Burkitt lymphoma cell lines as well as in half of primary samples from patients with Burkitt lymphoma.^{256,257} This caused p130 to be localized to the cytoplasm rather than the nucleus, where it would be expected to be inactive. Abnormalities in p107 were reported in one T-ALL and one diffuse large cell lymphoma cell line.²⁵⁸ However, the functional consequences of these abnormalities in p130 and p107 are unclear. Mouse knockout studies have shown that the other members of the pRb family can compensate for loss of one family member. However, the functional consequences may depend on the other abnormalities that exist in the cells. It is also possible that these are bystander effects that do not contribute to the disease, but cosegregate with other abnormalities that do.

Cyclins

The gene encoding cyclin D1 (*CCND1*) was identified as the *PRAD1* oncogene of parathyroid adenoma as well as the *bcl-1* oncogene in human B-cell lym

phomas (reviewed in reference 122). Amplification of the *CCND1* locus occurs in up to 50% of squamous cell, liver, and breast carcinomas. Mice carrying a *CCND1* transgene driven by the promoter of the mouse mammary tumor virus develop mammary hyperplasia and adenocarcinoma, providing further evidence that connects overexpression of cyclin D1 and tumorigenesis. When cyclin D1 overexpression is targeted to the lymphoid system and coupled with c-Myc overexpression, the transgenic mice develop lymphomas²⁵⁹ indicating that cyclin D1 cooperates with other proto-oncogenes in transformation. The hallmark of mantle cell lymphoma (MCL) is the t(11; 14) translocation that fuses the immunoglobulin heavy-chain enhancer/promoter to the *CCND1* gene. This constitutively activates the *CCND1* gene, disrupting its normal regulation. Importantly, gene expression profiling of MCL expressing cyclin D1 identified 20 'proliferation signature' genes that were prognostic of the duration of survival.²⁶⁰ Those rare MCL cases lacking cyclin D1 expression produce higher levels of cyclins D2 and D3, which are presumed to compensate for its function.

Overexpression of cyclin D1 in mammalian cell lines results in a shortening of G₁ phase of the cell cycle,²⁶¹ which leads to the appearance of hyperphosphorylated pRb.⁵¹ As mentioned in the section above on cell division, premature entry into S phase that shortens the time taken to progress through the cell cycle would lead to a reduction in cell mass upon cell division, with the result that the cells would be smaller. However, other cell cycle phases are prolonged when cyclin D1 is overexpressed, so the time taken to complete a cell cycle does not change. Other factors associated with cyclin D1 overexpression may contribute to malignancy, such as promotion of growth factor independence or escaping replicative senescence (see below).

Female mice lacking the *CCND2* gene have defects in the production of granulosa cells, and so are infertile.²⁶² This specificity is important, since even though cyclin D2 is expressed in a variety of cell types in the body, it is absolutely necessary for the FSH-driven proliferation of granulosa lutein cells. A possible role in cancer is indicated by the fact that cells from patients with granulosa cell malignancies contain elevated cyclin D2 levels. Furthermore, the *CCND2* gene is amplified in a colorectal cancer. There is also a critical role for cyclin D2 in the action of BCR-ABL. Elevated cyclin D2 correlates with BCR-ABL activity,^{263,264} and bone marrow cells from *cyclin D2*^{-/-} mice do not proliferate when transduced with a vector expressing BCR-ABL.²⁶⁴ These data indicate that cyclin D2 is a necessary downstream target of BCR-ABL in CML. Overexpression of cyclin D2 is a common feature of B-CLL.²⁶⁵⁻²⁶⁷ In one patient who transformed to non-Hodgkin lymphoma, a translocation disrupted a negative element in the *CCND2* promoter, which would be expected to elevate *CCND2* transcription.²⁶⁸ Cyclin D2 also cooperates with H-Ras, and, in the presence of a low serum concentration, the cells continue to increase their cell mass up to ten times their normal size but do not enter S phase.²⁶⁹ Thus, they engage the cellular growth cycle⁹ without being able to enter the cell cycle.

In normal B lymphocytes, engagement of the B-cell antigen receptor (BCR) induces a cascade of signaling events that culminate in B-cell proliferation and activation. In leukemias and lymphomas, these signaling pathways are dysregulated, which could lead to unscheduled proliferation, survival, and deregulated differentiation. In B-CLL, this allows CD5⁺ B cells to predominate. In splenic mature B cells, cyclin D2 is essential for BCR-induced hyperphosphorylation of pRb, p130, and p107, regulation of E2F activity, and S-phase entry.²⁷⁰⁻²⁷² Furthermore, genetic ablation of the *cyclin D2* gene causes a depletion of the B1 (CD5⁺) population of B cells, but not the conventional CD5⁻ B2 B cells or other hematopoietic cells.²⁷³ Cyclin D1 is not present in normal B cells, and the existence of normal B cells in *cyclin D2* null mice is due to the fact that cyclin D3 can compensate for the function of cyclin D2 in conventional B2 cells.²⁷⁰

The cdk inhibitor p27^{Kip1} is a potential downstream target of cyclin D2-cdk4/6, and there is a reciprocal relationship between cyclin D2 and p27^{Kip1} expression.^{270,274,275} Furthermore, forced p27^{Kip1} expression causes cell cycle arrest in G₁ and induces B-cell apoptosis.²⁷⁴ In B-CLL, cyclin D2 is overexpressed in CD5⁺ B cells,²⁶⁵⁻²⁶⁷ but cyclin D3 and p27^{Kip1} are also expressed in a higher proportion of CD5⁺CD19⁺ B-CLL cells than in normal controls.²⁶⁸ Cyclin D2-cdk4 and cyclin D3-cdk4 complexes are present in B-CLL cells stimulated to proliferate in vitro, whereas cyclin D3-cdk6 complexes predominate in normal B lymphocytes.²⁷⁶ In addition to cyclin D2, B-CLL cells also contain high levels of Bcl-2^{277,278} and express survivin upon stimulation with CD40L.²⁷⁹ It has been proposed that the expression of Bcl-2 and survivin protect the CD5⁺ B cells in B-CLL from undergoing apoptosis. In addition to its role in cell proliferation, cyclin D2 may also have a role in protecting lymphoid and myeloid cells from undergoing apoptosis.^{263,266,268} These data indicate that the molecular controls of cell cycle proteins are aberrant in B-CLL,²⁷⁶ and since this pathway is crucial for the development of CD5⁺ B cells, individual components of the pathway potentially offer opportunities for therapeutic intervention.

As described above, the third D-type cyclin, cyclin D3, is necessary for the production of CD4⁺CD8⁺ doublepositive T cells. Cyclin D3 is also necessary for development of mouse models of T-ALL that are induced by Notch1 or p56^{lck}. Furthermore, depletion of cyclin D3 by RNAi methods caused G₀/G₁ arrest of human TALL cell lines, indicating that cyclin D3 is necessary

for maintaining T-ALL proliferation.⁴⁷ The *CCND3* gene is also dysregulated by translocation to immunoglobulin loci in multiple myeloma (MM).^{280,281}

The D-type cyclins activate cdk6 and cdk4, and aberrant activation of one or both of these kinases could be responsible for the abnormalities caused by dysregulation of cyclin D1, D2, or D3. Indeed, the gene encoding cdk6 is also dysregulated or forms a fusion gene as a result of chromosomal translocations in several hematopoietic diseases. These include T-ALL, infant ALL (*t*(7; 11)(q22–23)), T-cell lymphoblastic lymphoma with leukemia (*t*(2; 7)(p12; q21–22) juxtaposes the *CDK6* and *Igκ* genes), and B-cell splenic lymphoma with villous lymphocytes (*t*(2; 7)(q21–22)). Inframe *CDK6-MLL* fusion genes have been detected in ALL, and in one case a three-way *MLL, AF4, CDKG* fusion occurred.^{282–284} In contrast, *CDKG* is disrupted in splenic marginal zone lymphoma (*t*(7; 21)).²⁸³ Overexpression of cdk6, but not cdk4, blocks erythroid differentiation in vitro,⁵⁰ and inhibition of cdk6 and cdk2, but not cdk4 and cdk2, leads to differentiation of erythroleukemia (MEL) cells.⁴⁹ Taken together, these data indicate that cdk6 and cdk4 have different roles and implicate cdk6 in regulating cell fates (cell cycle and differentiation).

Overexpression of the D-type cyclins may also affect cell fate decisions by mechanisms that are not dependent on activating cdk6 or cdk4. Most of the evidence (reviewed in reference 285) stems from studies on the role of cyclin D1 in non-hematopoietic cells, such as breast epithelium. Cyclin D1 expression does not correlate with cdk4 activity or other markers of cell proliferation. Cyclin D1 can effect the transcription of several genes, including those encoding chaperone proteins. This occurs at least in part by binding C/EBPβ, and the transcription factors affected include DMP1, androgen receptor, STAT5, BETA2/NeuroD, and thyroid receptors. Cyclin D1 also binds the estrogen receptor. However, it is not yet known to what extent some of these functions are also carried out by cyclins D2 and D3 in hematopoietic cells.

Cyclin E is also elevated in a number of cancers, including cervical and breast cancers (reviewed reference 286). This can occur by gene amplification but also by mutation of *hCDC4*.²⁸⁷ hCDC4 is an F-box protein that normally regulates cyclin E levels by targeting the cyclin E protein for poly-ubiquitination and proteolysis (Figure 4.4). In hematological malignancies, cyclin E protein is overexpressed in 27% of patients with AML, and in particular in 60% of patients with the M5 subtype.²⁸⁸ Furthermore, rates of complete remission and disease-free survival were low in patients with M4 or M5 AML with high levels of cyclin E. Cyclin E Overexpression is also associated with CLL as well as Hodgkin and non-Hodgkin lymphomas (reviewed in reference 289). The role played by elevated cyclin E is unclear. Elevated expression of cyclin E by transfection shortens G₁ phase of the cell cycle, as does elevating cyclin D1, and expression of both cyclins has an additive effect of shortening G₁.²⁶¹ However, it is not known whether this mechanism operates in AML or CLL. Cyclin E Overexpression also leads to changes in chromosome ploidy.²⁹⁰ This seems to be specific to cyclin E, as neither cyclin D1 nor cyclin A have the same effect. However, it is not known whether cyclin E contributes to malignant transformation in vivo by promoting changes in chromosome ploidy or by affecting the control of cell proliferation.

CKIs

Abnormalities in cyclin-dependent kinase inhibitors are implicated in a variety of malignancies (reviewed in reference 291). Specific *CDKN2A* mutations, which produce defective p16^{INK4A} protein, as well as deletions of the gene, have been detected in a wide range of malignancies.^{78,79,292} These include a high proportion of patients with T-ALL,²⁹³ some precursor B-ALL,^{293,294} and high-grade and transformed non-Hodgkin lymphoma.²⁹² In general, cancer-associated mutations in the *CDKN2A* locus do not affect the expression or function of p14^{ARF}.²⁹⁵ However, some changes in p14^{ARF} in human hematological malignancies have been noted, especially in diffuse large B-cell lymphoma.²⁹⁶

Although p14^{ARF} is not a CKI, abnormalities in the *INK4/ARF* locus must be considered both in the context of the roles of p14^{ARF} as well as p16^{INK4A} in malignancy. *Arf* is induced by oncogenes such as *myc*, *ras* and *v-abl*. As discussed in the section on CKIs earlier in this chapter, this causes p53 activation and cell cycle arrest or replicative senescence (Figure 4.6b). Losing the function of p14^{ARF} or p53 leads to a breakdown in this mechanism and potentially allows oncogenes such as *myc* to induce proliferation. This is supported by the fact that animals that contain *Eμ-myc* and aberrantly express c-Myc from an immunoglobulin promoter develop B-cell lymphomas in which there are also abnormalities in *Arf* or *TP53*. Furthermore, *Eμ-myc, Arf*^{-/-} animals develop rapid and aggressive disease (reviewed in reference 241). These examples show that the consequences of *Arf* abnormalities are complex and dependent on the molecular circuitry that is present in the cell (reviewed in reference 297). Furthermore, the functions of p14/19^{ARF} and p16^{INK4A} may be different in human and mouse cells (reviewed in reference 298). Such differences in function complicate our analysis and understanding of the functions of p14^{ARF} and p16^{INK4A}. They also indicate that any basic biological mechanisms that we may consider pertinent to human diseases must be validated with primary human cells rather than necessarily extrapolating from experiments with mice or other organisms.

Another mechanism of *CDKN2A* inactivation is by gene silencing caused by hypermethylation of 5' CpG islands. Silencing *CDKN2A* occurs in a number of different primary neoplasms and cell lines,²⁹⁹ including lymphomas, but is rare in leukemias (reviewed in references 248 and 300). Similarly, hypermethylation of *p14^{Arf}* is rare in leukemias and lymphomas but common in cancers such as colon and stomach (25% and 38%). Genes such as *CDKN2B* (encoding p15^{INK4B}), *DAPK*, *CDHI*, and *TP73* are more commonly hypermethylated in leukemias (62%, 9%, 40%, and 31% respectively of patients tested).³⁰¹ It should be noted that more than one gene is silenced by aberrant hypermethylation in different cancers and these differ depending on the cancer concerned. As mentioned in the earlier discussion of CKIs, both p16^{INK4A} and p15^{INK4B} prevent cdk4 and cdk6 phosphorylating pRb, and so loss of a functional p16^{INK4A} or p15^{INK4B} would be expected to remove the constraints on cdk6/4-cyclin D activity, thereby promoting cell cycle progression. This view is supported by studies where microinjection of p16^{INK4A} into cell lines deficient for pRb failed to inhibit progression into S phase, whereas elevated levels of p16^{INK4A} in cells containing functional pRb inhibited proliferation.^{45,51,177} Cells lacking in pRb have in fact been shown to overexpress p16^{INK4A}, and a negative feedback loop between p16^{INK4A} and pRb has been postulated (reviewed in reference 122). However, analysis of blasts from patients with AML showed that this reciprocal relationship occurs only in a subset of cases.³⁰²

The products of other cell cycle genes implicated in malignancy include cdk4 and p15^{INK4B}. The *CDK4* gene is amplified in some tumors, and deletions of *CDKN2B* have been reported in non-small cell lung cancer and in hematological malignancies. *CDKN2B* is abnormal in a high percentage of T-ALL cases, and about half of the cases were reported to have alterations in both *CDKN2B* and *CDKN2A*.^{293,303} Deletion of *CDKN2B* also occurs in precursor B-ALL, but at a low frequency.²⁹³

The importance of silencing of the *CDKN2B* gene comes from an analysis of the myelodysplastic syndromes (MDS). These are a group of hematological disorders that have been described as preleukemic, since many transform to acute leukemia (reviewed in reference 304 and see Chapter 40). Several molecular abnormalities in MDS have been described (reviewed in reference 305), for example *ras* mutations (48% in chronic myelomonocytic leukemia (CMML)),^{306,307} *Ras* overexpression (30%),³⁰⁸ *p53* (8%), *fms* (5–10%),³⁰⁹ *IRF1* exon skipping and nucleophosmin overexpression,^{310,311} fusion genes (<1%) and increased telomerase activity ($\times 10$ –50 in refractory anemia with excess blasts in transformation (RAEB_t)).^{312–314} As mentioned above, the gene encoding the CKI p15^{INK4B} is silenced by promoter hypermethylation in the later stages of MDS in up to 80% of cases.^{315–319} This is associated with poor prognosis, increased transformation rates to aggressive subtypes of MDS and AML, and resistance to standard combination chemotherapy regimens, such as those used in de novo AML. This underscores the importance of *CDKN2B* hypermethylation during the transformation of MDS to AML. Furthermore, a randomized trial of the DNA methyltransferase inhibitor 5-azacytidine increased the time taken for transformation to AML, although overall survival was unaffected.³²⁰ *CDKN2B* is also hypermethylated in de novo AML (79%) and in acute promyelocytic leukemia (APL) (73%).³²¹

The role of p15^{INK4B} in normal myeloid development is unclear and the effect of losing the p15^{INK4B} protein in the progression of MDS is not understood. Knocking out murine *CDKN2B* alone leads to lymphoproliferative disorders rather than myelodysplasia.³²² As detailed above in the section on proteins that regulate the cell cycle, p15^{INK4B} inhibits cdk6-cyclin D and cdk4-cyclin D activities, which would be expected to cause cell cycle arrest in G₁ via pRb- and p130-dependent pathways. However, p15^{INK4B} can also inhibit proliferation by a mechanism independent of pRb.³²³ Studies on the function of p15^{INK4B} have been carried out with cell lines or in mice, and not in primary cells from patients that contain other abnormalities that will affect the cellular phenotype. This is crucial since, for example, H-rasV12 causes replicative senescence in a normal genetic background²³¹ but transformation of cells in which the functions of pRb, p53, and telomerase are abrogated.³²⁴ Furthermore, *CDKN2B*^{-/-} mouse embryo fibroblasts, but not *CDKN2B*^{+/+} controls, undergo transformation and grow in soft agar when transfected with H-rasV12.³²² The reason why some wild-type cells are resistant to H-rasV12 may be that *CDKN2B* can be induced by ras activation and p15^{INK4B} expression is sufficient to stop transformation by H-rasV12.³²⁵ Taken together, these data would suggest that silencing *CDKN2B* could contribute to leukemic progression by allowing activated ras to cause deregulated growth without inducing replicative senescence, by shortening the time taken to progress from G₀ to G₁, by preventing full differentiation, or by a combination of these. However, several other proteins (p16^{INK4A}, p21^{Cip1}, and p57^{Kip2}) suppress transformation by ras or other oncogenes, and studies show that p19^{ARF} and p53 are required for ras-induced senescence.^{326,327} Thus, the expression of these proteins, as well as abnormalities such as N-rasV12 or pRb, will affect the cellular phenotype produced. Several studies have suggested that abnormalities or hypermethylation of *CDKN2A* or *CDKN2B* have prognostic significance. However, to date the data are equivocal (reviewed in reference 248).

Abnormalities in other CKI proteins are uncommon in hematological malignancies. Tissue microarray studies of samples from 316 Hodgkin lymphoma

patients showed absence of p18^{INK4C} immunostaining in nearly half of the patients studied. The *CDKN2C* gene promoter was hypermethylated in 5 of 26 patients analyzed.³²⁸ Silencing of the *CDKN2C* gene may give the abnormal stem cell a proliferative advantage as studies on *CDKN2C*^{-/-} mice show increased stem cell self-renewal.⁹⁰ Furthermore, haploinsufficiency in *CDKN2C* sensitizes the mice to carcinogen-induced tumors.³²⁹ In contrast to other INK4 proteins, no abnormalities in *CDKN2D* (encoding p19^{INK4D}) were found in a range of hematological malignancies.³³⁰

A mutation in *CDKN1A* was detected in a cell line derived from a patient with Burkitt lymphoma.³³¹ The mutated p21^{Cip1} protein may function by being less able to suppress cell proliferation than the normal p21^{Cip1} protein. *CDKN1A* was silenced by hypermethylation in 41% of ALL patients, and was an independent prognostic factor in predicting disease-free survival in children and adults.³³²

Abnormalities in the gene encoding p27^{Kip1} are uncommon,³³³ but a mutation in *CDKN1B* was reported in a child with ALL.³³⁴ However, p27^{Kip1} expression may be a prognostic indicator of survival in a number of cancers, particularly in combination with cyclin E.^{335–337} The abundance of p27^{Kip1} in the cell is controlled in part by Skp2 (see the earlier section on CKIs and Figure 4.4). Skp2 is elevated in a number of transformed cell lines³³⁸ and elevating Skp2 in fibroblasts prevents cell cycle exit upon serum withdrawal and causes entry into S phase even in the absence of serum.³³⁹ This provides a mechanism for deregulating the cell cycle, although a role in leukemogenesis has not been investigated. Haploinsufficiency in *CDKN1B*³⁴⁰ is also important, and animals lacking one copy of *CDKN1B* develop tumors late in life and are very sensitive to chemical carcinogenesis. In humans, hemizygous loss of *CDKN1B* indicates poor prognosis.³⁴¹

p57^{Kip2} is a candidate tumor suppressor, as mentioned earlier in this chapter. The *CDKN1C* gene is located at chromosome 11p 15.5 and this region is implicated in a number of human cancers, including breast, liver, and bladder cancers, rhabdomyosarcoma, as well as Beckwith-Wiedemann syndrome and Wilms' tumor.¹¹³ Indeed, mice lacking *CDKN1C* exhibit a range of cellular differentiation and proliferation defects reminiscent of Beckwith-Wiedemann syndrome in humans.¹¹² The *CDKN1C* gene was reported to be silenced by hypermethylation in AML patients, exclusively in those exhibiting a CpG methylator phenotype.³⁴² However, in another study, *CDKN1C* hypomethylation was detected neither in 14 AML patients nor in MDS or adult T-ALL, but it was hypermethylated in diffuse large B-cell lymphoma (55%) and follicular lymphoma (44%).³⁴³ The functional significance of *CDKN1C* silencing in different hematopoietic cell types remains to be determined.

Clinical implications of the analyses of pRb/cyclin-cdk/CKI families

Abnormalities in molecules that cause or are normally associated with a particular cancer provide markers that could be used for identifying and categorizing the disease as well as potentially being prognostic indicators. For example, abnormalities in the INK4 and Cip/Kip families have been analyzed in sufficient numbers of patients, so the prognostic significance of such CKI abnormalities can be evaluated. p27^{Kip1} is a predictor of poor prognosis in breast, prostate, gastric, and colon cancers (reviewed in reference 337). As described in the preceding subsection, silencing *CDKN1A* by promoter hypermethylation is a prognostic factor in ALL³²⁵ as well as other non-hematological malignancies.³³⁷ Abnormalities in the *CDKN2A* and *CDKN2B* genes are also common in ALL, but to date their prognostic value is controversial.^{248,337}

A number of studies have used 'global' gene expression profiling to identify genes that are characteristically expressed in a particular disease. Such analyses have been used to identify known diseases, such as correctly identifying samples from patients with AML, B-ALL, and T-ALL.³⁴⁴ Microarray studies have also enabled the subclassification of diffuse large B-cell lymphoma³⁴⁵ and to predict those patients who are more likely to respond to treatment.³⁴⁶ In each case, the expression of genes encoding proteins responsible for regulating cell proliferation were part of the cohort of 'predictive' genes. For example, the expressions of *cyclin CCND3*, *RBBP4* (a pRb regulator), and *MCM3* (part of the DNA replication origin recognition complex) were all low in AML and high in ALL.³⁴⁴ High levels of cyclin D2 were characteristic of Philadelphia chromosome-positive cells.²⁶⁴ Expressions of *CCNB1* and *CDC47* were high in DLBCL relative to follicular lymphoma,³⁴⁷ and a 'proliferation signature' of 20 genes predicted survival duration in mantle cell lymphoma.²⁶⁰

The cell cycle proteins that are abnormal or are aberrantly expressed in hematological malignancies are potential targets for new drugs. One goal is to target the molecules involved in DNA CpG methylation in order to re-express genes such as *CDKN2B* that are silenced by hypermethylation. The drugs 5-azacytidine and 5-aza-2'-deoxycytidine are effective in reactivating a number of silenced genes (reviewed in reference 348), including *CDKN2B* in MDS.³⁴⁹ Administration of 5-aza-2'-deoxycytidine at lower doses in combination with an HDAC inhibitor (TSA) synergistically cause gene re-expression.³⁵⁰ These drugs globally change the expression of silenced genes in the cell that may induce apoptosis or cause normal differentiation. However, in some cases, it may be more effective to target specific proteins, such as cdks, that are active in malignant cells. As described earlier in this section, a variety of cdk regulators have been

shown to be abnormal in hematological malignancies. These include activating abnormalities such as the expression of cyclins D2 and E, as well as removal of cdk inhibitors such as p16^{INK4A}. In addition, the chaperone protein hsp90 is elevated in MDS, AML and chronic lymphocytic leukemia (CLL),^{351–353} and this would be expected to stabilize active cdk4-cyclin D, as well as other kinases.

One criterion of carcinogenesis, as described by Hanahan and Weinberg,²⁴⁰ is that proliferation should become independent of external mitogenic stimuli. Therefore, inhibition of cdk activity should arrest these malignant cells and may induce apoptosis. However, it may also be possible to induce leukemic cells to differentiate by inhibiting cdk2 and cdk6.³⁵⁴ The active ingredient in a Chinese antileukemia medicine, indirubin, is a cdk inhibitor.³⁵⁵ The medicine has been used for hundreds of years, and indirubin is currently being tested in clinical trials for CML and chronic granulocytic leukemia (CGL). Flavopiridol and UCN-01 are both cdk inhibitors that have been tested in phase I and II clinical trials in non-Hodgkin lymphoma and non-hematopoietic cancers,³⁵⁶ and other cdk inhibitors are under development. Drugs that target hsp90, such as geldanamycin and derivatives (e.g. 17AAG), inhibit cdk4-cyclin D, as well as other kinases in the cell.³⁵⁷ There is much to be done to determine to what extent abnormalities in the CKI-cdk-pRb-E2F pathways are necessary for the maintenance of human leukemic cells and in particular for the survival of leukemic stem cells that can exist in a quiescent state for prolonged periods. Over the coming years, new drugs that target specific components of these pathways may come to the forefront in treating hematological malignancies.

Conclusions

The control of cell proliferation is a complex process, involving a number of key proteins in the cell. Many of these are part of a pathway that involves pRb, either directly or indirectly. In addition, pRb or one of a number of proteins with which it interacts is abnormal in a wide range of malignancies. pRb is also pivotal as it has a role in regulating cell proliferation, apoptosis, and differentiation, as well as replicative senescence. The roles of many of the proteins that are known to bind to or regulate pRb have been studied and we know a great deal about their modes of action. Similarly, defining combinations of proteins that are mutated or that are not expressed in various malignancies is giving us clues as to how they function in a coordinated way to affect the fates of various cell types. In particular, we are beginning to understand that the molecular circuitry is important for determining what consequence a mutation in a given gene will have on that cell. In particular, the molecular abnormalities in each malignancy may differ, but certain pathways are commonly deregulated. This is important as our knowledge is leading to therapies directed at abnormalities in specific cancers that should be more effective, with fewer side-effects on normal cells. However, our increasing knowledge of the mechanisms involved in carcinogenesis also highlights the fact that we cannot simply extrapolate from studies on mice or on cell lines to inform us of the role that specific abnormalities have in particular diseases, such as human leukemias. We know least about which abnormality initiates normal hematopoietic stem cells to become leukemic and which abnormality is necessary to maintain their leukemic potential. Such information would provide targets for early diagnosis and treatment. Obtaining this information presents a considerable challenge for the future, but meeting this challenge is crucial if disease-specific drug therapies are to be effective in eliminating leukemic stem cells from the body.

Acknowledgments

I thank my colleagues in Leukaemia Sciences at King's College London for critical comments on the manuscript. Work in my laboratory on cell cycle regulation is funded by the Charles Wolfson Charitable Trust, the Leukaemia Research Fund, and the UK Medical Research Council.

Transcription factors in hematopoietic differentiation and leukemia

Michael A Chapman and Anthony R Green

Introduction

One of the central issues of developmental biology concerns the molecular mechanisms whereby a multipotent cell gives rise to distinct differentiated progeny. Differences between specialized cell types reflect variations in patterns of gene expression. The regulation of transcription is an important control point for gene expression, and it is therefore not surprising that transcription factors play a pivotal role in mammalian development and differentiation.

Hematopoiesis, the process of blood cell formation, is a powerful experimental model for studies of these processes. During embryonic development, hematopoiesis occurs in sequential phases. Early hematopoiesis, and particularly erythropoiesis, is observed in the yolk sac, but later moves to the fetal liver and finally to the bone marrow. It has long been thought that stem cells formed in the yolk sac migrate to the fetal liver, but more recently it has become clear that stem cells can also arise independently at an early stage of development within the embryo in the region of the dorsal aorta.^{1,2} In an adult, pluripotent stem cells give rise to a hierarchy of multi- and oligopotent progenitor cells, which, in turn, differentiate into at least nine specialized and very different cell types. The scale of the process is staggering. Over 10¹¹ differentiated cells are produced each day.

How is hematopoiesis regulated? First, it should be made clear that different regulatory mechanisms are likely to operate in the different phases of hematopoiesis. The early embryo has very different requirements from an adult individual, and hence yolk sac and adult hematopoiesis are likely to be regulated differently. However, there are two broad views of how any stem cell gives rise to its various progeny. One possibility is that signals arising from growth factor/growth factor receptor interactions positively 'instruct' a multipotent cell to differentiate along a particular lineage.³ Alternatively, growth factors may allow the survival of daughter cells that have already become committed to a particular lineage. In the latter case, the decision to differentiate may represent a stochastic intracellular event independent of environmental cues. Cells subsequently finding themselves in an appropriate growth factor environment would then be 'selected' to survive and proliferate, whereas less fortunate cells would undergo apoptotic cell death. The stochastic or selective model is favored by evidence that growth factors are not essential for hematopoietic differentiation.⁴ Furthermore, exchanging the cytoplasmic signaling domains of the erythropoietin (EPO), thrombopoietin (TPO), and granulocyte colony-stimulating factor (G-CSF) receptors does not appear to alter their function, a finding that does not fit easily with the 'instructive' model of cell signaling.⁵⁻⁶ Regardless of which model is invoked, transcription factors represent the final common pathway that drives differentiation, and differences between cell types reflect the operation of distinct patterns of transcription factor expression.

Transcription factors and normal hematopoiesis

Combinations of transcription factors drive lineagespecific gene expression

One major route to identifying transcription factors important for individual hematopoietic lineages is to study the regulatory regions of lineage-specific genes. Studies of promoter and enhancer elements that control expression of globin and other erythroid genes have identified three recurrent motifs in various combinations: a GATA motif, an AP-1-like sequence and a CACC-like sequence.⁷ The implication is that transcription factors binding to these three motifs are likely to be important for erythroid differentiation, and subsequent work has identified the critical

transcription factors as GATA-1, NF-E2 (which binds to an AP-1-like sequence) and EKLF (which binds to the CACC motif). Indeed, it is possible to synthesize an artificial promoter that exhibits erythroid-specific activity by combining these three binding sites.⁸ See also Chapter 10 on erythropoiesis.

As shown in Table 5.1, analogous observations have been made in myeloid and lymphoid cells. Binding sites for PU.1, CBF α and C/EBP transcription factors are found in the regulatory elements of most genes expressed in myeloid cells. Similarly, binding sites for Ikaros, NF- κ B, OCT-1, OCT-2, E2A, LEF-1, and TCF-1 have all been identified in the regulatory elements of genes expressed in various categories of lymphoid cells.

Table 5.1 Transcription factor motifs commonly found in regulatory elements of lineage-specific genes

Lineage	Transcription factor motifs	Refs
Erythroid	GATA, NF-E2, CACC	113
Megakaryocyte	GATA, ETS	114
Mast	GATA	115
Myeloid	PU.1, RUNX1, C/EBP	19, 116, 117
Lymphoid	Ikaros, NF- κ B, OCT-1, OCT-2 E2A, LEF-1, TCF-1	118–120 121–123

The fact that no single transcription factor-binding motif is sufficient to direct lineage-specific expression suggests that combinations of transcription factors are required. Indeed, all 'lineage-restricted' hematopoietic transcription factors are expressed in more than one lineage—an observation that again implies that combinations of transcription factors are needed to provide true lineage-specific gene expression. A third and more tangible line of evidence also supports the combinatorial concept of gene regulation. In many instances, individual transcription factors form part of multicomponent transcription factor complexes. Thus, the helix-loop-helix protein SCL not only binds to other helix-loop-helix proteins encoded by the *E2A* gene, but also forms part of an oligomeric, DNA-binding complex that contains SCL, E2A, LMO2, GATA-1, and LDB-1 proteins.⁹ As indicated in Figure 5.1, the SCL, E2A, and GATA-1 proteins bind directly to DNA, and presumably recruit the LMO-2 and LDB-1 proteins. Recent evidence suggests that the complex can be recruited to DNA via the zinc finger protein SPI.¹⁰ Important target genes included the stem cell factor receptor, c-Kit, the promoter of which is activated by the complex.¹⁰ The complex has been best studied in erythroid cells—in other cell types, variations in individual components (e.g. replace

Figure 5.1 SCL and GATA proteins form part of a multiprotein complex implicated in erythroid differentiation and T-cell tumorigenesis.

ment of GATA-1 by GATA-2) may result in specificity for a distinct pattern of target genes.

Knockout studies identify transcription factors with important roles in vivo

A large number of transcription factors are now known to be expressed in various hematopoietic cell types. Their detailed patterns of expression give some clues as to where the transcription factors are likely to be important, but devising experiments to ascertain specific functions can be difficult. The most powerful approach has been a genetic one—the generation of targeted mutations in mice using homologous recombination (Figure 5.2). This technology has provided numerous insights into the transcriptional control of hematopoiesis.¹¹

Transcription factors critical for stem cells

Homologous recombination studies have led to the identification of a small number of transcription factors that are essential for normal stem cell behavior. The SCL gene was first identified by virtue of its disruption by chromosome rearrangements in T-cell acute lymphoblastic leukemia (T-ALL). These rearrangements (both translocations and deletions) result in SCL expression in T cells, a lineage normally lacking SCL protein. SCL is normally expressed in erythroid, mast, and megakaryocytic cells, as well as in multipotent progenitors. Early experiments in cell lines suggested that SCL controls the proliferation of primitive multipotent cells,¹² as well as acting as a positive regulator of erythroid differentiation.^{13,14} When SCL-knockout mice were generated, their phenotype was dramatic^{15,16}—mice lacking SCL protein were completely unable to produce any hematopoietic cells (Figure 5.3). Subsequent experiments showed that stem cells responsible for both primitive (yolk sac) and adult (fetal liver) hematopoiesis were affected. Moreover, embryonic stem (ES) cells null for SCL protein were unable to undergo differentiation in vitro to produce hematopoietic cells.^{17,18} These data suggest that the SCL protein is vital for the development or behavior of pluripotent hematopoietic stem cells. The nature of the target genes regulated by SCL is now clearly an important issue, as is the question of what regulates *SCL* itself.

Figure 5.2 Use of homologous recombination in embryonic stem (ES) cells to ‘knock out’ target genes. Once one allele has been mutated, the ES cells can be injected into blastocysts to generate chimeric mice; subsequent breeding generates heterozygous and homozygous mutants. Alternatively, homozygous mutant ES cells can be generated and used to assess the effect of the mutation on hematopoietic differentiation in vitro.

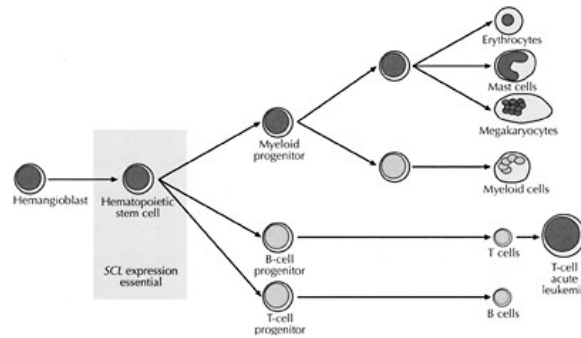

Figure 5.3 The *SCL* gene is essential for the development of all hematopoietic lineages. A dark nucleus indicates lineages/cell types expressing the *SCL* gene. *SCL* is expressed in the pluripotent hematopoietic stem cell. Its expression is maintained following commitment to the erythroid, mast, and megakaryocytic lineages, but not following commitment to other lineages. Ectopic expression resulting from chromosome rearrangements in a T-cell precursor results in T-cell acute leukemia. Adapted from Green.⁶⁰

RUNX1 (also known as *AML1*, *PEBPA2B*, or *CBFA2*) is another gene that was identified on the basis of its involvement in a leukemia-associated translocation.¹⁹ It too was subsequently demonstrated to have a critical role in the hematopoietic system following the generation of knockout mice. *RUNX1*^{-/-} embryos die at embryonic day 12.5–13.5, with a profound block in definitive hematopoiesis. There is necrosis and hemorrhaging within the central nervous system and a lack of definitive hematopoietic progenitors, definitive enucleated erythrocytes, and mature myeloid lineage cells.^{20,21} Like their *SCL*^{-/-} counterparts, ES cells homozygous for the *RUNX1* deletion do not contribute to any adult hematopoietic cells in chimeric mice.²¹ However, in contrast to *SCL*, *RUNX1* does not appear to be necessary for primitive hematopoiesis.^{20,21}

A number of other transcription factors have knockout phenotypes almost as dramatic as those of *SCL* and *RUNX1*, indicating a role in multipotent progenitors (Figure 5.4). The phenotype of the *LMO-2* knockout is similar to that of *SCL*, although small numbers of hematopoietic cells may still be found.²² Similarly, *LMO-2*^{-/-} embryonic stem cells do not contribute to any hematopoietic lineage in adult chimeric mice.²³ The similarity between the *SCL* and *LMO-2* knockout phenotypes is particularly provocative, since these two proteins have been shown to physically interact in vivo (see above), and, like *SCL*, *LMO-2* is a T-cell oncogene. These data suggest that a complex containing *SCL* and *LMO-2* may be crucial for both stem cell behavior and T-cell tumorigenesis.

The zinc finger protein *GATA-2* also affects the production of all hematopoietic lineages, but small numbers of hematopoietic cells can be produced by *GATA-2*-null mice and also by in vitro differentiation of *GATA-2*-null ES cells.²⁴ These results raise the possibility that *GATA-2* may be necessary for the expansion of early hematopoietic cells, but that its absence may not prevent at least some differentiation.²⁴

Transcription factors critical for the formation or function of specific lineages

GATA motifs known to bind *GATA-1* are prominent in the regulatory elements of all erythroid-specific genes, and so it is reassuring that the absence of *GATA-1* blocked erythropoiesis at the pro-erythroblast stage.^{25–27} *GATA-1* therefore seems to be particularly important for survival and terminal maturation of erythroid progenitors. By contrast, mice null for a different zinc finger protein, *EKLF*, exhibited a thalassemic syndrome resulting from the specific inhibition of β -globin transcription. Defects of other single lineages have also been observed. Mice lacking *NF-E2* protein failed to produce megakaryocytes,²⁸ whereas mice with no *Fos* protein developed osteopetrosis as a result of a specific lack of osteoclasts.²⁹ Similarly, in lymphoid development, *OCT-2* is reported to be essential for functional maturation of mature B cells,³⁰ and *TCF-1* for the differentiation of immature $CD8^+$ precursors into more mature $CD4^+CD8^+$ thymocytes.³¹

However, some transcription factors present a more complex picture. Mice null for the *PU.1* protein lack B

Figure 5.4 Homologous recombination experiments reveal roles for transcription factors in hematopoiesis. Knockout studies have identified a number of transcription factors important for the formation or function of specific hematopoietic cells. Adapted from Cantor and Orkin.¹⁶³

cells, macrophages, and neutrophils.^{32,33} This result could represent a defect of a multipotent myelo-lymphoid progenitor that results in restricted lineage commitment options. Alternatively, the data are also consistent with postcommitment differentiation defects in several independent lineages.

Caveats and limitations

Although a powerful approach to analyzing transcription factor function in vivo, homologous recombination experiments are subject to a number of limitations. First, if loss of function blocks an early step in differentiation, this will compromise the analysis of later stages of development. Thus, the death of mouse embryos at an early stage of development because of the failure of hematopoiesis has precluded analysis of SCL function in other tissues where it is expressed, such as in endothelium and in developing brain. Regulatable or conditional knockouts are being developed and should circumvent this problem. Second, the lack of an obvious phenotype may mean that the targeted transcription factor is superfluous, or that we are not looking in the right way to detect the phenotype, or that compensatory mechanisms are operating. Thus, the SCL gene is normally expressed in endothelial cells, but these appear to develop normally in SCL-null embryos. The possible function of SCL in endothelial cells therefore remains an open question. Finally, the phenotype observed in a given knockout mouse will reflect the net result of a complex interplay of direct and indirect effects. These may be influenced by the genetic background of the mouse, and so details of the knockout phenotype may vary between mouse strains.

Chromatin structure

It has been increasingly clear over the past decade that chromatin structure plays a vital role in regulating transcription.^{34–35} If placed end-to-end, the DNA packaged into the chromosomes of a single cell would stretch for over a meter. In order to accommodate this length of DNA within an individual nucleus, the DNA is wrapped around histone proteins and then folded into a complex higher-order structure termed chromatin. This solves the packaging issue, but raises a second problem: How do transcription factors gain access to DNA-binding sites buried within such chromatin structures? We still do not have all the answers, but it is clear that chromatin exists in a number of different states. Heterochromatin is densely packaged, and the genes within it are transcriptionally silent. In other regions, the chromatin structure is looser. Transcription factors can access the DNA in these regions, and so genes are potentially active if the appropriate transcription factors are present.

The basic building block of chromatin is the nucleosome, which consists of DNA wrapped around a cylinder of eight core histone proteins (two each of H2A, H2B, H3, and H4).³⁶ Individual nucleosomes are linked by intervening stretches of DNA, and can be unfolded to resemble 'beads on a string'. However, in the nucleus, the nucleosomes are stacked closely together in higher-order structures that are dependent on a large number of non-histone proteins. The precise structures found in different regions of the genome dictate whether genes in those regions are potentially active. Moreover, a form of molecular memory is needed to ensure that daughter cells inherit the same patterns of gene expression as a parent cell. Experiments in *Drosophila* have identified a number of non-histone proteins important for this molecular memory, including the Polycomb and Su(var) families, which play a role in maintaining inactive chromatin, and the Trithorax and E(var) families, which appear to maintain regions of active chromatin.^{36–38}

The products of these genes appear to interact with eight N-terminal histone tails that protrude from the nucleosome (reviewed by Jenuwein and Allis³⁶ and Spotswood and Turner³⁹). They are capable of covalently modifying specific residues on the tails, by acetylation (and de-acetylation), methylation, and phosphorylation. These modifications can be recognized by a number of highly conserved domains found within 'effector' proteins (including Polycomb, Trithorax, Su (var), and E(var) themselves), which can remodel the chromatin to a more open (active) or condensed (inactive) state. This complex interplay provides a mechanism for the spreading of active or inactive chromatin, and has given rise to the concept of the 'chromatin code', the idea that modifications of the histone tails can determine the transcriptional activity of regions of DNA. The turnover of these covalent modifications may be rapid (half-lives of a few minutes to hours),⁴⁰ as might be expected in the control of genes that need to be up- or downregulated quickly, such as hormone- and growth factor-responsive genes. Alternatively, the modifications may be very stable. This can provide the basis of longer-term 'molecular memory', including phenomena such as X-inactivation and imprinting.⁴¹

Stem cells, lineage commitment, and plasticity

The mechanisms responsible for lineage commitment of stem cells remain among the central mysteries of hematopoiesis. It is tempting to speculate that some transcription factors function as 'master regulators' capable of switching on lineage-specific programs of gene expression. However, direct evidence is sparse. Knockout data showing that individual transcription factors are essential for the development of certain lineages are consistent with, but do not prove, a role for those transcription factors in lineage commitment. More convincing evidence comes from studies in which specific transcription factors are overexpressed and shown to influence lineage choice.

Figure 5.5 Reciprocal repression between PU.1 and GATA-1. At the stem cell stage, neither transcription factor is dominant. However, following lineage commitment, each factor promotes its lineage choice whilst downregulating the other by protein-protein interactions.

Overexpression of *GATA-1* in a primitive myeloid cell line resulted in the acquisition of megakaryocytic features.⁴² This result is consistent with the observation that loss of *GATA-1* expression in megakaryocytes in vivo resulted in dysregulation of megakaryocyte development.⁴³ Even more convincing are elegant results from Graf and colleagues using chicken cell lines. Overexpression of *GATA-1* in myeloblasts resulted in a switch to erythroid cells, thromboplasts (equivalents of megakaryocytes), or eosinophils.⁴⁴ The level of *GATA-1* expression was crucial, with erythroid or thromboplast fates being favored by levels of GATA-1 only fourfold greater than the levels favoring eosinophil formation.

The same avian system has also provided evidence of another emerging principle—that of reciprocal repression. This refers to the situation where a given transcription factor may be important for directing the transcriptional program of one lineage while at the same time downregulating genes important for the program of a different lineage. The ETS-1 transcription factor is expressed in both erythroid and myeloid cells, whereas the MafB transcription factor is only expressed in myeloid cells. MafB appears to direct the expression of myeloid genes, but also inhibits the action of ETS-1 on target genes important for erythropoiesis.⁴⁵ A more complex example is provided by the transcription factors GATA-1 and PU.1. Each antagonizes the other by protein-protein interactions. The result is a cross-inhibition, in which the dominant factor promotes its lineage choice at the expense of the other (Figure 5.5).⁴⁶

Several important principles governing the role of transcription factors in hematopoiesis are therefore becoming clear, and are outlined in Figure 5.6. Lineage commitment of stem cells is likely to involve upregulation (by mechanisms that remain unclear) of one or more critical transcription factors. GATA-1 and PU.1 are prime candidates for erythroid and myeloid differentiation respectively. Activation of these pivotal transcription factors has multiple consequences, including autoregulation of the transcription factor gene itself, upregulation of receptors for lineage-specific growth factors, activation of lineage-specific

Figure 5.6 A model for erythroid lineage commitment of a multipotent stem cell. Upregulation of GATA-1 (by mechanisms that remain obscure) results in autoregulation of the *GATA-1* gene, activation of erythroid target genes, including the erythropoietin receptor (EPO-R), and repression of target genes normally expressed in other lineages (reciprocal repression). The net effect is commitment to terminal erythroid differentiation.

programs of gene expression, and reciprocal repression of genes expressed in other lineages. The net effect of these multiple changes is to produce a progenitor that has become committed to differentiate along a particular lineage.

The data presented above suggest that hematopoietic differentiation may not be as irreversible as previously thought, but instead exhibits a remarkable degree of plasticity. Pax5 is a transcription factor essential for the normal development of B lymphocytes. Pro-B cells derived from *Pax5*^{-/-} mice demonstrate a striking ability to differentiate not only into non-B lymphocytes (T cells and natural killer (NK) cells), but also into cells of other hematopoietic lineages, including macrophages, dendritic cells, and neutrophils. Moreover, restoration of *Pax5* expression induces differentiation into B cells.^{47,48} Lineage switches involving other cell types have been demonstrated *in vitro*, and are not limited to knockout or other mutant cell lines.⁴⁹ More striking still are data from a number of transplantation experiments that suggest an ability of hematopoietic cells to differentiate into non-hematopoietic cells (reviewed by Graf,⁴⁹ and see Chapter 2 on stem cell plasticity). Examples of cell types shown to arise from bone marrow cells include endothelium, parenchymal liver cells, neuronal and glial cells, and skeletal and cardiac muscle cells. However, in many cases, clonal analysis has not been performed, and it remains an open question whether these represent true plasticity of hematopoietic stem cells or the presence of non-hematopoietic stem cells in the bone marrow.^{49–50} Furthermore, as is the case with intrahematopoietic lineage switches, the *in vivo* significance is unknown.

It is clear that transcription factors play a central role in regulating proliferation and differentiation of multipotent hematopoietic progenitors. It is therefore not surprising that perturbation of transcription factor function has dire consequences and that transcription factor genes are common targets for leukemogenic mutations.

Transcription factors and leukemia

Genetic changes associated with leukemia

A multitude of acquired genetic alterations associated with leukemia have been characterized at a molecular level. This wealth of information has arisen largely as a result of the relative ease with which leukemias can be characterized at a cytogenetic level.⁵¹ Unlike cells of solid tumors, leukemia cells are readily accessible, and can be encouraged to divide in culture and so generate metaphases.

There are three main cytogenetic changes associated with leukemia: translocations, inversions, and deletions. Changes consistently found in particular leukemia types are highly likely to contribute to the pathogenesis of those leukemias. Translocations and inversions are the most informative abnormalities, since identification of the breakpoints is likely to lead directly to the location of critical target genes. The Human Genome Project is providing a massive increase in the molecular tools available for characterized rearrangements, and the past decade has seen an exponential rise in the number of leukemia genes identified.

However, despite this rapid increase in the identification of target genes, it is likely that we are still only scratching the surface. Deletions are commonly seen in various forms of hematological malignancy, but in most cases the tumor suppressor genes that they harbor have not been successfully identified. This is because most deletions are large and frequently contain hundreds of genes. In addition to cytogenetically visible changes, more subtle alterations can perturb the function of critical target genes: point mutations can activate or disable proteins; small deletions will be below the resolution of cytogenetic analysis; and even some translocations are not detectable using standard G-banding techniques. Moreover, most leukemias are likely to reflect acquired alterations in several target genes; and, to further add to the complexity, these acquired genetic changes are likely to interact with inherited polymorphisms—interactions that are likely to account for the varying degrees of inherited predisposition to leukemia.

Target cells for transformation

One view of the origin of different types of hematological malignancy is that they represent transformation of distinct progenitor cells. To some extent, this may be true. Lymphoid tumors are thought to result from transformation of committed lymphoid cells, perhaps reflecting the innate ability of lymphocytes to undergo self-renewal when stimulated. However, in the context of myeloid malignancies, this concept may be misleading. Thus, it has been suggested that megakaryocytic features may represent the transformation of acute myeloid leukemia (AML) with promyelocytic or maturation of normal progenitors committed to promyelocytic or megakaryocytic differentiation. However, this concept is not consistent with recent evidence that suggests that all forms of AML arise from transformation of a primitive multipotent stem cell. Thus, cytogenetic abnormalities associated with specific types of AML have been identified in a small population of primitive CD34⁺ 'leukemic stem cells' as well as in the bulk of the more differentiated leukemia cells.^{52,53}

Furthermore, these primitive 'leukemic stem cells' have been shown to be capable of initiating leukemia in immunodeficient mice.⁵⁴ These data suggest that

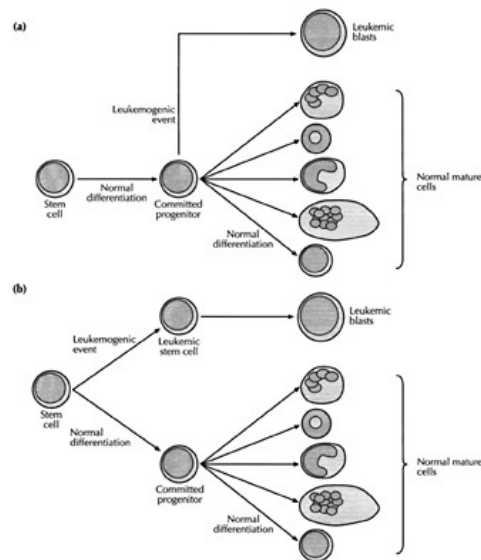

Figure 5.7 Models for the origin of acute myeloid leukemia (AML). (a) The leukemogenic event occurs in a committed progenitor, and the phenotype of the resultant leukemic blasts reflects the phenotype of the committed progenitor. (b) The leukemogenic event occurs in a stem cell. The transformed stem cell can still undergo limited differentiation. The choice of lineage and degree of differentiation depend on the nature of the transforming event. As discussed in the text, current evidence favors model (b).

the different phenotypes exhibited by distinct types of AML reflect the effect of diverse mutations on the differentiation capacity of the transformed stem cell (Figure 5.7).

Mechanisms responsible for target gene activation in leukemia

Numerous different target genes have now been implicated in the genesis of leukemia. In most cases, they have been identified by virtue of their presence at translocation or inversion breakpoints. Two broad conclusions can be drawn. First, transcription factor genes are common targets in leukemia. Second, translocations perturb target genes by two main mechanisms: dysregulation of a target gene or the generation of a fusion gene.

Transcription factor genes are common targets in leukemia

As summarized in Table 5.2, a large number of transcription factors have been implicated in human hematological malignancies (see also Table 17.1 in Chapter 17 on acquired genetic changes in myeloid malignancies). However, our existing knowledge is biased by the way in which these have been identified—namely by the characterization of chromosome rearrangements. It should be remembered that a point mutation can also perturb transcription factor function, the *p53* gene being a classic example. Similarly, tumor suppressor genes include those encoding transcription factors (e.g. *WT-1*). It remains to be seen whether the deletions associated with hematological malignancies will prove to harbor additional critical transcription factors. However, despite our incomplete knowledge, it is already clear that transcription factor genes are common targets for leukemogenic mutations. Why should transcription factors play such a central role in leukemogenesis? The neoplastic behavior of a malignant cell reflects altered patterns of transcription factor activity. One can speculate that mutations affecting cytoplasmic and cell surface components of signal transduction pathways may be vulnerable to a series of physiological checks and balances, which would tend to limit significant downstream alterations of nuclear transcription factor activity. By contrast, mutations that directly affect transcription factor activity may be less open to such regulation, and hence be more potently oncogenic.

Table 5.2 Transcription factor genes adjacent to the breakpoints of translocations associated with hematological malignancies. At least one of the two genes disrupted by each translocation encodes a transcription factor^{93,120–165}

Dysregulated expression of a normal protein

Normal lymphoid cells undergo genetic rearrangement of their antigen receptor genes. Errors in this process of recombination result in chromosome translocations that involve immunoglobulin and T-cell receptor loci. Such translocations may result in powerful regulatory elements from the antigen receptor loci being relocated to the vicinity of potential oncogenes. The net effect is dysregulated expression of the potential oncogene in lymphoid progenitors.

The classic example of this mechanism is activation of the MYC transcription factor in Burkitt lymphoma and other B-cell tumors by the t(2;8), t(8;14), and t(8;22) translocations involving the immunoglobulin heavy- or light-chain loci (reviewed by Rabbits⁵⁵). More recently the *SCL* gene has provided a complementary example of transcription factor that is activated by translocations involving the T-cell receptor loci. Translocations involving *SCL* account for approximately 3% of T-ALL. However, the *SCL* gene is also activated by cytogenetically invisible deletions that bring the promoter of the *SIL* gene (usually 90 kb upstream of *SCL*) into the immediate vicinity of the *SCL* promoter. In both translocation and deletion cases, the net effect is ectopic expression of *SCL* in T-cell progenitors, which do not normally express *SCL* (Figure 5.3). The two types of *SCL* rearrangements are found in up to one-third of pediatric T-ALL, and so rearrangement of the *SCL* locus is perhaps the commonest molecular pathology associated with this disease. It has also been reported that *SCL* is expressed in a further third of T-ALL cases that lack evidence of DNA rearrangement, and both *cis*- and *trans*-acting mechanisms have been implicated.⁵⁶

Transgenic experiments have confirmed that overexpression of the *SCL* protein in T-cell progenitors can result in T-cell tumors.^{57–59} However, the precise mechanism by which ectopic *SCL* expression is leukemogenic remains unclear. *SCL* may directly activate or inhibit transcription of target genes in T-cell progenitors. Alternatively, overexpressed *SCL* protein may bind to and sequester other transcription factors, thus producing an indirect effect on target genes regulated by those factors.⁶⁰ Whichever of these mechanisms is true, the consequences may include inhibition of apoptosis.⁶¹

Generation of fusion proteins

The second major mechanism by which chromosome rearrangements generate tumorigenic genes involves the formation of fusion proteins. Many proteins, and especially transcription factors, exhibit a modular structure—that is, they contain a number of domains that can function independently of each other.

Fusion proteins contain functional domains from two different proteins unnaturally welded together. The consequences will depend on the precise functions of the various domains in each case. When transcription factors are involved, several scenarios can be envisaged: abnormal DNA binding; normal DNA binding but abnormal transactivation; sequestration of other proteins by protein-protein interaction; and ectopic expression driven by the promoter of the fusion gene's upstream component.

The number of fusion genes identified in human leukemia (and solid tumors) is rapidly increasing.⁵⁵ This category of oncogene is particularly tantalizing from the therapeutic point of view, because each fusion protein forms a tumor-specific molecule. Such molecules provide the substrate for powerful polymerase chain reaction (PCR)-based methods to monitor residual disease. They also represent an attractive target for tumor-specific therapies targeted at DNA, RNA, or protein levels.

Leukemogenic alterations may target distinct steps in common signaling pathways

A recently emerging theme is that leukemias, like cancers, result from molecular alterations that interfere with signal transduction pathways regulating normal cell proliferation, differentiation, or death. It is becoming apparent that different genetic events in independent leukemias may prove to target distinct steps in a common pathway. Three examples will now be used to illustrate this principle: first, translocations involving 21q22 and inversion 16, which target different components of the core binding factor (CBF) complex; second, disruption of the CCAAT enhancer binding protein α (*C/EBP α*) leading to a block in granulopoiesis; and third, leukemogenic changes that perturb tyrosine kinase signaling pathways.

Translocations involving 21q22 and inversion 16

The CBF gene family consists of three subunits, encoded by *RUNX1*, *RUNX2*, and *RUNX3*, each of which heterodimerizes with *CBF β* , encoded by the *CBF β* gene (reviewed by Speck and Gilliland⁶²). The *RUNX1*-*CBF β* protein complex is essential for definitive hematopoiesis, as illustrated by the *RUNX1* knockout mouse,^{20,21} described above. *RUNX1*, like the other *CBF α* proteins, has DNA-binding properties. The exact role of the *CBF β* subunit is unclear. It does not contact DNA directly, but may either stabilize the *RUNX1* protein, or act as a recruitment moiety for other proteins in the complex.^{63–66} Whatever its precise role, it is essential for *RUNX1* activity; *CBF β* knockout mice have an identical phenotype to *RUNX1*^{-/-} mice.^{67,68}

The *RUNX1* gene is located on chromosome 21, and is involved in a number of cytogenetic abnormalities commonly associated with leukemia. Translocations t(8;21), t(12;21), and t(3;21) result in the generation of

the fusion proteins RUNX1-ETO, TEL-RUNX1, and RUNX1-EVI1 respectively (Figure 5.8a). Inv(16) results in fusion of the smooth muscle myosin heavy chain (SMMHC) to the CBF β subunit. The net result of all of these cytogenetic abnormalities is thought to be a fusion protein, which inhibits normal RUNX1 function (Figure 5.8b). This dominant negative effect has been demonstrated for the RUNX1-ETO and CBF β -SMMHC products by the generation of knockin mice, in which the fusion protein is expressed under control of the endogenous *RUNX1* promoter. Despite the presence of one fully functional *RUNX1* allele, the mutation results in a near phenocopy of the *RUNX1* knockout, and death during embryogenesis.^{69–71}

In some cases, the mechanism of the dominant negative activity may be mediated through aberrant recruitment of a nuclear transcriptional complex by the fusion protein. RUNX1-ETO recruits SINS and various histone de-acetylases,^{72–73} and TEL-RUNX1 recruits nuclear cofactor R (N-CoR).⁷⁴ The mechanism of the dominant negative activity of CBF β -SMMHC is as yet undetermined, but may involve sequestration of RUNX1 or introduction of a repressor domain into CBF β .⁶²

Abrogation of RUNX1 function is not limited to the dominant negative effect of fusion proteins. Point mutations in the *RUNX1* gene are found in families with a familial platelet disorder and a propensity to develop AML (FPD/AML syndrome; reviewed by Speck and Gilliland⁶²). Heterozygosity for the mutation appears to be sufficient for development of thrombocytopenia. However, progression to leukemia seems to require further genetic abnormalities, including mutations in the second *RUNX1* allele. Point

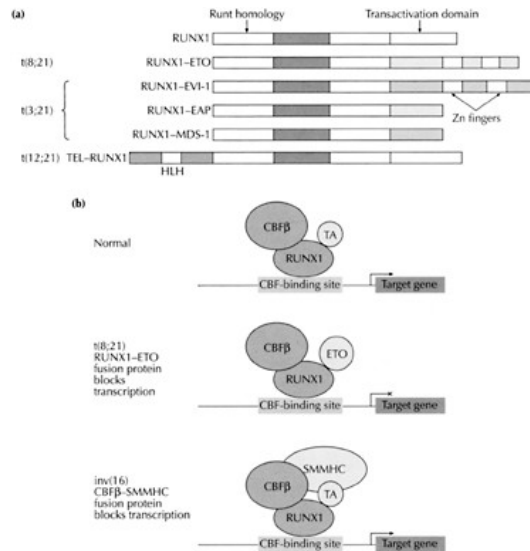

Figure 5.8 Fusion proteins involving the *RUNX1* and *CBF β* genes perturb normal transcription factor function, (a) Fusion proteins arising from t(8;21) and t(3;21) translocations result in loss of the *RUNX1* transactivation domain and its replacement by domains from several different genes. By contrast, the fusion protein created by the t(12;21) translocation fuses part of the TEL protein to the N-terminal end of the RUNX1 protein, (b) RUNX1 normally forms part of a multiprotein complex that includes CBF β and that regulates the expression of target genes with CBF-binding sites in their regulatory elements. The RUNX1-ETO and CBF β -SMMHC fusion proteins both perturb transcriptional regulation of normal target genes. Adapted from Sawyers.¹⁵⁷

mutations in *RUNX1* have also been found in 3–5% of sporadic leukemias. The majority of these involve biallelic mutations.

Disruption of the *C/EBPα* transcription factor

The transcription factor *C/EBPα* is expressed in many tissues, but within the hematopoietic system is largely confined to the granulocytic lineage.⁷⁵ It binds to the sequence CCAAT, or slight variations thereof, and is necessary for granulocytic lineage development.⁷⁶ It is expressed in the earliest myeloid cells, and other family members (*C/EBPβ* and *C/EBPε*) are induced later as differentiation proceeds.^{75–77} *C/EBPα* knockout mice develop all hematopoietic lineages normally, apart from the granulocytic lineage, which is subject to maturation arrest with an accumulation of early granulocytic blasts.⁷⁸ Cell lines derived from these mice can be induced to differentiate by conditional expression of *C/EBPα*.⁷⁹

It has recently become clear that inhibition of *C/EBPα* function by a number of different mechanisms is associated with distinct forms of AML (reviewed by Tenen⁷⁶). First, in a subset of patients with AML (M1 or M2) and no cytogenetic abnormalities, mutations in the *C/EBPα* gene itself are seen.⁸⁰ Most of the mutations are heterozygous, suggesting a dominant negative function, and this is supported by in vitro studies.⁸¹ Second, in t(8;21) AML, it has been demonstrated that the *RUNX1-ETO* fusion protein inhibits *C/EBPα* function and downregulates its expression.⁸² Third, in acute promyelocytic leukemia (APL, also known as AML M3), *C/EBPα* is neither downregulated nor mutated. However, the *PML-RAR* fusion protein found in APL interacts with *C/EBPα* and inhibits its DNA-binding activity. All-trans-retinoic acid (ATRA), an effective therapeutic agent in APL, reverses this interaction and restores DNA binding.

Tyrosine kinase and RAS signaling pathways

The t(9;22) translocation associated with chronic myeloid leukemia (CML) was the first tumor-specific abnormality to be described,^{83–84} and results in generation of the *BCR-ABL* fusion gene (reviewed by Melo⁸⁵). The N-terminal half of the BCR protein is fused to the majority of the ABL protein (Figure 5.9). The ABL protein contains a tyrosine kinase domain, and activity of this enzyme is dysregulated in the fusion protein.⁸⁶ The tumorigenic properties of the fusion protein depend on several other features: the ABL and BCR portions interact with adaptor proteins (CRKL and GRB-2 respectively), which connect the fusion protein to positive regulators of the RAS/MAPK signal transduction pathway.^{87–88} The *BCR-ABL* kinase therefore mimics the activity of receptor tyrosine kinases and of cytokine receptors, both of which respond to ligand stimulation by activating the RAS pathway.^{89–91} In many cases, it has been shown that ligand-receptor interaction results in dimer formation, which is essential for proper signaling. It is therefore probably no coincidence that the BCR portion of the *BCR-ABL* fusion protein contains a coiled-coil motif that can mediate dimer or tetramer formation.⁹²

A number of other examples of tyrosine kinase fusion proteins have been described in leukemias and lymphomas. The *TEL* gene on chromosome 12 is fused to the PDGF receptor by the t(5;12) translocation associated with a subset of patients with chronic myelomonocytic leukemia (CMML).⁹³ The *TEL* gene is also fused to the *ABL* gene in a small number of patients with AML or undifferentiated acute leukemia.⁹⁴ In the

Figure 5.9 Tyrosine kinase fusion proteins. The *BCR-ABL* fusion protein contains a tyrosine kinase motif (from ABL) and a coiled-coil dimerization motif (from BCR). In the *TEL-ABL* and *TEL-PDGFR* fusion proteins, the *TEL* helix-loop-helix (HLH) motif provides a dimerization domain. CML, chronic myeloid leukemia; AML, acute myeloid leukemia; ALL, acute lymphoblastic leukemia; CMML, chronic myelomonocytic leukemia; EMS, 8p11 myeloproliferative syndrome. Adapted from Sawyers.¹⁵⁷

8p11 myeloproliferative syndrome (EMS), the fibroblast growth factor receptor 1 (*FGFR1*) gene is fused to one of a number of partners, including *ZNF198*, *CEP110*, *FOP*, and *BCR*, following various translocations involving chromosome 8.⁹⁵

Comparison of the structures of these different tyrosine kinase fusion genes suggests some common principles (Figure 5.10a). All are potentially linked to the RAS pathway: TEL-PDGFR and the FGFR1 fusions by a GRB-2-binding site in the PDGFR portion; TEL-ABL by CRKL-binding sites in the ABL portion; and BCR-ABL by both GRB-2 and CRKL motifs. All contain oligomerization motifs: BCR-ABL and FGFR1-BCR contain the coiled-coil motif in their BCR portions; FGFR1-ZNF198 contains a prolinerich domain; and TEL-PDFGR and TEL-ABL contain a helix-loop-helix protein interaction domain in the TEL portion of the fusion protein. In the latter two cases, a transcription factor gene (TEL) is involved, but it merely contributes a protein-dimerization domain to the resultant fusion protein, which does not appear to function as a transcription factor itself.

Finally, downstream components of the RAS pathway have also been implicated in hematological malignancies. Activating mutations in *RAS* genes are found in numerous tumors, including myelodysplastic syndromes (MDS) and AML.^{96–98} *RAS* activity is normally regulated by a molecule called GAP (GTPase activating protein), which returns the activated *RAS* to an inactive form (Figure 5.10b). Neuro fibromatosis type 1 is an inherited condition in which a GAP molecule termed NF-1 is inactive. Intriguingly, children with neurofibromatosis type 1 have an increased risk of developing MDS, particularly juvenile myelomonocytic leukemia (JMML), and the wild-type *NF-1* allele is frequently deleted in the malignant bone marrow cells.^{99–101} Mutations in both *RAS* and *NF-1* are not seen in the same tumor, suggesting that they represent alternative ways of activating the same pathway. A causal role for *NF-1* mutations is strongly suggested by the observation that mice lacking NF-1 protein develop a disease closely resembling JMML.^{101–102}

Genes influencing chromatin structure may be targets for leukemogenic rearrangements

Two lines of evidence suggest that proteins that regulate chromatin structure may also be targets for leukemogenic rearrangement. The MLL gene (also

Figure 5.10 Aberrant activation of the RAS pathway. (a) PDGF induces receptor dimerization and phosphorylation. Subsequent binding of the adaptor protein GRB-2 results in activation of SOS and stimulation of RAS. The TEL helix-loop-helix (HLH) domain results in analogous dimerization, with subsequent activation of the RAS pathway. (b) BCR and TEL contribute a dimerization domain to their respective fusion proteins. Subsequent binding of adaptor proteins (GRB-2 and CRKL) results in activation of SOS, which in turn mediates activation of RAS. Conversion of the active RAS-GTP to the inactive RAS-GDP is regulated by NF-1. The active RAS-GTP leads to altered transcription in the nucleus, resulting in proliferation.

called *HRX* or *ALL-1*) forms a large number of different fusion genes in distinct forms of acute leukemia. Thirty fusion genes have been cloned,¹⁰³ all involving different partner genes, and cytogenetic data predict the existence of several more. The subtype of leukemia correlates with the particular MLL fusion protein. Thus, t(4;11) is found in ALL and acute undifferentiated leukemia, whereas t(9;11) is found mainly in AML.

The *MLL* gene encodes a large protein with homology to the *Drosophila Trithorax* family of genes. Like its *Drosophila* homologs, the *MLL* gene regulates genes encoding homeobox transcription factors, and is crucial for determining body structures during development. It is thought to act by creating regions of active chromatin, thus permitting gene transcription in that locality. The molecular basis of the leukemogenic effect of MLL fusion proteins is not yet clear. It seems likely that they interfere with the normal regulation of chromatin structures at specific regions of the genome. Perhaps different fusion partners influence which precise regions are affected, and hence the phenotype of the resultant leukemia.

The second line of evidence comes from murine experimental systems. The *BMI* gene was identified as an oncogene that cooperates with *MYC* in the generation of murine B-cell tumors.^{104,105} Proviral insertions adjacent to the *BMI* gene upregulated *BMI* expression and accelerated the formation of B-cell tumors. The *BMI* gene is homologous with the *Polycomb* gene family. Whilst no examples of human leukemias with *BMI* rearrangements have been reported to date, the *BMI* gene has been mapped to human chromosome location 10p13, a region involved in translocations and rearrangements in infant leukemias and T-cell lymphomas.¹⁰⁶

Genes regulating chromatin structure are likely to have a particularly powerful effect on cellular transcription programs, since they exert a dominant effect on the transcriptional activity of large numbers of target genes. Therefore, rearrangements involving such genes might be particularly leukemogenic. However, it is also possible that such rearrangements might be too potent and result in the death of the host cell.

Therapeutic significance

The clinical relevance of all this apparently arcane detail is considerable. PCR-based and fluorescence in situ hybridization (FISH)-based technologies already allow us to detect many of the molecular abnormalities. This in turn provides more accurate diagnostic and prognostic information. It seems highly likely that therapy will be more and more individualized as it becomes tailored to reflect the molecular profile exhibited by individual leukemias. The same molecular techniques are also permitting quantitation and monitoring of residual disease, with major implications for autografting as well as the early treatment of relapse.

Above all, treatments tailored to the molecular basis of a given leukemia are fast becoming a reality. Two current examples are the use of ATRA in APL (see above, and Chapter 39 on APL) and the specific BCR-ABL kinase inhibitor imatinib (STI571, Gleevec/Glivec) in CML.^{107,108} With the description of large numbers of molecular defects and the likelihood that many more will be described over the next few years, we shall have a wide range of potential therapeutic targets. Of these, the fusion proteins are particularly attractive in view of their tumor specificity. However, two important hurdles remain to be overcome. Transcription factors and many other leukemia oncoproteins are nuclear or cytoplasmic proteins, and so access to these targets is difficult. Second, not all molecular changes will prove useful therapeutic targets. Leukemia is likely to involve several sequential genetic events, some of which may no longer be required for the continued growth of leukemia cells. It will therefore be important to identify and concentrate on those genetic changes that are still necessary for tumor growth.

Cellular aspects of lymphoid differentiation: B cells

Claudine Schiff and Michel Fougereau

Introduction

Specific recognition by the immune system, often referred to as self-non-self discrimination, is essentially mediated by B and T lymphocytes, as opposed to innate immunity, basically supported by natural killer (NK) cells. These cells derive from hematopoietic stem cells through discrete differentiation pathways, although both originate in the bone marrow (and in the liver during embryonic and fetal life). T cells mature in the thymus, whereas B cells continue to differentiate in the bone marrow itself. A second feature that distinguishes B and T cells is their distinctive ways of recognizing antigens, due to the different nature of the recognition molecules that are expressed at their surface. B cells express immunoglobulins (Ig) that interact directly with native epitopes, i.e. subregions of the antigen that have a well-defined three-dimensional structure. Surface immunoglobulins are also the recognition module of the B-cell receptor (BCR), analogous to the TCR found on T cells. In contrast to the BCR, TCR do not interact directly with native epitopes, but identify peptides derived from the original antigen as presented by molecules encoded by genes of the major histocompatibility complex (MHC). Cleavage of the protein antigen into peptides is known as the 'antigen processing', and takes place within antigen-presenting cells (APC) before 'presentation' to T cells in association with an MHC molecule at the APC cell surface.

Both B and T cells have to face the repertoire problem, i.e. how to generate an extremely large number of different immunoglobulins and TCR to allow the recognition of an extraordinarily large number of discrete epitopes. A theoretical approach suggests that this number might be as large as 10^{17} . Since the total number of lymphocytes in a human adult averages 10^{12} (roughly divided into one-fifth B cells and four-fifths T cells), and taking their clonal organization into account, the numbers of BCR and/or TCR expressed at a given time appear to be well below this estimate, which implies some basic degeneracy in the immune recognition system. Nevertheless, the number of different structures must still be quite large, which therefore raises the problem of how to generate such a large repertoire with, necessarily, a limited number of genes. This is the main challenge faced by B and T cells, which is achieved during their respective differentiation processes. The second problem that the immune system has to face is the fact that self-recognition should be controlled so that harmful consequences do not occur. This implies that once the repertoire is at hand, it must be appropriately selected. In this chapter, we shall focus on the B-cell compartment, the T-cell case being discussed in Chapter 7.

During fetal life, B lymphocytes differentiate in the liver and then in the bone marrow. After birth, the first steps of B-cell differentiation take place in the bone marrow, which is a primary lymphoid organ, and drive precursors derived from the hematopoietic stem cells to become immature B lymphocytes. This period of differentiation is antigen-independent and is essentially devoted to generate the basic Ig repertoire, which is the result of a complex sequence of events involving multiple gene rearrangements. Immature B lymphocytes migrate to secondary lymphoid organs, namely the spleen, lymph nodes, tonsils, mucosa-associated lymphoid tissues (MALT), and gut-associated lymphoid tissues (GALT), including Peyer's patches. Further differentiation necessitates antigen encounter and a number of complex cellular interactions, among which T-B cooperation plays a major role. A second level of diversity is then generated, which mostly results from somatic mutations, and the final steps of differentiation, including isotype switching, lead to the emergence of plasma cells and memory B cells. Plasma cells secrete Igs in the bloodstream, which are also referred to as circulating antibodies.

Generation of immature B cells

The early steps of B-cell differentiation take place in the bone marrow, and are antigen-independent.

All differentiation events that drive the emergence of the various lineages (granulocytes, erythrocytes, monocytes, megakaryocytes, lymphocytes, etc.) derive from a common hematopoietic stem cell, which originates in the bone marrow.^{1,2} Emergence of the B lineage is initiated from a precursor common to the B, T, and NK lymphocytes.³ Evidence for this was first based on the phenotype of mutants of the *Ikaros* gene, encoding a transcription factor that is indispensable for the occurrence of the different lineages.^{4,5} Further engagement towards the B-cell lineage is driven by sequential expression of several transcription factors, including E2A, EBF, and Pax5.⁶ This engagement correlates with the selective inhibition of the pathways leading to pro-NK and pro-T cells, which necessitate the expression of Id2 and Notch1, respectively (Figure 6.1).

The main features of the molecular and cellular events that take place in the bone marrow^{7,12} and lead to B-cell commitment are shown in Figure 6.2. The use of various nomenclatures encountered in the literature may be somehow confusing; therefore we shall only consider three major subpopulations defining the B lineage: the pro-B, pre-B, and immature B cells. The successive steps of differentiation proceed towards the center of the bone marrow,¹³ and may be followed in several ways:

- acquisition and/or loss of surface antigens (CD markers; see Table 6.1), identified by monoclonal antibodies;
- identification of intracytoplasmic proteins and/or mRNA transcripts;
- analysis of the gene rearrangement status for each of the three Ig loci: H, κ and λ ;

Figure 6.1 Transcription factors involved in the early stages of lymphopoiesis. The common lymphoid progenitor (CLP) and the common myeloid progenitor (Pro My) are derived from hematopoietic stem cells (HSC). CLP gives rise to progenitors of the different lymphocyte lineages (Pro B, Pro T, and Pro NK). Cooperation of E2A and EBF conditions the engagement of CLP towards the B lineage, which becomes definitively committed upon Pax5 expression.

Figure 6.2 The early steps of B-cell differentiation take place in the bone marrow and are antigen-independent. The main discrete steps that lead from the hematopoietic stem cell to the immature B lymphocyte are identified by the successive Ig gene rearrangements, by the presence of intracytoplasmic markers, and by the expression of characteristic markers at the cell surface. The very early stages that go from the stem cell to the early pro-B cell encompass several precursors that are not completely defined to date. TdT, terminal deoxynucleotidyl transferase, responsible for including N diversity; ψL , surrogate light chain that combine with the Ig μ chain to form the pre-B receptor; RAG, recombination activating genes, which encode for the recombinase enzyme. See Plate 2.

Table 6.1 Cell surface molecules of central interest expressed at various stages of the B-cell lineage (this is not exhaustive)

Molecules	Localization ^a	Function
BCR		
IgM	Immature B cells	Antigen recognition
IgM+IgD	Mature B cells	''
IgG	''	''
IgA	''	''
IgE	''	''
Igα/Igβ (CD79a/79b)		Signaling module
Pre-BCR		
μ+ΨL	Pre-B cells	Regulation of early B-cell differentiation Control of allelic exclusion.
Igα/Igβ (CD79a/79b)		Signaling module
CD5	B1 cells	Minor population of B cells Role in autoimmunity?
CD10(CALLA)	Pro-B to immature B cells and GC-B ^b	Neutral endopeptidase
CD19	Pan B	Regulation of activation
CD20	Pre-B and B cells	Regulation of activation?
CD21	T2, mature follicular and marginal zone B cells	C3d/EBV receptor. With CD19 and CD81 forms coreceptor for B cells
CD22	Mature B cells	Adhesion of B cells to monocytes, T cells
CD23	T2, mature follicular B cells	Low-affinity IgE receptor (FcεRIIa), ligand for CD19/CD21/CD81 coreceptor
CD24	Pan B	B-cell growth?
CD27	Memory B cells	?
CD38	Early B and GC-B ^b	?
CD40	B cells	B-cell activation. Switch. Binds CD40L
CD45	Hematopoietic cells	PhosphoTyr-phosphatase. Signaling
CD77	GC-B ^b	Apoptosis?
CD79a (Igα)	Pre-B and B cells	<i>mb1</i> gene-encoded. See above, BCR
CD79b (Igβ)	Pre-B and B cells	<i>B29</i> gene-encoded. See above, BCR
CD138	Plasma cells	Ligand for collagen type 1

^aMost indicated CDs are also expressed on other cell types. CD19, CD20, CD21, CD22, CD23, and CD24 are mostly expressed on the B lineage, although some of them (CD19, CD21, and CD23) may be expressed on follicular dendritic cells (FDC). CD23 is found on eosinophils, platelets, and other cells. Therefore expression of only one marker is not sufficient to assign a cell a given phenotype.

^bGC, germinal center.

- localization of blockage points resulting from mutations leading to primary immune deficiency.

Interaction of B-cell progenitors with stromal cells in the bone marrow

The first steps of differentiation involve a sequence of direct interactions of the precursors with the stromal cells,¹⁴ ensured by various sets of cellular adhesion molecules (CAMs). The VLA-4 integrin expressed at the cell surface of the precursors interacts with stromal VCAM-1,¹⁵ and the resulting early pro-B cells now express c-Kit,¹⁶ a receptor that binds the stem cell factor (SCF, Steel factor) of stromal cells. This interaction triggers proliferation of the pro-B cells, which continue to differentiate through other stimuli. Late pro-B cells are stimulated by a soluble growth factor, also from stromal origin, interleukin-7 (IL-7),¹⁷ which drives proliferation of pre-B cells.

As these steps of differentiation proceed, cells are cycling and Ig-gene rearrangements that generate the basic repertoire take place in a sequential fashion. One way to characterize the various populations at each stage of differentiation relies on the identification of a number of CD markers (Figure 6.2, see Plate 2). CD34, which is already expressed in hematopoietic stem

cells,¹⁸ remains present at the surface of precursors and pro-B cells. Late pro-B cells can be characterized by the coexpression of CD34 with CD19,⁷ which is a very specific marker of the B lineage, as it is found on all subsequent stages, with the exception of plasma cells. CD10, also known as the common acute lymphoblastic leukemia antigen (CALLA), is expressed up to the immature B-cell stage, and seems to be expressed slightly before CD19.^{19,20} Other markers are expressed as differentiation proceeds, including CD20, CD21, CD22, CD23, and CD24.

Development of the basic Ig repertoire in the bone marrow as B cells differentiate

As already stated, the main feature of the early steps of differentiation is the acquisition of the basic repertoire of immunoglobulins, which becomes expressed as surface IgM (sIgM) on immature B cells. Immunoglobulins are symmetrical molecules composed of two heavy (H) chains and two light (L) chains (κ or λ). Depending upon the nature of the H chain, immunoglobulins exist as discrete classes or isotypes, termed IgM, IgG, IgA, IgD, and IgE, corresponding to the μ , γ , α , δ , and ϵ heavy chains, respectively. All classes may exist as surface or secreted immunoglobulins. When expressed at the surface of B cells, immunoglobulin molecules are associated with the Ig α -Ig β heterodimer, encoded by the *mb1* and *B29* genes respectively, to form the so-called B-cell receptor (BCR).²¹ Each of the H and L chains has a variable and a constant region. The variable regions of the H and L chains interact in the antibody-combining site, which is responsible for specific antigen recognition. Heavy and light chains are encoded by genes that are localized on three discrete gene clusters, *H*, κ , and λ , located on chromosomes 14, 2, and 22, respectively.

The unique feature of the organization of Ig genes is that they must be rearranged before becoming functional.²² These rearrangements allow the immune system to generate a very large repertoire by recombination and random association of a limited number of gene segments (between 200 and 300 in humans), leading to at least 10 million discrete Igs, thus having different specificities. In the light chains, the variable region results from the random association of V and J genes. The heavy chains are more complex, since their diversity results from the random association of V_H , *D*, and J_H genes. Immunoglobulin genes are rearranged exclusively in the B lineage, and these events constitute the hallmark of B-cell differentiation in the bone marrow.

Ig gene rearrangements necessitate a precise signaling on the DNA, known as 'recombination signal sequences' (RSS), which flank each of the *V*, *D*, and *J* gene segments, and that are recognized by highly specific recombinases encoded by two genes, termed *RAG-1* and *RAG-2*.^{23,24} In addition to the RAG proteins, other molecules such as DNA-PKcs and Artemis play a critical role in the ultimate steps of DNA rearrangements, mostly by cleaving and repairing double-stranded DNA elements.²⁵ The first recombination event, D_H to J_H takes place in early pro-B cells (see Figure 6.2) and is rapidly followed by the rearrangement of one of the V_H segments to DJ_H . Another enzyme, terminal deoxynucleotidyl transferase (TdT), is also active in pro-B cells, for which it represents an additional intracytoplasmic marker. This enzyme adds nucleotides in a random fashion, during the joining of *D* to J_H and V_H to DJ_H rearrangements.²⁶ The addition of these non-germline-encoded nucleotides is known as N-diversity and obviously amplifies the repertoire. Pro-B cells are cycling, and it seems likely that at least some molecules that drive the differentiation are cell cycle-dependent, as is the case for RAG-2.

Pro-B cells that have rearranged the *IGVH* locus must 'make' two decisions. One is to remain 'monoclonal' with respect to H-chain production, the second is to activate the rearrangement of the light-chain genes. Both events are regulated by the μ chain itself, which must be in its membrane form. Once the first allele of the *IGH* locus has completed the rearrangement process, the resulting gene may be functional or not, depending on whether the recombination has generated a sequence of nucleotides with an open reading frame. Because of the triplet organization of the genetic code, this happens only once every three rearrangements. If the first rearrangement is out of frame, the second allele will recombine, with the same probability of success. A new failure will lead to cell death. Conversely, once a functional gene has been obtained, the resulting heavy chain will exert a negative feedback on a further rearrangement of the *IGH* locus, ensuring 'monoclonal' expression of the μ chain.²⁷ The negative feedback presumably results in the turning off of the *TdT* and *RAG* genes.⁸

There is considerable evidence suggesting that the heavy chain must be expressed at the cell surface to regulate these events. Expression of the μ chain at the cell surface requires that it associate with another partner, which resembles the light chain and is therefore termed the Ψ L or surrogate light chain. First described by Melchers in the mouse²⁸ and then identified in humans,^{29,30} the surrogate light chain is composed of two polypeptides, encoded by the λ -like (or $\lambda 5$ in the mouse) and the *Vpre-B* genes,³¹ which pertain to the regular *IGL* locus. The μ - Ψ L complex becomes expressed at the surface of what is now a large pre-B cell, which also expresses CD10 and CD19, but no longer CD34. It is of note that μ - Ψ L is associated with the Ig α -Ig β heterodimer to form the pre-B cell receptor (pre-BCR).³²⁻³⁴ Expression of the pre-BCR is required for further progression along the B-cell differentiation pathway. Recent identification of galectin-1 as a physiological ligand of the pre-BCR

has provided the first experimental basis for the mode of interaction of pre-B cells with stromal cells.³⁵ The next step of differentiation involves light-chain gene rearrangements, which occur in the order $\kappa \lambda$. The recombination process is regulated in the same manner as for the heavy chains, so that there is only one light chain that is expressed in any given cell, either κ or λ . The negative feedback on further rearrangements of the light-chain genes is exerted by the complete IgM, which is expressed on the surface of the immature B cell and has now replaced the pre-BCR.

Selection of immature B cells before leaving the bone marrow

Before leaving the bone marrow, immature B cells that express surface IgM are confronted to the local 'self antigenic environment'. They are particularly sensitive to triggering by multivalent antigens, resulting in their clonal deletion by apoptosis. Alternately, soluble self-antigens will not cause death of the immature B cells, but instead will induce an anergic state, which does not seem to prevent the cells from migrating to the periphery.³⁶ At this point, cells that have uncounted self-antigen may also escape cell death or anergy by changing their specificities. This is achieved by the so-called 'receptor editing' phenomenon, which allows the cells to replace one light chain by another one, or induces secondary rearrangement on both the heavy- and light-chain loci. It should be noted, however, that this negative selection has a threshold that leaves a fraction of autoreactive cells going to the periphery. These cells are responsible for the presence in the bloodstream of natural autoantibodies that must be of some physiological relevance. Once validated by this 'quality control', immature B cells circulate to the periphery, through blood vessels and the lymphatic system, colonize the secondary lymphoid organs, and actively recirculate.

Generation of plasma cells and memory B cells

The final steps of B-cell differentiation take place in the periphery and are antigen-dependent.

Germinal center formation and the acquisition of somatic mutations

As recently described, bone marrow immature B lymphocytes emigrate to the spleen, as transitional T1 ($IgM^{high}IgD^{low}$) and T2 ($IgM^{high}IgD^{high}CD21^{+}CD23^{+}$) B cells.^{37,38} Depending upon the stimulating conditions, transitional T2 cells will progress either to mature follicular or to marginal zone B cells, the former being preferentially involved in T-cell-dependent responses (Figure 6.3). Within the first days after antigenic stimulation and T-cell help involving molecules such as CD40L and various monocytic-derived factors, such as BAFF (B-cell activating factor of the tumor necrosis factor family) or APRIL, another member of the TNF superfamily,³⁹ the activated B cells may differentiate into plasma cells and memory B cells, which are the terminal stages of B-cell differentiation (Figures 6.3 and 6.4). Plasma cells are large cells that have an abundant endoplasmic reticulum and secrete immunoglobulins. After a primary stimulation, the first antibodies that are produced belong to the IgM isotype. Alternatively, some stimulated B cells may

Figure 6.3 Late events of B-cell differentiation, which take place in the periphery, are antigen-dependent. Immature B cells produced in the bone marrow migrate as transitional T1 and T2 cells to the spleen. T2 cells may evolve either to marginal zone B cells (MZ) or to follicular B cells (FO). Upon antigenic challenge and T-cell help, the latter develop in the germinal center, where somatic hypermutations and isotype switching take place. Ultimate steps of differentiation lead to plasma cells that produce circulating antibodies, and memory B cells that will be available for secondary responses.

Figure 6.4 Last stages of B-cell differentiation. The germinal center organization plays a key role in mounting a T-dependent B-cell response, during which affinity is tuned upon the acquisition of somatic mutations, and the biological functions of the antibodies are adapted by isotype switching. Each step of differentiation may be followed by cell surface markers, which define classes denoted Bm1 to Bm5, according to Liu and Arpin.⁴⁰

colonize the primary follicles of a lymph node and generate a germinal center,⁴⁰ where they interact with follicular dendritic cells (Figure 6.5).⁴¹ B cells divide rapidly, giving rise to a clonal amplification in situ. They present a blastic morphology and are termed centroblasts, which delimitate the so-called dark zone of the germinal center. As the centroblasts actively divide, they accumulate somatic mutations, which occur at a very high rate (i.e. 10^{-3}) and which are mostly localized in the regions of the V_H and V_L segments that interact with the antigen. This mechanism, which underlies a specialized machinery found only in B cells (see below), considerably amplifies the anti-body diversity. As a result of these mutations, the array of affinities is largely increased, and the organization of the germinal center permits the antigen to

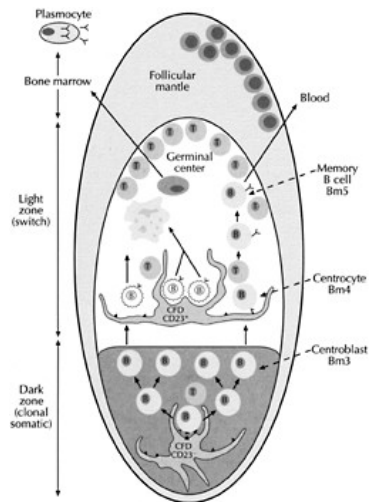

Figure 6.5 Schematic organization of a germinal center. As a result of antigenic stimulation, centroblasts develop as discrete clones in the dark zone, where they actively divide and start to accumulate somatic mutations. As they migrate to the light zone, they stop dividing and enter the centrocyte stage, where isotype switching takes place. They migrate through the germinal center and recirculate, either as plasma cells or as memory B cells. Adapted from Banchereau and Rousset.⁴¹

positively select the B cells that express at their surface the immune-globulins with the highest affinities.⁴² At this stage, centroblasts cease to divide, and become small non-dividing centrocytes that accumulate in the light zone of the germinal center, where they actively interact with numerous follicular dendritic cells. There is evidence that these cells play a major role in the selection of centrocytes with the highest affinity because they retain antigen at their surface. As a result of this interaction, the selected centrocytes can now either proceed towards plasma cell differentiation or become long-lived memory B cells.⁴³

Isotype switching

It has long been known that, upon antigenic stimulation, circulating antibodies first belong to the IgM isotype, before being replaced by immunoglobulins of another class (most frequently an IgG in the blood-stream). This phenomenon is known as isotype switching (or switch), and is the consequence of a new type of gene rearrangement, which takes place in the centrocytes, located in the light zone of the germinal center (Figure 6.5). As a result, the VDJ rearranged region of the mature B cell, which was initially associated with a constant C_{μ} to make a complete μ chain, now becomes associated with the constant region of another isotype.⁴⁴ This gene rearrangement involves recognition sequences termed 'switch regions', which are located 5' of each constant C_H gene (with the exception of the δ -chain gene). These regions present high levels of homology and are recognized by an enzymatic system that does not involve the Rag proteins (see below). As a result of this recombination event, the portion of DNA localized between the two switch regions concerned is deleted. The light-chain genes are not affected by isotype switching, so the antibody-combining site remains unaffected. In other words, isotype switching changes the Ig isotype without modifying the specificity of the antibody. It simply confers on the antibody a distinct biological function, which can amplify the physiological action of the immune system in a number of ways, such as to enable a more appropriate fight against pathogens, to ensure fetal protection through transplacental transfer, or to be expressed in secretions, depending upon the selected isotype. Isotype switching is another example of a mechanism that necessitates interaction between T and B lymphocytes and makes use of two molecular signals. One involves CD40 ligand (CD40L) and CD40, expressed at the cell surface of T helper (T_H) and B lymphocytes respectively and ensuring direct contact between the cells.⁴⁵ The second signal is provided by the T_H cell, and is a cytokine that is released as a soluble factor in the immediate proximity of the B cell. Depending upon the nature of the cytokine, and therefore on the type of interacting T cell, the switch mechanism will address a discrete isotype. For instance, secretion of IL-4 will favor a switch towards the IgE class,⁴⁶ whereas transforming growth factor β 1 (TGF- β 1) will induce switching to IgA.⁴⁷

Isotype switching and somatic mutations may be driven by the same basic mechanisms

A major breakthrough in the understanding of the mechanisms that drive isotype switching and generation of somatic hypermutations has recently been reported,⁴⁸ with the identification of mutations in the gene encoding activated induced deaminase (AID). As a result of these mutations, identified both in mice⁴⁹ and in human patients suffering from a type 2 hyper IgM syndrome,⁵⁰ absence of isotype switching coexisted with the absence of somatic mutations, leading to the exclusive expression of IgM germline genes in the bloodstream. AID is a deaminase enzyme that transforms a cytidine into a uracil in the RNA. Thus it may play a major role in the so-called mechanism of RNA editing, which operates at the mRNA level, by changing one nucleotide as a consequence of the C \rightarrow U replacement. This is expected to change the nature of the messenger, one interesting possibility being the transformation of an inactive mRNA into a new species that now encodes for an active protein.

Furthermore, recent data demonstrate that the AID protein is also able to perform the C \rightarrow U replacement directly at the DNA level.⁵¹ In that case, uracil is excised by uracil-DNA glycosidase (UNG) and replaced by any of the other deoxyribonucleotides under the action of the cell DNA repair machinery.⁵²

For isotype switching, the general scheme would be as follows: (i) opening of the chromatin in the S regions upon the specific action of cytokines; (ii) transitional transcription of the region of DNA that is now accessible; (iii) cleavage of the appropriate S regions by the newly generated endonuclease, specifically expressed in germinal centers; (iv) ligation of the new constant heavy-chain region gene, with a concomitant looping out of the intervening section of DNA. Since the absence of switching correlated with the absence of somatic mutations in AID-mutant mice and in patients suffering from the type 2 hyper IgM syndrome, it was proposed that this endonuclease was also at hand for the generation of somatic mutations.

Conclusions

Differentiation of B cells is a highly sophisticated process, which takes place continuously in the bone marrow and results in the constant emergence of a very large repertoire of immunoglobulins, expressed both as membrane B-cell receptors (BCR) and soluble antibodies. The numerous molecular events that lead from the hematopoietic stem cell to the mature B cell

are under constant selective pressure, implying a high level of cell death. Therefore the available repertoire appears, at any given time, as a compromise between the necessary economy in gene number, compensated by the recombination processes, and an unavoidable wastage due to the stochastic aspects of gene rearrangements and to negative selection of clones having a high affinity for self components.

Alterations in the differentiation of B cells either in the bone marrow or in secondary lymphoid organs could lead to pathological situations such as B-cell malignancies. These disorders may be considered as amplification—frequently clonal—of one B-cell subpopulation ‘frozen’ at a given stage of differentiation, as a result of malignant transformation. The second group of disorders relates to inherited primary immune deficiencies, which are very rare diseases resulting from mutations of genes encoding various factors necessary to ensure the B-cell differentiation pathway.^{53–56} Finally, defects in selection processes may also lead to the generation of self-reactive B cells and thus to autoimmune diseases.⁵⁷

Cellular aspects of lymphoid differentiation: T and NK cells

Anna Cambiaggi, Sophie Ugolini, and Eric Vivier

Introduction

Cells belonging to the lymphoid lineages ensure the protection of their hosts against an enormous variety of (potential pathogenic) microorganisms as well as against alterations of self tissues (e.g. tumor cells). T and B cells are the most studied type of lymphocytes: their recognition of foreign antigens through rearranged T-cell receptors (TCR) and B-cell receptors (BCR) has been extensively investigated. TCR and BCR are generated by gene rearrangement, providing T and B cells with a virtually infinite capacity to recognize antigens. T and B lymphocytes comprise the cellular component of adaptive immunity and provide the lifelong immunity that can follow exposure to disease or vaccination. The third type of lymphocytes, natural killer (NK) cells, do not express rearranged antigen receptors on their surface; they are effector lymphocytes contributing to host defense against viral infections and to immune surveillance against the establishment of primary tumors through cytolytic activity and cytokine secretion.

All hematopoietic cells originate from one pluripotent stem cell that has the ability of self-renewal. The existence of a common progenitor cell that should be able to differentiate only into cells of the lymphoid lineages is generally accepted, but this common lymphoid progenitor has not yet been identified. Evidence for this model is provided by mice deficient for the Ikaros transcription factor, which lack B, T, NK, and dendritic cells, but not the myeloid and erythroid compartments.¹ Further, it has been shown that T and NK cells are more closely related to each others than to B cells, supporting the existence of a bipotential T/NK precursor.²

T lymphocytes and NK cells can be defined via morphological, phenotypical, and functional criteria. Mature circulating T lymphocytes are small cells with condensed chromatin in the nucleus and few cytoplasmic organelles; upon antigen recognition and activation, the T-cell volume increases, the chromatin in the nucleus becomes less dense, and abundant mitochondria and rough endoplasmic reticulum are present in the cytoplasm. Circulating NK cells are large granular lymphocytes with abundant cytoplasm containing granules loaded with molecules involved in the execution phase of the cytolytic mechanisms. Phenotypically, T cells are characterized by the surface expression of the TCR/CD3 complex that is totally absent on NK cells. Otherwise, the two cell types share the expression of numerous differentiation antigens, as shown in Table 7.1. The cell surface markers commonly utilized to define human NK cells (CD16 and CD56) can also be expressed by discrete subpopulations of T lymphocytes. Activation markers such as CD69 and CD25 are also shared between activated T and activated NK cells.³ T lymphocytes can be subdivided into two subsets on the basis of their phenotype and function. CD4⁺ T helper (Th) lymphocytes are specialized in the activation of other immune effectors (B cells and macrophages) with cytokine secretion upon recognition of pathogen antigens in the context of major histocompatibility complex (MHC) class II molecules. CD8⁺ cytotoxic T lymphocytes (CTL) recognize antigenic peptides in the context of MHC class I molecules and exert their function in one of two ways: cytolytic activity and cytokine secretion. CTL are commonly considered as counterparts of Th cells, but a comparison of CTL and NK cells on the basis of functional parameters reveals striking similarities.⁴ Both T and NK cells lyse their target using both perforin-dependent mechanisms and Fas/Fas-ligand interactions. They also respond to the same cytokines both for proliferation and for increase of cytolytic activity, and they produce a similar set of lymphokines—interferon- γ (IFN- γ), granulocyte-macrophage colony-stimulating factor (G-CSF), and tumor necrosis factor α (TNF- α)—shown in Table 7.2. Despite these similarities, CTL and NK cells' effector mechanisms are triggered by distinct molecular pathways. After recognition of the specific MHC class I/antigenic peptide complex, T lymphocytes proliferate, acquire an effector potential, and also become memory T cells. NK cells are also able to

interact with MHC class I molecules, but through NK receptors for MHC class I molecules (NKR), and this recognition results in the inhibition of NK cells' effector functions. Downregulation or absence of MHC class I molecules on target cells induces lysis by NK cells; as a consequence, NK cells can eliminate cells that, through lack of MHC class I molecules, evade CTL recognition. Total or partial loss of MHC class I expression is a common feature of viral infections and malignant transformations. NK cells are also able to participate in the adaptive response through the expression of the Fc γ RIIIA (CD16) receptor complex, which allows them to perform antibody-dependent cell-mediated cytotoxicity (ADCC) against antibody-coated target cells.

T- and NK-cell development

Hematopoietic cells originate in the yolk sac, then migrate to the fetal liver, which is the major hematopoietic organ during fetal life. T-cell precursors

sors and mature NK cells can be identified in the fetal liver starting from week 6 of gestation. A rudiment of thymus of epithelial origin, the thymic anlage, is formed at week 7 of gestation, but only at week 9 of gestation is it colonized by dendritic cells, macrophages, and thymic precursors. After birth, bone marrow becomes the major hematopoietic organ and is likely to be the development site for NK cells, whereas the vast majority of T cells mature in the thymus. The importance of the thymus in T-cell development can be observed in the DiGeorge syndrome in humans, as well as in nude mutant mice. In these cases, as the thymus fails to form, the affected individuals lack the vast majority of T lymphocytes, but produce normal B lymphocytes and NK cells. Recent evidence indicates that some T cells can have an extrathymic differentiation in the gut mucosa or in the liver, but these cells differ from thymic T lymphocytes in phenotype and function.⁵ Within the thymus, T-cell precursors proceed to differentiation and education. As shown in Figure 7.1, the more immature precursors lack TCR/CD3, CD4, and CD8 molecules and are defined as triple-negative (TN). The earliest thymic precursors are CD34⁺CD33⁺CD45RA⁺; then they acquire the expression of CD7 and CD38 at the cell surface and of CD3 molecules in the cytoplasm. These cells are still able to generate both T and NK cells. The first committed T cells acquire the

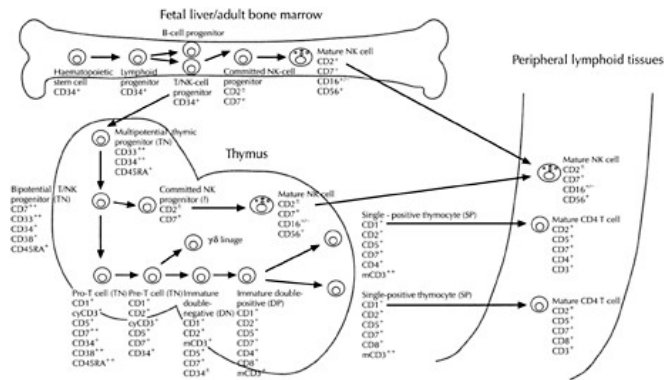

Figure 7.1 Schematic representation of human T- and NK-cell development. The development of T and NK lymphocytes from hematopoietic precursors (fetal liver/adult bone marrow) is shown here schematically, m, membrane (cell surface expression); cy, cytoplasm (cytoplasmic expression).

expression of CD1, an MHC class I-like protein associated with β_2 -microglobulin, CD2, and CD5; at this stage, TCR β -chain rearrangement starts.⁶ Probably, at this point, T-cell precursors for the TCR $\gamma\delta$ T-cell lineage differentiate from TCR $\alpha\beta$ -committed thymocytes. The rearranged TCR β chain is expressed at the cell surface associated with a pre-TCR (pT α) chain and with CD3 molecules (Figure 7.2) (double-negative stage, DN). Expression of the pre-TCR complex prevents further rearrangements at the TCR β locus, controls the initiation of TCR α -chain rearrangement and is required for the expression of CD4 and CD8 molecules on the thymocytes (double-positive stage, DP).⁷ In the mouse, the most immature thymocytes express c-Kit and CD44, but not CD25 (Figure 7.3). Concomitant with CD25 surface expression, DN thymocytes proliferate strongly. The downregulation of c-Kit and CD44 that follows indicates a stage of fully T-cell commitment as well as the initiation of TCR α rearrangement. The availability of genetically modified mice has allowed the identification of the molecules involved in early T-cell maturation as well as major checkpoints of T-cell thymic development. The first checkpoint occurs at the transition from TN to DN cells and is blocked by the absence of RAG-1 and RAG-2, enzymes involved in TCR rearrangements. Thymocytes isolated from TCR $\beta^{-/-}$ or CD3 $\epsilon^{-/-}$ mice are blocked at the CD25⁺CD44⁺ stage: in these mice, TCR β rearrangement is unaltered, but the preTCR is not expressed on the surface and cannot transduce further development signals. Evidence for the role of pre-TCR in allelic exclusion at the TCR β locus was documented with the introduction of a rearranged TCR β gene into the mouse genome: the transgenic receptor prevents any rearrangement at the endogenous TCR β locus. The rearrangement of TCR genes occurs during early stages of thymocyte maturation, and allows the generation of a large number of immature T cells bearing a single specificity. It has been estimated that the repertoire of thymocytes before selection ranges between 10^{10} to 10^{15} distinct specificities. The mechanisms of TCR chain rearrangement are similar to those that occur in B cells to generate immunoglobulins (Igs), and the genomic organization of TCR genes resembles the organization of Ig genes. Each TCR locus consists of variable (*V*), joining (*J*), and constant (*C*) region genes, TCR β and TCR γ chain loci also contain diversity (*D*) segment genes. The β -chain locus is on chromosome 7; it consists of two *C β* regions associated with a 5' cluster of five *J β* segments and one *D β* segment, most of the *V β* segments are 5' of *C β* and *J β* clusters. The α locus is on chromosome 14, there is a single *C α* segment associated with a 5' cluster of up to 50 *J α* segments; 5' from the cluster, there are around 75 *V α* segments. The TCR8 locus is located between *V α* and *J α* genes. The TCR γ chain locus is on chromosome 7 and has an organization similar to that of the TCR β chain locus. We will discuss in detail TCR β and TCR α chain rearrangement. The TCR β chain locus rearranges first with the joining between a *D β* and a *J β* segment; the *D β J β* segment is joined to a *V β* segment to form a *V β D β J β* gene (Figure 7.4). If the rearrangement is productive, a long mRNA also containing some intronic sequences

Figure 7.2 Schematic representation of the pre-TCR/CD3, TCR/CD3, and ADCC-R complexes. The oligomeric preTCR/CD3, TCR/CD3, and ADCC-R (CD16) complexes are represented according to their canonical stoichiometry. Immunoreceptor tyrosine-based activation motifs (ITAM) are shown as black cylinders; the three CD3 ζ ITAMs are indicated by a, b, and c respectively. Ig-like domains and carbohydrate moieties are also indicated. The charged amino-acid residues in the transmembrane domains are represented by the single-letter code.

is synthesized and spliced out to obtain a mature mRNA. Once the TCR β has been produced and associated with pT α on the cell surface, the cell undergoes active proliferation and CD4 and CD8 molecules are expressed on the cell surface. With the end of the proliferative phase, the TCR α locus starts its rearrangement, with the production first of a $V_{\alpha}J_{\alpha}$ segment. The large number of V_{α} and J_{α} segments allows the cell to undergo successive rearrangements, in the case of initial non-productive rearrangements. The allelic exclusion at the TCR α locus is less stringent than at the TCR β locus, and a single T cell can express on its surface two distinct TCR α s.⁸

When both TCR β and TCR α loci are rearranged, the thymocyte undergoes selective processes: positive selection assures that only thymocytes that recognize self MHC molecules progress in their maturation, and the thymocytes that cannot interact with any self MHC molecule die by neglect; negative selection eliminates potentially self-reactive cells that have been generated during random rearrangement of $V_{\beta}D_{\beta}J_{\beta}/V_{\alpha}J_{\alpha}$ segments. It has been calculated that more than 95% of thymocytes are eliminated during the positive and negative selection processes. Most of the evidence for positive selection comes from animal models, in particular when lethally irradiated mice were injected with bone marrow cells from mice of another MHC haplotype. In the host mice, all the bone marrow-derived cells are of donor origin; these mice are known as bone marrow chimeras. In the experiment depicted in Figure 7.5, donor cells are derived from F₁ of MHC^a and MHC^b parents (MHC^a \times ^b) and the irradiated hosts are mice of the parental strains (either MHC^a or MHC^b) in which only radioresistant thymic epithelial cells survive. When MHC^a \times ^b cells develop in an MHC^a mouse, the mature T cells are able to recognize antigens presented only by MHC^a antigen-presenting cells (APC), but not by MHC^b APC, showing that the T cells had been restricted by the MHC^a molecules that they encountered during thymic maturation. The use of TCR transgenic mice has provided another model to investigate positive selection processes. These mice were created by injecting into their genome DNA coding for the α and β chains of a TCR of defined MHC restriction. Mature T cells were found only in mice of the appropriate MHC haplotype, but not in mice of other MHC haplotypes.⁹ During positive selection, the thymocytes undergo transition from a DP to an SP stage: cells restricted for MHC class I molecules will express CD8 on their surface, while cells restricted for MHC class II molecules will express CD4 (Figure 7.1). Again, TCR transgenic mice turned out to be a good model to investigate the role of TCR/MHC interactions and the expression of CD4 or CD8 coreceptors. In mice with a TCR restricted

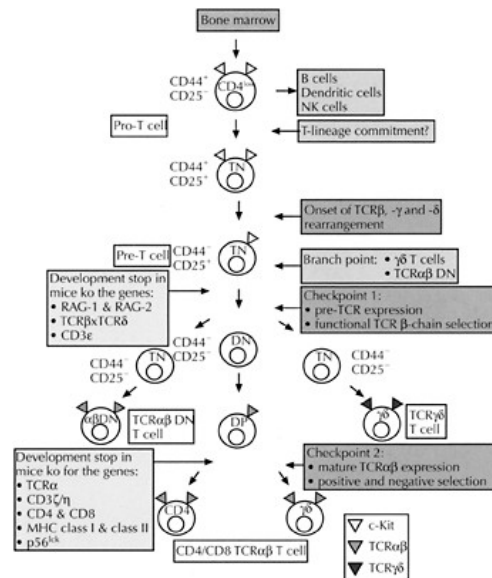

Figure 7.3 T-cell development in the thymus. The major stages of T-cell development in the thymus are schematized. The large shaded boxes on the left show the blocks in T-cell development observed in the indicated knockout (ko) mice.

for MHC class I molecules, all the peripheral lymphocytes are CD8⁺; when the TCR is specific for MHC class II molecules, the mature T cells express CD4 on their membrane. The same TCR transgenic mice mentioned above to demonstrate the requirement of TCR/MHC interactions during positive selection were also useful to study negative selection. Injection of the antigenic peptide recognized by the transgenic TCR results in the apoptotic death of developing thymocytes because the peptide is then presented as self antigen in the thymus and autoreactive cells are thus deleted.⁹ Only recently has the answer to the central question of selective events been obtained: How does TCR engagement lead to cell maturation during positive selection and to cell death during negative selection? The 'avidity hypothesis' is now accepted and supported by experimental evidence. It postulates that the strength of the interaction between TCR and peptide/MHC complexes and the density of the complexes are responsible for the selective events. If the signal is weak, the thymocytes are selected to mature, but if the signal is too low, the thymocytes will die of neglect; if the signal is strong, the thymocytes are driven to programmed cell death and negatively selected.¹⁰

As discussed above, there are several lines of evidence indicating that T and NK cells derive from a common progenitor.¹¹ Most of the indications for the existence of a bipotential progenitor derive from studies of human thymic precursors. In particular, one report showed that immature CD34^{high} thymocytes are able to develop in T cells in fetal thymic organ culture (FTOC) and to generate NK cells when cultured in the presence of stem cell factor (SCF, Steel factor, c-Kit ligand), interleukin-3 (IL-3), and IL-7. To demonstrate directly that CD34^{high} cells retained a bipotential capacity, they were single-cell-sorted, expanded for a short period with SCF, IL-2, and IL-7 on feeder cells, and then pooled together. Half of these were cultured in FTOC and matured into T cells; the other half were cultured with SCF, IL-3, and IL-7 in the absence of a thymic environment, and almost all the cells developed into NK cells.¹²

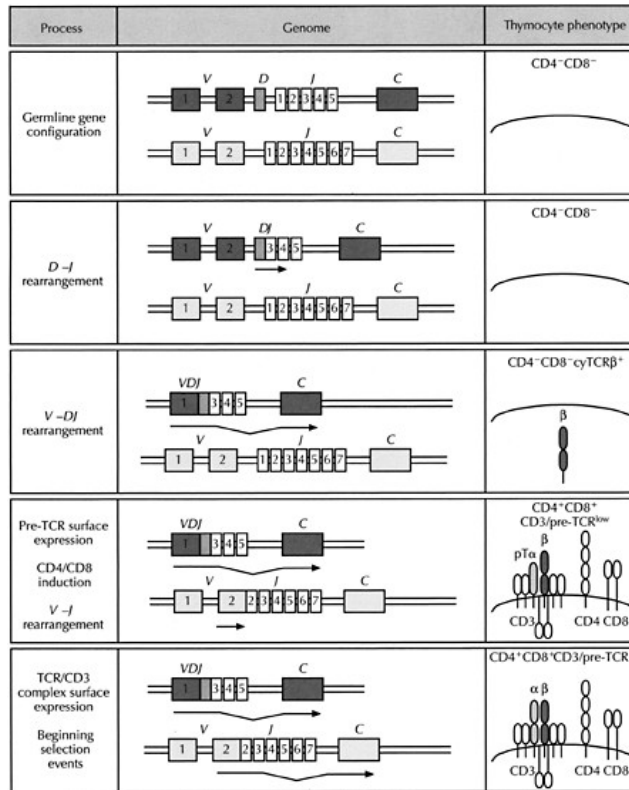

Figure 7.4 TCR gene rearrangements in TCRαβ cells. V, D, and J segments on homologous chromosomes are depicted. The cell surface phenotype of thymocytes is indicated at each stage of development.

The demonstration that there exists a T/NK bipotential precursor in the thymus indicates that NK cells can develop in the thymus; however, the thymus is not required for normal NK-cell development, since athymic nude mice have normal NK cells. The main site of NK-cell development is likely to be the bone marrow (Figure 7.1). In humans, a bone marrow origin for NK cells is supported by experience with aplastic patients transplanted with allogeneic bone marrow. In these patients, the emergence of a wave of NK cells of donor origin is reported 2–3 weeks after transplant. Early studies with murine models showed that an intact bone marrow environment is necessary for NK-cell development. Mice treated with the radioisotope strontium-89 (⁸⁹Sr) are characterized by the destruction of bone marrow and present a marked decrease in

Figure 7.5 Evidence of positive selection in mouse bone marrow chimeras. T cells from $MHC^{a \times b} F_1$ mice are able to respond in vitro to antigens presented by antigen-presenting cells (APC) of both MHC^a and MHC^b origin. If bone marrow cells from these mice are transferred to lethally irradiated mice of MHC^a (or MHC^b) parental haplotype, the T cells mature and are positively selected in the host thymus. T lymphocytes isolated from these bone marrow chimeras are able to respond in vitro to antigens presented only by APC of recipient MHC (bottom panel).

NK-cell activity. Moreover, bone marrow grafts from normal mice to ^{89}Sr -treated mice failed to reconstitute the NK-cell compartment, indicating the need of stromal and/or humoral signals provided by an intact bone marrow environment to support NK-cell maturation.¹³

Mature T and NK cells

Mature naive T cells leave the thymus and migrate through the bloodstream into the peripheral lymphoid organs. Then, in the presence of specific antigens, T cells proliferate and differentiate into effector T cells, which are able to participate in the adaptive immune response. All mature T lymphocytes express on their surface the TCR/CD3 complex (Figure 7.2). $\text{TCR}\alpha$ and $\text{TCR}\beta$ chains have two Ig-like domains in the extracytoplasmic portion, two or one positively charged amino-acid residues in the transmembrane portion respectively, and a short intracellular domain. They are associated with the CD3 complex, which consists of three distinct IgSF proteins, $\text{CD3}\gamma$, $\text{CD3}\delta$ and $\text{CD3}\epsilon$, and a dimer of $\text{CD3}\zeta$ polypeptides. Molecules of the CD3 complex contain in their intracytoplasmic portion immunoreceptor tyrosine-based activation motifs (ITAMs), which are responsible for the transduction of activating signals upon TCR engagement. The CD3 proteins are also required for the assembly and cell surface expression of TCR.¹⁴

The activation of naive T cells in the lymph nodes requires the engagement of TCR (signal 1) and also of costimulatory molecules such as CD28 (signal 2). Only professional APC (macrophages, dendritic cells, and B lymphocytes) express on their surface, together with MHC class I and class II molecules, B7.1 (CD80) and B7.2 (CD86), which serve as CD28 ligands. Antigen recognition by naive T lymphocytes without costimulatory signals induces a state of anergy in the cell (signal 1 only). This mechanism helps to ensure tolerance of T lymphocytes to self antigens. Indeed, negative selection in the thymus is not totally efficient; some tissue-specific proteins are not presented to T cells during their thymic maturation. Once T cells encounter the antigen presented by a professional APC, they rapidly proliferate and differentiate into progenies of effector and memory T cells. CD8^+ T lymphocytes are predominantly cytotoxic effectors, while CD4^+ T cells can differentiate into inflammatory T cells (Th1) and helper T cells (Th2). Upon activation, Th1 lymphocytes produces cytokines ($\text{IFN-}\gamma$, GM-CSF, and $\text{TNF-}\alpha$) that activate macrophages to more efficiently eliminate intracellular microorganisms. Th2 lymphocytes secrete a different set of cytokines (mainly IL-4, IL-5, and IL-6) that regulate B-cell activation programs to differentiate and to produce immunoglobulins.

Mature NK cells migrate from the bone marrow to the blood, where they constitute around 4–15% of peripheral blood mononuclear cells (PBMC); the spleen also constitutes a source of NK cells (which represent 3–4% of splenic lymphocytes). In healthy individuals, rare NK cells are barely detectable in non-inflammatory lymph nodes. The presence of NK cells has also been demonstrated in the gut mucosa.¹⁵

All mature NK cells have a high density of adhesion molecules, such as CD2 and the three β_2 integrins (CD11a/CD18, CD11b/CD18, and CD11c/CD18); in humans, NK cells also express at their surface CD56, an isoform of neural cell adhesion molecule (NCAM), whose function on NK cells is still unknown. Around 10% of NK cells express a high density of CD56 (CD56^{bright}); these cells constitutively express the trimeric high-affinity IL-2 receptor (IL-2R), together with the intermediate-affinity IL-2R. The remaining 90% of NK cells have a lower expression of CD56 (CD56^{dim}) and express only the intermediate-affinity IL-2R. IL-2 stimulation of CD56^{bright} NK cells results in a proliferative response and an increase in their cytolytic function, whereas IL-2 stimulation of CD56^{dim} NK cells only results in an enhancement of their cytolytic activity. Therefore CD56^{bright} NK cells resemble immature NK cells with poor cytolytic activity but high proliferative capacity; while CD56^{dim} cells have the attributes of more differentiated cells.¹⁶ The vast majority (>90%) of NK cells express the lowaffinity receptor for the Fc portion of immunoglobulins (Fc γ RIII or CD16), which is part of the ADCC receptor (ADCC-R) complex and mediates the lysis of antibody-coated cells. The elucidation of ADCC-R molecular structure revealed striking structural and functional homologies with the TCR/CD3 complex (Figure 7.2). CD16 is non-covalently associated with CD3 ζ and FcRI disulfide-linked dimers. Similarly to TCR $\alpha\beta$ (and TCR $\gamma\delta$) chains, the signaling properties of the ADCC-R complex are dependent upon the association between GD16 and polypeptide subunits specialized in transducing activating signals. CD3 ζ and FcR γ express in their intracytoplasmic domain three and one ITAM respectively; this motif is necessary and sufficient for transducing activating signals. Irrespective of their role in coupling to the transduction pathway, that is dependent upon the integrity of their ITAM domains, CD3 ζ and FcR γ are also required for the assembly and the surface expression of the ADCC-R complex via a charged amino-acid residue present in their intracytoplasmic portion.¹⁷ PEN5 is a highly glycosylated molecule selectively expressed on CD56^{dim}CD16⁺ human NK cells and thus represents a useful phenotypic marker of a large proportion of NK cells.¹⁸

Whereas T cells are MHC-restricted (i.e. they only recognize antigens presented by self MHC molecules), NK cells are *not MHC-restricted*. However, their function is *controlled* by the MHC. Indeed, human and mouse mature NK cells express on their surface inhibitory receptors for MHC class I molecules (natural killer cell receptors, NKR); engagement of NKR with their MHC class I ligands transduces a negative signal that leads to the inhibition of NK cell activation programs. In humans, NKR belong to two distinct families: IgSF and type C lectins¹⁹(Figure 7.6 and Table 7.3). In mice, only type C lectin NKR have been described.²⁰ During maturation, NK cells acquire the expression of at least one inhibitory receptor for self MHC class I alleles, the engagement of which prevents the killing of autologous cells. IgSF NKR are defined as killer-cell Ig-like receptors (KIR), they belong to a multigenic and multiallelic family and all the genes are localized on chromosome 19 (at 19q13.4). KIR are characterized by two or three Ig-like domains in their extracytoplasmic portion, a transmembrane portion, and a long intracellular domain that contains two immunoreceptor tyrosine-based inhibitory motifs (ITIM). The integrity of ITIM sequences is necessary for the recruitment of intracytoplasmic effector substrates involved in the inhibition of NK-cell activity (i.e. the protein tyrosine phosphatases SHP-1 and SHP-2). In humans, the lectin-like NKR are heterodimers between the CD94 molecule and members of the NKG2 family. In mice, NKR are constituted by homodimers of lectins belonging to the Ly49 family, as well as CD94/NKG2 heterodimers.

Inhibitory recognition of MHC class I molecules accounts only in part for the target cell specificity of NK cells. Indeed, some sensitive target cells express normal level of MHC class I molecules while some others are not sensitive to lysis by NK cells despite low or absent class I expression. These observations imply the existence of activating receptors on NK cells. Several activating molecules, such as CD2, CD28, CD40L, 2B4, and leukocyte function-associated antigen (LFA)-1, are expressed on NK cells. However, we shall not focus here on these structures, which appear to 'co-activate' rather than directly stimulate NK cells. Several stimulatory structures expressed on NK cells have been identified.²¹ As with inhibitory receptors, these activating receptors include members of the KIR, Ly49, and CD94/NKG2 families (Table 7.4). Activating receptors are highly homologous to the inhibitory molecules in their extracytoplasmic

Table 7.3 Human MHC class I specific inhibitory receptors expressed on NK cells

and CD8⁺ $\alpha\beta$ T cells. NKG2D forms a homodimeric structure, in contrast with other receptors of the NKG2 family, which form heterodimeric receptors with CD94. Two structurally distinct families of molecules, MIC and ULBP (ULI6-binding proteins), have been identified as ligands of human NKG2D. The extracellular portions of ULBP and MIC proteins share weak homology with MHC class I molecules. Mouse NKG2D ligands are the glycosyl-phosphatidylinositol (GPI) anchored membrane proteins of the Rae (retinoic acid early inducible 1) family and the transmembrane protein H60, both of which are also distantly related to MHC molecules. Interestingly, these human and mouse NKG2D ligands are induced and/or upregulated upon cellular distress. Finally, in humans, three natural cytotoxicity receptors (NCR) have been described—NKp30, NKp44, and NKp46—whose engagement, alone or in combination, accounts for an important part of NK-cell natural cytotoxicity against multiple types of tumors *in vitro*.²¹ Their ligands on tumor cells are unknown but it has been reported that NKp46 and NKp44 can recognise viral hemagglutinins.²⁴

A common feature of all stimulatory receptors resides in the presence of a charged amino-acid residue in their transmembrane domains that is required for association with adapter signaling proteins (Table 7.4). The adapter proteins—FcR γ , CD3 ζ , and the killer cell activating receptor-associated protein (KARAP/DAP12)—have very short extracellular domains but contain ITAM in their cytoplasmic domains, which allows them to associate with the signaling ZAP 70 and/or Syk protein tyrosine kinases. NKG2D is included in an oligomeric complex with the transducing polypeptide DAP10/KAP10 that contains a cytoplasmic YINM motif allowing the recruitment of the p85 subunit of the phosphatidylinositol 3'-kinase (PI3K).²⁵ In the mouse, two alternative splice products of the NKG2D gene have been described: NKG2D-L and NKG2D-S. Whereas mouse NKG2D-L associates selectively with DAP10, NKG2D-S is more promiscuous and associates with KARAP/DAP12 and DAP10.²⁶

NK cells thus appear to have evolved at least two complementary mechanisms that ensure self-tolerance and elimination of pathogens: recognition of infectious non-self and stressed-induced self by activating receptors, as well as recognition of constitutive self by inhibitory receptors. If it holds true for other activating and inhibitory NK receptors, this strategy of NK-cell recognition is of major importance in the development of novel immunotherapeutic approaches based on NK-cell manipulation.²⁷

Dendritic cell development

M Schnurr, Eugene Maraskovsky, and Jonathan Cebon

Introduction

The immune system has evolved to protect the host from invasion by pathogens. Dendritic cells (DC) are a heterogeneous family of rare, phagocytic leukocytes, which form sentinel networks throughout the body, particularly at sites of potential pathogen entry such as epithelial and mucosal surfaces. Sentinel DC normally exist in an 'immature state', sampling the local environment for evidence of pathogens, tissue damage, or inflammation. These immature DC are particularly effective at antigen capture, uptake, and processing, but less efficient at antigen presentation. DC are rapidly activated in response to environmental stimuli, which signal 'danger', such as microbial products and cytokines found at inflammatory sites. Activation initiates a coordinated sequence of processes, which in their sum are termed 'maturation'. Mature DC switch off their capacity to capture antigen, and increase the expression of antigen-presenting molecules (major histocompatibility complex (MHC) molecule-peptide complexes and costimulatory molecules) on their cell surface. In addition, they gain the ability to migrate into T-cell areas of draining lymphoid tissue. This uniquely enables DC to present antigens to lymphocyte populations, thereby priming naive antigen-specific T cells, which recognize immunogenic peptides presented on MHC molecules. In this way, DC regulate the proliferation and differentiation of effector T cells. There is also evidence that DC can play a complimentary, yet paradoxically opposing, role in downregulating immunity in order to maintain tolerance toward self antigens. In addition to initiating and regulating T-cell responses, DC play roles in the activation of B cells and in innate immunity.

DC are not a homogeneous population of cells. As well as displaying heterogeneity in relation to activation or maturation state, they also derive from different hematopoietic lineages, although the common source is the marrow-derived multipotential CD34+ hematopoietic progenitor cell. The 'lineage model' proposes that different DC types emerge from distinct lineage pathways, each with distinct functions that regulate immune responses, such as helper T-cell differentiation. However, DC function is strongly influenced by the local environment. Environmental effects are mediated by cytokines and chemokines, through the activation of pattern recognition receptors by microbial products and through interaction with other leukocyte populations. The 'instruction model' proposes that the diversity of immune outcomes results from environmental instruction of DC. Most of our knowledge to date about DC has been gained from studying the murine system and from culturing human DC in vitro. DC research has gained momentum from the discovery that DC can be exploited as adjuvants in the immunotherapy of cancer and infectious disease. In this chapter, we shall discuss the heterogeneity of DC based on their development from hematopoietic precursors and their functional diversity due to environmental influences. Finally, we shall provide a clinical perspective for using DC in the immunotherapy of human disease.

Development of DC from hematopoietic precursors

DC origins and differentiation pathways

DC represent a heterogeneous population of antigenpresenting cells, which appear to develop via multiple differentiation pathways (Figure 8.1).¹⁻³ The life cycle of DC involves the differentiation from CD34+ progenitor cells into blood-borne DC precursors that seed peripheral tissues. Seminal work by Steinman and Cohn⁴ in 1973 suggested that DC are myeloid in origin. This was based upon similarities with monocytes and macrophages in their tissue distribution, morphology, phenotype, and enzymatic and phagocytic capacities. Further evidence that DC have a myeloid origin derives from in vitro differentiation assays, in which DC were generated from monocytes or from intermediate precursors that retained the

Figure 8.1 Differentiation pathways for dendritic cells (DC). BM, bone marrow; CLA, (cutaneous lymphocyte-associated antigen)

capacity to generate macrophages.⁵⁻⁷ However, DC may also derive from early thymic progenitors⁸⁻¹¹ or from lymphoid progenitors.¹²⁻¹⁴

Human DC populations

Human DC are found throughout the body, being present in most organs except for the brain, parts of the eye, and the testes.²⁰ Despite their widespread distribution, it was not possible to study their function adequately until the discovery of effective tissue culture conditions and the determination of appropriate cell sorting techniques to enable sufficient numbers of DC to be isolated for functional studies. Most of our understanding of DC biology has been gained by studying DC derived from monocytes in vitro. Nonetheless, it is unclear whether monocyte-derived DC (MoDC) have a physiological counterpart, and two recent reports from our own group have demonstrated striking functional differences between MoDC and physiologic DC types in the blood.^{21,22} Two DC populations are present in the peripheral blood, expressing a myeloid and a lymphoid/myeloid phenotype respectively. Epidermal DC or Langerhans cells are the prototype of tissue-resident DC and have also been generated in vitro using various precursor populations and cytokines. These DC types are discussed below.

DC derived from CD34⁺ hematopoietic progenitors

Caux et al^{5,23} produced landmark experimental evidence that DC could be generated from CD34⁺ progenitors. These progenitors, which can be derived from cord blood, bone marrow, or peripheral blood, differentiate into DC when cultured with granulocytemacrophage colony-stimulating factor (GM-CSF) and tumor necrosis factor (TNF)- α . Differentiation proceeds through two independent, immature DC progenitors, defined by their mutually exclusive expression of CD1a and CD14. When cultured with GM-CSF and TNF- α , CD14⁺CD1a⁻ precursors become E-cadherin-negative mature DC, with a dermal or lymphoid-organ DC phenotype. By contrast, CD14⁻ CD1a⁺ intermediates generate E-cadherin-positive Langerhans cell-like DC. DC can also be generated from human bone marrow CD34⁺ CD10⁺ Lin⁻ precursors with combinations of interleukin (IL)-1 β , IL-7, GM-CSF, stem cell factor (SCF, Steel factor, c-Kit ligand) and Flt3 ligand (FL).^{12,17,18}

Monocyte-derived DC

The best-studied model for human DC biology is the MoDC. A variety of techniques have been used to isolate monocytes and to generate DC in vitro. Generally, monocytes are cultured for 5-7 days with GM-CSF and IL-4,^{6,24} although modifications of this cytokine combination have been reported. For example, MoDC could be generated using GM-CSF and interferon (IFN)- α ,²⁵ GM-CSF and IL-13,⁷ or IL-3 and IFN- β .²⁶ Of note, the majority of culture systems generate MoDC that are functionally immature. These immature MoDC can rapidly mature in response to microbial and other stimuli. Evidence that monocytes can differentiate into DC in vivo has been provided by a study from Randolph et al.²⁷ The same group also demonstrated that a subset of human monocytes is able to differentiate into DC-like cells in vitro during transendothelial migration, particularly following a phagocytic stimulus such as ingestion of latex beads.^{28,29} Further studies are required to determine whether this pathway is the primary mechanism for differentiation of DC in vivo.

Peripheral blood DC

At least two human DC subsets exist in the peripheral blood (PBDC),^{30–32} collectively representing less than 1% of all mononuclear cells. PBDC express CD4 and high levels of MHC II molecules, but lack lineage markers such as CD3, CD14, CD16, CD19, CD20, and CD56. When isolated from blood, PBDC have an immature appearance and lack dendrites. Following appropriate *in vitro* tissue culture, they rapidly acquire dendritic processes and potent T-cell stimulatory capacity. The two PBDC populations differ in their expression of various cell surface markers (Table 8.1). One population expresses the myeloid markers CD11b, CD11c, CD13, CD33, and GM-CSFR α (CD116),

as well as the MHC-like molecules CD1b, c and d, but exhibits low expression of IL-3R α (CD123w). This population is referred to as ‘myeloid’ or CD11c⁺ PBDC. The second population is known as plasmacytoid DC (formerly also called plasmacytoid T cells or plasmacytoid monocytes due to their distinct plasmacytoid morphology).^{33,34} Plasmacytoid DC have very different cell surface molecules when compared with myeloid PBDC, expressing high levels of IL-3R α , low levels of GM-CSFR α , and low levels of the above myeloid markers. Plasmacytoid DC can also be distinguished by the expression of BDCA-2 (a novel C-type lectin) and BDCA-4 (neuropilin-1).³⁵

While it is generally accepted that CD11c⁺ PBDC are myeloid in origin, the lineage origin of plasmacytoid DC is less clear.^{10,36–39} Plasmacytoid DCs are functionally distinct from CD11c⁺ PBDC. They depend on IL3, whereas CD11c⁺ PBDC depend on GM-CSF for *in vitro* survival.^{37,40,41} The two PBDC populations differ also in their sensitivity to microbial stimuli. Lipopolysaccharide (LPS) is a potent stimulus for CD11c⁺ PBDC.⁴² In contrast, plasmacytoid DC are highly sensitive to certain viruses or unmethylated CpG DNA motifs and produce large amounts of IFN- α in response to these stimuli.^{43,44} These differences are due to distinct expression of receptors for microbial products known as Toll-like receptors (TLR). CD11c⁺ PBDC express the LPS-receptor TLR4 and plasmacytoid DC express TLR9, a receptor recognizing unmethylated CpG DNA, which is characteristic of bacteria.^{45,46} Plasmacytoid DC also appear to skew the T helper cell cytokine response differently to CD11c⁺ PBDC.^{47,48} However, this seems to depend on the maturational stimuli that they encounter,⁴⁹ demonstrating that both lineage and environmental instruction play roles in T helper cell regulation. A new tissue culture technique that allows the *in vitro* generation of plasmacytoid DC from blood CD34⁺ CD45RA[–] IL-3R α [–] cells^{14,36} is likely to facilitate the study of this rare DC type.

Langerhans cells and dermal DC

Epidermal DC, or Langerhans cells (LC), together with dermal DC, form an immune surveillance network in the skin. LC possess unique trilaminar cytoplasmic structures known as Birbeck granules and express langerin, a type II lectin that can bind mannose, a sugar that is rarely displayed as a terminal sugar residue on mammalian cell surfaces although it is ubiquitous on the surfaces of lower organisms. The induction of Birbeck granules is a consequence of the antigen-capture function of langerin.⁵⁰ Additionally, LC may be identified by their expression of CD 1a, MHC II and Fc-IgG receptors type II (CD32), Fc-IgE receptors type I, and C3bi receptor (CD11b). LC may be generated from CD34⁺ progenitors. Exposure of CD34⁺ progenitors to GM-CSF and TNF- α gives rise to a population of cells that possess Birbeck granules

and are CD1a⁺ and E-cadherin-positive.^{23,51} Langerhans cell-like cells have also been generated in vitro from monocytes^{52,53} or from blood CD11c⁺ PBDC⁵⁴ by culturing these cells with the cytokine combination of GM-CSF, IL-4, and transforming growth factor (TGF)- β .

Dermal DC may also be generated from CD34⁺ progenitors when cultured with GM-CSF and TNF- α via an alternative differentiation pathway involving CD1aCD14⁺ intermediates.⁵ These dermal DC possess factor XIIIa, lack Birbeck granules, and do not stain for Ecadherin. The functions of both LC and dermal DC can be modulated by a range of cytokines produced by keratinocytes.⁵⁵ Pathogens may also activate LC directly. Functional differences between LC and dermal DC remain to be clearly defined.

DC differentiation from multipotential thymic precursors

Although most studies examining the origins of DC indicate that they are of myeloid lineage, they may also arise from lymphoid-committed precursors. This has best been described in the mouse, where CD8 α ⁺ thymic DC appear to be derived from lymphoid-committed progenitors that lack myeloid potential.¹³ Although CD8 α ⁺ DC are also found in the spleen and lymph nodes, it is less clear whether these DC subsets (which are phenotypically similar to their thymic counterparts) are derived from lymphoid-committed precursors. Traver et al¹⁵ demonstrated that both CD8 α ⁺ and CD8 α DCs could arise from common lymphoid and myeloid progenitors in thymus and spleen.¹⁵ Thus, CD8 α expression may not reflect lineage derivation but more likely maturation or differentiation stage and perhaps functional commitment of the DC. Studies by Wu et al¹⁶ further clarified these findings by demonstrating that myeloid precursors give rise to both CD8 α and CD8 α ⁺ DC, whereas lymphoid precursors predominantly give rise to CD8 α ⁺ DC.¹⁶ Therefore, the hematopoietic precursor origin of DC may bias but not dictate the phenotype of the DC produced.

In the human, evidence for a lymphoid origin of DC relies predominantly on in vitro studies. Bone marrow CD34⁺ CD10⁺ Lin⁻ precursors with T-, B-, and NKcell potential, but lacking myeloid differentiation capacity, can generate DC after culture with IL-1 β , IL7, GM-CSF, SCF, and FL.¹² Putative lymphoid-derived DC may also be generated from CD34⁺ CD1a⁻ lymphoid-committed thymic precursors after culture with IL-7, TNF- α , SCF, and FL.^{17,18} Importantly, the myeloid growth factor GM-CSF was dispensable in these culture systems. Despite their apparent lymphoid commitment, these thymic precursors retained myeloid capacity, as they could give rise to monocytes when cultured with macrophage colony-stimulating factor (M-CSF). More recently, it has been shown that the thymus contains a DC precursor population with lymphoid and myelomonocytic potential.¹⁹ It was found that intrathymic DC are myeloid in origin, since they arise from CD34⁺ early thymic progenitors that display myelomonocytic differentiation potential. Furthermore, phenotypically and functionally equivalent myeloid precursors devoid of T-cell potential were shown to exist in vivo in the postnatal thymus. Although these studies seem to contradict each other, they demonstrate that DC precursors are capable of considerable plasticity. They also indicate that the differentiation pathways are not exclusive or irreversible. Thus, apparent commitment to 'myeloid' or 'lymphoid' pathways may be contingent on the context in which DC develop.

Cytokines that expand DC numbers in vivo

Several cytokines are known to expand DC numbers in vivo, including granulocyte colony-stimulating factor (G-CSF),^{56,57} GM-CSF,⁵⁸ FL,⁵⁹⁻⁶⁰ and a synthetic G-CSF-FL fusion protein called progenipoinetin (ProGP).⁶¹ FL stimulates the proliferation of stem and progenitor cells by binding to the FL-receptor (Flt3), which is a type III receptor tyrosine kinase member of the platelet-derived growth factor (PDGF) family. Although FL is expressed by many different cell types and in many tissues, its receptor Flt3 is restricted to hematopoietic progenitors, early B cells, and myeloid cells.⁶² Daily subcutaneous injections of recombinant human FL for 10 days in healthy volunteers resulted in a 40-fold increase in the numbers of circulating CD11c⁺ PBDC.⁶⁰ These DC were phenotypically immature, expressing low levels of CD80, CD83, and CD86 and intermediate levels of HLA-DR. Following in vitro culture, these markers were rapidly upregulated. While FL expands both CD11c⁺ PBDC and plasmacytoid DC, G-CSF only expands plasmacytoid DC.⁵⁷ A recent study in mice compared the effect of all of the above DC-expanding cytokines on DC generation in vivo.⁶¹ The study found not only that different cytokines expanded different DC subpopulations, but that DC populations that appeared to be identical at the phenotypic level functioned differently depending on the cytokines that were used to generate them. This suggests that the use of certain cytokines in vivo could be used to generate DC with distinct functions.

Cytokines inhibiting DC differentiation

The study of culture conditions leading to DC development from precursors has provided insight into cytokine environments that can interfere with DC differentiation. A number of inhibitory cytokines have been found to act during early phases of DC differentiation, including vascular endothelial growth factor (VEGF),⁶³ TGF- β ,⁶⁴ IL-10,⁶⁵⁻⁶⁷ IL-6,⁶⁸⁻⁶⁹ M-CSF,⁶⁹ and prostaglandin (PG)E₂.⁷⁰ Interestingly, tumor cells can

produce these factors. It therefore appears that tumors may be able to inhibit DC function, and deploy this as a mechanism for evading immune surveillance.

Maturation and functional development of DC

DC display extraordinary plasticity, transforming from one form to another in order to perform a variety of distinct and highly specialized functions. Immature DC are extremely efficient in the uptake and processing of antigen, but are poor inducers of T-cell proliferation. Upon maturation, DC develop characteristic cytoplasmic processes (dendrites), lose their capacity to take up antigens, and upregulate molecules for DC-T-cell interaction, such as costimulatory and MHC molecules (Figure 8.2). Furthermore, DC upregulate certain chemokine receptors, enabling them to migrate from peripheral tissues to lymph nodes, which is a prerequisite for interaction with T cells.¹ To control these transformations, complex regulation is required throughout the DC life cycle. Soluble and membrane-associated signals enable fine control of phenotype and function through maturation and migration and, finally, orchestrate immune responses.

Figure 8.2 Maturation and functional development of dendritic cells (DC). MHC, major histocompatibility complex; TCR, T-cell receptor.

Signals inducing DC maturation

The tissue environment plays a major role in the differentiation of DC and provides an important link between the innate and adaptive immune system. DC mature in response to four classes of stimuli found at sites of infection or inflammation: (1) pro-inflammatory mediators, (2) pathogen-derived signals, (3) T-cell-derived signals, and (4) mediators of cell stress and damage. These factors generally accumulate only under pathological conditions and are recognized by the DC as 'danger' signals.⁷¹

Pro-inflammatory mediators that induce DC maturation include prostaglandins and cytokines, such as $\text{IFN-}\alpha/\beta$, $\text{TNF-}\alpha$, and $\text{IL-1}\beta$. These factors can be released by monocytes⁷² and keratinocytes.⁷³ Microbes (bacteria, viruses, and parasites) and their products, such as LPS, double-stranded RNA, and bacterial DNA motifs, are recognized through TLR on DC.⁷⁴ Other potent DC stimuli are members of the TNF family, such as CD40 ligand (CD40L), which is present on activated T helper cells^{75–77} and mediates DC activation when T cells and DC engage in lymphoid tissues. CD40L is also present on other immune and tissue cells, so this mechanism is also likely to be important in peripheral tissues. Mediators released during cell stress and damage, such as nucleotides⁷⁸ and heat-shock proteins,⁷⁹ also have the potential to

activate DC. Stimulation by these various mediators alone or in combination results in qualitative and quantitative differences in DC maturation. This is reflected in differences in the levels of various DC surface molecules, T-cell stimulatory capacity, and cytokine production. As a result, the final immune outcome depends on the net composition of the stimuli experienced by the DC. This in turn reflects the context in which activation occurs.

Regulation of antigen uptake, processing, and presentation

Immature DC take up antigens very efficiently by macropinocytosis and receptor-mediated endocytosis using a variety of receptors such as integrins, C-type lectins and Fc receptors, which bind to immune complexes. Integrins such as $\alpha_v\beta_5$ also mediate the uptake of apoptotic cells.⁸⁰ Examples of C-type lectin receptors that are expressed by DC are the mannose macrophage receptor (MMR) and DEC205, which bind to molecules that have distinguishing carbohydrate structures (reviewed in reference 81). Following internalization, antigen is transported to the late endosomes and lysosomes of the endocytic system of the MHC II compartment. In immature DC, MHC II molecules are almost entirely located within intracellular endocytic vacuoles, colocalizing with lysosomal-associated membrane proteins. Under these conditions, internalized antigens are loaded onto MHC molecules. Upon maturation, antigen uptake is rapidly downregulated and MHC II molecules are redistributed to the cell surface over 12–24 hours for antigen presentation.⁸² In addition, MHC II levels are regulated by their rate of turnover. In immature DC, MHC II molecules are constantly degraded, whereas in mature DC, a lower rate of degradation results in a longer half-life and surface accumulation.^{82,83} These mechanisms contribute to the highly efficient presentation of antigen to CD4 T cells by mature DC (Figure 8.2). In addition to presentation on MHC II molecules, DC are also capable of stimulating CD8⁺ T-cell responses by presenting exogenous antigen on MHC I molecules, a phenomenon termed ‘cross-presentation’. Processing of antigen for the MHC I pathway involves an intracellular proteolytic enzyme complex known as the proteasome; however, the precise mechanisms regulating cross-presentation are not fully understood. For clinical vaccine purposes, targeting antigens to DC surface receptors, such as DEC205 or $\alpha_v\beta_5$ integrin, can enhance MHC I antigen processing, but productive T-cell immunity only occurs if an associated maturation stimulus is included in the strategy.^{80,84} The ability of DC to cross-prime naive T cells in order to induce the generation of tumor antigen-specific T cells provides the rationale for clinical vaccination trials using DC (see the final section of this chapter).

Regulation of migratory function

Both immature and mature DC are mobile cell populations, migrating to peripheral sites and lymphoid tissue respectively. DC homing is regulated by migration in response to chemokine gradients. It has been proposed that DC migration occurs in a stepwise fashion in which each distinct step is regulated by a particular chemokine-receptor pair.⁸⁵ For homing to peripheral inflammatory sites, immature DC migrate towards chemokines such as macrophage inflammatory protein (MIP)-1 α (CCL3), monocyte chemoattractant protein (MCP)-1 (CCL2), and RANTES (regulated upon activation normal T-cell expressed and secreted, CCL5). Upon maturation, DC upregulate chemokine receptors in order to then migrate to lymphoid tissue. Here, the homing chemokines include the CCR7-binding chemokines, 6CKine (CCL21) and MIP-3p (CCL19).^{85–87} Mature DC can express chemokine receptors for (and migrate towards) both of these chemokine classes. The trafficking outcome may therefore depend on which gradient is strongest at any given tissue location in which the DC resides.

T-cell activation by DC

The interaction between DC and T cells involves the binding of cell surface receptors and their ligands, which are responsible for (i) specificity, (ii) adhesion, and (iii) the regulation of T-cell proliferation through costimulatory and inhibitory signaling molecules. In addition, soluble mediators stimulate the proliferation and polarization of the T-cell response. The antigen, presented as MHC-peptide complexes, determines the specificity of the T-cell response. These are present on DC at densities 10- to 100-fold higher than on other antigen-presenting cells, such as B cells and monocytes.⁸⁸ Physical contact between DC and T cells is facilitated by adhesion molecules, such as integrins and members of the immunoglobulin superfamily (CD54 and CD58).¹ DC-SIGN is a C-type lectin abundantly expressed on DC that mediates adhesion to T cells and stabilizes DC-T-cell contact.^{89,90} Costimulatory molecules, such as CD86,^{91,92} amplify the T-cell response. This is potentially countered by regulatory inhibitors such as CTLA4 (reviewed in references 93 and 94). In addition to specificity signals provided through the MHC-peptide complexes and regulatory signals via the costimulatory factors, DC provide a ‘third signal’, which reflects information concerning the local environment. This signal polarizes the T helper (Th) repertoire toward a Th1 or Th2 response.⁹⁵ Th1 cell polarization is favored by several cytokines produced by DC, such as IL-12, IFN- α , IL-18, IL-23, and IL-27 (reviewed in reference 96). Additionally, the cytokine response by T cells may be determined by the activation stage of the DC, the dose of antigen, the strength of DC-T-cell interaction, the ratio of DC to T cells, and the type of DC (these are reviewed in reference 97).

DC and the induction of tolerance

In addition to stimulating immunity, DC also present antigens in order to maintain tolerance to 'self and suppress autoimmune responses. This process requires the silencing of self-reactive T cells. This probably takes place in two separate sites; in both, however, DC play the critical role.^{98–99} Central tolerance occurs in the thymus, where DC present self antigens to developing T cells with the specific purpose of deleting those that are self-reactive.¹⁰⁰ However, this mechanism has limitations: self-reactive T and B cells may escape deletion, some antigens may not access the thymus, and others may only be expressed in later life after the lymphocyte repertoire has been established. In addition, lymphocyte receptors specific for foreign antigens may also cross-react with self-antigens. As a result, a separate mechanism known as 'peripheral tolerance' appears to exist. Here, DC are able to silence self-reactive T cells in tissues, outside the thymus. The switch between maintaining tolerance and stimulating immunity appears to depend on the maturation state of the DC. Steinman and Nussenzweig⁹⁷ suggest that DC in the steady state (i.e. in the immature stage in the absence of danger signals) define immunological self and tolerize T cells. In contrast, activation and maturation of DC converts them into cells that stimulate immunity. This hypothesis is supported by investigations that used either immature or mature DC to vaccinate healthy volunteers against an influenza antigen. A single injection of peptide-pulsed mature DC rapidly expanded peptide-specific immunity.¹⁰¹ In contrast, the injection of immature peptide-pulsed DC resulted in inhibition of peptide-specific IFN- γ -secreting T cells and the appearance of peptide-specific IL-10-secreting T cells.¹⁰² IL-10 is a cytokine produced by 'regulatory' T cells, which are able to suppress the responses of other T cells.¹⁰³

Clinical perspectives

The ability of DC to rapidly induce T-cell immunity has been demonstrated in normal human volunteers and cancer patients. Several clinical trials using DC-based anticancer vaccine therapy have been published to date, some with promising results (reviewed in references 104 and 105). The study protocols for DC preparation and the choice of antigen and vaccination routes as well as schedules have varied considerably, making it difficult to compare different strategies. In most protocols, DC are expanded *in vivo* with growth factors or derived from cultured monocytes or CD34⁺ progenitor cells. DC are then pulsed with antigen in the form of peptides, proteins, tumor RNA, or tumor cell lysates, exposed to maturation-inducing stimuli, and subsequently injected into the patient's skin, blood, or lymph nodes. The production of such a DC vaccine is shown in Figure 8.3. The optimization of DC vaccination protocols will require a better understanding of DC biology. Several critical variables are currently under preclinical and clinical investigation, such as the identification of new tumor antigens, choice of DC type and antigen source, DC maturation stimuli, use of adjuvants, and routes of vaccine delivery, as well as the dose and timing of vaccinations. Strategies to manipulate DC function genetically in order to improve vaccine delivery and the subsequent induction of a powerful immune response are also being developed. In parallel approaches, DC are also being developed in strategies that seek to delete autoreactive T cells. Clinical trials for the treatment of autoimmune disease have not yet been reported. Considerable progress has been made in recent years in monitoring rare antigen-specific lymphocytes in the peripheral blood of cancer patients. Ongoing trials should be helpful in correlating immune with clinical responses and to identify subgroups of patients who

Figure 8.3 Production of a dendritic cell (DC) vaccine. PBDC, peripheral blood DC.

might benefit from such a treatment. Results from controlled clinical trials have to be awaited to assess the value of DC vaccination in the treatment of cancer, infectious disease, and autoimmunity.

Granulomonopoiesis

Willem E Fibbe and Rob E Ploemacher

Introduction

An appropriate inflammatory response requires the recruitment of large numbers of leukocytes to sites of injury or infection. These cells are produced in the bone marrow, which serves as the major hematopoietic organ during adult life. Mature myeloid blood cells have a relatively limited lifespan and are incapable of further cell division. Therefore, large numbers of cells have to be replaced each day. For instance, an adult human being must produce an average of about 120 million neutrophils per minute.¹ In steady state, the levels of mature cells in the blood are maintained within relatively narrow limits. In response to hematological stress such as occurs during infection, the numbers of circulating cells can increase significantly. These considerations indicate the requirement for a complex control system that regulates hematopoietic cell production. In this chapter, the function of granulocytes and mononuclear phagocytes as well as the regulation of their production will be discussed.

Monocytes, macrophages, and neutrophils provide the phagocytic defence against microbial invasion. Under most circumstances, neutrophils are more efficient phagocytic cells than monocytes and macrophages. But when the particle is large, or when the load of particles increases, mononuclear phagocytes are more effective. The antimicrobial capacity of macrophages is markedly enhanced upon activation by activating substances such as bacterial endotoxin. Activated cells may kill ingested microorganisms by generating toxic metabolites.

Granulocytes and mononuclear phagocytes

Both mononuclear phagocytes and neutrophils are able to phagocytose and kill bacteria in sites of infection. They exhibit chemotaxis (i.e. directed movements towards sites of infection) in response to various stimuli. This movement is influenced by chemotactic factors, which include complement (C5a) and substances derived from bacteria, cells, and connective tissue proteins. Chemokines form a novel class of small (92–99 amino acids) chemotactic cytokines that have the ability to activate leukocytes as mediators of inflammation.^{2–4} Two subfamilies are distinguished by the arrangement of the first two cysteines, resulting in the family of so-called C-X-C chemokines, in which either cysteine is separated by one amino acid, or the C-C chemokines, where they are adjacent. While the C-C chemokines, including monocyte chemoattractant (chemoattractant) proteins (MCP-1, -2, and 3) predominantly stimulate monocytes, the C-X-C chemokine family, consisting of interleukin-8 (IL-8) and a number of related molecules (e.g. macrophage inflammatory protein 1 α , MIP1 α), is mainly active on neutrophils. In response to the primary pro-inflammatory cytokines IL-1 and tumor necrosis factor α (TNF- α), fibroblasts, endothelial cells, epithelial cells, smooth muscle cells, and a variety of more specialized cells are able to produce monokines as well as IL-8. Under specific conditions, IL-8 can also be produced by neutrophils. Heparinbinding sites on chemokines provide a mechanism for their retention in the extracellular matrix and may serve to enhance concentration gradients.

Granulocytes

Polymorphonuclear neutrophils

Neutrophil production in the adult occurs exclusively in the bone marrow. The life cycle of the neutrophil comprises phases in the bone marrow, blood, and tissue differentiated cells that remain in the circulation sites. Polymorphonuclear neutrophils in the blood are for only 6–7 hours before migrating into the tissues. Neutrophils circulate at a lower limit of approximately 1800 cells/ μ l.⁵ During infection, these numbers may increase 10- to 30-fold within hours. These numbers illustrate the requirement for relatively large

storage compartments, enabling the rapid release of mature cells into the circulation. In addition to the large storage compartment in the bone marrow, a portion of the neutrophils in the blood are found in the marginating granulocyte pool comprising cells that adhere to the endothelial walls of post-capillary venules. There is a continuing exchange between these two compartments and the circulating blood granulocyte pool, until neutrophils migrate from the blood into the tissues.

Morphologically recognizable myeloid precursor cells are only found in the bone marrow under steady-state conditions. They include myeloblasts, promyelocytes, and myelocytes that are still capable of cell division and that comprise the *mitotic compartment*. The cells that mature in the bone marrow no longer have the capacity of cell division: these are the metamyelocytes, band forms, and mature neutrophils, which form the *maturation compartment*. Mature neutrophils remain for several days in the bone marrow and form the *storage compartment*. During infection, and also during treatment with granulocyte colony-stimulating factor (G-CSF), the marrow transit time can be significantly reduced, thereby allowing rapid increments in circulating neutrophil concentrations during infection. The mechanisms controlling the release of mature neutrophils from the marrow into the blood are not fully understood, but it is clear that bacterial endotoxins or proinflammatory cytokines such as IL-1 and TNF- α induced by endotoxins are able to induce rapid migration through endothelial cells. This involves a highly regulated process mediated by cell adhesion molecules.

Polymorphonuclear neutrophils play a crucial role in host defense against bacterial infections, their primary function being phagocytosis. Impaired neutrophil function or a reduction in their number are directly associated with an increased risk of infections, for example bacterial sepsis in newborn infants and chronic bacterial infections in older children and adults. The dysfunction may result from inborn errors (e.g. congenital neutrophilia) or from neutropenia induced by chemotherapy or following conditioning for stem cell transplantation. Both the duration and the severity of neutropenia will increase the likelihood of infections. In particular, severe neutropenia (i.e. a neutrophil count $< 500/\mu\text{l}$) is likely to be associated with the development of recurrent bacterial infections.

Eosinophilic and basophilic granulocytes

Neutrophilic, eosinophilic, and basophilic granulocytes follow similar patterns in their development in the bone marrow and their release into the blood. Using standard staining techniques, only the more mature stages can be distinguished morphologically. The association of eosinophilic granulocytes with some parasitic infections is well known. Their major function relates to hypersensitivity reactions and to host defence mechanisms against the larval states of parasitic infections. Basophils and tissue mast cells are capable of phagocytosis, but their major function may be associated with their high content of histamine, present in basophilic granules. Histamine is released from the granules in response to a variety of stimuli, including antigen exposure (IgE) in sensitized subjects,⁶ and also (a variety of) cytokines (e.g. IL-3 and granulocyte-macrophage colony-stimulating factor, GM-CSF).

Monocytes and macrophages

The mononuclear phagocyte system comprises monocytes, macrophages, and their precursor cells. The bone marrow is the major site of de novo mononuclear phagocyte production. Cells of the monocytemacrophage series and neutrophilic granulocytes are derived from a common progenitor cell, i.e. the colony-forming unit granulocyte-monocyte (CFUGM, see below). This progenitor cell matures into promonocytes and monocytes that are released into the blood. Monocytes remain in the blood for approximately 12 hours before they migrate into the tissues, to become tissue macrophages. Resident tissue macrophages do not re-enter the circulation; these include Kupffer cells in the liver, alveolar macrophages in the lung, dermal Langerhans cells, peritoneal and pleural macrophages, reticular dendritic cells in lymphatic tissues, and possibly osteoclasts and chondroclasts. The pool of resident macrophages is largely self-sustaining.

Function of mononuclear phagocytes

In addition to their function as phagocytic cells, mononuclear phagocytes are also essential for the development of cellular and humoral immune responses. The recognition of antigens by T lymphocytes is usually preceded by phagocytosis and processing of antigens by macrophages. Mononuclear phagocytes may thus act as antigen-presenting cells (APC). In particular, dendritic cells (which are phenotypically different from macrophages) act as professional antigen-presenting cells. These cells also secrete IL-1,⁷ which enhances T- and B-lymphocyte proliferation. Mononuclear phagocytes secrete a number of other soluble factors that promote the proliferation of other cell types. In addition to IL-1, macrophages are able to produce TNF- α as well as a number of myeloid colony-stimulating factors (i.e. G-CSF, GM-CSF, and macrophage colony-stimulating factor (M-CSF)).⁸ They also produce factors that inhibit hematopoiesis (e.g. interferon- α (IFN- α) and MIP-1 α).⁹

Mononuclear phagocytes may also exhibit antitumor activities. Activated macrophages may recognize

tumor cells in a non-antigen-dependent way. This cytotoxic activity requires cell-cell contact and a number of mediators, including nitric oxide (NO). Mononuclear phagocytes may also kill tumor cells through a mechanism termed antibody-dependent cellular cytotoxicity (ADCC), which involves the killing of antibody-coated tumor cells.

The hematopoietic precursor cells

Mononuclear phagocytes and granulocytes are derived from a common precursor cell, committed to differentiation into the granulocytic or mononuclear phagocytic lineage (CFU-GM). In contrast to true pluripotent stem cells, committed progenitor cells are restricted to differentiation into one or various lineages, and are limited in their capacity for self-renewal. Committed progenitor cells are recognized by the ability to form colonies of mature cells in semisolid culture media in vitro in the presence of designated hematopoietic growth factors. Therefore, hematopoietic committed progenitor cells are referred to as colony-forming cells (CFG) or colony-forming units (CFU). Different types of mature cells can be recognized in these colonies. For instance, myeloid progenitor cells (CFU-GM) are capable of differentiation into aggregates of mature granulocytes and/or monocytes/macrophages. Similarly, CFU-G, CFU-M, CFU-Eo refer to cells forming colonies of granulocytes, macrophages, or eosinophils respectively. The large majority of the myeloid bone marrow cells belongs to the heterogeneous population of postprogenitor cells, ranging from cells that still have some proliferative capacity to those becoming morphologically recognizable to mature, fully functional end cells.¹⁰

Hematopoietic growth factors

The formation and development of in vitro colonies by hematopoietic progenitor cells requires the presence of specific regulatory molecules. In early experiments, colony growth was dependent on the presence of feeder cell layers that could later be replaced by media conditioned by a variety of cell populations, including peripheral blood leukocytes, spleen cells, vascular endothelial cells, and lung and placental cells. These conditioned media were referred to as colony-stimulating activity and contained combinations of growth factors. Over the past decade or so, a large number of distinct human hematopoietic colony-stimulating factors and interleukins have been purified and their cDNA has been cloned. Cytokine receptors are found in many tissues, and specificity results mainly from local production of cytokines and specific localizations of target cells at the site of cytokine presentation. The major cytokine activities include enhancement of cell survival and proliferation, induction of cell differentiation, and functional activation of mature cells (Table 9.1). In this chapter, emphasis will be placed on growth factors regulating the production of granulocytes and macrophages (Table 9.2). These include the colony-stimulating factors (M-CSF, G-CSF, and GM-CSF), IL-3 and IL-5, stem cell factor (SCF), and Flk2/Flt3 ligand (Flk2/Flt3-L (Fms-like tyrosine kinase receptor)).

Table 9.1 General activities of hematopoietic: growth factors

- Enhancement of cell survival
- Enhancement of cell proliferation
- Induction of cellular differentiation
- Activation of mature effector cells

Table 9.2 The myeloid factors

Factor	Chromosome locus	Cellular source	Target cells
GM-CSF	5q23–31	Monocytes, fibroblasts, endothelial cells, T cells, mast cells	CFU-G, CFU-M, CFU-GM, CFU-GEMM, CFU-Mk, CFU-GE, BFU-E, neutrophils, eosinophils
G-CSF	17q11.2–21	Monocytes, fibroblasts, endothelial cells, mesothelial cells	CFU-G, neutrophils
M-CSF	1p13–21	Monocytes, fibroblasts, endothelial cells	CFU-M, mononuclear phagocytes
IL-3	5q23–31	T cells, mast cells, monocytes	CFU-G, CFU-M, CFU-GM, CFU-Eo, CFU-GEMM, CFU-Mk, CFU-GE, BFU-E
SCF	12q22–24 12q14.3–12qter	Stromal cells, endothelial cells, monocytes	Mast cells, CFU-E, BFU-E, CFU-Mk, CFU-GEMM
IL-5	5q23–31	T cells	Eosinophils, B cells

GM, granulocyte-macrophage; G, granulocyte; M, macrophage; GEMM, granulocyte-erythroid-macrophage-megakaryocyte; Mk, megakaryocyte; GE, granulocyte-erythroid; E, erythroid; Eo, eosinophil; CSF, colony-stimulating factor; IL, interleukin; SCF, stem cell factor (Steel factor, c-Kit ligand); CFU, colony-forming unit; BFU, burst-forming unit

Physiological role of myeloid growth factors

Inducible hematopoiesis

Hematopoietic growth factors play an important role in the body's response to trauma or infection by initiating its repair and defense mechanisms. The acute phase response to most infectious diseases is usually accompanied by increased numbers of peripheral blood neutrophils, in particular band forms. This neutrophilia is attributed to premature and accelerated release of mature neutrophils from the bone marrow reservoir. Under these circumstances, the production of hematopoietic growth factors is induced by endotoxin or by pro-inflammatory cytokines such as IL-1 and TNF- α . For example, IL-1 induces fibroblasts, endothelial cells, and marrow stromal cells to synthesize G-CSF, GM-CSF, M-CSF, IL-6, and TNF- α , as well as IL-1 itself.^{11–13} In vivo, a single injection of IL-1 itself induces a rapid neutrophilia within several hours,¹⁴ and in mice, administration of IL-1 accelerates myelopoiesis following cyclophosphamide-induced neutropenia.¹⁵ Furthermore, increased production of colony-stimulating factors induced by these pro-inflammatory cytokines may contribute to the leukocytosis observed during infection.

Steady-state hematopoiesis—growth factors act at a local level

Since hematopoietic cytokines exert their effect in a paracrine or autocrine fashion rather than acting as classical hormones, most factors (e.g. GM-CSF and IL3) are undetectable in the serum of healthy human subjects. SCF and Flk2/Flt3-L are produced constitutively. Through alternative splicing, M-CSF^{16,17} and Flk2/Flt3-L¹⁸ are expressed in a soluble form and in a biologically active transmembrane form on stromal cells. Healthy individuals have serum concentrations of M-CSF in the range of 2–7 ng/ml¹⁹ and soluble SCF concentrations of approximately 3 ng/ml.²⁰ The transmembrane form of SCF expressed on stromal cells may serve as a cell adhesion molecule that binds hematopoietic progenitor cells expressing C-Kit, the receptor for SCF.¹⁷ Soluble growth factors (e.g. GMCSF) can also be retained in the microenvironment and presented to hematopoietic stem cells through binding to glycosaminoglycans such as heparin sulfate in the extracellular matrix.²¹ G-CSF is found in serum at detectable concentrations in a minority of healthy persons. During neutropenia, however, there is a direct relationship between serum concentrations of G-CSF and the absolute neutrophil count.²² During chemotherapy-induced neutropenia, G-CSF levels may rise to concentrations that are close to the levels observed following therapeutic administration of GCSF. Following bone marrow recovery, levels decrease to baseline. A similar inverse correlation between GCSF levels and neutrophil counts has been reported for patients with aplastic anemia or cyclic neutropenia.²³ Such an inverse correlation is not observed for the other myeloid growth factors, with the exception of thrombopoietin. These data are consistent with GCSF being a physiological feedback regulator of neutrophil production. Finally, increased serum levels of Flk2/Flt3-L have been reported in patients with aplastic anemia, supporting a possible role in the development of primitive hematopoietic cells.²⁴

Growth factor-deficient animals

Much insight in the role of growth factors in regulating steady-state hematopoiesis has been derived from mice deficient for the gene encoding the growth factor or the growth factor receptor. In these experiments, targeting constructs are designed to eliminate exons of the gene of interest in embryonic stem cell clones undergoing homologous recombination. These mutations will result in the removal of one or several critical regions of the protein and lead to functional inactivation. Following injection of targeted clones into blastocysts, chimeric animals are generated that will transmit the mutant allele through the germline. Homozygous mutant animals are generated by mating of heterozygous mutants. GM-CSF-deficient mice exhibit completely normal peripheral blood hematocrits, platelet, and white blood cell counts, while differential counts reveal similarly normal proportions of lymphocytes, neutrophils, eosinophils, and monocytes.²⁵ The numbers of granulocyte-macrophage (CFU-GM) as well as multipotent (granulocyte-erythroid-macrophage-megakaryocyte: CFU-GEMM) progenitor cells in bone marrow and spleen are also normal. Mutant bone marrow cells can engraft lethally irradiated mice, although the rate of reconstitution is somewhat delayed in comparison with animals transplanted with bone marrow from normal littermates. The only abnormality observed in GMCSF-deficient mice is an accumulation of surfactant in the lungs reminiscent of human pulmonary alveolar proteinosis.²⁵ These data do not support the major role initially attributed to GM-CSF as a critical regulator of hematopoiesis.

Mice lacking the gene for G-CSF are viable, and fertile, and although they appear healthy, they have chronic neutropenia.²⁶ Blood neutrophil counts are in the range of 20–30% of wild-type mice. Similar defects have recently been reported in mice deficient for the G-CSF receptor (G-CSFR). Mature neutrophils are still present in G-CSF-deficient mice, indicating that other growth factors are able to support neutrophil production in vivo. G-CSF-deficient mice also have a markedly impaired ability to control infection with *Listeria monocytogenes*, with diminished neutrophil and delayed monocyte increases in the blood in response to infection. In the bone marrow, the numbers of early (myelocyte and promyelocyte) and late (metamyelocyte) neutrophil precursors are reduced. The frequency of total marrow progenitor cells

responsive to a variety of growth factor combinations is consistently reduced. This includes not only granulocytic precursor cells in the eosinophilic, megakaryocytic, and erythroid lineages, but also blast colony-forming cells. Following G-CSF administration, neutrophil levels in the blood return to normal and the bone marrows are morphologically indistinguishable from those of control mice. These data indicate that G-CSF is indispensable for maintenance of normal neutrophil production during steady-state hematopoiesis and also indicate an important role for G-CSF in inducible granulopoiesis during infections.

In humans, no defects in the G-CSF gene have been reported. However, mutations in the gene encoding the G-CSFR have been reported in patients with acute myeloid leukemia (AML) preceded by severe congenital neutropenia (Kostmann syndrome).²⁷ Kostmann syndrome comprises a heterogeneous group of disorders characterized by severe chronic neutropenia and recurrent bacterial infections. The bone marrow of affected patients shows an arrest of granulocytic maturation at the stage of promyelocytes or myelocytes. Patients with Kostmann syndrome are at an increased risk of developing AML. The in vitro response to G-CSF of myeloid progenitor cells is often reduced. Following administration of pharmacological doses of G-CSF, neutrophil counts increase in the majority of Kostmann syndrome patients. In some patients, a truncated G-CSFR lacking the C-terminal maturation domain has been observed as a result of a point mutation.²⁷ In addition, point mutations have also been found in patients with AML secondary to severe congenital neutropenia. In one of these patients, the mutation was already present during the neutropenic phase of the disease. However, mutations have not been found in all patients with congenital neutropenia, indicating that the disorder is heterogeneous in its pathogenesis. Collectively, these findings indicate that mutations in the genes encoding G-CSFR, or molecules involved in intracellular signaling, may induce a block in maturation that can be associated with the progression to AML. Recent evidence has implicated a possible role for thrombopoietin (TPO) in the regulation of myelopoiesis.²⁸ TPO-deficient mice exhibit a substantial reduction in the size of the bone marrow stem and progenitor cell pool of 60–80%. In spite of this, TPO-deficient mice display thrombocytopenia only and have normal numbers of circulating red blood cells and neutrophils. Mice that are deficient for both TPO and G-CSFR exhibit excessive neutropenia—far greater than that observed in either TPO-deficient or G-CSFR-deficient mice.²⁸ Not only do these data suggest that TPO plays a role in the regulation of myelopoiesis, but they also support the hypothesis that G-CSF may compensate for the deficiency in marrow stem and progenitor cells, by expansion of the pool of relatively mature myeloid progenitors, in particular the mature stages of granulopoiesis.²⁸ As an experiment of nature the M-CSF gene is deleted in the naturally occurring osteopetrotic (*op*) mice that lack functional osteoclasts.²⁹ This mutation was demonstrated to be due to an alteration in the *M-CSF* gene resulting in the introduction of a stop codon and the production of a truncated and biologically inactive protein.³⁰ In addition to osteopetrosis, these mice exhibit severe deficiencies in mononuclear phagocyte subpopulations, including blood monocytes and macrophages in serosal cavities and in the bone marrow.²⁹ They develop skeletal abnormalities, have low birthweight, and have a reduced life expectancy.^{29,31} Administration of M-CSF to new born *op/op* mice cures osteopetrosis and corrects the numbers of blood monocytes and macrophages in the bone marrow, but not the numbers of macrophages in the serosal cavity.³¹ These data support the crucial role of M-CSF in macrophage development and function.

Mutations at the *Steel* locus encoding SCF or in its receptor, which is the product of the dominant *White spotting (W)* locus, in the mouse, have also been described.^{32,33} These animals develop similar abnormalities in multiple organs, including marrow hypoplasia, reduced fertility, and diminished or even lack of skin pigmentation. The hematopoietic defects comprise macrocytic anemia, reduced production of granulocytes and megakaryocytes, and a severe deficiency in tissue mast cells. Mice carrying mutations at the *W* locus have a reduced number of multipotent stem cells, including CFU-GEMM, in the bone marrow that can be entirely corrected by transplantation of bone marrow from unaffected littermates. Mutations at the *Steel* locus result in a deficient microenvironment, which can be restored by transplanting marrow stromal cells. These observations led to the discovery of the human c-Kit tyrosine kinase receptor and its ligand SCF (also known as C Kit ligand, Steel factor, or mast cell growth factor). A related gene defect in men has been described that affects hair pigmentation (piebald trait).³⁴

Biological effects of hematopoietic growth factors in vitro

Enhancement of cell survival

The culture of hematopoietic progenitor cells in the absence of exogenously added growth factors and under conditions that exclude the endogenous production of growth factors by accessory cells results in rapid initiation of the process of programmed cell death (apoptosis).³⁵ Apoptotic cell death starts shortly after withdrawal of growth factors. It is associated with distinct morphological changes, including nuclear condensation and cleavage of nuclear DNA by endonucleases. This results in the formation of small pieces of DNA appearing as a characteristic ladder fragmentation pattern on gel electrophoresis. Not

only progenitor cells but also mature cells are subject to apoptosis.³⁶ Thus, apoptosis may account for the normal physiological destruction of neutrophils. Similarly, monocytes undergo apoptosis unless their survival is promoted by the action of IL-1, GM-CSF, or M-CSF.³⁷ The concentrations of these factors required for maintaining cell viability are usually considerably lower than those required for the proliferation and functional activation of cells.³⁸ Promotion of cell survival appears to occur at all stages of differentiation. Following clearance of infection, apoptosis may thus be a physiological mechanism to rapidly reduce the number of cells in a population that has been expanded by stimulatory cytokines.

Enhancement of cell proliferation

Proliferation of hematopoietic progenitor cells requires the continuous presence of hematopoietic growth factors. Induction of cycling is mediated by 'competence' factors (e.g. G-CSF, SCF, IL-6, Flt3-L, or IL-11) that support the transition from G₀ to the G₁ phase of the cell cycle. To enter S-G₂ phases of the cell cycle, the cell then needs 'progression' factors (e.g. GM-CSF, IL-3, or M-CSF). Upon exposure to higher concentrations of the factors, the cell cycle time of progenitor cells progressively decreases, thereby increasing the number of progeny cells generated.³⁹ Individual growth factors affect multiple hematopoietic lineages, and each lineage may be regulated by various hematopoietic growth factors. For instance, neutrophil production is stimulated by GM-CSF, G-CSF, SCF, IL-3, and IL-6. Even the relatively lineage-restricted factors such as G-CSF and M-CSF, which induce a selective proliferation for neutrophils or macrophage precursor cells respectively, stimulate other cell types at higher concentrations. At high concentrations, G-CSF also stimulates macrophage and granulocyte-macrophage progenitor cells, while M-CSF stimulates granulocyte-macrophage and granulocyte progenitor cells.⁴⁰

The response of progenitor cells to hematopoietic growth factors also depends on the stage of maturation of the responding cell. IL-3 and GM-CSF both initiate the proliferation of granulocyte-macrophage precursor cells. During maturation, however, the number of receptors for IL-3 decreases, whereas receptor numbers for GM-CSF are maintained.⁴¹ As a result, the proliferative response on GM-CSF is maintained while the IL-3 response decreases.

Another property of many hematopoietic growth factors is their synergistic interaction. The maximal production of eosinophils *in vitro* requires the combined presence of IL-3, GM-CSF, and IL-5.⁴² Synergy is particularly evident when early-acting cytokines such as IL-3, IL-6, or SCF are combined with factors affecting committed progenitor cells (i.e. GM-CSF, G-CSF, or M-CSF). Other interactions between growth factors are even more complex, since they may influence the differentiation lineage of the progeny cells. IL-4 represents an example of a cytokine that as a single factor has no colony-stimulating activity. However, it may profoundly affect colony formation in the presence of other hematopoietic growth factors. In both murine and human bone marrow cultures, addition of IL-4 enhances granulocyte colony formation in the presence of G-CSF⁴³ and erythroid colonies in the presence of erythropoietin (EPO). Inclusion of IL-4 in cultures stimulated with GM-CSF results in almost complete disappearance of macrophage colonies.⁴⁴ Thus, in the presence of G-CSF and GM-CSF, IL-4 will favor the formation of neutrophils over macrophages. In contrast, IL-6 will favor differentiation into macrophages over neutrophils.

Activation of mature effector cells

In addition to their proliferative effects, colony-stimulating factors stimulate the function of mature end cells. G-CSF promotes the survival of neutrophils, and also enhances their function by stimulating adhesion to endothelium and by enhancing the ability to respond to microorganisms with a respiratory burst.⁴⁵ G-CSF also enhances antibody-dependent cell killing,⁴⁶ IgA-mediated phagocytosis,⁴⁷ and generation of superoxide anions.⁴⁸

GM-CSF is also directly chemotactic for neutrophils⁴⁹ and inhibits cell migration.⁵⁰ GM-CSF primes neutrophils for oxidative bursts,⁵¹ enhances phagocytosis, and increases the expression of certain adhesion molecules.⁵² It also increases the capacity of neutrophils to phagocytose and to kill intracellular yeasts, parasites, and bacteria, in particular in antibody-dependent cell killing.

The action of hematopoietic growth factors on mature cells that circulate or that reside in tissues will enhance their ability to overcome infections and to promote tissue repair. The release of growth factors at local sites of infection attracts effector cells to the site of infection, and directly activates the cells for enhanced ingestion and killing of bacteria. The recruitment of other inflammatory cells to the site of infection will be promoted by the induction of other cytokines. Thus, the functional activation of granulocytes and other phagocytic cells is an important activity of hematopoietic growth factors in addition to their growth-promoting properties.

GM-CSF

GM-CSF is the product of T lymphocytes, macrophages, endothelial cells, fibroblasts, and a variety of neoplastic cells.⁵³ It acts as a growth factor on a number of cells belonging to hematopoietic as well as non-hematopoietic lineages.⁵⁴ GM-CSF is a multilineage colony-stimulating factor that promotes

the growth of progenitor cells belonging to the granulocyte, macrophage, eosinophil, and basophil lineages.⁵⁵ In enriched monocyte-depleted cultures of CD34+ cells, GM-CSF stimulates the colony formation development of eosinophil (CFU-Eo), erythroid (BFUE), and multipotent (CFU-GEMM) progenitor cells, but not the formation of granulocyte-macrophage (CFU-GM), granulocyte (CFU-G), or macrophage (CFU-M) colonies.⁵⁶ However, following the addition of monocytes, development of CFU-GM, CFU-G, and CFU-M is observed. Most likely, growth factor release from monocytes in response to GM-CSF is responsible for this effect.⁵⁷ Nevertheless, it is widely accepted that GM-CSF directly affects the growth of granulocytes and monocyte/macrophage progenitor cells.⁵⁸ In addition, GM-CSF has been reported to stimulate the growth of megakaryocytic colonies in vitro.⁵⁹ GM-CSF has a number of synergistic interactions with other growth factors. GM-CSF and G-CSF act synergistically on the growth of CFU-GM.⁶⁰ GM-CSF synergizes with M-CSF in the formation of CFU-M.⁵⁶⁻⁵⁸ It has some burst-promoting activity in the presence of EPO.⁶¹ In addition, GM-CSF and IL-3 increase the number of multipotent progenitor cells in the presence of EPO.⁶²

G-CSF

G-CSF is produced by a variety of normal and neoplastic cells. Mouse and human G-CSF exhibit more than 70% homology at a protein level and are highly cross-species reactive.⁶³⁻⁶⁴ G-CSF is a primary stimulator of the proliferation and differentiation of committed progenitor cells into the neutrophil-granulocytic lineage. It primarily acts as a lineage-restricted lateacting colony-stimulating factor for committed neutrophilic progenitor cells.⁶⁵ In addition, it is a potent activator of mature neutrophils, inducing enhanced phagocytosis and chemotaxis.^{66,67} Although G-CSF is relatively specific for cells belonging to the neutrophil lineage, at higher cell concentrations it has some effect on multipotent progenitor cells. In this way, it may induce resting stem cells to enter the cell cycle, rendering the cells responsive to the action of other growth factors.⁶⁸⁻⁷⁰ In addition to having a colonystimulating effect on late committed neutrophilic progenitors, G-CSF may thus be considered as a competence factor for primitive hematopoietic progenitor cells.

M-CSF

M-CSF is a lineage-specific factor for progenitor cells and mature cells belonging to the monocytemacrophage lineage.⁷¹ Similar to other growth factors, M-CSF has potent effects on the function of mature monocytes.⁷² It enhances the antibody-mediated antitumor cytotoxicity of monocytes. It is also believed to be a survival factor for these cells, explaining its presence in the serum of healthy subjects.⁷³ At higher cell concentrations, M-CSF stimulates other cell lineages and promotes the formation of neutrophil colonies. In addition to a soluble form of M-CSF, a membrane-bound biologically active form of this molecule has been reported.¹⁶ The soluble isoform may be important as a survival and developmental factor for monocytes and macrophages, whereas its glycosamoglycan chain may aid in the specific binding to extracellular matrix molecules.^{74,75} The cell-associated form may be involved in cell-cell interaction. The M-CSF receptor is identical to the product of the proto-oncogene *c-fms*. This receptor has also been detected in placental tissues and in human choriocarcinoma cell lines established from malignant placental trophoblasts.⁷⁶ These data suggest a possible role for M-CSF in placental development.

IL-3

IL-3 is primarily produced by activated T lymphocytes, but also by mast cells.⁷⁷ It stimulates the growth and differentiation of multiple lineages, including granulocytes, macrophages, megakaryocytes, erythrocytes, eosinophils, and mast cells. It is also a factor promoting the growth of relatively primitive stem cells. It synergizes with a number of other factors, including SCF, Flt3-L, GM-CSF, G-CSF, EPO, and IL-6 and IL-11, thus promoting the formation of granulocyte-macrophage, neutrophile, erythroid, and megakaryocyte colonies.⁷⁸⁻⁸⁰ As a single factor, it has relatively little activity and it does not fully support development into a single lineage. IL-3 is one of the factors that has independent stimulatory activity on the in vitro growth of megakaryocytic progenitor cells.⁵⁹ However, later-acting factors, such as IL-6 and TPO, are required for full maturation into megakaryocytes. IL-3 potentiates the functional activities of eosinophils, basophils, and monocytes, but not of neutrophils, since IL-3 receptors decrease in number along the neutrophilic maturation pathway and matured neutrophils have no receptors for IL-3.^{41,80} In conjunction with GM-CSF and the eosinophil-specific factor IL-5, IL-3 is involved in the regulation of eosinophils.⁸¹ Mast cells and P cells (persistent cells in long-term culture) both produce histamine and persist for a considerable time (months) in long-term cultures in the presence of IL-3 as a single factor.⁸²

SCF

SCF is the ligand for the receptor c-Kit encoded by the *c-kit* proto-oncogene. It is a highly pleiotropic cytokine with multiple activities on myeloid and lymphoid cells as well as on non-hematopoietic cells.⁸³⁻⁸⁵ It is expressed in a variety of organs, this expression being especially high in the cerebellum. SCF plays a role in the development and migration

of germ cells, neural crest cells, and mast cells, as well as hematopoietic cells, where it preferentially promotes the growth of relatively primitive progenitor cells.⁸⁶ By alternative splicing, SCF is produced as a membrane-bound form and as a soluble form. The importance of the membrane-bound form is clearly illustrated by the presence of hematopoietic defects in mice with a mutation in the *Steel* locus, resulting in the absence of the membrane-bound isoform of SCF but normal levels of the soluble form.¹⁷ As a soluble factor, it has limited activities on myeloid colony formation. However, it enhances the formation of myeloid and erythroid colonies when combined with other factors, such as GM-CSF, G-CSF, IL-3, and EPO.^{83–86} In synergy with IL-3 and GM-CSF, SCF stimulates the formation of megakaryocytes.⁸⁷ Primitive hematopoietic progenitor cells do not express detectable levels of c-Kit. This receptor is downregulated by cytokines such as IL-3 and GM-CSF⁸⁸—a phenomenon that may play a role in the release of stem cells from the bone marrow microenvironment.

Flt3-L

The identification of Flk2/Flt3-L was directly derived from the discovery of its receptor: Flk2 in mice⁸⁹ and Flt3⁹⁰ in humans. This receptor belongs to the immunoglobulin superfamily of tyrosine kinase receptors and is similar to the receptors for SCF, MCSF, and platelet-derived growth factor (PDGF) α and β . It has five extracellular immunoglobulin-like domains and split tyrosine kinase catalytic domains in its cytoplasmic region. In the mouse, Flt2 is reported to be expressed in a variety of different organs, including (fetal) liver, ovary, skin, thymus, spleen, lymph node, testis, kidney, and brain,⁹⁰ although others have found a more limited expression.^{89–91} The human receptor was found to be expressed in bone marrow, thymus, spleen, liver, and lymph nodes.⁹² Flt3 was found to be expressed on monocytes in bone marrow and blood, but not on granulocytes.⁹³ Primitive multilineage progenitor cells have been reported to express low levels of Flt3, while high levels have been found on myelomonocytic precursors.⁹³ Flt3-L is expressed in virtually all murine and human tissues studied. As a single factor, Flt3-L has a modest proliferative effect on c-Kit-positive mouse bone marrow cells and it synergizes with IL-3.⁹⁴ It had no activity on purified mouse stem cells, but colony formation is synergistically enhanced in combination with IL-3 or IL-6. Similarly, Flt3-L promotes the formation of secondary colonies of mouse Thy-1^{low}Sca-1⁺ stem cells in combination with G-CSF, SCF, IL-3, or IL-6. In combination with IL-6, it expands the numbers of CFU,⁹⁵ and combinations with G-CSF, IL-11, or IL-12 expand the numbers of cells with an immature blast cell appearance.⁹⁶ Flt3-L alone has relatively little activity on colony formation of high-proliferative-potential colony-forming cells of purified CD34⁺CD33⁻Lin⁻ cells derived from human fetal liver, but synergizes with IL-3 and GM-CSF.⁹⁴ In contrast to SCF and IL-3, Flt3-L has no effect on the growth or activation of mast cells. These data indicate a role for Flt3-L as a synergistic factor for primitive hematopoietic progenitor cells.

Role of adhesion molecules

Cell adhesion molecules have been identified as mediators of cellular and cell-matrix interactions in immune responses and tissue repair. More recently, they have also been implicated in the regulation of hematopoiesis, and are considered to play an important role in the proliferation and differentiation of progenitor cells. Studies in long-term bone marrow cultures have indicated that primitive progenitor cells are preferentially bound to the extracellular matrix in the stromal layer.⁹⁷

Two major families of adhesion molecules have been identified, namely selectins and integrins.⁹⁸ L-selectin is expressed on all circulating leukocytes except for a subpopulation of memory lymphocytes. P-selectin is stored in the Weibel-Palade bodies of endothelial cells and the granules of platelets. E-selectin is induced on vascular endothelial cells by cytokines such as IL-1 and TNF- α . All selectins recognize a sialylated carbohydrate determinant on their counterreceptors. Selectins mediate the attachment of circulating leukocytes to the vessel wall through labile adhesions that permit the leukocytes to roll in the direction of flow. Shedding of neutrophil Lselectin is rapidly induced by IL-8 and is associated with demargination of granulocytes from the endothelial vessel wall and subsequent tissue invasion.

Integrins are mediators of the cellular interactions between hematopoietic cells and stromal cells and components of the extracellular matrix in the bone marrow microenvironment. They also mediate the second step in leukocyte accumulation, which involves firm adhesion of the granulocyte to the vessel wall. Integrins are heterodimers composed of an α subunit non-covalently associated with a β subunit. Eight different β subunits and 14 different α subunits have been identified thus far. Several distinct α subunits can associate with only one β subunit. Based on the β subunits, several families can be distinguished within the family of integrins. The β_1 integrins are also called very late antigens (VLA) and consist of receptors for cell matrix components such as fibronectin, laminin, and collagen. VLA are expressed on a variety of cells, including hematopoietic cells. Human CD34⁺ progenitor cells have been found to express the integrin β_1 chain (CD29) as well as VLA4 α and VLA-5 α .⁹⁹

Expression of the $\beta 2$ integrins is mainly restricted to leukocytes, i.e. T and B lymphocytes, monocytes, and granulocytes. This group of integrins consists of three members: LFA-1 (leukocyte function antigen), CR3 (Mac-1), and P150,95. These members have distinct subunits (GD11a, b, and c respectively) but share a common β subunit (CD18). LFA-1 (CD11a/CD18)-mediated cell-cell interaction involves the binding of one of its three counter-receptors belonging to the immunoglobulin superfamily, called intracellular adhesion molecules 1, 2, and 3 (ICAM-1, -2, and -3). LFA-1 is expressed on all leukocytes. It is involved in functions such as T-cell-mediated killing and leukocyte adhesion to endothelial cells. LFA-1 is also expressed on the majority of hematopoietic progenitor cells. Altered cytoadhesion of CD34+ progenitor cells induced by (stimulatory) anti-CD34 antibodies is associated with activation of the $\beta 2$ -integrin pathway and can be inhibited by LFA-1 or ICAM-1 antibodies.¹⁰⁰ Very primitive hematopoietic progenitor cells seem to lack LFA-1 expression,¹⁰¹ suggesting that expression of LFA-1 on CD34+ cells identifies an intermediate stage in the differentiation of progenitor cells, and may therefore be used to characterize progenitor cell subsets. The differences between bone marrow-derived and peripheral blood-derived progenitor cells with respect to the expression levels of cytoadhesion molecules has not yet been fully studied, but the selective recruitment of specific types of leukocytes into various tissues has been suggested to result from the use of various combinations of selectins, leukocyte-activating factors, and integrins.

Erythropoiesis

Paul-Henri Roméo

Introduction

Erythropoiesis is the pathway that produces mature red blood cells from hematopoietic stem cells. This cellular process is characterized by a series of commitment and differentiation steps that restrict the proliferative capacity and differentiation potential of the cells as the erythroid-specific program of gene expression is established. Like the other hematopoietic lineages, erythropoiesis is regulated by the combined effects of growth factors that promote the survival, proliferation, or differentiation of hematopoietic progenitor cells and nuclear regulators, mostly transcription factors, that activate erythroid-specific genes. Presently, no single transcription factor has been shown to induce erythropoiesis from hematopoietic stem cells or even from early hematopoietic progenitors, and it is quite possible that the erythrocytic phenotype is controlled by a combination of cell-specific and widely expressed transcription factors that integrate the proliferation, survival, and differentiation signals driving the pluripotent hematopoietic stem cell towards mature red blood cells.

Among the different hematopoietic lineages, erythropoiesis is one of the best studied and might be considered as a major model system for hematopoietic differentiation for two main reasons. First, adult erythropoiesis is completely dependent on the presence of a growth factor, erythropoietin (EPO), owing to the tissue-specific expression of its receptor (EPO-R), and this EPO/EPO-R association is one of the best studied systems for signal transduction and regulation of a hematopoietic lineage. Second, the globin genes, which are exclusively expressed during erythropoiesis, represent a model system for gene activation during cellular differentiation. This chapter summarizes our present knowledge on erythropoiesis at the cellular level, including the function of the EPO/EPOR association and at the transcription level, with a focus on how study of the regulators of erythropoiesis addresses questions of hematopoietic lineage selection and commitment.

Adult erythropoiesis at the cellular level

During mammalian development, erythropoiesis takes place successively in the visceral yolk sac, the fetal liver, and the bone marrow. Many features of primitive erythropoiesis are completely different from the fetal and adult erythropoiesis, indicating at least two separate waves of erythroid cells, and the properties of primitive erythropoiesis will only be indicated here when differences might be of biological interest.

At the cellular level, committed erythroid progenitors are detected by the formation of erythroid colonies after *in vitro* culture in methylcellulose, and are called the burst-forming unit erythroid (BFU-E) and the colony-forming unit erythroid (CFU-E).^{1,2} BFU-E are the most immature hematopoietic cells already committed to the erythrocyte lineage. These cells represent 0.02% of bone marrow hematopoietic cells, and only 30% of BFU-E are cycling.³ CFU-E represent 0.2% of bone marrow hematopoietic cells, and most of them are cycling.⁴ There is a continuous cellular process from the earliest BFU-E to the latest CFU-E,^{1,2} but the growth factor requirement defines mainly these two cellular entities. CFU-E will differentiate into the first morphologically identified cell of the erythrocyte lineage, the proerythroblast; erythrocytic differentiation will then produce the basophilic erythroblast, the polychromatophilic erythroblast, and the acidophilic erythroblast, which is the last nucleated cell of the mammalian erythrocyte lineage. Enucleation of the acidophilic erythroblast occurs only during fetal and adult mammalian erythropoiesis, giving rise to reticulocytes and finally red blood cells (Figure 10.1). Some of the known human antigens used to characterize the different steps of erythropoiesis are shown in Figure 10.1. The early-expressed erythrocytic antigens (e.g. CD33) are also expressed by precursors of other hematopoietic lineages, while most of the late antigens are erythrocyte-specific.

Figure 10.1 Growth factor requirement and expression of different surface markers and growth factor receptor during erythrocytic differentiation. The primitive burst-forming units erythroid (BFU-E) are at present the most immature known hematopoietic cells already committed to the erythrocytic lineage. Interleukin-3 (IL-3), granulocytemacrophage colony-stimulating factor (GM-CSF), and stem cell factor (SCF), in addition to erythropoietin (EPO), for efficient differentiation of BFU-E. CD34, HLA-DR, and CD33 are present on BFU-E and are not detected on colony-forming units erythroid (CFU-E), and c-Kit and EPO-R have overlapping expression during erythropoiesis. Glycophorin A is just one of the final surface markers that is specific to red blood cells.

The formation of BFU-E in cell culture is regulated by EPO and other growth factors, including stem cell factor (SCF), interleukin-3 (IL-3), insulin-like growth factor I (IGF-I) and granulocyte-macrophage colony-stimulating factor (GM-CSF),⁵ while the formation of CFU-E is highly dependent on low concentrations of EPO alone.⁴ EPO is necessary for erythrocytic differentiation until the late basophilic erythroblast stage, and then the erythroid cells are no longer dependent on EPO for final maturation.⁶ Genetic analyses of mice with a null mutation in the genes encoding GM-CSF or IL-3^{7,8} have indicated that these factors are not crucial for erythropoiesis or that other factors can compensate for their function, while mice lacking SCF or its receptor c-Kit,⁹ or lacking EPO or EPO-R,¹⁰ exhibit a dramatic reduction of CFU-E progenitors or erythroid cells derived from CFU-E. Thus this chapter will mainly review the functions of the SCF/c-Kit and EPO/EPO-R associations in erythropoiesis.

Stem cell factor and its receptor

SCF (also called Steel factor, mast cell growth factor, and c-Kit ligand) is a pleiotropic growth factor. Studies of mice with mutations at the locus that encodes SCF, the *Steel* locus (*Sl*), have shown that SCF is absolutely required during adult hematopoiesis to maintain an adequate output of mature red cells and tissue mast cells.^{11,12} SCF is synthesized by bone marrow stromal cells as a transmembrane glycoprotein,¹³ which can be proteolytically processed by matrix metalloproteinase-9 (MMP-9) to produce a soluble factor that enables bone marrow-repopulating cells to translocate to a permissive niche favoring differentiation and reconstitution of the hematopoietic stem/progenitor cell pool.¹⁴ Membrane-anchored SCF (mSCF) not only is a precursor of the soluble form (sSCF) but also has its own biological activity, which is necessary in vivo as mice that produce only the soluble SCF isoform die from severe anemia.¹⁵

SCF interacts with a specific receptor, c-Kit, which is a growth factor receptor with ligand-dependent tyrosine kinase activity.¹⁶ Signaling mediated by cKit involves homodimerization of SCF-bound receptor, activation of the intrinsic receptor kinase, autophosphorylation, and association of the phosphorylated receptor with intracellular signaling molecules.^{17,18} Briefly, the phosphorylated c-Kit receptor binds the Grb2 protein, phospholipase C γ_1 (PLC γ_1), and the regulatory subunit (p85) of phosphatidylinositol 3'-kinase (PI3K).¹⁷⁻¹⁸ These bindings turn on four different intracellular pathways: (i) Raf1/MAPK, (ii) Src kinase, (iii) Akt kinase, and (iv) the Janus family of protein tyrosine kinases. The activation of these pathways ultimately results in cell proliferation, survival, and adhesion. Inactivation of the c-Kit pathway is mediated by association of the hematopoietic protein tyrosine phosphatase SHP-1 (also called HCP and PTPIC) with phosphorylated tyrosine of the SCF-activated c-Kit receptor¹⁹ and by a ligand-dependent ubiquitination followed by internalization of the c-Kit receptor.²⁰ This inactivation is modulated differentially, depending on the nature of the c-Kit ligand. In the case of sSCF, the tyrosine phosphorylation of c-Kit is rapid and is followed by a decrease in phosphorylation, while mSCF-induced c-Kit phosphorylation is more durable, likely due to prevention of c-Kit internalization and inactivation.^{21,22}

Erythropoietin and its receptor

EPO is a 34 kDa glycoprotein hormone secreted mainly by the kidney, where its synthesis is regulated, at the transcriptional level, by hypoxia.²³ This regulation of EPO production by hypoxia is controlled by a hypoxia-inducible transcription factor called HIF1 α .²⁴ EPO is not required for primitive erythropoiesis, but is the crucial growth factor for definitive erythropoiesis as *EPO-1*-mice generated committed BFU-E and CFU-E but died around embryonic day 13 from severe anemia due to the absence of erythrocytic terminal differentiation.¹⁰ EPO specifically interacts with a receptor (EPO-R) that is mainly expressed in cells of the erythrocyte lineage, making EPO highly specific for erythroid progenitors.²⁵

EPO-R is a member of the cytokine receptor superfamily, which are type I membrane-spanning glycoproteins with extracellular and cytoplasmic domains of varying sizes. The EPO-R extracellular domain consists of two fibronectin III-like subdomains (D1 and D2) separated by a hinge. In the D2 region, there is a conserved Trp-Ser-X-Trp-Ser motif, which has been shown to be important for EPO-R folding. The EPO-R cytoplasmic domain contains no intrinsic catalytic activity and contains two regions (Box 1 and Box 2) conserved in the membrane-proximal portion of several of these cytokine receptors and a negative regulatory domain present in its membrane-distal portion²⁶ (Figure 10.2).

Despite the lack of a catalytically active region in the cytoplasmic tail of EPO-R, binding of EPO induces rapid and transient phosphorylation of eight EPO-R cytoplasmic tyrosines.²⁷ These phosphorylations are mediated by a kinase, Janus kinase 2 (JAK2), whose activity is dependent on EPO stimulation.²⁸ Actually, JAK2 is bound to the region of EPO-R that contains Box 1 and Box 2 segments, but is inactive in the absence of EPO. Until recently, EPO was assumed to induce dimerization of EPO-R, but investigation of crystal structures has shown that EPO-R in the unliganded state exists as a dimer.^{29,30} In response to EPO, this dimer undergoes a dramatic conformational change,^{31,32} which is believed to be translated to the cytoplasmic domain, where it brings associated JAK2 into proximity and thus enables them to auto- or trans-phosphorylate each other (Figure 10.3). Phosphorylation of JAK2 dramatically activates its kinase activity and leads to tyrosine phosphorylation of eight EPO-R tyrosines as well as other substrates. This JAK2 pathway plays a pivotal role in the EPO-R signaling pathway, as kinase-deficient JAK2 protein or mutations in the Box 1/Box 2 region block signaling by EPO.³³ Among the other JAK2 substrates, a member of the STAT (signal transducers and activators of transcription) family, STAT5, is phosphorylated and then translocates, as a homo- or heterodimer, to the nucleus, where it can activate transcription³⁴ (Figure 10.3). More than 20 signal transduction factors are recruited and activated after EPO-R phosphorylation.³⁵ In addition to STAT5, they include Cis1, SHP-1 and -2, PI3K p85 subunit, PLC γ , Grb2, She, Cbl, Gab1 and 2, Vav, and mSOS.³⁵ Recruitment of these molecules to the EPO-R/JAK2 complex leads to the activation of several signaling cascades, including the Ras and the PI3K pathways.^{36–37} Inactivation of EPO-R signaling seems to occur by a direct interaction between EPO-R and the phosphatase SHP-1 via the phosphorylated tyrosine residue 429 (Figure 10.3). After binding to EPO-R, SHP-1 dephosphorylates JAK2 and thus terminates EPO-R signaling.³⁸ The role of SHP-1 in EPOR signaling is emphasized by the fact that mice with defects in the *motheaten* locus, encoding SHP-1, have CFU-E that are hypersensitive to EPO *in vitro*³⁹ and by the study of two families with dominant benign erythrocytosis. In these two families, a stop codon or a frameshift results in an EPO-R C-terminal truncation that completely suppresses the SHP-1-binding site,

Figure 10.2 Structure of the erythropoietin receptor (EPO-R). The extracellular domain of EPO-R contains one hematopoietin domain characterized by two fibronectin III-like subdomains (D1 and D2) linked by a hinge. The first subdomain contains four conserved cysteine residues linked two-by-two by disulfide bonds, while a second subdomain contains the WSXWS (Trp-Ser-X-Trp-Ser) sequence. This extracellular domain is linked to the intracellular domain by a single transmembrane domain. The intracellular domain consists of a proximal domain characterized by two conserved regions (Box 1 and Box 2), which are involved in JAK2 binding to EPO-R, and a distal domain that acts like a negative growth-regulatory domain.

Figure 10.3 Activation, signal transduction via the STAT pathway, and inactivation of EPO-R. In the absence of EPO, EPO-R is dimeric, but the two JAK2 which are associated with this EPO-R through the Box 1/Box 2 region are kept away (a). Binding of EPO to EPO-R induces a dramatic conformational change of EPO-R. This EPO-induced conformational change of the EPO-R extracellular domains is translated to the cytoplasmic domains, puts the two JAK2 into close proximity, and thus allows *trans*-phosphorylation of these two kinases (b, c). These phosphorylations increase JAK2 activity and lead to phosphorylation of numerous tyrosines in EPO-R as well as in other substrates, including STAT5 (d). Once STAT5 has been phosphorylated, it can form homo- or heterodimers, which are translocated to the nucleus, where they can activate transcription through binding to specific sequences known as cSis-inducible elements (SIE). Indeed, JAK2 activity also leads to phosphorylation and activation of proteins involved in other mitogenic pathways, such as the Ras and PI3K pathways, but for simplicity these pathways are not indicated in the figure. JAK2 also phosphorylates tyrosine 429 of EPO-R (e). This phosphotyrosine becomes a docking site for SHP1, a hematopoietic phosphatase that dephosphorylates JAK2 and thus terminates EPO-R signaling.

and erythroid progenitors from these individuals are also hypersensitive to EPO *in vitro*.^{40–41}

Synergy between EPO and SCF during adult erythropoiesis; role of the glucocorticoid receptor

During erythrocytic differentiation, c-Kit and EPO-R have an overlapping expression that is indeed biologically relevant. c-Kit is highly expressed at the BFU-E stage, after which its expression decreases until the CFU-E stage, where it is weakly detectable.⁴² Conversely, early BFU-E have very little EPO-R on their surface and are not responsive to EPO. Mature BFU-E express a low level of EPO-R and become responsive to EPO; EPO-R expression then increases until the CFU-E stage.⁴³ CFU-E express more than 1000 EPO-R on their surface, and EPO alone can sustain the terminal erythrocytic differentiation from the CFU-E stage.

These expression patterns are correlated with growth factor requirements during erythropoiesis. SCF is crucial for proliferation and/or differentiation of BFU-E progenitor cells to the CFU-E stage, since mice lacking SCF (*Sf* mutants) or c-Kit (*W* mutants) exhibit a normal number of BFU-E but a significant reduction of CFU-E progenitors. During the transition from BFU-E to CFU-E, there is a synergy between SCF and EPO, SCF increasing EPO sensitivity more than 100-fold and inducing EPO-R phosphorylation.⁴⁴ This synergy is mediated by a direct interaction between c-Kit and EPO-R through the EPO-R cytoplasmic region that contains Box 2, and might induce mitogenic and/or

differentiation signals that enhance the JAK2 pathway.⁴⁵ Thus, before but close to the CFU-E stage, the interaction between c-Kit and EPO-R may be important for triggering subsequent cell proliferation and/or differentiation. After the CFU-E stage, erythropoiesis becomes absolutely dependent on EPO for survival, proliferation, and/or terminal differentiation, since mice lacking EPO or EPO-R produce committed BFU-E and CFU-E progenitors but die from severe anemia as these CFU-E cannot proliferate and terminally differentiate.

Finally, glucocorticoids together with SCF and EPO contribute to stress erythropoiesis in hypoxic mice.⁴⁶ In humans, glucocorticoids cooperate with EPO and SCF to induce erythroid progenitors to undergo 15–22 cell divisions corresponding to a 5×10^5 -fold amplification of erythroid cells.⁴⁷ This glucocorticoid-dependent amplification may involve the maintenance of c-Kit expression, and is of the greatest interest for molecular and cellular studies of erythropoiesis.

Adult erythropoiesis at the transcriptional level

From the BFU-E stage to the erythrocyte, the expression pattern of erythroid-specific genes follows a precise timing that is mainly regulated at the transcriptional level. Studies of (i) the regulatory regions of terminally expressed erythroid-specific genes, (ii) the perturbations of erythropoiesis in pathologies such as leukemias, and (iii) the experimental animal models established by gene disruption have greatly increased our knowledge on the *cis*- and *trans*-acting elements involved in erythroid-restricted gene expression and have pinpointed erythroid-restricted and pleiotropic *trans*-acting factors specifically involved in erythrocytic differentiation.

Cis-acting sequences involved in the regulation of erythroid-specific genes

Functional analysis of erythroid-specific genes, such as the globin genes, the porphobilinogen deaminase gene, the glycophorin A and B genes, and the EPO-R receptor gene, have shown the importance of a sequence 5' A/T GATA A/G 3', now called the GATA motif, in the regulated expression of these genes.⁴⁸ This sequence is often associated with a GT or CACCl-like sequence, and the GATA/GT or CACC association is presently considered as a hallmark of an erythroid-specific regulatory region.⁴⁸ Another motif occurs in the core region of erythroid-expressed gene promoters, enhancers, or locus control region (LCR). This motif, 5' TGA C/G TCAGCA 3' is an AP1-like sequence that seems to be necessary for efficient erythroid-specific gene expression.⁴⁹ No other motif has been repeatedly found in regulatory regions of erythroid-specific genes, and, for example, the *cis*-acting elements involved in the timing of the expression of these genes during erythropoiesis are yet to be characterized. For each type of binding motif identified as recurrent in the regulatory regions of erythroid-specific genes, a nuclear factor has been identified and cloned. None of these nuclear factors, the nuclear factor(s) that recognizes the lineage-specific factors is restricted to a single cell type, showing that specificity of gene expression in erythropoiesis, as in the other hematopoietic lineages, is established by a specific combination of nuclear factors rather than by specific factors (Figure 10.4).

Trans-acting factors that are required for setting up erythropoiesis

In the mouse, targeted disruption of many different genes (including *Rb1* and *AML1*) results in death at the fetal stage from severe anemia.^{50–52} These mutant mice have a normal primitive erythropoiesis, indicating again that yolk sac (primitive) and fetal liver (definitive) erythropoiesis are regulated by two distinct

Figure 10.4 Regulation of the different stages of erythropoiesis by *trans*-acting factors. Nuclear factors that are necessary for the different steps of erythropoiesis are shown and the function of their target genes in erythropoiesis is indicated. Rb1n-2/LMO2 and TAL-1/SCL are also necessary for primitive erythropoiesis. The potential interregulation of GATA-1 and GATA-2 during terminal erythropoiesis is indicated.

genetic programs. Analysis of most of these geneknockout mice shows a block in the development of all of the definitive hematopoietic lineages, indicating that these gene products are not specifically involved in erythrocytic differentiation but in the proliferation and/or commitment of hematopoietic progenitors, including erythroid ones. However, these targeted disruptions have indicated the importance of two widely expressed genes, DNA ligase I⁵³ and DNase II,⁵⁴ for setting up erythropoiesis. DNA ligase I is central to DNA replication and repair, and a patient with altered DNA ligase I displayed growth retardation and immunodeficiency similar to Bloom's syndrome.⁵⁵ Mice lacking DNA ligase I died from anemia at the fetal liver stage, and analysis of the fetal liver hematopoietic cells of these mice indicated only a small decrease in the total number of BFU-E but very few erythrocytes.⁵³ Since the total number of non-erythroid hematopoietic cells in these *DNA ligase-1* mice is normal, this knockout pinpoints a major role of this widely expressed enzyme in erythropoiesis at a stage (BFU-E to CFU-E) where an extremely high replicative pressure is exerted on this differentiation (Figure 10.4). DNase II, a lysosomal DNase, degrades DNA of apoptotic cells. *DNase II*^{-/-} mice die in utero due to severe anemia. This defect is non-cell-autonomous, as mutant fetal liver cells transferred into lethally irradiated mice produce mature red blood cells, but is related to abnormal macrophage function in the destruction of the nuclear DNA expelled from erythroid precursor cells.⁵⁴ Two other nuclear factors, TAL-1/SCL and Rbtl2/LMO2 play a major role in setting up erythropoiesis. Both TAL-1/SCL and Rbtl2/LMO2 have been identified by the cloning of chromosomal translocation breakpoints associated with human T-cell acute lymphoblastic leukemia (T-ALL).⁵⁶⁻⁵⁷ The *TAL-1* gene encodes a basic helix-loop-helix (bHLH) transcription factor and the *rbtn2/LMO2* gene encodes a nuclear Lim-domain protein that does not display any sequence-specific DNA binding. During hematopoiesis, TAL-1 and LMO2 are mainly expressed in early hematopoietic progenitors, and then their expression is restricted to the erythrocyte, mastocyte, and megakaryocyte lineages, but not the T-cell lineage.⁵⁸ These two proteins are physically linked, as the in vivo immunoprecipitable LMO2 protein is complexed with TAL-1⁵⁹ and GATA-1 in erythrocytes, indicating that the TAL-1-LMO2 complex might be important for gene regulation during erythropoiesis. Indeed, while LMO2, TAL-1, and GATA1 alone have little effect on erythropoiesis in *Xenopus*, their ectopic coexpression in *Xenopus* embryos enlarges the ventral blood islands at the expense of dorsal mesoderm (muscle and notochord) embryogenesis,⁶⁰ and LMO2, TAL-1, and GATA-1 overexpression in activin-treated *Xenopus* pole explants further increases the production of hemoglobinized cells.⁶⁰

Mice lacking the Rbtl2/LMO2 or the TAL-1/SCL protein die in utero at day 8.5 with a severe anemia that is thought to be the cause of death.^{61,62} These in vivo data indicate that both TAL-1/SCL and Rbtl2/LMO2 are required for primitive erythropoiesis. In vitro differentiation of *tal-1*^{-/-} ES cells have shown an impaired hematopoiesis, and complementation of the lymphoid defect in RAG-2-deficient mice has shown that TAL-1 is also required for adult hematopoiesis.⁶³ Finally, conditional *tal-1* gene targeting has shown that TAL-1 is essential for the genesis of hematopoietic stem cells but is not essential for the hematopoietic stem cell functions.^{64,65} As for erythropoiesis, deletion of the *tal-1* gene results in the complete loss of early progenitors of this lineage, as BFU-E are absent from spleen and bone marrow of these *tal-1*^{-/-} mice.^{64,65} Thus, this TAL-1/LMO2 complex might activate target genes involved in proliferation and/or cell death (Figure 10.4), and the identification of these target genes is now an important challenge (Table 10.1).

Trans-acting factors involved in the expression of erythroid-specific genes

The first motif identified in the regulatory regions of erythroid-specific genes is the 5' A/T GATA A/G 3' or GATA motif. This sequence is recognized by a family of nuclear proteins called the GATA proteins, whose members are structurally defined by the presence of two highly conserved zinc fingers Cys-X₂-Cys-X₁₇-Cys-X₂-Cys, which display different but cooperative functions. The range of genes regulated by members of the GATA family extends well beyond hematopoietic cells, but only two members of this family, GATA1 and GATA-2, are expressed during erythropoiesis and play a major role in this hematopoietic lineage⁴⁸ (Figure 10.4).

GATA-1 expression is restricted to the erythrocyte, megakaryocyte, and mast cell lineages, and targeted disruption of the mouse *GATA-1* gene has shown that GATA-1 is a key regulator of erythrocytic differentiation. Indeed, GATA-1- embryonic stem (ES) cells contribute to every hematopoietic lineages except the erythrocyte lineage.⁶⁶ In vitro differentiation of these GATA-1- ES cells has shown that erythrocytic differentiation was blocked at the proerythroblast stage of development, where the cells die by apoptosis.⁶⁷ Interestingly, most of the presumptive GATA-1 target genes in erythroid cells (Table 10.1) are expressed at normal levels in GATA-1- proerythroblast and it is believed that transcription of these genes occur through the action of GATA-2, whose expression is 50-fold upregulated in the GATA-1- ES cells.⁶⁷ Thus, survival and terminal differentiation of proerythroblasts appear to be completely dependent on GATA-1. GATA-1 activity is highly regulated by FOG-1 (friend of GATA), a 998-amino-acid nuclear multitype zinc finger protein that interacts with GATA-1 and does not seem to bind to DNA.⁶⁸ *FOG-1*^{-/-} mice die in utero at day 10.5–11.5 with severe anemia due to an arrest

Table 10.1 *Trans*-acting factors involved in DNA-binding sites, potential target genes, the phenotypes of their genes inactivation, and the human pathologies associated with their genes mutations are indicated

Trans-acting factor	DNA-binding site	Target genes	Phenotype of gene inactivation	Human pathology
GATA-1	5'A/T GATAA/G3'	Glob in; enzymes of the heme biosynthetic pathway; <i>GATA-1</i> ; <i>EKLF</i> ; glycoporphins; <i>EPO-R</i>	Anemia and thrombocytopenia	Familial dyserythropoietic anemia Recessive X-linked thrombocytopenia Megakaryoblastic leukemia of Down syndrome

TAL-1/SCL	5'AA/C CAGATGG/T T3'	<i>c-kit</i>	No hematopoiesis	T-cell acute lymphoblastic leukemia (T-ALL)

in erythroid maturation that is similar to that observed in the GATA-1- mice, providing a genetic evidence that these two factors act in a common pathway.⁶⁹ Erythropoiesis required the GATA-1/FOG-1 interaction, as shown by severe familial X-linked dyserythropoietic anemia found in patients harboring a *GATA-1* missense mutation that impairs the GATA1/FOG-1 contact.⁷⁰

PU.1, a member of the Ets family of transcription factors, can interact directly with GATA-1 and repress GATA-1-mediated transcriptional activation.⁷¹ Ectopic expression of PU.1 in *Xenopus* embryos blocks erythropoiesis, and exogenous GATA-1 is able to relieve this blockage of erythroid differentiation, suggesting that erythroid commitment is regulated by the relative levels of these two transcription factors.⁷¹

GATA-2 expression occurs in all the myeloid lineages and in early hematopoietic progenitors, and the role of GATA-2 in erythropoiesis is presently difficult to define since mice lacking GATA-2 exhibit a severe hematopoietic defect where all hematopoietic lineages are affected as no expansion of early hematopoietic progenitors can occur.⁷² However, two recent observations have defined a possible role of GATA-2 in erythropoiesis. First, GATA-2 expression is detected in erythroid progenitors and decreases as GATA-1 expression increases during erythrocytic differentiation.⁷³ Second, forced expression of GATA-2 in chicken erythroid precursors promotes proliferation and blocks differentiation of these cells.⁷⁴ Thus GATA-2 might be essential for appropriate expansion of early erythroid progenitors (Figure 10.4) and one attractive hypothesis would be that, just like c-Kit and EPO-R, GATA-2 and GATA-1 have overlapping functions during erythropoiesis, GATA-2 regulating genes associated with the c-Kit signaling pathway (Table 10.1) and GATA-1 regulating genes associated with the EPO-R signaling pathway (Table 10.1).

The CACCC motif associated with the GATA motif is recognized by erythroid-specific and widely expressed nuclear factors, and the relative contributions of these transcription factors have been the subject of numerous studies. Members of the SP1 family are among the widely expressed nuclear factors that bind the CACCC motif, but targeted disruption of these genes does not impair erythropoiesis. The cloning of erythroid Kruppel-like factor (EKLF), an erythroid-specific CACCC-binding protein, has enlightened the role of this regulatory element.⁷⁵ EKLF binds with a very high affinity to the CACCC site found in the human adult β -globin gene promoter and activates this promoter. Mutation of this sequence is found in some patients with β -thalassemia and impairs EKLF binding and transactivation.⁷⁶ EKLF-binding sites are also found in the human β -globin LCR, and the transcriptional activity of HS3 is EKLF-dependent.⁷⁷ Mice lacking EKLF die at the fetal liver stage with a major thalassemia syndrome due to inefficient β -globin production.⁷⁸ Other erythroid-specific genes whose promoters or enhancers contain CACCC sites are expressed at normal level in these *EKLF*⁻¹ mice, suggesting that EKLF is required principally for the expression of the β -globin gene (Table 10.1). However, a role for EKLF in the coordination of erythroid cell proliferation and hemoglobinization has also been shown by studies on a genetically engineered *EKLF*⁻¹

hematopoietic cell line.⁷⁹ Despite this function, EKLF is very different from the GATA proteins, as it might only be required for activation of a few erythroid-specific genes that are of the greatest importance for the function of red blood cells (Figure 10.4).

Besides the GATA and CACCC motifs, a third motif recurs in the regulatory regions of erythroid-specific genes. This motif is an AP1-like sequence that is recognized by a nuclear factor designated NF-E2, which is a heterodimer with a hematopoietic-restricted subunit (p45) and a widely expressed subunit (p18) linked by a leucine zipper.^{80,81} Although studies in transgenic mice have indicated that globin gene expression requires the NF-E2 DNA-binding motif (Table 10.1), mice lacking p45 NF-E2 have normal erythropoiesis but die from a hemorrhagic diathesis caused by the absence of platelets.⁸² This result strongly indicates a redundancy at the level of the p45 subunit during erythropoiesis and does not provide any enlightenment regarding the role of NF-E2 in erythropoiesis.

Conclusions, unresolved questions, and perspectives

Regulation of the erythrocytic commitment

The commitment of multipotential hematopoietic progenitors to the erythrocytic pathway is likely to be mediated by a set of transcription factors that promotes erythrocytic differentiation and provides negative signals for differentiation towards the other hematopoietic lineages. These cross-antagonisms between lineage-specific transcription factors have been shown for GATA-1 and PU.1,⁷¹ C/EBP β and FOG-1,⁸³ and GATA-2 and PU.1.⁸⁴ They occur by direct interaction (GATA-1 and PU.1), by transcription regulation (C/EBP β and FOG-1), or by both direct interaction and transcription regulation (GATA-2 and PU.1). With regard to erythrocytic commitment in the adult, forced expression of GATA-1 in a murine multipotential cell line does not promote erythrocytic but rather megakaryocytic differentiation,⁸⁵ although forced expression can reprogram avian myelomonocytic cell lines towards eosinophils, thromboblats, and erythroblats at the expense of the myelomonocytic lineage.⁸⁶ As erythrocytes and megakaryocytes are derived from a common precursor, these experiments suggest that GATA-1 may play a major role in the determination of a pluripotent hematopoietic precursor towards the common precursor of these two lineages, differentiation towards the megakaryocyte or the erythrocyte lineage being regulated by other presently unknown factor(s) or, as recently suggested, by the intracellular level of GATA proteins.⁸⁶

Interplay between growth factors receptors and *trans*-acting factors

Among the genes required for appropriate erythrocytic differentiation and coding for proteins different from transcription factors, growth factors receptor genes such as *EPO-R* and *c-kit* are of major interest. The structure of these genes has been elucidated and potential GATA-, Myb-, Ets-, and SP1-binding sites have been found in their promoter regions.⁸⁷ While little is known about the transcriptional regulation of the *c-kit* gene,⁸⁸ GATA and SP.1 has been shown to bind specifically to the *EPO-R* promoter in vitro and to transactivate this promoter in vivo.⁸⁹ These results indicate how *EPO-R* gene transcription can be maintained during erythropoiesis, but the molecular mechanisms that activate *EPO-R* gene expression during the initial stages of erythropoiesis are presently unknown. On the other hand, the effect of the binding of EPO or SCF to EPO-R or c-Kit on lineage-specific transcription factors such as GATA-1, EKLF, and NFE2 is presently not explored and might illuminate the interplay between these receptors and major transcription factors.

Cell cycle, apoptosis, and erythroid-specific *trans*-acting factors

Terminal differentiation of erythroid cells is accompanied by a progressive loss of their proliferative capacity without apoptosis. One attractive hypothesis is that the combination of *trans*-acting factors involved in the regulation of erythroid-specific genes can also reduce cell proliferation without apoptosis. Again, GATA-1 appears to play a major role in erythroid survival and to be a cell cycle-linked factor, since differentiation of GATA-1- ES cells leads to premature apoptosis⁹⁰ and since ectopic expression of this factor in hematopoietic and non-hematopoietic cell lines can lead to alterations in the length of the different phases of the cell cycle.⁹¹ The subset of genes implicated in these phenomena and regulated by GATA-1 are presently unknown and represent a fruit-ful area for future study.

Megakaryocyte differentiation and regulation

William Vainchenker, Najet Debili, and Françoise Wendling

Introduction

Platelets are anucleate blood cells that play an important role in hemostasis by their adhesion to the endothelium and subendothelial matrix and by the release of the contents of their storage organelles following activation. Platelets are produced by the cytoplasmic fragmentation of their polyploid bone marrow precursors, the megakaryocytes. Understanding of megakaryocytopoiesis has been hampered by the rarity of megakaryocytes in the marrow (< 0.1%). The discovery in 1994 of the physiological regulator of platelet production, thrombopoietin (TPO), has been a major breakthrough in the understanding of the regulation of platelet production and megakaryocyte biology. Whereas, a few years ago, megakaryocytopoiesis was poorly understood, important progress has recently been made that now permits a better understanding of the normal differentiation as well as several pathologies of the megakaryocyte lineage.

In this chapter, we shall focus on the cellular aspects of megakaryocyte differentiation and its regulation by growth factors and particularly by TPO.

Megakaryocytic cells

The megakaryocyte/platelet lineage is one branch of hematopoiesis, deriving from the differentiation of multipotent hematopoietic stem cells. The megakaryocyte and erythroid lineages have many similarities in their differentiation pathways and in the regulation of their specific genes, and there is evidence for a bipotent progenitor common to the erythroid and megakaryocyte lineages.^{1,2}

Megakaryocytopoiesis has many features that distinguish it from all of the other hematopoietic lineages and other cellular differentiation pathways. It can be divided into four steps. In the early stages, megakaryocyte progenitors are capable of proliferation and give rise to *in vitro* megakaryocyte colonies. These cells undergo a variable number of mitoses (DNA duplication followed by cytokinesis) to differentiate further into transitional cells (promegakaryoblasts, PMKB), which begin to synthesize numerous platelet proteins and enter an endomitotic process (DNA duplication without cytokinesis). This process induces a parallel increase in both nuclear and cytoplasmic volumes and gives rise to a characteristic cell containing a single polylobulated typical nucleus with a 2^N ploidy. After an average of three DNA cycles of duplication (from zero to five or six), cytoplasmic maturation, which had already begun, accelerates and further increases the cytoplasmic volume of the cell. Thereafter, terminal cytoplasmic maturation occurs, leading to proplatelet formation and platelet production (Figure 11.1). Platelet production occurs through a highly regulated process of cytoplasmic fragmentation, each successive stage having increased platelet production, and depends on three parameters: the number of megakaryocytes, their sizes, and the efficiency of platelet release.

Megakaryocyte progenitor cells

Several clonal assays have been developed to investigate megakaryocyte progenitors, and these have usually been coupled with the use of differentiation markers for a precise identification of megakaryocyte colonies. *In vitro* techniques have shown that, similarly to other hematopoietic cell lineages, megakaryocyte progenitors are heterogeneous and represent a continuum of cells. They have been schematically divided into three main types: burst-forming units megakaryocyte (BFU-Mk), colony-forming units megakaryocyte (CFU-Mk), and low-density CFU-Mk (LD-CFU-Mk).

BFU-Mk

These progenitors produce colonies (in 12 days in mice and 21 days in humans), which are composed of more than 50 cells organized in subcolonies on the

Figure 11.1 The process of megakaryocyte differentiation. BFU-Mk, burst-forming unit megakaryocyte; CFU-Mk, colony-forming unit megakaryocyte; PMKB, promegakaryoblast; proMk, pro megakaryocyte; Mk, megakaryocyte; Gp, glycoprotein; PF4, platelet factor 4; vWF, von Willebrand factor.

same model as BFU erythroid (BFU-E)- derived colonies. BFU-Mk are considered to be very primitive megakaryocyte progenitors. However, megakaryocyte progenitors with even higher proliferative capacities (high-proliferative-potential colony forming cells megakaryocyte, HPP-CFC-Mk) have been found in fetal bone marrow.⁴

CFU-Mk

These progenitor cells differ from BFU-Mk in their lower proliferative capacities. They give rise to colonies composed of 3–50 cells in mice⁵ and 12 days in humans.⁶ Unlike BFU-Mk, which are in G₀/G₁ phase of the cell cycle, CFU-Mk have a high [³H] thymidine suicide rate and are destroyed by chemical agents such as 5-fluorouracil. BFU-Mk and CFU-Mk are also found in fetal tissues, especially in fetal and neonatal blood.

LD-CFU-Mk

These cells have been identified in the mouse as megakaryocyte progenitors with a density lower than 1.050 g/ml. They give rise within 2–3 days to colonies composed of a few megakaryocytes with a high ploidy.⁷ The developmental stage of this progenitor is extremely close to the transitional cell that has switched towards an endomitotic process.

The use of differentiation markers has allowed a more precise delineation of the megakaryocyte progenitors and transitional cell compartments.

Megakaryocyte precursor cells identified by stagespecific differentiation markers

Initial work used cytochemical markers such as acetylcholinesterase (AChE) in the mouse.⁸ Studies have shown the presence in mouse marrow of a compartment of small AChE-positive cells (SACHE) that differentiate into polyploid megakaryocytes in a few days.⁸ A very similar type of cells has been identified in normal human marrow using the platelet peroxidase marker, and has been called a promegakaryoblast (PMKB).⁹ Acute megakaryoblastic leukemia corresponds to the proliferation of a cell blocked at this stage of differentiation.

The use of immunological markers has allowed a better characterization of the early steps of megakaryocyte differentiation (Figure 11.1). The initial aspect of these studies involved distinguishing BFU-Mk from CFU-Mk by their immunological phenotype. These two megakaryocyte progenitors express the CD34 antigen, like almost all hematopoietic progenitor cells. In addition, the HLA-DR antigen is detected on CFU-Mk as well as on the majority of hematopoietic progenitors (CFU granulocyte-macrophage (CFUGM) and immature BFU-E).¹⁰ In contrast, there is a very low expression of HLA-DR on BFU-Mk. CD109 and CD133 are expressed on nearly all types of megakaryocyte progenitors.¹¹

Antibodies directed against platelet glycoproteins for example GpIb/IIIa ($\alpha_2\beta_3$ integrin, CD41) GpIb, and different α -granule components such as von Willebrand factor (vWF) and platelet factor 4 (PF4) have been used to monitor megakaryocyte differentiation.^{12–13} These studies have indicated that most platelet proteins are expressed by small megakaryocyte precursor cells and all along the differentiation pathway. Among these markers, platelet GpIb/IIIa seems to be expressed slightly earlier than the others (GpIb, PF4, and vWF). These results have been confirmed more recently by flow cytometry. GpV, a component of the GpIb complex, might be expressed even later than the other markers.¹⁴ However, with the exception of β_1 -tubulin, there is no marker allowing the identification of only post-endomitotic cells. The expression of all the main platelet proteins within a short range of differentiation is probably related to the fact that all these genes have very similar promoters that bind the same transcription factors (see later in

this chapter). It has also been shown that immature megakaryocytes express CD4,^{15,16} which may be relevant for the mechanisms of thrombocytopenia in HIV infection.

Platelet GpIIb/IIIa is expressed at a high level on late megakaryocyte progenitor cells (equivalent in humans to LD-CFU-MK) and on a fraction of true CFU-Mk.¹⁷ It is also detected at a low level on all myeloid hematopoietic progenitor cells, including CPU granulocyte-erythroid-macrophage-megakaryocyte (CFU-GEMM), and also on lymphoid progenitors in humans, mice, and chickens.^{18–20} In humans, GpIIb/IIIa seems to be more widely expressed on cord blood progenitor cells than in adults.²¹

GpIb (CD42) is considered to be a late marker of megakaryocytic differentiation. However, it is also detected on some late megakaryocyte progenitors and on erythroid progenitor cells.^{17,21,22}

Thus, most platelet-restricted glycoproteins, especially GpIIb/IIIa, which is not entirely specific, allow the direct identification of late megakaryocyte progenitors and $2N$ cells that are entering endomitosis.

The endomitotic compartment

Endomitosis is the cellular process that leads to polyploidization and transforms a small megakaryocyte precursor cell into a giant cell, the megakaryocyte. It was considered until recently that megakaryocyte polyploidization was part of megakaryocyte maturation. In fact, there is increasing evidence that polyploidization and megakaryocyte cytoplasmic maturation leading to platelet shedding are two independently regulated processes, since platelet shedding may occur in a $2N$ cell. During this process, the megakaryocyte increases its ploidy and can stop its DNA duplication at any stage between $2N$ and $64N$, and eventually at $128N$. In humans, as well as in the majority of mammals, the modal ploidy is $16N$ (about 50% of megakaryocytes).

The process leading to megakaryocyte polyploidization was initially called endomitosis because it was believed that it was a mitosis occurring without rupture of the nuclear membrane.²³ Description of the endomitotic process has been extremely difficult due to the scarcity of megakaryocytes in the marrow and to the low frequency of megakaryocytes undergoing endomitosis. Initial ultrastructural studies described the endomitotic process and showed that the first steps of endomitosis are identical to mitosis, with chromosome condensation and the presence of a metaphase, suggesting a blockage in the metaphase/anaphase transition.^{24,25} More recent studies performed on TPO-stimulated cultures have demonstrated that endomitosis of human and murine megakaryocytes correspond to an abortive mitotic process.^{26,27} Mitosis normally occurs until anaphase, with chromosome condensation and a single multipolar spindle with nuclear membrane breakdown. The first stage of anaphase (anaphase A), characterized by sister chromatid separation, is also observed. However, late stages of anaphase B, consisting of spindle elongation and chromosome movement to the spindle, are not observed. Mitosis ends with the absence of cytokinesis after chromosome decondensation and the formation of a membrane around a single nuclear mass.²⁸ Thus, megakaryocyte endomitosis is an incomplete multipolar mitosis characterized by skipping of late mitotic stages.

The molecular mechanisms that control the switch from a mitotic to an endomitotic process are presently unknown. The cell cycle of endomitotic megakaryocytes has now been studied in detail, and is characterized by a very high expression of cyclin D3.²⁹ Transgenic mice overexpressing cyclin D3 have megakaryocytes with higher ploidy than wild-type mice.³⁰ No evident abnormalities in cell cycle checkpoints have been found, in particular at the metaphase/anaphase transition, although chromosome segregation to each spindle may be asymmetrical.²⁸ Recent results suggest that the absence of an aurora kinase (AIM1) during the cell cycle may be a key event in the switch from mitosis to endomitosis.³¹ At the end of the endomitotic process, megakaryocytes express extremely high levels of p21 and p27, which are members of the Cip/Kip family of cyclin-dependent kinase inhibitors (CKI).³² p21 and p27 may block the cell cycle and arrest the endomitotic process, permitting synchronization of the end of DNA replication and megakaryocyte terminal differentiation.

Although not directly demonstrated, the major aim of polyploidization is to increase megakaryocyte size and to control platelet production—not by the number of megakaryocytes but by their total mass. Polyploidization consequently induces gene amplification and may thus facilitate parallel increases in cell size and gene expression. In addition, it has been hypothesized that polyploidization contributes to gene regulation during megakaryocyte maturation. There has been much controversy regarding changes in platelet size and function related to increase in megakaryocyte ploidy. In particular, it has been suggested that platelets derived from high-ploidy megakaryocytes are larger and more easily activated.

Polyploidization is regulated by growth factors, especially TPO. An increase in megakaryocyte ploidy is one of the first events occurring after induction of acute severe thrombocytopenia in mice: as early as 24 hours, the modal ploidy increases from $16N$ to $32N$. These changes are maximal at 48 hours and return to normal values within 120 hours.

During human ontogenesis, megakaryocytes increase their ploidy, with the majority of fetal and neonatal megakaryocytes being $2N$ or $4N$ in culture.³³

The compartment of cytoplasmic maturation

Following endomitosis, megakaryocyte cytoplasmic maturation accelerates. The synthesis of specific organelles (demarcation membranes and a granules), which began early during megakaryocyte differentiation, increases markedly in post-endomitotic megakaryocytes. Demarcation membranes, an intracytoplasmic membrane system, are invaginations of the surface cell membrane and act as a reservoir of membranes that plays a major role in proplatelet formation.^{34,35}

The α granules store the main platelet proteins that are released after platelet activation. They are distinguished at the ultrastructural level by the presence of a dense central core giving the appearance of a 'bull's eye'. Synthesis of most α -granule components arise from the Golgi apparatus, such as vWF, PF4, β -thromboglobulin (β -TG), platelet-derived growth factor (PDGF), transforming growth factor β 1 (TGF- β 1), basic fibroblast growth factor (bFGF), thrombospondin (TSP), P-selectin (CD62P/GMP 140), osteonectin, clusterin, and serglycin. Other proteins, such as fibrinogen, albumin, and immunoglobulins, are packaged in α granules after endocytosis through clathrin vesicles arising from the cytoplasmic membrane.^{36,37} This explains why the main platelet glycoproteins such as GPIIb/IIIa, GpIb, and CD36 are present in a granules. Fibrinogen, one of the main protein of the α granules, is not synthesized by megakaryocytes, but is endocytosed after binding to activated GpIIb/IIIa.³⁷⁻³⁹ This process occurs late during megakaryocyte maturation.⁴⁰ Inside the α granules, there is a protein compartmentalization, some proteins being localized at the inner face of the α -granule membrane and others in the matrix.⁴¹⁻⁴³

Proteins packaged in the α granules are involved in platelet aggregation, regulation of fibroblast and endothelial cell proliferation, and regulation of extracellular matrix protein synthesis. Indeed, important cytokines such as TGF- β 1, PDGF, and vascular endothelial growth factor (VEGF), and chemokines such as PF4, are packaged in the α granules and are released either by megakaryocytes in the marrow or by activated platelets. Abnormal release of these mediators in the marrow environment leads to myelofibrosis.

In addition to α granules, other types of granules are present in megakaryocytes, including dense bodies (which contain serotonin, calcium ions, and nucleotides), microperoxisomes, and lysosomal granules. At the ultrastructural level, dense bodies are detected at late stages of megakaryocyte differentiation.⁴⁴ However, the serotonin uptake, which occurs by an active mechanism involving specific receptors, begins in small megakaryocyte precursor cells.⁴⁵

Platelet shedding

At the end of maturation, mature megakaryocytes are large spherical cells of about 50 μ m diameter. The large nucleus is polylobulated. The organelles are located in a zone concentric with the nucleus. In contrast, the zone around the plasma membrane is devoid of organelles. In order to shed platelets, profound morphological changes have to occur. The mechanisms of platelet shedding are beginning to be well understood at both the ultrastructural and the molecular level.^{34,35,46-48} In contrast to what had been believed for many years, demarcation membranes do not delineate platelet territories, but membranes are evaginated to form long proplatelet extensions. Proplatelet formation leads to pseudopods—which are completely different from cytoplasmic blebs in that they contain all platelet organelles. The cytoskeleton plays an important role in these morphological changes, especially the microtubules. Microtubules are absolutely required for evagination of demarcation membranes.^{34,49,50} Proplatelets contain a peripheral bundle of microtubules formed from β_1 -tubulin.⁵¹ This tubulin subtype is synthesized at the end of megakaryocyte maturation and is responsible for both proplatelet formation and the definitive discoid shape of platelets.^{51,52} The actin filament also plays an important role in permitting the growth and extension of proplatelets by creating branching on the pseudopods.^{53,54} The mechanism of platelet release is still a subject of debate. In the opinion of some, it may occur by breaking off of the long proplatelet extensions at the level of the constrictions, this rupture possibly being due to the mechanical effect of blood flow pressure.^{50,55} Platelets are first released into the blood with a longitudinal orientation of the microtubules⁵⁵ and are elongated; thereafter, platelets in the circulation acquire their definitive shape. An alternative view is that platelets are formed directly at the end of the proplatelet extensions. Indeed, microtubule coils that are similar to those observed in blood platelets are detected only at the ends of the proplatelet extensions as 'teardrops'.⁵³

In normal individuals, platelet shedding occurs not in the marrow but directly in the circulation. In the marrow, megakaryocytes are located in the subendothelial region,⁵⁶ in close contact with endothelial cells, which may be involved in megakaryocyte terminal differentiation.⁵⁷ Proplatelets may pass through the endothelial barrier and enter the circulation. Alternatively, entire mature megakaryocytes can also migrate through this blood barrier and are detected in the circulation. Several authors have pointed out that megakaryocytes are present in significant numbers in the small vessels of the lung and are trapped in the pulmonary capillary beds, where they release platelets.⁵⁸ Thus, the exit of megakaryocytes from the marrow is an important phenomenon regulating platelet production. Regulation of megakaryocyte migration is still poorly understood; it may be controlled by receptors of the extracellular matrix and chemokines.

After platelet shedding, the megakaryocyte (the nucleus surrounded by the remains of the cytoplasm) becomes senescent and dies by apoptosis.⁵⁹ The nucleus is engulfed by macrophages.⁶⁰ It has been suggested that megakaryocyte fragmentation has many similarities with apoptosis. In favor of this hypothesis is the observation that mice overexpressing the anti-apoptotic Bcl-2 protein or deficient for the apoptotic *bim* gene develop thrombocytopenia with a normal number of megakaryocytes.^{61,62}

Regulation of megakaryocytopoiesis by transcription factors

Analysis of expression patterns of cis-regulatory elements important in the regulation of megakaryocyte-specific genes, gene targeting experiments in embryonic stem (ES) cells, and creation of mutant mice have established the essential involvement of a number of transcription factors in megakaryocytopoiesis.⁶³ These include SCL/TAL-1, c-Myb, the Ets family member Fli-1, GATA-1, GATA-2, FOG, NF-E2, MafG, MafF, and some *Hox* genes.⁶⁴ In addition, studies of megakaryocyte-specific gene promoters such as GpIIb, GpIb α , GpIb β , GpIX, GpV, c-Mpl, and GpVI have shown the existence of binding sites for GATA-1 and members of the Ets family.^{65–67} Disruption of these binding sites markedly diminishes the activity of these promoters. Targeted disruption of these transcription factor genes has shown that three of them—FOG, GATA-1, and Fli-1—are involved in the early stages of megakaryocyte differentiation, including the expression of megakaryocyte-specific genes and polyploidization. In contrast, NF-E2 and its partners (MafG and MafF) play a crucial role in the expression of genes involved in proplatelet formation and platelet activation (Figure 11.1).

Mice with a disruption of *GATA-1* die in utero from anemia.⁶⁸ Orkin and co-workers have characterized sites in the *GATA-1* promoter permitting its megakaryocyte-specific expression.⁶⁹ Mice with a megakaryocyte-specific disruption of *GATA-1* have an increased number of megakaryocytes, with a severely impaired cytoplasmic maturation in hematopoietic tissues and a profound thrombocytopenia with structurally and functionally abnormal giant platelets.⁶⁹ GATA-1-deficient megakaryocytes fail to undergo complete maturation, remain small and immature, and contain markedly reduced levels of all megakaryocyte-specific mRNA.⁷⁰ Their small size might be due to their low ploidy. In addition, these small cells have an increased proliferative capacity, which has been related to downregulation of inositol polyphosphate 4-phosphatase type I.⁷¹ This indicates that GATA-1 is indispensable to the promotion of megakaryocyte maturation. The *FOG* gene has been isolated as a partner of *GATA-1*.⁷² Targeted disruption of the *FOG* gene in mice results in the same phenotype for the erythroid lineage as *GATA-1* gene disruption, with embryonic lethality during mid-gestation due to severe anemia. However, the phenotype of *FOG*- and *GATA-1*-null mice is quite different for the megakaryocyte lineage. FOG-deficient mice have a total absence of megakaryocyte development, including the absence of megakaryocyte progenitor cells. This indicates that FOG is required for the earliest stage of megakaryocyte development and may be associated with a partner other than GATA-1 at these stages of differentiation.⁷³

Recent studies have also demonstrated a role of Fli-1 in megakaryocytopoiesis. Target-disruption of the *Fli1* gene results in an embryonically lethal phenotype with hemorrhage due to disorganization of tissue integrity and disruption of normal hematopoiesis and hemostasis.^{74,75} In addition, the megakaryocyte lineage displays important abnormalities similar to those described in GATA-1-deficient mice, with the presence of small immature megakaryocytes.⁷⁴ Among the platelet-specific genes, expression of *GpIb* and *c-mpl* are markedly reduced.

The p45^{NF-E2} transcription factor was thought to play a crucial role in the regulation of erythroid gene expression such as that of β -globin.^{76,77} Unexpectedly, p45^{NFE2}-deficient mice present a profound and lethal thrombocytopenia without any erythroid differentiation defect.⁴⁷ This thrombocytopenia is due to a marked dysmegakaryocytopoiesis characterized by an increased number of megakaryocytes associated with an abnormal demarcation membrane distribution and a deficiency in granules. No proplatelet formation is observed.⁴⁸ To explain this phenotype, it has been suggested (i) that the absence of erythroid phenotype in p45^{NF-E2}-deficient mice might be due to the presence of a transcription factor redundant with p45^{NF-E2} in erythroblasts, and (ii) that p45^{NF-E2} regulates as-yet uncharacterized genes in megakaryocytes. By comparing gene expression in normal and p45^{NF-E2}-deficient megakaryocytes it has been shown that p45^{NF-E2} regulates a set of genes involved in cytoskeletal organization and platelet functions.^{52,78} Among them, the β_1 -tubulin gene seems to be the most important because it is expressed only at the end of megakaryocyte maturation in a lineage-specific manner, and its gene disruption leads to thrombocytopenia with non-discoid platelets.^{51,52}

p45^{NF-E2} is one of two components of the NF-E2 transcription factor and belongs to a subset of bZip proteins termed cap'n collar (CNC). It associates with small Maf proteins to form the heterodimeric NF-E2 protein. In erythroblasts, its predominant partner is the p18/MafK polypeptide,⁷⁹ whereas in megakaryocytes, it associates predominantly with MafG and MafF.⁸⁰ Recent

experiments have shown that MafG-deficient mutant mice have moderate thrombocytopenia with a similar but milder defect in megakaryopoiesis as p45^{NF-E2}-deficient mice.⁸¹ MafG- and MafK-deficient mice have the same phenotype as p45^{NF-E2}-deficient mice.⁸²

Regulation of megakaryocytopoiesis by growth factors

Although many growth factors act at either early or late stages of megakaryocyte differentiation (Figure 11.2), regulation of megakaryocytopoiesis is dominated by the role of TPO, which is presently the only growth factor involved in homeostatic platelet production.

Thrombopoietin, a ligand for the Mpl receptor

A factor, called thrombopoietin, able to correct abnormalities of platelet count in a regulated manner and present in plasma from thrombocytopenic rodents and humans, was described in 1958.⁸³ However, this factor remained elusive for 35 years, despite many attempts to obtain a purified fraction. During the late 1980s, a mutant acutely leukemogenic murine retrovirus (MPLV, for MyeloProliferative Leukemia Virus) was fortuitously isolated from a mouse infected with a Friend helper virus (F-MuLV).⁸⁴ This virus isolate had a unique ability to confer growth factor independence and immortalization on progenitor cells from several hematopoietic lineages. Molecular cloning and sequencing demonstrated that the transforming properties of MPLV were related to the presence of a truncated cellular sequence (the viral oncogene *vmp1*) inserted in the rearranged envelope region of the retro virus.⁸⁵ Subsequently, the human and murine proto-oncogene *c-mpl* was cloned, providing definitive evidence that the product of the *c-mpl* gene, Mpl, was an orphan type I transmembrane receptor characterized by conserved cysteine residues and a common amino-acid motif (WSXWS) in the extracellular domain and lack of intrinsic tyrosine kinase activity in the intracellular domain.^{86,87} Major insights into the physiological role of Mpl arose from several observations. It was demonstrated that its expression was restricted to hematopoietic tissues, progenitor cells included in the CD34+ cell fraction, megakaryocytes, and platelets, *c-mpl* antisense oligodeoxynucleotides selectively inhibited CFU-Mk colony formation in vitro without affecting the growth of erythroid or myeloid colonies.⁸⁸ Disruption of the *c-mpl* gene in mice resulted in a highly specific loss of megakaryocytes and platelets, leaving other cell lineages unaffected.⁸⁹ Together, these results strongly suggested that Mpl and its ligand had key functions in the regulation of megakaryocytopoiesis and platelet production. The *c-mpl* gene and its encoded proteins is summarized in reference 90.

A ligand capable of binding and activating Mpl was purified in 1994 by five independent groups. Two groups used Mpl-affinity columns to capture the ligand in plasma from thrombocytopenic pigs and dogs. Degenerate oligonucleotides were designed from the N-terminal sequence of the protein and used to screen a human fetal liver cDNA library.^{91,92} One group mutagenized a factor-dependent murine cell line expressing Mpl to select mutants for autonomous growth. Among these mutants, one clone produced an activity that could be neutralized by a soluble Mpl form. Breakdown cDNA library pools were prepared and expressed in mammalian cells. A positive clone was identified, from which a full-length cDNA encoding the murine Mpl ligand was isolated.⁹³ The other two groups directly isolated a thrombocytopoietic factor from the plasma of thrombocytopenic animals using

Figure 11.2 Regulation of megakaryocyte differentiation by growth factors. TPO, thrombopoietin; IL, interleukin; GM-CSF, granulocyte-macrophage colonystimulating factor; SCF, stem cell factor; LIF, leukemia inhibitory factor; OSM, oncostatin M; EPO, erythropoietin. For other abbreviations, see the caption to Figure 11.1.

standard purification methods.^{94–95} All of these proteins were identical but received different names: Mpl ligand (ML or Mpl-L), or thrombopoietin (TPO), or megakaryocyte growth and development factor (MGDF), or megapoietin. Evidence was rapidly provided that the recombinant molecule had the property to sustain both complete megakaryocytopoiesis and thrombocytopoiesis in vitro and in vivo (reviewed in reference 96).

The human native protein is a 68–85 kDa glycosylated polypeptide comprising 332 amino acids. The molecule can be structurally and functionally divided into two domains: an N-terminal domain of 153 amino acids that shares considerable sequence similarity with erythropoietin (EPO) (the EPO-like domain) and a C-terminal domain that contains all of the potential glycosylation sites. The EPO-like domain is sufficient to fully activate Mpl and to induce the full spectrum of biological responses in vitro and in vivo. The C-terminal domain is required for efficient secretion. Glycosylation increases the stability and potency of the protein in vivo. TPO is mainly produced in the liver and kidneys, but transcripts are also detected in several other organs, including stromal cells from the bone marrow. TPO levels in plasma are inversely correlated with platelet number;⁹⁷ however, production of TPO is not regulated by platelet demand or by platelet mass, since no transcriptional regulation of the gene is detected in livers or kidneys from thrombocytopenic or thrombocythemic animals.^{98,99} Nevertheless, transcriptional regulation in response to platelet demand has been reported in bone marrow stromal cells.^{100,101} The current model for TPO regulation is a constitutive synthesis and a clearance from the circulation by sequestration through binding to Mpl receptors present on the surfaces of both platelets and megakaryocytes, followed by internalization and degradation.^{102,103} The contribution of both platelet and megakaryocyte masses to TPO clearance is best demonstrated in murine knockout models. In *c-mpl* deficient mice, which have low platelet numbers and high levels of TPO in the plasma, platelet transfusions from normal donors rapidly decrease plasma TPO levels. In *NF-E2*-knockout mice, which are profoundly thrombocytopenic because megakaryocytes are unable to produce platelets, the predicted elevation of TPO levels is not observed. However, these mice have normal number of megakaryocytes.^{47,104} Similarly, high TPO levels are found in thrombocytopenic patients with aplastic anemia,¹⁰⁵ while TPO levels are normal or only mildly elevated in patients with immune thrombocytopenic purpura (ITP).

The potent and lineage-dominant action of the Mpl/TPO system on the regulation of megakaryocytopoiesis and platelet production is clearly demonstrated by the generation of *c-mpl*- and TPO-knockout mice.^{89,106} An identical phenotype is seen in homozygous animals, with a 90% reduction in platelet counts, very low numbers of megakaryocytes with a reduced ploidy in marrow and spleen, but no abnormalities in nucleated cell counts or hematocrit. However, these mice display a 50% reduction in the numbers of all myeloid-committed progenitors,^{107,108} and bone marrow stem cells from *c-mpl*-deficient mice have a significantly reduced self-renewal potential.¹⁰⁹ These murine knockout models highlight the essential physiological role of the Mpl/TPO system in the regulation of megakaryocytopoiesis and platelet production, and clearly indicate that interactions of TPO with Mpl are required to maintain and/or expand early and committed progenitor cells. In vitro, TPO alone has a potent and lineage-specific action on late megakaryocyte progenitor cells, inducing proliferation, ploidization, maturation, and proplatelet formation.^{110–113} Several studies have provided evidences that TPO acts in synergy with early-acting cytokines (stem cell factor, interleukin-3, and Flt3 ligand) to sustain the survival and stimulate the proliferation of primitive hematopoietic progenitors by speeding entry of quiescent stem cells into the cell cycle.^{114–123} Thus, TPO is not only a lineage-specific cytokine, but also an important cytokine acting on a broad spectrum of primitive stem cells.

Interaction of TPO with Mpl leads to rapid stimulation of multiple intracellular signaling events, including tyrosine phosphorylation and activation of Jak2 (Janus tyrosine kinase 2), Tyk2, STAT1 (signal transducer and activator of transcription 1), STAT3, and STAT5.^{124–126} Jak2 and Tyk2 are non-receptor tyrosine kinases that, upon activation, phosphorylate their major target proteins, the STATs. Tyrosine phosphorylation of STATs leads to their translocation from the cytoplasm to the nucleus where they bind to specific DNA motifs and function as transcriptional activators.^{127,128} In platelets, megakaryocytes, and the megakaryoblastic UT-7 cell line, other intracellular targets of Mpl activation have been found. They include Shc, Grb2, MAPK, JNK, Raf-1, Cbl, Vav, protein kinase C (PKC), phosphatidylinositol 3'-kinase (PI3K), and the phosphatases SHPTP-1 and SHPTP2.^{129–136} Using mutant receptors containing deletions within the intracytoplasmic domain, it has been shown that the C-terminal 25 amino-acid residues of Mpl are crucial for mitogenic signals,¹³⁷ while activation of the MAPK and Ras pathways seem to be involved in megakaryocytic differentiation and polyploidization, especially under conditions of stress.^{138,139}

Other hematopoietic growth factors

Interleukin-3 and granulocyte-macrophage colony-stimulating factor

The use of recombinant hematopoietic growth factors has revealed that at least two pleiotropic

cytokines acting on early stages of hematopoiesis, interleukin-3 (IL-3) and granulocyte-macrophage colony-stimulating factor (GM-CSF), induce megakaryocyte colony formation. Indeed IL-3 was also initially named Mk-CSF.¹⁴⁰ Both cytokines act on CFU-Mk and BFU-Mk.¹⁰ IL-3 is the most effective cytokine on megakaryocyte progenitors after TPO and is capable as a single agent of inducing megakaryocyte colony formation on isolated megakaryocyte progenitors. GM-CSF and IL-3 have additive effects at non-optimal doses. An IL-3/GMCSF fusion protein (PIXY321) has more effects on *in vitro* megakaryocytopoiesis than each cytokine used alone, suggesting a true synergy between GM-CSF and IL-3.¹⁴¹ In primates, injection of IL-3 leads to an enhancement of platelet production, whereas GMCSF does not result in a significant platelet response.¹⁴² Neither GM-CSF nor IL-3 plays a role in the hemostatic regulation of platelet production.¹⁴³

Members of the interleukin-6 family

IL-6, leukemia inhibitory factor, (LIF), IL-11, oncostatin M (OSM), and ciliary neurotropic factor (CNTF) have pleiotropic effects on numerous cell types. The redundancy of these cytokines is now explained by the molecular biology of their receptors. All utilize a common signal transducing chain (GP130).¹⁴⁴

IL-6 was the first cytokine of this family to be demonstrated to act on megakaryocytopoiesis. This cytokine induces an enhancement of (i) megakaryocyte size, (ii) ploidy, (iii) cytoplasmic maturation, including synthesis of platelet proteins, and (iv) number.¹⁴⁵ More recently, it has been shown that IL-6 also induces proplatelet formation by isolated megakaryocytes.¹⁴⁶ Injection of IL-6 *in vivo* increases platelet production to a greater degree than injection of IL-3 by acting both on CFU-Mk and eventually megakaryocyte numbers, size, and ploidy.^{147,148} A synergistic effect between IL-3 and IL-6 on platelet production is also found *in vivo* in non-human primates. As a consequence, several authors hypothesized that TPO and IL-6 were the same molecule, slowing research on the identification of TPO.¹⁴⁹

LIF, OSM, and IL-11 have effects very similar to IL-6 on megakaryocytopoiesis.^{150–152} IL-11 is considered to be the most potent molecule of this family with regard to platelet production.¹⁵² Injection of IL-11 in mice results in a 1.25-fold increase in platelet counts, mainly due to an increase in 32N megakaryocytes. Although the number of CFU-Mk is increased in the spleen, the effects of IL-11 on platelet counts are not abrogated by splenectomy. IL-11 is used in humans to enhance platelet recovery.¹⁵³ These different cytokines do not play a significant role in homeostatic platelet production,¹⁵⁴ but are important as mediators of inflammation. They may be responsible for the thrombocytosis observed in inflammatory diseases.

Stem cell factor

Stem cell factor (SCF; also known as Steel factor and c-Kit ligand) is one of the most potent cytokines, with Flt3 ligand (Flt3-L) acting as a synergistic factor with all hematopoietic growth factors, with the exception of macrophage colony-stimulating factor (M-CSF). Its effect predominates on the erythroid lineage as a costimulator with EPO and on the early stages of hematopoiesis. SCF also plays an important physiological role in megakaryocytopoiesis.^{155,156} *In vitro* studies, SCF greatly potentiates the effects of IL-3, GM-CSF, IL-6, and TPO on the growth of megakaryocyte progenitors, increasing both cloning efficiency and the size of colonies.^{157–159} In the mouse, SCF injection increases the numbers of both CFU-Mk and platelets, especially in immunodeficient mice. SCF in association with TPO plays an important role in the normal regulation of megakaryocytopoiesis.

Erythropoietin

In mice and humans EPO seems unable by itself to induce megakaryocyte colony formation. However, EPO acts as a costimulator at high concentration and is able to favor terminal differentiation.¹⁶⁰ This effect is also observed on individual transitional cells.¹⁶¹ Like IL-6, EPO induces proplatelet formation by purified murine megakaryocytes.¹⁴⁶ *In vivo*, EPO does not appear to be a major regulator of platelet production, but may increase platelet functions. However, EPO injection can increase platelet counts in some human pathologies in the absence of iron deficiency.

Stromal cell-derived factor 1

Stromal cell-derived factor (SDF-1) is a chemokine having for its only receptor CXCR4, a seven transmembrane receptor coupled to G proteins. SDF-1 plays an important role in the migration and homing of hematopoietic stem cells. It is involved in the retention of hematopoietic cells in the marrow. CXCR4 is expressed all along the megakaryocyte differentiation pathway until platelets, and its expression increases with maturation.^{162–164} Surprisingly, the response to SDF-1 decreases with maturation, suggesting that CXCR4 signaling is inhibited at the end of megakaryocytopoiesis.^{163,165,166} For this reason, it has been suggested, but not demonstrated, that the loss of SDF-1 signaling in mature megakaryocytes may be involved in the regulation of megakaryocyte exit from the bone marrow. In addition, there is increasing evidence that SDF-1 has a synergistic effect with TPO on megakaryocyte survival, proliferation, polyploidization, and maturation.^{167–169}

Other hematopoietic growth factors

Several other characterized cytokines may also act *in vivo* or *in vitro* on megakaryocytopoiesis. Among the

most studied cytokines are IL-1 α and IL-1 β . These two cytokines have marked effects on megakaryocytopoiesis, but most (if not all) of these effects seem to be indirect, by the induction of numerous other cytokines, such as IL-6, GM-CSF, and SCF. IL-1 has been injected into both animals and humans, resulting in an increase in platelet production. However, and as a consequence of its broad effects, IL-1 has major toxic effects, which reduce its interest as a therapeutic agent.¹⁷⁰

Granulocyte colony-stimulating factor (G-CSF) also has a synergistic effect with IL-3 on the growth of megakaryocyte progenitors, which has been interpreted as a consequence of its proliferative activity on primitive cells. However, it has been shown that platelets are able to bind G-CSF and to respond functionally to this cytokine.¹⁷¹ In vivo injection of G-CSF has no effect on platelet recovery in humans.

IL-10, a potent immunoregulatory factor, promotes the growth of pure and mixed megakaryocyte colonies in association with IL-3 from Thy^{low} Sca⁺ murine primitive cells.¹⁷² In contrast, IL-10 induced thrombocytopenia in therapeutic trials.¹⁷³

Non-hematopoietic growth factors

Basic fibroblast growth factor (bFGF) is a nonhematopoietic growth factor acting on megakaryocytopoiesis, probably by both direct and indirect effects. In humans, the megakaryocyte-stimulating activity of bFGF is totally blocked by antibodies against GM-CSF, IL-3, or IL-6.^{174,175} It is noteworthy that megakaryocytes synthesize bFGF and express its receptor.¹⁷⁶ It seems that the effects of bFGF are related to an augmentation of IL-6 secretion by megakaryocytes.¹⁷⁷

Platelet-derived growth factor (PDGF) increases the expansion of megakaryocyte progenitors in association with other cytokines without inducing maturation.¹⁷⁸ PDGF-B/PDGF-B-receptor-null mice display a lethal phenotype. Embryos have thrombocytopenia, but no abnormalities in megakaryocyte maturation or megakaryocyte progenitor numbers were noted. The thrombocytopenia seems to be related to a decrease in liver size. Thus, most of the effects of PDGF on hematopoiesis and megakaryocytopoiesis seem to be related to the release of cytokines by stromal cells.¹⁷⁹

In cell therapy, combinations of cytokines are used to expand megakaryocyte progenitors and megakaryocytes from CD34⁺ cells with the goal of shortening platelet recovery after myeloablative therapy.¹⁸⁰

Inhibitory factors

As soon as the megakaryocyte colony assay was available, it became evident that, unlike the erythrocyte or granulocyte lineages, megakaryocyte colony formation was partially inhibited by serum in a dose-dependent manner.¹⁸¹ In contrast, plasma or serum derived from platelet-poor plasma did not have this inhibitory effect. These results strongly suggested that platelets stored and secreted one or several molecules inhibitory of megakaryocytopoiesis.

It was subsequently demonstrated that these inhibitory proteins are present inside platelets, especially in a granules.¹⁸² Two proteins may be involved in this inhibition: transforming growth factor β 1 (TGF- β 1) and platelet factor 4 (PF4).

TGF- β 1 has an extremely potent inhibitory effect on megakaryocytopoiesis, inhibiting megakaryocyte colony formation, endomitosis, and terminal differentiation.¹⁸²⁻¹⁸⁴ Megakaryocytopoiesis is the hematopoietic lineage whose primitive cells are the most sensitive to the inhibitory effect of TGF- β 1.¹⁸⁵ TGF- β 1 increases the synthesis of TPO by stromal cells. On the other hand, TPO induces an increase in TGF- β receptor expression on megakaryocytes, enhancing in turn their response to TGF- β 1.¹⁸⁶ Treatment of mice for 7–14 days with TGF- β 1 induces a 95% reduction in platelet counts, as well as anemia and an increase in granulopoiesis.¹⁸⁷ In contrast, TGF- β 1-null mice or mice reconstituted with bone marrow cells from TGF β 1-null mice have no thrombocytosis (authors' unpublished data), demonstrating that TGF- β 1 is not a physiological negative regulator of platelet production.

PF4, β -thromboglobulin, and CTAP-III belong to the family of chemokines that are capable of binding heparin. In vitro, PF4 inhibits megakaryocyte colony formation.^{188,189} In vivo, injection of PF4 into mice induces thrombocytopenia.¹⁹⁰ However, the inhibitory effect of PF4 on megakaryocytopoiesis is non-specific. Like other members of this family, such as macrophage inflammatory protein 1 α (MIP-1 α), PF4 acts on primitive hematopoietic cells, including all types of hematopoietic progenitors. PF4 may also be used as a hemoprotector.¹⁹¹ However, it does not seem to be a physiological regulator of megakaryocytopoiesis, because PF4-null mice do not develop thrombocytosis.

As well as these platelet molecules, other cytokines, such as interferons and tumor necrosis factor α (TNF α), also inhibit megakaryocytopoiesis in vitro.¹⁹² Among the interferons, IFN- α inhibits megakaryocyte colony formation, whereas IFN- γ induces proliferation by a TPO-independent mechanism.¹⁹³ The inhibitory effect of IFN- α is related to the induction of SOCS1, an inhibitor of the Jak-STAT pathway activated by TPO.¹⁹⁴

Finally, there is also evidence that extracellular matrix proteins regulate megakaryocytopoiesis by inhibiting proplatelet formation.

Megakaryocytopoiesis and human pathology

Recent progress in the understanding of megakaryocytopoiesis has permitted identification of the molecular mechanisms of several human diseases involving platelet production. Three types of molecules have been implicated: (i) TPO/Mpl, (ii) transcription factors, and (iii) molecules involved in the process of proplatelet formation.

Involvement of TPO/Mpl in human pathology

Mutations and/or deletions of the *c-mpl* and *TPO* genes have been examined to gain insight into the pathophysiology of various thrombocytopenic and thrombocytic disorders. In congenital amegakaryocytic thrombocytopenia (CAMT), a loss of Mpl function has been demonstrated, due to missense or nonsense mutations in the coding region of *c-mpl* resulting in amino-acid substitutions or the presence of a premature stop codon.^{195,196} It is noteworthy that the homozygous mutation in human induces a more profound thrombocytopenia than that observed in *c-mpl*-null mice. In the TAR syndrome (thrombocytopenia and absent radii), megakaryocytes and platelets respond poorly to TPO. No mutation or rearrangement in the *c-mpl* gene or its promoter has been detected, but *c-mpl* mRNA and protein levels are found to be decreased in platelets, suggesting possible abnormal signaling.¹⁹⁷⁻¹⁹⁸ In myeloproliferative disorders, including essential thrombocythemia (ET) and idiopathic myelofibrosis, no mutation in the *c-mpl* gene has been reported so far, although a fraction of CFU-Mk from these patients have the ability to grow autonomously in culture.^{199,200} In addition, no aberrant protein tyrosine phosphorylation has been observed in platelets of patients with sporadic ET before TPO activation, indicating that thrombocytosis is not related to a constitutive activation of Mpl signaling. However, expression of Mpl has been found to be strikingly diminished, suggesting that excessive production of platelets might be attributable to the impaired uptake and catabolism of TPO.²⁰¹⁻²⁰³ The *TPO* gene is located on human chromosome 3q27-28. Patients with 3q21 or 3q26 rearrangements often develop thrombocytosis or dysmegakaryopoiesis. No transcriptional activation or chromosomal rearrangement of the *TPO* gene has been detected in these patients, excluding involvement of this gene in these malignancies.^{204,205} Studies performed on two families with hereditary thrombocythemia in which all affected members had elevated TPO serum levels have demonstrated that single point mutations in the 5'-untranslated region (UTR) of *TPO* mRNA resulted in more efficiently translated transcripts, causing overexpression of TPO.^{206,207} However, not all congenital cases of ET are due to increased secretion of TPO.

Transcription factors and abnormal megakaryocytopoiesis

It has been shown that four transcription factors (GATA-1, FOG, Fli-1, and NF-E2) are essential regulators of megakaryocyte differentiation (Figure 11.1). Mutations in two of them (GATA-1 and Fli-1) cause congenital thrombocytopenia.

X-linked thrombocytopenia (XLT) usually corresponds to mutations in the *WASP* gene and is associated with small platelets.^{208,209} Cases of XLT associated with large platelets have been described, but these patients do not carry mutations in the *WASP* gene. These pathologies are associated with mild anemia or dyserythropoiesis. It has been demonstrated in two families that this disorder corresponds to a mutation in the *GATA-1* gene resulting in a loss of FOG binding to GATA-1.^{14,210}

Deletion in the locus 11q23.3, where Fli-1 is located, leads to a thrombocytopenia called Jacobsen syndrome or Paris-Trousseau thrombocytopenia. Thrombocytopenia is associated with numerous congenital anomalies, including cardiac defects.^{211,212} Platelets in Paris-Trousseau thrombocytopenia are characterized by giant granules. In the bone marrow as well as in culture, two populations of megakaryocytes are observed. One is normal, while the other one comprises small immature megakaryocytes that express a low level of platelet glycoproteins and are extremely sensitive to apoptosis.²¹² In this syndrome there is a large terminal deletion of 11q that leads to a hemizygous loss of Fli-1 as well as of other genes. *Fli1*^{+/-} mice have normal megakaryocytopoiesis with an absence of thrombocytopenia. Thus, Paris-Trousseau thrombocytopenia may be related to deletions in more than one gene (*Fli-1* plus ?) or to a difference in the regulation of *Fli-1* between human and mouse. This hypothesis is supported by the fact that the abnormal megakaryocytes of Paris-Trousseau thrombocytopenia have the same phenotype as those observed in *Fli1*^{-/-} embryos.^{74,212}

More surprisingly, haploinsufficiency of transcription factors, which has not yet been implicated in the regulation of megakaryocytopoiesis, may induce congenital thrombocytopenia. Haploinsufficiency of CBFA2/AML1 leads to a thrombocytopenia associated with a defect in platelet function.²¹³ The target genes of CBFA2/AML1 in megakaryocytes are presently unknown as are the molecular mechanisms underlying this thrombocytopenia. This haploinsufficiency predisposes to the development of acute myeloid leukemia.²¹³ In the mouse, haploinsufficiency of CBAF2 does not lead to thrombocytopenia but to alterations in the ontogenic changes of hematopoietic stem cells.²¹⁴

Some thrombocytopenias may be related to mutations in *Hox* genes. A mutation in *HoxA11* has been

described, associated with a syndrome similar to the TAR syndrome, i.e. amegakaryocytic thrombocytopenia with radio-ulnar synostosis.²¹⁵ However, no mutation in *HoxA10* on *HoxA11* has been found in true TAR syndrome.

The two genes involved in the t(1;22)(p13;q13) translocation and associated with infant acute megakaryoblastic leukemia have been characterized.^{216,217} One of these genes, *OTT*, is the human homolog of the *Drosophila spen* gene involved in the *Hox* gene as well as the Ras/MAPK kinase pathways.^{218,219} The other MAL is a co-activator of SRF.

Abnormalities in platelet formation

Up to now, no mutation in NF-E2 associated with thrombocytopenia has been described in humans. In contrast, several congenital thrombocytopenias may be related to genes involved in proplatelet formation, but the molecular mechanisms of most of these thrombocytopenia are still unknown.

Autosomal dominant giant platelet syndromes with or without leukocyte inclusions (Fechtner syndrome, May-Hegglin anomaly, and Sebastian syndrome) are related to mutations in the gene encoding non-muscle myosin heavy chain A.^{220–222} It has been suggested that this gene may be involved in proplatelet formation.

Bernard-Soulier syndrome, initially described as an inherited bleeding disorder with mild thrombocytopenia and giant platelets, corresponds to mutations in genes encoding members of the GpIb complex (GpIb or GpIX). Thrombocytopenia is also observed in GpIb-null mice and seems to be related to abnormal proplatelet formation.²²³ In humans, the heterozygous form of Bernard—Soulier syndrome seems to be a frequent cause of autosomal dominant macrothrombocytopenia.²²⁴

Wiskott-Aldrich syndrome (WAS), which associates eczema, immune deficiency, and microthrombocytopenia, and its variant, which only involves microthrombocytopenia (X-linked thrombocytopenia), are due to mutations in the WASP gene.^{208–209} The WASP protein is involved in actin polymerization. It is a target molecule for activated Cdc42, permitting actin polarization and the formation of filopods.²²⁵ Mutation of *WASP* results in loss of function and induces a cytoskeletal disease. The mechanism of thrombocytopenia is complex and seems to be related essentially to peripheral platelet destruction. Despite divergent results, no marked abnormality in *in vitro* proplatelet formation from megakaryocytes of WAS patients have been observed, although branching structures have not yet been studied.²²⁶ However, megakaryocytes from WAS patients present abnormal actin filaments, especially after matrix adhesion, which may be responsible for abnormal megakaryocyte exit from the marrow.

Clinical potentials of TPO

Two different forms of recombinant TPO molecule have been used in clinical trials. One is a full-length glycosylated human protein (rHu-TPO) produced in mammalian cells. The other is a C-terminally truncated version of the human cDNA sequence produced in bacteria and covalently attached to a polyethylene glycol tail to increase *in vivo* potency (PEG-rHuMGDF).

Treatment of normal animals with glycosylated rHuTPO or PEG-rHuMGDF potently stimulates the expansion of marrow megakaryocytes and their progenitors, and greatly augments the production of platelets, with only minimal effects on leukocyte and red cell counts.^{142,227} Platelets generated in response to PEG-rHuMGDF show normal morphology and hemostatic function. Although PEG-rHuMGDF by itself does not induce aggregation of platelets *in vitro*, the aggregatory response to ADP or collagen is enhanced in a dose-dependent manner. Nevertheless, in a model of thrombus formation, treatment with PEG-rHuMGDF had no effect.²²⁸ Either of the recombinant molecules used alone markedly expand circulating levels of multiple types of hematopoietic progenitor cells, and this effect is potentiated by G-CSF. A variety of animal models of myelosuppression, including chemotherapy, irradiation or combined treatment, have been used to reveal the effects of rHu-TPO and PEG-rHuMGDF. TPO treatment accelerates multilineage hematopoietic recovery and efficiently improves thrombocytopenia and, in most models, anemia and neutropenia.^{229–232} Concurrent administration of PEG-rHuMGDF and G-CSF does not interfere with the *in vivo* effects of each cytokine, but rather has synergistic effects.^{233–235} In bone marrow transplantation (BMT), administration of PEG-rHuMGDF has little or no efficacy.^{236,237} However, the use of transplants from TPO-pretreated donors prompts hematopoietic recovery and improves platelet counts.^{237,238}

Results of initial clinical trials revealed that the two forms of recombinant molecules were well tolerated, with few adverse events. Phase I trials conducted in patients with advanced cancer have shown that both molecules potently stimulate platelet production when given prior to chemotherapy.^{239,240} After chemotherapies that require minimal or no platelet transfusions, administration of TPO alone or in combination with recombinant G-CSF reduces the duration of thrombocytopenia and, in some cases, the platelet nadir.^{241,242} TPO given after peripheral blood progenitor cell transplantation (PBPC) or BMT may not be effective in platelet recovery, since levels are extremely high in the circulation.¹⁰⁵ A placebo-controlled, blinded study was conducted in normal human volunteers to examine the effects of a single bolus administration of PEG-rHuMGDF on platelet

production, lifespan, and function.²⁴³ The results show that, within 1 week, megakaryocytopoiesis doubles, leading to a doubling of circulating platelet numbers on day 12. Platelets exhibit normal function and viability during the ensuing 10 days. No increase in thrombotic events was reported in this study. However, the development of PEG-rHuMGDF is presently suspended because of the development of neutralizing antibodies that inactivate endogenous TPO in some individuals after repeated injections.

It is too early to draw definitive conclusions regarding the potential clinical applications of TPO. Nevertheless, TPO in combination with other cytokines remains a key growth factor for cord blood stem cell expansion *ex vivo*. Encouraging results have suggested that pluripotent stem cells can be expanded for several weeks without losing pluripotency.¹²¹ Studies with TPO are ongoing to expand CFU-Mk and megakaryocytes *ex vivo* in order to produce platelets that could be useful for transfusion.^{159,180}

DNA repair and malignant hematopoiesis

Lieneke R van Veelen, Roland Kanaar, and DC van Gent

Introduction

Proper maintenance of the genome is crucial for the survival of all organisms. It is of major importance for the functioning of the cell that the information encrypted in the genome be transcribed correctly. However, endogenous and exogenous DNA-damaging agents constantly threaten the integrity of the genome. When a cell detects genome injury, it can arrest the cell cycle at specific checkpoints. The activation of cell cycle checkpoints provides time to repair the DNA lesions before they can be converted into permanent mutations. When DNA damage cannot be repaired, the cell is triggered to go into apoptosis or replicative death (Figure 12.1). Incorrect repair or accumulation of DNA damage results in genome instability, which may lead to impaired functioning of the cell and even to the development of cancer. Therefore, all organisms are equipped with a complex network of DNA repair mechanisms, each of which is able to repair a subset of lesions. The biological significance of DNA repair mechanisms is underlined by the fact that many repair genes are conserved from yeast to humans, which are separated by more than 1.2 billion years of evolution. The importance of the DNA repair pathways is also emphasized by the fact that defects in DNA repair genes often lead to cancer predisposition in humans.

DNA repair mechanisms

Different DNA-damaging agents cause a wide variety of lesions in the DNA strands. Depending on the type of injury, a specific DNA repair mechanism will remove the damage (Figure 12.2). Irrespective of the mechanism that is used to repair the lesion, there is a similar succession of events that needs to take place in order to repair the damage. The first step is to recognize the DNA lesion. Subsequently, the lesion is processed, which will eventually lead to its removal. The processing of lesions frequently involves the incision of DNA strands and the removal of the damaged sites, including the surrounding nucleotides. Consequently, the final steps in DNA damage repair are re-incorporation of the missing nucleotides and coupling of the DNA ends by a DNA ligase. Depending on the pathway used to repair the lesion and the stage of the repair reaction, different sets of proteins are required.

There are several pathways available that the cell can use to repair the damage. DNA damage can be

Figure 12.1 Cellular consequences of damage to DNA. DNA damage triggers activation of cell cycle checkpoints. This can lead to cell cycle arrest at G_1/S , intra-S, or G_2/M phases. During cell cycle arrest, DNA damage can be repaired. Incorrect repair of DNA may lead to genome instability and oncogenesis. An alternative to repair of DNA damage is the induction of apoptosis or replicative death.

Figure 12.2 Overview of different DNA repair pathways in mammalian cells. Various types of lesions in DNA can be caused by exogenous or endogenous DNA-damaging agents. They may affect a single strand or both strands of the DNA. Different DNA repair pathways that operate on the various lesions are indicated here.

categorized into two classes: one in which only one of the two strands of the DNA is damaged and a second class of lesions that affects both strands of the DNA. If only one strand is damaged, the DNA repair machinery uses the complementary DNA strand as a template for repair. Examples of this type of repair are base excision repair (BER), nucleotide excision repair (NER), and mismatch repair (MMR) (Figure 12.2).^{1,2} Repair of a DNA double-strand break (DSB) cannot be accomplished by using the complementary strand as a template, since both strands are broken at the same site. In this case, the cell can utilize the recombinational repair pathways of non-homologous end-joining (NHEJ) or homologous recombination (HR) (Figure 12.2).³⁻⁵

An interesting aspect of the hematopoietic system is its unique position in DNA repair: precursor B and T cells are capable of introducing programmed DNA damage in the form of site-specific DSB. Correct repair of these DSB results in functional immunoglobulin and T-cell receptor genes. Occasionally these programmed DSB can be repaired incorrectly, leading to undesirable genomic rearrangements, which might activate oncogenes responsible for the development of leukemia or lymphoma. For this reason, the mechanisms of DSB repair are discussed more extensively in this chapter.

DNA double-strand break repair

DSB, as well as the less genotoxic single-strand breaks (SSB), can be caused by ionizing radiation, free radicals, and chemicals such as alkylating agents. Furthermore, DSB may arise during replication of a region containing an SSB. Several repair mechanisms can deal with DSB, emphasizing the importance of repairing this type of DNA damage.

The two major DSB repair pathways are HR and NHEJ. The difference between these two pathways is the use of a homologous sequence. HR uses the sister chromatid or homologous chromosome as a template for repair, whereas NHEJ simply joins the broken ends without the use of a template (Figure 12.3). This difference in repair mechanism leads to a difference in the fidelity of repair. HR restores the original DNA sequence and is therefore a precise type of repair. NHEJ, on the other hand, often leads to addition or deletion of nucleotides at the joining site. In this way, important information may be lost, thus making NHEJ an error-prone repair pathway.

The relative contribution of these pathways to DSB repair likely depends on the cell cycle stage. In G_1 phase, when the sister chromatid is absent, a DSB is most likely to be repaired through NHEJ.^{6,7} HR is most efficient in S and G_2 phases of the cell cycle, when the sister chromatid is available as a template.⁸ However, NHEJ may also occur in S and G_2 phases.^{9,10} The detection, processing, and ligation of the break are organized by a large number of proteins, which are specific for each pathway, although some proteins may be involved in both HR and NHEJ (Figure 12.3). The exact function of many repair proteins involved in these pathways is still unknown.

Homologous recombination

HR is mediated by the so-called RAD52 group of proteins, which includes RAD50, RAD51, RAD52, RAD54, MRE11, and NBS1.^{4,5,11} Recognition of the broken DNA ends may occur by the RAD50/MRE11/ NBS1 complex or by RAD52.^{12,13} Nucleolytic process

Figure 12.3 Major repair pathways of DNA double-strand break repair. DNA DSB can be repaired by at least two mechanistically distinct pathways: homologous recombination (HR) and non-homologous end-joining (NHEJ). This figure shows a simplification of the models for DSB repair. During HR, the damaged DNA (thick lines) uses the sister chromatid or homologous chromosome (thin lines) as a template to repair the DNA accurately. NHEJ repairs the damaged DNA by joining the DNA ends in a way that is not necessarily error-free. The succession of events that take place during repair of the damage is presented. A number of proteins involved in each pathway are indicated and discussed in the text.

ing of the broken ends leads to the formation of single-stranded tails (Figure 12.3). RAD51 proteins form a nucleoprotein filament on this single-stranded tail. The RAD51 nucleoprotein filament searches for the homologous piece of DNA.¹⁴ Once the homology has been detected, a joint molecule is generated between the damaged DNA and the undamaged sister chromatid. Several proteins assist RAD51 in this complex reaction, including the breast cancer susceptibility proteins BRCA1 and BRCA2, five RAD51 paralogs, RAD52, and RAD54.^{4,15–19} The information that was lost during processing of the DNA ends is restored by DNA polymerases that synthesize new DNA using the undamaged sister chromatid as a template. Finally, the DNA strands are ligated, resulting in accurate repair of the DSB. A putative link between reduced HR efficiency and cancer predisposition is provided by the observation that many carriers of mutations in either *BRCA1* or *BRCA2* develop breast or ovarian cancer.²⁰

Non-homologous end-joining

Several proteins that are involved in NHEJ have been identified (Figure 12.3). The KU70/KU80 protein complex forms a ring around the DNA ends.²¹ End-bound KU70/KU80 activates the DNA-dependent protein kinase catalytic subunit (DNA-PKcs). Together they form a protein complex known as DNA-PK, which is involved in the early recognition of the DSB.²² Consequently, the DNA can be processed by nucleases or polymerases. Nucleases, such as the ARTEMIS protein, remove nucleotides from the DNA ends.²³ DNA polymerases synthesize new DNA, in order to prepare the DNA ends for ligation. Finally, both ends are joined by the LIGASE IV/XRCC4 complex.²⁴

Two groups of patients with defects in NHEJ have been identified. A small subset of patients with severe combined immunodeficiency (SCID) have a mutation in the *ARTEMIS* gene.²⁵ Furthermore, patients have been described in which a mutation on one allele of the *LIGASE IV* gene is detected.²⁶ The phenotype of these patients is heterogeneous, although most of them suffer from immunodeficiency. It is not clear whether patients with a defect in either *ARTEMIS* or *LIGASE IV* display cancer predisposition.

DNA rearrangements in the immune system

V(D)J recombination

Not only is the NHEJ repair pathway used to repair DSB that are induced by exogenous factors, but it is

also involved in processing the programmed DSB that arise during the generation of immunoglobulin (*Ig*) and T-cell receptor (*TCR*) genes. These programmed DSB are natural intermediates in a specialized recombination event called *V(D)J* recombination.²⁷ This recombination reaction is required for the creation of functional B and T cells.

Mature *Ig* and *TCR* genes are assembled from separate gene segments in B and T cells, respectively. The lymphoid-specific proteins RAG1 and RAG2 initiate this DNA recombination process. They bind to recombination signal sequences (Figure 12.4a) that flank the variable (*V*), diversity (*D*) and joining (*J*) segments of the *Ig* and *TCR* genes (Figure 12.4b).²⁷ Subsequently, a DSB is made at the border of the recombination signal sequence and the coding gene segment. The products of this cleavage reaction are blunt DNA ends at the side of the recombination signal sequence. The coding gene segment ends in a hairpin structure, in which the top strand is coupled to the bottom strand. The DNA ends are recombined such that the two coding gene segments form the coding joint, from which the *Ig* or *TCR* genes arise, while the signal sequences are ligated in the signal joint, which is not used any further (Figure 12.4a). For this joining process, the NHEJ machinery of the cell is used.

V(D)J recombination is a highly regulated process. In B-cell development, the *Ig* heavy-chain locus is recombined first. If this yields a functional heavy-chain polypeptide, the cell will start a proliferation phase, after which the *Ig* light-chain loci (κ or λ) are rearranged. These cells enter the circulation as virgin B cells, provided that they produce functional immunoglobulins that are not autoreactive. A similar order of events leads to the formation of virgin T cells.²⁸ A deficiency in one of the RAG proteins or in one of the components of the NHEJ process severely impairs the capacity to perform *V(D)J* recombination, which results in low levels of mature B and T cells.²⁹

Immunoglobulin class switching

A later step in B-cell development is immunoglobulin heavy-chain class switching. This leads to expression of a different class of antibodies, which are also initiated by programmed DSB formation.^{30,31} Most

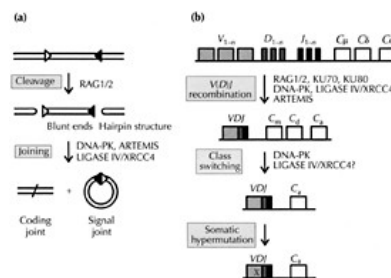

Figure 12.4 DNA rearrangements in the immune system, (a) The mechanisms of *V(D)J* recombination. DSB are made by the RAG1 and RAG2 proteins at the border of the recombination signal sequences (triangles) that surround the *V*, *D*, and *J* segments of the immunoglobulin (*Ig*) and T-cell receptor (*TCR*) genes. Recombination signal sequences contain motifs separated by a spacer of 12 or 23 base pairs of non-conserved sequence. Recombination always takes place between one signal sequence with a 12 bp spacer and one with a 23 bp spacer (open and closed triangles). The DSB are made in such a way that the ends form a hairpin structure in which the top strand is coupled to the bottom strand. The joining reaction is accomplished by the NHEJ machinery, which involves end recognition by the KU/DNA-PK complex and ligation by the LIGASE IV/XRCC4 complex. The DNA hairpin intermediates are probably opened and processed by the ARTEMIS protein. The coding joint gives rise to the functional *Ig* or *TCR* genes. The signal joint is irrelevant for the further process, (b) Overview of the different types of DNA rearrangements in the immune system. In pre-B cells, the immunoglobulin loci undergo *V(D)J* recombination. As an example, the *IgH* locus is shown. First, one of the *D* segments is coupled to one of the *J* segments, followed by *V* to *DJ* joining. After successful assembly of functional *Ig* genes and stimulation by antigen, a second DNA rearrangement can delete a number of constant regions (indicated by *C* with different subscripts), resulting in expression of a different immunoglobulin isotype. This class switch recombination reaction requires at least the components of the DNA-PK complex, and possibly also the LIGASE IV/XRCC4 complex. Finally, the affinity of the antibodies for the antigen can be modulated by introduction of point mutations into the *V(D)J* exon. The mechanism of this somatic hypermutation reaction is not yet clear, although DSB have been found at the site of hypermutation, suggesting that DSB repair mechanisms may be involved.

circulating B cells never encounter antigens that are recognized by the immunoglobulins on their surface. The few B cells that are stimulated by an antigen go into a regulated differentiation scheme. These stimulated B cells are able to change the type of immunoglobulin they produce using a DNA recombination process called immunoglobulin heavy-chain class switching (Figure 12.4b).^{30,31} The mechanism of this recombination reaction is less well understood than the process of *V(D)J* recombination. However, it is clear that class switch recombination requires DNA-PK, which might indicate that DSB are intermediates in this process that may be repaired by the NHEJ proteins.^{32–34} After the B cells have undergone the maturation program, they enter the circulation as plasma cells, which produce large amounts of secreted immunoglobulins that recognize the antigen for which they were selected. When the antigen has been removed from the system, some of these plasma cells can develop into memory cells, which survive for a very long time and react very quickly when the organism is invaded for a second time by the same antigen.

Somatic hypermutation

Somatic hypermutation is another process in the immune system in which the DNA sequence is altered (Figure 12.4b). It changes the binding efficiency of immunoglobulins, by introducing point mutations in the DNA region containing the *V(D)J* segment.^{35,36} It has been demonstrated that DSB occur in hypermutating *Ig* genes, preferentially at mutational hotspots.^{35,37} However, the exact function of these DSB is still poorly understood.

Cell cycle checkpoints

DSB are particularly dangerous lesions when they occur during replication of the genome or during mitosis when the duplicated chromosomes are divided between the daughter cells. When broken chromosomes are carried through mitosis, the chromosome fragments will not distribute evenly between the two daughter cells, thus causing chromosomal aberrations.^{38,39} Several checkpoints can stop the cell at different points in the cell cycle when DNA damage is present. The G₁/S checkpoint prevents the cell from starting DNA replication, intra-S check-points slow down replication, and G₂/M checkpoints arrest the cell before division.⁷ Among the many proteins involved in DNA damage-induced cell cycle arrest are p53, ATM, and the protein complex MRE11/RAD50/NBS1. p53 plays a role in a number of different checkpoints. ATM and the MRE11/RAD50/NBS1 complex are mainly involved in the intra-S checkpoint.^{40,41}

Several human syndromes are associated with defects in these checkpoint genes. Mutations in *ATM* or *MRE11* cause syndromes called ataxia telangiectasia (AT) or AT-like disorder (ATLD), respectively.^{42–44} A mutation in *NBS1* leads to the Nijmegen breakage syndrome.⁴⁵ These syndromes have a number of overlapping features, such as growth retardation, neurological problems, increased sensitivity to ionizing radiation, and a predisposition to cancer (mainly lymphoma). A heterozygous mutation in *p53* can cause the Li-Fraumeni syndrome, a disorder that is characterized by a high tumor incidence, especially breast cancer, sarcomas, brain tumors, and, to a lesser extent, hematological and adrenocortical neoplasms.⁴⁶ Additionally, the *p53* gene is frequently found to be mutated in tumors, which gives an indication of the tumorigenic effects of a defect in *p53*.

Double-strand breaks and chromosomal aberrations

DSB repair plays a role in the prevention of chromosomal instability and potentially oncogenic translocations.^{5,47} Paradoxically, some proteins required for proper DSB repair are likely to be involved in the creation of translocations as well. These translocations arise when a fusion occurs between parts of different chromosomes. A DSB is most probably the initiating DNA lesion that can result in translocations as a consequence of misrepair (Figure 12.5). Since proteins involved in DSB repair are essential for the ligation of DNA ends, this must mean that the generation of translocations requires their activity. Translocations are a characteristic feature of many tumors and have become important markers in diagnosis and prognosis. However, little is known about the relationship between oncogenesis and DSB repair defects in humans.⁴⁸ Studies involving mouse models and cell lines with mutations in DNA repair genes have highlighted the relationship between defects in DSB repair pathways and the formation of translocations and oncogenesis (Table 12.1).⁴⁹

Homologous recombination and chromosomal aberrations

HR uses the sister chromatid or the homologous chromosome as a template for repair of the broken ends. Probably because of its proximity, the sister chromatid is commonly used as the repair template. The preference of the sister chromatid over the homologous chromosome is biologically relevant, since recombination between homologous chromosomes can lead to loss of heterozygosity (LOH).⁵⁰ Defects in HR, such as errors in template choice, could even be more harmful when recombination occurs between repetitive sequences, which are present throughout

Table 12.1 Consequences of homozygous mutations in cell cycle checkpoint genes and genes involved in DSB repair

Genome instability		Mouse knockout: cancer predisposition	Mouse knockout combined with <i>p53</i> knockout: cancer predisposition	Refs
Cell cycle checkpoint genes				
<i>ATM</i>	Chromosomal aberrations	T-cell lymphomas	Early-onset B- and T-cell lymphomas	67, 68
<i>p53</i>	Chromosomal aberrations	T- and B-cell lymphomas	Not applicable	69–71
Non-homologous end-joining				
<i>DNA-PKcs</i>	Chromosomal aberrations	No overt cancer predisposition	Early-onset pro-B-cell lymphomas	57, 72–74
<i>Ku70</i>	Chromosomal aberrations	T-cell lymphomas	ND	58, 59, 75, 76
<i>Ku80</i>	Chromosomal aberrations	No cancer predisposition	Early onset pro-B-cell lymphomas	77–79
<i>Artemis</i>	ND	ND	ND	25
<i>XRCC4</i>	Chromosomal aberrations	Embryonic lethal	Rescues embryonic lethality; early-onset pro-B-cell lymphomas	60, 64
<i>Ligase IV</i>	Chromosomal aberrations	Embryonic lethal	Rescues embryonic lethality; early-onset pro-B-cell lymphomas	49, 61, 66
Homologous recombination				
<i>Rad51</i>	Chromosomal aberrations	Embryonic lethal	Embryonic lethal	54, 80, 81
<i>Rad52</i>	ND	No cancer predisposition	ND	82
<i>Rad54</i>	No instability	No cancer predisposition	ND	83, 84
<i>Brca2</i>	Chromosomal aberrations	Embryonic lethal	Embryonic lethal	85, 86
Miscellaneous				
<i>Brca1</i>	Chromosomal aberrations	Embryonic lethal	Embryonic lethal	16, 85
<i>Rad50</i>	Not viable	Embryonic lethal	ND	87
<i>Mre11</i>	Chromosomal aberrations	Embryonic lethal	ND	88
<i>NBS1</i>	Translocations	Embryonic lethal	ND	89
<i>V(D)J</i> recombination genes				
<i>Rag1</i>	Translocations	Unknown; mice die at early age	Early-onset T-cell lymphomas	70, 90, 91
<i>Rag2</i>	Translocations	Unknown; mice die at early age	Early-onset T-cell lymphomas	70, 90, 91
The influence of a homozygous mutation (knockout mutation) of either of these genes on genomic instability in cells and cancer predisposition in mice is indicated. An additional homozygous mutation of <i>p53</i> rescues viability in several embryonic lethal mice and influences the spectrum and time of onset of tumors in these mice. The four rows headed 'Miscellaneous' represent genes that may be involved in more than one of the pathways listed above. ND, not determined.				

the genome (Figure. 12.5). This type of ectopic recombination may lead to chromosomal translocations.

The importance of HR is emphasized by the finding that inactivation of genes involved in HR often results in embryonic lethality. Therefore animal models have been designed in which the effect of mutations in specific tissues can be investigated. The role of BRCA1 in genomic instability was studied by creating mice in which the *Brca1* gene was specifically inactivated in epithelial cells.⁵¹ In the mammary tumors that developed, translocations were frequently observed. Additional inactivation of the *p53* gene accelerated the formation of mammary tumors in these mice. The same results were seen in mice that carry a specific mutation in the *Brca2* gene.⁵² *Brca2*-mutant mice have an increased sensitivity to ionizing radiation, growth retardation, infertility, and frequent development of thymic lymphomas, and cells derived from these mice show spontaneous chromosomal aberrations.⁵³ Chromosomal instability was also observed in a chicken B-cell lymphoma cell line that was conditionally mutated for *Rad51*.⁵⁴ Results from these animal studies suggest a role for HR in the development of chromosomal translocations and oncogenesis.

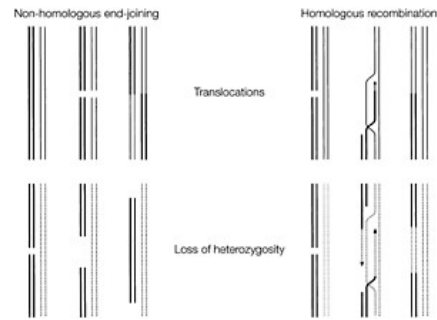

Figure 12.5 Translocations and loss of heterozygosity during aberrant DSB repair. *Upper left:* Translocations by NHEJ can occur when two DSB on heterologous chromosomes are ligated. Unbroken heterologous chromosomes are depicted by two parallel thick and thin lines, respectively. They are shown to undergo breakage and misligation, resulting in a reciprocal translocation. *Upper right:* Translocations by HR can occur when a DSB is repaired using repetitive sequences located on a heterologous chromosome. *Bottom left:* Loss of heterozygosity (LOH) by NHEJ can occur when DNA sequences around a DSB are degraded before ligation. The sets of thick and dashed lines represent homologous chromosomes. *Bottom right:* LOH during HR can occur when the homologous chromosome instead of the sister chromatid is used for DSB repair.

Non-homologous end-joining and chromosomal aberrations

The role of NHEJ in oncogenesis has been studied more extensively. Defects in NHEJ not only lead to genomic instability but also to impaired functioning of the *V(D)J* recombination process. Immuno-deficiency is therefore a characteristic feature of humans and mice with defects in one of the NHEJ genes. Mice carrying mutations in NHEJ genes have been studied in more detail. The phenotypes of these mutant mice reveal similarities, such as increased radiation sensitivity and immunodeficiency, but striking differences have also been observed. Mice lacking *Ku70*, *Ku80*, or *DNA-PKcs* are viable, and *Ku70*-deficient and possibly *DNA-PKcs*-deficient mice develop T-cell lymphomas at late onset.^{55–59} This is in contrast with *Xrcc4*- or *Ligase IV*-deficient mice, which die during embryogenesis due to neuronal apoptosis.^{60–63} The lethality of the *Xrcc4*- and *Ligase IV*-mutant mice, together with the apoptosis and senescence phenotype of cells derived from the NHEJ-mutant mice, reveal that the NHEJ pathway is critical for the repair of spontaneously occurring DSB. Cells that are deficient in one of the NHEJ genes indeed show genomic instability, particularly spontaneous chromosome and chromatid breaks (Table 12.1).

The main evidence for a role of NHEJ in tumorigenesis is seen in experiments where mice that lack one of the NHEJ genes are crossed with *p53*-deficient mice. Interestingly, the lethality, but not the *V(D)J* recombination capability, of the *Xrcc4*- and *Ligase IV*-deficient mice is rescued by the absence of *p53*.^{61,64} However, these viable double-mutant mice develop pro-B-cell lymphomas at an early age. Pro-B-cell lymphomas are also observed in other double-mutant mice, which lack *p53* and one of the other NHEJ genes (Table 12.1). A possible explanation for this additional effect of the *p53* mutation can be found in the reduced level of apoptosis in *p53*-deficient mice. Damaged NHEJ-deficient cells, which would normally go into apoptosis, are not eliminated efficiently in this genetic background. The pro-B-cell lymphomas that occur in these mice have a characteristic t(12; 15) translocation between the *IgH* locus and the *c-myc* locus.⁶⁵ The *IgH* locus is the first target of the RAG endonucleases in the development of B lymphocytes. Most likely, the initiating lesion of the pro-B-cell lymphomas is a RAG-induced DSB. This hypothesis is supported by the fact that triple-mutant *DNA-PK/p53/RAG2* mice do not develop pro-B-cell lymphomas.⁶⁵

The development of mouse models has enabled a detailed analysis of genetic interactions between NHEJ deficiencies and mutations in other genome stability genes. Mice that are deficient for one of the NHEJ genes and heterozygous for *p53* are also prone to get solid tumors, mainly sarcomas. Although this broad spectrum of tumors can also be observed in the heterozygous *p53* mouse, the NHEJ deficiency accelerates this process, leading to development of the tumors at an earlier onset. Complementary to this, heterozygosity for *Ligase IV* also influences tumor development in mice carrying a homozygous deletion in a tumor suppressor gene. These knockout mice are predisposed to get lymphomas, but an additional

heterozygous mutation in *Ligase IV* provokes the development of soft tissue sarcomas that possess chromosomal amplifications, deletions, and translocations.⁶⁶ This implies that a heterozygous mutation in an NHEJ gene by itself does not lead to an increased cancer risk. However, a combination of such a mutation and a defect in other genes involved in genome stability may accelerate cancer development, emphasizing the importance of the genetic background in oncogenesis. The genetic background on which a mutation in one of the repair genes occurs determines whether a tumor will develop and influences the time of onset. These findings are very important to understand the intricate genetic interactions that may influence the risk for cancer.

Future perspectives

It is evident that DNA DSB repair proteins play an important role not only in the prevention, but also in the generation of genomic instability. The findings described in this chapter are just the beginning of a deeper understanding of the genetic interactions underlying oncogenic changes. The development of mouse models, which allows investigation of the effects of a combination of two or more mutations, will yield a wealth of information in the near future. In combination with genomics and proteomics, this will lead to a new view on the exact role of the genes involved in DNA repair and their involvement in the etiology of cancer.

Senescence and telomeres

Peter M Lansdorp

Introduction

Telomeres are essential genetic elements that consist of specific DNA repeats and associated proteins. Telomeres cap chromosome ends and prevent chromosome fusion and genetic instability. Telomeric DNA is lost with each round of replication and from other causes including (failed repair of) oxidative DNA damage. To compensate for this loss, telomeres are elongated by the reverse transcriptase enzyme telomerase. In most hematopoietic cells, telomerase activity is tightly controlled and present in limiting amounts. As a result, telomeres in leukocytes shorten with age, upon transplantation *in vivo*, and when cultured *in vitro*. Progressive telomere shortening eventually results in telomere dysfunction and apoptosis or senescence, but also promotes chromosome instability in hematological disorders such as chronic myeloid leukemia (CML). Here, we review the role of telomeres and telomerase in cells of the hematopoietic system in the context of the emerging concept that telomere shortening represent a tumor suppressor mechanism in long-lived mammals that limits the growth of most (but not all) stem cells and lymphocytes.

Telomere structure and function

Telomeres or the ends of linear chromosomes consist in all vertebrates of tandem repeats of $(TTAGGG/CCC-TAA)_n$ and associated proteins.^{1,2} The length of the repeats varies between chromosomes and between species. In humans, the length of telomere repeats varies from 2 to 15 kilobase-pairs, depending on the tissue type, the age of the donor and the replicative history of the cells. Individual chromosome ends also vary in length, and chromosome 17p typically has the shortest track of telomere repeats.³ Telomeres prevent the ends of linear chromosomes from appearing as DNA breaks and protect chromosome ends from degradation and fusion. Telomeres also play a role in meiosis and the organization of chromosomes within the nucleus.⁴ Telomeres contain DNA-binding proteins specific for duplex telomeric DNA, which include TRF1 and TRF2⁵ and a protein specific for the single strand overhang that is typically present at the 3' ends of chromosomes.⁶ In addition, many other proteins are known to indirectly bind to telomeres, for example via TRF1 and TRF2 (reviewed in reference 2). The single-strand overhang at the 3' end of telomeres folds back onto duplex telomeric DNA, forming a protective 'T-loop'.⁷ The 3' overhang associates with telomere repeats via TRF2 in a way that is incompletely understood but which appears to be important for telomere stability.^{8,9}

Telomeric DNA is lost in human cells via several mechanisms that are related to DNA replication, remodeling, and repair. Causes of telomere loss include the 'end replication problem',^{10,11} nucleolytic processing of 5' template strands following DNA replication to create a 3' single-strand overhang,^{12,13} and failed repair of oxidative DNA damage to telomeric DNA.^{14,15} The relative contributions of these different causes of telomere shortening to the overall decline in telomere length with age are not known and most likely vary between cell types and with age. That telomeres shorten as a result of oxidative damage has only recently been realized. It has been shown that telomeric DNA, with its G-rich repeats, is 5- to 10-fold more vulnerable to oxidative damage than non-telomeric, genomic DNA.^{16,17} Repair of oxidative damage to nucleotides is typically achieved using nucleotide excision repair (NER) pathways, which may involve a DNA polymerase template switch.¹⁸ This essential mechanism may fail for lesions near chromosome ends as the repeat nature of target sequences may pose a problem for repair by homologous recombination. In general, the contribution of oxidative damage to telomere shortening and the importance of the redox state in cells to prevent such damage remains to be precisely defined.

The mechanism by which short telomeres signal a DNA damage response is currently not fully understood.^{15,19} Recent studies have highlighted the

dynamic structure of telomeres (reviewed in reference 20). It now appears that individual telomeres can be either 'on' or 'off' in terms of signaling downstream DNA damage pathways. It seems likely that the terminal 3' end is involved in generating such signals, but details other than that ATM²¹ and p53²² are likely to be involved are lacking. An important related question is when telomeres signal during the cell cycle. DNA replication inevitably involves remodeling of the telomere structure. Because telomere loss is known to occur during DNA replication, the inability to form functional telomeres following replication is expected to generate a DNA damage signal during S or G₂ phase of the cell cycle. However, when diploid human fibroblasts reach replicative senescence, they typically enter an irreversible growth arrest in G₁. It has furthermore been shown that disruption of TFR2 binding to telomeres generates a DNA damage signal that is independent of DNA replication.⁸ Perhaps telomeres cycle continuously between 'on' and 'off' states even when the cells are in G₀/G₁, with the likelihood of the 'on' state being inversely and indirectly correlated with the length of telomere repeats (Figure 13.1). According to this idea, the strength of DNA damage signals generated by telomeres would gradually increase with overall telomere shortening. Anti-apoptotic effects of long telomeres or telomerase expression, as well as increased levels of p53 (and the increased sensitivity to apoptosis) in 'older' cells (with shorter telomeres), are in agreement with this model. Differences between individuals and cells in the telomere length required to activate downstream signaling pathways complicate the use of telomere length as an absolute predictor of cellular responses.²³ Such differences, together with variable heterogeneity in telomere length at individual chromosome arms, help explain the marked variation in telomere length between similar cells from normal individuals of the same age.^{24,25}

Telomere maintenance pathways

To compensate for the loss of telomere repeats, cells require expression of functional telomerase. Telomerase is a ribonucleoprotein containing the reverse transcriptase telomerase protein (hTERT) and the telomerase RNA template (hTERC) as essential components. In addition, a number of proteins have been described that are important for telomerase assembly, nuclear localization, and stability (reviewed in reference 2). Telomerase is capable of extending the 3' ends of telomeres. Telomerase levels are typically high in immortal cells that maintain a constant telomere length, such as the stem cells of the germline in the testis and embryonic stem cells. For reasons that remain to be precisely defined, telomerase levels are insufficient to maintain the telomere length in hematopoietic stem cells. Nevertheless, telomerase is functionally very important in hematopoietic stem cells, as is highlighted in patients with the disorder dyskeratosis congenita. Patients with the autosomal dominant form of this disease have one normal and one mutated copy of the telomerase RNA template gene. As expected, such patients show a modest reduction in telomerase levels, yet they typically suffer from progressive aplastic anemia, immune deficiencies, or cancer, and rarely live past the age of 50.^{2,26–28} These findings are in stark contrast to those in the mouse, where complete lack of telomerase activity is tolerated for up to six generations.²⁹ Together with the age-related decline in telomere length in leukocytes, these observations have provided strong support for the idea that telomerase levels are extremely tightly regulated and limiting in human hematopoietic stem cells.

The role of so-called alternative ('ALT') pathways³⁰ in the elongation and/or maintenance of telomeres in hematopoietic cells is not clear. Most likely, such

Figure 13.1 Dynamic model of DNA damage signals generated by short telomeres. (a) Following replication and processing, a chromosome end with a G-rich single-strand overhang is created. (b) This structure is processed and bound by various telomere-binding proteins, including hPOT1⁶ (indicated by the small clear circle), which binds to the 3' single-strand overhang, and TRF1 and TRF2 (indicated by light and dark gray circles), which are capable of folding telomeric DNA.⁵⁰ (c) If the length of telomere repeats is sufficiently long (L), double-stranded telomere repeats can easily fold back on to the single-strand overhang, resulting in a relatively stable structure.⁷ The stability of the poorly understood foldback structure could be compromised when telomeres are short (S), resulting in a shift of the equilibrium between capped and uncapped telomeres⁴ that is independent of DNA replication.

pathways are not very efficient in elongating telomeres in cells that express telomerase. Because telomere lengthening via telomerase and/or ALT appears to be limiting in hematopoietic cells, molecular defects that result in accelerated telomere shortening may result in aplastic anemia. In many cases, it is not possible or straightforward to distinguish direct from indirect causes of telomere shortening. In dyskeratosis, the cause appears to be directly related to telomerase deficiency, whereas in Fanconi anemia,³¹ for example, telomere shortening could be caused directly by defective repair of telomeric DNA or indirectly because loss of stem cells (resulting from defective DNA repair) will result in increased (compensatory) proliferation of remaining stem cells.

Following loss of telomere repeats, a DNA damage signal likely via upregulation of *p53*. When short telomeres signal is generated that signals cell cycle arrest, most are subsequently elongated by 'telomere repair' pathways involving telomerase and/or recombination, the cell cycle arrest will be transient. However, the continued loss of telomeric DNA eventually generates too many short telomeres for the limited capacity of telomere repair pathways (Figure 13.2). At this point, otherwise-normal cells as well as premalignant cells are destined to die by apoptosis or convert to an unresponsive state ('replicative senescence'), depending on the response to high and sustained levels of *p53* in a particular cell type. Possibly, the replicative lifespan of cells in long-lived species has been under selective pressure to (1) permit sufficient divisions for the maintenance of cellular function during a normal lifespan while (2) acting as a brake to prevent excessive cellular proliferation and tumor development. It appears that in most hematopoietic cells, the required balance is achieved by regulating telomerase activity at levels that are sufficient to maintain a minimal length in only a proportion of the 92 telomeres in a human cell. Limiting levels of telomerase and the resulting telomere shortening could contribute to organismal aging in at least two ways. First, some increasing proportion of cells could reach the end of their programmed proliferative lifespan in old age. As a result, T-cell responses could be compromised in the elderly. Second, gene expression in cells near or at senescence may be abnormal, resulting in aberrant secretion of molecules, including enzymes and cytokines (see also reference 32). Both factors could contribute to impaired immune responses in old individuals. In general, the study of telomere biology in relation to human aging is in its infancy. Major challenges are difficulties related to longitudinal studies in humans and the limited use of rodent models.

Telomeres and replicative senescence

In contrast to embryonic stem cells or tumor cell lines, hematopoietic stem cells are not immortal. Forty years ago, Hayflick suggested that most normal human cells are unable to divide indefinitely but are programmed for a given number of cell divisions.³³ In 1990, several papers described loss of telomeres with replication and with age and suggested that progressive telomere shortening could explain Hayflick's original observation.^{34–36} This model was confirmed by subsequent studies showing that transfer of the telomerase reverse transcriptase gene could prevent telomere erosion and resulted in immortalizing of the cells that Hayflick studied in most detail: normal diploid human fibroblasts.^{37,38} Since then, many papers have appeared that are compatible with the notion that telomere shortening limits the number of times most normal diploid cells can divide (for a review, see reference 39). An emerging consensus is

Figure 13.2 The telomere checkpoint. Loss of telomere repeats following replication and oxidative damage results in activation of a DNA damage signal that triggers DNA repair reactions involving telomerase and/or molecules involved in recombination, such as BRCA1, WRN, and BLM. Following effective repair, cells can go through another round of cell division. However, eventually too many short telomeres accumulate for the limited telomere repair capacity. The resulting high levels of *p53* will trigger apoptosis or replicative senescence. Because telomerase levels are limiting in hematopoietic stem cells, such a threshold will be reached earlier in cells that express subnormal levels of telomerase as in, for example, dyskeratosis congenita.

that telomere shortening evolved as a checkpoint mechanism in long-lived mammals that controls unlimited and life-threatening proliferation of organ-specific stem cells and lymphocytes.

Since the important original observation that telomeres in adult blood leukocytes are significantly shorter as compared with germline material (sperm) from the same donor,⁴⁰ the decline of somatic telomeres has been documented in three ways. The original observation was confirmed,^{36,41} it was shown that telomeres in various tissues were shorter in older donors,^{34,35} and telomere shortening was documented during in vitro culture of human cells.^{35,42} In the decade that followed these initial reports, a large number of papers have appeared that have greatly refined our understanding of telomere shortening in human nucleated blood cells (reviewed in reference 43). Studies in this general area have been facilitated by the development of quantitative fluorescence in situ hybridization techniques to measure the telomere length in suspension cells using flow cytometry (flow FISH⁴⁴). With these techniques, it was shown that the age-related decline in telomere length in lymphocytes is much more pronounced than in granulocytes and that rapid telomere shortening early in life is followed by a much more gradual decline thereafter.²⁵ The telomere length in granulocytes can be used as a surrogate marker for the telomere length in hematopoietic stem

Figure 13.3 The decline in telomere length with age in lymphocytes (dotted line) is more pronounced than in granulocytes (full line). The mean telomere length is shown for both cell types extracted from several hundred measurements over the entire age range (GM Baerlocher and PM Lansdorp, unpublished observations). Not shown is the considerable variation in telomere length values between individuals at any given age.²⁵ The gray bar at the bottom represents non-telomeric DNA contributing to the telomere length measurements (flow FISH measurements were calibrated using Southern blot analysis in which on average 2–4 kb of subtelomeric DNA between restriction sites and start of telomere repeats is included in the measurement). Both granulocytes and lymphocytes show a highly significant decline, which is best described by a cubic function.

cells if one assumes that the number of cell divisions between stem cells and granulocytes is relatively constant throughout life and that telomere shortening in stem cells is (1) primarily resulting from replication and (2) relatively constant with each cell division. This approach has been used to model the turnover of human hematopoietic stem cells on the basis of telomere length data.⁴⁵

A striking observation is that telomere length at any given age in humans is very heterogeneous.^{24,44} This variation appears to be primarily genetic.⁴⁶ For example, monozygous twins of over 70 years of age were shown to have very similar telomere length in both granulocytes and lymphocytes, whereas dizygotic twins differed more but not as much as unrelated individuals.²⁵ Using further refinements in the flow FISH method (GM Baerlocher and PM Lansdorp, unpublished observations), it was recently shown that the rapid decline early in life is followed by a slow decline until the age of 50–60 years, after which the decline again accelerates (Figure 13.3). The decline in both granulocytes and lymphocytes is nonlinear and fits a cubic curve. The pronounced decline in T-cell telomere length could activate the telomere checkpoint in specific T and natural killer (NK) cells during a normal lifetime and as a result compromise immune responses in the elderly.

In view of the modest age-related decline in telomere length in granulocytes, it seems unlikely that hematopoietic stem cells during normal hematopoiesis encounter irreversible cell cycle arrest or undergo apoptosis as a result of telomere shortening. Most likely, the total production of blood cells from a single hematopoietic stem cell is primarily determined by differentiation of stem and progenitor cells and not by replicative senescence. Furthermore, the occasional loss of individual stem cells via telomere shortening is not expected to impact on overall hematopoiesis (or overall telomere length in granulocytes) in the presence of a variable ‘reserve’ of additional hematopoietic stem cells. That normal hematopoietic stem cells and tissues have extensive replicative potential is also in agreement with extensive experience using allogeneic and autologous stem cell transplantation. Nevertheless, the telomere checkpoint does appear to operate in hematopoietic stem cells, as is indicated by the age-related loss of telomeres in granulocytes (Figure 13.3), the (modest) loss of telomeres following allogeneic transplantation,^{43,47} and the aplastic anemia that follows partial telomerase deficiency.² Recent studies have shown that the number of hematopoietic stem cells can be altered by manipulating decisions that control self-renewal and differentiation.⁴⁸ Indeed, the number of mature ‘end’ cells such as granulocytes produced by individual stem cells is most likely highly variable and primarily determined by the processes that regulate self-renewal versus differentiation at the level of individual stem

cells. Even a limited number of additional self-renewal divisions in a stem cell will greatly increase cell output. As a result, individual stem cells can produce staggering numbers of cells. This is illustrated in clonal proliferative disorders such as paroxysmal nocturnal hemoglobinuria (PNH) and CML. However, even in CML, clonally expanded Philadelphia-positive stem cells eventually appear to encounter the telomere checkpoint.⁴⁹ Unfortunately, with a large number of cells to select from, the genetic instability triggered by the loss of functional telomeres appears to favor the selection of a subclone with additional genetic abnormalities and more malignant properties.

Not all cells in the hematopoietic system are programmed to encounter the telomere checkpoint. B cells appear to be a particularly interesting exception, as the telomere length in B cells is increasingly heterogenous with age (Figure 13.4). Apparently, some B cells express sufficient telomerase (and presumably other factors) to effectively elongate telomeres. Perhaps the many cell divisions required for effective selection, 'affinity maturation', and maintenance of antibody responses favored inactivation of the telomere checkpoint. It is tempting to speculate that B cells are, as a result, at a higher risk for tumor development,

Figure 13.4 Telomere length analysis in subpopulation of human nucleated blood cells using flow FISH (GM Baerlocher and PM Lansdorp, unpublished observations). For this type of analysis, nucleated blood cells following red cell lysis are hybridized with a fluorescently labeled telomere probe together with fixed cow thymocytes (with long telomeres: vertical bars, left panels) as internal controls. Following wash steps to remove unlabeled probe and incubation with labeled antibodies (e.g. phycoerythrin-labeled anti-CD20: right panels) the cells are analyzed by flow cytometry. Note the decline in telomere fluorescence (on a linear scale) with age in both granulocytes (with high side-scatter: left panels) and lymphocytes (low side-scatter, increased heterogeneity with age: left panels) and the presence of some CD20⁺ B cells with very long telomeres in the 90-year-old normal donor.

which could explain the much higher incidence of B versus T-cell lymphomas in the human population.

Conclusions

Based on observations from several areas, telomeres have emerged as important regulatory elements that control the number of times normal human somatic cells can divide. Activation of the telomere checkpoint results from loss of telomeric DNA with replication and from oxidative damage to telomeric DNA (Figure 13.2). The DNA damage response that is triggered by activation of the telomere checkpoint can be resolved by telomere elongation pathways that involve telomerase or recombination. However, in most somatic cells, including hematopoietic stem cells, the capacity of such telomere repair pathways appears to be limiting, and telomere shortening effectively limits the proliferative potential of such cells. Most likely, the telomere checkpoint evolved as a tumor suppressor mechanism in long-lived species. The function of the telomere checkpoint may help explain poorly understood aspects of stem cell biology, including stem cell 'exhaustion' in aplastic anemia and other proliferative disorders. Cells may bypass the telomere checkpoint by expressing high levels of telomerase or by inactivating downstream signaling events, for example by loss of p53 function. Some cells, including subsets of B cells, may avoid the telomere checkpoints altogether, and high levels of telomerase could make such B cells more vulnerable to tumor development. Loss of p53 function also inactivates the telomere checkpoint. This is expected to be a rare event, as both copies of the normal *p53* allele in a cell must typically be lost or mutated in order to continue proliferation in the presence of many short and dysfunctional telomeres.³ Loss of p53 function results in chromosome fusions and breakage that drive genetic instability and facilitate malignant progression. This is illustrated in CML, where the onset of blast crisis and additional genetic changes is inversely correlated with the length of telomeres in Philadelphia-positive chronic-phase cells.⁴⁹

Angiogenesis and tumor development

William T Bellamy

Introduction

Angiogenesis, the formation of new blood vessels from an existing vascular network, is distinguished from vasculogenesis, a process that occurs during the developmental period. Angiogenesis plays a central role in both physiologic processes and pathologic disorders. Under normal conditions, it is a complex process regulated through interactions between endothelial cells, growth factors and cytokines, and the extracellular matrix.¹⁻⁶ Physiologic angiogenesis is characterized by a very tightly controlled balance between angiogenic growth factors and inhibitors, and occurs during the monthly reproductive cycle to generate the endometrium, to form the corpus luteum, and during pregnancy to build the placenta.¹ Angiogenesis also occurs following tissue injury and is key to proper wound healing. In pathologic disorders such as diabetic retinopathies, rheumatoid arthritis, and cancer, there is an uncontrolled proliferation of vessels that subsequently develop in a disorganized manner.¹⁻⁶ Tumors produce large amounts of angiogenic growth factors that act to upset the normally well-controlled balance between pro- and anti-angiogenic factors, thus stimulating the proliferation of new vessels. It has now become well established that the viability and growth of tumors is dependent on this process. When solid tumors such as lung, breast, and colon cancers are less than 2 mm³ in size, all cells within the tumor mass can receive required nutrients and oxygen through diffusion; however, for these tumors to grow further, there is a strict requirement for a vascular supply, provided through the process of angiogenesis. Clinical studies have demonstrated that both the number and density of microvessels in several different human cancers directly correlate with invasion and metastasis and predict for an unfavorable prognosis.⁷⁻¹¹ Such findings are consistent with the belief that angiogenesis is both an independent prognostic marker of outcome and a mechanistic target for therapy. While it is well established that the growth of solid tumors is dependent upon neovascularization, the role of angiogenesis in hematopoietic malignancies has only recently been appreciated (see below).

The angiogenic process

Both physiologic and pathologic angiogenesis, as mentioned above, are initiated by an imbalance between pro- and anti-angiogenic factors. The initiation of this process has been termed the 'angiogenic switch' and in tumors is associated with the activation of several proto-oncogenes, including *ras*, *src*, and others, as well as by inactivation of the tumor suppressor gene, *p53*.¹²⁻¹⁴ Once the angiogenic process begins, a number of well-orchestrated events begin to occur. First, under the influence of pro-angiogenic growth factors such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF, FGF-2), endothelial cells, which under normal circumstances are quiescent, begin to proliferate. There is an increase in vascular permeability, mediated by VEGF, allowing the release of fibrin into the interstitial space. The release of fibrin acts as a scaffold for the growth of the newly forming vessels. Proteolytic enzymes such as the matrix metalloproteinases (MMP) are produced to dissolve the basement membrane, thus facilitating vascular growth. Following the binding of the growth factor to its receptor located on the surface of the endothelial cell, a series of signaling pathways are activated. The endothelial cells begin to proliferate and migrate into the interstitial space along a chemotactic gradient towards the source of the angiogenic factor(s). Specific integrins are expressed on the vascular endothelium ($\alpha_v\beta_3$, $\alpha_v\beta_5$) and help to guide the vessels. Ultimately, the newly formed vascular sprouts will begin to roll up and form a tube. These vascular tubes then anastomose to form patent vessels. Smooth muscle cells and pericytes then provide structural support to stabilize the vascular network. When comparing physiologic and pathologic angiogenesis, there are significant differences.

Physiologic angiogenesis is self-limited temporally; once the immediate need is met, the balance between stimulators and inhibitors is restored and the process terminates. Evidence now suggests that physiologic angiogenesis may be regulated in a tissue-specific manner, with specific tissues employing unique angiogenic regulators.¹⁵ Frequently, tumor angiogenesis is uncontrolled and unlimited in time, and is characterized by a 30- to 40-fold increase in endothelial cell proliferation. In addition, there are morphologic differences in the vessels formed in tumor angiogenesis. Normal vasculature has a predominance of straight, non-branching microvessels, while in tumors, there is often a complex, tortuous architecture. Tumor vasculature has generally widened lumens, fewer associated smooth muscle cells and pericytes, irregular blood flow, regions of vascular stasis, and high permeability. Finally, in tumor-derived angiogenesis, there may be involvement of growth factors, such as placental growth factor (PlGF), that, while not critical for angiogenesis during development, clearly have the capacity to stimulate new vessel growth in the tumor.¹⁶

Tumor angiogenesis

Angiogenesis is a key component of cancer progression and metastasis.⁷⁻¹¹ It was not until 1971, when Folkman¹⁷ published his theory on tumor angiogenesis, that the concept of tumor-initiated angiogenesis was recognized. All tumors begin their existence as a small, avascular cluster of cells, growing above the basement membrane (carcinoma in situ). Tumors at this stage rely upon nearby blood vessels for oxygen and diffusion of nutrients. In the absence of angiogenesis, tumor growth would remain dormant at a size of only 2–3 mm³, with the size being limited by the diffusion of oxygen and nutrients. Progression from in situ tumors to invasive and metastatic solid tumors requires, and is correlated with, the formation of new microvessels. As the tumor accumulates additional genetic changes, a small percentage of the tumor cells gain the ability to express genes encoding angiogenic growth factors. This theory was initially met with much skepticism, but has now been recognized as a cornerstone of tumor growth. It is now established that angiogenesis is not only essential for tumor growth but is also implicated in the initial progression from a premalignant tumor to a cancer,^{3,13} invasion of the cancer cells into the circulation,¹⁸ and growth of dormant micrometastases into frank metastatic lesions.¹⁹ As a component of tumor growth, inflammatory cells that infiltrate the tumor also produce and release angiogenic growth factors and thus help stimulate the growth and spread of the tumor.^{5,20}

Angiogenic factors

Angiogenesis is influenced by a number of positive and negative regulatory factors. Soluble molecules (e.g. growth factors), non-cellular constituents of tissues (extracellular matrix), and peri-endothelial cellular elements (e.g. pericytes) contribute to the character and extent of vessel growth.⁴⁻⁶

The first recognized angiogenic growth factor, bFGF, was reported in 1984.²¹ This was followed in 1989 by the discovery of VEGF.²² It was soon realized that VEGF was identical to a molecule previously characterized as a mediator of vascular permeability, vascular permeability factor (VPF), discovered in 1979 by Dvorak.²³ Although angiogenesis is influenced by a number of regulatory factors, VEGF is a central player in this process. VEGF is a multifunctional cytokine commonly expressed by many tumors.²⁴⁻²⁶ In support of its role in tumor growth, levels of VEGF mRNA and protein expression correlate positively with malignant progression and poor outcome in numerous human tumors.²⁷⁻²⁹ Consistent with the notion of an angiogenic switch, VEGF expression is positively activated by both Ras- and Src-mediated oncogenic pathways.^{30,31} While it is presently unclear what fraction of neovascular growth can be attributed to VEGF as opposed to other polypeptides with angiogenic activity, a critical role of VEGF in tumor growth in vivo was demonstrated by Kim et al,³² who showed that the addition of neutralizing antibodies to VEGF resulted in a marked suppression of tumor growth in human tumor xenografts, thus providing the first direct evidence that tumor growth was VEGF-dependent.

In addition to its effects on vascular permeability, VEGF is a potent mitogen and survival factor for endothelial cells and promotes endothelial cell proliferation and survival. VEGF displays chemotactic effects on endothelial cells and increases the expression of proteolytic enzymes in endothelial cells involved in stromal degradation.²⁴ Its activity is mediated through interactions with high-affinity tyrosine kinase receptors. To date, three cell surface receptors have been identified that bind VEGF and its family members (reviewed in reference 4). All three consist of an extracellular domain with seven immunoglobulin-like loops, a transmembrane region, followed by a kinase domain that is divided into two parts by the insertion of a non-catalytic 100-amino-acid residue sequence. The first of these is known as VEGF receptor 1 (VEGFR1; also known as Flt1: Fms-like tyrosine kinase 1), and binds both VEGF-A, VEGF-B, and PlGF.⁴ In addition to its expression on vascular endothelial cells, VEGFR1 is also present on smooth muscle and monocytes.⁴ The role of VEGFR1 in pathologic angiogenesis is perplexing. In adult endothelial cells, VEGFR1 phos

phorylation has been difficult to demonstrate, thus leading most investigators to the belief that VEGFR2 (see below) is playing a dominant role in this process. However, evidence is beginning to emerge suggesting that VEGFR1 may indeed be playing an important role. Ribozymes targeting VEGFR1 mRNA are effective in halting angiogenesis.³³ Conversely, overexpression of PlGF, a VEGFR1-selective ligand, has been shown to stimulate tumor progression.³⁴ The second receptor, VEGFR2 (also known as Flk1 (fetal liver kinase) or KDR (kinase domain receptor)) binds VEGF as well as VEGF-C through VEGF-E.⁴ VEGFR3, the most recently described member of the VEGFR family, was previously designated Flt4. This receptor appears to be restricted predominantly to endothelial cells lining lymphatic channels, although it is functionally expressed in a certain subset of leukemic cells.^{4,35} Ligands for VEGFR3 include VEGF-C and VEGF-D.⁴ In addition to the three high-affinity VEGF receptors, an additional receptor that binds VEGF in an isoform-specific manner has been identified.³⁶ Neuropilin-1 (NP-1) belongs to the collapsing/semaphorin family of receptors that mediate neuronal cell guidance. In conjunction with VEGFR2, NP-1 binds specifically to sequences found in exon 7 and therefore binds VEGF₁₆₅ but not VEGF₁₂₁. Binding of VEGF₁₆₅ by NP-1 appears not to signal directly but rather acts to enhance VEGFR2-mediated chemotaxis,³⁶ as well as to enhance the survival of breast cancer cells.³⁷

In addition to bFGF and VEGF, other pro-angiogenic growth factors include platelet-derived growth factor (PDGF), transforming growth factor β (TGF- β), interleukin-8 (IL-8), the angiopoietins, and many others (Table 14.1). Negative factors that act to suppress angiogenesis include platelet factor 4 (PF4), thrombospondin-1, tissue inhibitors of metalloproteinases (TIMP), prolactin, angiostatin, endostatin, and interferon- α (IFN- α) (Table 14.2). An interesting phenomenon that has been demonstrated is the production of endogenous angiogenic inhibitors by the primary tumor. These inhibitors are believed to suppress the angiogenic growth of distant metastases.³⁸ Surgical removal of experimental primary tumors lowers the level of these endogenous inhibitors and thereby promotes metastatic growth, a phenomenon that mirrors clinical experience.

There is growing evidence that the level of circulating angiogenic factors may have significant prognostic value and other clinical implications in various human cancers. Circulating VEGF expression has been the most widely studied of the angiogenic factors, and is generally believed to be a good reflection of tumor angiogenic activity in various cancers. Numerous studies have demonstrated a strong correlation between elevated tumor expression of VEGF and advanced disease or poor prognosis in various cancers.³⁹

Interleukin-10
Platelet factor 4 (PF4)
Prolactin (16 kDa fragment)
Thrombospondin-1
Tissue inhibitors of metalloproteinases (TIMP)
Soluble Flt1 receptor
Soluble bFGF receptor
Vasostatin (fragment of calreticulin)

Angiogenesis and hematopoiesis

Human bone marrow is a heterogeneous mixture of various cell types, including hematopoietic stem cells, endothelial cells, osteoblasts, and other supporting elements. Cells within the marrow cavity form a continuous network in which stromal cells are interspersed with hematopoietic and endothelial progenitors. Hematopoiesis is regulated by several cytokines, including granulocyte and granulocyte—macrophage colony-stimulating factors (G-CSF and GM-CSF), IL-3, IL-4, IL-6, and IL-8.⁴⁰ Recent evidence suggests that the growth factors involved in angiogenesis also promote hematopoietic stem cell growth. bFGF has been shown to regulate hematopoiesis by acting on stromal cells, early and committed hematopoietic progenitors, and some mature blood cells.^{41,42}

A role for VEGF in embryonic hematopoiesis was suggested by results from knockout mice. The loss of a single *VEGF* allele results in embryonic lethality.⁴³ *VEGF*^{+/-} embryos were found to be devoid of most endothelial and hematopoietic cells in the blood island, the site of active hematopoiesis during early embryogenesis, and die around day 10 of embryonic development as a consequence of the absence of vascular structures. In the absence of VEGFR2, hemangioblasts fail to differentiate into endothelial cells,⁴⁴ while, in the absence of VEGFR1, the vascular defect is due to an increase in the number of hemangioblasts.⁴⁵ Such studies demonstrated the essential role of VEGF and its receptors during development.

With the discovery that, in the adult, VEGFR2 was expressed on a subset of multipotent human stem cells in the bone marrow and that VEGF was produced by hematopoietic stem cells in response to cytokine stimulation,⁴⁶⁻⁴⁸ there was a realization that VEGF plays a key role not only in angiogenesis but also in normal hematopoiesis. CD34⁺ VEGFR2⁺ progenitor cells display pluripotent activity, whereas CD34⁺ VEGFR2⁻ cells are committed progenitors.⁴⁸ Stimulation with VEGF has been shown to mobilize both endothelial precursors as well as hematopoietic stem cells.⁴⁹ Studies have demonstrated that tumor angiogenesis is associated with the recruitment of both of these cell types and that this recruitment of VEGF-responsive bone marrow-derived precursors is both necessary and sufficient for tumor angiogenesis.⁵⁰

Angiogenesis in hematologic tumors

While it is well established that growth in solid tumors is dependent on angiogenesis, the role of this process in hematologic tumors is not fully appreciated. Increased microvessel density has now been described in several hematologic malignancies, including multiple myeloma, B-cell non-Hodgkin lymphoma (NHL), myelodysplastic syndromes (MDS), and acute and chronic leukemias representing both lymphocytic and myeloid lineages. As discussed below, hematologic tumor cells are capable of producing several angiogenic growth factors, including VEGF, VEGF-C, and bFGF, as well as expressing receptors for these molecules (Tables 14.3 and 14.4). Thus, different angio-regulatory molecules may be operating in a given hematopoietic tumor. Such findings suggest that the angiogenic process is commonly activated in these malignancies and is likely playing a functional role. While these findings suggest a role for angiogenesis, they do not prove that these tumors are dependent on this process; the elevated microvessel densities that are observed may reflect an epiphenomenon secondary to the elevation of a variety of cytokines, including VEGF. If one considers the pro-survival role of VEGF, however, the elevation of such factors begins to become more evident. That said, there is also evidence to support a direct role for angiogenesis in many of these tumors. Direct inhibitors of vascular endothelial cells such as endostatin have been shown to prolong survival in these

diseases.^{51,52} The following is a brief overview of the involvement of angiogenesis in hematologic malignancies.

Multiple myeloma

Multiple myeloma (also known as plasma cell myeloma or simply as myeloma) is a B-cell neoplasia in which there is an accumulation of terminally differentiated B cells (plasma cells), primarily in the bone marrow. In most patients, the disease follows a course in which the plasma cells are predominantly in a non-proliferative phase in the bone marrow. This may be followed by an active phase in which a small percentage of proliferating tumor cells (usually <5%) may be detected among the predominantly non-proliferating plasma cells. Finally, there is a fulminant phase with an increase in the proliferating plasmablastic compartment and in which extramedullary disease may be observed.⁵³ The growth of myeloma cells in the bone marrow is subject to both autocrine and paracrine regulation, and malignant plasma cells secrete a number of cytokines that act on bone marrow stromal cells (Figure 14.1).

In myeloma patients, there is a strong correlation between increased angiogenesis, as measured by microvessel density and survival. The first report demonstrating a high correlation between increased bone marrow microvascular density, plasma cell labeling index (a measure of proliferative activity in myeloma), and disease activity in myeloma patients was published in 1994.⁵⁴ Subsequent studies have confirmed the prognostic value of bone marrow angiogenesis in myeloma.⁵⁵⁻⁶¹ (Table 14.5) The increased microvessel density in myeloma has been associated with elevated levels of angiogenic cytokines, such as bFGF and VEGF, as well as MMP-2, in addition to increased marrow levels of mast cells, which are known to secrete a variety of angiogenic factors.^{54,56,57,62-64}

Table 14.5 Bone marrow angiogenesis in plasma cell disorders^a

Group	Median MVD (per 400×field)	Angiogenesis grade (%)

Figure 14.1 Potential interaction in the bone marrow between tumor cells and bone marrow stromal cells. Tumor cells elaborate a variety of growth factors, including angiogenic cytokines that may act on the stromal cells to stimulate angiogenesis or the release of hematopoietic cytokines through a paracrine mechanism. In addition, subsets of tumor cells possess receptors for angiogenic growth factors such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), which may act on the cells in an autocrine manner to stimulate cell proliferation or mediate survival. PlGF, placental growth factor; PDGF, platelet-derived growth factor; IL-6, interleukin-6; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage CSF; ...R, ...receptor.

In addition to its potent angiogenic and pro-survival activities, VEGF has the potential to impact several key areas related to tumor growth and progression through autocrine- and paracrine-based mechanisms. Plasma cell expression of VEGF was observed in the bone marrow from 78% of myeloma patients,⁶² and elevated levels of VEGF in the bone marrow correlate with the stage of the disease.⁶⁴ While neither the VEGFR1 nor the VEGFR2 receptors were found to be expressed by malignant plasma cells, both were markedly elevated in the normal marrow myeloid and monocytic cells surrounding the tumors in these patients. Such a pattern of expression is consistent with a paracrine role of VEGF in myeloma, although an autocrine mechanism cannot be ruled out at present. In support of a paracrine role for VEGF in myeloma, elevated levels of IL-6 induce VEGF expression in endothelial cells,⁶⁵ and elevated VEGF levels, in turn, stimulate IL-6.^{62, 66}

Paracrine control mechanisms are increasingly recognized as being important for tumor growth. While the requirement of tumor-stromal interactions is well established in myeloma, the involvement of angiogenic factors, which act primarily on the stromal elements, is not fully appreciated. In myeloma, the stromal compartment is involved in interactions between the malignant plasma cells and the microenvironment of the bone marrow by means of cell-cell contact, adhesion molecules, and the release of cytokines.⁵³ Adhesion of myeloma cells to bone marrow stromal cells has been shown to upregulate VEGF secretion, mediated through VEGFR1, by marrow stromal cells as well as malignant plasma cells.^{67,68} In normal bone marrow as well as that of myeloma patients, endothelial cells are found in close contact with hematopoietic cells and have been demonstrated to produce IL-6, a key growth factor in myeloma.⁶⁶ Exposure of microvascular endothelial cells to VEGF results in increased expression of several growth factor cytokines, including IL-6.⁶²

The potential effects of VEGF in myeloma are not limited to the neoplastic plasma cell alone. Bone disease in myeloma is the most common presenting clinical symptom, resulting in pathologic fractures and bone pain.⁵³ This serious complication is due in part to increased bone resorption secondary to the activation of osteoclasts.⁶⁹ Numerous osteoclast-activating factors, including tumor necrosis factor α (TNF- α), IL-1 β , and IL-6, are released by myeloma cells directly or by the normal marrow cells in response to the myeloma cells.⁶⁹ Several studies have demonstrated that VEGF can directly or indirectly, through its stimulatory actions on TNF- α and IL-1 β , stimulate the activation of osteoclasts, thus contributing to the lytic lesions in myeloma.^{70,71}

Immunoassay of plasma cell extracts revealed significant higher levels of bFGF in patients with active myeloma than in those with smoldering myeloma or monoclonal gammopathy of undetermined significance (MGUS).⁵⁰ In vitro studies indicate that antibodies directed against bFGF inhibit the ability of

conditioned media from myeloma patients to stimulate angiogenesis in a CAM assay.⁵⁹ The association of the bFGF receptor syndecan-1 (CD138) in the growth and progression of myeloma and the occurrence of the translocation involving the *FGFR3* gene in myeloma provide additional evidence for the role of angiogenesis in the pathogenesis of this disease.^{72,73}

Considerable interest has been generated in targeting angiogenesis and angiogenic growth factors in myeloma and, by extension, other hematologic diseases. Thalidomide, an agent introduced to treat morning sickness in pregnant women, was marketed in Europe and Australia with disastrous consequences in the 1950s. The drug never completely disappeared, and its pariah status has recently begun to be lifted due to the recognition of its activity in several disease states, including cancer. Thalidomide undergoes rapid and spontaneous non-enzymatic hydrolytic cleavage at physiologic pH to generate up to 50 metabolites, some of which possess anti-angiogenic activity.⁷⁴ In experimental systems, thalidomide has been shown to inhibit angiogenesis induced by bFGF and VEGF.^{75,76} Results of thalidomide use in myeloma are particularly promising, with thalidomide demonstrated to be beneficial in approximately one-third of patients with refractory disease, both as a single agent and in combination therapies.^{58,77–82} Serial measurements of bone marrow microvessel density, however, have failed to reveal a consistent reduction among responders.⁵⁸ In addition, plasma levels of bFGF, VEGF, IL-6, and TNF- α do not appear to change appreciably in patients responding to thalidomide,⁸³ thus raising questions related to its mechanism of action in myeloma.

Although its anti-angiogenic effects are believed to contribute to its antimyeloma activity, thalidomide has additional effects on the cell, including inhibition of TNF- α , stimulating cytotoxic T-cell proliferation and increasing the secretion of IFN- γ and IL-2, induction of cytokine production by type 2 T helper cells, inhibition of cytokine production by type 1 T helper cells, and regulation of adhesion molecule expression. There also appears to be a direct effect on the myeloma cell and/or bone marrow stromal cell to inhibit tumor growth and survival (reviewed in reference 74).

Currently, thalidomide analogs are being examined for their efficacy and safety in myeloma patients. The first of these to reach clinical trials is CC-5013 (Revimid). As a class, these IMiDs are more potent than thalidomide at inhibiting TNF- α production and have been shown to induce apoptosis via a caspase-8-mediated mechanism in both myeloma cell lines and patient-derived material.⁸⁴ IMiDs have also been shown to target the bone marrow microenvironment by enhancing the production of IL-2 and IFN- γ relative to that achieved following treatment with thalidomide.⁸⁵

Additional agents with anti-angiogenic properties are being assessed in myeloma, and include the proteasome inhibitor PS-341, the humanized anti-VEGF antibody bevacizumab, and several small-molecule receptor tyrosine kinase inhibitors of the VEGF pathway such as SU-5416 (Table 14.6).

Acute myeloid leukemia

Acute myeloid leukemia (AML) is characterized by an accumulation of immature myeloid blasts in the bone marrow, finally resulting in disturbed production of normal hematopoietic cells. Different mechanisms have been recognized that contribute to the growth

Table 14.6 Anti-angiogenic agents in clinical trials in hematologic malignancies^a

Agent	Mechanism	Status
PTK787/ZK2284	Small-molecule inhibitor of VEGF and PDGF receptors	Phase I
SU6668	Small-molecule inhibitor of VEGF, FGF, and PDGF receptors	Phase I/II
2-Methoxyestradiol	Inhibition of endothelial cells	Phase I/II
Prinomastat (AG3340)	Synthetic MMP inhibitor	Phase II
Neovastat	Natural MMP inhibitor	Phase II
Bevacizumab (Avastin)	Humanized anti-VEGF antibody	Phase II
PS-341	Proteasome inhibitor	Phase II
CC-5013 (Revimid)	Immunomodulatory thalidomide analog	Phase II
Interferon- α	Inhibition of bFGF and VEGF production	Phase II/III
Thalidomide	Unknown	Phase II/III

^aFor a complete listing of angiogenesis inhibitors in clinical trials, the reader is referred to the website http://www.cancer.gov/clinical_trials/.

advantage of the leukemic progenitor cell. It has been demonstrated that AML cells can produce growth factors, including IL-1, IL-6, and GM-CSF, that act in an autocrine or paracrine manner, leading to spontaneous *in vitro* proliferation of AML cells and making them less susceptible to programmed cell death (apoptosis).

Microvessel density in AML was found to be significantly greater in leukemic bone marrow biopsy samples from untreated patients than in those from normal patient controls.⁸⁶ Following successful induction therapy, the microvessel density was shown to decrease by approximately 60% in one of these studies.⁸⁷ Additional studies have also demonstrated increased angiogenesis in AML.^{88,89} Elevated VEGF levels displayed a positive correlation with both shorter overall and disease-free survival times, and proved to be an independent predictor of outcome in AML patients with high white blood cell and blast counts.⁹⁰ Interestingly, cellular VEGF levels were found to be significantly lower in one study of pediatric AML patients compared with adult AML patients, while there was no difference in VEGFR2 levels.⁹¹ Similar to adult AML, higher VEGF and VEGFR2 levels in pediatric patients correlated with higher white blood cell counts, but, unlike the adult situation, VEGF and VEGFR-2 expression did not correlate with survival.⁹¹ A more recent study produced contradictory results, demonstrating that VEGF expression was an independent prognostic variable in pediatric AML.⁹² VEGF-stimulated endothelial cells secrete different growth factors, such as GM-CSF, G-CSF, IL-6, and macrophage colony-stimulating factor (M-CSF), that affect AML cell behavior.^{62,93}

Overexpression and secretion of VEGF in approximately 70% of AML specimens has been reported in conjunction with a corresponding expression of the VEGFR1 and VEGFR2 receptors in AML blasts in approximately 50% and 20% of cases, respectively.⁹³ The presence of VEGFR1 and VEGFR2 on many of these cells raises the question whether VEGF acts to stimulate the cells in an autocrine manner. Using VEGFR⁺ cells derived from AML patients, a functional autocrine mechanism has been established.⁹⁴ With the identification of an autocrine mechanism operating in diseases such as AML, the possibility exists that overexpression of angiogenic factors in leukemias may serve two purposes. First, factors such as VEGF could promote the growth and proliferation of hematopoietic cells through direct effects. Second, they could activate pathways related to leukemic cell survival. The first suggestion that VEGF acted as a survival factor came from studies in which it was demonstrated that VEGF reduced apoptotic cell death in normal hematopoietic stem cells and tumor cell lines following exposure to ionizing radiation or chemotherapeutic agents,^{95,96} in part by inducing the expression of the anti-apoptotic gene *mcl-1*. More recently, it has been shown that VEGF promotes survival of endothelial cells by increasing Bcl-2 levels.⁹⁷ VEGF stimulation has also been demonstrated to increase levels of heat-shock protein 90 (Hsp90), a molecule observed to mediate anti-apoptotic and survival-promoting effects of VEGF via activation of the MAPK cascade. Elevated Hsp90 levels also serve to increase the expression of Bcl-2 and are thus likely contribute to the survival advantage of VEGFR⁺ leukemia subsets.⁹⁸ VEGF-C is secreted from endothelial cells in response to stimulation with bFGF or IL-1.³⁵ Expression of its specific receptor, VEGFR3, has been demonstrated in a subset of leukemic cells that, when stimulated by VEGF-C, promoted increased leukemia survival and proliferation.³⁵ The improvement in survival was apparently due to an increased Bcl-2/Bax ratio and served to protect the leukemic cells from the apoptotic effects of several cytotoxic chemotherapeutic agents.

Other angiogenic molecules reported in AML include the matrix metalloproteinases (MMP). These are a family of zinc- and calcium-dependent endopeptidases that are able to degrade extracellular matrix components. The action of MMP is counteracted by the interaction with tissue inhibitors of MMP (TIMP). Metalloproteinase-2 (MMP-2) and MMP-9 efficiently degrade native collagen types IV and V, fibronectin, and elastin to facilitate the invasion of interstitial stroma by endothelial cells.⁹⁹ MMP-2 secretion is frequently found in AML cells, but not in normal hematopoietic progenitor cells.¹⁰⁰ In contrast, MMP-9 is expressed in AML cells, normal mononuclear cells, and CD34⁺ cells.^{100,101}

As in myeloma, there is an interest in targeting angiogenesis in AML. A phase I/II dose-escalating trial of thalidomide was performed to study its safety and efficacy in patients with AML.¹⁰² A total of 20 patients, including 10 with secondary AML defined as a history of myelodysplasia, other antecedent hematologic disorders, or previous exposure to cytostatic drugs or radiotherapy, were entered into the study. Of 13 patients receiving thalidomide for longer than 4 weeks, 4 achieved a partial response. VEGF plasma levels decreased in 3 of the responders, whereas an increase was observed in 5 of 6 non-responders. In contrast to findings with thalidomide in myeloma, microvessel densities decreased significantly in the responding patients. More recently, several reports have documented inhibitory effects by small-molecule inhibitors targeting VEGFR1 and VEGFR2, such as SU5416, on the growth of a human myeloid leukemia cell line and in AML blasts, independently from their effects on angiogenesis.^{103–105}

Acute lymphoblastic leukemia

A correlation between angiogenesis and bFGF levels has been found in acute lymphoblastic leukemia

(ALL).¹⁰⁶ In this study of childhood ALL, there was a significant increase in the microvessel density as well as serum and urinary bFGF at diagnosis compared with a controlled group of non-leukemic patients without marrow involvement. Additional studies have demonstrated the expression of both VEGF and VEGFR1 in human ALL cell lines, thus raising the possibility that it may be playing a role in certain cases.⁶²

Chronic myelogenous leukemia

Chronic myelogenous leukemia (CML) is a clonal myeloproliferative disorder resulting from the *BCR-ABL* fusion oncogene.¹⁰⁷ As with the acute leukemias, increased angiogenesis, as evidenced by increased microvessel density, has been reported in the chronic leukemias. The bone marrow microvessel density in patients with CML is approximately twice that of controls and correlates with production of VEGF in these patients.^{108,109} CML is among the diseases with the largest number of bone marrow vessels, and it came top of the list when the relative areas of vascular beds in the bone marrow of various diseases were calculated. While high VEGF levels have been demonstrated to correlate with shorter survival of patients in chronic CML, the impact of VEGF expression on the course of chronic CML is unknown and no significant differences have been observed in VEGF levels based on the phase of the disease.¹¹⁰

Murine cells transfected with *BCR-ABL* constructs have been shown to secrete a variety of angiogenic factors, including VEGF, bFGF, IL-8, and MMP-2 and -9 and to stimulate angiogenesis in in vitro models.¹¹¹ Myeloblasts from the bone marrow of Philadelphia-positive CML patients secreted up to 10 times more VEGF, bFGF, and IL-8 as compared with myeloblasts obtained from normal donors.¹¹¹ In addition, peripheral blood mononuclear cells isolated from CML patients expressed both MMP-2 and MMP-9.

Chronic lymphocytic leukemia

Bone marrow MVD from patients with B-cell chronic lymphocytic leukemia (CLL) was significantly increased when compared with normal bone marrows,¹¹² and correlated with the clinical stage. Increased intracellular levels of VEGF and expression of VEGFR2 correlated with a poor prognosis in patients with CLL.^{113–115}

In addition to VEGF, increased intracellular, urinary, and plasma levels of bFGF have been reported in CLL and have been shown to correlate with disease stage.^{112,113,116,117} Mechanistically, increased intracellular bFGF levels have been demonstrated to increase the expression of Bcl-2, thereby augmenting apoptotic resistance.¹¹⁸

While it has now been well established that B-CLL cells produce several pro-angiogenic factors, it has also been demonstrated that they are capable of producing and secreting several anti-angiogenic molecules, including endostatin, IFN- α , and thrombospondin-1.¹¹⁷ The significance of this finding is unclear, but it is interesting to speculate that it might be related to the angiogenic switch that occurs in hematologic tumors just as it does in solid tumors. Mutations in *p53* are fairly common in advanced CLL and are known to downregulate thrombospondin-1.¹¹⁹

Myelodysplasia

Myelodysplastic syndromes (MDS) are preleukemic disorders, particularly in patients who present with measurable leukemia burden or unfavorable karyotype. Ineffective hematopoiesis, the hallmark of MDS, arises from underlying genetic aberrations leading to alterations in cytokine regulation and response to cytokines, with a consequent increased apoptosis of hematopoietic progenitor cells and aberrant hematopoiesis.¹²⁰ Generally 35–40% of MDS cases transform to AML, and most patients die from infection or bleeding.¹²⁰

The microvessel density has been found to be significantly greater in patients with advanced MDS, including those with refractory anemia with excess blasts in transformation (RAEB-t) or chronic myelomonocytic leukemia (CMML) compared with refractory anemia with excess blasts (RAEB), refractory anemia (RA), or refractory anemia with ring sideroblasts (RARS).¹²¹ Following successful induction chemotherapy, the microvessel density has been demonstrated to decrease significantly.⁸⁷

Cytologically, VEGF is expressed by immature myeloid elements, particularly leukemic monocytoid precursors, but not erythroid elements or lymphocytes (Figure 14.2).⁹⁴ Increased expression of VEGF in MDS appears to correlate with the high frequency of *ras* proto-oncogene activation found in these tumors, which is known to induce *VEGF* gene expression. Foci of abnormal localization of immature precursors (ALIP) often indicate transformation to a higher grade of MDS. These foci of myelomonocytic precursors coexpress VEGF and VEGFR1, suggesting the possibility of an autocrine mechanism. Support for this was derived from VEGF neutralization studies that were shown to suppress leukemia progenitor formation in a concentration-dependent manner, whereas recombinant human (rHu)VEGF promoted the growth of leukemia colonies.⁹⁴ rHuVEGF promoted in vitro expansion of myeloid progenitors while inhibiting the formation of erythroid bursts and multipotent progenitors; thus, excessive local elaboration of VEGF may accelerate apoptotic death of receptor-naive erythroid progenitors.⁹⁴ VEGF neutralization also suppressed the concentrations of TNF- α and IL-1 β in

Figure 14.2 Immunohistochemical staining for vascular endothelial factor (VEGF) in the bone marrow of a patient with MDS. VEGF was expressed in a diffuse cytoplasmic pattern predominantly in the myeloid and monocytic precursors. (400×magnification)

supernatants from control bone marrow mononuclear cultures, whereas the addition of rHuVEGF resulted in increased levels of these cytokines, thereby suggesting an additional mechanism where non-VEGFR-expressing cells may also be affected.

MDS have few therapeutic options, none of which is curative, particularly if hematopoietic stem cell transplantation is not an option.¹²² As in other hematologic malignancies, there is an increased interest in therapies directed against angiogenesis in MDS. In several clinical trials examining the use of thalidomide in MDS patients, responses have been reported.^{123–125} Although no complete responses have been described, there has been marked hematologic improvement, particularly in the erythroid series, with several previously transfusion-dependent patients becoming transfusion-independent. As in myeloma, it is unclear whether the reduction in blast cells that is observed in the bone marrow of high-risk MDS patients is attributable to a cytotoxic effect of thalidomide on the malignant cells or to a modulation of their interaction with the bone marrow microenvironment.

Lymphomas

Elevated levels of angiogenesis and angiogenic growth factors are also associated with adverse prognosis in patients with non-Hodgkin lymphoma (NHL). Excessive angiogenesis has been shown in lymph nodes of patients with hyperplastic and dysplastic B-cell disorders, such as Castleman's disease.¹²⁶ In a study of 88 patients with B-cell NHL representing mixed subtypes, there was an increase in the microvessel density in lymph nodes that correlated with the severity of the disease, increasing from low-grade to high-grade subtypes (i.e. follicular versus diffuse large cell; Figure 14.3).¹²⁷ Increased angiogenesis, as reflected by microvessel density, has also been described in T-cell lymphomas such as mycosis fungoides.¹²⁸

VEGF has been implicated in the overall course of this disease, however. Elevated levels of both VEGF and bFGF have been reported in NHL and are associated with an adverse prognosis, with those patients having elevated levels of both growth factors in the highest-risk group.¹²⁹ VEGF is expressed in the tumor vasculature as well as in the malignant cells in the majority of NHL patient samples studied to date. The expression of VEGF and its receptors was related to tumor grade, with a higher percentage of VEGF-positive cells in the intermediate/high-grade group than in low-grade lymphomas. These findings were in contrast to reactive lymphoid tissues, where there was an absence of VEGF expression in normal lymphocytes. In addition

Figure 14.3 CD31-related antigen staining of vasculature in non-Hodgkin lymphoma. (a) A case of follicular lymphoma demonstrating staining primarily limited to the perifollicular areas, (b) Large cell lymphoma demonstrating a diffuse pattern of vascular staining. (40×magnification)

to VEGF expression, the neoplastic lymphocytes from both low-grade and high-grade lymphomas were found to express VEGFR1 and VEGFR2, with VEGFR1 being observed more frequently but VEGFR2 being expressed solely in the higher-grade tumors. In another series of NHL patients, VEGF was expressed in 96% of cases.¹³⁰ Both hypoxia-inducible factors 1 α and 2 α were only weakly expressed in these cases, suggesting that VEGF expression may not be hypoxically driven in the setting of NHL. Expression of the anti-apoptotic factor MCL1 correlated with VEGF expression and was found to be elevated in patients with progressive NHL as compared with those achieving a complete remission.¹³¹ VEGF expression has also been demonstrated in Hodgkin lymphoma, where it was found to be expressed in the Reed-Sternberg cells.¹³² Although there was expression of VEGF in the tumor cells, there was no correlation between VEGF expression and the subtype of Hodgkin lymphoma or with microvessel density. Immunohistochemical detection of bFGF and its receptor FGFR1 has also been demonstrated in patients with NHL, but the expression did not correlate with either serum bFGF levels or microvascular densities.¹³³ Patients whose tumors expressed bFGF did, however, have a poor prognosis.

Serum levels of both VEGF and bFGF are elevated in NHL and correlate with high-grade disease and poor prognosis.^{129,134} The highest prognostic power was observed when VEGF and serum bFGF levels were examined in combination. The risk of death in patients whose VEGF and bFGF levels were both within the highest quartiles was nearly three times greater than it was for other patients.¹²⁹

Evidence for a functional role of VEGFR2 during lymphoma growth was provided by experiments studying the effects of a function-blocking antibody for VEGFR2 that has been demonstrated to inhibit proliferation in mice bearing human tumors.¹³⁵ Based on such findings, inhibition of VEGF or signaling by VEGFR1 and VEGFR2 may be effective in the treatment of hematologic malignancies, since it potentially interferes with both hallmarks of tumor growth—angiogenesis and tumor cell proliferation. Mantle cell lymphoma, an aggressive subtype of NHL, has been reported to respond to single-agent thalidomide.¹³⁶ Clinical trials are currently underway examining the efficacy of a humanized anti-VEGF antibody, bevacizumab, in refractory NHL.

Conclusions

Numerous studies have now established the presence of elevated angiogenesis and the expression of a variety of angiogenic growth factors in hematopoietic malignancies, suggesting a role in the pathobiology of these diseases. There is increasing evidence that angiogenic growth factors play a role in hematologic malignancies. Production of these factors by malignant hematopoietic cells may serve as both an autocrine growth stimulus and a diffusible paracrine signal mediating the local generation of growth factors that foster tumor survival and self-renewal. Adding support to the hypothesis that angiogenic factors are playing a functional role in these tumors are the recent reports that thalidomide has been demonstrated to be effective in patients with refractory myeloma and other hematologic diseases. Although the mechanism responsible for such efficacy remains to be established, thalidomide has been demonstrated to possess anti-angiogenic activity. The presence of tumor angiogenesis and the elevated expression of angiogenic growth factors thus suggest new targets for therapeutic intervention in these disorders, and the initiation of clinical trials to assess anti-angiogenic therapies is well underway.

Lymphoproliferations associated with human T-cell leukemia/lymphoma virus type 1 or 2 infection

Renaud Mahieux and Antoine Gessain

Introduction

Since the early discovery of leukemia/sarcoma avian retroviruses by Ellerman and Bang in 1908, a long period had elapsed, covering most of the 20th century, with a succession of ups and downs for oncogenic viruses. In 1980, after 70 years of search, the first human oncoretrovirus (human T-cell leukemia/lymphoma type 1 or HTLV-1) was isolated by the group of Gallo,¹ and soon after independently, by Japanese researchers, in a sample of a rare and peculiar T-cell leukemia (named adult T-cell leukemia/lymphoma [ATLL]) that had been uncovered in Japan in 1977.^{2,3}

Exogenous retroviruses (i.e. viruses that are transmitted horizontally) naturally cause leukemias in many animal out-bred species such as cats, cattle, gibbon, mice etc. These exogenous viruses do not contain an oncogene per se, i.e. a gene that encodes for a protein that is directly involved in cellular transformation. In humans, three families of exogenous retroviruses (i.e. oncoretroviruses, lentiviruses and spumaviruses) have been described. Of these, the spumaviruses have not yet been linked to any pathology. In contrast, oncoretroviruses (such as HTLV-1 and HTLV-2) and lentiviruses (human immunodeficiency virus [HIV]-1 and HIV-2) have been strongly associated with lymphoid malignancies. With respect to HIVs, there is no evidence that any of the proteins that are encoded by HIV-1 or HIV-2 can directly cause any human lymphoid neoplasia. The frequent B-cell lymphomas that are observed in acquired immune deficiency syndrome (AIDS) patients seem most likely, at least for a large part of them, to result from the reactivation of latent viruses such as Epstein—Barr virus. Similarly, a probable reactivation of human herpesvirus 8 is linked to the development of Kaposi sarcoma and primary effusion lymphomas in HIV-infected patients. In fact, HTLV-1 remains at this time the only human retrovirus that is the etiological agent of a human leukemia or of a lymphoma. However, even in that case, a number of other events have to occur, usually over a long latency period, before cancer will develop. By contrast, HTLV-2, the second human retrovirus to be isolated, has not yet been conclusively associated with any malignant lymphoproliferation.

In this chapter, after a review on the molecular and epidemiological aspects of HTLV-1 and HTLV-2, it will present the current knowledge of the clinical, epidemiological, viromolecular and therapeutic characteristics of ATLL that is associated with HTLV-1 infection. This chapter will also discuss the controversial association of HTLV-1 or of a related virus with some cutaneous T-cell lymphomas such as mycosis fungoides (MF) and Sézary syndrome. Finally, data regarding the possible association of HTLV-2 and rare CD8 lymphoproliferative disorders will be briefly presented.

HTLV-1: A human oncogenic retrovirus

Epidemiology and associated diseases

HTLV-1 infection was found to be endemic, in the south western islands of the Nippon Archipelago (Kyushu-Shikoku), then in large parts of the Caribbean area, in intertropical Africa, Central and South America, and in some restricted areas of the Middle East and Melanesia (reviewed in^{4,5}). It is estimated that HTLV-1 infects 15–20 million individuals throughout the world. The HTLV-1 antibody prevalence rate varies from 0.2–10% among adults, depending on the geographical area. Furthermore, significant variations in prevalence exist in endemic

areas, with a puzzling micro-epidemiology associated to foci of high prevalence. In Japan, where nationwide surveys were carried out in the early 1980s, the prevalence rate in blood donors varied initially from 0.1–1% in central Japan, to 2–10% in the Kyushu island.⁶ Even there, foci of higher prevalence were observed. In this HTLV-1 endemic area, a female preponderance has been observed. The prevalence increases with age, reaching eventually 20–50% of the female population aged 60 and above.^{4,5}

The two major diseases associated with HTLV-1 (ATLL and tropical spastic paraparesis/HTLV-1-associated myelopathy [TSP/HAM]) are present in all the endemic areas^{1,7} (Table 15.1) with however significant differences in the incidence as well as prevalence. While the incidence of ATLL exhibits minor variations (1–5/100 000/year) in Japan, in the Caribbean area, and in South America,^{8–11} the incidence of TSP/HAM seems to be higher in the Caribbean islands and in some countries of South America than in Japan.

Three modes of contamination are known for HTLV-1, and via any of these routes, infected cells are essential for transmission:

1. Mother-to-child transmission,^{5,12,13} in which efficiency varies from 10–20% and which occurs after prolonged breast-feeding (with HTLV-1-infected milk lymphocytes), mainly after the baby is 6–9 months of age, i.e. when the protective IgG maternal antibodies decrease. In Japan, advice to HTLV-1-seropositive mothers not to breast-feed their babies led to a very significant decrease in mother-to-child transmission of the virus with however, for yet unknown reasons, inconsistent results according to areas. The excess of non-Hodgkin T-cell lymphomas (T-NHL—corresponding to the lymphoma type of ATLL), observed among adults in the Caribbean, especially in Jamaica, appears to be directly related to the HTLV-1 infection, and more specifically to an early infection.^{9,14} Though, the prevention of HTLV-1 vertical transmission could result in a 70–80% reduction in such HTLV-1-associated T-NHL among infected adults in high HTLV-1 endemic areas.
2. HTLV-1 is also sexually transmitted.⁹ Japanese studies clearly demonstrated higher transmission efficiency from male to female than from female to male. Such differences might account for the increase in the HTLV-1 seroprevalence with age that is observed in females.
3. The intravenous route of infection, mainly by blood transfusion, appears to be the most efficient mode for HTLV-1 transmission. This risk was estimated to reach 15–60% after the transfusion of a tainted lymphoid cellular blood product. Contamination through blood is associated with a

Table 15.1 Diseases associated with HTLV-1 infection*

Adult disease	Association

specific risk of developing TSP/HAM.¹⁵ By contrast, the risk of developing ATLL after acquiring HTLV-1 through blood transfusion seems extremely rare. For these reasons, the screening of the blood donations was implemented in Japan, starting in 1986, in French Caribbean in 1989, in the USA in 1989, in Canada in 1990, in France in 1991, and in Denmark and the Netherlands in 1994.¹⁶

Cellular tropism and viral receptor

While HTLV-1 can infect several different cell types of various origin in vitro, it has been thought for long to preferentially infect CD4⁺ lymphoid cells in vivo. However, some data also indicated that CD8⁺ cells constitute an additional in vivo reservoir for the virus.¹⁷ Recent reports have brought new insights on the HTLV receptor.^{18,19} These authors first reported that quiescent CD4 and CD8 T lymphocytes did not express the HTLV receptor and that the HTLV receptor was an early activation marker in neonatal and adult T lymphocytes, detected as early as 4 h following T-cell receptor (TCR) stimulation. Finally, after 20 years of intensive scrutiny, an HTLV-1 receptor was identified and reported to be the ubiquitous glucose transporter Glut-1.²⁰ Glut-1 is also a receptor for HTLV-2.

Molecular biology

Genetic organization

As members of the oncoviridae subfamily, the HTLVs (Figure 15.1), together with the BLV, and STLV represent a group (delta-type retroviruses) that is distinct from avian and murine oncoretroviruses. They do not harbor oncogene sequences of cellular origin, but rather specific genes encoding regulatory proteins (Tax and Rex), that regulate the viral replication and interact with the host cell machinery.^{21,22}

The genetic organization of HTLV-1 is shown on Figure 15.2. The HTLV-1 genome encodes three major (structural/enzymatic) proteins, i.e. Gag, Pol and Env, whose genes are flanked by the long terminal repeat (LTR). The HTLV-1 LTR, which contains several regulatory elements, is divided into three regions: U3, R and U5. U3 contains the polyadenylation signal, the TATA box and the 3 Tax responsive elements (TREs). R contains the transcription initiation site and the Rex responsive element (RRE). In addition to these structural and enzymatic genes, a region referred to as the X region is present at the 3' end of the genome.

Like in other retroviruses, the *gag* gene is translated from the full length RNA to yield a precursor polyprotein (Pr53) that is subsequently cleaved by the viral protease to yield the matrix (p19), the capsid (p24) and the nucleocapsid (p15). The protease is in a frame distinct from *gag* and its synthesis is accomplished with a ribosomal frameshift. A second ribosomal

Figure 15.1 Type C retroviral particles in the extracellular spaces of a CD4⁺ lymphoid cell line infected by HTLV-1. The cell line has been established from the long-term culture, in presence of interleukin 2, of the peripheral blood lymphocytes obtained from a patient with a TSP/HAM.

frameshift event is necessary to express the *pol* gene. The *env* gene encodes two envelope glycoproteins: the surface glycoprotein (gp46) and the transmembrane glycoprotein (gp21), which are themselves cleaved by cellular proteases from a larger precursor.²³ The X region located at the 3' end of the genome contains at least four open reading frames (ORFs). The ORFs III and IV are transcribed through a single polycistronic doubly spliced mRNA. These ORFs encode two major regulatory proteins: Tax and Rex. The Rex protein acts at the post-transcriptional level to regulate viral gene expression. It increases the expression of viral structural and enzymatic protein by facilitating the shuttling from the nucleus to the cytoplasm of unspliced mRNAs coding for Gag, Pol and Env proteins.²⁴

Using reverse transcriptase/polymerase chain reaction (PCR), alternatively spliced mRNAs coding for the ORF I and II of the pX region have also been discovered (for a review, see ²⁵). These mRNAs encode three proteins named p12^I, p13II and p30II. The p12^I is a proline- and leucine-rich hydrophobic protein of 99 amino acids, which is localized in the cellular endomembranes and bears structural and functional analogies with the E5 oncoprotein of the bovine papilloma virus. p12^I interacts specifically with the interleukine-2 receptor β and γ chains, but not with the α chain. It enhances STAT5 activation, suggesting its possible involvement in the mechanism of T-cell transformation. p12^I also binds calcineurin and modulates NFAT activation to promote early virus infection of T lymphocytes.²⁶

The functions of the p13II and p30II are also under intense examination. Recent reports suggest that p13II might alter mitochondrial permeability and morphology without however inducing apoptosis. p13II acts as a negative regulator of cell growth and underscores a link between mitochondria, Ca(2⁺) signaling, and tumorigenicity.²⁷

The role of p30II is more controversial. Some authors reported that the protein can be viewed as a factor that activates transcriptions from the HTLV LTR when expressed at low levels, while it would repress the same promoter when highly expressed.²⁸ These results were not confirmed by others.²⁹ p30II also binds to, and retains in the nucleus, the doubly spliced mRNA encoding the Tax and Rex proteins. Because Tax and Rex are positive regulators of viral gene expression, their inhibition by p30II reduces virion production. p30(II) inhibits virus expression by reducing Tax and Rex protein expression.

Tax protein and its role in leukemogenesis

Tax is a 40-kDa phosphoprotein that can be detected both in the cytoplasm and nucleus of the cells, depending on the cell line used for the transfection. Several lines of evidence have demonstrated a central

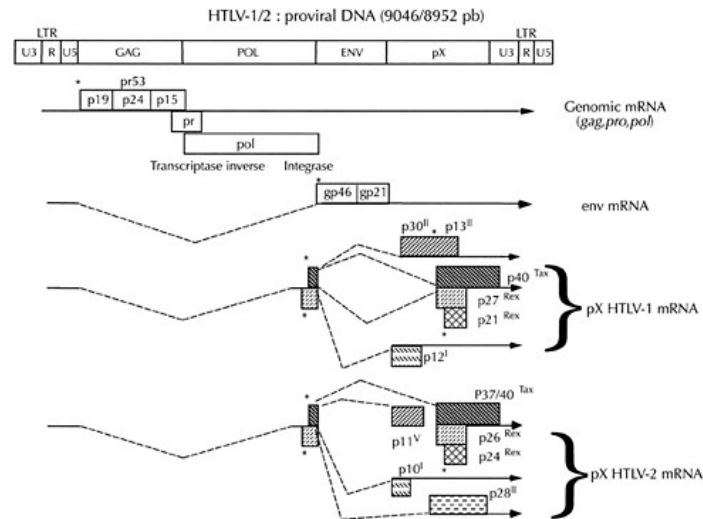

Figure 15.2 Genomic structure of the HTLV-1/2 proviruses and of the different mRNAs with their corresponding encoded proteins.

role for the 40-kDa Tax protein in the immortalization or transformation of HTLV-1-infected cells (for a review see³⁰):

1. The transduction of the *tax* gene into primary human T lymphocytes using a defective simian herpesvirus is sufficient to immortalize them.³¹ Other experiments have further demonstrated that ablating Tax expression prevents the cell transformation as well as induces a G1 arrest. This suggests a role for Tax in the deregulation of the G1/S transition.³²
2. Similarly, the expression of Tax or the co-transfection of Tax and Ras in rodent fibroblasts or T lymphocytes is sufficient to transform them.³³
3. Wild-type Tax can also convert IL-2-dependent murine CTLL cells to an IL-2-independent stage.³⁴
4. Tax transgenic animals expressing Tax under the control of the granzyme B promoter develop peripheral lymphomas consisting of CD8⁺ and natural killer cells.³⁵

Tax does not bind directly to DNA, but rather interacts with several cellular proteins being either transcriptional factors or modulators of cellular function. Therefore, the viral transactivator has the unique ability to activate 3 major cellular transduction pathways:

1. Tax binds to members of the activating transcription factor/cyclic AMP-responsive element-binding protein (ATF/CREB) family of transcription factors to stimulate their dimerization and their association onto the viral Tax TRE sequence to promote viral transcription.³⁶
2. Tax also activates transcription from the serum response factor (SRF). Tax interactions with CREB-binding protein (CBP) and p300- and GBP-associated factor (p/CAF) were found to be essential for Tax activation of both the CREB/ATF and the SRF-mediated transcription.³⁷
3. Finally another remarkable aspect of the Tax protein resides in its ability to activate permanently the NF- κ B pathway (for a review, see³⁸).

Through such pathways, Tax has pleiotropic effects: not only does it transactivate the viral promoter, but it is also able to activate or repress the expression or functions of a wide array of genes (see^{21,30} for a review and Figure 15.3). Many of them are regulators of the

Figure 15.3 Pleiotropic effects of Tax expression. Tax does not bind directly to DNA, but rather interacts with several cellular proteins being either transcriptional factors or modulators of cellular function. Therefore, the viral transactivator has the unique ability to activate three major cellular transduction pathways such as NF- κ B, ATF/CREB (activating transcription factor/cyclic AMP-responsive element-binding protein) and SRF (serum response factor). Through such pathways, Tax not only transactivates the viral promoter, but it is also able to activate or repress the expression or functions of a wide array of genes including regulators of the cell cycle (p21, p53, p16^{INKA}), or of apoptosis (Bcl-2, Bcl-X₁, and caspases) or cytokines, or their receptor, as interleukin-2, IL-2 receptor α chain, IL-15, IL-6. All these genes play a crucial role in T-lymphocyte growth and function. Their dysregulation could therefore be linked to tumorigenesis. Tax has also an important effect on the maintenance of the genomic stability. It inhibits DNA repair, (via DNA topoisomerase 1 and human telomerase reverse transcriptase (hTERT) transcription) and acts also as a transrepressor of the human β -polymerase gene.

cell cycle (p21, p53, p16^{INKA}), or of apoptosis (Bcl-2, Bcl-X₁, and caspases).^{21,39,40} Tax also enhances the expression of interleukin-2 (IL-2), IL-2 receptor (IL2R) α chain, IL-15, IL-6 and granulocyte-macrophage colony-stimulating factor (GM-CSF). It was also recently shown that Tax was a repressor of TGF- β 1 signaling through JNK/c-Jun constitutive activation. All these genes play a crucial role in T-lymphocyte growth and function. Their dysregulation could therefore be linked to tumorigenesis.⁴¹

Tax may also have an effect on the maintenance of the genomic stability (for a review, see ³⁰). It is competent for inhibiting DNA repair via the suppression of the nucleotide-excision repair (NER) and the base excision repair (BER) pathways.⁴² Tax acts also as a transrepressor of the human β -polymerase gene.⁴³ Lately, Yoshida et al have proposed that Tax physically interacts both in vitro and in vivo with the DNA topoisomerase 1, which plays a role in DNA repair.⁴⁴ Consequently, the enzyme is partially inactivated. Finally, recent data showed that Tax can inhibit human telomerase reverse transcriptase (hTERT) transcription, which is the rate-limiting factor of telomerase activity.^{45,46} hTERT repression by Tax at an early phase of carcinogenesis might contribute to the massive ploidy changes associated with the development of HTLV-1-associated malignancies.

Hematological manifestations of HTLV-1 infection: ATLL

ATLL is a malignant lymphoproliferation of T cells, mostly CD4-activated T cells, characterized by the clonal integration of one or more HTLV-1 proviruses in the tumor cells.^{11,47,48} Present in every HTLV-1 endemic area, ATLL presents a wide clinical diversity. This makes the diagnosis occasionally difficult at the onset of the disease.

Epidemiology

ATLL was first discovered and reported by Takatsuki et al in the Southwestern regions of Japan, where it has a high incidence.^{2,10,11,49,50} It was then described in Caribbean immigrants living in the UK by Catovsky et al.⁵¹ Later, ATLL cases were reported in most of the HTLV-1 endemic areas, i.e. intertropical Africa, South and Central America and Iran.^{52–55} Sporadic cases of ATLL have also been described in areas of low HTLV-1 endemicity such as Europe and the USA, often in immigrant patients originating from HTLV-1 endemic regions. Despite this wide geographical distribution, reliable data concerning the ATLL prevalence and incidence are available only for Japan, some Caribbean areas and Brazil.

A nationwide study in Japan revealed that 50% of ATLL patients were registered from Kyushu and 25% were from large metropolitan cities.^{10,50} However, 80% of the latter patients were born in Kyushu. In Japan, the ATLL sex ratio (male/female) is roughly 1.4. Age- and sex-specific incidence rates of ATLL in Japan showed a steep increase with age after 40. These rates then reach a plateau at the age of 50 in males, but keep on increasing in females until 70 years of age. In Japan, the average age of those with ATLL is 57 years,^{10,50} while it is roughly 40–45 years in the Caribbean and in South America (Brazil, Columbia, and French Guyana). This suggests the presence of yet unknown cofactors that are linked to the pathogenesis of ATLL. In Japan, the annual incidence of ATLL cases is estimated to be 700, while the number of HTLV-1 carriers is 1.2 million. This gives an estimated yearly incidence of ATLL in the range of 0.6–1.5 for 1000

adult HTLV-1 carriers older than 40.^{10,50,56} In Jamaica, this rate is similar.^{9,52} The additive lifetime risk for developing an ATLL among HTLV-1 carriers was estimated to be 1–5% for both sexes in Japan and Jamaica. Strikingly, a much higher incidence is observed in the Noir-Marrons population in French Guyana (⁵³ and Gessain et al, unpublished).

Studies performed in Brazil,^{54,57} Gabon, and French Guyana⁵³ concluded that the ATLL prevalence is usually underestimated, until a specific disease research is performed. This is mostly due to the severity and rapid evolution of the disease and to confusion of ATLL with similar diseases, such as Sézary syndrome, MF or other types of T-cell non-Hodgkin lymphoma (NHL). In addition, HTLV-1 serological confirmatory tests such as western blot and/or molecular investigations are not easily available in most tropical countries.

Diagnosis and classification of ATLL

Diagnosis

The diagnostic criteria for ATLL have been defined by Takatsuki et al:^{2,49,58}

1. Histologically and/or cytologically proven lymphoid malignancy with T-cell surface antigens (mostly CD2, CD3 and CD4 positive).
2. Abnormal T lymphocytes always present in the peripheral blood except in the lymphoma type of ATLL. These abnormal T lymphocytes include the typical ATLL flower cells, as well as some small and mature T lymphocytes with incised or lobulated nuclei that are characteristic of the chronic or smoldering type of ATLL.
3. Antibodies to HTLV-1 must be present in the patient's serum at diagnosis.

Classification

The main clinical features of ATLL are summarized in Table 15.2.

Table 15.2 Main clinical features of ATLL

	Japan*	Caribbean
	58 years (range 27–82)	47 years
Age at onset		
Sex ratio male/female	1.4	0.6
Lymphadenopathy	60%	70%
Hepatomegaly	26%	27%
Splenomegaly	22%	31%
Specific skin lesion	39%	41%
Hypercalcemia	32%	51%

* From references^{49,58} based on a series of 187 patients;
 + From reference¹⁵⁹ based on a series of 57 patients seen in the UK, 46 of Caribbean origin.

Because of the diversity in the clinical presentation, and in the evolution, Shimoyama and the members of the lymphoma study group in Japan (^{59,60}, Table 15.3) have proposed a classification of ATLL into four major subtypes: a smoldering type,⁶¹ a chronic type, a lymphoma type⁶² and a leukemic/acute type. Both chronic and smoldering types can progress into an acute form of leukemia or lymphoma following a progressive aggravation of the clinical picture. This classification is very useful to discriminate ATLL from other types of leukemias or lymphomas, including cutaneous T-cell lymphomas. An accurate diagnosis is indeed critical for therapeutic decision since, based on Japanese studies, patients with smoldering type and about 30% of those with chronic ATLL have a somewhat 'good prognosis', even without being treated with chemotherapy.^{59,60,63} A classification of the different clinical stages of ATLL has been proposed by Shirono et al⁶⁴ based on the expression of Ki 67 antigen in the peripheral blood T lymphocytes. Aggressive ATLL (death occurring within 1 year, mean survival: 105 days) is defined by a percentage of Ki 67⁺-positive cells greater than 18% in the peripheral blood T lymphocytes. Stable ATLL (mean survival of 750 days) are defined by a percentage of Ki 67⁺ cells lower than 18%. The criteria for determining the diagnosis of ATLL for epidemiological studies have also been proposed,⁶⁵ (Table 15.4). These could be used in order to compare the epidemiological characteristics of ATLL in areas such as the Caribbean, Central and South America and intertropical Africa. Interestingly, a recent report demonstrated that distinct sets of genes are up- or down-regulated during the transition from the chronic to acute phase of ATLL.⁶⁶

Cytological, immunovirological and molecular features of ATLL

All ATLL cases are, by definition, associated with HTLV-1 infection. ATLL patients' sera contain specific antibodies directed against HTLV-1 antigens, as demonstrated by Western blot. Particle agglutination, enzyme-linked immunosorbent assay (ELISA) or immunofluorescence assays can also be used to titer these sera.

A high number of abnormal peripheral blood lymphocytes is commonly detected in acute and chronic ATLL patients, while anemia, neutropenia or thrombocytopenia are rarely observed. ATLL cells are variable in size and characteristics according to the subtype: in the typical acute leukemia type, most of the lymphoid abnormal cells exhibit a multi-lobulated nuclei (flower cells) as seen in Figure 15.4. In terminal crisis, the cells often greatly vary in size (10–40 μ). They display a cytoplasmic basophilia and a marked nuclear lobulation. Some cells may resemble Sézary cells. In chronic ATLL, cells are generally small and of

Table 15.3 Diagnosis criteria for clinical subtypes of HTLV-1-associated ATLL

	Smoldering	Chronic	Lymphoma	Acute
Anti-HTLV-I antibody	+	+	+	
Lymphocyte ($\times 10^3/\mu\text{l}$)	<4	>4+	<4	
Abnormal T lymphocytes	$\geq 5\% \S$	+‡	<1%	+‡
Flower cells of T-cell marker	#	#	No	+
LDH	<1.5N	<2N		
Corrected Ca (mEq/l)	<5.5	<5.5		
Histology proven lymphadenopathy	No			
Tumor lesion				
Skin and/or lung	*§			
Lymph node	No		Yes

Definition of ATL	
Clinical/routine laboratory criteria	
Hypercalcemia	1 point
Skin lesions*	1 point
Leukemic phase+	1 point
Research laboratory criteria	
T-cell lymphoma or leukemia	2 points
HTLV-I antibody	2 points
TAC-positive tumor cells	1 point
HTLV-I-positive tumors‡	2 points
ATL classification	
Classical	≥ 7 points
Probable	5 or 6 points
Possible	3 or 4 points
Inconsistent with ATL	<3 points
Exclusion criteria	
B-cell positivity, nodular or follicular lymphoma, lymphoblastic lymphoma, small lymphocytic lymphoma	
*Lymphomatous cells documented morphologically; †More than 2% abnormal lymphocytes. ‡Determined by PCR or Southern blot analysis of the DNA of tumoral cells and indicating a monoclonal integration of HTLV-I provirus(es). Adapted from reference ⁶⁵ .	

**Figure 15.4** Peripheral blood smear from a Caribbean ATLL leukemic patient showing a cluster of atypical lymphoid cells with multilobulated nuclei (May Grunwald Giemsa staining).

uniform shape; with minor nuclear abnormalities such as indentation or convolutions. In smoldering ATLL cases, cells are often relatively large with a bi- or trifoliate nucleus.⁶⁷

ATLL cells are mature T cells of helper/inducer phenotype ($\text{CD}2^+$, $\text{CD}3^+$, $\text{CD}4^+$, $\text{CD}7^-$, $\text{CD}8^-$) displaying activation markers ($\text{CD}25^+$, HLA DP^+ , DQ^+ , DR^+).^{49,68,69} $\text{CD}4^-$, $\text{CD}8^-$ ATLL cells are unusual, but a decrease of the $\text{CD}3/\text{T}$ -cell receptor expression is common.⁷⁰

Figure 15.5 (a) Ethidium-bromide-stained agarose gel analysis of PCR products generated with specific HTLV-1 *pol* primers. High molecular weight DNA were extracted from negative controls (lanes 1, 3 and 4), PBMCs and cutaneous tumor of a lymphoma type ATLL with skin lesions (lanes 5 and 6), and from an HTLV-1 infected cell line (lane 7). (b) Southern-blot analysis of the same gel after transfer of the PCR product to a nylon membrane and hybridization with a specific *pol* HTLV-1 oligomer of 30 base pairs. Positive specific amplification was observed in lanes 5, 6 and 7. (c) Southern blot analysis: control peripheral blood mononuclear cells (lane 1), PBMCs of an ATLL with a defective HTLV-1 provirus (lane 2), PBMCs of the patient with the skin tumors (lane 3) and cutaneous tumor biopsy of the same patient (lane 4). Because there is no known EcoRI site in the HTLV-1 provirus, the observation of three bands in lane 4 denotes a clonal integration of three proviral genomes in the DNA of the cutaneous lesions. Pst I digestion generates three internal bands, one of them of 2.4 Kb can be detected with the HTLV-1 probe. This observation indicates also a polyclonal integration of the HTLV-1 provirus in the PBMCs of this patient.

Phenotypic changes in ATLL have also been observed in some patients during the clinical course of the disease, i.e. typical CD4⁺CD8⁻ ATLL cells changed into CD4⁺CD8⁺. A case of CD20-positive ATLL has also been described.

The lymph node histology often demonstrates infiltration by medium and large T cells with irregular nuclei effacing the nodal architecture, a pattern consistent with the diagnosis of pleiomorphic large T-cell lymphoma.⁶² However there is no specific histological pattern for ATLL.^{54,60,71}

The cytogenetic abnormalities found in ATLL are not specific but are more frequent in the acute and lymphoma type than in the chronic or the smoldering types.⁷² They include various karyotypic abnormalities on chromosome 14: 14 q 32, 14 q 11 translocations and 6q deletions. There are also abnormalities such as trisomies 3, 7 and 21 as well as X chromosome monosomy or loss of the Y chromosome.

Mutations on the p53 encoding tumor-suppressing gene are detected in 20–30% of ATLL patients, mostly in advanced cases, suggesting the involvement of the p53 mutation in a late stage of leukemogenesis, or as a consequence of the cancerous transformation.⁷³ However, several laboratories have also shown that wild type p53 was transcriptionally inactive in HTLV-1-infected cells and that the Tax protein alone could inactivate p53 function.³⁹

HTLV-1 sequences can always be amplified from the DNA extracted from tumoral cells.⁷⁴ These PCR products can be cloned and sequenced, allowing the determination of the viral genotype (HTLV-1 molecular subtype). However, a positive PCR signal does not demonstrate the link between HTLV-1 and the tumoral status of the cells. In fact, proviral DNA can also be amplified from the PBMCs of any HTLV-1-seropositive individual (Figure 15.5). The demonstration by Southern blot analysis of the clonal integration of HTLV-1 provirus in the tumoral cells (leukemic, lymph nodes, skin infiltrate, pleural or ascitic fluid) represents the gold standard to define biologically ATLL (^{47,48,75,76}, Figure 15.5). Indeed, monoclonal integration of the HTLV-1 provirus is never detected in the malignant cells from patients with other T-cell malignancies, even if patients are HTLV-1 seropositive. In 5–20% of the cases, the integrated HTLV-1 proviruses are defective (Figure 15.5). The pX region is generally conserved, while deletions occur preferentially in *gag*, *pol*, and/or *env* sequences. Using Southern blot and long PCR, a Japanese study of 72 various ATLL subtypes, revealed two main types of defective viruses.⁷⁵ The first one retained both LTR and lacked internal sequences in the 5' region of the provirus. The second one retained only one LTR, while the 5' LTR was preferentially deleted. This second type was more frequently detected in the acute and lymphoma type samples than in the chronic type.

In most cases, only one copy of the provirus is integrated in the tumoral cells, while two or three copies are detected in 5–20% of ATLL cases. Some authors have suggested that the HTLV-1 integration pattern in the host DNA may be linked to the severity of the disease.^{77,78} In a study conducted on 89 ATLL cases, a band whose size was greater than 9 kb was detected in 83 patients while an ‘extraordinary’ integration pattern of HTLV-1 pro viral DNA was detected in six patients. Three showed two bands and three exhibited one band smaller than 9 kb. The patients with such ‘extraordinary’ integration pattern had clinical characteristics (including an extremely aggressive clinical course) different from those of the other 83 patients.^{77,78} These data are however controversial since the genomic DNA extracted from some patients with chronic ATLL also contained two proviral copies, while some patients with aggressive ATLL had only one proviral copy.⁷⁹

Numerous studies have demonstrated that the presence of HTLV-1 oligo or monoclonal populations was not characteristic of a malignant proliferation.^{80–82} Indeed, some healthy carriers as well as 10–20% of all TSP/HAM exhibit a proviral clonal integration that can sometimes be detected by classical Southern blot analysis.⁸⁰ Furthermore, oligoclonal or polyclonal proliferation of HTLV-1-infected T cells can also be detected by inverse PCR in most TSP/HAM patients as well as in healthy HTLV-1-seropositive carriers.⁸³ Some clones were shown to persist *in vivo* several years in the same infected individual. The detection of a clonal proliferation of HTLV-1-infected cells that are not malignant could therefore be used as a molecular tool for monitoring groups at risk for the development of ATLL. It could also be instrumental for detecting residual ATLL cells after bone marrow transplantation.^{81,84}

Clinical features and complications

Hypercalcemia

It is a very frequent and rather specific biological feature of ATLL. It is present in 20–30% of the patients at admission and in more than 50% of them during the entire clinical course with or without lytic bone lesions,^{49,58,85} (Table 15.2). The degree of hypercalcemia might be linked to the expression of the parathyroid hormone (PTH)-related protein (PTHrP) gene in cooperation with IL-1 and TGF- β . Interestingly, the HTLV-1 Tax protein has been shown to transactivate the PTHrP promoter.⁸⁶ It has recently been suggested that ATLL cells induce the differentiation of hematopoietic precursor cells to osteoclasts via receptor activator nuclear factor κ B ligand (RANKL), expressed on their surface, in cooperation with M-CSF (Macrophage colony stimulating factor). This may ultimately cause hypercalcemia.⁴¹

Cutaneous lesions

Skin infiltration of a clonal population of HTLV-1 tumoral cells represents a frequent clinical feature of ATLL. It is found in 20–40% of all ATLL types and in more than 50% of smoldering ATLL patients (⁶¹, Table 15.3). Various cutaneous lesions have been described. They include papules, nodules, erythroderma, plaques, tumors and ulcerative lesions. ATLL cells densely infiltrate both dermis and epidermis, forming Pautrier micro-abscesses (Figure 15.6).^{87–89} When skin lesions dominate the clinical picture, the disease is often referred to as cutaneous ATLL.^{87–89} In such cases, clinico-pathological differentiation of these lesions with other cutaneous T-cell lymphomas (CTCLs) might be difficult to establish and requests molecular studies. Interestingly, a recent study showed that HTLV-1-immortalized T cells and fresh ATLL cells frequently express CCR4.⁹⁰ Thus, the frequent involvement of skin in ATLL may be accounted for, in part, by the frequent expression of CCR4. However, only a fraction of patients have skin lesions. It is thus evident that CCR4 positivity of the leukemic cells *per se* is not sufficient for skin invasion. Other factors such as expression of cutaneous lymphocyte antigen (CLA) by leukemic cells and inflammatory responses in lesional skin leading to up-regulation of thymus and activation-regulated chemokine (TARC) and macrophage-derived chemokine (MDC) are also likely to contribute to skin involvement of ATLL. Fresh leukemic cells derived from patients with acute ATLL also produce vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) proteins. Angiogenesis, cell adhesion, and communication are likely to contribute to the development of ATLL.^{91,92}

Infective dermatitis (ID), a rare dermatological condition originally described in Jamaica in 1966 was subsequently linked in 1990 to HTLV-1 infection.^{93,94} ID is a relapsing skin disease with infectious and

Figure 15.6 Histology of skin invasion in a Caribbean patient with a cutaneous ATLL showing an infiltration of the dermis and epidermis with presence of Pautrier abscess. These tumoral cells were CD2⁺, CD3⁺, CD4⁺, CD8⁻ and CD25⁺.

dermatitis-like features that is distinct from atopic dermatitis. So far, most cases of ID have been described in children living in Jamaica, however few cases have been reported in other HTLV-1 endemic areas including west Africa.⁹⁵ ID has been described in some patients with ATLL^{94,96} and it has been suggested that ID defines a group of patients at increased risk for ATLL development.^{93,96}

Infectious complication

The frequency of opportunistic infections (*Pneumocystis carinii*, herpes viruses etc.), is quite high in patients with ATLL,⁹⁷ indicating that T-cell-mediated immunity is severely impaired in such patients. Furthermore, a mild T-cell immune deficiency state has been reported among HTLV-1 healthy carriers.⁵ Infestation by *Strongyloides stercoralis* (SS) is quite frequent among HTLV-1-seropositive carriers and SS-infected individuals are often infected by HTLV-1 in highly endemic areas such as the Okinawa islands and Caribbean area. Numerous studies showed the presence of SS in acute or lymphoma ATLL, suggesting that infection by SS may play a significant role as a candidate cofactor for HTLV-1 induced leukemogenesis.⁹⁸ A study in Martinique, French West Indies, indicated that ATLL patients infected with SS were younger (39 vs. 70 years) and survived longer (median survival 167 d vs. 30 d) than uninfected patients.⁹⁹ A monoclonal integration of HTLV-1 proviral DNA has been detected by Southern blot in some patients infected with SS but who did not have overt ATLL.¹⁰⁰ In addition, Gabet et al demonstrated that the mean circulating HTLV-1 proviral load was more than five times higher in HTLV-1 carriers who were infected with strongyloidiasis than in those without SS infection. Such increased proviral load was found to result from the extensive proliferation of a restricted number of infected clones.⁹⁸ The positive effect of SS on clonal expansion was however reversible under effective treatment against strongyloidiasis in only one patient.

Pulmonary complications are also very frequent in ATLL patients. These are either leukemic infiltrate or infections. Gastrointestinal tract infiltration by ATLL cells is quite frequent while central nervous system localization rarely occurs in ATLL (10%).

Differential diagnosis: other cutaneous T-cell lymphomas

The difference between smoldering or chronic forms of ATLL and other post-thymic T-cell malignancies, including cutaneous T-cell lymphoma may be difficult to establish. In cases of cutaneous lesions, only molecular studies can distinguish HTLV-1-related specific skin malignancies from cutaneous lesions of other etiology, which could also occur among HTLV-1 carriers.^{61,76,87-89} Histopathologic data may also closely resemble cutaneous lesions that are present in other T-cell lymphomas that are not linked to HTLV-1 infection. Similarly, the presence of activated T-cell markers such as CD25, HLA-DR, HLA-DP, can also be found in some cases of CTCL. Therefore, an HTLV-1-positive serology combined to the presence of circulating ATLL-like cells, together with an HTLV-1 positive PCR signal on the DNA extracted from PBMCs and/or from tumor biopsy cells, are important clues in favor of an ATLL diagnosis. Nevertheless, they do not demonstrate a direct etiologic link between the presence of the virus and the cutaneous lesions since these features are also present among healthy HTLV-1-seropositive individuals. Therefore, the definitive evidence for a causal link between HTLV-1 and a cutaneous T-cell tumoral proliferation is the demonstration by Southern blot analysis of the monoclonal HTLV-1 proviral integration in the tumor cells of the skin infiltrate.⁸⁸

In summary, according to Matutes et al,⁵⁴ the features that could be considered as specific of an ATLL are hypercalcemia, peripheral blood cell morphology and the presence of clonally integrated HTLV-1 in the neoplastic cells. Some features such as skin and lymph node histology, immunological markers and certain chromosome abnormalities can be found in other T-cell leukemias or lymphomas and thus do not distinguish them from ATLL.

Therapeutic aspects of ATLL

The survival rate of ATLL patients, especially those who develop the acute leukemic or lymphomas forms, remains very poor and such tumor remains one of the most severe lymphoproliferations. Treatment of ATLL patients using conventional chemotherapy has indeed very limited benefit, since HTLV-1 cells are resistant to most apoptosis-inducing agents (for a review, see ¹⁰¹⁻¹⁰³). In a Japanese survey coordinated by Shimoyama based on 818 ATLL cases, the median survival time was 9 months, with a survival rate of only 27% and 10% at 2 and 4 years, respectively. The situation is very contrasted when subtypes are considered, with a 4-year survival rate of 66% for the smoldering type, of 27% for the chronic type and of 5-6% for the lymphoma and acute types.^{59,63} Furthermore, spontaneous regression can also be observed in few cases of ATLL.^{59,63}

The main prognostic factors associated with a poor response and a poor survival rate in ATLL patients are: a high lactic acid dehydrogenase (LDH) value, high leukemic counts (both reflecting a high tumor burden), hypercalcemia, and a poor clinical performance.¹⁰¹ Furthermore, the main obstacles to an efficient response to treatment are: infectious complications (*Pneumocystis carinii*, *Cryptococcus*

meningitis, disseminated herpes zoster), hypercalcemia, and liver or kidney dysfunction. Various strategies including classical combination chemotherapy, deoxycoformycin, leucocytapheresis, photochemotherapy, low-dose total-body irradiation, interferon, monoclonal antibodies directed against the IL-2 receptor, GM-CSF-supported combination chemotherapy and allogenic hematopoietic stem cells transplant¹⁰⁴ have been used during clinical trials.^{101,105} However these therapeutic regimens induce in very few long-term disease-free survival.

Zidovudine (AZT), which was originally synthesized as part of an anti-cancer drug discovery program, has been shown to inhibit HTLV-1 transmission in vitro.¹⁰⁶ Gill et al¹⁰⁷ initiated a clinical trial on 19 ATLL patients (including those with acute and lymphoma types) using interferon- α (INF- α) in combination with AZT. A major response was achieved in 58% of patients, including a remission in 26% (five out of 19). In France, Hermine et al¹⁰⁸ also reported the efficacy of such a therapeutic regimen in five ATLL patients (four acute and one smoldering cases). A more recent study confirms the efficacy and safety of AZT/INF- α in ATLL, with some high response and complete remission (CR). However, despite some with impressive prolonged CR of more than 3 years, most of the patients relapse, stressing the need for additional therapy after achieving CR with AZT/INF.^{109,110} Initial treatment of ATL patients with CHOP therapy has also temporary beneficial effects.¹¹⁰ Other studies performed in Jamaica and Great Britain found a response rate to be lower than in the two previous studies.¹¹¹

In vitro, retinoic-acid^{112,113} or arsenic trioxide (As₂O₃), in combination with INF- α can induce cell death in HTLV-1-transformed cells.^{114,115} The mechanism involves the reversion of the NF- κ B activation as well as the degradation of the Tax-1 protein.¹¹⁶ The current authors also recently demonstrated that in vitro As₂O₃ treatment could induce apoptosis in all HTLV-1/2 cell lines tested, whether they were IL-2 dependent or independent, as well as in cells obtained from HTLV-1 ATLL patients. The apoptosis is correlated with caspase-3 activation, and caspase-3-dependent cleavage of Poly (ADP-ribose) polymerase (PARP), as well as of Bcl-2. The cleavage of Bcl-2 promotes the release of cytochrome c from the mitochondria.¹¹⁷ The cell death might involve the down-regulation of NF- κ B. Phase II clinical trials with As₂O₃ are ongoing.¹¹⁸ The first results show that in vivo, arsenic/IFN α treatment is feasible and exhibits an anti-leukemia effect in ATL patients with a very poor prognosis despite a significant toxicity. More recently, NF- κ B inhibitors were found to be efficient for preventing the tumor growth in NOD-SCID/gamma (null) animals previously inoculated with HTLV-1-infected cells.¹¹⁹ Proteasome inhibitor PS-341 combined or not to anti-Tac therapy was partially successful for treating NOD/SCID animals or Tax transgenic mice.^{120,121}

Risk factors for ATLL development and pathogenesis

Among HTLV-1 carriers, the risk factors for developing ATLL as well as the determinants of disease progression remain largely unknown. There could be viral factors, host genetic factors or environmental ones.¹²²

Viral factors

Soon after the discovery of TSP/HAM, a question arose as to whether the same virus could induce two different diseases (ATLL and TSP/HAM). In fact, it could be hypothesized that, as it is the case with murine leukemia viruses, specific mutations in structural and/or regulatory viral genes could direct HTLV-1 tissue tropism and pathogenesis. Such questions led numerous groups to study the sequence of the LTR and of the *env* gene of HTLV-1 in ATLL or TSP/HAM patients. These works demonstrated that the few nucleotide changes observed between isolates were specific of the geographical origin of the patients but not of the associated pathologies (ATLL, TSP/HAM).¹²³ However, Japanese researchers have proposed that one Tax-specific molecular subgroup (within the Cosmopolitan subtype) was more frequently found in TSP/HAM, as compared to ATLL and asymptomatic carriers.¹²⁴ Regarding molecular epidemiology, based on sequence and/or RFLP analysis of more than 500 HTLV-1 isolates originating from the main viral endemic areas, four major molecular geographical subtypes (or genotypes) emerged. Their existence is strongly supported by phylogenetic analysis (high bootstrap values). Each of these genotypes (Cosmopolitan [A], Central African [B], Melanesian [C] and Central-African-Pygmy [D]) appeared to arise from ancient interspecies transmission between monkeys infected by STLV-1 (the simian counterpart of HTLV-1) and humans. It is worthwhile to note that STLV-1, which infects several Old World monkey species, can also cause in some infected animals 'ATLL-like' diseases.¹²⁵

Regarding *host genetic factors*, several arguments strongly suggest the existence of such factors involved in the HTLV-1 infection *per se* as well as in the development of ATLL or of TSP/HAM among HTLV-1-infected individuals. Ethnic and familial aggregations of ATLL have been reported in different HTLV-1 endemic areas.⁵³ Furthermore, numerous HLA studies performed in Japan and Jamaica have also suggested that some class I as well as class II HLA alleles may predispose to ATLL.¹²⁶ The authors suggest that

HLA-A*26, B*4002 and B*4801 predispose to ATLL, because of the limited recognition of the HTLV-1 Tax peptide anchor motifs and epitope capable of generating anti-HTLV-1 Tax cytotoxic T cells (CTLs).¹²⁶ Consistent with these results, others have also suggested that at some stage of the ATLL development, HTLV-1-infected cells can escape the immune system (reviewed in ⁴¹). This could in part be due to mutations in the Tax 11–19 epitope, which is the major target of the antiviral cellular response.¹²⁷ Some polymorphisms of the tumor necrosis factor alpha gene (TNF- α), have been shown to be associated with ATLL in comparison with asymptomatic carriers. Furthermore, among an endemic population of African origin, a major gene predisposing to HTLV-1 infection in children has also been detected.¹²⁸

Regarding *environmental factors*, the mode of infection, the infectious dose and the age of infection seem decisive for developing ATLL or TSP/HAM.¹²² Thus, early HTLV-1 infection of babies through infected breast-milk appears to be a major risk factor, especially for developing ATLL but not for TSP/HAM. Several studies conducted in Japan as well as in the Caribbean area and in Brazil have demonstrated that, most if not all the mothers of ATLL patients, were infected with HTLV-1.^{129,130} Interestingly, the acquisition of HTLV-1 through blood transfusion represents an important risk factor for developing TSP/HAM but not for ATLL. Indeed, cases of post-transfusion ATLL are exceptional. It has been hypothesized that the route of infection and size of the initial inoculum allow HTLV-1 to infect different target cell populations (CD4, dendritic cells, etc.). Finally, as described earlier, the role of SS infection as a cofactor in ATLL among HTLV-1 carriers is obvious.

Pathogenesis of ATLL

The fact that in man, oncogenesis proceeds, in most cases, from a multistage process is widely accepted.

For ATLL, the first step seems to be the primary infection through prolonged breast-feeding (>6 months) of a child born from an HTLV-1-infected mother (Figure 15.7). After few replication cycles using the viral reverse transcriptase, a clonal expansion of HTLV-1-infected cells arises progressively. The HTLV-1 provirus is integrated at random in the genome of the host. It is now hypothesized that HTLV-1 replicates and increases its copy number through the proliferation of infected cells, thus using the cellular DNA polymerase, which possesses a proof-reading activity and not the reverse transcriptase, an error prone DNA polymerase. Such a model could explain, in part, the very high genetic stability of HTLV-1, by contrast to other retro viruses.

The second step is thus the clonal proliferation of the infected CD4⁺ lymphocytes, which is linked to the pleiotropic effects of Tax (Figure 15.3). As seen earlier, this includes the activation of several cellular cytokines such as IL2, IL15, the dysregulation of the cell cycle, the inhibition of apoptosis and the promotion of genetic instability. The observation of an oligoclonal or a monoclonal integration of HTLV-1 in the PBMCs (Peripheral blood mononuclear cells) of TSP/HAM patients or of HTLV-1 healthy carriers suggests that neither the monoclonal integration of the virus nor the CD4⁺ cell proliferation per se is sufficient to cause the disease. The exact roles of cofactors, such as infection by SS are largely unknown. The level of Tax expression in vivo in HTLV-1-infected individuals, is still a matter of debate. Several

Figure 15.7 Pathogenesis of ATLL. Natural course from HTLV-1 primary infection by prolonged breast-feeding to ATLL onset (adapted from ⁴¹).

observations paradoxically suggest that HTLV-1 was transcriptionally silent in most infected cells. With the use of new procedures, Hannon et al¹³¹ recently showed that a high proportion of naturally infected CD4⁺ peripheral blood mononuclear cells (between 10% and 80%) isolated from TSP/HAM patients or HTLV-1 asymptomatic carriers were capable of expressing Tax. Furthermore, they provided direct evidence that autologous CD8⁺ T cells rapidly kill CD4⁺ cells that express Tax in vitro by a perforin-dependent mechanism. Those results suggested that virus-specific CTLs participate in a highly efficient immune surveillance mechanism that persistently destroys Tax-expressing HTLV-1-infected CD4⁺ T cells in vivo. Such CTL control of the HTLV-1-infected cell proliferation may also result in the prevention of ATLL. The role of the genetic background, especially HLA haplotypes, in such CTL control could be crucial.

A third critical step toward ATLL leukemogenesis would be the accumulation of alteration of the host genome of ATLL cells mediated in part by the mutator phenotype of Tax linked to its action on the DNA damage repair machinery. Furthermore, at the ATLL stage, low levels of HTLV-1 *tax* mRNA are present in the ATLL cells.¹³² Different hypotheses (deletion and/or methylation of the 5'LTR, nonsense or missense mutations of the *tax* gene) have been proposed to explain such phenomenon, which could facilitate the escape of the ATLL cells from the host immune system. This correlates to the fact that ATLL patients also appear to have an impaired CD8⁺ T-cell response.¹³³

Community-based prospective studies allowing the comparison of multiple characteristics between the ATLL cases and controls with minimal bias are ongoing in order to define precisely the risk factors associated to ATLL development.^{41,134} However the rare occurrence and the long latency period of ATLL makes difficult such long-term prospective studies.

IS HTLV-1 associated with cutaneous T-cell lymphomas other than ATLL?

As described earlier, there are some strong similarities between the clinical and histopathological features of some types of ATLL and other CTCLs including Sézary syndrome, MF and CD30 anaplastic large-cell CTCLs.^{61,87–89} This led a number of investigators to determine whether HTLV-1 (including defective nonreplicative forms) or a related virus might be present in such post-thymic mature T-lymphoproliferations.^{135–138} This possibility was under active investigation in the 1990s, and a matter of controversy.¹³⁹ Several groups had thus demonstrated the presence of HTLV-1 proviral sequences in the DNA extracted from the PBMCs and/or the cutaneous lesions of HTLV-1 seronegative Sézary syndrome as well as in MF patients originating from the USA, Sweden, UK and Italy.^{135,137,138} In these studies, the amplified PCR product was either a part of the pX region (mostly *tax* and/or *rex*) or, in some cases, *pol* and other gene fragments. Sequencing revealed a complete identity with the HTLV-1 prototypic sequence. Other groups failed to detect HTLV-1 sequences in similar patients originating from France, Portugal, Spain or the USA.¹⁴⁰ The presence of defective HTLV-1 provirus was also detected in some patients suffering from CD30 anaplastic large-cell CTCLs.

It is therefore widely accepted that the only HTLV-1-associated lymphoproliferation is ATLL.

Lymphoproliferative diseases associated with HTLV-2

HTLV-2, the second human oncoretrovirus to be discovered, was isolated in 1982 from a T-cell line established from the splenic cells of a patient suffering from a hairy T-cell leukemia.^{141,142} A number of further isolates have been obtained from intravenous drug abusers, healthy HTLV-2-seropositive carriers and rare cases of CD8⁺ lymphoproliferative diseases and chronic neuro-myelopathies. This virus is endemic in some Amerindian populations in which the HTLV-2 seroprevalence can reach up to 50%¹⁴² as well as in some rare African Pygmy populations.¹⁴³ Furthermore HTLV-2 is also endemic/epidemic (1–30% of seroprevalence) in intravenous drug user (IVDU) population that is present in the large American cities.¹⁴² It is also detected (0.5–10%) in some groups of IVUDs from European countries including the UK, Italy, Ireland and Spain.¹⁴⁴ From a molecular point of view, three main molecular subtypes have been discovered (A, B and D), with a nucleotidic divergence of 4–7% depending on the studied gene.^{142,144}

While based on epidemiological and phylogenetic analyses, HTLV-1 and STLV-1 can be considered as 'Old World' viruses present in Africa and Asia, probably for millennia; HTLV-2, on the contrary, appears as a 'New World' virus brought from Asia into the Americas by migrations of population through the Bering strait, some 10000 to 40000 years ago. The presence of HTLV-2 in west and central Africa, especially in remote populations (Pygmies), raised however the possibility that HTLV-2 has also been present in Africa over a long period of time.^{143,144}

Among HTLV-2-infected individuals, the virus is mainly present in the T CD8⁺ lymphocyte subpopulation in vivo.¹⁴⁵ An overall increase of T CD8⁺ cells is often detected in such individuals.¹⁴⁶ In vitro,

the growth of PBMCs obtained from HTLV-2-seropositive individuals often leads to the establishment of mainly T CD8⁺ transformed cell lines. This preferential tropism is however not exclusive, and HTLV-2 can also infect the T CD4⁺ lymphocytes.¹⁴⁷

The etiological role of HTLV-2 has been suggested in some rare cases of CTCL, or of T CD8 lymphoproliferative disorders.^{142,148,149} A review of the literature on the possible involvement of HTLV-2 in such diseases revealed only six published cases where a clear evidence of HTLV-2 infection (by specific serological and/or molecular means) has been demonstrated in CD8⁺ lymphoproliferations (reviewed in^{149,150}, Table 15.5). These patients, originated from the USA. They include a case of T hairy cell leukemia,¹⁵¹ cases of large granular leukemia (LGL) and of cutaneous T-cell lymphoma^{149,151–153} and two cases of Sézary-like diseases.^{154,155} However, in none of these cases could a clonal integration of HTLV-2 be demonstrated in the malignant tumoral cells. In the so-called ‘hairy T-cell leukemia’,¹⁵⁶ the virus was oligoclonally integrated in the CD8⁺ cells, while the clonal tumoral cells, which did not contain an integrated provirus (i.e. negative by Southern blot), were of B-cell type (as it is the case for most, if not all, hairy cell leukemias). In one LGL patient, the HTLV-2 provirus was detected in the normal CD3⁺, CD8⁺ cells, but not in tumoral large granular lymphocytes of NK phenotype (CD3⁺ and CD18⁺) that did not contain proviral sequences (PCR negative).¹⁵³ In the other case, HTLV-2 was only detected in the DNA of a cell lysate, from paraffin-embedded slides of a bone marrow biopsy. It was not possible to ascertain the role of HTLV-2 in the pathogenesis of this disease in this last patient, who had a clonal lymphoproliferation of CD3⁺, CD8⁺, CD57⁺ phenotype.¹⁵¹ A large study involving 51 patients failed to demonstrate any association of LGL with HTLV-2 infection. In fact, only one patient with a NK (CD3⁻) phenotype LGL leukemia was HTLV-2 positive, but there was no evidence for a clonal proviral integration in the neoplastic cells.¹⁵² In the two patients who developed MF or Sézary-like syndrome, in whom clonal proliferation was not demonstrated, the search for the presence of HTLV-2 in the tumoral cells was not performed.^{154,155} The last case, is the best documented.¹⁴⁹ An HIV-1 and HTLV-2 co-infected IVDU developed a clonal CD3⁺, CD8⁺, CD4⁻ CTCL. It was positive for HTLV-2 by immunostaining and PCR. The copy number of both HTLV-2 and a specific V β clonotype DNA was much higher in the patient’s skin than in the peripheral blood. This finding further supports the hypothesis that HTLV-2 was directly involved in the pathogenesis of the lymphoma.

In contrast to HTLV-1, whose etiological role in ATLL is now well established, there is thus currently neither a serological association nor molecular evidence that would definitely suggest that HTLV-2 is etiologically associated to a malignant lympho-

Table 15.5 T CD8⁺ disorders with clear evidence of HTIV-2 infection by serological and/or molecular means.

proliferative disease. In order to gain new insight on such an issue, further studies are indeed needed in the HTLV-2 highly endemic population, including especially patients who are HTLV-2 and HIV-1 coinfecting.

Conclusion

Prospective studies on HTLV-1-infected individuals should therefore be developed. They shall put together molecular biologists, clinicians and epidemiologists. Among HTLV-1-infected individuals, they should allow the characterization of a high-risk biological profile for ATLL, so that preventive interventions or pre-clinical therapies could be envisaged.¹³⁴ The vaccine approach^{157,158} could also be pursued through the establishment of acceptable recombinant viral vaccines of proper experimental models, in which ATLL syndromes could be obtained. Furthermore, the characterization of 'disease susceptibility genes' is being actively pursued for HTLV-1-associated diseases.¹²⁸

Immunosuppression: Epstein-Barr virus and other herpesviruses in hematological malignancies

Martine Raphaël, Fanny Baran-Marszak, and H el ene A Poirel

Introduction

Immunodeficiency, either primary or acquired, is associated with an increased incidence of lympho-proliferative disorders (LPD) and lymphoma. Among the pathogenic mechanisms underlying the primary immune disorders (PID), which are widely heterogeneous, defective immune surveillance of herpesviruses, particularly to Epstein-Barr virus (EBV), is involved in the majority of PID, leading to EBV-driven LPD. These EBV-driven LPD are observed in PID where the T-cell defect is partial or complete, as in severe combined immunodeficiency (SCID), Wiskott-Aldrich syndrome (WAS), combined variable immunodeficiency disorder (CVID), and X-linked lymphoproliferative syndrome (XLP, Duncan syndrome).^{1,2} In acquired immunodeficiency, two main clinical settings are described: the post-transplant lymphoproliferative disorders (PTLD) occurring after transplantation and the lymphoid neoplasms developing in HIV-infected patients (AIDS-related lymphomas). In PTLD, the pathogenic mechanisms are mainly linked to the immune defect with respect to EBV, especially in early lesions.³⁻⁵ In HIV infection, in addition to the immune defect with respect to the oncogenic viruses EBV and Kaposi sarcoma-associated herpesvirus (KSHV; also known as human herpesvirus 8, HHV8), antigenic stimulation and genomic abnormalities involving known oncogenes also play a role.^{5,6}

Epstein-Barr virus

EBV (HHV4), a γ -herpesvirus with double tropism for lymphoid and epithelial cells, shares the same biologic properties as the other viruses from this subfamily, such as latent infection in lymphocytes, cell proliferation, and an association with cancer.⁷ EBV, the causal agent of infectious mononucleosis, is also an etiologic agent in nasopharyngeal carcinoma and in lymphoid proliferations, including Burkitt lymphoma, Hodgkin lymphoma, extranodal NK/T-cell lymphoma nasal type, and LPD and lymphomas in immunosuppressed patients.⁸ Like other herpesviruses, EBV has a protein core wrapped with DNA, a nucleocapsid, a protein tegument, and an envelope with external glycoprotein spikes. The most abundant EBV outer envelope protein is gp350/220, which binds to CD21, the EBV receptor, on the surface of B lymphocytes.⁹

The EBV genome, which has been entirely sequenced, is linear, double-stranded 172 kbp DNA, and contains terminal repeats (TR), internal repeats (IR1-4), and unique sequence domains (U1-U5). EBV can manifest two different life cycles: latent and replicative, but in lymphoid cells, EBV is mostly latent. EBV exists in different forms: circular or episomal during latency, and linear in the replicative cycle.^{8,9} Circularization of the EBV genome is obtained by the joining of 500 bp tandem-repeat DNA sequences at both ends of the linear molecule. Because different episomes can have different numbers of TR, the analysis of the structure of the termini can also be used to assess the clonality of the lymphoid proliferation.¹⁰

In lymphoblastoid cell lines (LCL) and in recently EBV-infected lymphocytes, six different nuclear proteins, EBNA (Epstein-Barr nuclear antigens) 1,2, 3A, 3B, 3C, and LP, three different integral membrane proteins, LMP (latent membrane proteins) 1, 2A, and 2B, and two small non-polyadenylated RNAs (EBV-encoded RNAs, EBER) are expressed. Two types of EBV—EBV1/EBVA and EBV2/EBVB—are identified based on the genomic differences on genes encoding

for EBNA1P, 2, 3A, 3B, and 3C. EBV2 is more frequent in Africa where half of the Burkitt lymphoma (BL) are associated with EBV2.⁹

Recombinant EBV technologies developed in several laboratories have allowed identification of the proteins and their roles in continuously proliferating lymphoblastoid cell lines and in human malignancies. Recombinant EBV genetic analysis of transformation using specifically mutated cloned restriction fragments of viral DNA transfected into infected cells is one of the experimental strategies used to analyze viral genes essential for transformation. The P3HR1 strain of EBV, which is deleted for a DNA segment that contains all of the EBNA2 exons and the last two exons of EBNA1P, is unable to immortalize B cells. Among other approaches to analyze EBV-transformed genes are marker rescue of a transformation-defective EBV genome, the mini-EBV genome, and recombinant cloning of EBV as a bacterial artificial chromosome (BAC).¹¹

EBV may lead to B-cell immortalization by activating a set of host cellular genes. EBNA1P and EBNA2 are the first viral proteins to be expressed after cellular infection. EBNA2, a specific transactivator of the *Bam*HI C-promoter (Cp) and the promoters of *LMP1* and *LMP2*, is a key viral protein in the immortalization of B cells. Thus, EBNA2 transactivates viral genes such as *LMP1* and *LMP2* and cellular genes, including *CD21*, *CD23*, and the *fgf* oncogene, as well as the *c-myc* oncogene,⁹ and represses transcription of the immunoglobulin heavy-chain locus.¹² EBNA2 is tethered to cellular genes with the cellular repressor RBP-J involved in the Notch signaling pathway. In the latter, after activation by ligands belonging to the Delta, Serrate, Lag-2 (DSL) family of proteins, the extracellular part of the Notch receptor is cleaved, releasing the intracellular part of Notch (Notch-IC), which is translocated to the nucleus, where it interacts with RBP-J and modulates gene expression. In fact, EBNA2, resembling the physiologically switched-on form of this gene modulator, can be regarded as a viral functional equivalent to the activated Notch receptor, Notch-IC. However, Notch-IC cannot maintain B-cell proliferation in the absence of EBNA2.^{13,14} Thus, EBNA2 should be able to transactivate genes that can lead to cellular transformation and neoplasms. Moreover, cooperation between EBNA1P and EBNA2 may induce the cell cycle transition from G₀ to G₁ by inducing cyclin D2.¹⁵

EBNA3A, 3B, and 3C, encoded by three genes that are likely to have had a common origin, have structural similarities and probably similar roles in cell growth transformation. EBNA3A and 3C are essential for B-cell immortalization. It has been shown that EBNA3C upregulates *LMP1* expression and *CD21* mRNA, cooperates with *RAS*,¹⁵ and downregulates p27, one of the proteins involved in cell cycle regulation.¹⁶ EBNA1 is the only EBNA protein that associates with chromosomes during mitosis and there are at least three independent domains mediating EBNA1 binding. EBNA1 activates the origin of replication OriP during S phase and may also contribute to the partition and/or retention of the viral genome during mitosis.¹⁷

The *LMP1* protein, which is expressed in a wide variety of malignancies, may contribute to EBV-driven neoplasia.¹⁸ Evidence of its oncogenic properties was demonstrated by the acquired malignant phenotype of rodent fibroblasts induced by *LMP1*.¹⁹ The different functions of *LMP1* that confer its oncogenic ability can be summarized as induction of DNA synthesis together with suppression of apoptosis by the induction of antiapoptotic genes such as *BCL2*, *MCL1*, *BFL1*, *A20*, and *c-IAP*. The potential indirect role of *LMP1* in angiogenesis and metastasis has also been involved.²⁰ *LMP1* is regarded as a constitutively active receptor, mimicking the activation of B cells via the tumor necrosis factor receptor (TNFR) activation pathway. Two regions of *LMP1*, CTAR1/TES1 and CTAR2/TES2, are critical for B-cell immortalization. The CTAR1 domain binds with TNFR-associated factors (TRAF) 1, 2, 3, and 5, which suggests a similarity between *LMP1* and the superfamily of TNF receptors and a mimicry of the CD40/CD40-ligand activation pathway.²¹ *LMP1*, as a key transforming viral protein, activates very complex signaling cascades, including the NF- κ B, MAPK, JNK, p38, and JAK-STAT pathways through its C terminus, plays a leading role in most of the pleiotropic malignant effects.^{9,20,21} Its involvement in the PI3K/Akt signaling pathway has also been identified.²⁰ Interferon regulatory factor 7 (IRF7), which was cloned and identified in the context of EBV infection, is regulated by *LMP1*, which induces its expression, activation by phosphorylation, and nuclear translocation. Thus, IRF7 appears to be a cellular mediator of *LMP1* in EBV latency and transformation.²²

Two small non-polyadenylated RNAs, EBER1 and EBER2, are the most abundant viral transcripts in latently EBV-infected cells. They are therefore used as targets for in situ hybridization to detect EBV in tissue; however, examples of EBER-negative latent infection do exist.²³ EBER, which are involved in the interferon response, may also have a role in oncogenesis. In fact, they are also implicated in the maintenance of the malignant phenotype in BL cells by conferring resistance to various stimuli that normally induce apoptosis.²⁴ They also induce transcription of IL-10 as an autocrine growth factor in BL²⁵ and contribute to the local immune deficiency.

EBV, using many different signaling pathways to induce lymphocyte proliferation and survival, generates a highly complex molecular crosstalk between signaling events inducing transcription of the genes encoding the cytokines interleukin-6 (IL-6) and IL-10,

signaling molecules linked to the cell cycle and molecules implicated in the inhibition of apoptosis.^{26,27} The use of gene array technology to analyze virally regulated cellular genes in EBV-transformed Burkitt cell lines have identified several functional groups of genes involved in the cell cycle, apoptosis, and signal transduction pathways, including the TNFR and interferon pathways. Moreover, this study has identified the involvement of three families of transcription factors: Rel/NF- κ B, STAT1, and the Ets-related proteins spi-B, Elf-1, and Ets-1.²⁸

Approximately 1 in 10³–10⁴ peripheral blood B lymphocytes are latently infected. In the general healthy population, the persistence of EBV is related to its ability to use the cellular machinery of the normal B cell during immunopoiesis. Recent studies have identified the memory B cell as a reservoir of EBV,²⁹ and have demonstrated that these latently infected B cells express the same restricted pattern of latent genes previously found only in EBV-associated tumors.³⁰ EBV-infected B cells have to evade the germinal center reaction to gain access to the B-cell memory compartment, the reservoir of EBV. The latent gene expression of EBV depends on the location and differentiation state of the infected B cell. In newly infected B cells, all nine latent proteins and both EBER are expressed under the transactivation of EBNA2. Whereas in the germinal center, viral gene expression is restricted to LMP1, LMP2, the EBER, and EBNA1, in memory B cells in the tonsils and in peripheral blood, the latency is characterized as latency 0, with only the EBER and LMP2 transcripts being expressed.³¹

Thus, four types of latency (0, I, II, and III) have been described from analysis of EBV latent gene expression in LCL, primary infection and persistence of EBV, and tumors. They are characterized by differential expression of latent genes; the four types of EBV latency are summarized in Table 16.1.

The replicative life cycle of EBV appears when latently infected lymphocytes become permissive for virus replication.³² *BZLF1* and *BRLF1* are the immediate early genes expressed at the induction of the lytic cycle. These genes are transactivators of early EBV lytic gene expression, such as that of *BHLF1*, *BHRF1*, *BSMLF1*, and *BALF2*. Several EBV early genes are linked to DNA replication, including those encoding DNA polymerase (*BALF5*), major DNA-binding protein (*BALF2*), ribonucleotide reductase (*BORF2* and *BarF1*), thymidine kinase (*BXLF1*), and endoalkaline exonuclease (*BGLF5*). The late genes are mostly involved in encoding structural viral proteins, the most abundant of which is gp350/220 (encoded by *BLLF1*), which is found on the virus and in the plasma membrane of lytically infected cells.⁹

Because some EBV sequences have homology to cellular genes, it appears that some lytic genes have been appropriated from the primate genome. These genes are the EBV immediate early gene *BZLF1*, which is closely related to the *jun/fos* family, the early gene *BHRF1*, with functional homology to the *BCL2* gene, one of the most important anti-apoptotic genes, and the late gene *BCRF1*, which is close to the human *IL10* gene. IL-10, which is involved in proliferation and terminal B-cell differentiation, can induce local immunosuppression by blunting the initial interferon, natural killer (NK), and CD8⁺ T-cell response.⁹

EBV and immunodeficiency

Identifying positive serology to EBV, epidemiological studies show that more than 95% of adults in all populations worldwide are infected with EBV.⁸ In the general population, however, only a very few proportion of people develop LPD. In contrast, patients with immunodeficiencies have a 60–200 times greater risk of developing LPD. This observation reflects two fundamental features: (1) a tightly controlled and strong cellular immune response to EBV-infected cells, (2) the ability of the virus to establish interactions with cellular genes, leading to a breakdown of cellular homeostasis control, including both cell cycle and apoptosis.

Table 16.1 Types of EBV latency

	Latency				Functions
	0	I	II	III	
EBERS	+/-	+	+	+	Interferon response, resistance to apoptosis, transcription of IL-10
EBNA1	ARN	+	+	+	Partition/retention of viral genome
EBNA2	-	-	-	+	Transcription, tethered to RBP-J
EBNA3A	-	-	-	+	Transcription
EBNA3B	-	-	-	+	Transcription
EBNA3C	-	-	-	+	Cell cycle interaction
EBNALP	-	-	-	+	Cooperation with EBNA2
LMP1	-	-	+	+	Activation pathways: NF- κ B, STAT1
LMP2A	ARN	-	+	+	B-cell receptor interaction
LMP2B	-	-	+	+	?

ARN, acute retinal necrosis

Defective T-cell control in immunosuppressed patients is one of the key pathogenic mechanisms in EBV-related LPD. There is evidence of virus-specific T-cell mediated immunity, with restriction mainly through HLA class I but also through HLA class II (reviewed in reference 33). The specific response against different viral antigens determined by the HLA class I of the responder has been demonstrated using expansion and subsequent cloning of reactive T cells and a complex viral system with vaccinia recombinants expressing individual viral genes.^{34,35} Immunological studies have been conducted using mapped antigenic peptide epitopes within the primary sequence of several of the viral proteins expressed in transformed cells,³⁶ the interferon- γ (IFN- γ) Elispot assay for quantitative detection of EBV-specific CD8⁺ cells,³⁷ together with the use of synthetic peptides and tetramer technology.³⁸ These studies have demonstrated the lack of a specific T-cell response and the long-term restoration of immunity against EBV infection by adoptive transfer of genemodified virus-specific T lymphocytes.³⁹ Besides a quantitative defect, studies of the functional diversity of the CD8⁺ T-cell response to EBV have shown that EBV-specific CD8⁺ T cells that express type 2 cytokines (IL-4, IL-5, IL-6, IL-10, and IL-13) possess the ability to activate resting B cells.⁴⁰ This is in accordance with previous experiments in SCID mice engrafted with human peripheral blood lymphocytes, showing that the presence of T cells is required for the development of EBV-induced lymphoproliferative disorders.⁴¹

Targets of EBV CD8⁺ T cells are immunogenic latency proteins such as EBNA3C, EBNA2, and LMP1,^{8,42} as well as immediate early and early lytic cycle proteins.⁴³ EBNA1, which is a major latent protein of EBV, does not generate a specific CD8⁺ T-cell response due to selective inhibition of processing by glycine—alanine repeats.⁴⁴ However, recent immunological data have shown that CD4⁺ cells are specific for EBNA1.⁴⁵

Besides the defective T-cell response to a given antigen, the importance of the role of different processing of the epitope and its presentation has also been demonstrated.⁴⁶ Recent data show that the interaction of EBV with monocytes can prevent the development of dendritic cells, suggesting that interference with the dendritic cell functions plays a role in escaping the virus-specific immune response.⁴⁷ The secretion of IL-10 by EBV-infected B cells⁴⁸ and by a subset of CD8⁺ T cells leads to an enhancement of immunosuppression.^{40,49}

As a consequence of the lack of the immune control, there is an increase in viral load. This increase has been demonstrated in immunodeficient patients by semiquantitative and quantitative polymerase chain reaction (PCR).⁵⁰ The relationship between the high viral load and the occurrence of LPD has been demonstrated in post-transplant patients,⁵⁰ although in HIV patients, the link between a high viral load and the occurrence of a lymphoma is less clearly demonstrated.⁵¹

The importance of these mechanisms of immune surveillance in limiting the growth advantage of EBV-infected cells is clearly illustrated in immunodeficient patients. Regressions of LPD have been reported after reduction of immunosuppression⁴ and also after infusion of blood lymphocytes or in vivo activated EBV-specific cytotoxic T-lymphocyte cultures of donor origin in bone marrow recipients developing lymphomas.^{52–54}

KSHV/HHV8

In 1994, using a new technique of viral identification, representational difference analysis (RDA), a new human γ -herpesvirus was identified^{55,56} in an AIDS-related Kaposi sarcoma (KS) biopsy. The same virus was identified in a peculiar lymphoma confined predominantly to the body cavities and persisting as effusion, now named primary effusion lymphoma (PEL), that had developed in AIDS patients.⁵⁷ This virus has also been identified in HIV-related multicentric Castleman disease (MCD),⁵⁸ which is frequently associated with secondary tumors such as KS and lymphomas. This virus was named Kaposi sarcoma-associated herpesvirus (KSHV) or human herpesvirus 8 (HHV8). KSHV/HHV8 has sequence similarity to the oncogenic herpesvirus saimiri (HVS), EBV, and murine herpesvirus 68 (MHV68), and leads, like these transforming viruses, to neoplasms. The complete genome of KSHV/HHV8 was sequenced from both KS biopsy and PEL cell lines (BC1).^{59,60} The virus consists of a long unique coding region (LUR) flanked by 800 bp terminal repeat sequences. The LUR comprises 81 open reading frames (ORF). A large number of genes pirated from eukaryotic cellular DNA are recognized, mimicking cytokine and cytokine response pathways. Comparisons between KSHV/HHV8 and EBV have shown similarities in the use of cellular machinery by these two viruses, both virus employing the same signaling cascades to survive in their hosts.⁶¹

The cellular genes pirated by KSHV/HHV8 include those specifying functions associated with signal transduction, immune evasion, and cellular proliferation and survival. Thus, they can be categorized according to their function. Genes involved in cell proliferation are *v-cyclin* (ORF72),⁶² *v-GPCR* (ORF74),⁶³ and *v-IRF* (K9).⁶⁴ The latter two have oncogenic potential and transform 3T3 cells.^{63,64} Apoptosis inhibitors are encoded by *V-BCL2* (ORF16),⁶⁵ *v-FLIP* (ORF71), and *v-IL-6* (ORFK2).⁶⁶ Broad-spectrum chemokine antagonists are also encoded by the

KSHV/HHV8 genes *v-MIP-I* (ORFK4), *v-MIP-II* (ORFK6), and *v-MIP-III* (ORFK4–2). The virally encoded chemokines *v-MIP-I* and *v-MIP-II* bind to both CC and CXC receptors preferentially over cellular chemokines.⁶⁷ The protein encoded by *v-NCAM* (ORFK14) has an intercellular signaling function. The captured eukaryotic genes have acquired unique properties abrogating normal responses; for example, the D-type cyclin encoded by KSHV/HHV8 does not respond to the cell cycle inhibitors p16 and p21 after binding to CDK6.⁶⁸

Like EBV, KSHV/HHV8 is latently present in B lymphocytes. A punctuate nuclear staining detected after immunofluorescence using KSHV/HHV8 immune sera as well as immunoblots detected a 222–234 kDa doublet, leading to the discovery of a latent antigen, latency-associated nuclear antigen (LANA, LNA, or LNA1), encoded by ORF73. Serological assays based on antibodies to LANA and to a recombinant structural (capsid-related) protein encoded by ORF65, and then polymerase chain reaction (PCR) detection on peripheral blood mononuclear cells, semen, and saliva, has allowed wide epidemiological studies.⁶⁹

The gene expression of KSHV/HHV8 in PEL is important for understanding the pathogenetic role of this virus in this peculiar lymphoma. Three KSHV/HHV8 gene products, *v-GPCR*,⁶³ *v-IRF*,⁶⁴ and *kaposin*,⁷⁰ can induce transformation of rodent fibroblasts, and K1 can substitute for the transforming protein of HVS.⁷¹ In PEL-derived cell lines, associated or not with EBV,⁵⁹ KSHV/HHV8 is latent, with only a minority being replicated. Exposure of these cell lines to 12-tetradecanoylphorbol 13-acetate (TPA) or butyrate can induce an increase in virus-producing cells. Based on the responsiveness of PEL cells lines to TPA-induction, three classes of transcription of KSHV/HHV8 genes have been identified: class I genes, which are constitutively transcribed; class II, which are transcribed in the absence of TPA with much higher expression after exposure to TPA; and class III, reflecting lytic viral replication transcribed only following TPA induction.⁷² Studies on PEL, using reverse transcriptase (RT)-PCR, revealed the expression of *V-BCL2*, *v-IL-6*, *v-MIP-I*, *v-MIP-II*, *v-cyclin*, and *v-GPCR*.⁷³ High levels of KSHV/HHV8 viral load and human IL-6 and IL-10 correlate with exacerbation of MCD in HIV-infected patients.^{74–76} Interaction between LANA and cellular IL-6 was demonstrated through the AP1 response element.⁷⁷ Moreover, LANA inhibits p53, leading to protection against apoptosis of KSHV/HHV8-infected cells. These pathogenic mechanisms can lead in MCD to a spectrum of LPD having the features of plasmablastic lymphoma. Thus, oncogenes encoded by KSHV/HHV8 can potentially induce cell transformation and suppress host defense mechanisms.

EBV-associated hematological malignancies in immunosuppression

Whatever the immunodeficiency, it is now well established that the EBV-related LPD induced in the context of immunosuppression result from the cooperative action of several EBV genes, interactions between the virus and the cell in complex signaling pathways, and cooperation with genetic aberrations of the cellular genome.²⁶ However, besides the role of EBV, cellular genetic abnormalities are also present and may have synergy with the role of the viruses, leading to very aggressive LPD in the context of immunodeficiency.

EBV-associated tumors in PID

In PID, the cause of the LPD is related to the underlying primary immune defect.² In the case of EBV-related LPD, the defective immune surveillance of EBV is the primary mechanism. This is present in XLP, WAS, SCID, and some CVID.⁷⁸ The absence of T-cell control may be complete, as in fatal infectious mononucleosis (FIM) due to mutations of the SAP/SLAM protein leading to a deficient immune response to EBV.^{79,80} The defect can be partial, as in lymphomatoid granulomatosis, mostly linked to WAS, a complex PID where T cells, B cells, neutrophils, platelets, and macrophages are deficient.^{81,82}

Most LPD in patients with PID are of B-cell lineage, displaying B-cell markers corresponding to their differentiation status. EBV infection of B cells often leads to downregulation of these B antigens, which may be negative or expressed in only some of the neoplastic cells. On the contrary, activation molecules such as CD30 often related to the presence of the expression of the EBV latent protein LMP1, which is expressed in most cases, is upregulated and present in a variable number of EBV-infected B cells.

FIM, primarily seen in patients with XLP, results from the proliferation of EBV-positive B cells in the absence of effective immune surveillance. This abnormal B-cell proliferation is systemic, involving both lymphoid and non-lymphoid organs, most commonly the terminal ileum. This EBV-related LPD is characterized by a highly polymorphous proliferation of lymphoid cells with plasmacytoid and immunoblastic differentiation, and some Reed-Sternberg-like cells may be seen. FIM may be polyclonal at the genetic level.^{78,83}

Lymphomatoid granulomatosis is an EBV-driven proliferation of B cells associated with a marked T-cell infiltration, mostly located in extranodal sites: lung, skin, brain, and kidney. The lymphoid proliferation is characterized by an angiocentric and angiodestructive

infiltrate, often with extensive necrosis. Variable numbers of atypical large EBV-infected B cells are described, and this lymphoproliferative disorder may progress to diffuse large cell lymphoma (DLBCL),⁸² which can be observed de novo in PID.⁸⁴

EBV and post-transplant lymphoproliferative disorders (PTLD)

The overall incidence of PTLD for solid organ transplant recipients is 2%. However, the frequency of PTLD varies from less than 1% in renal allografts to 5% after heart-lung or liver-bowel allografts.^{85,86} After bone marrow transplantation, the risk of PTLD is low (1%), except after mismatched bone marrow transplantation, T-cell-depleted bone marrow, or immunosuppressive therapy for graft-versus-host disease, where the occurrence rate of lymphoma can reach 20%.⁸⁷ In solid organ recipients, the majority of PTLD are of host origin, while in marrow allograft recipients, they are of donor origin.⁸⁷ EBV-related PTLD tend to occur earlier after transplantation, with a median interval of 6–10 months, than EBV-negative lymphomas, which tend to occur later than 5 years following the transplant.^{5,88}

The majority of PTLD associated with EBV infection occurring in a setting of iatrogenic impaired T-cell immune surveillance are EBV-induced polyclonal, oligoclonal, or monoclonal B-cell proliferations.^{85,86,89,90} A physical association of LMP1 with TRAF molecules was demonstrated in EBV-positive PTLD, showing that LMP1-mediated signaling through the TRAF system plays a role in the pathogenesis of PTLD.⁹¹ PTLD comprise a spectrum ranging from early EBV-driven polyclonal proliferations resembling infectious mononucleosis to lymphomas of predominantly B-cell or less often T-cell type. Several categories have been identified according to clinical presentation, morphology, and phenotypic and molecular features^{85,86,89,90} (Table 16.2).

Early lesions, often arising within the first 2 years, and seen more frequently in children or in adult solid organ recipients who have not had prior EBV infection, are characterized as plasmacytic hyperplasia (PH) and infectious mononucleosis-like (IM-like). The lymphoid proliferation involves lymph nodes or tonsils and adenoids and may regress spontaneously or after reduction in immunosuppression. Plasmacytic hyperplasia contain numerous plasma cells and rare immunoblasts, while the IM-like lesion in lymph nodes or tonsils has the typical morphologic features of IM, with paracortical expansion and numerous immunoblasts in a background of T cells and plasma cells. Immunoblasts are EBV-infected B cells expressing LMP1. Small monoclonal or oligoclonal bands on Southern blots probed for episomal EBV genomes may be detected in these lesions. Some cases may be followed by polymorphic or monomorphic PTLD.⁹²

Table 16.2 Histological categories of post-transplant lymphoproliferative disorders⁹⁰

• Early lesions
Reactive plasmacytic hyperplasia
Infectious mononucleosis-like
• Polymorphic PTLD
• Monomorphic PTLD (classified according to the WHO lymphoma classification)
B-cell neoplasms;
Diffuse large B-cell lymphoma Burkitt lymphoma (classical or atypical)
Plasma cell myeloma
Plasmacytoma-like lesions
T-cell neoplasms
Peripheral T-cell lymphoma, not otherwise categorized
Other types
• Hodgkin lymphoma and Hodgkin lymphoma-like

Polymorphic PTLD, developing mostly in extranodal localizations in one or multiple sites (including the allograft), are destructive lesions effacing the architecture with some areas of necrosis. They are composed of a range of lymphoid cell types, including immunoblasts, plasma cells, and intermediate-sized lymphoid cells. Clonal rearrangements of immunoglobulin genes and/or EBV genomes are frequent, and the presence of distinct clones at different sites in the same patient has been demonstrated. There are no genetic abnormalities involving oncogenes such as *c-MYC*, *RAS*, and *p53*, but chromosomal abnormalities/imbances may be detected by comparative genomic hybridization (CGH).⁹³ These lesions contain numerous EBV-infected cells detected by in situ hybridization using EBER probes. The EBV-infected lymphoid cells express EBV latent genes such as *LMP1* and *EBNA2*, reflecting in the majority of cases a type III latency pattern of EBV.^{94,95} The evolution of these lesions is variable; reduction of immunosuppression can lead to regression of the PTLD, while some cases can evolve to a monomorphic lymphoma.^{85,86}

Monomorphic PTLD are mostly DLBCL with clonal immunoglobulin gene rearrangements in virtually all cases. These lymphomas satisfy the histological criteria according to the WHO classification. The majority are subclassified as immunoblastic with plasmacytic features.^{89,90} Many cases are CD30+, containing EBV genomes that are in clonal episomal form, and the three types of EBV latency are also described in these tumors. Genetic abnormalities involving mutations of the *BCL6* and *RAS* genes, *c-MYC* rearrangement and mutations, and numerous chromosomal imbalances such as in the region containing *BCL2* are present in the great majority of cases.^{92,93}

Monomorphic T-PTLD showing clonal T-cell receptor gene rearrangements occur after a longer interval from the graft than B-cell lymphoma. They are classified according to the categories of T-cell lymphomas recognized in the WHO classification and are variable with respect to EBV positivity, about 25% showing clonal episomal EBV genomes.^{89,90}

Other PTLT where EBV is virtually always present are Hodgkin lymphoma and Hodgkin-like lesions showing infiltrates with morphologic and immunophenotypic features of classical Hodgkin lymphoma, including the expression of CD15 and CD30; some have B-cell antigen expression. Some cases have responded to therapy for Hodgkin lymphoma, while others have been clinically aggressive.^{89,90}

Polymorphic and less often monomorphic PTLT may regress with reduction in immune suppression; a proportion of cases of both types fail to regress, and require cytotoxic chemotherapy.⁴ Overall, the mortality rate of PTLT in solid organ allograft recipients is approximately 60%, while that of marrow allograft recipients with PTLT is 80%. Administration of antibody to CD20 antigen has been useful in abrogating PTLT development in some cases.⁹⁶ Monitoring for evidence of reactivation of EBV infection may provide an early warning of PTLT development,⁵⁰ leading to a better clinical management of PTLT.

EBV and AIDS-related lymphomas

Lymphomas that develop in HIV-positive patients are predominantly aggressive B-cell lymphomas, and in a proportion of cases they are the initial manifestation of AIDS. The incidence of Hodgkin lymphoma may be increased up to eight-fold. These lymphomas are heterogeneous, and include lymphomas usually diagnosed in immunocompetent patients, as well as those seen much more often in the setting of HIV infection and some appearing in other immunodeficiencies.⁹⁷ AIDS-related lymphomas are heterogeneous, reflecting several pathogenic mechanisms. The herpesviruses EBV and KSHV/HHV8 play a major role in some categories of HIV-related lymphomas. Disruption of the cytokine network, with high serum levels of IL-6 and IL-10, is a feature of HIV-related lymphomas associated with EBV or KSHV/HHV8. Other pathogenic aspects of lymphomas are also involved, such as chronic antigen stimulation, genetic abnormalities involving the *c-MYC* and *BCL6* genes, as well as tumor suppressor genes.^{6,98} EBV is identified in the neoplastic cells of approximately 60% of HIV-related lymphomas, but the detection of EBV varies considerably with localization and histological subtype.⁹⁹

The most common HIV-associated lymphomas include BL, DLBCL, plasmablastic lymphomas of the oral cavity, Hodgkin lymphoma, lymphoproliferative disorders, and lymphomas associated with KSHV/HHV8, particularly PEL (Table 16.3).⁹⁷

Besides classical BL, the morphological variant of BL with plasmacytoid differentiation is nearly confined to AIDS patients and represents about 20% of NHL cases in these patients. Those developing such tumors have more pronounced immunosuppression than in classical BL. Medium-sized cells with more abundant basophilic cytoplasm are characteristic, as is an eccentric nucleus, often with one centrally located prominent nucleolus. The cells often contain cytoplasmic immunoglobulin, and EBV is positive in about 50–70% of cases. At the molecular level, HIV-associated BL, like other BL, have genetic abnormalities affecting band 8q24, the location of the *c-MYC* locus.¹⁰⁰ Besides the truncation within or around the *c-MYC* locus, point mutations in the first intron-first exon regulatory regions and amino-acid substitutions in the second exon are also detected and contribute to the deregulation of *c-MYC*.⁹⁸

DLBCL having centroblastic features are associated with EBV in 30% of cases and represent about 25% of HIV-related lymphomas. The immunoblastic variant, usually exhibiting plasmacytoid features as in

Table 16.3 Categories of HIV-associated lymphomas and frequency of EBV⁹⁷

Categories of HIV-associated lymphomas	EBV-positivity (%)
Lymphomas also occurring in immunocompetent patients	
Burkitt lymphoma	30–70
Classical	30
With plasmacytoid differentiation	50–70
Atypical	30–50
Diffuse large cell lymphoma	20–100
Centroblastic	20–30
Immunoblastic	90–100 ^a
Extranodal marginal zone B-cell lymphoma of MALT type (rare)	
Peripheral T-cell lymphoma (rare)	
Classical Hodgkin lymphoma	
Lymphomas occurring more specifically in HIV-positive patients	
Primary effusion lymphoma	90
Plasmablastic lymphoma of the oral cavity	50
Lymphomas also occurring in other immunodeficiency states	
Polymorphic B-cell lymphoma (PTLT-like)	90

^a In primary central nervous system lymphomas, almost all cases are associated with EBV.

primary central nervous system lymphoma, is associated with EBV in 90–100% of cases, and often occurs late in the course of HIV disease.¹⁰¹ Phenotypic markers that allow distinction between mature B cells as virgin B-cell, germinal center B-cell, and postgerminal center, namely BCL6, MUM1/IRF4, and CD138, are differentially expressed in AIDS-related lymphomas according to their origin. Two main categories are identified: lymphomas reflecting the germinal center, which are BCL6⁺, MUM1/IRF4⁻, CD138⁻, and those belonging to the post-germinal center expression pattern BCL6⁻, MUM1/IRF4⁺, CD138⁺. In EBV-positive lymphomas expressing high amounts of LMP1, BCL6 may be downregulated.¹⁰² Another interaction between EBV latent protein and the regulatory cell protein is abrogation of the inverse relationship between the p27^{Kip} inhibitor of cell cycle expression and a high rate of proliferation in these tumors.¹⁰³

Plasmablastic lymphoma of the oral cavity, a rare lymphoid neoplasm, localized in the oral cavity or the jaw, and having plasmablastic features is rapidly growing, with a high mitotic index. The large tumor cells display a diffuse pattern of growth interspersed by macrophages. Some cells display cytoplasmic immunoglobulins. EBV is present in more than 50% of cases, but no association with KSHV/HHV8 has been detected.¹⁰⁴

Polymorphic lymphoid proliferations resembling polymorphic PTL, mostly EBV-positive, may be seen in adults and also in children, but are much less common than in the post-transplant setting, comprising less than 5% of AIDS-related lymphomas.¹⁰⁵

Most cases of Hodgkin lymphoma correspond to either the mixed cellularity or lymphocyte-depleted forms of classical Hodgkin lymphoma. Some cases of nodular sclerosis Hodgkin lymphoma are also seen. HIV-related Hodgkin lymphoma is associated with EBV in nearly all cases; the pattern of EBV latent gene expression is characteristic of latency II (EBER+ LMP1+EBNA2-).¹⁰⁶

KSHV/HHV8-related LPD and lymphoma develop in HIV-infected patients because KSHV/HHV8 is highly pathogenic in the context of HIV infection and immunosuppression. The LPD, which are almost all of B-cell origin, include PEL (initially termed body cavity-based lymphomas) and MCD associated with micro or frank plasmablastic lymphoma.

PEL, a rare lymphoma with lymphomatous effusions, was not fully characterized until the discovery of KSHV/HHV8. It represents a distinct clinicopathological entity, based on morphological, immunophenotypic, molecular, and viral features. Typically presenting with either pleural or peritoneal effusion, it can present as a solid tumor mass, most commonly affecting the gastrointestinal tract or soft tissue. PEL is associated with both Kaposi sarcoma and MCD in HIV-positive patients. Tumor cells exhibit variable cell types, from large immunoblastic or plasmablastic cells to cells with more anaplastic morphology and plasmacytoid differentiation, or Reed-Sternberg cells may be seen. The tumor cells originate from post-germinal center B cells and express CD45, CD38, CD138, and also activation markers such as CD30. However, they are usually negative for B-cell markers such as CD19, CD20, and CD79a, as well as for surface and cytoplasmic immunoglobulins. At the molecular level, they are characterized as late differentiated B cells with rearranged and mutated immunoglobulin genes. No *c-MYC* abnormalities have been found. This rare lymphoma has a very aggressive clinical outlook, with a median survival of less than 6 months.^{107,108}

Plasmablastic lymphoma in the context of MCD is a lymphoproliferative disorder that can lead to frank plasmablastic lymphoma, associated in all cases with KSHV/HHV8.¹⁰⁹ A variable number of KSHV/HHV8-positive scattered large lymphoid cells are detected in the mantle zone. These cells, having the morphology of plasmablasts, containing large amounts of IgM, and expressing exclusively A, light chain, are proliferating (Ki67⁺). These plasmablasts may coalesce to form confluent clusters with the constitution of microlymphomatous lesions and sometimes frank plasmablastic lymphomas. Although of monotype IgM λ , the KSHV/HHV8 microlymphomatous lesions are polyclonal, while frank plasmablastic lymphomas are monoclonal. This molecular spectrum is similar to those described in EBV-driven lymphoproliferative disorders. The characteristic of these KSHV/HHV8-associated plasmablastic lymphomas is the lack of somatic mutations in their rearranged heavy and light chains, suggesting their origin from a naive B cell. The plasmablastic features of these lymphomas without somatic Ig gene mutations are evidence in favor of the role of KSHV/HHV8 driving infected cells to differentiate into plasmablasts without going through the germinal center.¹¹⁰

Acquired genetic changes in myeloid malignancies

Cristina Mecucci and Anne Hagemeijer

Introduction

Cytogenetic findings

Chromosomal changes can be detected in the majority of cases of acute myeloid leukemia (AML) or myelodysplastic syndromes (MDS). These abnormalities are an acquired and clonal intrinsic feature of leukemia. They are the visible indicator of malignant transformation: with response to treatment, the malignant clone may disappear, but in the case of relapse, the leukemic cells carry the same original aberration, sometimes with additional changes.

Recurrent patterns of numerical changes (gain and loss) or structural changes (translocation, inversion, deletion, and duplication) have been identified and found to be characteristic of specific subtypes of leukemia.

Several chromosomal rearrangements, and the molecular abnormalities that they produce, identify distinct clinical subgroups with predictable clinical features and therapeutic responses.

De novo AML and therapy-related AML (t-AML) may exhibit different karyotype changes. In AML in children and young adults, there is a predominance of balanced translocations; in the aged and in secondary leukemia, there is a predominance of numerical and unbalanced abnormalities. Complex karyotypes (more than three abnormalities) are particularly ominous in all age groups (Figure 17.1).

Gene rearrangements

Molecular analyses of recurrent translocations have revealed how genes controlling cell proliferation, survival, or apoptosis are rearranged or modified and become oncogenic. As a consequence of translocation of chromosome segments, genes are recombined illegitimately (gene fusion) and give rise to a new hybrid gene encoding chimeric neoproteins. Many of these

Figure 17.1 G-banded abnormal complex karyotype from bone marrow cells of an aged patient with refractory anemia and very short survival (5 months from diagnosis).

oncoproteins are transcription factors. Master genes have been identified that may recombine with a variety of other genes; this gives rise to different translocations and to leukemia that can be of different phenotype. Examples of ‘multipartner’ genes are *MLL* on 11q23, *ETV6* on 12p13 and *RUNX1 (AML1)* on 21q22.

Chromosomal translocations can also lead to altered transcription of intact genes through positioning them ectopically under the control of other constitutively active promoters or transcriptional enhancers. While this is more common in lymphoid malignancies, including acute lymphoblastic leukemia (ALL), chromosomal translocations involving the formation of chimeric fusion proteins are more frequently seen in myeloid malignancies.

Chromosome numerical changes and deletions result in gene imbalance. Deletions are suggestive of a mechanism of leukemogenesis by tumor suppression. Many studies are currently concentrating on the definition of tumor suppressor genes on 5q, 7q, and 20q, which are sites of recurrent deletions. Mutations resulting in transcriptional upregulation of a gene also occur.

In addition to numerical or structural chromosomal changes that can be detected with classical cytogenetics or fluorescence in situ hybridization (FISH), an increasing number of molecular changes are being identified with higher-resolution techniques, including gene amplification, deletions, internal domain duplications, and point mutations in growth factor receptors or signaling molecules. From the molecular identification of these changes, two general classes of leukemia-inducing changes are emerging: those conferring a proliferative and/or survival advantage, and those impairing hematopoietic differentiation. While the former class can be molecularly targeted by specific small-molecule inhibitors, the latter class might be targeted by compounds that restore or promote hematopoietic differentiation.

In summary, leukemia, like other malignancies, arises as a consequence of a major genetic insult and/or a cascade of more subtle mutations. Current molecular studies provide information on these mechanisms of leukemogenesis, and additional insight is gained into the genetic control of normal hematopoiesis.

Methods of detection

Genetic abnormalities of leukemic cells are investigated using a number of different techniques: classical karyotype analysis using banding techniques, FISH, Southern blotting, reverse-transcriptase polymerase chain reaction (RT-PCR), and immunological detection of a specific oncoprotein.

Classical cytogenetics

This provides a complete picture of genetic changes at the chromosomal level. It is performed on leukemic cells in metaphase, obtained after short-term culture with or without the use of growth factors or mitogens.

Cytogenetics provides information on specific changes, on the complexity of abnormalities, and on the presence of more than one leukemic clone. Apparently normal karyotype may harbor a genetic defect at submicroscopic level that can be detected using molecular methods.

FISH

FISH makes use of specific DNA probes directly or indirectly labeled with fluorochromes and hybridized on cellular DNA in metaphase or interphase. The method is highly specific and the characteristics of the probes determine its sensitivity. Currently, the probes used are chromosome-specific (centromeric, subtelomeric, whole paint) or locus/gene-specific. For the detection of translocations, a double-color strategy (also applicable on interphase cells) is usually applied using gene-specific probes (Figure 17.2, see Plate 2).

Some probe combinations detect a ‘fusion signal’ in leukemic cells; other probes are designed as ‘break-apart’, giving a split signal in rearranged genes such as *MLL* and *ETV6* (Figure 17.2, see Plate 2). FISH can be combined with other detection methods,

Figure 17.2 Double-color metaphase FISH in a patient with a cryptic *ETV6-ABL1* fusion gene and only a $t(8;12)(p12;p13)$ translocation on classical cytogenetics. Red signals mark the *ETV6* gene both in the abnormal 12p and in the abnormal 8 derived from the chromosomal translocation. Green signals label the *ABL1* gene in both the normal chromosome 9 and the abnormal 8. See Plate 2.

Figure 17.3 AML with extra material in the short arm of chromosome 16 derived from chromosome 1 (arrow), as revealed by multicolor FISH karyotype. See Plate 2.

such as cytology, cytochemistry, and immunology, which allows the investigation of selected subsets of cells.

Complex painting probes allowing 24-color karyotyping are also available, and are useful in analysis of complex abnormalities, and sometimes the detection of cryptic changes (Figure 17.3, see Plate 2).

RT-PCR

This technique amplifies the ‘fusion transcript’ characteristic of a given translocation. RT-PCR detects known fusion events with high sensitivity and is particularly useful for detecting residual disease. The new Taqman technology makes quantitative assessment of transcripts in real time, which allows the evaluation of therapeutic response, monitoring of remission, and prediction of relapse.

cDNA microarray

Fluorescently labeled mRNA of leukemic cells can be hybridized to a high-density cDNA microarray. This provides a quantitative assessment of transcripts (genome-wide) and has proven very useful to determine the specific expression profile associated with specific cytogenetic subtypes of leukemia.¹

Fusion genes

Fusion genes are generated by chromosome translocations or inversions. A summary is given in Table 17.1. Most of them will be discussed separately.

Frequently occurring translocations in AML are t(15;17) in 7% (95% of acute promyelocytic leukemia (APL)); t(8;21) in 10%; inv(16) in 9%; t(11q23) in 5–7%, and t(3q) in 5%. All other translocations have a frequency of 1% or less, with some age-related and geographical differences. Correlations between specific cytogenetic subgroups and prognosis are shown in Table 17.2.

t(15;17)(q22;q21): PML/RARA

Acute promyelocytic leukemia (APL, AML-M3) is characterized by a specific reciprocal translocation that involves chromosome 17q21 in more than 95% of cases. The *RARA* (retinoic acid receptor α) gene at 17q21 recombines with the *PML* (promyelocytic leukemia) gene at 15q22.² Both fusion products, PML-RAR α and RAR α -PML may be present in leukemic cells. In transgenic mice, the PML/RAR α fusion protein is expressed in the myeloid lineage. APL with t(15;17) is responsive to treatment with all-*trans*-retinoic acid (ATRA). Mice developed an abnormal hematopoiesis resembling a myeloproliferative disorder, but only 10% of them, after a latency of 12–14 months, developed an acute leukemia with clinical and hematological features mirroring human APL, including responsiveness to retinoic acid treatment.³

Molecular analysis of APL without the classical t(15;17) has documented the existence of complex or simple variant translocations, involving chromosomes 15 and/or 17 plus other chromosomes.⁴ Moreover, masked translocations/insertions with apparently normal chromosomes 15 and 17 have been shown. Among simple variants, in a subgroup of AML with morphological features intermediate between M2 and M3 subtypes, a t(11;17)(q23;q22) results in fusion of the *RARA* gene with the *PLZF* (promyelocytic leukemia zinc finger) gene.⁵ This t(11;17)/*PLZF*-/*RARA* APL represents a distinct entity characterized by poor response to chemotherapy, little or no response to treatment with ATRA, and a bad prognosis, worse than t(15;17)/APL.

Table 17.1 Summary of specific translocations and inversions found in myeloid malignancies, the genes involved, and the main clinicopathological associations

(Figure 17.4). In other rare cases, the *RARA* gene recombines with the *NPM* (nucleophosmin) gene in the presence of a t(5;17)(q35;q21). Similarly to t(11;17)/APL, this entity is refractory to ATRA treatment. Other partners of *RARA* are the *NuMA* (nuclear mitotic apparatus) gene in the t(11; 17)(q13;q21), and the *STAT5b* gene in the t(17;17)(q11;q21).⁶⁻⁸ In both translocations, the leukemia presents with morphological, immunophenotypic, and clinical features overlapping those of t(15;17)/APL.

Serial screenings of APL patients by RT-PCR assay for the PML/RARα fusion protein on bone marrow cells is helpful to predict clinical course after treatment.⁹ A negative result of RT-PCR at the end of therapy is strongly associated with long-term remission, whereas persistent positive tests are highly predictive of relapse.

In addition to t(15;17), secondary chromosomal changes have been reported in 25–40% of APL cases.¹⁰ The most frequent additional change is trisomy 8. Other abnormalities may involve chromosomes 9, 17, 7, 21, 16, 6, and 12. The prognostic value of additional cytogenetic abnormalities in APL is controversial. However, in a large cohort of patients

uniformly treated with ATRA in combination with chemotherapy, no differences were found in terms of clinical and biological features, event-free survival, risk of relapse, and overall survival.

Table 17.2 Prognostic value of karyotype in acute myeloid leukemia

Good

Complex (>3) abnormalities

t(8;21)(q22;q22): RUNX1-ETO

The t(8;21)(q22;q22) translocation is found in around 10% of AML cases, predominantly those of M2 subtype, with a good response to chemotherapy, high remission rate, and long median survival. Immunophenotyping is particularly useful to identify this type of myeloid leukemia with significant high expression of the CD 19 antigen.¹¹ Fusion occurs between the *RUNX1* gene (previously called *AML1*), a core binding factor (CBF) at chromosome 21q22, and the *ETO* gene, a transcription factor at chromosome 8q22. The RUNX1-ETO fusion protein acts as an inhibitor of transcription through heterodimerization with the CBFβ domain and subsequent interaction with CBF DNA-binding sites (Figure 17.5). CBF is a heterodimer consisting of a DNA binding α subunit (AML1, CBFα, RUNX1) and a β subunit (CBFβ), which enhances the DNA-binding affinity of the α subunit. CBF acts as a transcriptional organizer that, depending on the cellular context and the target gene, can recruit transcriptional activators and co-activators, or transcriptional repressors. The RUNX1-ETO fusion protein acts as a dominant-negative inhibitor of the native CBF complex through recruitment of the nuclear corepressor complex.¹²

FISH and PCR studies revealed the existence of RUNX1-ETO⁺ leukemias in the absence of the

Figure 17.4 Schematic representation of the mechanism of all-trans-retinoic acid (ATRA) responsiveness and refractoriness in APL associated with t(15;17) (a) and t(11;17) (b), respectively. The link between RARα and the nuclear corepressor-histone deacetylase (NCOR-HD) complex is broken by ATRA. The link between PLZF and NCOR-HD is not broken by ATRA.

Figure 17.5 Schematic representation of the core binding factor, CBF, which is composed of two subunits. Disruption and rearrangement of the genes encoding for RUNX1 (AML1, CBFα) and CBFβ are found as recurrent aberrations in AML and ALL.

classical t(8;21).¹³ Cytogenetically, these cases are characterized by complex variant translocations involving 8q22, 21q22, or another chromosome, masked translocations, and insertions.¹⁴ The RUNX1-ETO fusion protein, which consists of the N terminus of RUNX1 fused to nearly the full length of ETO, is not sufficient to drive the leukemogenic process, as demonstrated in transgenic mice.¹⁵ The prognostic significance of RT-PCR for RUNX1-ETO has not been completely clarified, owing to the presence of the RUNX1-ETO fusion protein in case of long-term hematological remission.¹⁶ A good correlation, however, was found between negative PCR results and the absence of relapse in a prospective study of patients with t(8;21).

Additional chromosome aberrations are estimated to occur in around 70–80% of AML cases with t(8;21). The most frequent additional abnormalities are represented by loss of a sex chromosome, partial deletion of the long arm of chromosome 9, and, less frequently, trisomy 8 and partial deletion of the long arm of chromosome 7. Whereas the loss of a sex chromosome does not influence the clinical outcome of the disease, a partial deletion of the long arm of chromosome 9 seems to be related to an unfavorable prognosis.¹⁷

inv(16)(p13q22)/t(16;16)(p13;q22): *CBFB-MYH11*

inv(16)(p13q22) and t(16;16)(p13;q22) are associated with the M4Eo subset of AML and, less frequently, with the M2 and M5 subtypes. Prognosis is relatively good. However, quantitative molecular monitoring may identify a group with low copy number at low or non-existing risk of relapse, and a group with higher numbers of transcripts at high risk for relapse.¹⁸ The chimeric gene consists of the 5' part of CBF β , a transcription factor at 16q22 that interacts with the RUNX1 DNA-binding factor (Figure 17.5), and the 3' coding sequence of *MYH11* at 16p13, encoding the smooth muscle myosin heavy chain (SMMHC). This results in a CBF β —SMMHC fusion protein, which in a dominant-negative way inhibits CBF function through mobilization of the nuclear corepressor complex or through RUNX1 sequestration in the cytoplasm. By applying molecular investigations, masked inv(16) have been identified, including cases with an inverted 16 that is also involved in a translocation with another chromosome, as well as submicroscopic rearrangements in leukemias with normal karyotype or trisomy of chromosome 8 and/or 22.^{19,20} Molecular studies using RT-PCR revealed that the frequency of this change is higher than reported using conventional cytogenetics. Molecular studies are also highly sensitive in monitoring the disease during and at the end of therapy. However, the value of molecular monitoring in inv(16) cases is limited, since *CBFB-MYH11* transcripts can be detected in long-term remission patients.

FISH with appropriate probes for the 16p13 region detects accompanying deletions in the p arm, including the *MPR* gene, in around 20% of patients.²¹ No significant differences in the survival of patients with or without 16p deletions associated with inv(16)/t(16;16) were observed.²¹

Additional karyotypic abnormalities are present in about half of the patients with inv(16)/t(16;16). Trisomy 8, 21, and 22 are common. No prognostic differences were found on comparing patients with inv(16) alone versus patients with additional karyotypic abnormalities.²²

t(6;9)(p23;q34): *DEK-CAN*

The t(6;9)(p23;q34) fuses the 5' part of *DEK*, coding for a nuclear DNA-binding protein, located on chromosome 6p23, to the 3' part of the *CAN* (also known as *NUP214*) gene, located on chromosome 9q34, encoding for a nucleoporin. The *DEK-CAN* chimeric gene is transcribed into the DEK-CAN 165 kDa protein, whereas no transcription could be detected from the reciprocal *CAN-DEK* fusion.²³ This rare translocation may be found in both AML and MDS. It is frequently associated with bone marrow basophilia and predicts an unfavorable prognosis. The *CAN* gene has also been activated by fusion of its 3' half to the *SET* gene, located at 9q34, in a case of acute undifferentiated leukemia.²⁴ The *SET-CAN* fusion gene contains a single open reading frame (ORF), coding for a 155 kDa chimeric SET-CAN protein. Since *CAN* recombines with either *DEK* or *SET*, its role as an oncogene, activated by fusion of its 3' part to different genes, has been suggested.

t(8;16)(p11;p13): *MOZ-CBP*

The t(8;16)(p11;p13) is a hallmark of AML, including both M4 and M5 subtypes.²⁵ Typical features are erythrophagocytosis from bone marrow blast cells, extramedullary infiltration, and disseminated intravascular coagulation (DIC). The malignant disorder affects both infants and adults, as a de novo or as a therapy-related or occupationally related AML. At chromosome 8p11, the breakpoint was identified within the *MOZ* (monocytic leukemia zinc finger protein) gene, a zinc finger protein with acetyltransferase activity. This gene is also rearranged in other 8p11 changes, involving *TIF2* in inv(8)(p11;q13)²⁶ and *p300* in t(8;22)(p11;q13).²⁷

At chromosome 16p13, the gene implicated is *CBP* (CREB (cAMP response element binding)-binding protein), which codes for a transcriptional adaptor/coactivator protein, and which undergoes monoallelic mutations, with loss of one functional copy, in the Rubinstein-Taybi constitutional syndrome. The *CBP* gene has also been identified as the target of a t(11;16)(q23;p13) in therapy-related AML/MDS, in which it rearranges with MLL.²⁸

t(1;22)(p13;q13): *OTT-MAL*

The t(1;22)(p13;q13) is a specific cytogenetic marker of acute megakaryocytic leukemia (AML-M7 subtype) in infants, presenting with extensive infiltration of abdominal organs and rare response to therapy. This translocation is usually found as an isolated anomaly in infants younger than 6 months, while hyperdiploid or complex karyotypes are more often found in infants older than 6 months.²⁹ Duplication of the derivative chromosome 1, i.e. der(1)t(1;22), is one of the most frequent additional chromosomal changes. Recently, other genes involved in this translocation have been identified in two infants with AML-M7 carrying a classical and a variant t(1;22).³⁰ The gene on chromosome 22 was named *MAL* (megakaryocytic acute leukemia), and may be involved in chromatin organization, whereas the gene on chromosome 1 was named *OTT* (one twenty-two) and seems to be related to the *Drosophila* split-end (spen) family of proteins. The OTT—MAL fusion product, encoded by the der(22) and detectable by PCR assay, contains almost all of the identified domains of both the OTT and MAL proteins. Its role in the pathogenesis of leukemia has not yet been established. The reciprocal MAL-OTT fusion product has not been detected.

t(3;5)(q25;q35): *NPM-MLF1*

The t(3;5)(q25;q35) is found in MDS and AML preceded by MDS, and predicts a bad prognosis. This translocation has been observed in all FAB subtypes except M3 (APL), with a higher incidence in AML-M6. Bone marrow specimens consistently show an increased number of megakaryocytes and trilineage dysplasia.

Both genes involved in this chromosomal change have been identified. At chromosome 5q35, the target gene is *NPM* (nucleophosmin, protein B23, NO38, numatrin) a nucleolar phosphoprotein, which is already known for its involvement in the t(2;5)/*NPM-ALK* in large cell lymphomas, and as a partner of the *RARA* gene in the t(5;17)/*NPM-RARA* variant translocation in APL. At chromosome 3q25, a novel gene named *MLF1* (myelodysplasia/myeloid leukemia factor 1) has been identified. The *MLF1* gene encodes a 31 kDa protein expressed in the cytoplasm.³¹ The chimeric NPM-MLF1 protein is transported into the nucleus by NPM, and is expressed at high level in the nucleolus. In vitro studies showed that NPM-MLF1 induces apoptotic cell death of the expressing cells, which can be rescued by anti-apoptotic proteins such as BCL2. These findings suggest that the pro-apoptotic effect of the NPM—MLF1 fusion protein plays a role in causing ineffective hematopoiesis and MDS in the t(3;5) translocation, while the evolution to AML would imply an additional event with activation of antiapoptotic proteins.³²

Promiscuous genes: *MLL*, *NUP98*, *ETV6*

A number of reciprocal translocations producing fusion genes in AML are promiscuous recombinations of one specific gene with multiple genomic partners. The paradigm for such phenomenon in AML is the *MLL* gene, which is known to recombine with more than 40 different genes. In this section, we also include a discussion of both *NUP98* and *ETV6* recombinations in AML.

***MLL*/11q23**

MLL (alternatively called *ALL1*, *HRX*, and *Htrx-1*) is the human homolog of the *Drosophila trithorax* gene, which encodes a putative DNA-binding protein involved in the control of embryonic development. It is a 90 kb gene with 36 exons, characterized by multiple zinc finger DNA-binding domains. Murine models suggest that *MLL* plays an important role in hematopoietic differentiation as regulator of transcription of other genes, namely the *HOX* genes.³³ *MLL* gene translocations involve different chromosomal partners, some of which have not been completely characterized at a molecular level. In AML, the t(9;11), t(10;11), t(6;11), and t(11;19) are most frequent (Table 17.1). Using standard cytogenetics, only some *MLL* translocations can be detected. Molecular analyses and FISH are necessary in cases negative for classical cytogenetics. These cases are represented by reciprocal translocations between chromosome bands sharing the same staining property, such as the t(6;11)(q27;q23), by complex translocations involving more than one chromosome in addition to 11q23, and by a cryptic insertion either of the 5' end of *MLL* into a partner chromosome or of the 3' end of a partner gene into the 11q23 band.^{34,35} Accompanying deletions of the 3' end of *MLL* have also been identified in a number of cases by applying FISH probes for the 3' and 5' ends of *MLL* in double-color experiments.

The *MLL* gene also rearranges by internal tandem duplication of the portion spanning exons 2–6 in AML cases with normal karyotype or in the presence of trisomy 11.³⁶ Rearrangement of *MLL* by self-fusion can be detected only by molecular studies, which have further demonstrated that the partially duplicated *MLL* is transcribed into mRNA capable of encoding a partially duplicated protein. These findings suggest that the *MLL* gene plays a critical role in leukemogenesis on its own, regardless of the partner genes involved in translocations.

The *MLL* breakpoints map in the same 8.3 kb break-point cluster region (bcr). Within the bcr, two different breakpoints have been identified. In infant leukemias and in leukemias induced by DNA topoisomerase II inhibitors, the breakpoints occur in the 3'

half of the bcr, so that a similar mechanism of DNA damage has been hypothesized.^{37,38} In the majority of de novo leukemias, breakpoints map at the 5' half of the bcr. In vivo experiments in knock-in models with the t(9;11) translocation evidenced a long period of latency before the onset of leukemia, suggesting that the *MLL* rearrangement per se is not sufficient for the expression of a full leukemic phenotype.³⁹ The disruption of normal Ikaros function in *MLL-AF4* in infants further supports this hypothesis.⁴⁰

Rearrangements of *MLL* occur in about 80% of acute lymphoblastic leukemia (ALL) and AML of infants, in de novo AML, and therapy-related leukemias, mainly following treatment with anti-topoisomerase II or intercalating topoisomerase II inhibitors, but also after alkylating agents and/or radiotherapy. The prognostic significance of these rearrangements has not been definitively established, except for the t(4;11)(q21;q23), which is associated with a poor prognosis.⁴¹

Despite the distribution of *MLL* rearrangements between ALL and AML according to current morphological/immunological classifications, a unique expression profile is emerging for all the acute leukemias bearing an *MLL* translocation.⁴²

NUP90/11p15

The 98 kDa nucleoporin protein (NUP98) is a member of a nucleoporin family characterized by FXFG or FG repeats. It is located at the nucleoplasmic side of the nuclear pore complex and regulates nucleo-cytoplasmic transport of proteins and RNA by its docking function.

Rearrangement of the *NUP98* gene was first identified by cloning the t(7;11)(p15;p15) translocation in de novo and therapy-related AML/MDS and in chronic myeloid leukemia (CML). Since this translocation is most frequently observed in Oriental populations and found only sporadically in Caucasians, a racial or geographical predisposition has been hypothesized. In this translocation, the partner of *NUP98* is the homeobox gene *HOXA9*.^{43,44}

The *HOX* genes are a superfamily of transcription factor genes organized in class I, corresponding to four clusters (A, B, C, and D) on chromosomes 7,17,12, and 2, respectively, and class II, with a divergent homeodomain, dispersed throughout the genome. The *HOXA9* gene consists of three exons, and the translocation breakpoint lies between exons 1A and 1B. The *NUP98* breakpoint is located on either intron 11 or 12. The *NUP98-HOXA9* chimeric transcript, originating from this translocation, contains the FG repeat docking site of *NUP98* and most of the coding region of *HOXA9*. The reciprocal *HOXA9-NUP98* has never been detected. The NUP98-HOXA9 fusion protein is predicted to function as an aberrant transcription factor deregulating HQX-responsive genes. The leuke-

^a Not yet molecularly demonstrated.

mogenic potential of the NUP98-HOXA9 protein has been tested in vitro by transformation of NIH3T3 fibroblasts, and in vivo on transplanted mice. Fusion partners of *NUP98* are summarized in Table 17.3.

In all of the *NUP98* rearrangements identified so far, a chimeric transcript from the 5' portion of *NUP98* is fused in-frame to the 3' portion of the partner gene, while the reciprocal fusion transcript has only been sporadically detected.^{45,46} These findings suggest that the NUP98 N-terminal part, containing the FG repeats, may play an important role in leukemogenesis.

ETV6/12p13

The human *ETV6* (ETS-variant gene 6) encodes a member of the ETS family of transcription factors. The gene spans 240 kb and consists of eight exons encoding a helix-loop-helix (HLH) domain (exons 3 and 4) and a DNA-binding domain (exons 6–8). The first chromosomal translocation affecting *ETV6* was a t(5;12)(q33;p13) found in a patient with chronic myelomonocytic leukemia (CMML). The molecular consequence of this translocation is fusion of the 5' HLH domain of *ETV6* to the transmembrane and tyrosine kinase domains of the *PDGFR* (platelet-derived growth factor β receptor) gene.⁴⁷ In addition to the t(5;12) translocation, involvement of *ETV6* has also been reported in number of translocations associated with myeloid (Figure 17.6) as well as lymphoid leukemias.⁴⁸

ETV6 displays different functions in the fusion transcripts derived from these rearrangements. The t(1;12) and the t(12;15)(p13;q25) are rare *ETV6* translocations in myeloid disorders, each having been described in only one case of AML. The t(1;12) results in the ETV6-ARNT chimeric protein, which contains the 5' end of ETV6 and almost the entire ARNT (aryl hydrocarbon receptor nuclear translocator) component.⁴⁹ The t(12;15), which is also found in congenital fibrosarcoma, fuses the *ETV6* gene with the *NTRK3* (neurotrophin-3 receptor) gene. The resulting

ETV6-NTRK3 fusion transcript contains the HLH dimerization domain of *ETV6* and the protein tyrosine kinase domain of *NTRK3*, and may contribute to leukemogenesis by dysregulation of the NTRK3 signal transduction pathway.⁵⁰

A particular type of fusion has been found in the t(3;12)(q26;p13) and in the t(12;13)(p13;q12), where *ETV6* drives the expression of the partner genes, namely of *MDS1/EVII* in the t(3;12), and of *CDX2* in the t(12;13).^{51,52}

The t(4;12)(q12;p13) translocation is typically associated with CD7⁺ AML in adults and with B-lymphoid leukemias in children. The involvement of *ETV6* in this rearrangement was first demonstrated by FISH in two AML cases. The partner gene at 4q12 was identified as *BTL* (Brx-like translocated in leukemia), now renamed *CHIC2*.⁵³ The *CHIC2-ETV6* transcript, but not the reciprocal *ETV6-CHIC2*, was detected by molecular studies in four AML-M0 patients. Of note is the ectopic expression of the *GSH2* gene, located upstream of *CHIC2* and most probably upregulated by *ETV6* regulator sequences.

Similarly to the t(4;12), in the t(7;12)(q36;p13) rearrangement, both the HLH and DNA-binding domains of *ETV6* are present in the fusion protein. The t(7;12)(q36;p13), associated with myeloid malignancies of children characterized by poor prognosis, fuses the *ETV6* gene to the *HLXB9* homeobox gene, with the expression only of the *HLXB9-ETV6* fusion transcript.⁵⁴

The t(9;12)(q34;p13) was found in ALL and in AML cases using molecular and FISH investigations, since it is rarely detectable by classical cytogenetics. This translocation results in the fusion of the 5' part of *ETV6* to the 3' part of *ABL1*, producing a chimeric *ETV6-ABL1* protein with elevated tyrosine kinase activity.⁵⁵

The t(12;22)(p13;q11), observed in different myeloid malignancies, including myeloproliferative disorders (MPD), MDS, and AML, fuses the *ETV6* gene to the *MNI* gene already known for its involvement in 22q rearrangements of meningioma. Both reciprocal chimeric transcripts, *ETV6-MNI* and *MNI-ETV6*, are expressed in tumor cells. The *MNI-ETV6* chimeric protein, which contains the 3' DNA-binding domain of *ETV6*, acts as a transcription factor, whose transforming potential has been shown in NIH3T3 cells.⁵⁶

Chromosomal changes resulting in altered gene expression: 3q21-q26

Recurrent structural changes of chromosome 3 in AML involve bands q21 and q26, and include an inv(3)(q21q26), a translocation, and an insertion between the long arms of both homologs broken at q21 and q26, and reciprocal translocations, namely t(3;21)(q26;q22), t(3;13)(q26;q14), t(3;7)(q26;q22), t(3;12)(q26;p13).

Activation of *EVI1* at 3q26 has been identified as the common denominator of these cytogenetic changes.⁵⁷ The abnormal expression is due to the activity of the enhancer of the *ribophorin I* gene at 3q21 in the typical inversion, but also as result of translocations leading to a fusion gene, such as the t(3;12) translocation (Figure 17.6). Another gene that has been shown to be activated by a non-random reciprocal translocation in AML, namely the t(1;3)(p36;q21) translocation, is *MEL1* at 1p36, which belongs to the same family of *EVI1*.⁵⁸ Interestingly the gene involved at 3q21 is the *ribophorin I* gene, as in the inv(3).

The leukemias associated with these genetic lesions are disorders with a very poor prognosis. A specific hematological feature is the high number of platelets at presentation, even in the presence of massive blastic infiltration in the bone marrow. Cytogenetically, inv(3) is frequently associated with monosomy 7.

t(2;3)(p23;q26)

The t(2;3)(p22-p23;q26-q28) is a rare non-random translocation observed in myeloid disorders such as MDS, AML, and blastic phases of Philadelphia (Ph)-positive and Ph-negative MPD. In the majority of cases, it is associated with other chromosomal aberrations, particularly -5/del(5)(q) and -7/del(7)(q), and it is also found in therapy-induced myeloid disorders. The molecular counterpart of this translocation is still unknown. Conventional cytogenetics shows heterogeneity for both 2p and 3q breakpoints. Overexpression of *EVI1*, possibly due to translocation, has been shown. However, RACE-PCR did not identify the translocation partner on chromosome 2p.⁵⁹

Gene amplification

Over-representation of a chromosomal region, from three to multiple copies, so-called 'gene amplification', is a recently discovered leukemogenetic event in which putative oncogene(s) within the over-represented region are thought to be involved. Some cases show an intrachromosomal amplification, as jumping translocation of the same DNA sequence to different partner chromosomes or as a marker chromosome/ ring with contiguous amplified region and homo-geneously staining region (hsr). Some cases have extrachromosomal amplification on double minutes (dmin).

In AML, two recurrent regions of amplification have been identified: 8q24 and 11q23.⁶⁰⁻⁶² Amplification of the 8q24 region has been found sporadically in AML.

ETV6

Fusions involving the pointed domain of ETV6:

t(12;13)(p13;q12)	ETV6-CDX2	Transcription factor

Figure 17.6 Schematic representation of the known *ETV6* fusion partners, illustrating the different mechanism involving *ETV6* in the production of oncogenic fusion proteins in myeloid disorders. Fusion partners of *ETV6* are shown in bold, their function is described in the last column. PNT, pointed domain (oligomerization domain); EDB, ETS DNA-binding domain.

Cytogenetically, all cases with *dmin* were shown to contain *c-MYC* amplicons.

MLL amplifications have been described in *de novo* AML/MDS and in therapy-related AML/MDS, especially if alkylating agents have been included in the treatment. Patients are in general old and have a bad prognosis.⁶²

Besides *c-MYC* and *MLL*, other regions may contain the target genes of genomic amplification in myeloid disorders.⁶¹ *RUNX1* amplifications have also been documented, but are more frequently associated with ALL.⁶³

Gene mutation

More recently, recurrent genetic mutations have been identified in leukemic cells. These mutations detectable by molecular techniques constitute an additional marker of the leukemic clone that can be used for diagnosis, prognosis, and follow-up of residual disease. The genes most often studied are summarized in Table 17.4.⁶⁴⁻⁷³ Among these, the receptor tyrosine kinase as well as the *RAS* oncogene have gained in importance because selective inhibitors are being developed to treat AML by selective molecular targeting, with encouraging preliminary results.

Table 17.4 Gene mutations in acute myeloid leukemia (AML)/myelodysplastic syndromes (MDS)

<i>FLT3</i> (13q12)	<ul style="list-style-type: none"> ● Receptor tyrosine kinase class III ● Expressed in hematopoietic lineage ● ITD (internal tandem duplication) of juxtamembrane domain in 20% of AML, associated with poor prognosis ● Mutation Asp 835 in 7% of AML. Prognostic implication uncertain
<i>c-KIT</i> (4q12)	<ul style="list-style-type: none"> ● Receptor tyrosine kinase class III ● Expressed in CD34⁺ cells, mast cells and melanocytes ● Expressed in 65% of AML ● Mutation in 8%, sometimes associated with inv(16)
<i>N-RAS</i> (1 p22)	<ul style="list-style-type: none"> ● GTP-binding protein
<i>K-RAS</i> (12p12)	<ul style="list-style-type: none"> ● Major switch in signal transduction by activation of kinase cascade: MARK, PI3K, and others ● Ubiquitously expressed ● Mutations at codon 12, 13, or 61 in 25% of MDS and AML
<i>WT1</i> (11 p13)	<ul style="list-style-type: none"> ● Zinc finger transcription factor ● Tumor suppressor gene implicated in Wilms' tumor ● Expressed in CD34⁺ cells, not in mature cells ● Highly expressed in 75% of AML. Can be used for monitoring of residual disease ● Mutation in 15% of AML
<i>CEBPA</i> (19q13)	<ul style="list-style-type: none"> ● Transcription factor with tumor suppressor gene function expressed in myeloid/myelomonocytic cells ● Mutated in 7% of AML
<i>RUNX1</i> (21q22)	<ul style="list-style-type: none"> ● Core binding factor CBFA2 involved in t(8;21), t(3;21), etc. ● Biallelic mutation in 5% of AML (FAB-M0), trisomy 21 with AML ● Mutations reported in a familial platelet disorder with predisposition to AML (FPD/AML)
<i>TP53</i> (17p13)	<ul style="list-style-type: none"> ● Nuclear phosphoprotein involved in control of cell cycle, proliferation, and apoptosis ● Tumor suppressor gene implicated mainly in solid tumors ● Deletion of one allele and mutation observed in 5% of AML and MDS
<i>MLL</i> (11q23)	<ul style="list-style-type: none"> ● Internal tandem duplication (discussed under promiscuous genes)

Trisomies

Among numerical chromosomal changes, trisomies are the most commonly occurring as isolated karyotypic aberrations in AML. Well-established trisomies in AML are listed in Table 17.5.

The most frequent change is trisomy 8, often as an additional change to more typical structural rearrangements. The incidence as a primary anomaly is higher in other myeloid disorders, such as MDS and MPD. A specific pathogenetic role of this trisomy in AML has been strongly supported by expression profiling showing a significant difference with leukemias with a normal karyotype due to a more pronounced downregulation of apoptosis-regulating genes.⁷⁴ These results have been related to a lack of response of trisomy 8-bearing leukemic cells to cytarabine,⁷⁵ a drug inducing apoptosis. Interestingly some authors have focused on the meiotic origin of this trisomy, which would be present as a part of constitutional mosaicism in the bone marrow of affected patients.⁷⁶ The trisomic clone would undergo preferential expansion in the proliferating malignant population. In a subgroup of cases, the trisomy may be the first step in the evolution of AML associated with a more advanced polysomy, such as tetrasomy 8.

Table 17.5 Most frequent autosomal trisomies occurring as single anomalies in myeloid malignancies

Trisomy	Disease (frequency as % of all cases)
+4	AML (<1%), MDS (rare)
+6	AML (<1%), MDS (<1%), hypoplastic MDS (rare)
+8	AML (3–4%), MDS (3–6%), CMPD (4–7%)
+9	AML (<1%), MDS (<1%), CMPD ^a (21%)
+11	AML (1%), MDS (1%)
+13	AML (<1%), MDS (rare)
+14	AML, MDS (rare)
+21	AML (1–3%), MDS (<1%), CMPD (<1%)

AML, acute myeloid leukemia; MDS, myelodysplastic syndromes; CMPD, chronic myeloproliferative disorders. ^a Especially polycythemia vera, often associated with +9.

AML with trisomy 4 likely originates from an early myeloid precursor, as suggested by the occurrence of the lesion either in MDS with a high blast component or in AML. This trisomy is consistently found in cases with double minutes and *c-MYC* amplification.

Studies of the molecular counterpart have focused on the duplication of a mutated form of the *c-KIT* gene as well as on *c-KIT* overexpression in leukemic cells with trisomy 4.^{77,78}

Other recurrent trisomies in AML involve chromosomes 13, 14, and 21.

Myelodysplastic syndromes

The incidence of karyotypic abnormalities is less pronounced in the MDS group (50% of cases) than in AML (80%). Structural changes, such as complete or partial deletions, are found more typically in MDS than in AML (Table 17.6), where reciprocal translocations represent the most frequent primary aberration. Moreover, the incidence of MDS deletions has been increasing since the application of loss of heterozygosity (LOH) studies as well as FISH investigations on interphase nuclei. In cases with progression of MDS to overt AML, a clonal karyotypic evolution, i.e. the appearance of new chromosomal anomalies in addition to those present at diagnosis, may be observed. However, additional chromosomal changes with a predictive value for evolution to AML have not been definitively established.

The fact that the same change may occur in MDS as well as in de novo AML suggests that, at least in those cases, the malignant clone originates from a genetic insult at the level of a multipotent stem cell and that the clinico-hematological findings of the malignant disorder are related to additional factors influencing the balance between cell growth, survival, and differentiation of bone marrow populations.

Strong correlations between typical cytogenetic changes and prognosis of MDS have been well documented.⁷⁹

s, secondary disorder.

For a listing of critical genomic rearrangements in MDS the reviews in references 80 and 81 are recommended. Here some entities with specific cytogenetic-hematological correlations will be presented.

Typical deletions in MDS

del(7)/-7

Chromosome 7 is often involved, either as a partial deletion of the long arm (7q-) or as loss of one homolog (-7), in different types of MDS. Monosomy 7 is the most frequent aberration in myeloid proliferations in children.⁸² Both the 7q- and the -7 changes are consistently associated with MDS or AML induced by radiotherapy and/or chemotherapy for a previous lymphoma or solid tumor. Alkylating agents have mostly been implicated. Interestingly, loss of 7q is also the result of a genomic imbalance due to the t(1;7)(q10;p10) translocation consistently found in secondary MDS.

Despite its frequency, the biological significance of monosomy 7 is still undefined. An intriguing observation is that a clone with monosomy 7 may emerge during the evolution of a number of genetic conditions predisposing to MDS/AML, such as Fanconi anemia, Shwachman syndrome, familial myelodysplasia, and Kostman syndrome. In the last syndrome, the emergence of a monosomy 7 is possibly favored by treatment with granulocyte colony-stimulating factor (G-CSF). In the multistep process of malignant transformation, monosomy 7 in children may be preceded by mutations of the *RAS* and/or *NF1* genes.⁸³

Monosomy 7 is a marker of poor prognosis in both children and adults, and very serious infectious complications are related to a deep disturbance of chemotaxis.

The 5q- syndrome

The WHO Classification keeps this syndrome separate from all other refractory anemias.⁸⁴ It is a distinct clinico-hematological disease characterized by macrocytic anemia, normal or elevated platelet count, and trilineage bone marrow dysplasia with typical monolobulated micromegakaryocytes. The disorder significantly affects aged women. The prognosis is relatively good, with a chronic course and very rare evolution to acute leukemia. However, the need for intensive support with red cell transfusions may lead to serious complications from hemosiderosis. Attempts of treatments with different growth factors, including erythropoietin, granulocyte-macrophage colony-stimulating factor (GM-CSF), and G-CSF, have been successful in controlling anemia only in sporadic cases of 5q- syndrome.

The chromosomal rearrangement is always an interstitial deletion, with loss of a variable extent of

material. The minimal common deletion is located at band 5q31, in which a number of genes responsible for regulation of growth and/or differentiation of hematopoietic cells are located. The critical molecular event underlying the 5q- syndrome, however, is still unknown.⁸⁵

Combined immunophenotypic and FISH studies have shown that the cell of origin of the 5q- change is an early progenitor such as a CD34+CD19+ lymphomyeloid stem cell.⁸⁶ Similarly to the Ph chromosome, T lymphocytes are not involved.

The occurrence of a 5q- chromosome is not limited to the 5q- syndrome,⁸⁷ since it can also be found in other MDS, such as refractory anemia with excess of blasts (RAEB), and secondary MDS, especially after radiotherapy or alkylating agents for a previous malignancy. In those cases the anomaly may result not only from simple deletions, but also from unbalanced translocations, such as t(5;17). In secondary MDS, loss of an entire homolog (monosomy 5) is also frequent. A 5q- in a complex karyotype is associated with bad prognosis.

The 17p- syndrome

A deletion on the short arm of chromosome 17 may result from different types of chromosomal rearrangements, i.e. unbalanced translocations, isochromosome of the long arm, and simple deletions. The anomaly is usually associated with other rearrangements. A common molecular event is the involvement of the *TP53* gene at 17p13: a *TP53* mutation is found in around 70% of patients with 17p deletion and MDS, so that both *TP53* alleles are abnormal, one being deleted and the second mutated. The typical hematological stigmata of the 17p- syndrome are represented by dysgranulopoiesis, with pseudo Pelger-Huet hypolobulated nuclei and small vacuoles in the cytoplasm of neutrophils. Prognosis is usually adverse.⁸⁸

Chromosome 17p is also a hot site for rearrangements arising after radiochemotherapy or exposure to environmental toxics.

20q-

del(20)(q11q13) has been reported in a large spectrum of myeloid malignancies: in approximately 5% of MDS, in 10–15% of polycythemia vera (PV), and less frequently in AML. It is a primary change not associated with poor prognosis in PV. In MDS, the prognostic value of 20q- is more controversial, although as an isolated karyotypic anomaly it has been associated with relatively low-risk disorders.

Experimental data are in favor of 20q- occurring in a progenitor common to granulomonocytes and erythroid cells. A peculiar cellular kinetics of cells bearing a 20q- chromosome has been described, in that positive bone marrow granulocytes are not discharged into the peripheral blood.⁸⁹ Whether this phenomenon reflects a high level of apoptosis of granulocytes in leukemic bone marrow with 20q- remains to be determined.

The size of the deletion is heterogeneous. FISH studies have indicated an SRD (shortest region of deletion) of less than 1 Mb in MPD and a somewhat larger one (3 Mb) in MDS.⁹⁰ Putative candidate genes have been analyzed for deletion or mutations on the second allele.

Myelodysplastic—myeloproliferative disorders

This category, which contains a subgroup of diseases with morphological signs of both MDS and chronic MPD, has recently been introduced in the WHO Classification.⁸⁴ Cytogenetically, changes common to MDS and Phi-negative CML as well as myelofibrosis have been described, including iso(14q), trisomy 14, monosomy 7, -Y, and t(5;12). The reciprocal translocation t(5;12), originally described in CMML and resulting in a fusion gene between *PDGFBR* on 5q33 and *ETV6* on 12p13, is very interesting, as other changes involving the *PDGFBR* gene with alternative partners have also been found in hematological cases diagnosed as MDS or atypical CML.^{91–93} Tyrosine kinase inhibitors, such as imatinib, are able to induce hematological remission in malignancies with *PDGFBR* gene rearrangements.

t(8)(p11) Myeloproliferative syndrome

A new syndrome has recently been identified.⁹⁴ It presents as a CML-like myeloid hyperplasia, with marked eosinophilia, a high incidence (60%) of T-cell non-Hodgkin lymphoma, and rapid progression to AML. It results from various translocations, all involving the *FGFR1* (fibroblast growth factor receptor 1) gene at 8p11.3. *FGFR1* is a transmembrane tyrosine kinase receptor. Its tyrosine kinase domain is fused to other transcription factors as a consequence of chromosomal translocations: t(8;13) encodes ZnF198-FGFR1, t(6;8) FOP-FGFR1; t(8;9) CEP110-FGFR1, and t(8;22) BCR-FGFR1. This syndrome is associated with a very poor prognosis.

Cytogenetic and molecular abnormalities in lymphoid malignancies

William B Slayton and Stephen P Hunger

The nature of oncogenes and tumor suppressor genes

Remarkably, the basic tenets of molecular cytogenetics and molecular oncology were outlined in the early 1900s by Theodor Boveri.¹ He hypothesized that gain of 'growth-promoting' chromosomes or loss of 'growth-inhibitory' chromosomes might each cause unrestrained cell growth and cancer. We now know that Boveri's general concept was correct, and that alterations in chromosomes play a pivotal role in oncogenesis. The details are both more complicated and more elegant than Boveri imagined. The important functional unit is not the chromosome, but rather individual genes located on the chromosomes. Consistent with Boveri's original hypothesis, the genes responsible for oncogenesis fall into two broad classes: growth-promoting onco-genes and growth-inhibitory tumor suppressor genes (TSG).

Identification and characterization of genes involved in the pathogenesis of human cancer has been a major biomedical advancement of the past quarter century. Cytogenetic and molecular genetic characterization of recurrent changes observed in leukemias and lymphomas has played a crucial role in these advances and has revealed two fundamental axioms: first, that specific, cytogenetically-evident changes occur non-randomly, and are often tightly linked with distinct clinical subtypes of disease; second, that these Cytogenetic changes are harbingers of alterations in oncogenes/TSG, and can facilitate identification of these genes.² We now know that cancer is the cumulative phenotypic manifestation of mutations in oncogenes and/or TSG. In most, and likely all, cases, full expression of the malignant phenotype requires that mutations occur in a number of different oncogenes/TSG.³

Mechanisms of oncogene activation and TSG inactivation

Visible cytogenetic alterations occur in a substantial majority of lymphoid malignancies. Cytogenetic abnormalities are classified as structural or numerical.⁴ Structural changes include translocations (rearrangements that involve two or more different chromosomes) and inversions (rearrangements within a single chromosome). Numerical changes include deletion or gain of all or a portion of individual chromosomes.

Chromosomal translocations are detected cytogenetically or molecularly in the majority of cases of acute lymphoblastic leukemia (ALL) and non-Hodgkin lymphoma (NHL). Translocations cause altered expression of, and/or structural changes in, cellular proto-oncogenes by one of two mechanisms. First, proto-oncogenes can be translocated into the vicinity of active regulatory elements of another gene, usually one of the immunoglobulin (*Ig*) or T-cell receptor (*TCR*) genes, causing dysregulated expression of a structurally intact (or occasionally truncated) protein. Translocations in B-lineage leukemias/lymphomas often involve chromosome bands 14q32 (heavy-chain gene, *IgH*), 2q12 (light-chain gene, *Igκ*), or 22q11 (light-chain gene, *Igλ*), while T-lineage malignancies involve 14q11 (*TCRδ* or *TCRα*) or 7q35 (*TCRβ*). The second class of translocations are those that create fusion genes encoding chimeric proteins that possess novel structural and functional properties not present in the constituent wild-type proteins. This type of translocation most commonly affects transcription factors, often fusing a DNA-binding and/or protein oligomerization domain from one protein with effector domains, such as a transcriptional activation domain (TAD), from another. These translocations typically occur in introns of each gene; exons of the

two genes are then joined together during mRNA splicing. Creation of a functional chimera generally requires that the joined exons from each gene are in the same reading frame.⁵

Numerical changes are conceptually easy to envision, but their functional consequences have been difficult to elucidate. Cytogenetically visible deletions involve loss of millions of base pairs of DNA encoding many different genes. Smaller deletions also occur that are not cytogenetically evident, but can be detected by molecular techniques. Current evidence indicates that the important target of deletions is usually one specific TSG. Molecular analyses of solid tumors have shown that when deletions are observed, the other allele of the relevant TSG is usually mutated, leading to complete loss of protein function. It is also possible that the remaining allele may not be altered and that an alteration in dosage of one or more genes is the critical consequence of the deletion. Identification of the critical target gene(s) is a daunting challenge. The consequences of complete or partial chromosome gains are poorly defined. Chromosome gains may result in higher levels of expression of certain proteins by altering gene dosage. This hypothesis is difficult to test, and the critical genes affected by chromosome additions remain unknown.

Other types of mutations affect a small number of nucleotides, and can be detected only by targeted molecular techniques. Point mutations alter one nucleotide and can be grouped into neutral alterations/polymorphisms that do not alter protein coding, missense mutations that substitute one amino acid for another while maintaining an open reading frame, and nonsense mutations that create a stop codon. Frameshift mutations are insertions or deletions of a small number of nucleotides (not divisible by three) that alter the reading frame and generally lead to protein truncation.

Different types of mutations, with different functional consequences, occur in oncogenes and TSG. Missense mutations in oncogenes cause a gain of function, and are dominant, genetically and functionally, as they promote transformation even though the normal protein from the wild-type allele is still expressed. In contrast, missense mutations in TSG generally inactivate the protein product. For example, missense mutations in *TP53* generate mutant p53 proteins that are impaired in important transcriptional and cell cycle-regulatory functions.⁶ Nonsense and frameshift mutations almost always inactivate the function of proteins encoded by TSG by eliminating essential functional domains or by creating unstable proteins that are degraded rapidly. These mutations are typically genetically and functionally recessive, because the remaining wild-type allele still produces a normal protein that can perform the necessary cellular functions. In general, both alleles of a TSG must be inactivated to significantly alter cell growth. Frequently, each allele is inactivated by different mechanisms—for example, point mutation of one allele and deletion of the other. In some instances, TSG mutations may act in a so-called dominant-negative manner and exert their phenotype even in the presence of a non-mutated wild-type allele.

Methods used to detect genetic alterations

It is critical to karyotype leukemias and lymphomas at initial diagnosis and relapse, because specific cytogenetic abnormalities may clarify the diagnosis, provide important prognostic information, or identify patients who might benefit (or fail to benefit) from specific therapeutic interventions. A detailed discussion of the techniques of cytogenetic analysis is outside the scope of this text. However, it is critical to emphasize that cancer karyotypes are performed on cells derived from direct preparations or short-term (24–72 hours) unstimulated cultures of malignant cells, as contrasted with analyses performed to detect constitutional cytogenetic abnormalities, which use mitogens to stimulate T cells to divide. Chromosome abnormalities are classified by the well-accepted International System for Human Cytogenetic Nomenclature (ISCN) which is updated periodically.⁷

Molecular cytogenetics is now an important complement to conventional cytogenetics. Fluorescence in situ hybridization (FISH) uses DNA probes that are hybridized to metaphase or interphase chromosomes and visualized directly or indirectly with fluorescent dyes or fluorochromes. FISH can be used to determine gene copy number, to map the relation of genes to one another, and to detect translocations or inversions by using multiple probes labeled with different fluorochromes. Figure 18.1 (see Plate 3) shows how two color split-apart FISH probes can be used to detect *E2A* translocations in interphase cells.⁸ Alternatively, differentially labeled probes can be used for two different genes that give separate signals normally and merge to create a fusion signal when a translocation has occurred.⁹

Multicolor FISH (m-FISH) and spectral karyotyping (SKY) use a larger number of probes and allow each chromosome to be visualized in a unique color.² SKY and m-FISH are not yet used for routine clinical analyses, but can help identify the consequences of complicated or cryptic abnormalities that might be missed by FISH or by standard cytogenetics. Comparative genomic hybridization (CGH) involves cohybridization of tumor and control DNA to normal chromosome spreads and can identify region of chromosomes that have been amplified or deleted, but does not detect structural rearrangements such as translocations.¹⁰

Figure 18.1 Detection of *E2A* translocations in interphase cells via two-color 'split apart' FISH. (a) Schematic depiction of the *E2A* gene on chromosome 19 and location of probes centromeric (green) and telomeric (red) to *E2A*. (b) Interphase FISH of a normal cell shows two fused red/green or yellow signals from the adjacent signals on each chromosome 19 homologue. (c) Interphase FISH of a cell with a *t(1;19)(q23;p13)* shows one fused red/green signal from the normal chromosome 19, and single red and green signals from the der(1) and der(19) chromosomes, respectively. See Plate 3.

Other methods of detecting alterations in oncogenes and TSGs rely upon molecular techniques to analyze DNA, RNA, or proteins directly. This is feasible only for recurring abnormalities with previously defined molecular consequences. Important techniques include Southern blotting to detect gene rearrangement or gene copy number, polymerase chain reaction (PCR), which can be used to amplify diagnostic sequences or to produce sufficient material for other analyses, and methods to determine primary DNA sequence. As an understanding of these techniques is an important prerequisite for the discussions to follow, the underlying concepts will be reviewed briefly.

Southern blotting can be used to detect gene rearrangements that result from chromosomal translocations.¹¹ Technical considerations make this approach useful for detecting translocations that cluster within an area of less than approximately 20 kilobases (kb). Pulsed-field gel electrophoresis, which is generally available only in research laboratories, can be used to detect rearrangements that are spread out over a larger region of the genome. Figure 18.2 illustrates the use of Southern blot analysis to detect rearrangements within the 11q23 gene *MLL*, a frequent target of fusion gene-creating chromosomal translocations in acute leukemias.^{12,13}

It is critical to determine the presence or absence of specific translocations that create fusion genes encoding chimeric mRNA and proteins in ALL and NHL. The DNA rearrangements that produce translocations almost always occur within introns of each gene. Because introns can range in size from less than one hundred to hundreds of thousands of nucleotides, the genomic breakpoints may vary widely in location from one patient to another, and fusion products often cannot be amplified reliably from DNA with a standard set of primers. For this reason, RNA is usually the preferred starting material for PCR (RNA-PCR or reverse transcriptase (RT)-PCR), as removal of introns during mRNA splicing fuses specific exons of each gene to one another, and fusion transcripts can be consistently amplified from almost all patients with a given translocation using a standard set of primers. Figure 18.3 demonstrates how RT-PCR can be used to amplify *E2A-PBX1* chimeric mRNAs produced by the *t(1;19)(q23;p13)*.¹⁴ Multiplex PCR uses a combination of primers that can detect a variety of fusion transcripts derived from chromosome translocations. One group has developed a set of multiplex PCR reagents capable of detecting any of 29 common translocations that occur in acute leukemia.¹⁵

Quantitative real-time PCR provides a way to quantify the number of copies of a particular RNA species in a given sample. This technique uses a fluorescent dye that is incorporated into the amplified DNA. Levels of fluorescence are measured with each PCR cycle and compared to calibrated standard controls. Real-time PCR can be used to quantitate minimal residual disease (MRD) by measuring levels of RNA transcripts derived from chromosome translocations or DNA copies of clonotypic *Ig/TCR* gene rearrangements during treatment of patients with leukemia or lymphoma.¹⁶ This approach can stratify patients into groups with differential risks of relapse based on early response to therapy, and may become a major component of future systems for risk stratification.¹⁷

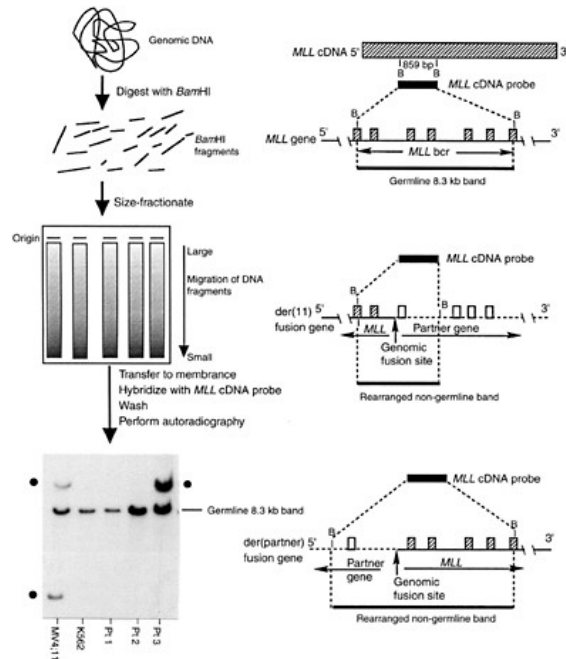

Figure 18.2 Southern blot detection of *MLL* gene rearrangements. The structures of germline and fusion *MLL* genes are schematically depicted at right (exons are denoted by filled (*MLL*) or empty (partner gene) boxes). In the germline *MLL* gene, restriction enzyme *Bam*HI sites (B) flank the breakpoint cluster region (bcr) in which translocations occur, and the *MLL* cDNA probe will hybridize with an 8.3 kb germline band. Following translocation, two *MLL* fusion genes are potentially created, one on the der(11) chromosome and one on the der(partner chromosome), and the *MLL* cDNA probe will hybridize with one or two rearranged non-germline bands of unique size. The process of Southern blot analysis is shown at left. Genomic DNA is first digested with the restriction enzyme *Bam*HI, generating DNA fragments of various sizes that are size-fractionated by electrophoresis in agarose gel, generating a continuous smear of DNA fragments. The fragments are then denatured, transferred to a charged nylon membrane, and immobilized on the membrane. The membrane is then incubated with a radioactively labeled DNA probe, in this case the 859 bp *MLL Bam*HI cDNA fragment depicted at top right. To eliminate non-specific background hybridization, the blot is washed under stringent conditions. The hybridized blot is then exposed to X-ray film and developed. As can be seen in the autoradiograph at bottom left, a single 8.3 kb germline *MLL* band is seen in the cell line K562 and patients 1 and 2, each of which lacks *MLL* translocations. One *MLL*-rearranged band is present in patient 3, an infant with ALL and a t(11;19)(q23;p13.3). Two *MLL*-rearranged bands are present in MV4;11, a t(4;11)-ALL cell line.

Figure 18.3 RT-PCR analysis of *E2A-PBX1* fusion mRNAs produced by the $t(1;19)(q23;p13)$. Portions of germline *E2A* and *PBX1* genes and the *E2A-PBX1* fusion gene produced by the $t(1;19)(q23;p13)$ are depicted at the top left. To perform RT-PCR, RNA is isolated from the sample and a cDNA copy is made using reverse transcriptase and an oligodT primer that anneals to the polyA mRNA tail. PCR is then performed using oligomers complementary to *E2A* and *PBX1* sequences on opposite DNA strands. A specific product can only be amplified from cells containing a $t(1;19)$ and *E2A-PBX1* fusion, as these genes are normally located on different chromosomes. At right are size-fractionated PCR products from RCH-ACV (a $t(1;19)$ -ALL cell line), REH (an ALL cell line lacking a $t(1;19)$), three patients (one of whom (no. 1) had a $t(1;19)$ and two (nos 2 and 3) who did not), and a negative control reaction containing no input DNA (water).

Advances in automated nucleotide sequencing have made it easier to directly analyze amplified DNA for mutations in specific genes. Microarray analysis has been a powerful tool to study the expression of a large number of genes in a single experiment (see Chapter 20).¹⁸

Chromosome translocations: prototypic examples

Chromosome translocations comprise the largest group of well-characterized mutations in lymphoid malignancies. A comprehensive listing of the hundreds of translocations that have been characterized molecularly is impractical and rapidly outdated. Table 18.1 lists prototypical examples of the major types of proteins that are activated by chromosome translocations in lymphoid malignancies.

An increasing number of oncogenes are recurrent targets of chromosome translocations. In some cases, these translocations involve juxtaposition with more than one of the *Ig/TCR* loci. For example, *c-MYC* is involved in translocations with each of the three *Ig* loci, at least one of the *TCR* genes and at least one other gene.¹⁹ In Burkitt lymphoma or leukemia, the $t(8;14)(q24;q32)$ juxtaposes *c-MYC* with the *IgH* regulatory elements and results in dysregulated high-level expression of *c-MYC*. *c-MYC* is a transcription factor that turns on expression of target genes that result in entry into S phase, decreased growth factor requirements, and escape from normal regulation of cell cycle progression.¹⁹ Other genes are fused to different partner genes by several different translocations. The extreme example is *MLL*, which is fused to a myriad of different partner genes by translocations in ALL and AML that involve more than 30 different partner loci.²⁰

In T-ALL, chromosomal translocations juxtapose a wide variety of genes with one of the *TCR* loci, resulting in dysregulated expression of structurally intact proteins. The majority of these proteins possess structural features and functional properties of transcription factors, and are not expressed normally in T cells, underscoring the prominent role of aberrant transcription regulation in oncogenesis.²¹ Transcription factors are grouped into functional classes or families on the basis of conserved protein motifs involved in DNA binding and protein oligomerization. Genes involved in T-ALL translocations encode members of the basic helix-loop-helix (bHLH) (TAL1, TAL2, and LYL1), bHLH-leucine zipper (ZIP) (*c-MYC*), LIM domain (LMO1 and LMO2), and homeodomain (HOX11) families.²² The involvement of different members of protein subfamilies with highly similar DNA-binding properties (e.g. TAL1, TAL2, and LYL1, or LMO1 and LMO2) is particularly striking. Several of these transcription factors play important roles in the development of the hematopoietic system. HOX11 is required for formation of the spleen and TAL1/SCL is essential for development of all hematopoietic lineages.^{23,24}

Some translocations observed in B-lineage ALL also cause dysregulated expression of structurally intact proteins, including transcription factors such as *c-MYC* and growth factors such as interleukin-3 (IL-

Table 18.1 Major classes and examples of mutations leading to lymphoid malignancies

Class	Protein	Translocation	Function
Transcription factor	c-MYC	t(8;14)(q24;q32)	Regulates genes involved in cell cycle progression and apoptosis
	E2A-PBX1	t(1;19)(q23;p13)	Heterodimerizes with Hox proteins, blocks differentiation, and transforms lymphoid cells
	TAL1/SCL	t(1;14)(p32;q11)	Required for definitive hematopoiesis; regulates genes involved in proliferation of myeloid progenitors
	HOX11	t(7;10)(q35;q24)	Required for formation of the spleen. Immortalizes hematopoietic cells
	LMO2	t(11;14)(p13;q11)	Complexes with other proteins that regulate definitive hematopoiesis (SCL/GATA-1/GATA-2)
Growth factor	IL-3	t(5;14)(q31;q32)	Dysregulated cytokine production produces autocrine and paracrine effects on early hematopoietic progenitors
Kinase	BCR-ABL	t(9;22)(q34;q11)	Constitutive kinase action has proliferative and anti-apoptotic functions
	NPM-ALK	t(2;5)(p23;q35)	Constitutive ALK kinase activates pathways involved in cell proliferation, transformation, and survival
Cell cycle protein	CCND1	t(11;14)(q13;q32)	Activates cell cycle progression of centrocytic cells
Apoptosis regulator	BCL2	t(14;18)(q32;q21)	Translocation dysregulates expression of this prototypical suppressor of apoptosis

3). However, the majority create fusion genes that encode fusion proteins, many of which are chimeric transcription factors. Prominent examples include E2A-PBX1 and E2A-HLF, encoded by the t(1;19) and t(17;19), respectively.²⁵ In both cases, chimeras contain the N-terminal portion of E2A, including two experimentally defined TAD, fused to heterologous DNA-binding domains, a homeodomain in the case of E2A-PBX1 and a bZIP in the case of E2A-HLF. E2A-PBX1 and E2A-HLF bind to DNA sequences that are completely different from one another and from wild-type E2A, and activate target gene transcription. The *E2A* gene encodes at least two splicevariant proteins, E12 and E47, that contain bHLH elements involved in protein dimerization as well as DNA binding.²⁶ E2A is a transcriptional regulator of B-cell development, is involved in the initiation of immunoglobulin gene rearrangement, and is absolutely required for proper B-cell development.²⁷ E2A fusion proteins act as chimeric transcription factors in vitro and transform hematopoietic cells in a variety of experimental systems.²⁵ Despite recognition of completely different target DNA sequences, *E2A-PBX1* and *E2A-HLF* transgenic mice develop T-cell malignancies with very similar features.^{28–30} The *E2A* gene behaves as a TSG in mice. Almost all of the rare *E2A*-null mice that survive the immediate perinatal period later develop T-cell tumors that have a striking similar phenotype to those that develop in *E2A-PBX1* and *E2A-HLF* transgenic mice.³¹ These and other observations suggest that transformation mediated by *E2A* chimeras may involve mechanisms other than direct transcriptional effects on target gene expression.³² Complicating this picture further, recent data suggest that wild-type *E2A* can also function as an oncogene and can collaborate with *c-MYC* to induce tumors in a murine model system.³³

Another major class of genes that are activated by a variety of mechanisms, including translocations, in lymphoid malignancies are those that encode tyrosine kinases. The prototype is *BCR-ABL*, the product of the t(9;22)(q34;q11), which occurs in chronic myeloid leukemia (CML), ALL, and acute myeloid leukemia (AML) (see Chapter 41).³⁴ The rational development of imatinib (STI571, (Gleevec/Glivec)) and its remarkable clinical efficacy in patients with CML³⁵ have prompted great scientific and clinical interest in small-molecule inhibitors of activated tyrosine kinases in cancer. One excellent candidate for such therapeutic strategies is anaplastic lymphoma kinase (*ALK*), which is fused to many other genes in anaplastic large cell lymphoma (ALCL) and inflammatory myofibroblastic tumors (IMT).³⁶ *NPM-ALK*, produced by the t(2;5)(p23;q35) in ALCL, is the founding member of this family. Experimental data indicate that the critical contribution of *NPM* and all other *ALK* fusion partners is an oligomerization domain that leads to constitutive activation of ALK tyrosine kinase activity.³⁶ General tyrosine kinase inhibitors can inhibit the activity of *NPM-ALK* in vitro and induce apoptosis of ALCL cell lines.³⁷ It can be anticipated that specific inhibitors of ALK will be developed and tested in patients with ALCL in the near future.

In NHL, specific translocations are frequently associated with distinct clinicopathologic subtypes of lymphoma. For example, the t(14;18)(q32;q21) or one of its variants are present in about 90% of follicular lymphomas (FL) and 20–30% of B-lineage diffuse large cell lymphomas (DLCL).³⁸ These translocations lead to dysregulated expression of *BCL2*, which inhibits programmed cell death.³⁹ A large body of evidence indicates that the clinically aggressive DLCL that contain a t(14;18) generally arise from more indolent t(14;18)-positive FL following acquisition of additional mutations in important growth-regulatory genes. Strikingly, a common second mutation in both *BCL2*-expressing animal models and human lymphomas is acquisition of translocations activating *cMYC* expression.^{38,40} Expression of *c-MYC* by itself promotes both proliferation and apoptosis; thus, the concomitant expression of *BCL2* and *c-MYC* has synergistic effects that allow cells to proliferate rapidly and survive.

Another important translocation in NHL is the t(11;14)(q13;q32), which is detected in 50–70% of mantle cell lymphomas (MCL), a recently delineated subtype of B-cell NHL.⁴¹ This translocation juxtaposes *CCND1* with the *IgH* locus, causing dysregulated expression of cyclin D1. In contrast to other lymphoid malignancies, almost all MCL overexpress cyclin D1, making this a useful diagnostic feature. It is not clear what genetic alterations cause cyclin D1 overexpression in the 30–50% of MCL lacking detectable gene rearrangements. Possibilities include translocations outside the region detected by commonly utilized molecular probes and more subtle mutations in *CCND1* regulatory elements.

Other recurrent mutations in lymphoid malignancies

Numerical alterations also play an important role in the pathogenesis of lymphoid malignancies. Additions of genetic material occur frequently, but the molecular consequences are not well-understood. For example, hyperdiploidy with a modal chromosomal number of more than 53 chromosomes is common in childhood ALL and is associated with an excellent prognosis.⁴ Although certain chromosomes are duplicated more frequently than others, the specific consequences of duplication are unknown. It is possible that abnormalities of this type do not have specific consequences in the sense that translocations do, but rather are themselves phenotypic effects of other important genetic changes. Arguing against this possibility are the facts that duplications occur non-randomly, and are usually stable within a clone.⁴² Single chromosome gains are also associated with specific subclasses of lymphoid malignancies, such as the frequent occurrence of trisomy 12 in chronic lymphocytic leukemia (CLL).⁴³

Chromosomal deletions are crucial harbingers of TSG in solid tumors, and are generally assumed to denote similar alterations in hematopoietic malignancies. Until recently, the target genes affected by deletions in leukemias have proved elusive. Two tightly linked and functionally related genes on chromosome 9, *INK4A* and *INK4B*, have been identified as the targets of deletions/mutations in a wide variety of malignancies, including ALL.^{44,45} These genes encode proteins of approximately 16 kDa (p16^{INK4a}) and 15 kDa (p15^{INK4b}), members of a large family of cyclin-dependent kinase inhibitors (CDI or CKI), which interact with specific cyclin-dependent protein kinase (CDK)/cyclin complexes and negatively regulate cell cycle progression (see Chapter 4).

There are a number of other areas of recurrent deletion in lymphoid malignancies. In many solid tumors, detailed molecular analysis of recurrent deletions has led to identification of a critical single TSG within the common deleted segment.³ In tumors such as colon cancer, one allele of the TSG is inactivated by deletion and one by point mutation. Identification of the point mutation allows one to focus on the critical gene from the region. To date, it has been very difficult to find such TSG within the areas of common deletion in lymphoid malignancies. This raises the possibility that different mechanisms may be operative in lymphoid malignancies. An example is provided by recent investigations of CLL. More than half of cases of CLL contain mono- or bi-allelic deletions of 13q14.⁴³ A common deleted segment of about 1 million base pairs has been identified and sequenced, but no single gene has been found that is consistently altered in CLL. A recent study identified micro-RNA genes *miR15* and *miR16* from the common deleted are deleted or downregulated in more than half of CLL segment of 13q14 and demonstrated that both genes cases.⁴⁶ These findings may facilitate identification of the target genes involved in other recurrent deletions in lymphoid malignancies.

Mutations in the *TP53* TSG are detected in a wide range of hematopoietic malignancies.⁶ Their occurrence is not random, but rather is disease-specific and generally linked with advanced stage and poor prognosis. For example, mutations are rare in B-lineage ALL and T-ALL at the time of initial diagnosis. At relapse, *TP53* mutations are found in a significant minority of T-ALL, but are still uncommon in B-lineage ALL.^{47,48} Similarly, approximately 15% of CLL contain *TP53* mutations at diagnosis versus 40–50% of transformed CLL (Richter syndrome).⁴⁹ A significant percentage (about 30%) of aggressive high-grade B-lineage NHL have *TP53* mutations, whereas they are rare in clinically indolent low-grade B-lineage NHL.⁵⁰

Chromosomal abnormalities, prognosis, and treatment decisions

Many cytogenetic and molecular abnormalities are tightly associated with distinct clinical subtypes of disease and have important prognostic or therapeutic implications. Perhaps the best example of this is the t(15;17) and *PML-RARA* fusion in acute promyelocytic leukemia (APL) (see Chapter 17). In childhood ALL, contemporary risk group stratification relies heavily on the presence or absence of specific cytogenetic abnormalities in the leukemic clone, including translocations and changes in ploidy. Patients with t(9;22) and *BCR-ABL* fusion and t(12;21) and *TEL-AML1* fusion or hyperdiploidy comprise two opposite ends of the spectrum. While there is no tight linkage of t(9;22)/*BCR-ABL* fusion with unique clinical features, the outcome of patients with this abnormality is extremely poor and few patients with *BCR-ABL*⁺ ALL are cured with chemotherapy alone.⁵¹ For this reason, many centers and cooperative groups now routinely perform RT-PCR for *BCR-ABL* fusion mRNA in patients with ALL. When it is detected, patients are offered alternative therapies. Until recently, this was usually early allogeneic bone marrow transplantation. New studies are also investigating the combination of intensive chemotherapy with imatinib. In contrast, about 40% of children less than 10 years of age with ALL will have either *TEL-AML1* fusion or a hyperdiploid DNA content.⁵² Children with *TEL-AML1*+/*hyperdiploid* ALL have a particularly good prognosis with modern chemotherapy and may have cure rates as high as 90%. Many contemporary clinical trials use the presence of either of these features in treatment stratification algorithms. However, the *BCR-ABL*⁺ and the *TEL-AML1*+/*hyperdiploid* group are not completely homogeneous. Some *BCR-ABL*⁺ patients will be cured with combination chemotherapy alone, and some *TEL-AML1*+/*hyperdiploid* patients will relapse. An ongoing challenge is to dissect the heterogeneity that exists even within molecularly defined groups at the extremes of the prognostic spectrum. Measures of early treatment response and/or gene expression profiles may help refine these groups.

Summary and perspectives

In this chapter, we have reviewed cytogenetic and molecular abnormalities in lymphoid malignancies. We have discussed different types of mutations that occur in proto-oncogenes and tumor suppressor genes, how they are detected, and how they contribute to malignant transformation. We have also highlighted the association between specific cytogenetic and molecular abnormalities and distinct clinical subtypes of disease or treatment outcomes. These associations are now recognized as important diagnostic criteria in leukemia and lymphoma classification systems, and are used to stratify therapy. It is anticipated that these trends will continue and that there will be further movement towards genetically based classification systems and the use of rationally designed therapies targeted at the fundamental molecular lesions that cause lymphoid malignancies.

Analysis of clonality using X-chromosome inactivation patterns

Rosemary E Gale

Introduction

The vast majority of human malignancies are derived from a single cell and are thus clonal in origin. Assessment of clonality has therefore been used to assist in the diagnosis of hematological malignancies. However, the distinction between malignant and non-malignant proliferations is not always clear-cut, and the clonality results must always be interpreted in the context of the type of analysis performed and the clinical information available (Table 19.1). The finding of a nonconstitutive clonal chromosome abnormality in a cell population almost always represents a malignancy and will usually define a disease-specific abnormality. The same cannot always be assumed in situations where clonality has been demonstrated using a less specific marker, for example, clonal lymphoid populations determined by immunoglobulin or T-cell receptor gene rearrangements can be reactive. Conditions such as benign monoclonal gammopathy are caused by clonal B-cell proliferations and are apparently neoplastic (nonreactive) but are not considered to be malignant. In essential thrombocythemia, demonstration of a clonal population of cells using X-chromosome inactivation patterns (XCIPs) is thought to indicate a malignant disorder, but in the absence of strokes and coronary thromboses some patients can live for years, not unduly troubled by the cell proliferation per se.

Current understanding of the complex pathways leading to cellular transformation in vivo remains limited and clonal analysis of different cell populations can be helpful in determining the target cell of the malignant transformation. In chronic myeloid leukemia (CML), where the Philadelphia chromosome can be identified in neutrophils, monocytes, erythroid progenitors and some B lymphocytes, it can be concluded that the disease arose at the 'stem cell level'. The converse is not invariably the case, however. The finding

Table 19.1 Assessment of clonality in hematological malignancies

Cytogenetic analysis (Chromosome loss, gain, partial deletion, inversion or translocation)
Conventional karyotyping
Karyotyping plus surface immuno-phenotyping
Fluorescent in situ hybridization (FISH)
FISH plus immunophenotyping
Molecular detection of somatic mutations (Detection of chromosome loss, translocations, inversions or point mutations)
Restriction fragment length polymorphisms
Microsatellite instability
(RT)-PCR across breakpoint regions
Single-stranded conformation polymorphism analysis
Heteroduplex analysis
Denaturing gradient gel electrophoresis
Mismatch detection analysis
Allele-specific oligonucleotide hybridization
Lymphocyte gene rearrangements
Surface expression of κ and λ , light chains on B cells
Rearrangement of immunoglobulin heavy and light chain genes
Rearrangement of T-cell receptor genes
X-chromosome inactivation patterns (see Table 19.2)
Protein expression, e.g. G6PD
DNA differential methylation, e.g. PGK, HUMARA
mRNA expression, e.g. G6PD

that a specific clonal marker is restricted to the neutrophil lineage does not necessarily mean that the disease arose in a late neutrophil precursor. It could have arisen at the stem cell level but other molecular events involved in the transformation process might have restricted proliferation to the neutrophil lineage. Furthermore, an acquired hyperproliferative phase

may be polyclonal in nature, only becoming clonal with the acquisition of a further 'hit'.

This chapter will consider techniques and interpretation of clonality using XCIPs. Technical aspects of cytogenetic analysis, immunoglobulin and T-cell receptor gene rearrangement studies and molecular analysis of somatic mutations are dealt with elsewhere.

X-chromosome inactivation patterns

Despite extensive progress in the identification of disease-specific molecular markers in hematological malignancies in recent years, clonal analysis using XCIPs in females remains a useful tool for the study of disorders because it does not require prior knowledge of a disease-specific abnormality. Instead it is based on the (pre-supposed) single-cell origin of a malignancy and determines the relative contribution of the two X chromosomes to the cell population under study. In mammalian female cells, one of the two X chromosomes is always inactivated at an early stage in embryogenesis, a process called Lyonization, after Mary Lyon, who first described it.¹ Which chromosome is inactivated is random and is stably inherited as such by all daughter cells,² so that a constitutional mosaic pattern is thereby laid down in each female (Figure 19.1). In a normal or reactive population, the cells should all demonstrate the same active X chromosome. An XCIP therefore has two basic requirements: the ability to distinguish between the two X chromosomes, which is achieved using an X-linked polymorphic marker, and the ability to differentiate between the active and inactive X chromosomes, which depends on the type of analysis employed (Table 19.2).

With the first descriptions of this technique using glucose-6-phosphate dehydrogenase (G6PD) analysis,

Figure 19.1 X-chromosome inactivation.

both objectives could be achieved simultaneously as isoenzymes of the expressed protein product can be electrophoretically separated.^{3,4} Furthermore, as a housekeeping gene the protein is detectable in all cell types, even enucleated red cells. However, despite the existence of more than 400 variant forms, the frequency of heterozygotes is low, reaching its highest (approximately 35%) in females of African origin who are heterozygous for the common B type and either the A or A- isoenzyme.⁵ To date no other X-linked genes with suitable polymorphic proteins have been described.

During the 1980s the search for polymorphic markers detectable using restriction enzymes revealed a number in X-linked genes that are present at sufficiently high frequency and can be analyzed using Southern blotting. They include base substitutions, as in the phosphoglycerate kinase (PGK) and hypoxanthine phosphoribosyl transferase (HPRT) genes,⁶ and variable number tandem repeat (VNTR) sequences such as the DXS255 locus recognized by the M27 β probe.⁷ Discrimination between active and inactive X-chromosomes depends on differential methylation patterns at these loci and can be demonstrated using methylation-sensitive enzymes such as *HpaII* and *HhaI*.⁸ DNA is first digested with the relevant restriction enzyme to enable separation of the two alleles, then divided into two aliquots, one of which is further digested with the appropriate methylation-sensitive enzyme. A relative ratio of expression of the two alleles can be obtained by comparison of the intensity of bands present after the first and second enzyme digestions (Figure 19.2) and results are usually reported either as the percentage expression of the two alleles (75%:25%, 50%:50%, 25%:75% etc.) or as a ratio of expression of the two alleles (3.0, 1.0, 0.25 etc.).

These loci have been used extensively in clonality assays, but Southern blotting analysis requires large amounts of DNA and there can be difficulties of interpretation due to the complexity of some methylation patterns.⁸ Attention therefore has turned to genes that are amenable to polymerase chain reaction (PCR) analysis, i.e. where the polymorphism and differential methylation sites are situated close together, within approximately one kilobase of each other. Suitable loci include the BstXI restriction enzyme polymorphism in the PGK gene,⁹ and VNTRs in the monoamine oxidase A gene,¹⁰ the human androgen receptor (AR) gene,¹¹ the fragile X (FMR1) gene¹² and at locus DXS15-134.¹³ To date, the human AR assay (HUMARA) is the most widely used due to the high level of heterozygosity of the AR gene in most populations, approximately 90%. PCR does not maintain methylation of the alleles so DNA is first digested with the methylation-sensitive enzyme, cutting only unmethylated (active) alleles and leaving uncut the methylated (inactive) alleles, which are thus available for PCR amplification. For quantitative purposes a

Figure 19.2 Clonal analysis using Southern blotting. For a restriction enzyme polymorphism such as the polymorphic Bst XI site in the PGK gene, DNA is first digested with Pst I (P) and Bst XI (B) to distinguish the two alleles of 0.9 and 1.05kb (PB). Further digestion with the methylation-sensitive enzyme *Hpa II* (H) cuts the unmethylated alleles, which are then too small to be detected. The intensity of the remaining 0.9 and 1.05 kb, undigested by *Hpa II* (H) bands reflects the relative expression of the alleles (PBH). Alternatively, for a variable number tandem repeat sequence (VNTR) as identified by the M27 (β) probe, DNA is first digested with Pst I to separate the two alleles of differing sizes (P). Digestion with Msp I (M), which is not affected by methylated cytosines, reduces each allele by approximately 500bp (PM). Digestion with its methylation-sensitive isoschizomer *Hpa II* (PH) demonstrates the proportion of each allele that is unmethylated and allows calculation of the relative expression of each allele.

radioactive or fluorescent-labeled primer is incorporated. PCR products of VNTR alleles can be directly separated electrophoretically on the basis of their size. Single nucleotide substitutions require prior digestion with the relevant restriction enzyme to allow separation of the alleles (Figure 19.3).

PCR-based clonal analysis has been successfully applied to small samples of DNA obtained from purified populations of cells or individual hemopoietic colonies grown in culture. Its speed and ease of analysis are obviously advantageous, and provided a number of technical considerations are carefully addressed such as extra bands due to Taq slippage, preferential amplification of shorter alleles, and heteroduplex formation that can interfere with restriction enzyme digestion, quantitative results comparable with Southern blotting can be obtained.¹⁴

An alternative DNA-based PCR method that uses chemical modification to differentiate between the active and inactive alleles has been recently described.^{15,16} DNA is first treated with sodium bisulphite, which converts all unmethylated cytosines to uracil but does not alter the methylated cytosines. One or two separate PCRs are then performed using

Figure 19.3 Clonal analysis using DNA-based PCR. The polymorphism and differentially methylated cytosines must lie sufficiently close together to allow amplification across both sites. PCR is performed on aliquots of DNA either undigested or pre-digested with the methylation-sensitive enzyme *Hpa II* (*H*), which cuts the unmethylated alleles, i.e. leaving intact the methylated alleles for amplification. The two alleles are then separated either by polymorphic enzyme digestion, as with the *Bst XI* site (B) in the PGK gene, or by different size alleles due to a VNTR sequence, as in the AR gene.

primers that are specific for methylated DNA in one reaction and/or unmethylated DNA in the other. Although only one PCR is necessary, the complementary results obtained from both reactions act as confirmation of the pattern obtained. This method circumvents false results arising from incomplete restriction enzyme digestion of unmethylated alleles, and although it has not yet been widely tested, it may be particularly useful for analysis of hematopoietic colonies where restriction enzyme digestion of small numbers of cells can be problematic.

A more direct approach to overcome the problem of complex DNA methylation patterns has been the introduction of methods using RNA, where relative expression of the two alleles can be analyzed directly at the transcript level. Genes suitable for this analysis must contain the polymorphism in their coding sequence, although it will not necessarily change the amino acid sequence, and be expressed in the cells of interest. Three single base substitutions have been used in a number of studies; all are house-keeping genes with widespread tissue expression: G6PD (different from the A/A- variants),¹⁷ iduronate-2-sulphatase (IDS)¹⁸ and the palmitoylated membrane protein p55.¹⁹ Together they provide a reasonably high degree of heterozygosity in most population groups (Table 19.2). Several different methods have been reported after the reverse-transcription step: either (1) PCR followed by allele-specific oligonucleotide hybridization,²⁰ (2) PCR using a mismatch primer to introduce a suitable restriction site plus restriction enzyme digestion specific to one of the alleles (Figure 19.4),^{21,22} (3) PCR with allele-specific

Figure 19.4 Clonal analysis using the C/T polymorphic site at codon 146 in the iduronate-2-sulphatase mRNA. PCR is performed on cDNA using a 3' primer, which introduces a G → C mismatch to create a *Bcl I* enzyme restriction site in products from the T-containing alleles but not the C-containing alleles. After RT-PCR and *Bcl I* digestion, the relative proportion of the two bands reflects expression of the two alleles.

primers,²³ or (4) PCR plus the ligase detection reaction with specific primers to distinguish the two alleles.¹⁹ Quantitative, reproducible results have been reported which correlate well with DNA-based assays.^{19,22} The VNTRs in the AR²⁴ and FMR1²⁵ genes also occur within the coding sequence and mRNA expression of these genes may be studied in some tissues.

RNA-based assays have a number of advantages over those using DNA. Not only are they less likely to be affected by aberrant or complex methylation patterns, but there is no requirement for the polymorphic site to be in close proximity to a site demonstrating the differential expression. Primers can be designed across an exon/intron boundary to eliminate interference from contaminating DNA. Furthermore, where appropriate, enucleated cells such as reticulocytes and platelets can be studied. However, important factors that may influence RNA assays but not those based on DNA include variation between tissues in the level of transcript expression and degree of sample purity required. For example, platelet contamination of T lymphocytes may give a false pattern for the latter cell population. In view of all these considerations, wherever possible results should be confirmed using more than one assay.

The loci mentioned earlier have all been reported in studies using XCIPs for analysis of clonality. With the sequencing of the entire X-chromosome as part of the Human Genome Project and the creation of a database for single nucleotide polymorphisms (SNPs) in the human genome (<http://www.ncbi.nlm.nih.gov/SNP/>), it is likely that many other useful polymorphic X-linked loci will be identified in the next few years. Of

1844 X-linked SNPs in the database in March 2001, Vasques and Pereira reported that 141 were within expressed sequences corresponding to 99 different genes.²⁶ Thus it should soon be possible to find a suitable marker for XCIP analysis in any female. However, a number of nonpseudoautosomal genes have been found to either completely escape^{27,28} or show variable X-inactivation²⁹ and gene expression may be tissue restricted.²⁶ Therefore any new marker should be carefully evaluated for its suitability before application to patient samples.

Interpretation of results

Despite the widespread use of XCIPs to address questions of clonality and lineage involvement in hematological disorders, many of the studies appear to have contradictory results. Recent evidence suggests that much of this confusion has probably arisen from the definition of a clonal XCIP and the failure to take into account other mechanisms that can mimic this. Since Lyonization is a random process, it has been argued that a normal polyclonal pattern will show approximately 50% expression of each allele, and the patterns that diverge from this indicate the presence of monoclonal or oligoclonal hematopoiesis. A skewed or imbalanced XCIP indicative of the presence of a clonal population of cells has therefore arbitrarily been taken to mean >75% expression of one allele, i.e. an allele ratio of >3 or <.25.⁶ A number of studies have shown, however, that there is considerable variation in the XCIPs obtained from blood or bone marrow of hematologically normal females, with an imbalanced or skewed Lyonization pattern in approximately 20–25%.^{30–32} This degree of skewing may relate to the size of the primordial stem cell pool committed to hematopoiesis at the time of X-inactivation, since the smaller the number of hematopoietic stem cells present at that time, the greater the number of individuals that will be observed with a skewed XCIP.³³ Consequently an apparently ‘clonal’ XCIP does not necessarily represent a clonal population of cells but may simply reflect the constitutive Lyonization pattern for that individual. Therefore, to interpret an XCIP in a tissue sample from an individual requires knowledge of their normal pattern.

Blood or bone marrow from a patient pre-dating the transforming event is rarely available for comparison to show that the pattern has altered and therefore alternative tissues such as skin, cultured fibroblasts and buccal mucosa have been used. However, these may not be appropriate controls as XCIPs appear to be tissue specific and can vary widely between tissues of the same individual, possibly because the progenitor cell pool size varies for different tissues.^{34,35} For most myeloid disorders, T lymphocytes are a suitable comparative control as they are not generally involved in the clonal process but derive from the same pluripotent stem cell and therefore will have the same constitutional XCIP.³⁶ However, where there are doubts regarding possible T-cell involvement in the disorder, assessment of clonality in individuals may not be feasible and large-scale studies to determine the distribution patterns for a particular disorder relative to the normal population may be necessary.

Further complication has arisen with the recent observation that XCIPs can change with age; approximately 40% of hematologically normal females ≥ 75 years of age acquire a skewed XCIP in their myeloid cells.^{37–39} These results are not necessarily indicative of a preleukemic phase or of stem cell depletion but may reflect random changes in stem cell usage, with fewer of the original stem cell pool actively contributing to the myeloid population. Longitudinal studies in cats, analysis of XCIPs in elderly monozygotic twins, and the study of different tissues from elderly females have all suggested that there may be a genetic component to this shift and that it results from a selective advantage of cells expressing one particular X chromosome.^{35,40–42} This proliferative or competitive advantage must, however, be small as it takes many years in humans before it is evident, and longitudinal studies of up to 3 years have shown stable XCIPs.^{43,44} Whatever the cause of this phenomenon, it has important implications for the use of these tests in the diagnosis of diseases of the elderly, which are arbitrarily defined as occurring in those >65 years of age. An imbalanced myeloid XCIP in the presence of a balanced T-cell XCIP cannot be interpreted in these patients as evidence of clonal hematopoiesis. Balanced myeloid XCIPs, however, can be used to indicate the presence of polyclonal hematopoiesis. Acquired skewing is also the probable cause of a number of cases of X-linked disorders that only present in the later years of life, such as late-onset X-linked sideroblastic anemia.⁴⁵

Finally, in addition to the importance of evaluating an XCIP with respect to a relevant tissue control and the age of the individual, technical considerations must also be taken into account. Unlike direct analysis of a clonal marker such as demonstration of the presence of a fusion transcript by RT-PCR, this technique is not sufficiently sensitive for detection of a small population of clonal cells on a predominantly polyclonal background. Results are generally highly reproducible, but duplicate analysis of samples can give quite wide variations,¹⁴ and only values differing by >20% are considered to be significantly different.

Application of techniques

Chronic myeloid leukemia

CML was the first hematological disorder shown to have a clonal origin when, in 1967, Fialkow and

colleagues examined G6PD isoenzymes in the red cells and granulocytes of three female patients and demonstrated that they expressed only the A type, whereas fibroblasts had both A and B types.⁴⁶ Subsequent studies concluded that the disease arose in a stem cell common to myeloid, erythroid, and megakaryocytic cells, and (at least in some cases) B-lymphoid cells.^{47,48} With the identification of the leukemia-specific t(9; 22) translocation giving rise to the bcr/abl fusion transcript and protein, there has been little further diagnostic application of XCIPs in CML. A number of studies have, however, used this technique to demonstrate a return of polyclonal hematopoiesis after interferon- or high-dose chemotherapy-induced cytogenetic remission^{49,50} and/or autografting with Philadelphia-negative, bcr/abl negative, peripheral blood stem cells.⁵¹ It has shown that, whereas Philadelphia-negative, bcr/abl-negative, CD34+ progenitors obtained from early chronic phase CML were polyclonal, in late chronic phase and accelerated phase CML the progenitors were mainly Philadelphia-positive, bcr/abl positive and clonal, and a polyclonal state could not be induced by chemotherapy.⁵²

Chronic myeloproliferative disorders

XCIPs have a potentially useful role in the diagnosis of polycythemia vera (PV), essential thrombocythemia (ET) and agnogenic myeloid metaplasia. Although characterized by the excessive proliferation of one or more hematopoietic cell lineages, their diagnosis is often one of exclusion and they may be difficult to distinguish from reactive processes accompanying various infectious, inflammatory, or neoplastic disorders. Although a variable proportion transform to acute leukemia (3–20%), relatively few patients present with clonal chromosomal abnormalities. Early studies suggested that they are clonal disorders of stem cell origin, with single G6PD isoenzyme types only observed in granulocytes, red cells and platelets.^{53,54} However, only small numbers of heterozygous patients were studied, results were compared with skin or cultured fibroblasts, not T lymphocytes, and age-related skewing was not taken into account. More recent studies have indicated that in ET and to a lesser extent PV, a significant proportion of patients may have polyclonal granulocyte and T-cell patterns.^{9,21,39,55–58} This may reflect heterogeneity of lineage involvement in these disorders, with restriction of the clonal population to the dominant cell type in some patients. PCR analysis of individual colonies demonstrated that one out of three PV patients had evidence for a clonal population in erythroid progenitors, whereas neutrophils had a balanced XCIP despite an increased neutrophil count.⁹ In ET, although mono clonal platelets with polyclonal neutrophils have been reported in a small number of patients; this lineage restriction is uncommon.^{21,55,57} Of clinical significance, polyclonal myelopoiesis in ET patients correlates with a reduced susceptibility of thrombotic complications.^{55,57}

These findings suggest that, unlike CML, where a specific marker is present in nearly all patients, the chronic myeloproliferative disorders may be genotypically heterogeneous despite many apparent phenotypic similarities. XCIPs may therefore be a useful tool to subclassify patients and to search for more specific molecular abnormalities that, to date, have proved remarkably elusive. Long-term follow-up studies are required to determine whether clonal myelopoiesis evolves from polyclonal disease through the acquisition of further pathogenic alterations, and whether myelofibrosis only develops in clonal patients or correlates with the development of clonal myelopoiesis. Since many patients have a relatively stable disease over long periods of time, such information may have particular relevance to the use of potentially leukemogenic therapy, especially in younger patients.

Aplastic anemia and paroxysmal nocturnal hemoglobinuria

The defect in acquired aplastic anemia (AA) affects multiple cell lineages and patients have a high incidence of evolution to a clonal disease with increasing time from diagnosis. Current data suggests that immune destruction causes the pancytopenia, and there is little evidence to indicate a possible causal link between AA and clonal disease with, for example, clonal expansion of a defective stem cell or reduction of the stem cell pool to a clonal composition. Clonal cytogenetic abnormalities are rare and XCIPs suggest that most patients have polyclonal hematopoiesis.^{59,60} Furthermore, XCIPs have not been useful in predicting development of a clonal disorder. In one study, three of four patients with clonal hematopoiesis showed no sign of clonal evolution after more than 1 year of follow-up; conversely six patients with polyclonal hematopoiesis developed paroxysmal nocturnal hemoglobinuria (PNH), acute myeloid leukemia (AML) or monosomy 7.⁵⁹ However, it must be noted that these techniques are relatively insensitive and will not detect minor clonal populations. This problem is particularly evident for PNH where the abnormal cells deficient in phosphatidylinositol glycan anchored proteins (PIG-AP) are known to be clonal,^{60–62} but their presence may be obscured by normal cells, so that unsorted cells from AA or PNH patients harboring PIG-AP-deficient cells may have a polyclonal XCIP.⁵⁹ These PIG-AP-deficient cells appear to be unique in that, although they carry an acquired, specific clonal marker, they have no

growth advantage and are not considered to be neoplastic.⁶³

Myelodysplastic syndromes and acute myeloid leukemia

The myelodysplastic syndromes (MDSs) and AML are clonal stem cell disorders frequently characterized by disease-specific karyotypic abnormalities. Monoclonal or skewed XCIPs can be demonstrated in myeloid cells, consistent with the presence of a predominant clone.^{30,64} Nevertheless, polyclonal hematopoiesis has been reported in a number of patients with diagnostic features of MDS, who can remain stable over many years before transformation.^{65,66} Nonclonal progenitor cells have been shown to persist in some MDS patients.⁶⁷

Before the molecular identification of some of the commonest translocations and deletions, XCIPs were used to determine the extent of lineage involvement in these disorders.^{64,68–70} Results were often contradictory, at least in some studies because suitable control tissues were not included. Most studies now indicate that a disease-specific defect can be identified in myeloid, erythroid and sometimes B-lymphoid cells, but the involvement of T-lymphoid cells in clonal development of MDS remains controversial.⁷¹ Acute promyelocytic leukemia is unusual in that early progenitor cells (CD34⁺, CD38⁻) are not only PML/RAR α negative by RT-PCR but also polyclonal by XCIP analysis.⁷² Early studies indicated that there may be heterogeneity of lineage involvement in AML, with lineage restriction of clonal progenitor cells in some younger but not older patients.⁷³ These results led to the suggestion that AML in the elderly may represent evolution from a preleukemic, myelodysplastic state. However, with the recent knowledge of acquired skewing of XCIPs in myeloid cells of the elderly, this issue needs to be re-evaluated.

Clonal analysis has been used to demonstrate that restoration of polyclonal hematopoiesis in morphological remission can be achieved post high-dose chemotherapy in MDS,^{74–76} and to confirm that non-clonal CD34⁺ progenitor cells can be harvested for autologous peripheral blood transplantation.⁷⁷ A recent study has also suggested that low-risk MDS patients with clonal and nonclonal patterns may have differing responses to antithymocyte or antilymphocyte globulin.⁷⁸ In AML, although some studies have suggested that remission may be clonal in approximately one-third of patients,⁷⁹ implying that this indicated the return to a pre-leukemic state, T cells were not included in these studies and at least some cases can probably be explained by a constitutionally imbalanced Lyonization pattern. Where T cells have been studied in parallel with remission granulocytes or bone marrow,³⁰ or where the disappearance of leukemia-specific products such as the PML/RAR α fusion product in acute promyelocytic leukemia has been correlated with XCIPs,⁵⁰ the results suggest that clonal remission is infrequent, and when present is often associated with trilineage myelodysplasia.^{80,81} An XCIP, however, will not distinguish between a truly clonal remission with repopulation by potentially leukemic cells, and an apparent clonal remission induced by regeneration from a small stem cell pool. In general, studies post allogeneic or autologous bone marrow transplantation have demonstrated that repopulation is polyclonal,^{82,83} although monoclonal/oligoclonal hemopoiesis of donor origin has been reported in two patients.⁸⁴

The risk of developing therapy-related myelodysplasia or AML after high-dose therapy and, in particular, autologous stem cell transplantation, is substantial and does not necessarily correlate with the presence of cytogenetic abnormalities.⁸⁵ Studies have therefore attempted to use analysis of XCIPs to follow disease progression. However, although clonal evolution can be detected in some patients through demonstration of progressively changing patterns,^{86,87} such studies are limited by the frequency of constitutionally skewed XCIPs and require careful interpretation of the results obtained. Furthermore, this technology will not identify the presence of minor clonal populations on a polyclonal background, and polyclonal hematopoiesis can persist despite myelodysplastic features.⁸⁷

In conclusion, clonal analysis with XCIPs can be used to provide information regarding clones of cells, both in disease entities as a whole and for selected patients, but the technology has a number of limitations and great care in the interpretation of data from individual patients is required.

Gene expression profiling in leukemias using microarrays

Torsten Haferlach, Wolfgang Kern, Alexander Kohlmann, Susanne Schnittger, and Claudia Schoch

Introduction

The classical methods to diagnose leukemias are cytomorphology and histology, which are both supplemented by cytochemistry and multiparameter immunophenotyping to refine classifications. Furthermore, insights into the genetic basis of the leukemia have substantially increased the diagnostic importance of cytogenetics, fluorescence in situ hybridization (FISH), and polymerase chain reaction (PCR). Besides the detailed classification of leukemias based on the knowledge provided by the different methods, the selection of disease-specific therapeutic approaches has become a reality, for example the use of all-*trans*-retinoic acid (ATRA) in acute promyelocytic leukemia (APL).¹ Also, the significant efficacy of imatinib (STI571), a specific tyrosine kinase inhibitor, in *BCR-ABL*-positive acute lymphoblastic leukemia (ALL) and chronic myeloid leukemia (CML) patients demonstrates the impressive advances in developing tailored disease-specific therapeutic approaches based on a molecular rationale.² As knowledge of disease-specifically altered pathways increases, microarray technology that can provide a vast amount of data on significantly altered gene expression may become an essential tool for optimization of leukemia classification. It also allows the detection of new biologically and clinically relevant subtypes in leukemia, and may guide therapeutic decisions in the near future. In addition, the development of new drugs may be within the focus of such functional genomic approaches in leukemia.

Gene expression profiling using microarrays

Technical aspects

Microarrays contain precisely positioned DNA probes designed to specifically monitor the expression levels of genes in a highly parallel manner. Common to all expression profiling approaches is the heteroduplex formation: structural features of nucleic acids enable every nucleic acid strand to recognize complementary sequences through base pairing. After the process of hybridization, complementary fluorescently tagged nucleotides can be detected.^{3,4} A detailed overview of the various options available for array-based expression analyses can be found elsewhere.⁵ Briefly, a number of basically different microarray platforms are available: filter arrays (formerly considered as macroarrays due to their lower probe density), in situ synthesized oligonucleotide arrays, and spotted glass slide arrays. The latter two vary according to the immobilized probe (i.e. cDNA, oligonucleotides, or genomic fragments) and according to the choice of substrate for surface modification.

In situ synthesized oligonucleotide arrays for expression monitoring contain hundreds of thousands of gene-specific polynucleotides fabricated at high spatial resolution at precise locations on a surface. Laser confocal fluorescence scanning enables the measurement of molecular hybridization events on the array (Figure 20.1, see Plate 3). On a current commercial chip design (e.g. HG-U133 plus 2.0 microarrays from Affymetrix), about 42 000 human genes are represented and thereby probably cover most human genes. Each sequence is represented by multiple oligonucleotides designed to hybridize to different regions of the same RNA. An additional level of redundancy comes from the use of mismatch control probes that are identical to their perfect match partners except for a single base difference in a central position. In contrast, spotted glass slide arrays are usually designed for two-color competitive hybridization. Co-hybridized preparations of both test RNA and reference RNA compete for the spotted DNA probe.⁵ Compared with commercially available in situ synthesized arrays with a predetermined number and selection of genes, spotted glass slide arrays can be produced at low cost at core facilities and may only focus on particular genes of interest.

Figure 20.1 Schematic illustration of microarray technology. For DNA oligonucleotide microarrays, one sample is hybridized per experiment. The detection is accomplished by a fluorescent dye, and results in an absolute expression level for each gene. The oligonucleotides are synthesized in situ onto the array surface. For spotted microarrays, the test RNA is co-hybridized with control RNA. Following detection of the signals, the ratio of differentially tagged test and control RNA is calculated. See Plate 3.

Data mining, interpretation, and storage

Microarray studies generate vast quantities of data. After image processing, the first step of analysis is to produce a large number of quantified gene expression values. These values represent absolute fluorescence signal intensities as a direct result of hybridization events on the array surface. It is also possible to qualitatively rate gene expression as absent/present detection call calculations.^{6,7} Before analyzing the data, it is a routine procedure to normalize the data.⁸

Data mining, the discovery of non-obvious information, often uses mathematical techniques that have traditionally been used to identify patterns in complex data. There are two different approaches to analyze the data: the supervised approach and the unsupervised approach. Typically, it is of great interest to correlate array data directly to, for example, clinical, cytomorphological, or cytogenetic features. The application of a supervised analysis then requires the grouping of patients according to predefined characteristics. There are several statistical algorithms available that can identify statistically significant differentially expressed genes. A detailed overview can be found elsewhere.⁹ After detecting differential gene expression, it is often necessary to accurately classify samples into known groups. Again, a wealth of machine-learning literature can be found elsewhere.¹⁰⁻¹³ Ideally, class prediction is done by dividing the gene expression data into training sets and test sets. First, a number of differentially expressed markers are selected to differentiate between groups that are already known (Figure 20.2). This list of genes is then used to predict independent samples in a test set, based on their discrete gene expression characteristics.

By contrast, clustering is an unsupervised method for organizing expression data into groups with similar signatures. It can be used both to reduce the complexity of the matrix-like data and to visualize it in a more understandable way, as well as predicting the categorization of unknown samples. Patterns in the data are discovered solely from the data itself, as there is no previous knowledge or grouping of the data. Twodimensional hierarchical clustering¹⁴ sorts both patients and genes according to similarities and leads to a tree-structured dendrogram, which can easily be viewed and explored (Figure 20.3a, Plate 2). It is clear that this hierarchical structure provides potentially useful information about the relationship between adjacent clusters. Common crossing points represent similar patient characteristics as well as similarities with regard to the coexpression of distinct genes. By

↓ represented genes

Figure 20.2 Schematic representation of a matrix-like gene expression raw data set. Individual patient samples are ordered in columns, while gene expression values are given in rows.

Figure 20.3 Two-dimensional hierarchical clustering (a) orders primary expression data. Genes with similar expression patterns are grouped together. Displayed graphically, the relationship among genes can be explored intuitively. Principal component analysis (PCA) (b) is a classical analysis technique to reduce the dimensionality of the data set. New uncorrelated variables summarize characteristic features of the original data. See Plate 4.

use of a detailed gene annotation, it is possible to find functional groupings of genes based on their similarity among the gene expression profiles. This information can be used to gain new insights into physiological pathways (www.ingenuity.com), and may also help to characterize previously uncharacterized genes.¹⁴ A structured and normalized annotation of the respective genes and gene products, essential for all evaluations, is provided by the Gene Ontology consortium.¹⁵ Public available databases such as NetAffx provide regularly updated functional gene annotations.¹⁶ Furthermore, relevant gene information is connected to other various databases such as OMIM (www.ncbi.nlm.nih.gov/omim/), SWISSPROT (<http://us.expasy.org/sprot/>).

Principal component analysis (PCA) is another technique that can be used to reduce the dimensionality of array data and visualize large data sets in an understandable way.¹⁷ The multidimensional and matrix-like structured array data set (with patient samples in columns and gene expression intensities in rows) is reduced to a new set of variables (i.e. the principle components) by transformation (Figure 20.3, see Plate 4). Since the variation of the original data can be retained and explained by a smaller number of transformed variables, PCA projects the data into a new two- or three-dimensional space and may provide valuable insight into the data (Figure 20.3b, see Plate 4).

The effective annotation of microarray experiments is a major task, which has been approached by the Microarray Gene Expression Data (MGED) group (www.mged.org).¹⁸ This consortium defines standards for the annotation of microarray experiments (MIAME: minimum information about a microarray experiment), as well as a standard data-exchange for-mat (MAGE-ML: microarray gene expression markup language). Based on these standards, global expression databases have been established with the aim of

giving access to, sharing, and comparing microarray data. In accordance with the MGED recommendations, ArrayExpress (www.ebi.ac.uk/arrayexpress) is such a public repository for microarray data. The NCBI has launched the Gene Expression Omnibus (GEO), a gene expression and hybridization array data repository, as well as an online resource for the retrieval of gene expression data from any organism or artificial source (www.ncbi.nlm.nih.gov/geo/).

Acute myeloid leukemia (AML)

Following the pivotal work of Golub et al,¹⁹ who provided data on the applicability of microarrays and new biostatistical analysis methods, several more detailed analyses have been performed over the last few years. These analyses have provided not only a ‘class prediction’ (prediction of a tumor entity based on specific gene expression profiles of selected informative genes),^{19–21} but also a ‘class discovery’ (discovery of new subentities within groups formerly regarded as homogeneous entities).^{22–25} This discovery is not limited to the pure identification of new biological entities of leukemia, but also includes the definition of prognostically different groups,^{22,24} which is anticipated to influence therapeutic strategies. Thus, it seems a realistic goal to predict response to therapy, relapse risk, and even risk of developing a secondary AML as suggested in children treated for ALL.²⁴

Class prediction in AML

The first study applying the microarray technology to AML samples demonstrated that both ALL and AML are characterized by distinct and specific gene expression profiles.¹⁹ The distinction between ALL and AML is routine daily practice and is necessary for therapeutic decisions. Today, it is based on cytomorphology, cytochemistry, and immunophenotyping. Golub et al¹⁹ showed that this distinction is also possible solely on the basis of gene expression profiles. In bone marrow samples from 27 patients with ALL and 11 patients with AML, a total of only 50 discriminatory genes were demonstrated to allow the separation of these large and heterogeneous entities from each other. In 36 out of the 38 cases, the molecular diagnosis of leukemia was made correctly based on the gene expression profile as analyzed on the microarray. These analyses represented the first and a major step towards molecular diagnostics of acute leukemias.

Moos et al²⁶ confirmed this finding and were able to discriminate in 51 childhood leukemias between AML and ALL as well as to subdivide B-lineage from T-lineage ALL using their cDNA arrays representing 4608 genes.

Class prediction on the basis of cytomorphology

Haferlach et al²⁷ addressed the question whether French-American-British (FAB) subtypes show distinct gene expression patterns allowing the prediction of subtype based solely on the expression status of a limited set of genes using microarrays (U133A, Affymetrix). All 130 analyzed cases were characterized by cytomorphology and cytogenetics. Reverse transcriptase (RT)-PCR was carried out in all cases with M2/t(8; 21), M3(APL), and M4Eo.

Immunophenotyping was performed in all M0 cases. Based on the expression signature of only 1–3 genes, it was possible to separate M3, M3v, M4Eo, and M6 from all other subtypes with 100% accuracy. Comparison between M2 and M4 resulted in the low-est accuracy (85%), which demonstrates the arbitrariness of selecting a threshold of over 20% positivity for non-specific esterase in the FAB system. As shown in Figure 20.4, however, the percentage of myeloperoxidase (MPO)- or non-specific esterase (NSE)-positive cells as measured by cytochemistry correlates highly with microarray signal intensities across all different FAB subtypes.

Correlation of gene and protein expression

To compare expression data obtained by microarray analyses with protein expression data determined by multiparameter flow cytometry, which is a standard method for diagnosing and subclassifying AML and ALL, Kern et al²⁸ analyzed 39 relevant markers in 113 patients with newly diagnosed AML and ALL and 4 normal bone marrow samples by both methods in parallel (Affymetrix U133A microarray). A high degree of correlation between protein expression and RNA abundance was observed with regard to both positivity/negativity and quantitative data. Thus, in 1512 of 2187 (69.1%) comparisons, congruent results were obtained with regard to positivity or negativity of expression, respectively. Moreover, among the genes most relevant for diagnosing and subclassifying AML and ALL, i.e. CD13 (Figure 20.5), CD33, MPO, CD22, CD79a, CD19, CD10, and terminal deoxyribonucleotidyl transferase (TdT), congruent results were obtained in 75–100%. These data are considered evidence that protein expression is highly correlated with mRNA abundance in AML and ALL. By taking advantage of these observations, new antigens maybe identified that are expressed on the cell surface of AML and ALL cells and that may be promising targets to monitor minimal residual disease.

Prediction of genetic abnormalities

Schoch et al²⁹ demonstrated that the cytogenetically defined subtypes—AML with t(8; 21), AML with t(15; 17), and AML with inv(16)—are characterized by different and specific gene expression profiles. The

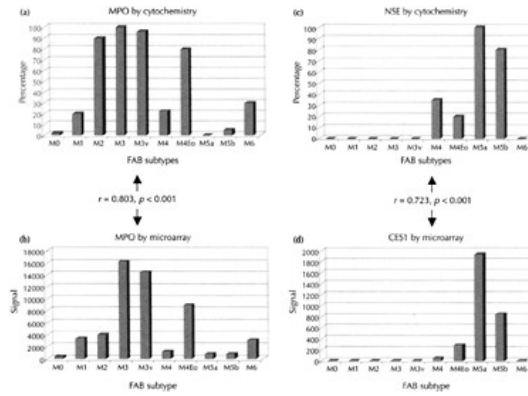

Figure 20.4 Comparison between cytochemistry and gene expression in AML ($n=130$). Percentage of myeloperoxidase (MPO)- or non-specific esterase (NSE)-positive cells as measured by cytochemistry on bone marrow smears in the different FAB subtypes in comparison with signal of MPO or CES1 (carboxylesterase 1) measured on the microarray in the same cases.

Figure 20.5 Correlation of protein and mRNA levels in AML. Mean fluorescence intensities for CD13 obtained by multiparameter flow cytometry (MFC) are plotted against signal intensities for CD13 obtained by microarray analysis (MA) in 85 cases with AML (Spearman rank correlation).

underlying basic genetic alterations lead to patterns of gene expression that can be unequivocally detected by microarrays (Figure 20.6, see Plate 4). A minimum set of only 13 genes was sufficient to accurately predict the karyotypes in the respective AML samples.

A further step consisted in the addition of samples with AML carrying aberrations of chromosome 11q23, i.e. *MLL* rearrangements, representing an analysis of AML subtypes with recurring chromosomal aberrations as defined by the WHO.³⁰ Based on the gene expression profiles, a minimum set of 39 genes was sufficient to classify samples as normal bone marrow or AML with one of the aberrations t(8; 21), t(15; 17), inv(16), or 11q23 rearrangements. A principal component analysis as calculated based on the expression intensities of these 39 genes visualizes this (Figure 20.7, see Plate 5).

The same approach was described by Debernardi et al.,³¹ when investigated 28 cases of AML with t(8;21), t(15;17), and inv(16), also including cases with dif-

Figure 20.6 Hierarchical clustering based on U133A expression data of 45 AML samples (columns) comprising the subgroups $t(15;17)$ ($n=20$), $t(8;21)$ ($n=13$), and $inv(16)$ ($n=12$) versus 36 informative genes represented by 58 U133A chip design probesets (rows). New patient samples, which were not previously hybridized to U95Av2 microarrays are marked by asterisks. The normalized expression value for each gene is coded by color, with the scale shown at the lower left (standard deviation from mean). Red cells represent high expression and green cells low expression. The previously published set of diagnostic markers is given by respective gene symbols. See Plate 4.

Figure 20.7 Principal component analysis based on U133A expression data of WHO-classified AML subtypes with recurrent chromosome aberrations and normal bone marrow mononuclear cells from healthy volunteers. Sixty AML samples comprising the color-coded subgroups $t(15;17)$ ($n=20$), $t(8;21)$ ($n=13$), $inv(16)$ ($n=12$), and $t(11q23)/MLL$ gene rearrangement-positive samples ($n=15$) can be discriminated accurately, and are different from normal bone marrow nBM ($n=9$). See Plate 5.

ferent 11q23 aberrations as well as 10 AML patients with a normal karyotype using U95A arrays (Affymetrix). In comparison with the data set described above, many discriminating genes were found in this independent cohort of AML cases. Furthermore, the expression status of specific genes correlated with 11q23 as well as with AML with normal karyotype. The latter group was characterized by a distinctive upregulation of members of the class I homeobox A and B gene families, implying a common underlying genetic lesion for AML with normal karyotype.

Virtaneva et al³² focused on AML with trisomy 8 as the sole cytogenetic aberration and asked whether this subgroup could be separated from AML with a normal karyotype based on its gene expression profile. CD34⁺ cells were analyzed after Ficoll-Hypaque gradient centrifugation, labeled with a secondary antibody conjugated to magnetic beads, and purified over a magnetic column. However, in this analysis using HuGeneFL arrays (Affymetrix), full separation of both cytogenetically different AML subgroups was not possible. This may be due to trisomy 8 not being the disease-defining abnormality but rather a secondary aberration in addition to pathogenetically essential but not yet identified molecular events. Nonetheless, a gene dosage effect was clearly demonstrated, since many genes coded on chromosome 8 were expressed at higher levels in the group of AML with trisomy 8.

AML subtypes characterized by molecular mutations

As 40–45% of AML cases show no chromosomal rearrangements in chromosome banding analysis, molecular studies are necessary to identify the underlying genetic defects. Several mutations have been found, the most frequent being length and point mutations within the *FLT3* gene and partial tandem duplications within the *MLL* gene (*MLL*-PTD).

In a cohort of 1992 unselected newly diagnosed AML cases, 125 (6.3%) had an *MLL*-PTD.³³ This mutation occurs mainly in cytogenetically normal AML, and like *MLL*-translocations (tMLL) is characterized by an unfavorable prognosis. Similar to translocations of 11q23 involving the *MLL* gene, *MLL*-PTD occur significantly more frequently in AML secondary to a previous cytotoxic therapy. Schnittger et al³³ asked whether it is possible to discriminate *MLL*-PTD cases from AML cases with normal karyotype without this aberration as well as from AML with tMLL based on different gene expression patterns using U133A microarrays (Affymetrix). By pairwise comparison, it was not possible to define a specific expression profile discriminating *MLL*-PTD-positive from negative cases. However, a specific expression profile was found for the various *MLL* translocations compared with the *MLL*-PTD group and normal karyotype group. Many of the discriminating genes encode for DNA-binding proteins involved in transcriptional regulation and developmental processes.

Class discovery in AML

A main focus in gene expression profiling studies of leukemias will be to refine the subcategorization in subgroups with so-far identical patterns of diagnostic results but different clinical outcomes. This is urgently needed, especially in the two major groups of AML, i.e. AMC with normal karyotype (45% of patients) and AML with complex aberrant karyotype (15% of patients).

Qian et al³⁴ were able to identify distinct subtypes of therapy-related AML (t-AML) when analyzing CD34⁺ hematopoietic progenitor cells from 14 patients using U95A microarrays (Affymetrix). Gene expression patterns typical of arrested differentiation in early progenitor cells were commonly detected in all cases. Furthermore, two specific characteristics could be found. Cases with a $-5/\text{del}(5q)$ had higher expression levels of genes involved in cell cycle control, check-points, or growth and a loss of expression of the gene encoding interferon consensus sequence-binding protein. Another subgroup was characterized by downregulation of transcription factors involved in early hematopoiesis and overexpression of proteins involved in signal transduction (e.g. *FLT3*) and cell survival (e.g. *BCL2*). Targeting these different pathways may lead to more specific treatment approaches in this very poor-prognosis group of AML.

Estimation of prognosis in AML

Yagi et al³⁵ analyzed 54 pediatric AML cases using Affymetrix U95A arrays and focused on the reproducibility of some FAB subtypes and especially on gene patterns to predict outcome. After unsupervised clustering, they were able to differentiate patients with t(8; 21) from those with inv(16) as well as from those demonstrating an AML M4/5 or AML M7 phenotype or immunophenotype by specific gene expression signatures. Within this unsupervised analysis, no specific profile was found that correlated with the prognosis of the patients. For further calculations, data were analyzed supervised with respect to outcome and prognosis. A subset of 35 genes was selected that was independent of the morphology or karyotype of the patients; some of these genes are associated with cell cycle regulation or apoptosis. By hierarchical cluster analysis, patients could be classified into high-risk and low-risk groups with respect to event-free survival ($p < 0.001$).

Myelodysplastic syndromes

Biologically, MDS is linked very closely to AML. Therefore, specific gene expression patterns discriminating MDS from AML and identifying cases with a high likelihood of progression to AML are of great interest. However, only a limited number of studies have focused on this topic.^{36,37}

Acute lymphoblastic leukemia (ALL)

As demonstrated by Golub et al,¹⁹ ALL can be distinguished from AML based on the expression status of a small number of genes. In addition, Moos et al²⁶ could discriminate in 51 childhood leukemias between AML and ALL as well as between B- and T-lineage ALL using cDNA arrays with 4608 genes. Furthermore, they identified cases with low- and high-risk ALL, respectively, and predicted patients having a *TEL-RUNX1 (AML1)* fusion transcript.

Armstrong et al²³ were the first to demonstrate that childhood ALL with chromosomal aberrations involving the *MLL* gene can be regarded as a molecularly defined entity distinct from other ALL (U95A, Affymetrix). *MLL*-positive ALL had a distinct gene expression profile consistent with an early hematopoietic progenitor expressing multilineage markers and specific *HOX* genes. Also comparison of these ALL cases with *MLL* aberrations with other ALL cases as well as with AML samples resulted in a clear separation between all three groups.

A milestone in microarray analysis with respect to class discovery, class prediction, and prediction of

outcome was the report by Yeoh et al²⁴ on 327 child-hood ALL cases analyzed by Affymetrix U95A arrays. Patients were discriminated according to their cytogenetic and immunological as well as their molecular subtype of ALL, i.e. T-ALL, *E2A-PBX1*, *BCR-ABL*, *TEL-RUNX1*, and *MLL* gene rearrangements, and hyperdiploid ALL. Yeoh et al²⁴ not only could predict the therapeutic outcome in most children with ALL, but also found specific genes in the ALL blasts at diagnosis that indicate an increased risk of developing therapy-induced AML after successful treatment of ALL.

Prediction of response in ALL

Hofmann et al³⁸ analyzed 25 bone marrow samples from 19 patients with Philadelphia(Ph)-positive ALL all treated with the BCR-ABL tyrosine kinase inhibitor imatinib using HuGeneFL arrays (Affymetrix). Patients were selected according to their cytogenetic response to the drug, and 95 genes were identified to predict the treatment outcome in all cases. Another 56 genes were found to predict leukemia cells that had secondary resistance to the drug after remission had been achieved. Resistant cells expressed ATP synthetases such as ATP5A1 and ATP5C1 and had a significantly reduced expression of the pro-apoptotic gene *BAK1* and the cell cycle control gene *p15^{INK4B}*.

Cheok et al³⁹ elucidated the genomics of cellular responses to treatment with methotrexate and mercaptopurine given alone or in combination before and after in vivo treatment in 60 childhood ALL cases (U95A, Affymetrix). A total of 124 differentially expressed genes were identified capable of accurately discriminating the four possible treatment groups. Genes included those involved in apoptosis, mismatch repair, cell cycle control, and stress response. These data indicate that leukemia cells in different patients react in a similar manner after specific treatments and therefore share common pathways of genomic responses to different drug schedules. This may also open the way to future trials to predict outcome of treatment protocols by gene expression profiling at diagnosis.

Ross et al⁴⁰ rehybridized 132 childhood ALL probes from their previous cohort to the Affymetrix U133 set and identified almost 60% of new discriminating genes in comparison with their previous analysis with U95A.²⁴ As a proportion of these new genes were highly ranked as class discriminators and led to an overall diagnostic accuracy of 97% in several analyses, the authors suggested that these gene expression profiles be assessed in a prospective clinical trial. The main clinical focus should be at diagnosis of ALL with respect to accuracy, practicality, and costeffectiveness in comparison with standard diagnostic techniques.

Summary of gene expression profiling of acute leukemias

An overview of important publications with respect to AML and ALL is given in Table 20.1.

Chronic myeloid leukemia (CML)

Class discovery

Ohmine et al⁴¹ used DNA microarrays (HO-1-3, Mergen, San Leandro, CA, USA) and analyzed the expression profiles of 3456 genes in purified AC133+ hematopoietic stem cells in 13 CML patients and healthy volunteers. They were able to find the potential inhibitor of STAT proteins, *PIASy*, to be downregulated in association with stage progression of CML. Accordingly, the forced expression of *PIASy* induced apoptosis in a CML cell line. The authors conclude that microarray analysis may help to identify molecular events that underlie stage progression in CML.

Prediction of response

Cohen et al⁴² analyzed 94 patients with CML treated with interferon and in some cases with bone marrow transplantation. All were proven Philadelphia-positive, at least by FISH. Thirty-four patients were studied at diagnosis, 60 at different time points during therapy. In 14 of 96 patients major deletion of the region proximal to the rearranged *ABL* gene on 9q was found. These patients had a significantly shorter chronic phase of the disease as compared with the non-deletion 9q patients ($p=0.0144$). Using Human 1.2 Atlas Arrays (Clontech, Palo Alto, CA, USA), a number of genes were found to be differentially expressed between these two groups of patients. These genes were involved especially in cell adhesion and migration. The authors concluded that this finding may help to identify a subgroup of CML patients with a relatively poor prognosis and may lead to the adaptation of treatment strategies.

Chronic lymphocytic leukemia (CLL)

Class prediction

Aalto et al⁴³ analyzed 34 patients with CLL using Clontech microarrays and found significant expression differences in 78 genes compared with the reference, tonsillar B lymphocytes. Within these genes, a cluster of genes was associated ($p<0.05$) with 11q23 deletions detected by FISH and also with unfavorable Binet stages B or C. As most of these genes had not been discussed with respect to progression in CLL, the authors concluded that gene expression profiling

Table 20.1 Summary of studies approaching the diagnosis and classification of acute leukemias based on gene expression profiling.

in CLL may provide important information about leukemogenesis and may help not only to define risk groups but also to design treatments aimed at specific molecular targets.

In their important analysis, Rosenwald et al⁴⁴ used the lymphochip, investigating 17 856 genes in 33 CLL patients, and were able to define a specific pattern of expression profile in all CLL. This was irrespective of rearranged immunoglobulins (Ig) being present or not in these patients. Nonetheless, the expression of hundreds of other genes correlated clearly with Ig mutational status. This latter group included many genes the expression of which is

modulated during mitogenic B-cell receptor signaling. Genes identified were used to build a CLL subtype predictor that may help in the clinical subclassification of patients with CLL.

Another marker recently correlated with CLL prognosis is CD38 expression as measured by flow cytometry. CD38⁺ patients with B-CLL are characterized by advanced stage, an inferior responsiveness to chemotherapy, and a shorter survival. Dürig et al⁴⁵ used Hugen FL arrays with 5600 genes and analyzed 25 CD38⁺ CLL versus 45 CD38⁻ patients. In concordance with others, they showed that B-CLL display a common gene expression profile that is, however, largely independent of CD38 positivity. Nonetheless, 14 genes differed significantly between the two groups, including genes involved in the regulation of cell survival. Using an unsupervised hierarchical cluster analysis in 76 CLL samples, two major subgroups of patients were identified comprising 20 versus 50 patients. Patients in the smaller group were characterized by a coordinate high expression of a large number of ribosomal and other translocation-associated genes and had a better clinical outcome. Thus, CD38 status may be measured by microarray platforms in comparison with flow cytometry or immunohistology, and gene expression profiling may also define different prognostic subgroups in CLL.

Wiestner et al⁴⁶ focused on *ZAP70* in 107 CLL patients using the lymphochip with 13 868 human cDNAs. The mRNA expression of *ZAP70* was found to be an excellent surrogate marker for the distinction between Ig mutated and non-mutated CLL subtypes and was also able to identify patients with a divergent clinical course. In 93% of cases, *ZAP70* expression correlated correctly with Ig mutation subtype. In comparison with all the other genes investigated, *ZAP70* was the best to predict outcome in CLL: high expression levels identified a group of CLL patients with a progressive form of the disease, with a median time to treatment following diagnosis of 6.4 years in comparison with the other group, with an interval of more than 10 years.

Jelinek et al⁴⁷ used U95A arrays (Affymetrix) to analyze 38 cases of B-CLL in comparison with 10 age-matched healthy controls. They identified 70 genes that discriminate leukemic cells from normal B cells. These genes were able to create a diagnostic signature tested in an independent cohort of 21 B-CLL and 20 normal subjects, leading to a perfect specificity and sensitivity of class prediction. Furthermore, a group of 31 genes was identified to distinguish between

Table 20.2 Summary of studies approaching diagnosis, prognosis and classification of chronic leukemias based on gene expression profiling

Standard method	Results	Ref	Study population	Technology
Immunophenotyping	Global gene expression signature in CLL	47	Adult CLL (n=35)	Affymetrix U95A
	Homogeneous phenotype In CLL versus memory B cells	49	Adult CLL (n=34)	Affymetrix U95A
Cytogenetics	CML with additional deletion of 9q	42	Adult CML (n=14/94)	Clontech
	Distinct expression profile in CLL with del(11)q23, or with Binet stages B and C	43	Adult CLL (n=34); 9 with 11 q23	Clontech
Molecular genetics	<i>ZAP70</i> demonstrates distinct gene expression profile in CLL	46	Adult CLL (n=107)	Lymphochip
	Gene expression and immunoglobulin mutation genotype in CLL	44	Adult CLL (n=33)	Lymphochip
Response to therapy; prognostic marker	Prognostic markers in CLL involved in lymphocyte trafficking	48	Adult CLL (n=54)	Incyte Pharmaceuticals

patients with Rai stage 0 and Rai stage 4, suggesting that the gene expression pattern may be associated with disease progression.

Class discovery

Stratowa et al⁴⁸ analyzed 54 peripheral blood samples from B-CLL patients using the Clontech arrays with 1024 selected genes. Several genes were identified as correlating significantly with patient survival and/or with the clinical stage of the disease. Most of these genes coded either for cell adhesion molecules such as L-selectin and β_2 integrin or for factors that induce cell adhesion molecules. The authors therefore concluded that prognosis of CLL may also be related to a defect in lymphocyte trafficking.

Klein et al⁴⁹ analyzed 34 peripheral blood samples from CLL patients and enriched CLL cells by MACS (Miltenyi). Sequences of IgV_H status were known in all patients. Using Affymetrix U95A microarrays, they compared leukemia cells with CD19⁺ enriched cord blood cells and found that CLL display a common and characteristic gene expression profile that is largely independent of their IgV_H genotype. However, on the basis of a restricted number of less than 30 differentially expressed genes, they were able to predict IgV mutated and non-mutated samples. Further genes were identified in comparison with purified normal B cells that indicate that CLL profiles are more closely related to memory B cells than to those derived from naive B cells or CD5⁺ B cells, as well as from germinal center centroblasts or centrocytes.

Summary of gene expression profiling of chronic leukemias

A short overview of important publications with respect to CML and CLL is given in Table 20.2.

Conclusions

Microarray technology provides a means for comprehensive and simultaneous analysis of the expression status of thousands of genes. The resulting signature allows the identification of a distinct molecular leukemic genotype. It is anticipated that the application of microarrays will significantly improve molecular diagnostics in leukemia,⁵⁰ and will provide deep insights into the pathogenetic alterations of malignant and non-malignant haematopoietic cells, which will allow the discovery of new entities, new prognostic markers, and markers for follow-up monitoring of minimal residual disease. Furthermore, it is expected that the results of microarray experiments will allow the identification of disease-specific target structures and the design of novel and specific drugs. Several studies have already shown that a variety of different diagnostic and prognostic questions can already be answered by gene expression profiling (Tables 20.1 and 20.2). Gene expression analyses are limited, however, to the RNA level and thus cannot be used to analyze alterations at the protein level, for example the phosphorylation and dephosphorylation of proteins. These aspects will be covered by other novel techniques such as proteomics.

Detection of minimal residual disease in lymphoid malignancies

JJM van Dongen, T Szczepański, VHJ van der Velden, and AW Langerak

Introduction

Lymphoid malignancies

Lymphoid malignancies are categorized into four main groups: acute lymphoblastic leukemias (ALL), chronic lymphocytic leukemias (CLL), non-Hodgkin lymphomas (NHL), and multiple myelomas (MM). Together they represent about 76% of all hematopoietic malignancies and affect about 75 000 patients per year in the European Union (with some 375 million inhabitants). Figure 21.1 shows the age-related incidence of the four categories of lymphoid malignancies in the Netherlands.¹ Although the incidence of most malignancies increases with age, the highest incidence of ALL is seen in early childhood. This is in contrast to CLL and MM, which do not occur in children, are rare in young adults, but have progressively increasing incidence rates from the age of 50–60 years onwards. NHL represent the largest category (about 60%) of lymphoid malignancies and are found at all

Figure 21.1 Age-related incidence of the four types of lymphoid malignancies in the Netherlands in 1989–1991: acute lymphoblastic leukemia (ALL), chronic lymphocytic leukemia (CLL), non-Hodgkin lymphoma (NHL), and multiple myeloma (MM). Data are derived from The Netherlands Cancer Registry.¹

ages, with increasing incidence in older age groups (Figure 21.1).¹

ALL are generally regarded as malignant counterparts of immature lymphoid cells, such as precursor B cells in the bone marrow (BM) and immature T cells in the cortical thymus.^{2–4} The maturation arrest of CLL generally occurs in more mature differentiation stages. Most cells in NHL are also arrested in more mature differentiation stages, whereas MM are regarded as malignant counterparts of plasma cells.^{2–4} However, it should be noted that malignant transformation probably occurs in earlier differentiation stages and that the offspring of the malignant clonogenic cells can further mature to form the dominant malignant cell population. This implies that reliable techniques for detection of malignant cells should also be able to detect malignant precursor cells.

Cytomorphological and histomorphological techniques generally form the basis for diagnosis and classification of lymphoid malignancies.⁵ However, additional diagnostic techniques are frequently needed for reliable and reproducible diagnosis and classification. This includes immunophenotyping, analysis of immunoglobulin (Ig) and T-cell receptor (TCR) genes, and detection of chromosome aberrations with molecular techniques or via classical cytogenetics.^{2–8}

Immunophenotyping appears to be useful for diagnosis and detailed classification of lymphoid malignancies as well as for detection of immunophenotypic aberrances and the recognition of subpopulations in the malignancy. Most lymphoid malignancies (93–95%) appear to belong to the B-cell lineage (Table 21.1).^{2–4}

Virtually all lymphoid malignancies (>98%) have rearranged Ig and/or TCR genes. This is probably related to the fact that Ig and TCR gene rearrangements start early during lymphoid differentiation.

Table 21.1 B-lineage and T-lineage origin of lymphoid malignancies

	ALL		CLL	NHL	MM
	Childhood	Adult			
B-lineage	80–85%	75–80%	95% (B-CLL, B-PLL, HCL)	90–95%	100%
T-lineage	15–20%	20–25%	5% (LGL, T-PLL, CTLL, ATLL ^a)	5–10%	0%

ALL, acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia; PLL, prolymphocytic leukemia; HCL, hairy cell leukemia; LGL, large granular lymphocyte leukemia; CTLL, cutaneous T-cell leukemia/ lymphoma; ATLL, adult T-cell leukemia/lymphoma; NHL, non-Hodgkin lymphoma; MM, multiple myeloma.

^a In Japan and Caribbean regions, ATLL occurs in essentially higher frequencies than in Europe and other Western countries.

Lymphoid malignancies are regarded as being derived from a single malignantly transformed cell, i.e. they are clonal diseases. Therefore, cells of a lymphoid malignancy in principle have identically rearranged Ig and TCR genes. This feature can be used as unique marker for identification of malignant (clonal) lymphoid cells between normal reactive (polyclonal) lymphoid cells.^{6,7}

Chromosome aberrations are found in 25–40% of lymphoid malignancies, depending on the type of malignancy and on the applied technique, such as classical cytogenetics, fluorescence in situ hybridization (FISH), Southern blotting, or polymerase chain reaction (PCR).^{8,8a,9} Chromosome aberrations are important genetic markers for classification of lymphoid malignancies, because they are directly related to the malignant transformation process.

Detection of minimal residual disease

Current cytotoxic treatment protocols induce complete remission in most ALL patients, in some patients with CLL, in most NHL patients, and in a proportion of patients with MM.^{10–12} The introduction of allogeneic and autologous stem cell transplantation (SCT) in treatment protocols has further increased the remission rates in ALL, NHL, and MM.^{10–12} Nevertheless, many of these patients ultimately relapse. Apparently, the treatment protocols are not capable of killing all clonogenic malignant cells in these patients, even though they reached complete remission according to cytomorphological criteria. The detection limit of cytomorphological techniques is not lower than 1–5% of malignant cells, implying that these techniques can provide only superficial information about the effectiveness of the treatment. More sensitive techniques are needed for detection of lower frequencies of malignant cells during and after treatment, i.e. detection of minimal residual disease (MRD).¹³ MRD techniques should reach sensitivities of at least 10^{-3} (one malignant cell within thousand normal cells), but sensitivities of 10^{-4} to 10^{-6} are preferred. Such sensitivities allow 'true' MRD detection and thereby evaluation of the effectiveness of the total treatment and assessment of the contribution of each treatment phase (Figure 21.2).^{13–15}

The application of MRD techniques is especially valuable in malignancies that potentially can be cured by use of cytotoxic therapy and/or SCT. This concerns ALL, several types of NHL, and possibly also MM. In these disease categories, MRD information either is already used or might be employed in the near future for adaptation of treatment.

During the last 20 years, several methods for MRD detection have been developed and evaluated. Most of these techniques appeared to have a limited sensitivity and/or applicability:

Figure 21.2 Diagram of the putative relative frequencies of leukemic cells in peripheral blood or bone marrow of acute leukemia patients during and after chemotherapy and during development of relapse. The detection limit of cytomorphological techniques as well as the detection range of immunophenotyping and PCR techniques are indicated. I, induction treatment; C, consolidation treatment; II, re-induction treatment.

- *Cytogenetics*: sensitivity of 10^{-2} . Applicability is limited to microscopically detectable chromosome aberrations and is dependent on the possibility to obtain cells in metaphase.
- *Cell culture systems*: sensitivity is variable, and standardized application on a routine basis is difficult.¹⁶
- *FISH techniques*: sensitivity of 10^{-2} to 10^{-3} . Application is restricted to malignancies with a well-defined chromosome aberration for which suitable DNA probes are available.^{17,18} The sensitivity of interphase FISH for translocations, inversions, and deletions is limited to 1–5%. The limited sensitivity of the classical fusion signal FISH is caused by artefactual colocalization of two independent (unlinked) breakpoint probe signals in normal cells, which might cause false positivity.¹⁸ The sensitivity can be slightly increased by the application of metaphase FISH, which does not cause false-positive results but like conventional cytogenetics is dependent on the availability of cells in metaphase.¹⁹ A better possibility to increase the sensitivity of FISH techniques is the the two differently labeled FISH probes are positioned at opposite sides of the breakpoint area, but application of ‘split-signal’ FISH, implying that sufficiently close to give a fusion signal in normal cells, whereas the signal is split in the case of a chromosome aberration.^{20,21,21a} In principle, the split signal FISH will not result in false-positive results and thus has an essentially higher sensitivity (10^{-2} to 10^{-3}) than the fusion-signal FISH.
- *Southern blotting*: sensitivity of only 10^{-1} to 10^{-2} , but application in virtually all lymphoid malignancies with rearranged Ig or TCR genes as well as in malignancies with well-defined chromosome aberrations for which suitable DNA probes are available.²²

So far only two techniques are sufficiently sensitive, specific, and have a relatively broad applicability: immunophenotyping techniques and PCR techniques (Figure 21.2). The application of immunophenotyping techniques is based on the occurrence of aberrant or unusual immunophenotypes, whereas PCR techniques can be used for the detection of tumor-specific sequences, such as junctional regions of rearranged Ig and TCR genes or breakpoint fusion regions of chromosome aberrations.^{14,15} Immunophenotyping and PCR techniques can reach sensitivities of 10^{-3} to 10^{-6} , depending on the immunophenotype and genotype of the lymphoid malignancy. In ALL and MM, both immunophenotyping and PCR techniques can be used for MRD detection. However in CLL and NHL, immunophenotyping techniques are generally not sufficiently sensitive to reach levels of 10^{-3} . Nevertheless, PCR analysis of Ig and TCR genes can be applied for MRD detection in the majority of these disease categories.

In this chapter, we shall discuss the technical aspects of immunophenotyping and PCR analysis for MRD detection. Subsequently, we shall summarize the clinical applications of these MRD techniques and discuss their clinical relevance in the four categories of lymphoid malignancies.

MRD detection by immunophenotyping

Aberrant immunophenotypes as targets for MRD detection

The resemblance of malignant lymphoid cells to cells of normal hematopoietic differentiation stages implies that the detectability of malignant cells is hampered by the presence of normal lymphoid cells within the cell sample.^{14,15,23–26} Despite this inherent limitation on the detection of malignant cells, MRD detection is still possible because lymphoid malignancies might display unusual or aberrant antigen expression (Figure 21.3) or clonal patterns of Ig or TCR chain expression.^{27–29}

Unusual or aberrant immunophenotypes are the result of cross-lineage antigen expression, asynchronous expression of antigens, antigen overexpression, absence of antigen expression, and/or ectopic antigen

Figure 21.3 Examples of uncommon and ectopic antigen expression in acute lymphoblastic leukemia (ALL), (a) Weak CD13 expression on $CD10^+$ precursor B-ALL cells, (b) Cross-lineage expression of CD66c (KOR-SA3544) antigen on $CD19^+$ precursor B-ALL cells, (c) Combined expression of the CD5 antigen and TdT constitutes a typical characteristic of T-ALL and is normally only found in cortical thymocytes but not in extrathymic locations such as bone marrow or peripheral blood.

expression.^{14,15,25} The latter refers to the expression of particular antigens on cells outside their normal breeding sites or homing areas or to the expression of antigens that are normally only expressed on nonhematopoietic cells. Cross-lineage antigen expression represents the expression of typical B-lineage anti-gens on T-lineage cells or vice versa, or even of myeloid or other non-lymphoid antigens on cells of either B or T lineages.^{14,15} Asynchronous antigen expression refers to the simultaneous expression of antigens that are normally not expressed during the same maturational stage.^{14,15}

Clonal Ig molecules can be found in most chronic B-cell leukemias, B-cell NHL (B-NHL), and MM; they are detectable as single Ig light-chain expression, i.e. Igκ or Igλ.^{27,28} In chronic T-cell leukemias and in TNHL, expression of most clonal TCRαβ molecules is detectable with antibodies against the variable (V) domains of TCRβ chains; virtually no antibodies against variable domains of TCRα chains are available.^{29–31} Antibodies against the various V domains of TCRγ and TCRδ chains might contribute to clonality assessment of suspect TCRγδ⁺ T-cell proliferations.³²

Previously, immunophenotyping of hematopoietic malignancies was performed with fluorescence microscopy using single- and double-immunofluorescence (IF) stainings.²⁷ However, flow cytometry is superior in analyzing unusual and aberrant antigen expression, because it enables routinely multiparameter analysis with two scatter parameters and at least four fluorochrome (antigen) parameters.³³ This multiparameter analysis can involve both surface membrane and intracellular antigens.³⁴

Precursor B-cell ALL

Several categories of aberrant antigen expression in precursor B-cell ALL (precursor B-ALL) might be used for MRD detection in multiparameter flow cytometry (Table 21.2 and Figure 21.3). This concerns cross-lineage expression of T-lineage antigens (e.g. CD5 and CD7) or myeloid antigens (CD13, CD15, CD33, and CD66c), asynchronous expression of antigens (e.g. CD20 on CD45⁻ cells), lack of CD45 expression (particularly the isoform CD45RA), and antigen overexpression (e.g. CD10 overexpression).^{23–26,35–39,39a,39b} The finding of NG2 expression on the surface membrane of precursor B-ALL carrying the t(4;11) or t(11;19) represents an example of a true ectopic antigen expression.^{40,41} The studies with cDNA microarrays, analyzing expression levels of thousands of genes, might further aid the discovery of new leukemia-specific markers.⁴² Flow-cytometric investigations based on double/triple antigen stainings showed the presence of leukemia-associated phenotypes in 60–95% of precursor B-ALL patients.^{38,43–45} Investigation of normal BM precursor B cells has enabled the establishment of multiparameter templates for normal B-cell development, whereas malignant precursor B lymphoblasts frequently display aberrant immunophenotypic features and thereby fall into so-called ‘empty spaces’ outside the normal B-lineage pathways.^{46–48} Preliminary data indicate that the ‘empty spaces’ approach with triple or preferably quadruple antigen stainings identifies leukemia-associated immunophenotypes in virtually all patients.^{47,49} The availability of specific antibodies to fusion proteins or ectopic antigens that are observed in precursor B-ALL with translocations, such as t(1;19) or t(12;21), might further facilitate the specific detection of malignant cells.⁵⁰

It should be emphasized that combinations of typical B-cell precursor markers, such as CD10 antigen and terminal deoxynucleotidyl transferase (TdT), are not suitable for MRD detection in precursor B-ALL. This is owing to the background of normal TdT⁺ precursor B cells in BM (generally <10% of mononuclear cells) and peripheral blood (PB) (generally <0.4%).^{23,51,52} Moreover, the levels of TdT⁺ (and TdT⁻) precursor B cells can be as high as 50% in regenerating BM after chemotherapy or after SCT.^{23,53} Substantial expansions of normal precursor B cells in regenerating BM take place not only after maintenance therapy, but also during treatment.^{54,55} At the end of short intervals after intensive induction and consolidation blocks, regeneration of B-cell development occurs in BM with large fractions of immature CD34⁺/TdT⁺ B cells. In contrast, in regenerating BM after cessation of maintenance treatment, the more mature TdT⁻/CD19⁺/CD10⁺ B cells are significantly increased, whereas the fraction of immature CD34⁺/TdT⁺ B cells is essentially smaller.^{54,55} The extent of B-lineage regeneration in BM also differs per treatment protocol and seems to be dependent on the intensity of the preceding treatment.⁵⁴ Interestingly, after maintenance treatment, a substantial proportion (10–30%) of PB B cells express CD10, indicating that CD10⁺ B cells are easily released from regenerating BM after cessation of therapy.⁵⁵ The discrimination between normal and malignant precursor B cells can only be made on the basis of atypical features such as CD10 overexpression on precursor B-ALL cells or molecular clonality analysis. On one hand, moderately increased frequencies of CD19⁺/CD10⁺/TdT⁺ BM cells should never directly be interpreted as relapse of ALL, particularly during the high-dose cytotoxic treatment phases. On the other hand, substantial increase in B-cell precursors after chemotherapy, particularly with a homogeneous immunophenotype, may herald a relapse of the disease.

T-cell ALL and T-lymphoblastic lymphoma

Nearly all T-cell ALL (T-ALL) express TdT as well as the pan-T-cell antigens CD2, cytoplasmic CD3 (CyCD3), CD5, and CD7. Additional T-cell antigens

ALL, acute lymphoblastic leukemia; LBL, lymphoblastic; NHL, non-Hodgkin lymphoma; MM, multiple myeloma; CLL, chronic lymphocytic leukemia.

such as CD1, surface membrane CD3, CD4, and/or CD8 are also often expressed. T-lymphoblastic lymphomas (T-LBL) are lymphomatous counterparts of T-ALL and they also express TdT in combination with one or more T-cell antigens. In healthy individuals, the combination of T-cell marker and TdT expression is found in the cortical thymus, but is absent or rare in extrathymic locations such as BM or PB (<0.3% and <0.02%, respectively). Moreover, if T-cell marker⁺TdT⁺ cells are found in BM or PB, they only express CD2 and/or CD7 and no other T-cell antigens such as CD3, CD4, or CD8. Early microscopic dilution experiments have demonstrated that the T-cell antigen/TdT double IF staining technique (Figure 21.4)

Figure 21.4 Double-IF staining for a T-cell antigen and TdT on peripheral blood (PB) mononuclear cells of a T-cell acute lymphoblastic leukemia (T-ALL) patient at 20 weeks after diagnosis, (a) Phase-contrast morphology, (b) T-cell antigen-positive cells. (c) TdT⁺ cell. One cell expresses both the T-cell antigen and TdT, and is probably a T-ALL cell, whereas the other T-cell antigen-positive cells probably represent normal PB T lymphocytes.

has a detection limit of 10^{-4} to 10^{-5} and that detection of such ectopic double-positive cells via this technique can be used for evaluating the effectiveness of the applied cytotoxic treatment.^{14,23} Currently, such analysis is routinely performed via flow-cytometric T-cell marker/TdT stainings, which allows MRD detection in 90% of T-ALL (Table 21.2 and Figure 21.3). Flow-cytometric analysis based on cross-lineage myeloid antigen expression, asynchronous antigen expression (e.g. CD34⁺/CD3⁺), and antigen overexpression (e.g. CD7⁺⁺), can also be used for MRD detection in T-ALL.^{56,57} Similarly to precursor B-ALL, multiparameter flow cytometry in T-ALL reveals ‘empty spaces’ outside the templates for normal T-cell development in BM and PB.⁵⁷ Together, the various leukemia-associated immunophenotypes can be employed for MRD detection in all T-ALL and TLBL.^{56,57} The presence of tumor-specific antigens resulting from chromosome aberrations may further increase the number of immunophenotypic MRD targets per T-ALL patient. One important candidate is the TAL1 protein, which is ectopically expressed in T-ALL with the *SIL-TAL1* fusion gene or *TAL1* gene translocations.^{58,59}

CLL and NHL

The relatively high frequencies of mature lymphoid cells in BM and PB hampers immunophenotypic MRD detection in patients with CLL of B or T lineage. In an analogous way, immunophenotypic MRD detection in B-cell or T-cell NHL (B-NHL or T-NHL) can also be hampered by the presence of mature lymphoid cells in lymph nodes and in potentially involved BM or PB compartments. Due to the normal background of lymphoid cells, low levels of MRD (< 10^{-3}) will only be detectable if antibodies against tumor-associated antigens are used, e.g. antibodies directed against fusion proteins derived from chromosome aberrations that are specific for a particular type of CLL or NHL or antibodies directed against particular antigens that are normally not expressed on normal counterparts of CLL and NHL.

Chronic B-cell leukemias and B-cell NHL

Single Ig light-chain (Ig κ or Ig λ) expression can be employed for the detection of Ig⁺ B-cell leukemias and Ig⁺ B-NHL, since normal and malignant B lymphocytes express only one type of Ig light chain.^{27,28} The distribution of Ig κ ⁺ versus Ig λ ⁺ cells (the Ig κ /Ig λ , ratio) can accurately be determined by analysis of Ig κ and Ig λ expression within the B-cell population in multicolor stainings, using CD19, CD20, and/or CD37 as pan-B-cell antigens. In normal B-cell populations, the Ig κ /Ig λ ratio ranges from 0.8 to 2.5. The size of the normal B-cell population in BM, PB, and lymph nodes obviously influences the detectability of leukemic B cells via analysis of the Ig κ /Ig λ ratio. Due to this

normal background, the detection limit of routinely performed Ig light-chain/B-cell marker stainings in BM and PB is only 10^{-1} to 10^{-2} (Table 21.2 and Figure 21.5).^{27,28}

The use of additional antigens in multicolor stainings may allow MRD detection with levels around 10^{-3}

Figure 21.5 Smlg κ /CD19 and Smlg λ /CD19 double-IF stainings on serial dilutions of Smlg λ ⁺ B-cell nonHodgkin lymphoma (B-NHL) cells in peripheral blood mononuclear cells of a healthy individual. The percentages of B-NHL cells that are present in each dilution step are indicated. The detection limit of Smlg/CD19 double-IF stainings is clearly influenced by the frequency of normal polyclonal B lymphocytes.

(Table 21.2). Such additional markers may involve antigens that are normally only expressed on a subpopulation of B cells. Examples include the CD103 antigen on hairy cell leukemia (HCL) and the CD5 antigen on B-CLL and mantle cell lymphoma (MCL) cells.^{60–62} Furthermore, protein products from particular chromosome aberrations may also be used as additional markers in IF stainings. Triple IF staining for BCL₂, a B-cell antigen and Ig light chain may be employed for MRD detection in patients with follicular lymphomas (FL), since BCL2 overexpression is observed in this type of B-NHL with t(14;18).⁶³ Similarly, the overexpression of cyclin D1 in MCL with t(11;14) or of MYC in Burkitt lymphomas with t(2;8), t(8;14), or t(8;22) may be employed for MRD detection of these types of B-NHL.⁶⁴

With the advent of multiparameter flow cytometry, particularly with quadruple stainings, it now seems to be possible to identify quantitative differences in the levels of antigen expression in B-CLL as compared with normal B cells. This approach, analogous to the detection of ‘empty spaces’ outside the normal B-lineage development in ALL, can potentially reach sensitivities of 10^{-4} .^{65,66} In a report by Rawstron et al,⁶⁵ the combination of CD19/CD5/CD20/CD79b antibodies was claimed to be informative for MRD detection in PB in all tested B-CLL patients. For MRD monitoring in BM, at least one of the combinations CD19/CD5/CD20/CD79b, CD19/CD5/CD38/CD79b, and CD19/CD5/CD38/CD20 was found to be sufficiently sensitive and specific.⁶⁵

Chronic T-cell leukemias and T-NHL

The relatively high frequencies of T lymphocytes and natural killer (NK) cells in normal BM and PB samples and lymph nodes have their impact on the immunophenotypic detectability of leukemic T cells and T-NHL cells. Even the expression of the less common CD3⁺CD4⁻CD8⁻, CD3⁺CD4⁺CD8⁺ or TCR $\gamma\delta$ ⁺ phenotypes as well as antigen loss (absence of particular T-cell antigens) will generally result in detection limits of only 10^{-1} to 10^{-2} .

The vast majority of chronic T-cell leukemias and T-NHL belong to the TCR $\alpha\beta$ lineage, whereas only a minor fraction express TCR $\gamma\delta$. During the last decade or so, a large series of antibodies against the protein products of V gene segments of most TCRBV gene families have been produced. Together, these V β antibodies recognize 60–70% of normal and malignant T cells with TCR β chain expression.^{29–31} Also, antibodies against most V γ and V δ domains of TCR $\gamma\delta$ molecules have become available. These V γ and V δ antibodies might be useful for the detection and monitoring of malignant (clonal) TCR $\gamma\delta$ ⁺ T cells,³² although the presence of normal TCR $\gamma\delta$ ⁺ T lymphocytes will interfere with these applications. This especially concerns V_{1B}/V₈ phenotypes, because

Figure 21.6 Double-IF staining for CD3 and $V_{\beta 7.1}$. In a healthy individual, only a minor subpopulation of $CD3^+$ T cells express $V_{\beta 7.1}$, whereas in a T-lineage large granular lymphocyte leukemia (T-LGL) patient at diagnosis (June 1992), virtually all $CD3^+$ T lymphocytes expressed $V_{\beta 7.1}$. This single V_{β} gene expression was in line with the clonally rearranged $TCRB$ genes. $V_{\beta 7.1}/CD3$ double-IF stainings during follow-up allowed rapid and precise monitoring of the $V_{\beta 7.1}^+$ T-LGL cells, which decreased to 43% and 23% of $CD3^+$ T lymphocytes during follow-up.

most normal $TCR\gamma\delta^+$ T lymphocytes have this TCR phenotype.⁶⁷ The application of V_{β} , V_{γ} , and V_{δ} antibodies in well-chosen multicolor stainings can result in sensitivity levels of approximately 10^{-2} (Table 21.2). Such sensitivities do not allow true MRD detection, but may enable monitoring of T-cell leukemia patients during treatment (Figure 21.6) or predicting the possible outgrowth of a dominant subclone in the case of oligoclonal T-cell proliferations.

Detection of lower MRD levels (of about 10^{-3}) in chronic T-cell leukemia or T-NHL is only possible upon analysis of tumor-associated antigens or translocation-specific fusion gene proteins. The availability of antibodies against the $NPM-ALK$ fusion gene protein that is produced in anaplastic large cell lymphomas with t(2;5) can become important in this respect.⁶⁸

MM

Immunophenotypic MRD detection in MM patients suffers from the presence of normal plasma cells in BM. Analogously to normal B cells, the distribution of $Ig\kappa^+$ and $Ig\lambda^+$ producing cells ($Ig\kappa/Ig\lambda$, ratio) can be

Figure 21.7 Double-IF staining for the plasma cell antigen CD138 (B-B4) in combination with Cylgk (a) and CD138 in combination with Cylg λ , (b) on bone marrow cells from a multiple myeloma patient.

determined within the plasma cell population via immunological marker analysis. Flow-cytometric detection of cytoplasmic single Ig light-chain production in combination with the plasma cell antigen CD138 may enable detection of MM cells, resulting in detection limits of 10^{-1} to 10^{-2} (Figure 21.7). Recent studies applying multiparameter flow cytometry have characterized phenotypic differences between normal and malignant plasma cells. While normal plasma cells are usually $CD38^{+++}$, $CD56^-$, $CD45^+$, $CD20^-$, $CD28^-$, $CD33^-$, and $CD117^-$, their malignant counterparts typically show aberrant expression patterns of one or more of these antigens. Quadruple flow-cytometric stainings are now claimed to reach sensitivities of 10^{-4} .⁶⁹

MRD detection by PCR analysis of rearranged Ig and TCR genes

Rearrangement of Ig and TCR genes and formation of antigen receptor diversity

The variable domains of the Ig and TCR molecules are involved in antigen recognition and constitute the enormous antigen-specific receptor diversity of the immune system. Each variable domain is encoded by two or more gene segments, which were joined to each other via gene rearrangement processes during early lymphoid differentiation. The variable domains of IgH, TCR β , and TCR δ chains are encoded by combinations of variable (V), diversity (D), and joining (J) gene segments, whereas variable domains of Ig κ , Ig λ , TCR α , and TCR γ chains are encoded by V and J gene segments. Based on the homology of their sequences, the V , D , and J gene segments are grouped in families. The rearrangement processes generally start with D to- J joining, followed by V -to- DJ joining, as illustrated in Figure 21.8 for an Ig heavy-chain (IGH) gene rearrangement.²²

Figure 21.8 Schematic diagram of human *IGH* gene rearrangement. In this example, D_{H3} is first joined to J_{H4} , followed by V_{H4} -to- D_{H3} - J_{H4} joining; as a result of the gene segment couplings, all intervening DNA sequences are deleted. The rearranged gene complex can be transcribed into precursor mRNA, which is further processed into mature mRNA by splicing out all noncoding intervening sequences.

Due to the multiple *V*, *D*, and *J* gene segments per Ig and TCR gene locus, many different $V(D)J$ combinations can be made via the rearrangement process (Table 21.3). The $V(D)J$ combinations and the combination of two protein chains with different variable domains per antigen receptor molecule (IgH and Igκ or Igλ, TCRα and TCRβ, TCRγ and TCRδ) determines the so-called combinatorial repertoire (Table 21.3). The combinatorial repertoire for Ig molecules and TCRαβ molecules (encoded by *TCRA* and *TCRB* genes) is at least 2×10^6 . For TCRγδ molecules, the combinatorial repertoire is smaller (about 5000) due to the limited number of *V*, (*D*), and *J* gene segments in the TCRγ- and TCRδ-encoding genes, i.e. *TCRG* and *TCRD*, respectively (Table 21.3).²²

The repertoire of Ig and TCR molecules is further extended by so-called junctional diversity, which is based on deletion of germline nucleotides by trimming the ends of the rearranging gene segments and by random insertion of nucleotides between the joined gene segments.^{70,71} The insertion of nucleotides at the junction sites is mediated by the nuclear enzyme TdT, which adds nucleotides to 3' ends of DNA breakpoints without the need for a template. The junctional diversity varies per Ig and TCR gene, depending on the number of junction sites per junctional region (*VJ*, or *VDJ*, or *VDDJ*, etc.) and upon the activity of TdT during the rearrangement process. For instance, junctional regions of *IGH* gene rearrangements are generally extensive (Figure 21.9) as compared with the relatively small junctional regions of the Igκ- and Igλ-encoding genes, i.e. *IGK* and *IGL*, respectively (Table 21.3).⁷²

Secondary rearrangements in Ig and TCR genes

Secondary rearrangements can replace or adapt preexisting rearrangements, depending on the involved Ig or TCR gene and the type of pre-existing rearrangement. *DJ* replacements concern the deletion of preexisting *DJ* complexes by the joining of an upstream *D* gene segment to a downstream *J* gene segment. In a comparable way, *VJ* replacements can delete a pre-

Table 21.3 Estimation of potential primary repertoire of human Ig and TCR molecules^a

	Ig molecules			TCRαβ molecules		TCRγδ molecules	
	IgH	Igκ	Igλ	TCRα	TCRβ	TCRγ	TCRδ

^a Numbers are based on the IMGT (ImMunoGeneTics) database.^{300,300a}

^b In *TCRD* gene rearrangements, multiple D segments might be used; this implies that the number of junctions can vary from one to four. In *IGH* and *TCRB* gene rearrangements, generally only one *D* gene segment is used.

Figure 21.9 Schematic diagram of a V_H gene segment joined to one of the J_H gene segments via a Junctional region. *IGH* Junctional regions may contain one, or rarely two, D_H gene segments. The presented *IGH* Junctional region sequences are derived from precursor B-cell acute lymphoblastic leukemia (precursor B-ALL) patients and illustrate the deletion of nucleotides from the germline sequences as well as the size and composition of the Junctional regions. D_H gene segments and inserted nucleotides are indicated by capital letters and small capital letters, respectively.

existing VJ complex in the *IGK*, *IGL*, *TCRA*, and *TCRG* genes (Table 21.4).^{73,74}

Another type of secondary rearrangements concerns V replacement in complete $V(D)J$ complexes. The V gene segment of the $V(D)J$ complex is replaced by a new upstream V gene segment. This process is mediated via a recombination signal sequence in the downstream part of the V gene segments of the *IGH*, *TCRB*, and *TCRG* genes.⁷⁵ Such signal sequences are not found within the V gene segments of the *IGK*, *IGL*, *TCRA*, and *TCRD* genes (Table 21.4).

Secondary rearrangements occur in immature B and T cells and have been found to replace pre-existing nonproductive (out-of-frame) rearrangements as well as productive (in-frame) rearrangements. Therefore, it is assumed that secondary rearrangements are not only involved in rescuing precursor B cells and T cells from non-productive rearrangements, but are also involved in receptor editing during selection processes of immature B cells in the BM and immature T cells in the thymus.⁷⁶ This implies that such secondary rearrangements can also occur in the malignant counterparts of immature lymphoid cells, i.e. precursor B-ALL and T-ALL.^{76–85}

Somatic mutations in Ig genes

The repertoire of Ig molecules can be further increased and adapted via antigen-induced somatic mutations in the $V(D)J$ exon of rearranged Ig genes.⁸⁶ These point mutations occur in follicular center B lymphocytes and are not found in virgin B lymphocytes. They are assumed to serve affinity maturation and clonal selection, and precede or coincide with IgH class switching.

Consequently, also malignant counterparts of follicular center B lymphocytes and ‘post-follicular’ B-cell malignancies have somatically mutated *IGH*, *IGK*, and *IGL* genes.⁸⁷ In particular, B-cell malignancies with Ig molecules of non-IgM class (IgG, Ig λ , etc.) show mutated Ig genes. In follicular B-cell lymphomas, the somatic mutation process can still be active, resulting in the formation of subclones with different specificities of the Ig molecules.⁸⁸ However, in post-follicular B-cell malignancies (e.g. MM), the somatically mutated *IGH*, *IGK*, and *IGL* genes remain stable.⁸⁹

Junctional regions as PCR targets for MRD detection

The Junctional regions of rearranged Ig and TCR genes are unique ‘fingerprint-like’ sequences, which are assumed to be different in each lymphoid cell and thus also in each lymphoid malignancy.^{14,22} Therefore, Junctional regions can be used as tumor-specific targets for MRD-PCR analysis (Table 21.2).^{90–93} The PCR primers for amplification of Junctional regions are designed at opposite sides, generally within a distance of less than 500 bp. The size limitation of PCR products is an advantage for PCR analysis of junctional regions of rearranged Ig and TCR genes, because the distance between the vast majority of

Table 21.4 Occurrence of secondary rearrangements in Ig and TCR genes

<i>V</i> replacement	+	–	–	–	+	(+)	–

+, replacement reported to occur; (+), replacement can potentially occur, but is not (yet) reported;
–, replacement not likely or impossible to occur.

germline gene segments is far too large to be covered by PCR amplification, whereas juxtaposed rearranged gene segments are easily amplified. For almost every possible gene rearrangement, a primer pair can be made. However, to reduce the number of PCR primers and PCR tests for detection of all possible rearrangements within a particular Ig or TCR locus, generally *V* and *J* consensus primers are designed that recognize (virtually) all *V* and *J* gene segments of the involved Ig or TCR locus, or *V* family and *J* family primers are designed that recognize (virtually) all *V* and *J* gene segments of one family.^{90–93} The BLOMEO-2 Concerted Action ‘PCR-based clonality studies for early diagnosis in lymphoproliferation disorders’ (BMH4-CTgδ-3g3b) has developed 14 PCR multiplex tubes which can detect the majority of *IGH*, *IGK*, *IGL*, *TCRB*, *TCRG* and *TCRD* gene rearrangements.^{93a}

For MRD-PCR studies, the various Ig and/or TCR gene rearrangements have to be identified in each lymphoid malignancy at diagnosis by using the various PCR primer sets (Table 21.2). It should be assessed whether the obtained PCR products are derived from the malignant cells and not from normal polyclonal cells with comparable Ig or TCR gene rearrangements. For this purpose, the PCR products are analyzed for their clonal origin, for example by heteroduplex analysis or by GeneScan analysis (Figure 21.10).^{94,95} Subsequently, the

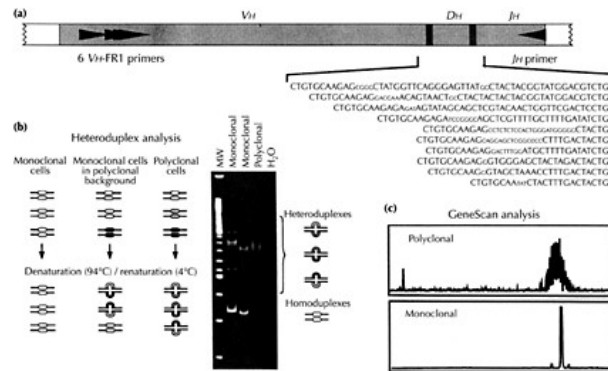

Figure 21.10 (a) Schematic diagram of V_H - D_H - J_H junctional regions with primers for PCR analysis. The approximate positions of the V_H -family-specific framework 1 (V_H -FR1) primers as well as of a J_H consensus primer are indicated. The presented junctional region sequences are derived from precursor B-ALL patients and illustrate the deletion of nucleotides from the germline sequences as well as the size and composition of the junctional regions. Nucleotides of V_H - D_H and J_H gene segments are indicated by capital letters, whereas small capital letters represent inserted nucleotides. (b) Schematic diagram of heteroduplex PCR analysis, in which the junctional region heterogeneity of PCR products of rearranged Ig or TCR genes is employed to discriminate between PCR products derived from monoclonal and polyclonal lymphoid cell populations. In heteroduplex analysis, PCR products are heat-denatured and subsequently rapidly cooled to induce duplex (homo- or heteroduplex) formation. In cell samples consisting of clonal lymphoid cells, the PCR products of rearranged Ig or TCR genes give rise to homoduplexes after denaturation and renaturation, whereas in samples that contain polyclonal lymphoid cell populations, the single-strand PCR fragments will mainly form heteroduplexes upon renaturation. In the case of an admixture of monoclonal cells in a polyclonal background, both homo- and heteroduplexes are formed. Because of differences in conformation, homo- and heteroduplexes can be separated from each other by electrophoresis in non-denaturing polyacrylamide gels. Homoduplexes with perfectly matching junctional regions migrate more rapidly through the gel than heteroduplex molecules with less perfectly matching junctional regions. The latter form a background smear of slower-migrating fragments. (c) Automated high-resolution fluorescence-based PCR fragment analysis for identification of clonally rearranged *IGH* genes (fluorescent GeneScan analysis). Polyclonal V_H - J_H PCR products form a cluster of peaks reflecting a Gaussian distribution of average junctional region sizes in normal B cells. Monoclonal gene rearrangements form single high-fluorescence peaks, representing products of identical size.

precise nucleotide sequence of the junctional regions should be determined. This sequence information allows the design of junctional region-specific oligonucleotides (Table 21.2). These oligonucleotides can be used to detect malignant cells among normal lymphoid cells during follow-up of patients in two different ways. One possibility is the use of the oligonucleotides as patient-specific junctional region probes in hybridization experiments to detect PCR products derived from the malignant cells (Figures 21.11 and 21.12). The other possibility is to use the junctional region-specific oligonucleotides as PCR primers to amplify the rearrangements of the malignant clone specifically.

Sensitivity of PCR analysis of junctional regions

Theoretically the detection limit of MRD-PCR analyses of junctional regions is maximally of order 10^{-6} .

Figure 21.11 Precursor B-cell acute lymphoblastic leukemia (precursor B-ALL) patient with a $V_{\delta 2}$ - $D_{\delta 3}$ rearrangement as a PCR target for MRD detection. The specificity of the junctional region is based on the deletion of six nucleotides and the random insertion of seven nucleotides. This sequence information was used for the design of a patient-specific junctional region probe. DNA from the ALL cells was diluted into DNA from normal mononuclear blood cells (MNC) and subjected to PCR analysis with $V_{\delta 2}$ and $D_{\delta 3}$ primers. PCR products were size-separated in an agarose gel, blotted onto a nylon membrane, and hybridized with the junctional region probe. In all dilution steps and in the MNC, $V_{\delta 2}$ - $D_{\delta 3}$ PCR products were found, but only the first five dilution steps appeared to contain leukemia-derived PCR products, i.e. a sensitivity of 10^{-5} was reached.

Figure 21.12 A complete $TCRD$ rearrangement was used to monitor a T-cell acute lymphoblastic leukemia (T-ALL) patient. The large junctional region of the $V_{\delta 1}$ - $J_{\delta 1}$ rearrangement contained $D_{\delta 2}$ and $D_{\delta 3}$ sequences. The size of the junctional region was 48 nucleotides, the $D_{\delta 2}$ and $D_{\delta 3}$ sequences inclusive. PCR amplification was performed using $V_{\delta 1}$ and $J_{\delta 1}$ primers on DNA from the diagnosis dilution series and from bone marrow follow-up samples (in weeks). Hybridization of the spotted PCR products with the junctional region probe resulted in a sensitivity of 10^{-4} . All followup time points tested gave a signal representative of a high tumor load of $\geq 10^{-2}$, based on comparison with the signals from the diagnosis dilution series. This patient had a clinical relapse 50 weeks after diagnosis. According to molecular MRD detection, this patient was persistently positive and never reached remission.

This is based on the assumption that one million cells, equivalent to about 6.5 μg of DNA, can be tested in one reaction tube, although generally only 1 μg of DNA is used per tube.¹⁴ However, the sensitivity of MRD-PCR analysis of junctional regions is also dependent on the type of rearrangement, on the size of the junctional region, and on the 'background' of normal lymphoid cells with comparable Ig or TCR gene rearrangements. Junctional regions of complete *VDJ* rearrangements are extensive, whereas junctional regions of *VJ* rearrangements are 3–4 times smaller. Normal cells can contain the same rearranged gene segments as the leukemic cells. For instance, $V_{\delta 1}\text{-}J_{\delta 1}$ rearrangements frequently occur in T-ALL, but also in a small fraction (0.1–2%) of normal blood T cells; $V_{\gamma 1}\text{-}J_{\gamma 1.3}$ and $V_{\gamma 1}\text{-}J_{\gamma 2.3}$ rearrangements occur in many T cell malignancies, but are also found in a large fraction (70–90%) of normal blood T cells. This might significantly influence sensitivity levels, particularly taking into account the abundance of polyclonal $V_{\gamma}\text{-}J_{\gamma}$ joinings in normal T cells in postinduction follow-up samples.⁹⁶ Therefore, MRD-PCR analysis of long $V_{\delta 1}\text{-}J_{\delta 1}$ junctional regions in PB samples is generally more sensitive (10^{-4} to 10^{-5}) than MRD-PCR analysis of short $V_{\gamma}\text{-}J_{\gamma}$ junctional regions (10^{-3} to 10^{-4}).^{97,98} Similarly, substantial expansions of normal precursor B cells with polyclonal *IGH* gene rearrangements in regenerating BM during and after therapy might affect the sensitivity of MRD detection using Ig gene rearrangements as PCR targets.^{54,55}

MRD-PCR analysis of junctional regions in ALL

Ig and TCR gene rearrangements in precursor B-ALL

Virtually all precursor B-ALL (96%) have rearranged *IGH* genes.^{99,100} In most cases (80–90%), this concerns complete $V_{H}\text{-}D_{H}\text{-}J_{H}$ rearrangements on at least one allele. Incomplete $D_{H}\text{-}J_{H}$ rearrangements can be identified in 22% of patients, being the sole *IGH* gene rearrangements in only 5% of patients.¹⁰⁰ The usage of V_{H} gene segments in complete $V_{H}\text{-}D_{H}\text{-}J_{H}$ rearrangements seems to reflect the proximity to J_{H} gene segments, with the preferential utilization of the most downstream V_{H6} segment.^{100,101} Most precursor B-ALL contain *IGK* gene rearrangements (30%) or deletions (50%); even 20% of precursor B-ALL cases have *IGL* gene rearrangements.^{99,102–104,104a} Deletions in the *IGK* genes are predominantly mediated via the *IGK* deleting element (*Kde*) sequence, which implies that *IGK* gene deletions can be identified as *Kde* rearrangements. Such rearrangements occur in 50% of cases, whereas in 20% even biallelic *Kde* rearrangements are found.¹⁰³ Interestingly, the size of the junctional regions in *Kde* rearrangements is relatively extensive in precursor B-ALL as compared with similar rearrangements in mature B-cell malignancies.¹⁰⁵

Cross-lineage TCR gene rearrangements occur at high frequency in childhood precursor B-ALL: *TCRB*, *TCRG*, and *TCRD* gene rearrangements and/or deletions are found in 35%, 60%, and 90% of cases, respectively.^{106,107,107a} However, the spectrum of crosslineage TCR gene rearrangements in precursor B-ALL is very limited. *TCRB* gene rearrangements are restricted to the $J_{\beta 2}$ region.¹⁰⁷ This is in contrast to normal T cells and T-ALL, which employ both $J_{\beta 1}$ and $J_{\beta 2}$ gene regions.¹⁰⁸ *TCRG* gene rearrangements in childhood precursor B-ALL are most frequently (about 70%) rearrangements to $J_{\gamma 1}$ region gene segments.¹⁰⁷ Remarkably, 80% of *TCRD* gene rearrangements represent incomplete $V_{\delta 2}\text{-}D_{\delta 3}$ or $D_{\delta 2}\text{-}D_{\delta 3}$ joinings,^{107,109} whereas complete rearrangements to the $J_{\delta 1}$ gene segment, characteristic of normal T cells and T-ALL blasts (particularly $\text{TCR}\gamma\delta^{+}$ ^{32,110}), have been reported in precursor B-ALL only anecdotally.¹¹¹ Furthermore, $V_{\delta 2}\text{-}D_{\delta 3}$ rearrangements are prone to continuing rearrangements, particularly to J_{α} gene segments with concomitant deletion of the C_{δ} exons and subsequent $V_{\alpha}\text{-}J_{\alpha}$ recombination.^{85,112} In fact, about 40% of *TCRD* gene deletions in childhood precursor B-ALL probably result from a $V_{\delta 2}\text{-}J_{\alpha}$ recombination, while the remaining approximately 60% of C_{δ} deletions most probably are caused by $V_{\alpha}\text{-}J_{\alpha}$ rearrangements.¹⁰⁷ Interestingly, the occurrence of cross-lineage TCR gene rearrangements seems to be age-dependent.^{113,114} For example, the incidence of incomplete $V_{\delta 2}\text{-}D_{\delta 3}$ gene rearrangements significantly decreases with patient age, while *TCRG* gene rearrangements are rarely found in patients below 2 years of age.^{113–115,115a}

TCR and Ig gene rearrangements in T-ALL

Subclassification of T-ALL into $\text{CD}3^{-}$, $\text{TCR}\gamma\delta^{+}$, and $\text{TCR}\alpha\beta^{+}$ subgroups reveals major differences in TCR gene rearrangement patterns.^{102,116} Although the frequency of TCR gene rearrangements in the total group of T-ALL is very high, approximately 10% of $\text{CD}3^{-}$ T-ALL still have all TCR genes in germline configuration;^{102,116} this mainly concerns immature $\text{CD}1^{-}\text{CD}3^{-}$ T-ALL of the prothymocytic/pre-T-ALL subgroup. The *TCRD* genes in $\text{CD}3^{-}$ T-ALL are rearranged in most cases (approximately 80%) and contain biallelic deletions in approximately 10% of cases.^{116,117} As expected, all $\text{TCR}\gamma\delta^{+}$ T-ALL have *TCRG* and *TCRD* gene rearrangements and the vast majority (approximately 95%) also contain *TCRB* gene rearrangements.^{32,117} All $\text{TCR}\alpha\beta^{+}$ T-ALL contain *TCRB* and *TCRG* gene rearrangements and have at least one deleted *TCRD* allele (= *TCRA* rearrangement); the second *TCRD* allele is also deleted in two-thirds of cases.^{102,117} Analysis of the *TCRG* gene configuration in T-ALL showed that $\text{TCR}\gamma\delta^{+}$ T-ALL display a less mature *TCRG* immunogenotype as compared with $\text{TCR}\alpha\beta^{+}$ and most $\text{CD}3^{-}$ cases.¹¹⁸ This is reflected by significantly higher usage of the more downstream V_{γ} genes and the more upstream $J_{\gamma 1}$ segments in $\text{TCR}\gamma\delta^{+}$ T-ALL.^{32,118} Despite the described immunobiological differences between the T-ALL subsets, in virtually all

childhood T-ALL (>95%), *TCRG* and/or *TCRD* junctional regions are potentially suitable targets for MRD monitoring.^{98,117,118}

Cross-lineage Ig gene rearrangements occur at a relatively low frequency in T-ALL (approximately 20%) and almost exclusively involve *IGH* genes.¹⁰² Interestingly, cross-lineage *IGH* gene rearrangements occur more frequently in CD3- T-ALL (approximately 20%) and TCR $\gamma\delta^+$ T-ALL (approximately 50%) than in TCR $\alpha\beta^+$ T-ALL (less than 5%).¹¹⁹ Heteroduplex PCR analysis showed a high frequency (approximately 80%) of incomplete $D_{H1}J_H$ rearrangements, as well as preferential usage of D_{H6-19} and the most downstream D_{H7-27} gene segment together with the most upstream J_{H1} and J_{H2} gene segments. Complete V_HJ_H recombinations comprised only 18% of cross-lineage IGH gene rearrangements in T-ALL patients.¹¹⁹

Ig/TCR gene rearrangements as MRD-PCR targets in ALL

Junctional regions of *IGH*, *IGK* (especially *Kde*), *TCRG*, and *TCRD* gene rearrangements are convenient MRD-PCR targets, because they require only a limited number of PCR primer sets. Furthermore, the vast majority (over 90%) of precursor B-ALL patients can be monitored by application of Junctional regions of *IGH*, *IGK*, *TCRG*, and/or *TCRD* gene rearrangements (Table 21.5). In virtually all T-ALL (over 95%) *TCRG* and/or *TCRD* Junctional regions are suitable targets for MRD monitoring (Table 21.5).

Oligoclonality and clonal evolution of Ig and TCR gene rearrangements

Ig and TCR gene rearrangements in precursor B-ALL and T-ALL might be prone to subclone formation due to continuing rearrangements or secondary rearrangements mediated via the active recombinase enzyme system in these immature lymphoid malignancies (reviewed in reference 120). The *IGH* gene rearrangements in particular are known to change in the time period between diagnosis and relapse. In fact, at diagnosis, multiple *IGH* gene rearrangements are already found in 30–40% of precursor B-ALL, indicating the presence of biconality or oligoclonality.⁹⁹ The problem of oligoclonality at diagnosis is the uncertainty as to which clone is going to emerge at relapse, and should be monitored with MRD-PCR analysis. Most continuing or secondary *IGH* gene rearrangements represent V_H to $D_{H1}J_H$ rearrangements or V_H replacements, respectively.^{80,81} During these rearrangements the $D_{H1}J_H$ Junctional region remains unaffected, leading to the concept of designing the primers around the relatively stable $D_{H1}J_H$ region in order to prevent false-negative PCR results.^{80,81,121}

TCR gene oligoclonality is rarely seen at diagnosis in T-ALL.^{77,102,118} In contrast, combined Southern blot and PCR data show that the frequency of oligoclonality in the cross-lineage TCR gene rearrangements of precursor B-ALL is approximately 20%, which is slightly less than in the *IGH* gene.¹⁰⁷ Initially, subclone formation at diagnosis was thought to be less

Table 21.5 Frequencies of identifiable Ig and TCR gene rearrangements as MRD-PCR targets in acute lymphoblastic leukemia (ALL)^a

Gene	Rearrangement type	Precursor B-ALL	T-ALL
<i>IGH</i>	V_HJ_H	93%	5%
	$D_{H1}J_H$	20%	23%
	Total <i>IGH</i>	98%	23%
<i>IGK</i>	V_KKde	45%	0%
	Intron <i>RSS-Kde</i>	25%	0%
	total <i>IGK-Kde</i>	50%	0%
<i>TCRG</i>	$V_\gamma J_\gamma$	55%	95%
<i>TCRD</i>	$V_\delta J_{\delta 1}$ or $D_\delta J_{\delta 1}$	<1%	50%
	$V_{\delta 2} D_{\delta 3}$ or $D_{\delta 2} D_{\delta 3}$	40%	5%
	Total <i>TCRD</i>	40%	55%
At least one PCR target		>95% ^b	>95% ^b
At least two PCR targets		90% ^b	90% ^b
At least three PCR targets		~65%	~50%

^a The indicated frequencies solely refer to the presence of PCR-detectable rearrangements.

^b When a high sensitivity of $<10^{-4}$ is included as an extra criterion, the frequency of at least one sensitive PCR target drops to 85–90% and the frequency of at least two sensitive PCR targets drops to approximately 80%.

frequent for the *TCRD* gene complex, as suggested by Southern blotting.¹¹⁷ However, PCR heteroduplex analysis and sequencing have shown that $V_{\delta 2} D_{\delta 3}$ and $D_{\delta 2} D_{\delta 3}$ rearrangements in newly diagnosed precursor B-ALL are oligoclonal in 30–40% of cases.^{82,107,113} $V_{\delta 2} D_{\delta 3}$ rearrangements are also prone to continuing rearrangements, particularly to J_{α} gene segments with concomitant deletion of the C_{δ} exons.^{82,85}

False-negative results due to clonal evolution are a major drawback of using Ig/TCR gene rearrangements as PCR targets for MRD detection. Changes in Ig/TCR gene rearrangement patterns at relapse occur at high frequency in childhood precursor B-ALL, particularly when subclone formation is already present at diagnosis.^{77,83,84,122} Monoclonal MRD-PCR targets in childhood precursor B-ALL are characterized by high stability, with approximately 90% of all targets detectable at relapse. In contrast, only 40% of the oligoclonal MRD-PCR targets are preserved at relapse.¹²² Therefore, it is probably important to discriminate between monoclonal and oligoclonal Ig/TCR rearrangements, which requires a combined Southern blot and PCR approach. Southern blotting is particularly informative for detection of oligoclonality in *IGH* and *IGK* gene rearrangements,^{99,102} whereas heteroduplex PCR analysis in combination with Southern blotting is informative for detection of oligoclonal *TCRD* gene rearrangements.^{82,107} At present, the *IGK-Kde* gene rearrangements are considered to be the most stable MRD-PCR targets, probably because they are rarely oligoclonal and represent end-stage rearrangements, which do not allow continuing or secondary rearrangements.^{122,123}

Despite the high frequency of immunogenotypic changes in childhood ALL at relapse, at least one rearranged *IGH*, *TCRG*, and/or *TCRD* allele remains stable in 75–90% of precursor B-ALL and in 90% of T-ALL.^{77,83,84,122,124,124a,b,c} More importantly, in most ALL patients, at least two suitable PCR targets are available (Table 21.5). Therefore, it is now generally accepted that MRD-PCR studies should preferably employ at least two Ig/TCR targets per patient. Such approach should result in a major reduction of falsenegative MRD results.

PCR analysis of Ig genes in mature B-cell malignancies

All mature Ig⁺ B-cell malignancies contain *IGH* gene rearrangements, most of them on both alleles. Igκ⁺ B-cell malignancies contain one rearranged *IGK* allele (about 80% of cases) or two rearranged alleles (about 20% of cases).^{102,103} *IGL* gene rearrangements are rare in Igκ⁺ B-cell malignancies (Table 21.6). Igλ⁺ B-cell malignancies contain *IGL* gene rearrangements on one allele (about 75%) or both alleles (about 25%) and also have at least one deleted *IGK* allele, but generally biallelic *IGK* gene deletions are found (Table 21.6).¹²⁵

The Ig gene rearrangements in mature B-cell malignancies provide several PCR targets for MRD studies (Table 21.2). Indeed, in most chronic B-cell leukemias, the Ig gene rearrangements can easily be detected and used as MRD-PCR targets, because they generally do not contain somatic mutations.¹²⁶ However in many B-NHL, especially follicular and

Table 21.6 Frequencies (%) of detectable Ig and TCR gene rearrangements and deletions in mature lymphoid malignancies

	<i>IGH</i>		<i>IGK</i>	<i>IGL</i>	<i>TCRB</i>		<i>TCRG</i>		<i>TCRD</i>		
	R	R			D	R	R	R	R	R	D
B-lineage											
Smκ ⁺ B-CLL, B-PLL, HCL, and MM		100	100	0	5		<5		<5	0	0
Smλ ⁺ B-CLL, B-PLL, HCL, and MM		100	25	75	>98		<5		<5	0	0
T-lineage											
ATLL, MF/SS, and T-PLL ^a		<5	0		0		100		100	10–25	75–90
LGL^b											
TCRαβ+ LGL		<5	0		0		100		100	<25	>75
TCRγδ+ LGL		0	0		0		~50		100	100	0
NK-LGL		0	0		0		0		0	0	0

R, at least one rearranged allele; D, both alleles deleted; CLL, chronic lymphocytic leukemia; PLL, prolymphocytic leukemia; HCL, hairy cell leukemia; MM, multiple myeloma; ATLL, adult T-cell leukemia/lymphoma; MF/SS, mycosis fungoides/Sézary syndrome; LGL, large granular lymphocyte leukemia.

^a The vast majority of ATLL, MF/SS, and T-PLL probably belong to the TCRαβ lineage.

^b Most LGL leukemias express TCRαβ (70–80%), some express TCRγδ (10–15%), and some belong to the NK lineage (10–15%).

post-follicular B-NHL, as well as in MM, somatic mutations in the Ig genes may lead to false-negative results, because of the inability of proper PCR primer annealing.^{86,89} This problem can partly be overcome by use of multiple *V* and *J* consensus primer sets in the hope that at least one primer set is not hampered by the somatic mutations. Such an approach is successful in 70–90% of cases.¹²⁷ In addition, D_H-J_H rearrangements as well as recombinations involving the *Kde* might provide extra MRD-PCR targets. Such a complementary approach involving all possible rearrangements in Ig loci will provide optimal targets in MRD-PCR studies in over 90% of cases.

The somatic mutation process tends to focus on the *V(D)J* exon of the rearranged *IGH*, *IGK*, and *IgL* genes, whereas further upstream and downstream sequences are progressively less affected. Consequently, the leader sequences upstream of the *V(D)J* exon and the constant (*C*) gene segments at the downstream side are probably much less affected by somatic mutations. Therefore, it would be worthwhile to use *V* leader primers and *C* primers for RT-PCR analysis of Ig gene transcripts. At the DNA level, this approach will not work easily because of the large intervening distance between the *V* leader primer and the *C* primer: 8–10 kb for rearranged *IGH* genes, 3.5–5 kb for rearranged *IGK* genes, and 2–2.5 kb for rearranged *IgL* genes. Sequencing of the *V(D)J* exons in the obtained RT-PCR products should allow the design of patient-specific *V* and *J* primers and junctional region probes for MRD-PCR studies at the DNA level. Nevertheless, it should be noted that false-negative results can still be obtained in follicular B-NHL, which may have an active somatic mutation machinery, leading to subclones that are no longer recognized by the patient-specific primers and/or probes. However, in post-follicular B-NHL and MM, the described approach should work smoothly, because their *V(D)J* exons are assumed to remain stable throughout the disease course.⁸⁹

PCR analysis of TCR genes in mature T-cell malignancies

The mature T-cell malignancies should be discriminated from T-ALL and lymphoblastic T-NHL, which are regarded as thymus-derived malignancies based on their positivity for TdT. Mature (post-thymic) T-cell malignancies do not have TdT expression and frequently express TCR molecules. Most chronic T-cell leukemias, such as adult T-cell leukemia/lymphoma (ATLL), mycosis fungoides/Sézary syndrome (MF/SS), and T-cell prolymphocytic leukemia (TPLL), express TCR $\alpha\beta$ molecules, whereas small subsets of large granular lymphocytic leukemias (T-LGL) belong to the TCR $\gamma\delta$ lineage or natural killer (NK)-cell lineage (Table 21.6). Also, most T-NHL belong to the TCR $\alpha\beta$ lineage, although small categories of TCR $\gamma\delta^+$ TNHL have been identified (e.g. hepatosplenic T-cell lymphoma).⁵

TCRG gene rearrangements are found in virtually all mature T-lineage malignancies, except for NK-LGL leukemias.¹⁰² In fact, all Ig and TCR genes are in germline configuration in NK-LGL leukemias. Southern blot analysis also showed that all malignancies belonging to the TCR $\alpha\beta$ lineage have *TCRB* gene rearrangements and most of them biallelic *TCRD* gene deletions (Table 21.6).¹⁰⁸ Thus, MRD studies in mature T-cell malignancies can generally use junctional regions of rearranged *TCRG* genes as PCR targets (Table 21.2). *TCRB* genes might also be used as MRD-PCR targets, although the currently available V_β and J_β consensus primers are less suitable for reliable detection of all V_β and J_β gene segments.¹²⁸ With the newly developed BIOMED-2 multiplex PCR strategy for *TCRB* detection, it is possible to precisely and relatively easily identify most V_β - J_β and D_β - J_β joinings, which are detectable by Southern blot analysis of *TCRB* gene rearrangements.^{93a,128a,b} Alternatively, it is possible to determine the precise *TCRB* gene rearrangement via RT-PCR analysis of *TCRB* gene transcripts using multiple V_β family primers in combination with a single C_β primer.³¹ As soon as the involved V_β and J_β gene segments as well as the junctional region are identified via sequencing, suitable primers and patient-specific junctional region probes can be used for MRD-PCR studies at the DNA level.

In contrast to mature B-cell malignancies, TCR genes are not affected by somatic mutations. For this reason, it should be relatively easy to monitor mature T-cell malignancies during and after treatment.

MRD detection by PCR analysis of chromosome aberrations

Chromosome aberrations as PCR targets for MRD detection

Breakpoint fusion regions of chromosome aberrations can be employed as tumor-specific PCR targets for MRD detection in which the PCR primers are chosen at opposite sides of the breakpoint fusion region. Amplification of breakpoint fusion sequences at the DNA level with standard PCR techniques can only be used for chromosome aberrations in which the break-points of different patients cluster in a relatively small breakpoint area of preferably less than 2 kb, as PCR products should not exceed about 2 kb in routine MRD-PCR analysis. This is the case in t(14;18), where the *BCL2* gene is juxtaposed to one of the *J* gene segments of the *IGH* locus. Other examples include TALL-associated aberrations such as t(11;14)(p13;q11), t(1;14)(p34;q11), t(10;14)(q24;q11), and the *TAL1* deletions. Despite the clustering of the breakpoints, the nucleotide sequences of the breakpoint fusion

regions of the above chromosome aberrations differ per patient. Therefore, these breakpoint fusion regions represent unique patient-specific and sensitive PCR targets for MRD detection.^{58,129,130}

In most translocations, however, breakpoints of different patients are more widespread, resulting in breakpoint regions of over 2 kb. This implies that in each individual patient, the exact breakpoint has to be determined for PCR primer design, which is more laborious and time-consuming. Recently, simplified strategies have been developed to determine precise DNA breakpoint sequences in ALL patients with t(4;11) and t(12;21) based on multiple long-distance PCR and long-distance inverse PCR, respectively, followed by cloning and sequencing.^{131,132} Alternatively, several malignancies with chromosome aberrations have tumor-specific fusion genes that are transcribed into fusion-gene mRNA molecules that are similar in individual patients despite distinct breakpoints at the DNA level. After reverse transcription into cDNA, these fusion-gene mRNA molecules can therefore be used as appropriate targets for MRD-PCR analysis. Examples include *BCR-ABL* transcripts in the case of precursor B-ALL with t(9;22), *E2A-PBX1* mRNA in most pre-B-ALL with t(1;19), *MLL-AF4* transcripts in pro-B-ALL with t(4;11), and *NPM-ALK* mRNA in large cell anaplastic lymphoma with t(2;5).^{8,133-136}

An advantage of using chromosome aberrations as tumor-specific PCR targets for MRD detection is their stability during the disease course. However, MRD detection of chromosome aberrations by PCR is not always applicable, because in many lymphoid malignancies, no PCR-detectable chromosome aberrations have yet been found. Depending on the type of tumorspecific PCR target, detection limits of 10⁻⁴ to 10⁻⁶ can be reached by using chromosome aberrations as MRD-PCR targets (Table 21.2). However, because of the high sensitivity of PCR techniques, cross-contamination of RT-PCR products between patient samples is a major pitfall in PCR-mediated MRD studies, resulting in up to 20% of false-positive results.¹³⁶ Such cross-contamination is difficult to recognize, since leukemia-specific fusion-gene mRNA PCR products are not patient-specific. This is in contrast to PCR products obtained from breakpoint fusion regions at the DNA level, such as in t(14;18) and *TAL1* deletions, which can be identified by the use of patient-specific oligonucleotide probes.

ALL

MRD detection is possible in several types of childhood and adult precursor B-ALL because of the presence of particular leukemia-specific fusion gene transcripts, which can be used as MRD-PCR targets. Examples are *BCR-ABL* fusion transcripts, which are especially observed in adult ALL cases with t(9;22), *E2A-PBX1* mRNA in most pre-B-ALL with t(1;19), *MLL-AF4* transcripts that are found at high frequencies in infant pro-B-ALL with t(4;11), and *TEL-AML1* fusion mRNA in childhood precursor B-ALL with t(12;21).¹³⁴ In this way, RT-PCR analysis of leukemiaspecific fusion gene mRNA for detection of low levels of MRD (<10⁻⁴) can be applied in 40-45% of precursor-B-ALL (Table 21.7).

Table 21.7 Chromosome aberrations in ALL as (RT-)PCR targets for MRD detection^a

Aberration	Target (mRNA or DNA)	Frequency of applicability (%) ^b	
		Children	Adults
Precursor B-ALL			
t(9;22)(q34;q11)	<i>BCR-ABL</i> (mRNA)	5-8	30-35
t(1;19)(q23;p13)	<i>E2A-PBX1</i> (mRNA)	5-8	3-4
t(4;11)(q21;q23)	<i>MLL-AF4</i> (mRNA)	3-5 ^c	3-4

	Total:	40-45	40-45
T-ALL			
<i>TAL1</i> deletion	<i>SIL-TAL1</i> (DNA/mRNA)	} 10-25	} 5-10
t(8;14)(q24;q11)	<i>MYC-TCRA/D</i> (DNA)		
t(11;14)(p15;q11)	<i>LMO1-TCRD</i> (DNA)		
t(11;14)(p13;q11)	<i>LMO2-TCRD</i> (DNA)	5-10	5-10
t(1;14)(p34;q11)	<i>TAL1-TCRD</i> (DNA)		
t(10;14)(q24;q11)	<i>HOX11-TCRD</i> (DNA)		
	Total:	25-30	10-15

^a The detection limit of PCR analysis of chromosome aberrations is 10⁻⁴ to 10⁻⁶.
^b The indicated percentages represent frequency within the precursor B-ALL and T-ALL groups.
^c In infant ALL, the frequency of t(4;11) can be as high as 50%.

In contrast, MRD-PCR analysis of chromosome aberrations is only possible in 15–25% of T-ALL cases and mainly concerns *TAL1* deletions and to some extent t(1;14), t(10;14), and t(11;14) (Table 21.7). Similarly to chromosome aberrations in precursor B-ALL, *TAL1* deletions can be detected at the mRNA level via of *SIL-TAL1* fusion gene transcripts. However, the T-ALL-associated chromosome aberrations can also be analyzed at the DNA level. This latter approach has the advantage that the breakpoint fusion regions can be employed for sensitive patientspecific MRD detection by use of patient-specific oligonucleotides.^{58,130}

CLL

In CLL, MRD detection by (RT-)PCR analysis of chromosome aberrations is hardly possible, because of lack of frequently occurring well-defined chromosome aberrations that can be used as PCR targets. Once particular aberrations are identified that turn out to be common and specific for any of the CLL, these may be employed for future MRD-PCR studies in these leukemias, either at the DNA level or at the mRNA level, depending on whether breakpoints cluster in small DNA regions or whether fusion genes are formed, respectively.

NHL

In B-NHL, chromosomal aberrations frequently involve Ig genes. For example, in FL with t(14;18), the *BCL2* gene is joined to *J_H* gene segments,¹³⁷ while in MCL with t(11;14), the *BCL1* gene is joined to *J_H* gene segments.¹³⁸ Furthermore, in Burkitt lymphoma with t(8;14), t(2;8), and t(8;22), one of the Ig loci (*IGH*, *IGK*, and *IgL*, respectively) is coupled to the *MYC* gene.¹³⁹ In all of these B-NHL types, the breakpoints generally occur outside coding regions, implying that these translocations are not amenable to RT-PCR analysis for MRD detection, but should be studied at the DNA level. Therefore, the detectability of these chromosome aberrations is dependent on the clustering of the breakpoints of different patients in rela-

Table 21.8 Frequent chromosome aberrations in NHL and their detectability by Southern blotting (SB) and PCR techniques

^a Rearrangements to 3q27 (*BCL6* locus) involve Ig genes in at least 50% of cases, i.e. t(3;14); t(2;3), and t(3;22).

^b Based on FISH experiments, the frequency of t(9;14) in LPL is at least 50%.

tively small DNA regions. Southern blotting can scan essentially larger DNA regions (10–15 kb) than PCR analysis (1–2 kb) and therefore detects higher frequencies of particular chromosome aberrations in B-NHL (Table 21.8). Nevertheless, in about 30% of B-NHL patients, chromosome aberrations can potentially be used for MRD-PCR studies at the DNA level. The t(14;18) has already proven to be an important and sensitive PCR target for MRD studies in FL due to the presence of a patient-specific breakpoint fusion region by coupling of the *BCL2* and *IGH* genes.¹⁴⁰

In T-NHL, only a few well-defined translocations are known so far. This concerns the *NPM-ALK* fusion gene that is observed in large cell anaplastic lymphoma with t(2;5) and that can be used for RT-PCR analysis and potentially in some cases for PCR analysis at the DNA level as well.¹³⁵ Furthermore, T-LBL in childhood might have the same chromosome aberrations as found in T-ALL, such as *TAL1* deletions (Table 21.8).

MM

In most MM, chromosome translocations involving *IGH* genes can be found, and several recurrent partner loci have been identified.^{141,142} In contrast to the chromosome aberrations in B-NHL, in which breakpoints within the Ig loci are frequently targeted to J_H gene segments, the translocations in MM often appear to involve the switch regions (*S*) of the *IGH* locus.¹⁴¹ Such illegitimate *IGH* class switch rearrangements or illegitimate deletion of the functional $V_H(D_H)-J_H$ allele might result in the lack of IgH protein production and IgH- MM phenotype.¹⁴³ Future application of these translocations as PCR targets for MRD detection awaits detailed study of the gene fusions in these chromosome aberrations.

Quantification of MRD levels via PCR analysis of junctional regions and chromosome aberrations

MRD quantification by PCR analysis of Ig/TCR gene rearrangements and chromosome aberrations is a complex process, which is essential for reliable disease monitoring. First, the quantity and ‘amplifiability’ of isolated DNA/RNA should be ensured. In RT-PCR-based MRD monitoring, the number of fusion mRNA transcripts should be normalized to the number of transcripts of a housekeeping gene. Second minor variations in (RT-) PCR efficiency, primer annealing, and primer extension may lead to major variations after 30–35 PCR cycles. The disadvantages of such PCR endpoint quantification might (partly) be overcome by using serial dilutions of DNA/RNA isolated from the leukemic cell sample at diagnosis into DNA/RNA of normal mononuclear cells (Figures 21.11 and 21.12).⁹⁷ The same dilution series of diagnosis DNA/RNA is generally used to determine the tumor load in a follow-up sample in a semiquantitative manner by comparison of the hybridization signals. This approach gives an indication of the tumor burden in the follow-up sample. More accurate methods are needed to define the tumor load in remission samples, since it is clear for several malignancies that the level of MRD (not simply its presence) provides important prognostic information. A more precise but also more laborious quantification method is based on limiting dilution of MRD-positive remission samples.^{144,145} To make this assay reliable, it is necessary to perform replicate experiments to determine the level of MRD positivity. Another less tedious strategy for quantitative PCR uses an internal standard that is coamplified with the target of interest.¹⁴⁶ The internal standard is added in a limited but constant number of copies in each reaction. Quantification by competitive PCR is performed by comparing the PCR signal of the specific target DNA with that of known concentrations of an internal standard, the competitor.¹⁴⁶

Finally, if the main purpose of the MRD detection is only the recognition of high-risk ALL patients, the sensitivities for detection of clonal Ig/TCR gene rearrangements of 10^{-2} to 10^{-3} might be sufficient. Such detection levels might be achieved with high-resolution electrophoresis systems such as radioactive fingerprinting or fluorescent gene scanning, without the need for application of patient-specific oligonucleotides.^{147,148,148a}

Real-time quantitative PCR

Within the last few years, a novel technology has become available—‘real-time’ quantitative PCR (RQ-PCR).^{149,150,150a,b} In contrast to the PCR endpoint quantification techniques described above, RQ-PCR takes place during the PCR amplification phase. The first available permits accurate quantification during the exponential phase of PCR amplification. This assay exploits the 5′-3′ exonuclease activity of the *Taq* polymerase to detect and quantify specific PCR products as the reaction proceeds.¹⁵¹ Upon amplification, an internal target-specific TaqMan probe (hydrolysis probe) conjugated with a reporter and a quencher dye is degraded, resulting in emission of a fluorescent signal by the reporter dye that accumulates during the consecutive PCR cycles. Because of the real-time detection, the method has a very large dynamic detection range over five orders of magnitude, thereby eliminating the need for performing serial dilutions of follow-up samples (Figure 21.13). Quantitative data can be obtained in a short

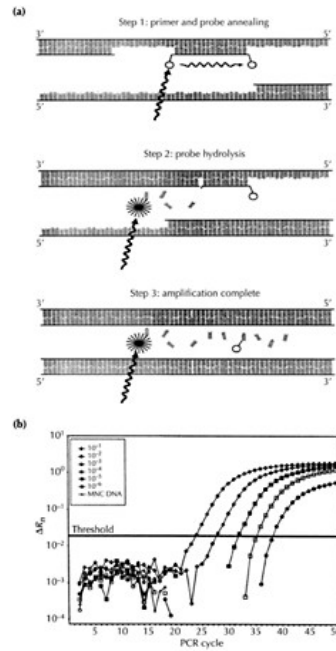

Figure 21.13 Real-time quantitative (RQ)-PCR analysis by use of the TaqMan technique, (a) The TaqMan probe contains a reporter dye and a quencher dye, which prevents emission of the reporter dye as long as the reporter dye and the quencher dye are closely linked. During the extension phase of each PCR cycle, the annealed TaqMan probe is hydrolyzed by the 5' β' exonuclease activity of the *Taq* polymerase, thereby separating the reporter dye from the quencher dye. This results in a fluorescent signal (ΔR_n), which further increases during each subsequent PCR cycle, (b) Example of an RQ-PCR analysis using the TaqMan approach. Tenfold dilutions of a diagnostic sample in normal mononuclear cell (MNC) DNA were analyzed using an *IGH* rearrangement and an ASO primer.

period of time, since post-PCR processing is not necessary. Several groups have shown that RQ-PCR via the TaqMan technology can be used for the quantitative detection of MRD using leukemia-specific chro-

Figure 21.14 RQ-RT-PCR analysis of *E2A-PBX1* fusion gene transcripts for MRD detection, (a) Schematic diagram of the classical *E2A-PBX1* fusion transcript (upper) and the variant transcript (lower) with an insertion of 27 nucleotides. The arrows and the bar indicate the relative position of the primers and the TaqMan probe, respectively, (b) Example of an RQ-PCR analysis using the TaqMan approach. Tenfold dilutions of a diagnostic sample in normal mononuclear cell cDNA were analyzed using the forward primer and probe positioned in the *E2A* gene and the reverse primer located in the *PBX1* gene. RQ-PCR analysis of the *E2A-PBX1* fusion gene transcript resulted in a sensitivity of 10⁻⁴.

mosome aberrations as PCR targets as well as junctional regions of Ig and TCR gene rearrangements (Figures 21.14 and 21.15).^{152-158,158a}

Another type of RQ-PCR technology exploits hybridization probes via the so-called fluorescence resonance energy transfer (FRET) technique, which is usually performed using rapid-cycle RQ-PCR (LightCycler) technology. This method requires two hybridization probes complementary to neighboring sequences—one labeled with a fluorochrome at the 3' end and the other carrying a fluorochrome at the 5' end. One fluorochrome is a donor fluorochrome, whereas the other (the acceptor) emits fluorescent light if it is positioned close to the donor dye. Fluorescence is measured during each annealing step, when both probes hybridize to adjacent target sequences on the same strand.^{149,159} Also, in this hybridization probe-based RQ-PCR analysis, the fluorescent signal increases exponentially during the consecutive cycles, in line with the amount of PCR product formed.

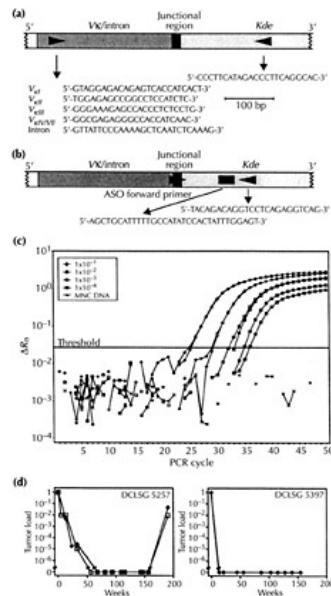

Figure 21.15 (a) Schematic representation of an *IGH Kde* rearrangement. The position and sequences of the primers used for target identification at diagnosis are indicated.¹⁰⁵ (b) Position of the patient-specific junctional region primer and the position and sequences of the TaqMan probe and the *Kde* reverse primer used for MRD detection via RQ-PCR analysis during followup of patients.¹²³ (c) RQ-PCR amplification plot of a $V_{\kappa 11}$ *Kde* rearrangement in a precursor B-ALL patient using a junctional region-specific primer in combination with the *Kde* TaqMan probe and primer. Tenfold dilutions of the diagnostic sample in normal mononuclear cell (MNC) DNA were analyzed at an annealing temperature of 60°C; a reproducible sensitivity of 10^{-4} was reached. Normal MNC DNA did not show amplification in any of the four wells tested, (d) Two examples of MRD kinetics during the follow-up as measured with *IGH-Kde* gene rearrangements as RQ-PCR targets. Patient 5257 had high MRD levels at the end of induction treatment and during early consolidation, and consequently was assigned to the MRD-based high-risk group. Patient 5397 was assigned to MRD-based low-risk group, because of the rapid MRD clearance, which was followed by long-term complete remission.¹²³

A third possibility for RQ-PCR is detection of SYBR Green I (DNA intercalating dye) fluorescence during PCR, employing patient-specific primers.^{149,160} The SYBR Green I dye binds to the minor groove of doublestranded DNA, which greatly enhances its fluorescence. During the consecutive PCR cycles, the amount of double-stranded PCR product will increase, and therefore more SYBR Green I dye can bind to DNA and emit its fluorescence. Maximal SYBR Green I dye binding will occur at the end of each elongation phase. This approach is most cost-effective and is sufficiently sensitive for MRD detection.¹⁶⁰ Future studies should assess whether SYBR Green I-based detection of PCR products also ensures satisfactory specificity.

For each of the above-mentioned RQ-PCR methods, a real-time amplification plot is generated (Figures 21.14 and 21.15). The cycle at which the fluorescence signal exceeds a certain background fluorescence level, referred to as the threshold cycle (C_T), is directly proportional to the amount of target DNA present in the sample. Using these approaches, a dilution series of the diagnostic sample can be made, and the amount of residual leukemic cells in follow-up samples obtained during or after treatment can be calculated by using the standard curve of the diagnostic sample. If fusion gene transcripts from chromosome aberrations are used as PCR target for the detection of MRD, copy numbers of fusion gene transcripts can be calculated by referring to a dilution curve of known amounts of plasmids containing (part of) the fusion gene transcript.

With current RQ-PCR methodology, a reproducible sensitivity of 10^{-4} can be reached for the majority of currently used MRD-PCR targets. The reproducible sensitivity of a TaqMan primer/probe combination is usually defined as the dilution step with a maximal difference in C_T value of 1.5 between the duplicate dilution samples. Furthermore, the C_T values of the reproducible sensitivity have to be at least three cycles lower than the C_T values found with any non-specific amplification in normal mononuclear cell DNA. In addition to the reproducible sensitivity, the maximal sensitivity can be defined as the maximal 10fold dilution of the diagnostic sample giving specific but non-reproducible amplification ($\Delta C_T > 1.5$) or giving specific amplification^{150a} in one out of the two duplicate wells only.

Specific clinical applications of MRD detection

Detection of CNS involvement in ALL patients

The incidence of central nervous system (CNS) involvement in ALL patients at diagnosis is relatively low according to classical morphological criteria for the presence of distinct blasts and/or increased cere-

brospinal fluid (CSF) pleocytosis (>5 cells/ μ l). However, prior to the use of CNS prophylaxis, up to 50% of ALL patients suffered from meningeal relapse, indicating the high frequency of asymptomatic CNS involvement in ALL patients.¹⁶¹ Therefore, the introduction of preventive therapy for meningeal leukemia is regarded to be a milestone in the progress of leukemia treatment.^{162,163}

Normal CSF does not contain TdT⁺ or CD34⁺ progenitor cells, which implies that their presence provides evidence for meningeal leukemic infiltration. Microscopic immunophenotyping of CSF samples at diagnosis showed the presence of TdT⁺ cells in about 25% (11 of 43) of children with ALL, whereas only 1 of the 11 positive cases had overt CNS leukemia according to cytomorphological criteria.¹⁶⁴ During follow-up, 6 children developed CNS leukemia, all belonging to the group with TdT⁺ CSF at diagnosis. This implies that TdT staining of CSF samples has high prognostic value and should supplement classical cytomorphology.¹⁶⁴ Monitoring of MRD in CSF samples of more than 100 patients with a TdT⁺ malignancy during a 5-year follow-up period showed the development of overt CNS involvement in 70% of the patients with repeated finding of TdT⁺ cells in CSF, despite normal cell morphology.¹⁶⁴ On the other hand, patients with increased CSF pleocytosis and/or CSF cells with 'suspicious' morphology but TdT negativity (probably indicative of activated lymphocytes) had no evidence of subsequent CNS disease.^{164,165}

Knowledge of the ALL-specific immunophenotypes allows CSF investigation with multiparameter flowcytometry. The finding of cells with such aberrant immunophenotype is almost always associated with CNS involvement or impending CNS relapse.¹⁶⁶ In contrast, the absence of cells with the ALL-specific immunophenotype in CSF samples suspected of CNS leukemia was reflecting CNS infection or toxicity.¹⁶⁶

Patient-specific *TCRD* rearrangements have been used as an MRD-PCR target for the detection of CNS involvement in childhood precursor B-ALL.¹⁶⁷ Identical rearrangements were found in both BM and CSF in 43% of the analyzed patients, which confirms the clinical assumption that asymptomatic CNS involvement occurs much more frequently than diagnosed on the basis of classical cytomorphological criteria.¹⁶⁷ Moreover, preliminary data indicate that the molecular finding of MRD in CSF during ALL treatment as assessed via patient-specific Ig/TCR gene rearrangements is inevitably associated with subsequent CNS relapse.¹⁶⁸

Early diagnosis of ALL in cases of 'smoldering leukemia'

Hypoplastic bone marrow in ALL patients at presentation is a rare phenomenon, which occurs with a frequency of about 2% in childhood ALL and is rarely seen in cases of adult ALL.^{169,170} In contrast to aplastic anemia, the presence of relatively high frequencies of CD10⁺TdT⁺ cells in BM and PB is a distinct feature in hypoplastic bone marrow with smoldering leukemia.⁵¹ A few case reports have been published demonstrating the presence of identical clonal cell populations during the hypoplastic phase, the subsequent recovery phase, and the phase characterized by overt leukemia, using patient-specific Ig/TCR gene rearrangements as PCR targets.^{171,172} In contrast, non-clonal gene rearrangements could not be detected in patients with idiopathic hypoplastic anemia.¹⁷²

Diagnosis of leukemia/lymphoma in patients with unexplained cytopenias

In a proportion of patients, unexplained cytopenias might mask underlying malignancies. In a comprehensive multiparameter flow-cytometric study of 121 patients with pancytopenias and/or refractory anemias, Wells et al¹⁷³ showed the presence of an abnormal cell population in 17 cases. Further immunophenotyping confirmed the diagnosis of HCL in 8 patients, NHL in 2 patients, and acute myeloid leukemia (AML)/myelodysplastic syndrome (MDS) in the remaining 7 patients. Importantly, the diagnosis of a lymphoid malignancy in 6 patients, which were previously diagnosed as MDS, resulted in a major treatment modification and deferral of SCT is already introduced.¹⁷³

Detection of bone marrow involvement during 'isolated' extramedullary relapse of ALL

'Isolated' extramedullary relapse (e.g. in CNS or testis) is usually associated with detectable MRD levels in BM. This is in concordance with the clinical observation that full systemic reinduction therapy is required in these patients to prevent impending hematological relapse.^{23,174–176} Nevertheless, some ALL patients with isolated CNS relapse were reported without detectable MRD levels in BM.^{146,174,177} MRD positivity of histologically normal end-of-treatment testicular biopsies was shown to be followed by overt testicular relapse.¹⁷⁸ Nevertheless, in some patients, testicular relapse did occur despite MRD negativity in testicular biopsies. Moreover, PCR-based MRD assays at the time of a unilateral testicular relapse allow reliable exclusion of occult leukemic blasts in the histologically normal contralateral testis.¹⁷⁸

Detection of bone marrow involvement during initial staging of NHL

Immunophenotypic and molecular detection of BM involvement has not yet been implemented into clinical staging of NHL. Initial evaluation of the tumor burden is based on cytomorphological findings, with requirement for bilateral BM aspirations and biopsies

in high-grade lymphoma.¹⁷⁹ Several studies demonstrated the presence of aberrant CD5⁺TdT⁺ cells in BM of children with T-LBL.^{23,180} Similarly, BM involvement detected by *BCL2-IGH* PCR analysis is a constant feature not only of advanced-stage FL with t(14;18) but also of localized stages I and II.^{181,182} Preliminary results of a PCR-based MRD study of *IGH* genes in B-NHL demonstrated a higher incidence of BM involvement than suggested by cytomorphological findings.¹⁸³ Further prospective studies should reveal whether detection of submicroscopic BM involvement with sensitivities of 10⁻³ to 10⁻⁵ would improve prediction of clinical outcome in lymphoma patients. If so, MRD-positive patients might receive more intensive treatment, including SCT.

MRD detection in autologous bone marrow grafts

Detection of MRD in autologous grafts in ALL patients

Autologous purged bone marrow transplantation (BMT) and autologous peripheral blood stem cell transplantation (PBSCT) following intensified chemotherapy are currently being evaluated as new treatment modalities in aggressive lymphoproliferative diseases. These treatment strategies are used in high-risk ALL patients in second complete remission who do not have a matched related donor. PCR studies showed that MRD positivity of the autologous BM graft before purging is the most predictive factor of treatment failure in ALL, regardless of a successful purging procedure (MRD-negative graft).¹⁸⁴ In fact, the remission duration after autologous SCT significantly correlates with MRD levels before the purging procedure. On the other hand, infusion of MRD-negative purged grafts in patients with MRD-negative pretransplantation BM is associated with durable clinical remission.¹⁸⁵ The study of *BCR-ABL*⁺ ALL patients revealed that autologous BM grafts are more heavily contaminated with leukemic cells as compared with autologous PBSC grafts.¹⁸⁶ Although the purging procedure might be more effective for autologous BM grafts, the chance of obtaining an MRD-negative autologous BM graft after purging is significantly lower than that of MRD in autologous BM or PBSC grafts is associated with achieving an MRD-negative PBSC graft.¹⁸⁶ Detection of with an increased risk of relapse in ALL patients after transplantation.¹⁸⁷ In addition, ex vivo gene marking of autologous BM grafts suggest that residual malignant clonogenic cells in the autologous grafts are responsible for relapse after transplantation.¹⁸⁸

Detection of MRD in autologous grafts in B-NHL patients

Several studies have focused on autologous SCT in BNHL with t(14;18), where BM infiltration is common at the time of diagnosis.¹⁸¹ Also, PBSC harvests are frequently contaminated by lymphoma cells, with MRD levels comparable to those in BM.^{189,190} Even CD34⁺CD19⁺ progenitors with t(14;18) could be identified in BM and PB.^{191,192} In fact, mobilization regimens before PBSCT might result in increased PB contamination with tumor cells, which was clearly shown for MCL.¹⁹³ With the currently available techniques, it is possible to effectively purge autologous grafts of FL cells, as assessed by the disappearance of clonal *BCL2-IGH* PCR products.^{194–196} In contrast, the purging procedure in MCL is generally unsuccessful.^{193,196,197} Also, PCR analysis of *IGH* gene junctional regions showed that purging in autologous BM harvests can be successful in 50% of FL cases, but is generally ineffective in patients with DLBCL.¹⁹⁸ Preliminary RQ-PCR data indicate that successful purging of t(14;18)-positive cells is only possible in patients with a low tumor burden in stem cell harvests.¹⁹⁹ It is virtually impossible to achieve MRD negativity after purging when PBSC aphereses contain more than 1% CD19⁺ B cells.²⁰⁰ Initial data suggested that patients transplanted with MRD-PCR-negative autologous grafts showed significantly longer disease-free survival in comparison with those whose marrow contained residual clonal lymphoma cells after purging.²⁰¹ Subsequent studies did not show a significant correlation between the PCR status of the reinfused bone marrow and FL outcome.^{202,203}

Detection of MRD in autologous grafts in MM patients

High-dose chemotherapy followed by autologous SCT is also becoming a treatment of choice for MM patients. Positive selection of CD34⁺ PBSC results in the reduction of contaminating tumor cells by at least two orders of magnitude, but residual MM-specific *IGH* gene rearrangements are frequently detectable.^{204–206} Only highly purified (over 99.9%) CD34⁺ PBSC of MM patients are MRD-negative.^{206,207} Preliminary observations indicate that transplantation of MM patients with purged PBSC seems to be associated with better event-free survival as compared with SCT with unmanipulated grafts.²⁰⁸

Clinical value of MRD detection during and after treatment

Clinical MRD studies have mainly been performed in lymphoid malignancies of B lineage, such as precursor B-ALL, chronic B-cell leukemia, B-NHL, and MM. A few studies have also included T-ALL, but virtually no studies on MRD monitoring in chronic T-cell leukemias or peripheral (post-thymic) T-NHL have been reported.

ALL

Most MRD studies in ALL have concerned childhood patients. The initial retrospective and small prospec-

tive studies with relatively short follow-up indicated that detection of MRD in childhood ALL has potent clinical value, although the results of these clinical studies were not fully concordant (summarized in references 72 and 209). This could be attributed to differences in sensitivities of MRD monitoring as well as to differences in the intensity of the cytotoxic treatment protocols. Several recent large prospective studies have confirmed the clinical value of MRD monitoring, justifying incorporation of the MRD information to refine risk-group assignment in current childhood ALL treatment protocols.^{43,124,210–215}

Clinical value of MRD detection for assessment of early response to first-line cytotoxic treatment in childhood ALL

The most significant application of MRD monitoring in childhood ALL is the assessment of the initial response to chemotherapy.²¹⁶ For example, a blast count in PB of less than 1000/ μ l after 1 week of prednisone therapy within BFM treatment protocols was found to be an important prognostic factor.²¹⁷ As a logical continuation of these clinical findings, low levels or absence of MRD after completion of induction therapy predicts good outcome, as found by PCR-based MRD studies.^{124,144,210,211,214,218,218a,b} Meta-analysis of published MRD studies showed that approximately 50% of children with ALL are MRD-positive at the end of induction treatment and approximately 45% of these MRD-positive patients will ultimately relapse.²⁰⁹ The risk of relapse has been found to be proportional to the detected MRD levels.^{124,144,210,219} The level of MRD-PCR positivity after induction therapy is the most powerful prognostic factor. Multivariate analyses showed that this prognostic value is independent of other clinically relevant risk factors, including age, blast count at diagnosis, immunophenotype at diagnosis, presence of chromosome aberrations, response to prednisone, and classical clinical risk group assignment, provided that sensitive and accurate MRD quantification on adequate BM samples is performed.^{124,210,211} Such sensitive and accurate MRD detection can be achieved via RQ-PCR analysis of junctional regions of Ig and TCR gene rearrangements (Figure 21.15).^{98,123,158,220}

The meaning of MRD positivity differs according to the cytogenetic subgroup of ALL. Philadelphia chromosome-positive (Ph⁺) ALL with t(9;22) is characterized by high drug resistance and a very poor prognosis.²²¹ This leukemia subtype is also associated with an increased percentage of MRD-positive patients and increased MRD levels at the end of induction treatment.²²² Chemotherapy can lower the degree of MRD by only 2–3 logs in most Ph⁺ ALL patients, which is not enough for prolonged hematological remission. Nevertheless, in some patients with favorable prognostic features (e.g. low initial leukocyte count or good prednisone response), the disease can be controlled with intensive chemotherapy.²²¹ MRD monitoring might identify this small drug-sensitive subgroup of Ph⁺ patients.²²³ However, due to the poor prognosis of ALL with t(9;22) and the very low frequency of complete cure in this patient group, this preliminary observation should be confirmed by large multicenter studies. The same holds true for other cytogenetic ALL subgroups with increased risk of relapse, such as precursor B-ALL with t(4;11). It is possible to identify a small subgroup of t(4;11)-positive patients with rapid achievement of molecular remission after intensive chemotherapy and/or allogeneic SCT and persistent PCR negativity in long-term complete remission.²²⁴ Therefore, prospective MRD monitoring can be used for assessment of treatment response and can be applied for individualization of therapy in order to further improve the outcome of high-risk t(4;11) positive leukemia, including infant ALL patients.²²⁵ MRD studies in patients with the prognostically favorable *TEL-AML1* aberration suggest that the MRD levels at the end of induction therapy are generally below the threshold associated with bad outcome.²²⁶ Nevertheless, using quantitative MRD analysis of early treatment response, it is possible to identify the subgroup of *TEL-AML1*⁺ patients with slower kinetics of tumor reduction being at higher risk of leukemia relapse.^{226,227}

The results from the large prospective study of the International BFM Study Group (I-BFM-SG) utilizing Ig and TCR gene rearrangements as MRD-PCR targets indicated that MRD analysis at a single time point is not sufficient for recognition of patients with poor prognosis as well as patients with good prognosis.¹²⁴ In contrast, combined information on the kinetics of tumor load decrease at the end of induction treatment and before consolidation treatment appeared to be highly informative. This combined MRD information distinguishes patients at low risk with MRD negativity at both time points (5-year relapse rate of 2%); patients at high risk with an intermediate (10^{-3}) or high ($\geq 10^{-2}$) degree of MRD at both time points (5-year relapse rate of 80%); and the remaining patients at intermediate risk (5-year relapse rate of 22%) (Figure 21.16).¹²⁴ The group of patients at MRD-based high risk is larger than any previously identified high-risk group (approximately 15%) and has an unprecedented high 5-year relapse rate of 80%. This group might benefit from further intensification of treatment protocols, including SCT during first remission or novel treatment modalities, such as including antibodies conjugated with immunotoxins or tyrosine kinase inhibitors. On the other hand, the MRD-based low-risk patients make up a group of a substantial size (approximately 45%), comparable to the frequency of survivors of childhood ALL before treatment intensification was introduced.¹⁶³ Within the MRD-based low-risk group, half of the patients have already low ($\leq 10^{-4}$) or undetectable MRD levels after 2 weeks of

Figure 21.16 Relapse-free survival rates of the three MRD-based risk groups of children treated for ALL according to protocols of the International BFM Study Group. The three risk groups were defined by combined MRD information at the end of induction treatment (time point 1) and before consolidation treatment (time point 2).¹²⁴ Patients in the low-risk group have MRD negativity at both time points (43% of patients), patients in the high-risk group have MRD degrees of $\geq 10^{-3}$ CH at both time points (15% of patients), and the remaining patients form the MRD-based intermediate-risk group (43% of patients). The numbers of patients at risk are given in parentheses for each group at 24 months and 48 months after time point 2.

treatment.²¹² This group in particular might profit from treatment reduction.

The reported clinical MRD studies all show the prognostic value of MRD information, but the definition of MRD-based risk groups, the relative distribution of patients over these groups, and the corresponding relapse rates are different between the studies. Most probably, these differences are related to the treatment protocol, the sensitivity of the MRD technique, and the timing of the follow-up BM samples. Therefore, it is important to realize that for each ALL treatment protocol, optimal time points and sensitivities for determination of early treatment response ('MRD window') should be determined. Modifications of chemotherapy regimens and the corresponding BM sampling time points might result in loss of clinical significance of MRD information if the MRD window is not adjusted appropriately.^{228,228a}

Clinical value of MRD detection for assessment of response to reinduction treatment after relapse of ALL

The predictive value of MRD monitoring is particularly clear after first relapse.^{229,230} This can be perceived as assessment of early treatment response after second induction treatment. The BFM group demonstrated the high prognostic value of MRD detection at day 36 of the ALL-REZ treatment protocol. Patients with MRD levels below 10^{-3} ($n=16$) had a probability of relapse-free survival rate of 86%, whereas MRD levels equal or more to 10^{-3} ($n=10$) were uniformly predictive of dismal outcome (with zero probability of relapse-free survival).²³⁰ These first MRD results in relapsed childhood ALL look very promising, but need further confirmation because of the limited number of studies patients.

Differences in MRD kinetics between precursor B-ALL and T-ALL of childhood

The MRD data suggest slower kinetics of leukemia clearance in T-ALL as compared with precursor BALL patients.^{214,231,232} In a study by Dibenedetto et al,²³¹ nearly all T-ALL patients (16 of 17) were found to be MRD-positive at the end of induction treatment, while a later time point at the beginning of maintenance treatment carried the most significant prognostic information. All but one (7 of 8) MRD-positive patients at this *late* time point subsequently relapsed, while all 8 MRD-negative patients remained in continuous complete remission.²³¹ This is in contrast to the MRD study of the I-BFM-SG, which showed that PCR-based measurement of *early* treatment response at two consecutive time points after induction treatment and before consolidation treatment results in highly prognostic MRD information: approximately 25% low-risk patients with 0% relapses, 50% intermediate-risk patients with 25% relapses, and 25% high-risk patients with 100% relapses.²³²

Clinical value of continuous MRD monitoring in childhood ALL

Continuous MRD monitoring in childhood ALL has shown that a steady decrease of MRD levels to negative PCR results during treatment is associated with favorable prognosis,²³³ whereas persistence of high MRD levels or steady increase of MRD levels generally leads to clinical relapse (Figure 21.17).^{124,234–236} Therefore, persisting MRD levels during treatment can be regarded as a good indicator of *in vivo* resistance to treatment. PCR-based MRD monitoring was shown to be able to select the group of 'poor responders' with early relapse during maintenance treatment.^{124,210,211} Sequential sampling generally shows positive MRD-PCR results prior to clinical relapse. However, the time span between the reappearance of MRD positivity and overt hematological relapse might be too short for earlier implementation of reinduction treatment.²³⁷

Low levels of MRD after therapy might be associated with late development of relapse, but absence of MRD at the end of treatment is not sufficient to assure that the patient is cured.^{124,236} Despite the high sensitivity of most MRD techniques, it should be noted that MRD negativity does not exclude the presence of leukemic cells in the patient, because each MRD test only screens a minor fraction of all BM and PB leukocytes. Curiously, one report claims that multiple PCR analy-

Figure 21.17 Flow-cytometric detection of MRD in a precursor B-cell acute lymphoblastic leukemia (precursor B-ALL) patient by use of CD45/CD10/CD19 (a, b) and TdT/CD10/CD19 (c,d) triple labelings. The leukemia-specific immunophenotypic detection was based on CD10 overexpression and CD45 negativity. In the follow-up bone marrow (BM) sample, taken 4.5 years from the diagnosis of ALL, the population of cells with leukemia-specific immunophenotype comprised 0.2% of BM cells, i.e. 1.5% of CD19⁺ cells. At that time, the patient was in complete clinical remission of the leukemia. However, he underwent the overt hematological relapse of precursor B-ALL, 9 months after this positive MRD test. (Courtesy of Dr EG van Lochem)

ses (testing a higher cell number) gave evidence for residual leukemia at very low levels in about 90% (15 of 17) of patients remaining in long-term clinical remission.²³⁸ In 7 out of these 15 patients, this PCR result was confirmed in a blast colony assay. So far, these data have not been confirmed by other investigators, even not by using extremely sensitive 10-fold PCR analyses (sensitivities 10^{-6} to 10^{-7}).¹²⁴ In contrast, large prospective studies showed 0–10% of patients being positive at the end of treatment; the majority of the MRD-positive patients relapsed later on.^{124,236}

These combined data suggest that continuous MRD monitoring in childhood ALL has limited value and might only be useful for a subgroup of patients with a relatively slow early response to treatment, i.e. patients at high risk of relapse and for patients at intermediate risk of relapse.

Clinical value of MRD detection before and/or after stem cell transplantation in childhood ALL

MRD monitoring is particularly informative for ALL patients undergoing BMT. In the extensive study of Knechtli et al,¹⁴⁷ high levels of MRD-PCR positivity (10^{-2} to 10^{-3}) before allogeneic BMT were invariably associated with relapse after transplantation, while the 2-year event-free survival rate in patients with a low level of MRD positivity (10^{-3} to 10^{-5}) approximated 36%. This study involved patients receiving Tcell-depleted grafts, while two other studies showed that the strong graft-versus-leukemia (GVL) effect associated with non-depleted grafts might overcome high levels of MRD positivity in selected cases.^{239–241}

In contrast, MRD negativity before allogeneic transplantation significantly correlated with better outcome and a 2-year event-free survival rate greater than 70%.^{147,240–242} Similar results were obtained in the study of pre-BMT samples with multiparameter flow cytometry, with disease-free-survival rates of 33% and 74% for MRD-positive and MRD-negative patients, respectively.²⁴³ Therefore, patients with a high MRD burden prior to BMT might be offered alter-native treatment (e.g. further cytoreduction before BMT, intensified conditioning, and/or early postBMT immunotherapy) in order to improve their generally poor outcome.^{147,240–242}

MRD-PCR positivity in ALL patients after BMT is suggestive of impending relapse.^{244,244a} This is true both for high-risk patients transplanted in first remission and for patients subjected to BMT in second remission after leukemia relapse. MRD was shown to occur in post-BMT samples in 88% of patients who subsequently relapsed, while only 22% of patients in long-term complete remission showed MRD at any time after BMT, mostly at low levels.²⁴⁴ The patients with persistent MRD positivity after BMT might be candidates for early treatment with immunotherapy, including donor lymphocyte infusions to increase the GVL effect.^{243,244,244a}

Clinical value of MRD detection in adult ALL

Preliminary results of MRD studies in adult ALL using junctional regions of Ig/TCR genes as MRD-PCR targets showed molecular responses to chemotherapy similar to those in childhood ALL, but with higher frequencies of persistent MRD positivity in adults.^{245,246} Not only the frequencies of MRD positivity but also the MRD levels in adult patients were significantly higher than in comparably treated children; this points towards a higher frequency of in vivo drug resistance in adult ALL.^{246,247,247a} A single prospective MRD study in t(9;22)-negative adult precursor B-ALL patients demonstrated the strong predictive value of MRD information at all investigated time points within 2 years of treatment.²⁴⁸ The prognostic value of semiquantitative MRD data was most significant 3–5 months after remission induction and beyond. In contrast to childhood ALL, the prognostic value of preBMT MRD levels was inferior to MRD information after allogeneic BMT.²⁴⁸

Comparison of MRD monitoring between bone marrow and peripheral blood in ALL

One of the serious limitations of continuous MRD monitoring is the need for multiple traumatic BM aspirations. Replacement of BM sampling by PB sampling has been a topic of debate in MRD studies for the last 15 years or so. Both early immunophenotypic data^{14,23} and a RQ-PCR study²⁴⁹ showed a very good concordance between MRD levels in BM and PB in T-ALL patients. This strong correlation was independent of the follow-up time point, underlining the disseminated character of T-ALL. Therefore, BM sampling might be replaced by PB sampling in T-ALL.²⁴⁹ In contrast, MRD levels in precursor B-ALL differed significantly between BM and PB.^{249,250,250a} The data from a single PCR study showed an 11.7-fold difference between BM and PB during induction treatment of precursor B-ALL patients.^{250,250a} Recent RQ-PCR-based results show a highly variable ratio between MRD levels in BM and PB, ranging from 1 to more than 1000.²⁴⁹ This implies that no simple straightforward relationship exists between MRD levels in paired BM and PB samples of precursor B-ALL patients—particularly not at later time points (>3 months). The difference between BM and PB might be less pronounced in Ph⁺ precursor B-ALL, most probably because of a generally higher degree of MRD as compared with other ALL subtypes. Nevertheless, PB sampling can-not easily replace BM sampling for MRD detection in precursor B-ALL patients. Moreover, the differences in MRD levels between BM and PB are additionally influenced by the degree of dilution of BM aspirates with PB. This is suggested by the finding of a 4.1-fold greater mean MRD level in trephine BM biopsies as compared with BM aspirates.²⁵¹

B-CLL

Persistence of residual disease in patients treated with conventional chemotherapy

B-CLL typically occurs at an advanced age, is characterized by an indolent course, and frequently requires no specific treatment.²⁵² Immunophenotypic monitoring of residual disease in B-CLL was traditionally based on overexpression of the CD5 antigen on CD20⁺ cells or an abnormal Igκ/Igλ₁ ratio within a B-cell-enriched population or on CD37⁺-gated B cells.^{28,253,254} With such an approach, characterized by a limited sensitivity of about 10⁻², residual leukemic cells were detected in the majority of B-CLL patients in cytomorphological remission after conventional chemotherapy. This finding was confirmed by the persistence of clonal *IGH* gene rearrangements as detected by Southern blotting.²⁵⁵ Immunophenotypic remission after chemotherapy was associated with significantly longer relapse-free survival of patients, but this remission was not related to prolonged overall survival.²⁵⁵ Immunophenotypic MRD analysis after treatment of B-CLL with fludarabine plus prednisone showed that the vast majority of patients in complete clinical remission had no detectable immunophenotypically aberrant cells.²⁵⁶ Relapse-free survival in this group was significantly longer compared with patients with MRD positivity by flow cytometry. Reappearance of cells with the B-CLL immunophenotype preceded overt clinical relapse by 3–14 months.²⁵⁶ Similarly, in the study by Brugiatelli et al,²⁵⁶ immunophenotypically defined remission after chemotherapy was associated with a significantly longer relapse-free survival of patients, but this remission was not related to prolonged overall survival. Persistence of immunophenotypically defined MRD was associated with a more rapid progression of B-CLL.²⁵⁷ During disease progression, there was no evidence for clonal evolution, which is in line with the absence of secondary rearrangements in B-CLL.²⁵⁸

Value of MRD monitoring in B-CLL patients treated with SCT

In a subgroup of patients with high-risk B-CLL, particularly those under the age of 60 years, intensive treatment (including autologous or allogeneic SCT) is being increasingly used (reviewed in reference 259). For patients in advanced-stage B-CLL referred for SCT, more sensitive PCR analyses of *IGH* junctional regions with sensitivities of 10⁻³ to 10⁻⁵ would be preferred. With such sensitive MRD detection, none of the patients reach molecular remission after conventional or salvage chemotherapy.²⁵⁸ Following allogeneic or autologous B-cell-purged SCT, a subset of disease-free patients could be identified without detectable MRD.^{258,260–262} In contrast, persistence of MRD-PCR positivity after SCT might be associated with impending relapse.²⁵⁸ Esteve et al^{66,263} analyzed

patients in complete remission after SCT with combined flow-cytometric and molecular analyses, reaching sensitivities of $\leq 10^{-4}$. Six out of seven patients who were MRD-positive at the first evaluation 3 months after autologous SCT experienced disease relapse, while only 1 of 11 MRD-negative patients at the same time point subsequently relapsed.^{66,263} This implies a high prognostic value of MRD after autologous SCT. Concerning MRD monitoring at later time points, some investigators have reported MRD positivity for several months or even several years in BCLL patients in complete clinical remission after SCT.^{261,264,265} In this aspect, quantitative MRD data might be particularly informative for discrimination between patients with persistently low MRD levels in stable clinical remission and those with increasing MRD levels at high risk of relapse. Rawstron et al⁶⁵ used multiparameter flow cytometry and quantitatively assessed MRD in patients treated with PBSCT and/or humanized anti-CD52 antibody (CAMPATH1H). All patients with MRD levels above 5×10^{-4} at the end of treatment experienced rapid B-CLL progression. Virtually all patients with MRD levels below 5×10^{-4} remained progression-free, although in half of these patients MRD levels subsequently increased.⁶⁵

In conclusion, MRD data in B-CLL are preliminary, mostly retrospective, and largely qualitative, and the clinical value of MRD in this leukemia type should be fully established. It is clear that MRD kinetics in BCLL differ according to the treatment protocol. Nevertheless, patients with high-risk B-CLL in particular should definitely profit from more precise, quantitative treatment monitoring. Assessment of MRD after autologous SCT especially might reveal prognostically significant information.

B-NHL

Limited value of MRD monitoring in PB in FL patients treated with conventional chemotherapy

MRD detection might be particularly important in the subgroup of high- and intermediate-grade lymphomas, where circulating lymphoma cells are frequently found in BM and PB. The vast majority of clinical studies have concentrated on FL with t(14;18) using the *BCL2-IGH* fusion gene as a DNA target for PCR-based MRD analysis.^{181,182,192,266–274} Most of the patients suffering from this disease harbor lymphoma cells in BM or PB at diagnosis, with BM being more informative than PB for MRD monitoring.^{181,182,267} More than half of the patients convert to MRD negativity during the first year of cytotoxic treatment, which is associated with a longer relapse-free survival.²⁶⁸ In patients with advanced t(14;18)-positive NHL (stage III/IV) treated with conventional induction therapy, no obvious correlation was found between the presence or absence of t(14;18)-positive cells in circulation and relapse-free survival.²⁶⁹ Using RQ-PCR, Mandigers et al²⁷⁵ prospectively assessed the response to induction chemotherapy in PB of FL patients. Half of the patients converted to PCR negativity, while another one-third had very low levels of MRD as measured in a *BCL2-IGH* RQ-PCR assay. However, this molecular response in PB was not associated with a better progression-free survival.²⁷⁵

Apparently, MRD monitoring in PB has limited value in FL patients, but MRD monitoring in BM might be more valuable.

MRD kinetics in FL patients treated with chimeric CD20 antibody

A combination of chemotherapy and chimeric (mouse-human) anti-CD20 antibody (rituximab) treatment has been shown to produce durable clinical remission in a subgroup of FL patients accompanied by PCR negativity.^{270,276} Patients who achieved sustained molecular remission had significantly better clinical outcome at 3-year follow-up as compared with persistently MRD-positive patients or those who converted to MRD-PCR positivity.²⁷⁶

t(14;18)-positive B cells can even be effectively cleared from PB and/or BM in a subset of patients treated with rituximab as *single* first-line treatment.²⁷⁷ PCR negativity in PB 1 month after treatment completion can identify patients with a significantly lower rate of disease progression during the first year of follow-up.²⁷⁷ Although a significant subset of patients remained MRD-negative 1 year after completion of rituximab treatment, the prognostic significance of such molecular remission should be established after longer follow-up.

Negativity or persistence of low MRD levels in FL patients in complete remission after SCT

MRD studies for the presence of *BCL2-IGH* transcripts in patients treated with purged autologous SCT showed that the patients in continuous molecular remission after SCT had significantly higher relapse-free survival as compared with patients with persistent PCR positivity.^{203,271} In another group of patients treated with autologous PBSCT, reappearance of PCR positivity at any time post transplantation was associated with an increased relapse risk.¹⁹² Diametrically different conclusions were drawn from another study, in which the majority of patients after purged autologous SCT remained MRD-PCR-positive and no correlation was found between MRD-PCR status and relapse-free survival.²⁷³

Furthermore, circulating t(14;18)-positive cells were detected in patients in long-term clinical remission after radiation therapy for localized FL.²⁷⁴ RQ-PCR data indicate that patients in continuous clinical remission after high-dose chemotherapy supported by autologous BMT might become transiently MRD-

negative.²⁰² More frequently *BCL2-IGH* fusion genes are persistently found with stable levels within one order of magnitude.²⁰² Further investigations and standardization on multicenter level are required to establish the quantitative criteria for molecular remission in FL and the potential applicability of MRD information for clinical decision-making.

BCL2-IGH fusions in normal individuals—reality or contamination ?

It should be noted that positive results in sensitive *BCL2-IGH* PCR studies should be interpreted with caution, because the presence of t(14;18)-positive B cells has also been reported in healthy individuals.^{278,278a} Also an international multicenter study revealed a high variability of *BCL2-IGH* PCR results between different laboratories, with an unexpectedly high frequency of false-positive results.²⁷⁹ Such falsepositive results, due to normal t(14;18)-positive cells or intralaboratory contamination, can be prevented by routine design of patient-specific oligonucleotides directed against the fusion-region sequence of the *BCL2-IGH* junction.²⁸⁰

Persistent MRD positivity in MCL patients

Using IGH gene rearrangements and *BCL1-IGH* fusion genes as DNA targets, MCL patients were found to be continuously MRD-positive in BM and/or PB during chemotherapy.^{193,197} In the majority of MCL patients, MRD levels in BM and PB vary between 10^{-2} and 10^{-3} , indicating extensive dissemination of MCL cells and significant resistance to conventional chemotherapy schemes.¹⁹³ With more intensive treatment, including a combination of rituximab and conventional chemotherapy, approximately one-third of MCL patients can reach a MRD-PCR-negative status.²⁸¹ However, in the majority of cases, this conversion to PCR negativity is transient and molecular remission is not associated with better progression-free-survival.

Value of MRD monitoring in B-NHL after autologous or allogeneic SCT

Persistence of MRD-PCR positivity in BM after autologous SCT was shown to be associated with impending clinical relapse, whereas all patients with eradication of PCR-detectable lymphoma cells remained in continuous clinical remission.¹⁹⁸ Nevertheless, persistence of patient-specific IGH gene rearrangements during long-term complete remission has also been reported.²⁸² MRD was investigated with patient-specific PCR techniques in a group of patients with advanced-stage FL or MCL.²⁸³ After high-dose sequential chemotherapy, it was possible to harvest MRD-PCR-negative autologous BM grafts in most FL patients. None of the patients who received an MRD-PCR-negative BM graft relapsed at a median follow-up of 24 months.²⁸³ These combined MRD studies indicate that transplantation with MRD-negative autologous BM or PBSC grafts is a promising treatment modality in patients with FL.

In contrast, it is virtually impossible to harvest autologous MRD-negative BM or PBSC grafts in MCL.^{193,197,283} Reinfusion of MRD-positive grafts is uniformly associated with the relapse of MCL.¹⁹⁷ Preliminary data suggest that high-dose chemoradiotherapy followed by autologous PBSCT might result in molecular remission in a subset of MCL patients.^{284,284a} MRD-PCR negativity after PBSCT is strongly predictive of progression-free survival.^{284,284a} These promising data should be confirmed for larger groups of patients. Currently, for patients with advanced MCL allogeneic SCT remains the only effective treatment regimen, and preliminary data show conversion to MRD negativity after SCT, which is related to long-term hematological remission.^{197,285}

MM

Detection of MRD in MM is a quite recent issue because of progress in the treatment of this formerly incurable disease. In particular, the application of high-dose chemotherapy in combination with allogeneic or autologous SCT has increased the overall survival and possibly leads to ultimate cure of MM.^{11,286} This treatment eradicates not only malignant plasma cells but also putative malignant B lymphocytes, which are found to be clonally related to the MM cells.¹² The malignant event apparently affects B lymphocytes with somatically mutated *IGH* genes before IgH class switching occurs; they are characterized by CD45RO, high-density CD38 expression, and CD56 expression.²⁸⁷ Rearranged *IGH* genes of MM cells contain somatic mutations, but show no further intraclonal variation.⁸⁹

Some studies have shown that after high-dose sequential chemoradiotherapy, malignant plasma cells might still be detectable by MRD-PCR analyses in PB and BM harvests as well as in BM after autologous transplantation, whereas clonally related B lymphocytes (before IgH class switching) were not detectable in the cell harvests.²⁸⁸ Persistent MRD positivity is a frequent finding in MM patients in complete remission after conventional chemotherapy or after high-dose chemotherapy followed by single or tandem autologous SCT (with MRD levels ranging from 10^{-4} to 10^{-2}).^{208,289} This combination of chemotherapy and autologous SCT results in a more significant reduction of residual malignant plasma cell levels as compared with conventional chemotherapy.²⁹⁰ However, only a small subset (5–15%) of MM patients in longterm complete remission after autologous SCT ultimately reach an MRD-PCR-negative status (sensitivity 10^{-3} to 10^{-4}).^{289,291,292} Nevertheless, even patients in transient molecular remission have a significantly lower relapse rate and a significantly longer relapse-free survival.²⁹²

In contrast, up to 70% of MM patients in long-term complete remission after high-dose chemotherapy and allogeneic SCT remain persistently MRDnegative, indicating that complete eradication of the malignant clone and real 'cure' of MM become realistic goals.^{286,289,292,293}

Conclusions

Several immunophenotyping and PCR techniques are available for MRD detection in patients with a lymphoid malignancy, as summarized in Table 21.9. Especially in precursor B-ALL and T-ALL, multiple sensitive MRD techniques can be used, showing a high correlation of the obtained results between different methodologies.^{294–296} Each MRD technique has its advantages and disadvantages, which have to be weighed carefully to make an appropriate choice (see Table 21.2). On the one hand, false-positive and falsenegative results should be prevented, but, on the other hand, the MRD techniques should be sufficiently sensitive and quantitative. These requirements can generally be met with RQ-PCR analysis of chromosome aberrations, if adequate precautionary measures are taken to prevent cross-contamination of PCR products. Speed and relatively low costs will also play a role in the choice of MRD techniques, and can be achieved with multiparameter flow-cytometric MRD analysis, which is also inherently quantitative. RQ-PCR analysis of junctional regions of Ig/TCR gene rearrangements is time-consuming and expensive, but has the advantage of broad applicability in all categories of lymphoid malignancies, as well as the advantage of high sensitivity levels (Table 21.9).

Although most MRD techniques are relatively sensitive, one should realize that MRD negativity does not exclude the presence of malignant cells.²⁹⁷ Generally each MRD test only screens 10^5 – 10^6 cells, which represent a minor fraction of the total amount of lymphoid cells. In addition, it might well be that the distribution of low numbers of malignant lymphoid cells throughout the body is not homogeneous and that the investigated cell sample is therefore not fully representative.^{298,299}

Finally, the clinical impact of MRD detection in the various categories of lymphoid malignancies is not yet established (Table 21.10). In ALL, the main application of MRD information was shown to be the evaluation of early treatment response, with precise measurement of tumor load reduction during remis-

Table 21.9 Applicability of MRD techniques in lymphoid malignancies^a

	Flow-cytometric immunophenotyping		PCR analysis	
	Aberrant immunophenotypes (10^{-3} to 10^{-4})	Igκ/Igλ distribution or TCR-V analysis (10^{-1} to 10^{-2}) ^b	Junctional regions of Ig/TCR genes (10^{-4} to 10^{-5})	Chromosome aberrations (10^{-4} to 10^{-6})
Precursor B-ALL:				
Children	70–90%	—	~95%	40–45%
Adults	70–80%	—	~95%	35–40%
T-ALL:

ALL, acute lymphoblastic leukemia; NHL, non-Hodgkin lymphoma. MM, multiple myeloma.

^a The percentages indicate the applicability of the MRD techniques to the category of lymphoid malignancies.

^b The sensitivity of flow-cytometric detection of Igκ/Igλ distribution or TCR-V gene usage can be improved to about 10^{-3} in triple labelings with specific markers such as BCL2, cytoplasmic CD3, and ALK proteins.

^c Based on the expression of TCRαβ molecules (20% of cases) and TCRγδ molecules (about 10% of cases).

^d TCR-V antibodies recognize TCR chains in 65–70% of TCRαβ molecules and in most TCRγδ molecules.

^e Somatic mutations hamper primer annealing in some of the patients with B-NHL, B-CLL, or multiple myeloma.

^f Based on T-ALL-like immunophenotype in T-lymphoblastic lymphoma and *NPM-ALK* expression in about 50% of large cell anaplastic lymphomas of T-cell lineage.

Table 21.10 prognostic value and clinical applicability of MRD detection in different lymphoid malignancies

MM		+?*	+?	+

ALL, acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia; NHL, non-Hodgkin lymphoma; MM, multiple myeloma.
 ++ value of MRD detection proven by prospective studies;
 + potentially clinically relevant (e.g. in a subset of patients) but not yet proven by large prospective studies;
 +? MRD results are statistically significant but their clinical implication is not yet established;
 * only relevant for patients treated with more aggressive protocols and/or including anti-CD20 antibody;
 – MRD detection has no additional value as compared with conventional cytomorphological techniques.

sion induction therapy. In mature lymphoid malignancies, the value of MRD information might probably rely on monitoring over a clinically relevant disease-specific time span, with the possibility of attuning the treatment based on MRD results. Further studies are required to fully define the disease-specific 'MRD windows' for clinically reliable MRD monitoring in CLL, NHL, and MM. Current prospective studies have to demonstrate whether MRD information can be used for adaptation of treatment protocols and how the persistence of MRD positivity during long-term complete remission should be interpreted.

Detection of minimal residual disease in myeloid malignancies

Jesús F San Miguel, Marcos González, and Alberto Orfao

Introduction

Some myeloid malignancies could be considered potentially curable with the treatment strategies currently available. In fact, around one-third of patients with acute myeloid leukemia (AML) are leukemia-free at 5 years. In addition, the use of AML-oriented therapy, including stem cell transplantation (SCT), in young patients with high-risk myelodysplastic syndromes (MDS) results in an actuarial 2-year survival rate of 20–30%. Finally, 30–50% of patients with chronic myeloid leukemia (CML) are theoretically cured following allogeneic SCT. However, relapses due to the persistence of low numbers of residual neoplastic cells that are undetectable by conventional morphological techniques—minimal residual disease (MRD)—still represent a major challenge.^{1–7} Owing to this, patients are indiscriminately subjected to consolidation treatments, including SCT, in order to eradicate MRD, with the risk of certain cases being either over- or undertreated. Therefore, more sensitive techniques are needed to evaluate the effectiveness of different treatment protocols and to lay the foundations for the design of patient-adapted consolidation therapies that would reduce the risk of both relapse and overtreatment. In addition, sensitive methods for detecting MRD could be also used to assess the efficacy of ex vivo purging protocols for autologous stem cells prior to reinfusion.

The efficacy and applicability of the different methodological approaches that are available for the detection of MRD depend on three main features:⁸

- *Specificity*: discrimination between malignant and normal cells, without false-negative and false-positive results.
- *Sensitivity*: Leukemic cells are undetectable by morphology when their number falls below 1–5% of total bone marrow (BM) nucleated cells, and consequently the detection limit of a MRD technique must be at least 10^{-3} , i.e. discrimination of 1 leukemic cell among 1000 normal cells.
- *Reproducibility*: The technique should allow for easy standardization and rapid collection of results for their clinical application.^{7,8}

In addition, the possibility of predicting whether or not the residual leukemic cells are really the clonogenic cells responsible for an impending relapse would be of great clinical benefit.

At present, the strategies used in MRD detection are usually based on the identification at diagnosis of singular characteristics of the leukemic cells that allow us to distinguish them from residual normal cells in complete remission samples. Based on these leukemia-associated characteristics, a patient's probe can be 'custom-built' at diagnosis for the identification of possible residual leukemic cells during followup. Accordingly, techniques for MRD detection can be classified based on the type of cell marker used to identify the malignant cell clone, as follows:^{8,9}

- morphology;
- cell culture techniques that evaluate the pattern of in vitro colony growth;
- cytogenetic characteristics of blast cells evaluated either by conventional chromosome analysis or by fluorescence in situ hybridization (FISH);
- the analysis of total cell DNA contents detected by flow cytometry;
- the immunophenotypic profile of blast cells assessed by multiparametric flow cytometry;
- DNA sequences analyzed by polymerase chain reaction (PCR).

It should be noted that these techniques cannot be used indiscriminately for all types of leukemias, but they should be adapted depending on the markers (cytogenetic, immunological, molecular, etc.) that characterize the malignant clone. Thus, immunophenotyping is ideal for T-cell acute lymphoblastic leukemia, while PCR analysis is the method of choice for CML. Ideally, two or more techniques should be simultaneously explored in each patient, in order to define the best approach for investigation of MRD (Figure 22.1).

Figure 22.1 Simultaneous monitoring of MRD in an acute promyelocytic leukemia by immunophenotyping (results on the vertical axis are expressed as the number of residual blast cells) and by RT-PCR (results are expressed in circles as+or-).

In this chapter, we shall first review the pros and cons of the different techniques for investigation of MRD, and then we shall focus on the detection of MRD in myeloid malignancies, including AML, MDS, and CML. As we have already mentioned, the utility of the MRD techniques varies depending on the type of disorder, and therefore AML, MDS, and CML will be discussed separately. Table 22.1 illustrates the applicability and sensitivity of the different methods in these myeloid disorders. In Table 22.2 we have summarized some of the most relevant general conclusions on MRD detection in myeloid malignancies. More specific conclusions for each type of leukemia and individual technique are specified in the corresponding sections of the text.

Table 22.1 Applicability^a and sensitivity of MRD techniques in myeloid malignancies

	Morphology	Cell cultures	Cytogenetics/FISH	DNA ploidy by flow cytometry	Phenotype	PCR
AML						
Applicability	100%	100% ^b	40–70%	<5%	70–80%	40%
Sensitivity	10 ⁻²	10 ⁻²	10 ⁻² –10 ⁻³	KM-10 ⁻⁵	10 ⁻⁴ –10 ⁻⁵	10 ⁻⁴ –10 ⁻⁶
MDS						
Applicability	NA	NSE	40–70%	<5%	NSE	NSE
Sensitivity			10 ⁻²	10 ⁻⁴ –10 ⁻⁵		
CML						
Applicability	NA	NSE	90–95%	<5%	NSE	95–100%
Sensitivity			10 ⁻³	10 ⁻⁴ –10 ⁻⁵		10 ⁻⁵ –10 ⁻⁶

AML, acute myeloid leukemia; MDS, myelodysplastic syndromes; CML, chronic myeloid leukemia; FISH, fluorescence in situ hybridization; PCR, polymerase chain reaction; NA, not applicable; NSE, not sufficiently explained.

^a Applicability is defined as the proportion of cases in which the technique is applicable.

^b By either CFU-L or CFU-GM assays.

Table 22.2 General conclusions on MRD detection in myeloid malignancies

- Prospective studies to evaluate the utility and specificity of the techniques used for MRD detection are still needed in some myeloid malignancies (e.g. myelodysplastic syndromes)
- The applicability of MRD techniques varies depending on the type of leukemia
- Assessment of the quality of the response to induction treatment by immunological or molecular methods is of prognostic value
- The terms ‘immunological/molecular response’ provide complementary information to morphological complete remission
- Evaluation of residual cells should be performed in the stem cell harvest to be used for autologous transplantation and to assess the efficacy of purging methods
- It is important to define relevant clinical time points to measure MRD, since sequential studies are laborious and expensive
- Switches from negative to positive results are highly predictive of impending relapse
- MRD negativity does not exclude the existence of minimal numbers of residual leukemic cells, since only 10⁶ cells are usually screened.

Methodological considerations concerning MRD techniques

Morphology

Morphology is not a real MRD technique but the current gold standard for the definition of complete remission (CR). As mentioned above, the sensitivity of morphological analysis for the detection of leukemic cells is low (10^{-2} , which represents a possible residual tumor burden of up to 10^{11} cells). Moreover, special difficulties emerge in regenerating bone marrow samples, and the need for routine bone marrow examination to detect relapse in acute leukemia has been questioned.^{10,11}

Cell cultures

The investigation of the persistence of leukemic cell colonies (colony-forming units leukemic, CFU-L) or the existence of an abnormal growth pattern of colony-forming units granulocyte-macrophage (CFUGM) can represent a useful approach for MRD detection in myeloid leukemias.^{12,13} A major concern with CFU-L assays is the discrimination between leukemic colonies and normal CFU-GM, which may be difficult to establish, especially if we consider that we are not dealing with diagnostic samples but with specimens from patients in morphological CR. However, the leukemic colonies grow faster than normal CFU-GM, so the former should be scored by days 3–6 and the latter by day +14. The characterization of each individual colony by means of tumor-specific markers such as cytogenetics, immunophenotype, or molecular markers will contribute to the unequivocal assessment of the leukemic origin of cells grown in vitro. Interestingly, the investigation of tumor markers (i.e. chromosomal aberrations or junctional regions of rearranged immunoglobulins) in the cells of the CFUL has shown that these cells may be more sensitive than the uncultured BM cells for showing up residual disease, since the tumor marker has been detected in the colony but not on the fresh cells.^{12,14} However, a major problem with this approach is that CFU-L may persist in patients who remain in continuous CR for many years and who are therefore cured,¹⁵ suggesting that in these cases, CFU-L are not really the clonogenic cells responsible for disease progression. Another possible pitfall of this approach for MRD detection is the presence of suboptimal culture conditions for leukemic cell growth, which would generate false-negative results.

Cytogenetics and FISH

Chromosomal abnormalities, both numerical and structural, are specific leukemic markers. However, the sensitivity of conventional cytogenetics for their detection is low (10^{-2}). Thus, although it is a most valuable technique for diagnostic purposes, it is not very useful for residual disease.¹⁶ Two additional limitations of cytogenetics are related to the fact that (i) analysis is restricted to metaphases, which are difficult to obtain in several types of leukemias, and (ii) when cells are cultured to obtain metaphases, a clonal selection can be induced.

FISH can be considered as cytogenetic studies at a molecular level, since it allows the identification of specific DNA sequences, both in chromosome metaphases and interphase nuclei using either chromosome-specific and/or gene-specific DNA probes. The possibility of studying interphase nuclei is particularly useful for the analysis of malignant disorders with low proliferative index. A limiting factor on the level of detection of chromosome changes with FISH is the efficiency of the hybridization process. The sensitivity of FISH when using centromeric probes for detection of trisomies is relatively low (around 1%), and even lower (10%) for monosomies. These figures are based on the false-positive (0.2–1%) and falsenegative (0.5–5%) rates obtained upon analyzing normal diploid cells.^{17,18} Nevertheless, when two or more numerical chromosome aberrations coexist, the possibility of false-positive and/or false-negative signals decreases, leading to an increased sensitivity of up to 10^{-3} to 10^{-5} .¹⁸ The detection of chromosomal translocations (e.g. *BCR-ABL*) by FISH, using probes that either flank or span a translocation breakpoint, can be used to identify the presence of such marker chromosomes in interphase and metaphase cells through the identification of one fused signal.¹⁹ However, its sensitivity for MRD detection is again low (10^{-2}), due to the possibility of artifactual colocalization of the two fluorochrome signals.¹⁹ An increase in sensitivity of up to one logarithmic decade is achieved for those probes that split into two signals once a translocation occurs, such as for t(16;16) or inv(16) and 11q23 abnormalities. An attractive possibility is the combination of FISH and immunophenotypical analysis, either simultaneously or after cell sorting on the basis of leukemic-associated immunophenotypic characteristics, which would notably increase the sensitivity since it would identify individual tumor cells with a double marker: chromosome/antigen.^{9,10}

Measurement of DNA ploidy by flow cytometry

The analysis of cell DNA contents by flow cytometry allows the identification of clonal abnormalities—DNA aneuploidy—present in leukemic cells through comparison of the DNA contents of the tumor cells with that of normal diploid cells in the same cell cycle phase. In cases with an aneuploid cell population, this could be easily monitored during follow-up. For the identification of an aneuploid peak, a gain or loss of total DNA greater than 5% is usually required.

Therefore, the sensitivity of this technique is similar to that of morphology when used alone. Nevertheless, we have shown that with simultaneous staining for DNA content and leukemic-associated antigens that identify the cells from the malignant clone, the sensitivity increases to between 10^{-4} and 10^{-5} , allowing a specific and sensitive detection of aneuploid cell populations during follow-up.²

Immunophenotype

Immune marker analysis and PCR studies are the two most commonly employed methods for the detection of MRD.^{2,4-8} Immunophenotypic analysis is theoretically an optimum method because of its relative speed and simplicity. In addition, it provides a quantitative evaluation of the number of cells present in the sample. However, it has two potential major pitfalls that could limit its specificity: (i) the lack of leukemia-specific antigens in most cases—with the exception of some proteins resulting from fusion genes such as *BCR-ABL* or *PML-RAR α* , although reliable monoclonal antibodies (MoAbs) for their detection are not yet available—and (ii) the occurrence of phenotypic changes at relapse. Regarding the first problem, our group^{20,21} as well as several others^{5,6,22-24} using large panels of MoAbs in three- and four-color combinations analyzed by flow cytometry, have shown that leukemic cells frequently display uncommon or aberrant phenotypic features that allow us to distinguish them from normal cells. These phenotypic aberrations generally concern cross-lineage antigen expression, maturational asynchronic antigen expression, abnormal differentiation pathways, antigen overexpression, altered light scatter patterns, and/or ectopic antigen expression.^{5,8,9,25,26} Such aberrations constitute unique phenotypic patterns that can be used as 'leukemia-associated' markers that will contribute to the specific identification of residual malignant cells during follow-up. In spite of initial concerns about the sensitivity of immunophenotyping for the detection of low numbers of leukemic cells, both in vitro dilutional experiments mixing-up leukemic and normal cells^{1,4-6} and in vivo studies^{2,21,22,24-26} point to a sensitivity ranging between 10^{-4} and 10^{-5} , depending on the type of leukemia and the combination of monoclonal antibodies used for monitoring residual neoplastic cells.

An additional advantage of immunophenotypical studies is that they provide dynamic information concerning the differentiation of leukemic cells as regards their maturational blockade.

Molecular biology

Leukemic cells may display two types of tumorspecific markers that can be used for MRD detection at a molecular level: breakpoint fusion regions of chromosome abnormalities and junctional regions of rearranged immunoglobulin (Ig) and T-cell receptor (TCR) genes.^{6,7,27} These targets can be analyzed by Southern blot or PCR techniques. The first method has a low sensitivity (10^{-2}), and thus is not really an MRD detection technique. By contrast, PCR is one of the best tools for the investigation of residual leukemia, with a potential detection limit of up to 10^{-6} , depending on the type of leukemia-specific PCR target. The junctional regions of rearranged Ig and TCR genes are 'fingerprint-like' sequences, which differ from one lymphocyte to the other and thus also within each lymphoid leukemia.^{7,8} The strategy for MRD detection using this target implies the identification at diagnosis of the various possible patterns of Ig and/or TCR gene rearrangements and then determination of the precise nucleotide sequence of the junctional region in order to design a patient-specific probe or primer for the detection of residual leukemic cells during follow-up. MRD via chromosomal abnormalities is simpler and can be analyzed either at the DNA level—so long as that the breakpoint occurs at a constant region of small size (<2 kb)—or at the RNA level. For this second choice (the most common one), the translocation should produce a leukemia-specific fusion mRNA that can be used as PCR target after reverse transcription into cDNA (RT-PCR).²⁷ In contrast to Ig/TCR gene rearrangements, translocations are not patient-specific but rather tumor-specific markers. Although PCR techniques are potentially very powerful for MRD detection, they have several limitations (including subclone formation and clonal evolution, cross-contamination of PCR products between patient samples, amplification of sequences of normal cells, and poor quality of DNA or RNA samples)—all of these problems may lead to either falsepositive or false-negative results in MRD investigations.^{6,7,28} Moreover, quality control studies have shown a great variability in both intra- and interlaboratory results. Therefore, improvement in the standardization of this methodology is still required. In this context, a collaborative program carried out through a BIOMED-1 concerted action led to the development of standardized nested RT-PCR assays, suitable for the detection of MRD as well as for diagnostic screening.²⁷ MRD studies by qualitative or semiquantitative PCR analysis have been shown to be clinically relevant in some particular situations (childhood ALL, *BCR-ABL* in CML patients following allogeneic transplant and *PML-RAR α* in acute promyelocytic leukemia (APL) patients after consolidation therapy).²⁷ However, these methods fail to demonstrate clinical impact in leukemias associated with other chromosome aberrations (e.g. *AML-ETO*). This is probably due to the fact that this 'endpoint' PCR analysis does not allow a precise quantitative evaluation of the number of residual tumor cells in the sample. Thus, a quantitative PCR assay (e.g. competitive PCR) could improve the predictive capacity

of RT-PCR in some chromosome aberrations (e.g. *MBCR* in CML, *CBFβ-MYH11*, *AML1-ETO*). However, competitive PCR techniques are labor-intensive, prone to cross-contamination, and time-consuming, which precludes their use in both standardization protocols and large prospective therapeutic trials. More recently, automated real-time quantitative PCR (RQ-PCR) technology has demonstrated its reliability and potential utility for MRD studies on different fusion transcripts (e.g. *M-BCR*, *PML-RARα*, and *AML1-ETO*) and for the detection of clonal rearrangements of Ig and TCR genes.^{29,30} The results of a Europe Against Cancer program of standardization and quality control studies of RQ-PCR for MRD detection of fusion-gene transcripts in leukemia have been published.²⁹

Detection of MRD in AML: clinical studies

Although experience in MRD detection is more limited in AML than it is in ALL, several clinical studies including small series of patients have been reported, based mainly on either molecular or immunophenotypical methods for the assessment of residual neoplastic cells.^{1,31–35} In this review, we shall comment on clinical results reported for the different techniques available for MRD detection in AML and discuss possible pitfalls of these techniques.

Morphology in AML

Relapse of AML patients is classically defined by the presence of 5% or more myeloblasts, morphologically identified in BM samples. As we have already mentioned, this is not a sensitive assay, particularly in those patients receiving chemotherapy, due to the difficulty in making a morphological distinction between leukemic blast cells and normal regenerating myeloid precursor cells. In fact, although the morphological assessment of BM is a very specific outcome-predictor assay for patients displaying over 5% blast cells following AML induction therapy—refractory disease with very poor prognosis—in the remaining patients (<5% blast cells, ‘morphological CR’), its predictive value is uncertain since some of these patients will remain in continuous CR while many others will relapse. Moreover, there is some controversy surrounding the value of routine morphological BM examinations to detect recurrence of AML. Accordingly, several cooperative groups such as Cancer and Leukemia Group B (CALGB), the Eastern Cooperative Oncology Group (ECOG), and the Southwestern Oncology Group (SWOG) have called for serial marrow aspirations every 2–3 months for the first year and every 3–5 months for the following 2 years. However, two reports including 69³⁶ and 444¹¹ relapsed AML patients showed that an abnormality in peripheral blood cell counts preceded or coexisted with BM relapse in 97% and 84% of cases, respectively. According to these results, BM aspirations for morphological examinations would be superfluous in over 80% of AML patients, providing that peripheral blood counts are frequently obtained (i.e. weekly). However, this would depend on the age of the patient and the planned therapy, since patients who are candidates for an allogeneic transplant may benefit from an earlier detection of relapse. In addition, as we shall discuss below, the situation may be completely different if the BM sample is going to be examined for residual cells using other MRD techniques.

Cell cultures in AML

Few studies have been performed to evaluate the clinical value of investigating the growth of leukemic colonies (CFU-L) for MRD detection in AML. In a series of 43 AML patients in remission before autologous transplantation, Miller et al¹² found that the assay was not predictive of relapse, since CR samples from 80% of the patients showed CFU-L growth. However, they observed that the sensitivity of the clonogenic cells to 4-hydroperoxycyclophosphamide (4-HC) used to purge the autografts correlated with outcome; of the 23 patients in which the CFU-L were sensitive to 4-HC treatment, only 18% relapsed, while of the 22 resistant AML patients, 77% had relapsed. Gerhartz and Schmetzer¹⁴ combined immunophenotyping with CFU-L analysis, demonstrating growth of colonies with abnormal antigen coexpression in 17 out of 19 AML patients in morphological CR. Although this pattern was associated with relapse, frequent false-positive results occurred in sustained remission.

A different approach to the exploitation of cell cultures for investigation of MRD is based on the hypothesis that the persistence of residual leukemic hemopoiesis will alter the growth pattern of normal granulomonocytic progenitors (CFU-GM) in AML patients. For this reason, we explored the utility of the CFU-GM assay in predicting relapse in 36 de novo AML patients in morphological CR.¹³ Our results showed that all patients who achieved a normal CFUGM growth pattern remained in CR, but that a median of 6 months after chemotherapy is necessary before a stable growth pattern is achieved. Leukemic relapse was always preceded by an abnormal CFU-GM pattern, although there were cases with anomalous growth who remained in CR.

Cytogenetics and FISH in AML

In spite of its low sensitivity, conventional cytogenetics has proved to be a reliable marker for monitoring response to therapy in AML patients due to its high

specificity. The persistence of cells in CR samples that show the same karyotypic abnormality found at diagnosis has traditionally been considered a high-risk prognostic factor for impending relapse. Accordingly, Freireich et al¹⁶ studied 71 AML patients in morphological CR who had specific karyotypic abnormalities at diagnosis (inv (16), t(15;17), trisomy 8, etc.). In 20 patients, the cytogenetic aberration persisted in CR samples and all of them relapsed within the next 78 weeks. Nevertheless, from the remaining 51 patients with normal cytogenetics at CR, 25 have also relapsed. Therefore, although false-positive results are unlikely to occur, false negatives are relatively frequent. A possible explanation for these latter cases is the technical inability to obtain metaphases from the leukemic cell clone when the number of these cells is very low.

Preliminary reports suggest that due to its high specificity and the possibility of analyzing both metaphase chromosomes and interphase nuclei, FISH is a promising approach to detect low numbers of residual leukemic cells. At present, the reported experience of the detection of MRD in AML is still scanty and, as mentioned above, the sensitivity usually found to be low (10^{-2}) unless combined with other methods. Nylund et al¹⁷ analyzed the predictive value of the investigation of trisomy 8 and t(15;17) in both metaphase and interphase nuclei obtained from BM samples in morphological CR from 11 AML patients. Eight patients had trisomy 8 at diagnosis, and this alteration was detected during follow-up in either metaphase or interphase cells from 3 and 2 patients respectively, who subsequently relapsed. In addition, in one patient, the use of appropriate probes showed persistence of residual cells with t(15;17) prior to relapse. By contrast, two M3 leukemias that became FISH-negative remained in clinical remission. Zhao et al³⁷ analyzed residual leukemic cells in 10 APL patients in clinical remission. In 6 of them, no cells with t(15;17) were found, and all these cases remained in CR for 25–33 months after the first FISH study. In 4 patients who had a relapse, FISH evaluation showed low numbers (2–4%) of residual cells with t(15;17) before relapse (1–14 months' interval between FISH detection and clinical relapse). Interestingly, these 4 cases were negative by conventional cytogenetics for t(15;17).

In an attempt to increase the sensitivity of FISH techniques, Varella-Garcia et al³⁸ sorted CD34⁺ cells from CR AML patients and analyzed by FISH the genetic aberrations detected at diagnosis, reaching a sensitivity of detection of 1 leukemic cell in 10^4 normal cells. They have used this approach to study 20 AML patients in morphological CR. Residual disease was observed prior to relapse in 5 of 7 evaluable patients. In contrast, out of the 12 AML patients in whom residual disease was undetectable, 11 remained in continuous CR for a median period of 38 weeks.

DNA aneuploidy in AML

The reported incidence of DNA aneuploidy detected by flow cytometry in AML ranges between 5% and 35%. In our experience, only 10 out of 205 de novo AML patients (4.9%) had DNA aneuploidy, many of these cases corresponding to tetraploid AML patients.³⁹ Therefore, this approach would only be applicable to a minority of AML patients, which, as previously discussed, together with its low sensitivity, indicate that it is useless for MRD investigation in AML.

Immunophenotyping in AML

Basis of MRD detection in AML

A precise identification of leukemic cells is essentially based on the ability to clearly distinguish them from the normal cells present in the specimen. Accordingly, phenotypic patterns of normal cells present in all types of samples used for the diagnosis of hematological malignancies must be well established. It has traditionally been considered that leukemic cells reflect the immunophenotypic characteristics of normal cells blocked at a certain differentiation stage. However, as we have previously mentioned, the use of multiparametric flow-cytometric analyses and large panels of MoAb combinations has shown that leukemic cells frequently display aberrant or uncommon phenotypic features that allow their distinction from normal cells.^{21,22,24,26,40–42} Table 22.3 shows several phenotypic patterns based on the assessment of myeloid antigens

Table 22.3 Acute myeloid leukemia: incidence of the most frequent phenotypic patterns that are absent or present at very low frequencies ($<10^{-4}$) in normal bone marrow

Phenotypic pattern	Incidence (%)
Asynchronous antigen expression	
CD33 ⁺⁺ HLA-DR ⁻ CD34 ⁻ CD15 ⁻ CD14 ⁻	17
CD33 ⁻ CD13 ⁺	14
CD117 ⁺ CD33 ⁺ HLA-DR ⁻	11
CD34 ⁺ HLADR ⁻ CD33 ⁺	9
CD34 ⁺ CD56 ⁺	8
CD33 ⁺ CD13 ⁻	7
CD117 ⁺ CD11b ⁺	6
CD117 ^{dim} CD34 ⁻ CD15 ⁻	6
CD34 ⁺ CD11b ⁺	5
Cross-lineage antigen expression	
CD2 ⁺	21
CD7 ⁺	9
Antigen overexpression	
CD33 ⁺⁺⁺	11
CD34 ⁺⁺⁺	9

that are undetectable ($<10^{-4}$) or present at very low frequencies ($<10^{-3}$ cells) in normal adult BM and therefore suitable for MRD investigation in those AML cases in which blast cells display such phenotypes. Although preliminary studies reported a variable incidence of aberrant or 'leukemia-associated' phenotypes in AML, ranging from 30% to 85% depending on the criteria used for their definition and the panel of monoclonal antibodies employed,^{5,7,21,22,24,26,31,41,43-45} more recent reports^{21,22,24} consistently find aberrant phenotypes in 70–80% of patients (Table 22.4). In our experience, 75% of AML patients display aberrant phenotypes, two or more aberrations coexisting in most of them (56%).^{21,41} Therefore, according to these results, immunophenotypic detection of MRD is feasible in three-quarters of AML patients. The most common type of leukemia-associated phenotype found is the presence of asynchronous antigen expression (in 78% of aberrant cases), caused by the coexistence of two antigens that are not simultaneously expressed in normal differentiation or by the lack of reactivity for the panmyeloid antigens CD13 and CD33. Examples of these phenotypic aberrations are CD34⁺CD56⁺, CD34⁺CD11b⁺, CD34⁺CD14⁺, CD117⁺HLA-DR⁺CD15⁺, and CD33⁺CD13⁻CD15⁺, CD33⁻CD13⁺CD15⁺. Crosslineage expression of lymphoid-associated markers (e.g. CD2, CD7, and CD19) in myeloid blast cells is observed in around one-third of cases.^{40,41} Finally, abnormal light scatter patterns and overexpression of the myeloid cell-related markers (CD34, CD13, CD33, CD15, and CD14) contribute to the definition of around 15% and 20% of leukemia-associated phenotypes, respectively.^{21,40,41} The sensitivity of this approach for the identification of residual AML blast cells ranges between 10^{-4} and 10^{-5} , depending on the type of aberration explored and the normal background. Since the strategy for MRD detection using immunological methods has up till now relied mainly on the identification of residual cells with the same phenotypic aberration detected at diagnosis, a possible major limitation on this type of study is the existence of phenotypic switches during the evolution of the disease. In this sense, several groups, including our own,^{1,6,21,22,25,40,44,46} have observed that at relapse, changes in the expression of individual markers

Table 22.4 Incidence of leukemia-associated immunophenotypes in acute myeloid leukemia

Leukemic phenotype	Incidence (%)
Asynchronous antigen expression	60–70
Cross-lineage antigen expression	30–40
Antigen overexpression	20–30
Abnormal light scatter	15–20
Overall	70–80

(CD15, CD14, CD11b, and HLA-DR) are relatively common in AML, involving between 63% and 90% of cases, depending on the number of antigens tested. Such changes are usually maturation-associated, more immature blast cell populations being present at relapse.^{22,41} Despite this instability, such phenotypic modifications do not usually affect antigens that define the 'leukemia-associated phenotypes',²⁵ and, in our experience, only occur in 16% of all AML patients.⁴⁶ Accordingly, in cases with more than one 'leukemic phenotype', simultaneous investigation of all of them will reduce the possibility of false-negative results due to the occurrence of a phenotypic switch. Moreover, the systematic use of multiple antibody panels analyzed by multiparameter flow cytometry would have the potential to identify different aberrant phenotypic patterns from residual leukemic cells during follow-up, but at the expense of increased cost.

Until recently, the immunophenotypic detection of MRD was based on the antigenic characteristics of the predominant blast cell population at diagnosis.^{5,31,44} However, it is well known that several leukemic subpopulations with different phenotypic characteristics may be present at diagnosis,^{5,20,22,43} and perhaps a minor one may be the resistant clone responsible for relapse. In our experience, 80% of AML patients have two or more cell populations, often small in size, containing less than 10% blast cells.²⁰ These subpopulations frequently correspond to different stages of maturation of the neoplastic clone. According to this observation, the investigation of MRD should be based on the phenotypic characteristics of each subpopulation. An additional conclusion from the study of cell subsets in AML is that some of the reported phenotypic switches are not real, but correspond to an expansion, during disease evolution, of a very small cell subpopulation that went undetected at diagnosis. Figure 22.2 illustrates an APL that relapsed with an immature CD34⁺ phenotype (100% of cells), while at diagnosis most leukemic cells were more mature and only 10% of the blast cells expressed this specific CD34⁺ phenotype.

Clinical results

Although the number of reports on the clinical value of immunophenotypic detection of MRD in AML has increased in recent years, the information so far available is still scanty, and sometimes not based on five or six parameter flow cytometry studies but simply on double marker combinations. Early studies by Adriaansen et al³¹ and Campana et al,¹ based on the aberrant coexpression of terminal deoxynucleotidyl transferase (TdT) and myeloid markers (CD13/CD33) (cross-lineage marker expression), showed the value of this phenotypic combination to detect MRD in AML patients. The criteria used to define TdT positivity at diagnosis were different in the two studies, since Adriaansen et al³¹ included all cases that displayed

Figure 22.2 Acute promyelocytic leukemia: at diagnosis (a), only 10% of blast cells expressed CD34 antigen, while at relapse (b), most leukemic cells (90%) expressed it.

over 1% TdT⁺ myeloid leukemic cells, while for Campana et al,¹ the cut-off value was much higher. In this latter series, from the seven patients included, residual disease persisted during follow-up in four patients, all of whom subsequently relapsed, by contrast, only one of the three negative cases relapsed. In the series by Adriaansen et al,³¹ 9 of the 10 relapses observed were preceded, over a period of 14–38 weeks, by a gradual increase of TdT⁺CD13⁺ cells. In five additional patients who remained in continuous CR, TdT⁺ CD13⁺ blast cells were detected, but their number did not increase during follow-up. It should be noted that later studies showed that early lymphoid progenitors may coexpress the myeloid-related CD13 and CD33 markers, which could at least partially explain these findings.⁴⁷ Drach et al⁴⁴ followed three patients who also displayed a lineage infidelity (CD13⁺CD7⁺) and in whom the persistence of these cells was predictive of relapse. Campana and Pui²⁵ studied by multiparameter flow cytometry 13 children in CR after BMT. In 4 patients, residual leukemic cells were observed, and all relapsed within 2 months after the phenotypical detection. In the remaining 9 patients, leukemic cells were not detected, and 7 of them remain in CR with a median follow-up of more than 1 year after transplant. The other two patients relapsed and, according to the authors, should be considered false-negative cases. Reading et al⁴³ studied 16 AML patients in morphological CR using three-color stainings analyzed at flow cytometry: 6 had over 0.2% phenotypically aberrant cells in the first-remission BM aspirate, and all relapsed between 1 and 7 months later. Conversely, of the 10 patients with less than 0.2% aberrant cells, only 1 relapsed during the followup period. These findings are consistent with those of Wörman et al,³² who also quantitated the number of residual cells in a series of 45 adult patients. In two-thirds of cases over 0.5% phenotypically aberrant cells were detected in the first-CR bone marrow samples, and half of these patients relapsed within 1 year. As far as our own experience is concerned,²¹ in a series of 126 AML patients followed for a median period of 2 years, we have observed that the immunophenotypic enumeration of residual cells with leukemia associated phenotypes on the first-remission BM sample, obtained at the end of induction therapy, correlates with both disease-free and overall survival. Accordingly, four different risk group categories could be established based on the MRD levels: (1) very low-risk (<10⁻⁴ residual leukemic cells); (2) low-risk (between 10⁻³ and 10⁻⁴ residual tumor cells); (3) intermediate-risk (between 10⁻² and 10⁻³ residual neoplastic cells); and (4) high-risk (>10⁻² residual leukemic cells); the relapse-free survival rates at 3 years for these risk groups were 100%, 85%, 55%, and 25%, respectively. An adverse prognostic impact of MRD levels was also observed once APL and non-APL AML cases were analyzed separately; multivariate analysis of prognostic factors showed that the MRD level together with cytogenetics were the most powerful independent prognostic factors for predicting disease-free survival.²¹

Reports by other groups have confirmed our observations. Accordingly, Vendetti et al²⁴ and Lahuerta et al⁴⁸ have found that the persistence of 3.5×10⁻⁴ or more and over 8×10⁻³ immunophenotypically aberrant cells either at the end of consolidation or prior to transplantation, respectively, strongly predict relapse.

Taking all this data together we can state that:

- The persistence or the increase in the number of phenotypically abnormal cells during follow-up of AML patients is usually associated with relapse.
- The number of aberrant cells in the remission BM aspirate correlates with relapse. This indicates that for predicting outcome in AML patients achieving CR, immunological evaluation of residual disease is more accurate than morphological examination. Therefore, the term ‘immunological remission’ is complementary to ‘morphological CR’.
- The enumeration during follow-up of residual leukemic cells by immunophenotyping may also help to individualize the therapeutic approaches in AML patients in order to reduce both over- and undertreatment during the consolidation and intensification phases.

Molecular biology in AML

Chromosomal translocations, including t(15;17), t(8;21), inv(16), 11q23 aberrations, t(6;9), and t(9;22), which together account for 30–40% of AML cases (Table 22.5), are the most efficient tumor-specific PCR targets in AML patients.²⁷ However, in order to cover a larger number of patients, other potential MRD-PCR targets (e.g. *WT1* and *FLT3*) have been developed. Moreover, other strategies could be used for MRD monitoring in patients without cytogenetic abnormalities in the allograft setting, such as detection of the Y chromosome or chimerism studies on FACS-sorted material (e.g. cells with the immunophenotypic characteristics of the original leukemic clone).⁴⁹ In addition, approximately 10–15% of AML patients have cross-lineage Ig or TCR gene rearrangements⁵⁰ with identifiable junctional regions, but clinical MRD—PCR studies using this approach have not been reported.

In this section, we shall comment on the clinical applications of MRD-PCR studies, concentrating on those for which clinical information is currently available.

Molecular monitoring of *PML-RARα* transcripts in AML with t(15;17)(q22;q21)

This reciprocal chromosomal translocation is a specific characteristic associated with APL, including both the hypergranular (French-American-British (FAB) AML-M3) and microgranular (FAB AML-M3v) variants, secondary APL, and the promyelocytic blast crisis of CML leukemia.⁵¹ As a consequence of the translocation, two chimeric genes, *PML-RARα* (detected in 100% of cases) and *RARα-PML* (detected in 70% of AML patients) are formed. The *PML* breakpoints cluster within three regions (intron 6 bcr-1 or L-long-form, exon 6 bcr-2 or V-variable-form, and intron 3 bcr-3 or S-short-form) that fuse with the 3' portion of *RARα* intron 2.⁵¹ Using appropriate primers, it is possible to amplify the different *PML/RARα* mRNA isoforms by RT-PCR in all APL cases, even if cytogenetic analysis has failed to identify t(15;17). The detection of *PML/RARα* has therapeutic implications, since the rare APL cases with the variant t(11;17) failed to respond to all-trans-retinoic acid (ATRA).⁵¹ Moreover, a reduced sensitivity to ATRA has also been described in patients with the bcr-2 (or V) isoform. However, the number of cases is limited and most of these patients display additional cytogenetic abnormalities, so that no clear conclusions can be drawn.^{52,53}

Several groups using conventional nested RT-PCR have reported that molecular monitoring of *PML-RARα* is clinically relevant in APL.^{33,51,54,55} These studies revealed that qualitative RT-PCR positivity after consolidation treatment was highly predictive of clinical relapse, whereas a PCR-negative result was associated with prolonged disease-free survival. On the other hand, studies performed within the first months after induction revealed PCR-positive results in nearly 50% of the cases, but this early positivity does not correlate with response to treatment.^{51,55} However, a study from the UK Medical Research Council (MRC) has shown that analysis of the kinetics of *PML-RARα* transcript reduction could be a useful parameter to identify subgroups of patients with a different risk of relapse.⁵⁶ These

Table 22.5 Detection of chromosome translocations by RT-PCR

Cytogenetic abnormality	Individual genes	AML subtype	Frequency of applicability (%)
t(15;17)(q22;q21)	<i>PML/RARα</i>	AML-M3 (APL)	10–30 ^a

^a The incidence of t(15;17) in some areas of Europe (Italy) and some US and South American Latino populations is higher (30%).

studies^{33,51,54–56} indicate that patients in whom *PML-RAR α* transcripts persist at the end of consolidation therapy or patients who convert to RT-PCR positivity after a negative result are at great risk of relapse. Indeed, preliminary data suggest that early treatment at the stage of molecular relapse leads to improved survival in comparison with patients who were retreated in overt hematological relapse.⁵⁷ Moreover, MRD studies are of value to predict outcome following autologous SCT in APL patients in second CR.^{51,55}

At present, the availability of modern protocols containing concomitant ATRA plus chemotherapy had produced a remarkable improvement in the outcome of APL patients, associated with a relapse risk of only 10–20%.^{51,53} Thus, the major limitation of qualitative RT–PCR assays is their failure to identify these small subgroup of patients who ultimately relapse, which may be a reflection of RNA quality and/or assay sensitivity.⁵⁸ Previous European quality control programs show that the number of unsuitable samples for MRD studies ranged from 20% to 50% due to poor quality samples that could potentially give rise to ‘falsenegative’ results.^{51,55} The sensitivity of conventional nested RT-PCR for detection of *PML-RAR* transcripts is lower than in other translocations, such as *AML1-ETO*, which could explain also the existence of false-negative results.²⁷ Interestingly, the detection of *RAR α -PML* is more sensitive than that of *PML-RAR α* , since in 8 out of 30 CR samples in which both chimeric genes were simultaneously analyzed, *RAR α -PML* transcripts were detected while *PML-RAR α* was negative.^{58,59} However, study of this transcript can produce both false-negative results (*RAR α -PML* negative in patients who ultimately relapse) and false-positive results (persistence of *RAR α -PML* fusion mRNA in patients in long-term remission).^{58,59} Taking all this data together, we can see that there is still room for improvement in MRD detection in APL, and RQ-PCR could provide additional information to overcome these limitations (quantitation of *PML-RAR α* and control gene transcripts to determine the exact level of MRD and identification of poor quality samples).²⁹ Preliminary studies using RQ-PCR are encouraging, and a retrospective analysis found that RQ-PCR increased rates of MRD detection in comparison with the qualitative assay and was an independent predictor of relapse risk and overall survival. However, it is clear that this new approach needs to be evaluated in the context of large-scale multicenter clinical trials to establish guidelines to use RQ-PCR data for clinical decision-making.²⁹

Molecular monitoring of *AML1-ETO* transcripts in AML with t(8;21) (q22;q22)

The t(8;21) is one of the most frequent chromosomal abnormalities in AML (7–20%), especially in the FAB M2 subtype (20–40%), with a higher incidence in younger patients.^{60,61} Although most t(8;21) (90%) have been described in AML-M2, it has also been reported in about 3–6% of AML-M1 and, less frequently, in AML-M4 and other myeloproliferative syndromes.^{60,61} Myeloid leukemias with t(8;21) show common features, both morphological (blasts with abundant cytoplasm with large vacuoles, numerous granules, and prominent Auer rods) and immunological (CD19, CD56, and CD34 expression, with absence or dim reactivity for CD33).⁶¹

Molecular characterization of t(8; 21) has shown that it involves the *AML1 (RUNX1)* gene on chromosome 21 and the *ETO* gene on chromosome 8, which fuse to form a new hybrid gene on the der(8) chromosome.⁶⁰ In contrast to t(15;17) and inv(16), the breakpoints within the *AML1* gene and the *ETO* gene occur in an area highly conserved within a single intron of both genes; therefore, an identically sized band is detected by RT-PCR in nearly all patients.^{60,61}

From a clinical point of view, this translocation has been associated with good response to chemotherapy (cytarabine), a high remission rate, and prolonged disease-free survival. For these reasons, and because *AML1-ETO* has also been described in AML patients negative by conventional cytogenetics,⁶¹ molecular screening for *AML1-ETO* would be advisable for all AML patients where morphology and/or immunophenotyping suggest the presence of t(8;21). This should avoid overtreatment strategies such as allogeneic SCT in patients who can be cured with standard chemotherapy.

Studies of MRD in patients with t(8;21) suggest that conventional nested RT-PCR may have limited value. Accordingly, *AML1-ETO* fusion transcripts have been found in patients in long-term remission after chemotherapy or autologous SCT and even allogeneic SCT.^{60,62,63} These data suggest that patients who are considered to be clinically cured may still have molecular evidence of MRD, suggesting that t(8;21) may represent only one of the necessary steps for the development of leukemia and that additional genetic abnormalities may be required for the overt clinical expression of the acute leukemia. Thus, the finding that in AML patients with t(8;21), the *AML1-ETO* fusion can also be expressed in non-leukemic stem cells, monocytes, and B cells is concordant with this hypothesis.⁶³ Moreover, these data are probably a reflection of the higher levels of the sensitivity achieved with qualitative RT-PCR for *AML1-ETO* (10^{-5} to 10^{-6}) as compared with those achieved for other AML fusion genes, such as *PML-RAR α* (10^{-4}). In line with this hypothesis, a study has shown that conventional *AML1-ETO* RT-PCR is predictive of outcome when a single-step PCR (sensitivity of 10^{-4}) instead of nested PCR (sensitivity of 10^{-6}) is carried out.⁶⁴

In order to improve the predictive value of qualitative RT-PCR studies, a quantitative analysis of *AML1-ETO* transcripts has been developed.

Miyamoto et al,⁶⁵ by studying peripheral blood stem cell (PBSC) harvest samples from 15 patients collected after both the first and the second consolidation cycles, have found that in all patients the number of *AML1-ETO* transcripts was lower in the second PBSC harvest than in the first. However, no correlation was found between the number of *AML1-ETO* transcripts in the infused PBSC harvest and the clinical outcome after autologous blood SCT (ABSCT). Other competitive RT-PCR studies performed by the Manchester group⁶⁶ have shown that this method could help to predict relapse for up to 6 months before the onset of overt relapse and, furthermore, it is able to identify MRD threshold levels above which patients would relapse within 3–6 months. On the other hand, patients with low or undetectable levels of *AML1-ETO* transcripts were associated with maintenance of continuous CR. Data produced to date, from RQ-PCR have essentially confirmed results obtained by competitive RT-PCR, but experience is limited to small numbers of patients. These encouraging results suggest that RQ-PCR assay could be applied in large-scale clinical trials.

Molecular monitoring of CBFβ-MYH1 / transcripts in AML with inv(16) and t(16;16) (p13;q22)

The pericentric inversion of chromosome 16 *inv(16)(p13;q22)*—and the less common but molecularly similar *t(16;16)(p13;q22)* are closely associated with the M4Eo AML subtype (in nearly 100% of cases), although they may also be detected in AML cases with FAB M2, M4, and M5 morphology and in MDS.^{35,67} This chromosomal abnormality involves the *CBFβ* gene on 16q22 and the *MYH11* gene on 16p13, which produce the *CBFβ-MYH11* fusion gene. RT-PCR assays have been developed to detect *CBFβ-MYH11* fusion transcripts, showing that this assay can detect chimeric mRNA in over 90% of cases with *inv(16)* or *t(16;16)*. These studies have demonstrated the existence of a marked molecular heterogeneity, and at least seven types of fusion transcripts (A-H) have been reported, type A being the predominant (80% of AML patients with *inv(16)* or *t(16;16)*).

The value of molecular monitoring of MRD in AML patients with *CBFβ-MYH11* by qualitative RT-PCR still needs to be determined; preliminary results are limited and contradictory.^{27,35,67,68} In most reports, the large majority of patients in continuous CR were found to be qualitative RT-PCR-negative, but some long-term survivors remained PCR-positive. Moreover, about 10–20% of PCR-negative patients eventually relapsed, suggesting that the achievement of PCR negativity is not predictive of cure. Studies using both competitive and real-time quantitative assays suggest that MRD monitoring can provide prognostic information on the response to treatment and can identify patients at high risk of relapse.²⁹ Moreover, Marcucci et al⁶⁹ reported that a cut-off level of 10 *CBFβ-MYH11* transcripts during remission can discriminate patients at different risks of relapse. However, due to the limited numbers of patients so far analyzed by RQ-PCR, longitudinal studies in large series of patients are still necessary in order to confirm these preliminary data.

Other chromosomal translocations: 11q23 aberrations, t(6;9)(p23;q34), and t(9;22)(q34;q11)

Molecular cloning of genes involved in additional chromosomal translocations in AML—11q23 rearrangements, *t(6;9)*, and *t(9;22)*—have made it possible to design sensitive RT-PCR assays for MRD monitoring.²⁷ However, the incidence of these chromosomal translocations is low (<5%) and up to now there have been no reports of any clear correlation with specific morphological or immunological features of AML that would orientate the investigation of these translocations to restricted subgroups of patients.

Translocations involving chromosome 11, band q23, have been detected in a variety of hematopoietic malignancies, occurring in 7–10% of ALL, 5–6% of AML, and 85% of secondary leukemias following treatment with topoisomerase II inhibitors.⁷⁰ Although over 20 partner loci have been shown to be involved in balanced 11q23 translocations, the most common translocations in AML are *t(9;11)(p22;q23)*, *t(11;19)(q23;p13.1)*, and *t(11;19)(q23;p13.3)*. In *de novo* AML, the 11q23 translocations have typically been associated with monocytic differentiation, as defined by FAB M4 and M5. In infant AML, 11q23 rearrangements are associated with hyperleukocytosis and a poor prognosis. In contrast, in adult cases, no association with specific clinical or prognostic features has been found. The gene on chromosome 11 interrupted by the 11q23 translocations is referred to as the *MLL* gene (mixed-lineage leukemia), and fuses with the *AF9* gene in *t(9;11)* and with *ENL* or *ELL* in *t(11;19)*.⁷⁰ The cloning of these partner genes has led to the development of an RT-PCR assay for the detection of the *der(11)*-derived chimeric mRNA in diagnostic leukemic samples. Molecular monitoring of MRD in leukemia with 11q23 rearrangement has so far been restricted to the analysis of *t(4;11)* in infant ALL, showing that remission samples lacked evidence of *MLL-AF4* fusion transcripts.

The *t(6;9)(p23;q34)* can be found in 2–4% of all AML patients (subtypes FAB M1, M2, and M4) and in some cases of refractory anemia with excess blasts (RAEB).²⁷ This translocation is associated with a subtype of AML with a bad prognosis that occurs in young people. Although, initially, *t(6;9)(p23;q34)* was also related with increase of basophils, myelodysplastic features, and immature phenotype (TdT⁺), these associations have not been confirmed in recent studies. The two genes involved in this translocation, *DEK*

on 6q23 and CAN on 9q34, produce a chimeric fusion mRNA that is expressed and detected by RT-PCR. The genomic breakpoints within both genes are restricted to a precise site, a uniform *DEK-CAN* fusion transcript being observed in all cases. A study by Nakano et al⁷¹ reported that in a young patient who relapsed after PBSC transplantation, RT-PCR assay was able to detect the fusion transcript in the harvested stem cell sample. Further studies are necessary to confirm its clinical value for MRD monitoring.

Approximately 1–2% of de novo AML display the reciprocal translocation t(9;22)(q34;q11). Although no MRD studies of Philadelphia-positive AML have been reported, a strategy similar to that for CML or Ph⁺ ALL could be used as discussed below.

Genetic markers for MRD study other than chromosome aberrations

Since at least half of AML patients do not have a suitable fusion gene target for MRD detection, there is a need to identify alternative molecular markers for MRD monitoring. Such potential targets include *FLT3* and *WT1*.

The *FLT3* (Fms-like tyrosine kinase) gene encode a receptor tyrosine kinase that is closely related to two well-known receptors, Kit and Fms, and is expressed predominantly in primitive hematopoietic CD34⁺.⁷² Studies have shown that an internal tandem duplication (ITD) in the *FLT3* gene is a somatic mutation detected almost exclusively in AML, occurring in 20–30% of AML patients.⁷² Controversy exists regarding the prognostic significance of these mutations, but in the largest study (854 patients) reported to date,⁷³ an *FLT3* ITD was associated with increased risk of relapse and with adverse disease-free survival, event-free survival, and overall survival, suggesting that detection of *FLT3* ITD should be included as a routine test at diagnosis. An RQ-PCR assay for *FLT3* ITD with high sensitivity and specificity has been reported, detecting between 0.01% and 0.001% of *FLT3* ITD-positive ADN in a background of 1 µg of normal bone marrow DNA.⁷⁴ However, these assays are labor-intensive, requiring the development of patient-specific primers (the size and location of the somatic mutations is different in each patient) as well as optimization procedures similar to those carried out for MRD assays based on IgH *VDJ* rearrangements in ALL. Moreover, these assays require that relapsed patients must have the same *FLT3* ITD as that observed at diagnosis, but a recent study has shown that one of 12 patients did not have an *FLT3* ITD at relapse. Thus, further studies to explore the stability of *FLT3* at relapse are needed.

The Wilms' tumor gene 1 (*WT1*) is a tumor suppressor gene that plays a key role in the carcinogenesis of Wilms' tumor. Several studies have shown that *WT1* is expressed in all AML, ALL, and CML, and that the expression levels correlate inversely with prognosis.⁷⁵ Moreover, monitoring of *WT1* expression by quantitative RT-PCR in patients with acute leukemia in remission can contribute to the prediction of impending hematological relapses. Moreover, quantification of *WT1* transcripts at specific time points (post induction and post consolidation) is prognostically valuable.⁷⁶ However, these results have not been reproduced by other groups, and the prognostic relevance in de novo AML of *WT1* transcript detection by RT-PCR in CR has not been demonstrated.⁷⁷ Data from RQ-PCR assay have been reported and appear to be encouraging, providing a basis for the evaluation of these targets by RQ-PCR in a large number of patients.⁷⁸

Myelodysplastic syndromes

Patients with poor-prognosis MDS under the age of 60 years are increasingly being treated with intensive chemotherapy, including SCT. Although the efficacy and effectiveness of these treatment modalities are inferior to those obtained in primary AML, CR rates varying from 20% to 60% have been reported.⁷⁹ In this latter subset of patients, the investigation of the quality of remission and the monitoring of residual disease will contribute to a better assessment of the efficacy of these new treatment strategies. Although theoretically most of the techniques used for MRD in AML could be applied to MDS, the information available so far is almost restricted to cytogenetic evaluation, including FISH analysis. Regarding the use of molecular techniques for MRD detection in female patients, PCR analysis of X-chromosome inactivation patterns may contribute to the assessment of clonal remission. Although chromosomal translocations are rare in MDS, if present they could be exploited as previously described for AML. In secondary MDS, the existence of balanced translocations involving chromosome ends 11q23 and 21q12 are increasingly being reported, and could also constitute a useful target for PCR analysis. However, in MDS, the most common cytogenetic abnormalities are numeric chromosomal changes or deletions such as 5q-/5 7q-/7, +8,12p-, and 20q-.⁷⁹ In this context, large numbers of non-dividing cells can be analyzed using interphase FISH and appropriate probes that would allow the demonstration of a small population of residual cells following therapy. Nylund et al⁸⁰ analyzed, by FISH, metaphase cells from two MDS patients with trisomy 8: following BMT, only normal cells were detected, and both patients remained in CR 9 and 24 months later. Flactif et al⁸¹ re-examined three patients with clonal -7 after CR was achieved following intensive chemotherapy: interphase FISH showed normal cells in all three cases.

Few studies have been devoted to the investigation of the immunophenotypic characteristics of MDS.^{82–85}

Although some of these studies^{83,85–87} were based on a comparative analysis with normal cell differentiation for the definition of phenotypic profiles present in MDS, which would allow the identification of the myelodysplastic clone during follow-up, with a few exceptions,^{83,86} they were restricted to the analysis of only a subset of bone marrow cells corresponding to either the erythroid,⁸⁵ neutrophil,⁸⁷ or CD34⁺ compartments.⁸⁶ In our experience, MDS frequently display aberrant phenotypic features such as the existence of asynchronous antigen expression, antigen overexpression, and differentiation blockade at early stages of maturation for the different myeloid cell lineages present in bone marrow, although these abnormalities may only involve a subset of all clonal cells.⁸⁸ In this sense, it has been pointed out that the ratio between immature/mature myeloid cells and the number of CD34⁺ cells may have prognostic implications, and consequently may represent valuable parameters for monitoring treatment.⁸² More recently, Stetler-Stevenson et al⁸³ showed that multiparameter flow cytometry detected immunophenotypic abnormalities in virtually all of the 45 well-established MDS patients they analyzed. Such abnormalities included aberrations involving the maturing neutrophil-lineage cells—i.e. decreased granularity (84%), absence of CD64 (66%) and CD10 (11%) expression, reactivity for CD56 (21%), and abnormal CD11b/CD16 (70%) and CD13/CD16 (78%) differentiation patterns—as well as in the monocytic lineage CD56⁺ (33%), together with increased numbers of CD45^{dim} precursor cells (53%), and coexpression of CD2 (27%) and other lymphoid-associated markers (38%) on myeloid cells. Nevertheless, unlike AML, MDS still lacks a precise definition for the patterns of phenotypic aberrations that would allow a sensitive detection of the clonal dysplastic cells, which is a prerequisite for a correct immunophenotypic investigation of MRD in MDS patients.

Chronic myeloid leukemia

CML has been one of the first malignancies to benefit from MRD studies. Two types of techniques have been used in these patients: molecular cytogenetics (FISH) and PCR. In fact, the terms ‘cytogenetic and molecular remission’ have already been included in the medical decision process concerning treatment strategies in CML.

FISH

One of the major goals in the therapeutic control of CML patients who achieve CR is the early detection of MRD and relapse, especially following allogeneic transplantation, in order to use new treatment rescue strategies such as donor lymphocyte infusion (DLI).

FISH permits the identification of the *BCR-ABL* fusion gene in metaphase and interphase cells, which is particularly attractive for monitoring response to therapy in CML patients. The use of a yeast artificial chromosome (YAC) probe spanning the breakpoint region within the *BCR* gene and a cosmid probe flanking the breakpoint within the *ABL* gene, in a dualcolor hybridization assay, provides a relatively high specificity with a decrease in the incidence of falsepositive results to less than 0.5%.¹⁹ Although this sensitivity is still lower than that of PCR, one of the advantages of FISH is that it is based on hybridization between the DNA of *BCR-ABL* probes and the genomic DNA, while the PCR technique explores the production of transcript RNA. Therefore, with FISH, it is feasible to detect the two types of *BCR-ABL* translocations (p210 and p190) in a single test. In addition, contamination is much less frequent in FISH than it is in PCR.

Amiel et al,⁸⁹ in five CML patients post BMT, have compared the sensitivity and specificity of FISH with cytogenetics and PCR with regards in the ability to detect the Philadelphia chromosome (Ph). The *BCR-ABL* translocation was detected in four of the five patients during the first 3 months following transplant. The proportion of residual positive cells ranged between 1% and 3%. A good correlation between FISH and PCR was observed. Knuutila's group⁹⁰ have used metaphase FISH for the detection of residual leukemic cells in 25 patients with CML following allogeneic BMT. According to their experience, three main conclusions can be drawn:

- The absence of residual leukemic cells is highly predictive of continuing remission (16 out of the 17 patients with no residual Ph⁺ cells remained in complete cytogenetic response (CCR).
- During the first 6 months, residual leukemic cells can be detected in about 25% of cases, but if the number of residual cells remains stable, it is not predictive of relapse, although careful follow-up is indicated.
- An increase in the amount of residual leukemic cells in subsequent samples is highly predictive of relapse (as observed in two of the three patients in whom relapse occurred).

Zhao et al³⁷ applied FISH to examine 10 CML patients who achieved complete cytogenetic remission following interferon- α (IFN- α) treatment. In six patients, residual *BCR-ABL*⁺ cells were observed, indicating that FISH is more sensitive than conventional cytogenetics for the detection of MRD in CML. This has also been confirmed by Cox-Froncillo et al.⁹¹

RT-PCR

The Philadelphia chromosome, resulting from the reciprocal t(9;22) translocation, occurs in more than

95% of patients with CML, in about 30% (20–55%) of adult and 2–10% of childhood ALL, and in less than 2% of AML. At the molecular level, part of the *ABL* proto-oncogene is translocated from chromosome 9 into the *BCR* gene on chromosome 22, which results in the formation of a *BCR-ABL* chimeric gene. In the majority of CML cases and 30% of adult ALL, the *BCR* breakpoint is located at M-bcr. In contrast, in 50–70% of adult ALL cases, the majority of pediatric ALL and rare cases of AML the m-bcr region is involved.⁹²

RT-PCR detection of *BCR/ABL* transcripts is possible in virtually all CML (>95%), even in those cases missed by standard cytogenetics (up to 10% of CML). However, a 3–5% of Ph⁺ CML escape molecular detection by conventionally used primer combinations.⁹³ The sensitivity of RT-PCR is usually down to 10⁻⁵ to 10⁻⁶. Therefore, RT-PCR is particularly useful in patients undergoing allogeneic or autologous SCT as well as in those who achieve a cytogenetic complete response following IFN- α treatment. Several MRD-PCR studies have been performed in patients in clinical and cytogenetic remission after allogeneic SCT in order to evaluate the incidence and significance of PCR-positive cells. The results reported so far have been conflicting, although a consensus appears to exist on the fact that most patients (>75%) are PCRpositive in the first 6 months after BMT and this positivity does not correlate with outcome.⁹³ After 1 year post BMT, the number of PCR-positive patients decrease to 20–40%, negativity being associated with withdrawal of immunosuppressive treatment and with both acute and chronic graft-versus-host disease (GVHD). However, 44% of patients without GVHD also have PCR-negative assays, suggesting the presence of mechanisms capable of suppression or eradication of CML independently of GVHD.⁹⁴ The existence of PCR-positive cells in a late post-transplant period again does not correlate with relapse, since such cells have been observed even several years after BMT without any signs of disease progression. Of greater value are sequential follow-up studies that allow patients to be divided into three main groups: persistently positive, intermittently negative, and persistently negative. These three groups have, respectively, a low, intermediate and high probability of maintaining remission.^{94,95} Several MRD studies have also been carried out on patients in cytogenetic response after IFN- α . The majority of these studies found that IFN- α does not eradicate the disease. Consequently, a large proportion of the patients who achieve CCR are PCR-positive, their incidence being 90% or more within the first year and slightly less (60–80%) in long-term cytogenetic remission patients. However, the existence of PCR-positive cells can be detected for a long period of time without relapse, suggesting that in these cases, the clonogenic potential of the residual leukemic clone is low. Moreover, patients taken off IFN- α therapy after CCR do not relapse in a short period of time, indicating that IFN- α may have a particular remnant effect.⁹⁶

The limitations of qualitative PCR for predicting relapse in individual patients has led to the development of quantitative techniques based on competitive RT-PCR. Competitive RT-PCR techniques have been successfully used in the monitoring of MRD in CML patients both after allogeneic SCT and during treatment with IFN- α .⁹³ This is particularly important in patients who are candidates for donor lymphocyte infusion (DLI), since response apparently correlates with residual tumor burden. Olavarria et al⁹⁷ showed that the probability of relapse correlates with the number of *BCR-ABL* transcripts found 3–5 months after SCT. Thus, they defined three levels of *BCR-ABL* transcripts—negative, positive at low level (<100 copies per μ g RNA), and positive at high level—which correlate with the cumulative incidence of relapse (16.7%, 42.9%, and 86.4%, at 3 years after SCT, respectively; $p=0.0001$). However, some authors consider the use of competitive RT-PCR for clinical decision-making to be premature, since this technique is difficult to standardize. Several groups have reported that real-time quantitative (RQ-PCR) could be an alternative, and have applied it successfully to monitor MRD in CML patients.²⁹ A study from Radich et al⁹⁸ on 379 CML patients explored the significance of *BCR-ABL* molecular quantification by RQ-PCR at 18 months onwards after SCT. Quantification was performed on 344 samples from 85 qualitative RT-PCRpositive patients, and showed that the slope of the *BCR-ABL* change was significantly steeper in those patients destined to relapse compared with those who did not ($p=0.002$). Moreover, quantitative values for these patients who did not relapse tended to be quite low, with a median *BCR-ABL* level of 24 copies per μ g RNA (62% of samples had fewer than 100 copies of *BCR-ABL* per μ g RNA). These data suggest that the prognostic significance of a qualitative *BCR-ABL* can be refined using an RQ-PCR assay. However, this latter technique is associated with some caveats that may affect its use for monitoring and guiding therapy; for example, *BCR-ABL* can be detected in normal individuals (although at levels not detectable by standard RT-PCR assay), and some patients display high levels of transcripts without relapse (15% of patients in the study by Radich et al⁹⁸ had more than 1000 copies). Thus, early therapeutic interventions based on *BCR-ABL* quantification should only be offered within a research setting.

Drug resistance and its modification in hematological malignancies

Jean-Pierre Marie

Introduction

Hematological neoplasms are usually primarily sensitive to chemotherapy, but the relapse rate is still high, except for Hodgkin lymphoma and childhood acute lymphoblastic leukemia (ALL). Drug resistance is therefore a major cause of chemotherapeutic failure and patient death in hemato-oncology.

A mathematical model for the development of drug resistance in tumors was proposed in 1979 by Goldie and Goldman.¹ This model was based on the postulate that cancer cells have a high spontaneous mutation rate, leading, over time, to the emergence of cells resistant to chemotherapeutic drugs. In accordance with this hypothesis, it was suggested that a reduction in the rate of emergence of resistant cells could be achieved by simultaneous administration of multiple drugs with different targets. However, despite combination chemotherapies, treatment failures were observed in lymphoid and myeloid malignancies, and relapses occurred in more than half of the cases in acute myeloid leukemia (AML) and adult ALL.

It is therefore clear that a better understanding of the mechanisms involved in drug resistance is still warranted for the development of new therapeutic strategies.

Measurement of drug resistance in clinical samples

In vitro assays have been developed to test the drug resistance of clinical samples (mainly acute leukemia).² Clonogenic assays offer the advantage of testing the drug sensitivity of progenitor cells, and have been successfully correlated with clinical outcome in AML: resistance to both anthracyclines and cytarabine (cytosine arabinoside, Ara-C) was highly correlated with clinical failure in adult AML, and was one of the best predictive variables in a multivariate analysis.³ Unfortunately, these clonogenic assays are time-consuming and cannot be automated. For these reasons, other viability tests have been developed. The most commonly used assay is the MTT assay, which relies on the ability of the mitochondria of living cells to convert a soluble tetrazolium salt (MTT) into an insoluble formazan. The formazan precipitate is purple, it can be dissolved, and its extinction can be read on a 96-well plaque reader. The extinction is linearly correlated with the number of viable cells in suspension. The 4-day MTT assay is an efficient tool for large-scale drug-resistance testing, and results have shown good correlation with prognosis in childhood ALL.⁴

Classification of drug resistance (Table 23.1)

The efficacy of cytostatic antineoplastic therapy is determined by a sequential cascade of events, including drug delivery, drug–target interaction, and the induction of cellular damage. The first part of this cascade corresponds to the ‘pharmacological’ resistance, and up to now has been the most widely studied mechanism of resistance.

Classically, resistance is divided into extrinsic and intrinsic causes.

Extrinsic resistance

This corresponds to an inability of the drug to reach the tumor cell. This is the case when the bioavailability of the oral form varies greatly from patient to patient, as with 6-mercaptopurine in ALL.⁵ Defects in tumor vascularization, frequently observed in solid tumors, are also probably relevant for hematological malignancies.⁶

Table 23.1 Drug-resistance classification

Proximal	Distal
Low uptake (nucleoside receptors for cytarabine) Efflux: ABC proteins (P-gp, MRPs, BCRP,...) Cellular traffic (LRP)	No DNA synthesis (low S phase) Target mutations (topoisomerases) Increased DNA repair (increased DNA-PK)
Chelation (GSTs) Activation/catabolism (cytarabine/ deoxycytidine enzymes)	Delay to chemo/ radiotherapy-induced apoptosis (<i>bcl-2</i> family, <i>p53</i> mutations, Cdk inhibitors)

Intrinsic resistance

This is directly due to the properties of the tumor cell. This phenomenon can be observed in vitro, and can be classified as *simple resistance*, when the cells are resistant to only one drug, or as *multidrug resistance* (MDR), when a cross-resistance is observed for chemostatic drugs with different biochemical targets. This latter type of resistance is mainly observed in patients, and can be due to several mechanisms. The underlying pharmacological mechanism corresponds mainly to active efflux of drugs out of the tumor cells. Molecular profiles giving rise to broader forms of resistance are now under investigation, and it is believed that a defect in drug-induced apoptosis is at least partly responsible.

Proximal and distal resistance

Another approach is to consider the resistance mechanisms as *proximal resistance*, when the events occur before the drug reaches the target (decreased influx, increased efflux or catabolism, reduced synthesis of active form, and compartmentalization), and *distal resistance*, when the mechanisms are not linked to the intracellular pharmacokinetics: decreased cell division, increased DNA repair, and increased anti-apoptosis proteins (or decreased pro-apoptosis proteins) (Figure 23.1).

Proximal (pharmacological) drug resistance

ABC proteins

MDR cells are resistant to several naturally occurring plant or microbial products, but are not resistant to synthetic compounds such as cisplatin, or to nucleotide analog such as cytarabine (Table 23.2). The resistant tumor cells maintain lower intracellular drug concentrations than their sensitive counterparts,⁷ and in the large majority of cases express transport proteins that are responsible for active efflux of the drugs.

The first—and probably most important—protein described in cellular models of MDR is P-glycoprotein (P-gp), encoded by the *ABC1* (*MDR1*) gene. This transmembrane protein belongs to a superfamily of ABC (ATP-binding cassette) proteins, specialized for energy-dependent cellular transport.⁸ The genes coding for these proteins are highly conserved between species, from bacteria to humans. Besides P-gp other members of the ABCC family (MRP1–6, multidrug resistance-associated proteins), with low homology with P-gp, have been described (for a review, see reference 9). A small ABC protein, ABCG2 (or BCRP), was described simultaneously by three different groups. It was described as a ‘specific’ ABC protein of the placenta (ABCP), as a new ABC protein expressed in a *MDR1*-*MRP1*-breast cell line resistant to anthracy-

Figure 23.1 Drug-resistance mechanisms.

Table 23.2 Drugs and P-glycoprotein (P-gp)

Expelled by P-gp	Not expelled by P-gp

Teniposide)	Glucocorticoids
Dactinomycin	
Mitomycin C	
Topotecan	
Homoharringtonine	

cline (BCRP), and in a colon carcinoma cell line resistant to mitoxantrone (MXR1).⁸

The expression of these genes is believed to confer resistance—the evidence for this being that the transfection of their cDNA in sensitive cell lines gives rise to the MDR phenotype (Table 23.3).^{10–12}

P-gp, the MRPs, and BCRP are not unique to drugresistant cells, and are expressed by tissues with excretory–secretory functions. In hematopoietic cells, progenitor cells express P-gp and BCRP, but not MRP. These localizations suggest that these proteins are involved in the protection of organisms (and cells of vital importance) against natural xenobiotics.¹³

A few years ago, several workshops^{14,15} proposed a consensus on technical recommendations for measuring P-gp. Protein detection and, more importantly, functional test by flow cytometry are recommended for leukemic samples. Several monoclonal antibodies, recognizing an external epitope, are available for protein expression, and several fluorescent probes can be used, with and without specific inhibitors, for measuring the drug efflux.

ABC proteins in hematological malignancies

The MDR phenotype conferred by expression of the *MDR1* gene can be ‘disease-related’, as in AML and probably in adult T-cell leukemia/lymphoma (ATLL), or ‘treatment-related’, as in ALL, non-Hodgkin lymphoma (NHL), and multiple myeloma (MM).

Acute myetoid leukemia

Several studies have reported a high frequency of *MDR1* gene expression in AML. Large multicentric studies (for a review, see 16) showed between one-third and one-half of ‘positive’ cases at diagnosis, whatever the technique used, and usually a higher proportion of positive cases were described in elderly patients.¹⁷ The MDR phenotype is associated with markers of bad prognosis, such as CD34 and CD7.

Except for the promyelocytic subtype (FAB M3), which is devoid of P-gp expression,¹⁸ all the other AML subtypes are able to express the MDR phenotype. In the majority of cases, the functional tests (dye efflux) were correlated with P-gp expression, except in CD34- cells, like myelomonocytic and monoblastic leukemias. For that reason, dye efflux appears to be more informative than quantification of P-gp itself in AML.

The MDR phenotype is also frequent in the myelodysplastic syndromes (MPS)¹⁹ and the blast crisis of chronic myeloid leukemia (CML)—both of which are known to be diseases with particularly bad prognosis.

The correlation between *MDR1* gene expression and treatment outcome is well documented in AML (for a review, see reference 16): many studies have reported a relationship between either the absence of remission (refractory disease and death during aplasia) and the overexpression of P-gp, or the overexpression of P-gp and refractory disease.

More discordant results have been published concerning the incidence of MRP expression in AML:²⁰ the range of MRP expression is narrow compared with

Table 23.3 Resistance spectrum of *MDR1*, *MRP*, and *LRP* genes

	Anthracyclines	Vincristine	Paclitaxel	Melphalan	Cisplatin
<i>MDR1</i>	++	++	++	–	–
<i>MRP</i>	++	++	–	–	–
<i>LRP</i>	++	++	?	+	+

++/+, confers resistance; –, does not confer resistance; ?, not described.

that of P-gp, and a basal expression is found in all cases. One-third of patients present with high expression. The prognostic value of MRP itself has not yet been clearly determined, but a functional test measuring efflux due to P-gp and MRP1 (using calcein AM and modulators) has clearly shown that both P-gp and MRP1 functions are of prognostic importance in adult AML.²¹ The roles of other MRPs are still under investigation.²²

Discordant results have been published concerning the incidence of expression and the prognostic value of BCRP in leukemia. The frequency of expression ranges from 5%²³ to 30%^{24,25} in adult AML, and, so far, no large series have been published concerning functional assay and prognostic value of this protein in adult acute leukemia. In pediatric AML, BCRP has been linked to a worse prognosis.²⁶

Acute lymphoblastic leukemia

Except for a few studies, the incidence of *MDR1* over-expression in untreated patients with ALL has generally been found to be low (<10%) at diagnosis and even at relapse, except during the latest stage of the disease, when clinical drug resistance is usually observed (for a review, see reference 16).

The MDR phenotype in ALL is found only in ALL subgroups with a bad prognosis: adult ALL (often Philadelphia chromosome-positive) and a subtype of CD7⁺CD4⁻CD8⁻ ALL, which is thought to originate from a hematopoietic stem cell.

P-gp expression was not found to be predictive for induction treatment failure in childhood ALL. This could be explained by the predominant role of corticosteroids—which are not expelled by P-gp—as the major drugs in ALL. In adult ALL, a recent study showed that protein expression, but not function (?), predicted the achievement of complete remission in patients treated according to the GIMEMA ALL0496 protocol.²⁷

Few publications have concerned MRP in ALL,²⁰ but all have shown a measurable level of MRP at diagnosis—comparatively higher than in AML cells—and some cases showed an increase after treatment. The prognostic value of MRP expression is at present not clearly demonstrated.

Until now, only one publication has described a low incidence of BCRP expression in pediatric ALL, with no prognostic significance.²⁸

Multiple myeloma

The limited bone marrow infiltration by plasma cells (15–60%) in MM argues for the use of immunocyto-chemistry as the method of choice for determining the MDR phenotype in this disease. An alternative technique is double labeling with anti-CD56 or anti-CD38 antibodies, together with another antibody against P-gp. A low incidence of P-gp in malignant plasma cells has been observed at diagnosis.²⁹ This incidence increased during progression, depending on the dose of anthracyclines and vinca alkaloids received, and reached 85% in patients refractory to VAD (vincristine, doxorubicin, and dexamethasone). This positivity is a factor of clinical resistance to VAD,³⁰ and even to melphalan. MRP expression is detectable in the majority of myeloma cells, but does not increase dramatically after treatment—the significance of this expression is not known.

Chronic lymphocytic leukemia

In chronic lymphocytic leukaemia (CLL), several authors have described a large majority of patients expressing P-gp, either before or after chemotherapy (for a review, see reference 19). Semiquantitative studies have shown that expression is moderate, and does not change after chemotherapy. The MDR phenotype is also detected in normal B lymphocytes, and therefore is probably constitutive in CLL, but expressed at a low level, and seems not to be implicated in clinical drug resistance.³¹

CLL cells express variable levels of MRP at diagnosis and after treatment, but the amount of MRP does not influence the course of the disease.³¹

Non-Hodgkin lymphoma

The majority of the cases published in the literature have been from retrospective studies, using immunohistochemical detection of P-gp on frozen lymph node sections (for a review, see reference 32).

In no report could any difference be observed between high- and low-grade lymphoma, or between B and T subtypes, except for adult T-cell leukemia/lymphoma (ATLL), which frequently expressed the MDR phenotype at presentation.

Several studies have addressed the question of the clinical significance of the MDR phenotype in NHL (for reviews, see references 16 and 32). In short series, the absence of P-gp was associated with a better response, but in the larger series of high-risk lymphoma, no correlation with treatment result was noted.

The *MRP* gene is expressed at a low level in all cases of lymphoma (low- or high-grade), and the level does not differ before and after chemotherapy, except in a very few patients.³³

Lung resistance protein/major vault protein

An additional protein has been described in a wide variety of P-gp-negative MDR cancer cell lines and in clinical samples. This protein is a non-ABC, MDR-associated protein originally termed lung resistance-related protein (LRP), and now identified as the major

vault protein (MVP) (for a review, see reference 34). Vaults are highly conserved among species, supporting the notion that their function is essential to eukaryotic cells. It was hypothesized that vaults mediate the bidirectional transport of a variety of substrates between the nucleus and the cytoplasm. So far, the cDNA of LRP/MVP has been unable to confer the MDR phenotype; therefore, a proof of the involvement of LRP/MVP in the MDR phenotype has not been demonstrated.

In the majority of cases of AML, LRP/MVP expression is low,³⁵ but detectable by RT-PCR.

The clinical significance of LRP expression is still controversial,^{35,36} and functional tests specific for LRP need to be developed.

Pharmacological resistance to cytarabine

Cytarabine plays a key role in the achievement and consolidation of complete remission in AML, and is also widely used at high dose as rescue treatment in refractory ALL and AML. This nucleotide analog is not expelled by ABC proteins, and is of particular interest in patients expressing P-gp or MRP. In vitro resistance to cytarabine has been given as a main parameter for predicting treatment failure^{37,38} or relapse³⁹ after conventional doses of cytarabine and anthracyclines in AML.

After transport into the cell, cytarabine must be phosphorylated to its active triphosphate form (arabinosylcytosine triphosphate, Ara-CTP) by a series of kinase enzymes (Figure 23.2). The ability of fresh human leukemic cells to retain the cellular concentration of Ara-CTP has been correlated with the duration of remission in patients treated with cytarabine and anthracyclines.⁴⁰ Although Ara-CTP is an inhibitor of DNA polymerase α , it is also a substrate, and is in competition with deoxycytidine triphosphate (dCTP, the natural compound) for DNA incorporation. It is thought that the incorporation of Ara-CTP into DNA is responsible for the lethal effect of this drug. Factors that reduce the intracellular concentration of Ara-CTP may induce chemoresistance in AML patients. These factors include reduced influx of cytarabine by the hENT1 transporter, reduced phosphorylation by deoxycytidine kinase (dCK), and increased degradation by high- K_m cytoplasmic 5'-nucleotidase (5NT) and/or cytidine deaminase (CDD). It has been suggested that expression of DNA Pol, 5NT, and hENT1 at diagnosis may be resistance mechanisms to cytarabine in AML patients.⁴¹⁻⁴³

Distal drug resistance

Alkylation of DNA, and more specifically the formation of DNA interstrand crosslinks, has been considered to be responsible for the cytotoxicity of alkylating agents. Resistance to these agents has been reported to be secondary to (i) alterations in the kinetics of the DNA crosslinks formed by these agents, (ii) overexpression of metallothionein, (iii) changes in apoptosis, and (iv) altered DNA repair activity (for a review, see reference 44).

p53 and proteins regulating the cell cycle

The ultimate success of genotoxic anticancer agents is determined by the ability of malignant cells to initiate an apoptotic response to induced DNA damage.⁴⁵ Among the numerous factors known to modulate can-

Figure 23.2 Resistance to cytarabine (cytosine arabinoside; i.e. arabinosylcytosine, Ara-C). Ara-CM/D/TP, arabinosylcytosine mono/di/triphosphate; dC, deoxycytidine; dCM/D/TP, deoxycytidine mono/di/triphosphate.

cer-related apoptosis, p53 and the Bcl-2 family are the most extensively characterized proteins. p53 is activated in response to DNA damage (Figure 23.3), and stops the cell in G₁ phase (via p21), permitting DNA repair, whereas apoptosis can be considered to be a failsafe mechanism to rid the organism of cells with severely damaged DNA. In cases of non-functional p53, the threshold of DNA damage leading to apoptosis increases, and this could contribute to drug resistance.⁴⁶ In hematological malignancies, p53 is usually functional at diagnosis, but mutations have been described during progression of the disease in both lymphoid and myeloid leukemias as well as in lymphomas,⁴⁷ and this progression corresponds mainly to highly resistant tumors.

Genetic alterations affecting the p16^{INK4A} and cyclin D1 (Figure 23.3) proteins, which govern phosphorylation of the retinoblastoma protein (pRb) and control exit from G₁ phase of the cell cycle,⁴⁸ are frequent in cancer, including ALL and mantle cell lymphoma, and are associated with an aggressive course of the disease. The first evidence of in vitro correlation between pRb pathway alterations and drug sensitivity has been described (for a review, see reference⁴⁹), opening a new field of investigation for a better understanding of drug resistance.

In chronic lymphocytic leukemia (CLL), a high cell content of p27, a universal cyclin–cyclin-dependent kinase (cdk) inhibitor, is correlated with poor survival but increased survival in the presence of drugs such as fludarabine.⁵⁰

Anti-apoptosis proteins and signals

Analysis of the t(14;18) translocation in follicular lymphoma has permitted the description of the *bcl-2* (B-cell lymphoma 2) oncogene. The anti-apoptotic properties of Bcl-2 and Bcl-x_L, another member of the same family, are now well documented, and their overexpression has been shown to protect tumor cell lines from the toxicity of several chemotherapeutic agents (for a review, see reference 51). The clinical impact of Bcl-2/Bcl-x_L overexpression on drug resistance has not been demonstrated, but correlations have been described between high Bcl-2 cell content and clinical drug resistance in NHL⁵² and AML,⁵³ but not in ALL.⁵⁴ On the other hand, Bax expression correlates with drug sensitivity to doxorubicin, cyclophosphamide, and chlorambucil in CLL,⁵⁵ and relapse in childhood ALL is associated with a decrease of the Bax/Bcl-2 ratio.⁵⁶

The chimeric protein BCR-ABL, specific to chronic myeloid leukemia (CML) and frequent in adult ALL, has been shown to confer resistance to genotoxic agent-induced apoptosis (by cytarabine, daunorubicin, etoposide, etc.) in vitro, via prolongation of cell cycle arrest at the G₂/M restriction point, without altering either the p53 pathway or DNA repair.⁵⁷ Imatinib (STI571, Gleevec/Glivec), a specific antityrosine kinase drug, is a very potent inhibitor of BCR–ABL effects, but resistance to this drug has been described in patients, as a result of amplification or mutations in the chimeric BCR–ABL protein (for a review, see reference 58).

Signals from the microenvironment could be strong stimulators for tumor cell survival and resistance to chemotherapy. In AML, the role of bone marrow endothelial cells has begun to be explored, and has revealed paracrine loops, involving vascular endothelial growth factor (VEGF) and its receptors.⁵⁹

In CLL, tumor cells express and are receptive to BlyS/BAFF, a signal of survival for normal B lymphocytes. An autocrine loop responsible for tumor cell survival has been described.⁶⁰

Figure 23.3 Cell cycle control.

Reversal of the MDR phenotype

P-gp inhibition

Numerous compounds have been identified that inhibit the efflux activity of P-gp and reverse cellular resistance in experimental systems (for a review, see reference 61). This has led to the strategy of concomitant administration of chemotherapy and an 'MDR modulator' to reverse clinical drug resistance. These compounds act mainly as competitive or non-competitive inhibitors, by binding to similar drug substrate-binding sites, or to other P-gp sites that cause allosteric changes of the molecule, resulting in a decrease in cytotoxic drug binding.

The most widely used modulators in randomized phases III in leukemia are quinine and cyclosporins (cyclosporin A (cyclosporine, CsA) and PSC833, an analog of cyclosporin D). More recently, other compounds, specially designed and developed for modulation of drug resistance, have entered phase I trials, namely VX710, LY335979, and XR9576.

The first large randomized study of an MDR modulator in hemato-oncology tested the usefulness of the addition of quinine to a combination of mitoxantrone and high-dose cytarabine in 315 bad-prognosis adult leukemia cases (relapsing/refractory/secondary).⁶² Global results showed no difference between the groups with or without quinine, but it was noted that (i) clinical drug resistance was higher in the control group and (ii) the toxic death rate was higher in the quinine group. The clinical toxicity of quinine could have masked the clinical benefit of MDR reversal.

The same kind of results were observed with PSC833 (10-fold more potent than CsA and without any renal or immunosuppressive toxicity) in elderly untreated patients.⁶³ The Cancer and Leukemia Group B (CALGB) phase III trial consisted of standard doses of cytarabine, with daunorubicin 60 mg/m² (40 with PSC833) and etoposide 100 mg/m² (60 with PSC833) daily for 3 days without (ADE) or with (ADEP) PSC833 (10 mg/kg/day by 3-day infusion). The ADEP arm was closed after randomization of 120 patients because of excessive early mortality. Nevertheless, disease-free survival (median 7 months versus 8 months; $p=0.38$) and overall survival (approximately 33% alive at 1 year) did not differ and were similar to historical results. For patients with PSC833-modulated efflux, the median disease-free survival was 5 months with ADE and 14 months with ADEP ($p=0.07$).

Several other phase III clinical trials in relapsed myeloid leukemia and multiple myeloma with PSC833 have now been completed, with globally negative results.⁶⁴

On the other hand, the Southwest Oncology Group (SWOG) conducted a randomized phase III study on 226 patients, randomly assigned to sequential treatment with cytarabine 3 g/m² daily for 5 days, followed by daunorubicin 45 mg/m²/day (continuous infusion) on days 6–8, with or without intravenous CsA (16 mg/kg/day).⁶⁵ Addition of CsA significantly reduced the frequency of resistance and increased the relapse-free and overall survival. The effect of CsA on survival was greatest in patients with P-gp⁺ leukemic cells. The same cooperative group performed another randomized trial with the same arms in blast crisis of CML, but in this disease CsA was unable to improve the complete response or survival rates.⁶⁶

Other P-gp inhibitors are now in phase II trials—mainly in solid tumors. LY335979 is a quinoline derivative, specific to P-gp, and delivered orally, with a weak effect on pharmacokinetics of co-administered drugs.⁶⁷ Phase II is now completed in AML, and a phase III trial is now beginning in the USA. XR9576, an anthranilic acid derivative, delivered orally or intravenously, is now in a phase I/II trial.⁶⁸

Reversion of other ABC pumps

GG120918, a derivative of acridonecarboxamide, was developed as an inhibitor of P-gp, but has also been described as a potent inhibitor of BCRP.⁶⁹ VX-710 (Bircodar), a pipercolinate derivative, is a modulator of P-gp and MRP1. It has no effect on doxorubicin pharmacokinetics, although an increase in bilirubin was noted in a phase II trial.⁷⁰

Reversal of other kinds of resistance

Resistance to cytarabine

High-dose (1–3 g/m²/12 h×8–12) infusion (2–3 h) of cytarabine is a very potent treatment in secondary/relapsing/refractory AML and in ALL. Resistance to standard doses of cytarabine (100–200 mg/m²/day×7 days) is usually overcome by increasing the dose, because of the competition between this nucleoside and natural deoxycytidine (dC): more cytarabine will enter the cell, more will be phosphorylated, and more will be incorporated into DNA. The cellular concentration of Ara-CTP in circulating leukemic cells during high-dose infusion of this drug is strongly correlated with clinical outcome,⁷¹ confirming the importance of cytarabine uptake and of cytarabine phosphorylation.

It has also been proposed to prime leukemic myeloid progenitors with growth factors granulocyte and granulocyte–macrophage colony-stimulating factors (G-CSF and GM-CSF) before cytarabine treatment. After several large trials, the value of this approach is inconclusive (for a review, see reference 72).

Inhibitors of farnesyl transferase

The membrane-associated G proteins encoded by the *ras* family of proto-oncogenes are potential target for new therapeutic agents. The Ras proteins are activated down-stream of protein tyrosine kinases, and in turn trigger a cascade of phosphorylation events through sequential activation of Raf, MEK1, and ERK1 and 2. To be active, the Ras proteins have to be farnesylated. Therefore, several inhibitors of farnesyl transferase have recently been developed. A phase I trial in refractory/relapsing acute leukemia with R115777 (Janssen) demonstrated a significant inhibition of ERK phosphorylation in bone marrow after treatment, and clinical response occurred in 29% of the patients (including 2 complete responses in 34 evaluable patients).⁷³ In *BCR-ABL*⁺ cells resistant to imatinib, another farnesyl transferase inhibitor, SCH66336 (Schering-Plough) was able to restore apoptosis usually induced by imatinib alone.⁷⁴

Restoring apoptosis: *bcl-2* antisense therapy

Restoration of drug-induced apoptosis could be obtained in vitro with *bcl-2* antisense oligonucleotides. A phase I study of *bcl-2* antisense therapy was performed in relapsed *bcl-2*⁺ NHL, using 14 days of subcutaneous infusion of G3139, an 18-mer oligonucleotide complementary to the first codons of *bcl-2*.⁷⁵ A steady-state concentration of the antisense oligonucleotide was achieved without major toxicity, although few responses were observed. Another phase I trial was performed in refractory/relapsed acute leukemia, treated with 10 days of G3139 continuous infusion) together with fludarabine, cytarabine, and G-CSF. A steady-state concentration of G3139 was achieved after 24 hours without major toxicity, and 6 of 20 patients achieved CR.⁷⁶ A randomized phase III trial is now running in untreated elderly patients with AML.

The theoretical basis of chemotherapy for hematological malignancy

AK McMillan and DC Linch

Introduction

In situations where chemotherapy is given with curative intent, multiple agents are usually used in combination. These are administered in pulses, with the non-treatment intervals being required for recovery from the drug-induced toxicities. The drug components of a regimen typically have different modes of action, so that the antitumor effects will be additive at least and the limiting side-effects will hopefully be non-overlapping. In hemato-oncology practice, there have been continual attempts to improve patient outcomes by increasing the doses of the chemotherapy agents employed, and the theoretical basis of dose escalation is discussed below.

The Skipper experiments

Skipper and co-workers published a series of fundamental papers in the early 1960s that have impacted greatly on subsequent clinical practice. The most important of these was entitled 'On the criteria and kinetics associated with curability of experimental leukaemia'.¹ These experiments reported studies using the intraperitoneal injection of L1210 leukemic cells in a mouse model. The underlying assumption was that small numbers of viable leukemia cells are ultimately lethal and, therefore, if a cure is to be achieved, the aim must be to eradicate each last tumor cell from the experimental animal. In the experiments reported in this paper, a logarithmic relationship was demonstrated between the size of tumor cell inoculum and the duration of survival of an animal without treatment. At a level of intensity of therapy where some animals might have either zero or one cell remaining, the Poisson distribution equation becomes applicable and a cure rate of around 40% would be expected. The antileukemic agent amethopterin was administered every other day after varying sizes of leukemia cell aliquot ranging over five logs of cell dose. The results showed an increase in the percentage of animals who survived 100 days from 0% through 8%, 82%, 96%, to 100% survival with each log decrease in the size of the inoculum. These experiments led to the concept of log-kill, which states that the relationship between the number of surviving tumor cells and chemotherapy dose is logarithmic rather than linear. The important corollary of this is that, with the decrease in the numbers of residual cells remaining after dose escalation, it becomes progressively harder to eradicate any further cells as the tumor burden decreases.

To translate these data to the clinical arena involves not only an understanding of the increase in complexity of factors in clinical practice, but also an understanding of the role of the immune system. 'Immune surveillance' may mean that it is not essential to eradicate every last cell, as it was in the above experiments when injections of syngeneic tumor cells were given in an experimental mouse model. Nevertheless, the principles operating are probably similar, so that, for a given patient, the threshold number of surviving cells below which patients may be cured is likely to be constant. The rules governing whether a reduction to below this threshold can be achieved are likely to adhere to the principles of logkill outlined above. Therefore, the same log increase in chemotherapy dose will progressively eradicate fewer and fewer cells as the possibility of cure is approached. A further useful concept articulated by Skipper and colleagues is the observation that clinical remission may be achieved when large numbers of tumor cells remain. In this situation, some animals may have no detectable leukemic cells, but because they have received a dose of chemotherapy insufficient to eradicate every last cell, these mice are destined to relapse. In the same way, patients treated with inadequate doses of chemotherapy may achieve remission but will inevitably relapse due to occult

tumor cells remaining. The mathematical equivalent of this, as described in the seminal paper, is that after a single dose of a chemotherapy agent that will reduce a 10^4 cell population by 4 logs to an average of 1 leukemia cell per animal (99.99% cell kill), there will be an anticipated 40% cure rate. However, the same dose administered to animals bearing 10^6 leukemia cells would be expected to result in an average of 10^2 leukemia cells surviving, with virtually no cures.

Chemotherapy scheduling was also considered by Skipper, so for a tumor with a very high growth rate, such as the leukemia model used in these experiments, there is a high likelihood of regrowth of tumor between doses, which can make repeated intermittent dose scheduling ineffective. If a single large dose of treatment is used, as long as toxicity to the host is sustainable, it could be shown to be more effective. Again, when consideration is given to actual clinical practice, it can be seen that tumor growth fraction and toxicity to the patient's vital organs will modify the optimum schedule. The idea of using large doses of single-agent therapy has been encompassed into the high-dose sequential therapy developed by Gianni but confirmation in other trials of the efficacy of this and colleagues.² Their results are very encouraging, strategy is required

Lastly, as a result of these experiments, Skipper commented on the existence of anatomical compartments that can be readily invaded by leukemia cells but not as readily penetrated by most chemotherapy agents—this for instance being in accord with the concept of the blood–brain barrier.

The Goldie-Coldman hypothesis

The experiments of Skipper suggest how a single chemotherapy agent can be used optimally, but as most chemotherapy regimens contain multiple agents, it is important to also consider the work of Goldie and Goldman.³ The hypothesis of Goldie and Goldman was based solely on theoretical mathematical modeling and not on laboratory or clinical data. The hypothesis related the drug sensitivity of a tumor to the rate of spontaneous mutation towards phenotypic drug resistance. In their summary, they state that 'the proportion, as well as the absolute numbers of resistant cells, will therefore increase with time and the fraction of resistant cells within tumour colonies of the same size will vary depending on whether the mutation occurs as an early or late event.' They go on to state that, from their mathematical model, 'the probability of the appearance of a resistant phenotype increases with the mutation rate and furthermore, for any population of tumours with a non-zero mutation rate, the likelihood of there being at least one resistant cell may go from a condition of low to high probability over a very short interval in the tumour's biologic history.' From these theoretical assumptions, it can be concluded that the probability of the number of resistant cells in a tumor is not linearly related to the size of the tumor, but increases rapidly as the number of cells increases. This means that at certain times in certain tumors there is a period when the tumor's susceptibility to chemotherapy is changing rapidly. This, in turn, leads to the conclusion that tumors early in their growth history can be expected to have a much better likelihood of cure than tumors that have reached an advanced stage, and it supports the concept of early dose intensification. It is clearly not possible to alter the rate of mutation, but the use of effective and independently acting agents in combination will have the effect of reducing the value for the effective spontaneous mutation rate. This is because it is then a requirement for the cell to spontaneously become resistant to two mechanisms of drug action simultaneously—and this is a less likely event. An analogy for this observation is the combination of antimicrobial chemotherapy agents used in the treatment of mycobacterial infection.

Relative dose intensity (RDI)

Models of dose intensity were further refined with the concept of relative dose intensity (RDI). This suggests that the efficacy of a chemotherapy regimen is not just due to the total drug dose administered, but is more closely related to the dose delivered over unit time. To quantify and allow comparison of protocols, Hryniuk et al⁴ defined RDI as the amount of drug delivered per unit time expressed as milligrams per square meter per week relative to an arbitrarily chosen standard single drug for the tumor being studied. In the case of a combination regimen, RDI is the decimal fraction of the ratio of the test regimen compared with the standard regimen. A major limitation, however, in the determination of the RDI is the lack of single-agent trials that allow the accurate assignment of the relative efficacies of the different components of a combination chemotherapy regimen for a specific tumor type. Using the Hryniuk model, for instance, regimens such as MACOP-B (used in non-Hodgkin lymphoma, NHL) have considerably higher RDIs than standard CHOP therapy, and yet the clinical results with these regimens are similar.⁵ With different assumptions about the relative efficacies of the individual drugs, it is possible to derive broadly similar RDIs more closely in accord with the clinical data, although the relationship between RDI and tumor response does not appear to be as clear as in Hodgkin lymphoma.⁶ A further limitation of the RDI, and other mathematical models relating administered chemotherapy dose to tumor control, is that it fails to take into account the marked interindividual variation in drug absorption and metabolism that have been well documented. In many situations, the extent of hematological toxicity

may more closely reflect the true drug exposure (TDE) rather than the amount of drugs administered over unit time or the individual's intrinsic marrow sensitivity. A recent analysis of patients with advanced Hodgkin lymphoma treated in Germany with the COPP/ABVD regimen indicated that those patients with relatively marked hematological toxicity received lower drug doses with reduced dose intensity, as a result of the toxicity, and yet achieved better disease control.⁷ This has important clinical implications, as, in some circumstances, the philosophy of using growth factors to achieve 'full dose on time' may merely increase the drug delivery to those patients who have already received the highest TDE.

Toxicity may also be dependent on dose intensity, and this is normally the case with hematopoietic toxicity. In some cases, toxicity may be related to the 'area under the curve', as has been demonstrated for carboplatin-induced hematopoietic toxicity,⁸ whereas with other toxicities, such as anthracycline cardiac toxicity, peak drug levels may also be relevant. These issues must be considered carefully in the scheduling of any intensive drug regimen.

Summation dose intensity (SDI)

In contrast to RDI, summation dose intensity (SDI)⁹ is an attempt to measure to what extent giving drugs in combination impairs giving the maximum total dose of an individual drug. If drugs are given in combination and there is no toxicity created by their use together then the summation dose intensity of a threedrug protocol will be 3. In reality, the use of drugs in combination almost always means that some reduction in dose will be required, so, for example, Frei¹⁰ uses the example of the MOPP protocol, where the summation dose intensity for the four drugs is 3.2 out of a possible 4, and contrasts this with the CMF protocol (used for breast cancer), where the summation dose intensity is only 1.2 out of a possible 3. In a third example, this time with respect to high-dose therapy and stem cell transplantation, the transplant conditioning schedule of three breast cancer protocols varied between 2.0 and 2.7, illustrating good additive dose escalation.

The effective dose approach

Hasenclever and colleagues⁶ have revisited the Skipper model in the setting of malignant lymphomas and have defined a 'generalized Skipper model' (GSM) by combining the Skipper concepts with a representation of the tumor heterogeneity with respect to the growth characteristics and chemosensitivity of that tumor type. Each tumor is assumed to have a specific chemosensitivity status and a characteristic latency time, which is derived from the time to disease progression after an initial response observed in clinical trials. The effective dose is then defined as

$$\frac{\text{total dose}}{1 + \text{treatment duration/average latency time}}$$

Using such models, the authors went on to propose that in Hodgkin lymphoma, where there is a long latency time (estimated to be 490 days), increasing the total dose is most likely to improve results and there is relatively little concern about tumor regrowth between treatment cycles. In histologically aggressive NHL, by contrast, the estimated latency time is 132 days and the tumor regrowth between cycles is a major concern, implying that the way forward is to shorten the intervals between therapy. Furthermore, they have suggested that a raised lactate dehydrogenase (LDH) is a surrogate measure of proliferation rate and thus latency time, and a more time-intense schedule is particularly important in those patients with a raised LDH at presentation. These concepts have formed the basis for the recent lymphoma trials in Germany,¹¹⁻¹³ and the results of these trials can be further used to modify and enhance the model.

Examples of dose intensification not requiring stem cell transplantation

A good illustration of an improvement in outcome with increased dose intensity is Burkitt lymphoma in adults. Historically, the survival rate was between 50% and 60%, but regimens such as CODOX-M/IVAC, which utilize a marked increase in dose intensity, as well as multiple chemotherapy agents, have produced survival rates in excess of 70%.^{14,15} It is interesting to note that this intensification of therapy has been achieved without the use of high-dose therapy and stem cell rescue but rather by changes in schedule and the addition of the hematopoietic growth factors. The use of growth factors to enable dose escalation should, therefore, be distinguished from the use of growth factors to maintain dose intensity with conventional-dose regimens (see above). The improvement attributable to CODOX-M/IVAC and a number of other modern Burkitt lymphoma regimens can be seen as a combination of the application of dose intensity (as per the Skipper log-kill hypothesis) and also the application of non-cross-resistant combination therapy (as per the Goldie and Colman hypothesis). Two further examples of increasing dose intensity, but this time without changing the drug combination, come from the German Hodgkin's Disease Study Group (BEACOPP versus escalated BEACOPP)¹¹ and also from the German Non-Hodgkin Lymphoma Study Group trial, where a comparison

was made between identical doses of CHOP or CHOP plus etoposide chemotherapy given over the standard 3 weeks or in the same dosage with a 2-week cycle accelerated by the use of hematopoietic growth factors.¹² In both of these cases, since exactly the same drugs are used, the improvement is only attributable to the increase in dose intensity achieved by the change in scheduling. The improvement in outcome with the escalated BEACOPP (freedom from treatment failure at 5 years 87%, versus 76% with standard BEACOPP) and time-accelerated CHOP in elderly patients (event-free survival at 5 years 44% with CHOP-14, versus 33% with CHOP-21) reflects the value of designing protocols from first principles and supports the concept of the GSM and effective dose model. Prior to these trials, the justification of various dose-intensity models has largely been derived from retrospective analysis of trial populations, where it has been shown that the worst outcome is achieved in patients where the relative dose intensity is poor. However, this can be a self-fulfilling prophecy, since the patients with a poor performance status at the outset (who are known to do badly) will also be the same patients in whom it is difficult to achieve the planned degree of dose intensity during treatment.

Drug selection in high-dose therapy and stem cell transplantation strategies

Special consideration needs to be given to drug selection in high-dose chemotherapy given with rescue by the infusion of hematopoietic stem cells. In this circumstance, where hematopoietic toxicity is effectively bypassed by the reinfusion of stem cells, close consideration has to be given to the toxicity profile of the agents in use. A good example of this is the anthracycline class of cytotoxics, whose dose-limiting toxicity is cardiac, and even though a drug such as doxorubicin is one of the most effective drugs in firstline lymphoma therapy, it is of little value in highdose chemotherapy. By contrast, alkylating agents such as melphalan are the most frequently used class of drugs, since doses can be escalated markedly over conventional dose levels, once hematopoietic toxicity has been excluded, before other critical organ toxicity (pulmonary, renal, or hepatic) becomes a consideration. The potential utility of drug classes in high-dose therapy can be assessed by their 'dose escalation index', which is the ratio of their maximum tolerated dose in conventional therapy and the increased dose achieved after stem cell rescue. The potential value of escalated therapy with stem cell rescue with respect to a particular tumor is also a property of the shape of the dose-response curve for the particular combination of a tumor/drug pair. Tumors where there is phase III evidence for the efficacy of high-dose chemotherapy, such as relapsed high-grade NHL,¹⁶ tend to be those illustrating a steep dose-response relationship, so that the higher doses of drugs delivered generate significantly higher tumor cell kill. Tumors where there is no evidence for the efficacy of high-dose therapy, such as breast cancer,¹⁷ tend to be those where the dose-response relationship is less steep.

Use of biological agents

In recent years, a number of biological agents have been introduced into the treatment of hematological malignancies, one of the most striking examples of which is the use of rituximab in combination with CHOP in the treatment of histologically aggressive NHL.¹⁸ Whether this can just be considered as another chemotherapeutic agent in the chemotherapy dose models is not clear. Thus, the addition of rituximab to CHOP-14 could further improve the results, but it is equally possible that when rituximab is used, there is no benefit in any further escalation over standard CHOP.

Maintenance therapy

Maintenance therapy comprising relatively low-dose therapy given over a long period of time has now been largely abandoned, except in acute lymphoblastic leukemia, as a result of clinical experience. The aim is to continue tumor reduction after the patient has achieved remission so as to bring about a cure. The drugs are often given on a semicontinuous schedule, and this type of scheduling has the theoretical advantage of being more active against any tumor cells that are in deep G_0 and only infrequently enter the cell cycle (when they become more accessible to chemotherapy attack).

Chemotherapy infusion and 'third spacing'

In tumors where the growth fraction is low (e.g. myeloma), alternative strategies for delivering the most effective use of chemotherapy may become applicable. One of the current standard treatments for myeloma is the VAD chemotherapy regimen,¹⁹ where the total dose and dose intensity are low but because the drugs are infused over a 4-day period, the area under the curve (AUC) in pharmacological terms is probably the key to the observed efficacy. The AUC has also proved a useful concept in dosing drugs where the toxicity threshold is close to the therapeutic level—for example carboplatin, where renal and hepatic handling are of particular importance. A fur-

ther example of the importance of the AUC is the observed toxicity noted with the phenomenon known as ‘third spacing’, which is where a drug is able to partition into extravascular fluid spaces such as pleural effusions or ascites, from where it is slowly returned to the intravascular space. This results in the prolonged presence of low drug concentrations and in turn increases the AUC and the risk of toxicity. This phenomenon has been well described for methotrexate²⁰ and cytarabine and more recently fludarabine.²¹ There had been an expectation that infusional therapy might be a means of either increasing efficacy or decreasing toxicity in other tumors, but there are few clinical data to support this.²²

Rescue strategies

It is not necessarily the case that theoretical principles can always be used to explain the value of clinical strategies. An example of where a frequently used strategy is not fully understood is the use of folinic acid (leucovorin) to rescue patients after very high doses of intravenous methotrexate. The true mechanism is probably unknown,²³ although the rationale for this is often said to be that the folinic acid allows normal tissues to recover without also ‘rescuing’ the tumor cells. The strategy has been used in a wide range of tumors, including head and neck cancer and NHL, and it is also said to allow the delivery of high doses of drug to protected compartments such as the central nervous system. The stated rationale is dependent upon alterations in the enzyme pathway of DNA synthesis (e.g. dihydrofolate reductase), but the experimental evidence for this is inconclusive.²⁴ To complicate the situation, the start of rescue protocols after less than 36–42 hours is probably too early to allow a genuine rescue phenomenon to occur with the administration of the folinic acid.²⁵

Conclusions

A sound knowledge of the principles underlying the practice of chemotherapy is fundamental to good clinical practice. The work of Skipper and of Goldie and Goldman indicates that dose intensity and scheduling may explain different outcomes between different regimens and should help in the design of future protocols. An understanding of the interaction between biological agents and chemotherapy should emerge from the results of ongoing trials.

Humoral immunotherapy and the use of monoclonal antibodies

Peter T Daniel

Introduction

Significant advances have been achieved in the therapy of hematopoietic malignancies. Polychemotherapy regimens in combination with radiotherapy, or bone marrow or stem cell transplantation yield high rates of complete remission. Nevertheless, a significant percentage of these remissions is not durable and therapy only prolongs survival. Primary or acquired resistance to DNA-damaging agents is the major problem of these conventional therapeutic strategies. In addition, the gains achieved by high-dose chemotherapy have been paralleled by an increase in drug-related multiorgan toxic side-effects, thereby limiting further dose escalation.

Recent developments in antibody technology have provided novel approaches to further improve the treatment of leukemia and lymphoma. In fact, the introduction of monoclonal antibodies in the treatment of different types of B-cell lymphoma has already shown impressive clinical efficacy. This has opened up the field, and antibodies targeted against a broad range of surface markers are now being successfully advertised as 'magic bullets' not only in the treatment of lymphoproliferative diseases but also in solid tumors and for immunosuppression in the control of autoimmune and graft-versus-host disease.

The history of antibody therapy

It was in the year 1897 when Paul Ehrlich developed the concept of immune bodies as the correlate for specific immunity and protection from infectious diseases. The basis for this concept was created only a few years earlier, in 1890, by Emil von Behring and Shibasaburo Kitasato, the founders of serotherapy, in their work on the transfer of specific immunity and protection from tetanus and diphtheria in experimental animals. Despite the interest in immune mechanisms and serotherapy in cancer starting as early as the start of the 20th century, the bulk of the work in this field has been done since the 1950s. Early investigations of serotherapy in malignant disease have been reviewed elsewhere.¹⁻³ The discovery of the molecular basis for antibody diversity by Susumu Tonegawa⁴ and the development of novel techniques for the immortalization of B cells and the production of monoclonal antibodies (mAbs) by Milstein and Köhler⁵ finally enabled the field for the use of specifically defined mAbs in diagnosis and therapy.

The generation of mAbs against tumor cells led rapidly to the discovery of novel tumor-associated markers that allowed new classifications and refined the diagnosis of lymphoid and myeloid malignancies. Ideally, the antibody should specifically target the tumor cell, and have no cross-reactivity with normal cells, since binding to non-malignant tissues will reduce effective tumor targeting. Moreover, the recognition of normal tissue by antibodies might cause severe damage to the patient. The majority of these tumor antigens are, however, not tumor-specific but only tumor-associated and therefore can also be found on the corresponding non-malignant counterparts. These antigens, which are often lineage-specific, can still serve as a target for tumor eradication provided that stem cells in the lineage of the normal cell are antigen-negative and hence able to reconstitute the cellular compartment or the tissue involved. A large number of tumor-associated antigens that may serve as putative targets for therapy have been identified by techniques such as Serex or more straightforward methods that measure genome-wide differential expression of gene products on the RNA or protein level, such as cDNA or oligonucleotide microarrays, differential display polymerase chain reaction (PCR), or proteome analyses. Truly tumor-specific antigens, in contrast, can be created by chromosomal translocations or point mutations leading to the formation of

neo-antigens such as the BCR–ABL fusion protein in chronic myeloid leukemia (CML). Such neo-antigens may also be found by the use of Serex, which employs low-titer antibodies found in patients' sera in an expression cloning strategy that yields the tumor antigen from a corresponding cDNA library.⁶ Nevertheless, the vast majority of these antigens represent embryofetal genes that are turned on in consequence of deregulated gene expression in tumor cells such as the cancer–testis antigens, i.e. tumor-associated antigens.⁷ Additional tumor-specific antigens being exploited in sero- and immunotherapy are the individual antigen receptors (idiotypes) found on the malignant lymphoid T or B cells (see below).

Due to the increasing number of monoclonal antibodies in the literature, which often reacted with the same molecule expressed during a distinct cellular differentiation stage, a unifying nomenclature was introduced. Based on the structures recognized by the antibodies, so-called clusters of differentiation (CD) were defined. Table 25.1 shows the expression pattern and lineage restriction of a few selected CD molecules identified as useful targets for antibody-based immunotherapy. These target structures were selected according to their biological properties, for example lineage restriction, expression levels, and signaling properties, or simply for historical reasons. Today, the vast majority of antibodies employed in anticancer therapy have been genetically engineered, in most instances, to replace antigenic murine structures by corresponding human framework sequences.

Recombinant antibodies

Classical mAbs are almost exclusively of murine origin. These antibodies were generated by immunization of mice and fusion of spleen cells from immunized animals containing a few antigen-specific cells with a murine plasmacytoma cell line followed to obtain immortalized hybridoma cells that secrete antibodies against the specific antigen employed for immunization.⁵ Such mAbs are xenogeneic proteins and therefore highly immunogenic. Individuals receiving murine monoclonals have been found to produce high titers of human anti-mouse antibodies (HAMA) within a few weeks after the first dose.^{8,9} These HAMA can neutralize the murine mAbs. This can reduce the efficacy of such antibody applications in vivo to the short time period before the neutralizing antibodies are detectable. Thus, efforts were undertaken to reduce the immunogenicity of the foreign proteins. One such approach was the generation of human mAbs by hybridoma technology, which, however, was not successful since the human hybridomas proved to be unstable and therefore not suitable for mass production. This, together with the need to facilitate the production of mAbs, which are still mainly produced in eukaryotic cells, led to the establishment of recombinant DNA technologies.^{10,11} The murine variable regions that contain the antibody recognition sites—the complementarity-defining regions (CDRs)—can now be cloned using PCR strategies. The structure of an IgG molecule is depicted in Figure 25.1. The cDNAs coding for the variable regions of the heavy and light chains of the murine immunoglobulins can be cloned and fused to the constant regions of human antibody cDNAs to produce human-like, chimeric monoclonal antibodies.¹² Apart from the murine variable regions, these chimeric antibodies resemble human self-structures, which largely reduces immunogenicity. Unfortunately, the few remaining amino acids of the murine variable regions can still be recognized as non-self and elicit neutralizing HAMA.

Table 25.1 Surface markers targeted in antibody therapy

Lineage	Stage of maturation			
	Early immature	Late immature and mature	Late, activated	Broad expression
T lymphocyte	CD1, CD7	CD3, CD4, CD8	CD25, CD30, CD95	CD2, CD5, CD7, CD45, CD52
B lymphocyte	CD10, CD38	sIgM, CD21, CD22, CD37, CD79	CD5, CD23, CD30, CD38, CD79, CD95	CD19, CD20, CD45, CD52, Idiotype
Myelomonocytic	CD33	–	CD16	CD13, CD14, CD15, CD45, CD52
Stem cells Carcinoma	CD34, HLA-DR	–	–	– EpCAM, HER2/ <i>neu</i> EGFR

Figure 25.1 Domain structure of IgG antibodies. C, constant region; V, variable region; H, heavy chain; L, light chain; CDRs, complementarity-defining regions, i.e. the three regions defining specificity of the antigen-binding region. They are located in the variable regions of the heavy and light chains (V_H and V_L).

Thus, efforts have been made to further decrease immunogenicity by grafting the regions responsible for antigen binding, i.e. the CDRs, to the constant parts of human heavy and light chains. This results in fully humanized antibodies. Nevertheless, due to the unique structure of their antigen-binding groove, these humanized antibodies still retain immunogenicity, and a humoral HAMA response has been observed against their foreign regions.

It should be noted, moreover, that a HAMA immune response can interfere with antibody-based detection systems in clinical chemistry and lead to falsely elevated assay results. Examples are sandwich enzymelinked immunosorbent assay (ELISA) systems for the detection of hormones or tumor markers. Such falsely elevated markers may misguide clinical decisions, and therefore caution should be exercised when such assays are performed on the sera of patients receiving antibody therapy.

Another promising development is the generation of recombinant single-chain antibodies. These consist of the variable region of the PCR-cloned antibody light chain fused to the variable region of the PCR-cloned heavy chain by means of an artificial linker peptide (Figure 25.2). Such single-chain variable region fragments (scFvs) can be easily produced in bacteria on a large scale as compared with eukaryotic cell-produced mAbs.¹³ In addition, the scFvs are much smaller than the original intact antibodies and therefore have different pharmacodynamic properties, such as improved tissue penetration (Table 25.2). In a similar approach, natural or genetically engineered ligands for surface receptors are employed to target receptor-bearing cells (see the discussion of immunotoxins later in this chapter).

To allow recognition of the antibody type employed, e.g. human, humanized or of murine origin, a nomen-

Figure 25.2 Recombinant DNA technologies for the production of monoclonal antibodies (mAbs). The variable regions of the heavy and light chain of a mAb can be cloned from the mRNA of a mAb-producing hybridoma using reverse transcriptase polymerase chain reaction (RT-PCR). Fusion of the cDNAs via a bridging linker yields the cDNA for the expression of a single-chain Fv fragment (scFv). The expression of such a scFv in bacteria allows the mass production of mAbs without the need for sophisticated eukaryotic cell culture techniques as in the case of the original hybridoma. Similar cloning techniques may be employed to humanize mAbs from mAbs of animal origin, i.e. to replace animal mAb framework sequences by the corresponding human sequences, mostly derived from human IgG1, while retaining the complementarity-defining regions.

clature has been introduced in which the generic name of the antibody has a suffix indicating its origin (Table 25.3). Thus, rituximab (IDEC-C2B8, i.e. chimeric 2B8) is a chimeric antibody (against human CD20) where the constant regions are derived from human IgG1 and the variable regions of the heavy and light chains are derived from the original IDEC-2B8 murine mAb.

Table 25.2 Targeting properties of different forms of antibodies

	IgG	bsAb	F(ab') ₂	Fab'	scFv	Diabody
Molecular weight (kDa)	150	300	100	50	20	40
Complement activation	Yes	Yes	No	No	No	No
ADCC	Yes	Yes	No	No	No	No
Blood half-life	1–3d	1–3d	~1d	~3h	~1h	~1h
Accumulation in	Liver	Liver	Liver	Kidney	Kidney	Kidney
Tumor penetration	Low	Low	Better	Good	Best	Good

bsAb, bispecific antibody; scFv, single-chain antibody; diabody, bispecific scFv; ADCC, antibody-dependent cell-mediated cytotoxicity

Table 25.3 Nonmenclature for therapeutic monoclonal antibodies

Suffix to generic name	Origin
-umab	Human
-zumab	Humanized
-ximab	Chimeric
-omab	Murine
-amab	Rat
-emab	Hamster
-imab	Primate

Serotherapy with unconjugated monoclonal antibodies

Despite their intellectual appeal, the initial therapeutic efficiency of unmodified tumor-reactive mAbs has been disappointing. In particular, the results of clinical studies in patients with solid tumors have shown little efficacy. In contrast to the disappointing results in carcinomas, however, some limited success had been reported with tumor-reactive antibodies in non-Hodgkin lymphoma (NHL), acute myeloid leukemia (AML), and T-cell leukemias. The first lymphoma patient was treated in 1979 by the group of Nadler and Schlossman.¹⁴ Despite the presence of soluble, blocking antigen in the circulation, a transient decrease in the numbers of circulating tumor cells was observed during and shortly after three infusions of the mAb. No side-effects were encountered on infusing doses up to 150 mg, and this study, despite the rather limited clinical success, pioneered the use of mAbs in the serotherapy of cancer. It is now clear that in many cases, the antibody doses employed might have been too low. Modern biotechnology and bioreactors were required to permit the gram-wise application of engineered antibodies in today's clinical studies.

Many of the early mAb trials focused on lymphoid neoplasms. mAbs capable of inducing tumor regression include mAbs to CD5, CD25, and CD52 (Campath-1) on T-cell leukemias and lymphomas, and mAbs to CD5, CD19, CD20, CD21, CD22, CD37, CD52, 2, HLA-DR, and the surface antigen receptor (idiotype) in B-cell neoplasms (Table 25.1). CD30 is restricted to a small subset of activated T and B cells, and may serve as a target structure for the treatment of Hodgkin and anaplastic large cell or other CD30/Ki-1⁺ lymphomas. Typical AML blasts may express the following surface markers: HLA-DR, CD45, CD33, CD34, CD13, CD15, and CD14, which can serve as targets for mAb therapy (Table 25.1). Efforts have therefore been made to also treat myeloid leukemias through this approach. The remarkable potency of these agents to kill leukemia and lymphoma cells has been demonstrated in trials of conjugated and unconjugated mAbs (see below).

Effector functions of mAbs

Unless the targeted structure is critical for the survival of the cell or for its proliferation, such as a growth factor or cell death receptor, binding of the antibody alone is not cytotoxic. There is considerable experimental and some clinical evidence that the nature of the antitumor response thereby largely depends on the ability of the mAb to activate immunological mechanisms (Figure 25.3). These are mainly complement-mediated cell lysis and antibody-dependent cell-mediated cytotoxicity (ADCC). They are determined by the antibody isotype: human or humanized IgM, IgG1, IgG2, and IgG3 can efficiently activate the complement cascade, leading to pore formation in the mAb-coated cell. Complement is a central component of the innate immune system involved in protection against pathogens. It induces death of targets either indirectly by attracting and activating phagocytes or directly by formation of a membrane pore, the membrane attack complex (MAC). Antibody-targeted cells may escape, however, from complement lysis through upregulation of the CD35 and CD59 receptors that play a role in inactivation of complement on antibody-targeted cells.¹⁵ Thus, induction of CD55 and CD59 has recently been

Figure 25.3 Effector mechanisms of mAbs. (a) Activation of the complement cascade (C'), which leads to the insertion of pore-forming channels in the cell membrane and lysis of the target cell, (b) Antibody-dependent cell-mediated cytotoxicity (ADCC): granulocytes (polymorphonuclear cells, PMN), monocytes/macrophages (Mφ), and natural killer cells (NK) can bind to mAb-coated tumor cells via Fc receptors and kill them, (c) Targeting of T cells by bispecific mAbs leads to polyclonal, T-cell receptor-independent T-cell I activation and target cell lysis, (d) Direct negative signaling by mAbs via activation of a signaling cascade upon binding to a surface receptor (growth arrest, apoptosis). (e) Killing of the target cell by toxins or radionuclides bound to the mAb, which is only used as a carrier to specifically target the cytotoxic compound to the tumor cell.

observed to correlate with failure of the anti-CD20 mAb rituximab to clear chronic lymphocytic leukemia (CLL) cells from the circulation.¹⁶

Binding of IgG isotypes, especially IgG1, IgG2, and IgG3, can attract Fc-receptor-bearing cells such as natural killer (NK) cells, granulocytes, and macrophages, which can then lyse the target cell (Figure 25.4). Differences, however, exist with regard to the species origin of the mAbs (e.g. murine, rat, or human). In particular, murine IgG1 mAbs bind little, if at all, to Fc receptors and do not activate complement (Figure 25.5).

More recently, it has been recognized that complement may cause other ‘non-classical’ effects that may not be aimed directly at the killing of pathogens. Products of complement activation collaborate with the adaptive immune system to enhance responses to antigens. The MAC of complement, apart from lysing cells, can also trigger diverse events in target cells, including cell activation, proliferation, resistance to subsequent complement attack, and either resistance to or induction of apoptosis.¹⁷ Moreover, attraction of phagocytes for ADCC either by bound antibodies or complement products results in induction of apoptosis in the affected target cell.¹⁸ This is mediated either through direct triggering of apoptosis by death-inducing ligands on the surface of the immune effector cell or by releasing apoptosis-promoting enzymes such as granzyme B into the target cell through channels formed by perforins. This indicates that antibody effector functions are more complex than previously believed.

Signaling functions of antibodies

Some tumor cells can produce growth factors that can bind to the corresponding receptors on the same or neighboring cells. The blocking of such autocrine or paracrine loops leads to cell cycle arrest or apoptosis (programmed cell death: Figure 25.6). Targeting the low-affinity interleukin-2 receptor (IL-2R) α chain (CD25) in T-cell malignancies or the IL-6 in multiple myeloma can disrupt autocrine or paracrine tumor cell stimulation both in vitro and in animal models. In adult T-cell leukemia (ATL) the infusion of anti-CD25 mAbs results in a significant rate of complete responses (CR) or partial responses (PR).¹⁹ In multiple myeloma, recent evidence suggests that an IL-6-like

Figure 25.6 Induction of apoptosis (programmed cell death) by antibodies against surface receptors. Apoptosis-inducing antibodies often mimic natural ligands, and mAbs against some surface receptors can trigger a death signaling cascade. Examples of this phenomenon are mAbs against the antigen receptors of B (or T) cells and the CD95 (APO-1/Fas) receptor. Apoptosis leads to destruction of the cell and is accompanied by chromatin condensation and DNA fragmentation to oligonucleosomal fragments, (a) Apoptosis of BL41 Burkitt lymphoma cells 16 hours after triggering with an anti-IgM mAb. DNA was visualized by ultraviolet light after acridine orange staining. Instead of a homogeneous staining, the nuclei show a patchy texture due to chromatin condensation and nuclear fragmentation, (b) Oligonucleosomal fragmentation of the genomic DNA (so-called DNA ladder). Low-molecularweight (fragmented) DNA was prepared after hypotonic lysis of apoptotic cells and was separated by agarose gel electrophoresis. BL41 cells were triggered for apoptosis by antigen receptor (surface IgM) crosslinking for 24 hours (lane 1, medium control; lane 2, anti-IgM Ab). Jurkat T cells were triggered for apoptosis by anti-CD95 mAb for 16 hours (lane 3, medium control; lane 4, IgG3 control mAb; lane 5, anti-CD95 (clone anti-APO-1 IgG3κ).

cytokine is produced by virally infected bone marrow stroma cells and stimulates plasma cell growth and survival. Stimulation via the IL-6R could thus be the causative agent for the disease as previously suggested.²⁰ Disappointingly, the use of an anti-IL-6R mAb in a phase I study in seven patients with multiple myeloma did not lead to a significant clinical response.²¹ Interestingly, myeloma cell proliferation was clearly decreased, indicating that IL-6 inhibition eventually might show efficacy in the future. Notably, the dose of the mAb was low in this study and only 20 mg per day were applied over a 12-day period. In another study, 11 myeloma patients were injected with 10–40 mg anti-IL-6 mAb: 1 had a PR and 7 showed stable disease.²² In both studies, low-grade fever resolved and C-reactive protein (CRP) levels

decreased, showing that the mAb was able to specifically block some IL-6-mediated effects. Clinical studies are underway to determine the clinical efficacy of IL-6 inhibition either by antibodies or pharmacological inhibitors of IL-6R signal transduction.

Antibody binding can also lead to direct negative signaling. This has been investigated in great detail with antibodies directed against the antigen receptors of normal and malignant T or B cells. Thus, anti-idiotypic but also plain anti-IgM or anti-IgD antibodies can mimic the natural ligand of the surface immunoglobulins, i.e. the antigen, and lead to cell cycle arrest in G₁ phase. Negative signaling for growth of B-NHL cells also can be exerted through antibodies against CD19, CD20, and the TAPA antigen. These molecules associate with the antigen receptor (e.g. surface IgM or IgD), and crosslinking them by mAbs mediates signal transduction events such as calcium fluxes, activation of receptor-associated kinases (Fyn, Lyn, and Blk), and activation of the mitogen-associated protein kinase (MAPK) cascade. Both animal experiments and clinical data show that antibodies directed against surface immunoglobulin, GD19, or CD20 can lead to tumor regression, and experimental evidence suggests that this is due to negative signaling (e.g. cell cycle arrest). Most likely, however, the immunological mechanisms described above contribute to the growth inhibition *in vivo*, and careful selection of the antibody isotype might increase the therapeutic effect.²³

In this vein, the direct induction of apoptosis by a tumor cell-reactive mAb is one of the most interesting developments and is a result of signal transduction events delivered by mimicking physiological ligands by the mAb. This has been demonstrated for mAbs directed against the antigen receptors of malignant T- or B-lymphoid cells, including anti-idiotypic mAbs^{24–26} (Figure 25.6—compare Figure 25.11). Other apoptosis-promoting molecules include the T-cell receptor-associated CD3-antigen ϵ -chain, the MHC class II molecules, CD20, CD30, CD52, and the CD95 (APO-1/Fas) molecule^{12,23,25,27–29} (Figure 25.6).

Obstacles in antibody therapy

Further issues for mAb therapy are mainly of pharmacokinetic and pharmacodynamic nature. Early studies indicated that neutralization of therapeutic antibodies may occur by HAMA/HACA (human antichimera antibody) humoral immune responses. Interestingly, the broad clinical use of chimeric antibodies such as the anti-CD20 chimeric antibody rituximab clearly demonstrated that HACA responses are limited in lymphoma patients and do not affect the clinical efficacy of rituximab.³⁰ Likewise, the occurrence of HAMA responses in up to 60% of patients treated with the entirely murine antibodies ¹³¹I-tositumomab or ⁹⁰Y-ibritumomab tiuxetan or other radiolabeled murine antibodies does not appear to affect clinical efficacy or result in high percentages of hypersensitivity reactions.³¹ This may be due to the high doses of the foreign protein and the fact that lymphoma patients are often immunocompromised. One of the major obstacles is, however, the insufficient tumor penetration of the large mAbs (150 kDa), particularly into bulky tumors. This furthermore depends on the mAb isotype, affinity, and epitope density on the target cell.²³ In addition, a pressure gradient from the core to the periphery of tumors and insufficient tumor vascularization makes it difficult for drugs and mAbs to reach the cells in the tumor core (Table 25.4). Thus, in high-affinity mAbs, the majority of the mAb may be absorbed around the initial tumor cell layers surrounding the supplying blood vessels.³² This insufficient tumor tissue penetration may severely affect the clinical efficacy, as observed in the case of the anti-CD 19 antibody anti-B4 coupled to a ricin toxin.³³ Tumor cell heterogeneity is another problem, and selection of clones that express low antigen density or even of antigen-negative clones can occur. Furthermore, tumor cells can evade the mAb by shedding the antigen, as in the case of the CD25 and CD30 antigens. This has been observed in ATL cells, where the CD25 antigen can be found in large quantities in the circulation.^{19,34} In contrast, the CD19 antigen, a pan-B-cell marker, is not released from the cell surface.³² Resistance to host

Table 25.4 Difficulties encountered in serotherapy with monoclonal antibodies (mAbs)

Delivery

- Non-specific binding of the mAb to normal tissue
- Absorbance of the mAb by shedded antigen
- Downmodulation of the tumor antigen by mAb binding
- Inactivation by neutralizing antibodies (HAMA)
- Inefficient penetration of the mAb macromolecules into bulky tumors
- Absorption of the mAb in the first tumor cell layers surrounding the blood vessels
- Short half-life of some antibodies

Tumor cell evasion

- Inefficient host cytotoxic mechanisms (complement, ADCC)
- Tumor cell resistance to host cytotoxic mechanisms
- Lack or heterogeneity of tumor antigen expression
- Selection of tumor cell clones with mutated epitopes

Toxicity

- Allergic reactions, serum sickness
- Targeting of host cytotoxicity towards non-malignant tissue
- Direct toxicity to normal cells

immune mechanisms such as complement lysis has been described *in vitro*, e.g. as a consequence of upregulation of endogenous complement-inhibitory receptors such as CD55 and CD59.¹⁶

Clinical use of unlabeled antibodies

In clinical studies, a humanized chimeric anti-CD20 antibody (rituximab) has now been established as a complement to classical chemotherapy in low- and high-grade B-NHL.³⁵ Notably, the vast majority of the more or less positive data on the clinical efficacy of rituximab are derived from phase I/II trials. Evidence from prospective phase III trials where rituximab alone or rituximab plus chemotherapy were compared with standard regimens is unfortunately still scarce despite the fact that an estimated over 50 000 patients worldwide have been treated with rituximab.

The human CD20 antigen shows lineage-specific expression on all B lymphocytes except plasma cells, pro-B precursor B cells, and hematopoietic stem cells. It is found in high density on the surface of most NHL and does not shed into the serum. CD20 is a non-glycosylated phosphoprotein that is essential for regulation of growth and differentiation of activated B cells. Crosslinking of CD20 by rituximab triggers calcium fluxes that result in growth arrest in G₁ phase of the cell cycle and trigger apoptosis in targeted B cells (Figure 25.7). In addition, ADCC and complement lysis have been described as effector mechanisms (reviewed in reference 36). There is an ongoing discussion as to which of these mechanisms is the major one determining the clinical efficacy of rituximab (or that of other mAbs).

A phase I/II study in 166 patients (median age 58 years, 151 patients evaluable) with low-grade B-NHL in relapse after prior polychemotherapy showed an overall response of 48%, including 10 patients (6%) with a CR, with a median time to progression of 13 months in responders. Patients received 375 mg rituximab as a single agent weekly for 4 weeks. The mAb infusion led to a rapid B-cell depletion, which recovered 9–12 months after therapy and did not result in a major decrease in IgM/IgG levels or increased susceptibility to infection. No neutralizing HAMAs were observed and only 3 patients developed HACA. The majority of adverse events occurred during the first infusion and were grade 1 or 2; fever and chills were the most common events. Only 12% of patients had grade 3 and 3% grade 4 toxicities.³⁷ These results are comparable to those obtained in historic controls with the use of the nucleoside analogs fludarabine and cladribine.

High-grade B-NHL shows a similar density of the CD20 antigen as compared with follicular lymphoma. Rituximab as a single agent was employed in first-line

Figure 25.7 Induction of apoptosis by the anti-CD20 mAb rituximab. BL41 Burkitt lymphoma cells were incubated in the presence of rituximab or an isotype-matched control antibody immobilized by coating of the mAbs to the plastic of the culture dish. Rituximab, but not the control antibody, induced apoptosis, as determined by flow-cytometric measurement of genomic DNA fragmentation, (a) Percentages of cells with a hypodiploid DNA content are shown. Apoptosis started to be detectable at 8 hours and reached a maximum at 20-hour culture with rituximab. (b) Apoptotic morphology of rituximab-treated BL41 cells was visualized by staining of cellular DNA with acridine orange under ultraviolet light. The upper left of the photograph shows a non-apoptotic cell with intact nucleus and homogeneously distributed chromatin.

therapy in elderly patients above 60 years of age or as second- or third-line therapy in younger patients in first or second relapse. This randomized multicenter phase I/II trial compared eight cycles of weekly rituximab at 375 mg/m² with one cycle at 375 mg/m² followed by seven weekly cycles at 500 mg/m². There was a slight tendency for more pronounced adverse reactions in the higher-dose arm and, as expectable, no difference regarding the therapeutic efficacy.³⁸ Of the 54 patients, 9% achieved a CR and 31% a PR. These response rates are concordant with those observed in the plethora of additional, more or less uninformative, phase I/II trials that can be found in the literature.

Interestingly, there is evidence that lymphoma subtypes may respond differently to such anti-CD20 treatment. In low-grade lymphoma, good overall response rates of approximately 50% were seen in follicular lymphoma, whereas immunocytoma with lymphoplasmacytoid differentiation showed a far worse response. This may be due to differences in the level of CD20 expression. Notably, another phase I/II study in 70 patients with therapy-refractory follicular lymphoma demonstrated that pretreatment status matters, as the highest number of responders (80%) was found in patients who had received only one prior course of chemotherapy.³⁹ This indicates that chemotherapy utilizes similar effector mechanisms as rituximab and that prior chemotherapies may select for resistance to antibody therapy. In line with other studies and in contrast to other NHL subtypes, immunocytoma showed an overall response rate of 28% among 28 patients, and in B-CLL a rate of only 14% among 29 patients.³⁹ A rather interesting phase II trial investigated the efficacy of retreatment with rituximab in patients with low-grade or follicular NHL who relapsed after a response to rituximab therapy. The overall response rate in 57 assessable patients was 40% (11% CR and 30% PR). The median time to progression (TTP) in responders and the median duration of response (DR) as estimated by Kaplan-Meier analyses were 17.8 months and 16.3 months (range 3.7+ to 25.1 months), respectively.⁴⁰

Better results as compared with rituximab monotherapy can be obtained when rituximab is combined with conventional chemotherapy.⁴¹ In fact, *in vitro* studies demonstrated that rituximab sensitizes B-lymphoma cells to drug-induced apoptosis.⁴² This is very similar to the anti-HER2/neu antibody trastuzumab (Herceptin), which sensitizes breast carcinoma cells to anthracycline-induced cell death.⁴³ Upon ligation of CD20, rituximab activates the mitochondrial pathway of apoptosis,⁴⁴ which mediates the final demise of the targeted cell through a caspase-3-dependent pathway.⁴⁵ Anticancer drugs depend critically on the same mitochondrial cell death pathway. Thus, the molecular basis for the synergism between rituximab and anti cancer drugs appears to be lowering of the threshold for mitochondrial activation in apoptosis.

A phase II trial in newly diagnosed or relapsed lowgrade lymphoma yielded a CR in 58% and a PR in 42% of the patients when CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) was combined with rituximab for six cycles every 3 weeks. Rituximab was administered prior to CHOP and did not increase toxicity when compared to historic controls. Remissions were sustained, with 74% of the patients remaining in remission at 29 months.⁴⁶ This favorable effect of combined rituximab/CHOP was also established by a large randomized multicenter trial by the Groupe d'Etude des Lymphomes de l'Adult (GELA) in elderly patients with high-grade B-NHL (Figure 25.8). Previously untreated patients with diffuse large B-cell lymphoma, 60–80 years old, were randomized to receive either an optimal 'standard' regimen of eight cycles of CHOP every 3 weeks (197 patients) or eight cycles of CHOP plus rituximab given on day 1 of each cycle (202 patients). This trial clearly established a significantly higher rate of CR of

Figure 25.8 Combination of CHOP chemotherapy with rituximab in first-line therapy of high-grade B-NHL. Patients received either eight cycles of CHOP or eight cycles of CHOP plus rituximab (CHOP+R). CHOP+R-treated patients showed a significantly better event-free survival. This was apparent in patients younger or older than 70 years (a and b, respectively). Adapted from reference 47.

76% in the group that received CHOP plus rituximab as compared with the group that received CHOP alone (63% CR). Both event-free and overall survival times were significantly higher in the CHOP-plus-rituximab group during a median 2-year follow-up. Notably, clinically relevant toxicities were not significantly greater with CHOP plus rituximab. This indicates that the addition of rituximab to the CHOP regimen increases CR rates and prolongs event-free and overall survival in elderly patients with diffuse large B-cell lymphoma, without a clinically significant increase in toxicity.⁴⁷ Nevertheless, it remains to be established whether these remissions are durable and really result in sustained prolongation of event-free survival. In this context, a promising finding is the propensity of this immunochemotherapy regimen to overcome resistance as a consequence of *bcl-2* overexpression in this patient cohort.⁴⁸

In contrast, rituximab does not improve response rates and duration of remission in low-grade B-NHL patients treated with interferon- α 2a (IFN- α 2a).⁴⁹ Nevertheless, promising data were generated in low-grade B-NHL in a randomized phase III study by the German Low-Grade Lymphoma Study Group. This trial evaluated rituximab in combination with FCM (fludarabine, cyclophosphamide, and mitoxantrone) in a randomized setting versus FCM alone in patients with relapsed or refractory follicular, mantle cell, or lymphoplasmacytic lymphoma. An interim analysis of 94 evaluable patients demonstrated a significantly higher response rate for rituximab plus FCM (overall response rate, ORR 83%; CR rate 35%) as compared with FCM alone (ORR 58%; CR rate 13%), with no increase in toxicity. Superiority of rituximab plus FCM was seen both in follicular lymphoma ($n=53$; ORR 92% versus 75%; CR rate 40% versus 21%) and, most strikingly, in mantle cell lymphoma ($n=38$; ORR 65% versus 33%; CR rate 35% versus 0%). Moreover, a trend towards longer overall and disease-free survival for rituximab plus FCM was reported.⁵⁰

In contrast, the efficacy of rituximab is low in immunocytoma and quite limited in B-CLL.^{39,51} Of 28 patients treated with four intravenous infusions of rituximab 375 mg/m² over 4 weeks, only 7 responded with a PR.⁵² This may very well be due to the generally lower expression of CD20 in B-CLL as compared with follicular and high-grade lymphomas such as diffuse large B-cell lymphoma. Moreover, toxicities are in general more pronounced in B-CLL, probably as a consequence of the large number of circulating malignant B cells. Thus, in particular, CLL patients with high peripheral blood B-cell counts are prone to potentially lethal tumor lysis syndrome accompanied by fever, chills, nausea, seizure and thrombocytopenia. Such syndromes may arise following the secretion of tumor necrosis factor α (TNF- α), IFN- γ and IL-6 upon the first infusion of rituximab.⁵³ It remains to be established whether the addition of conventional chemotherapy such as nucleoside analogs may improve these so-far unsatisfactory results. A recent phase II study indicates in fact that such a combination with fludarabine shows increased efficacy in B-CLL. The overall response rate (CR+PR) was 87% (27 of 31 evaluable patients). Of 20 previously untreated patients, 17 (85%) responded. Of 31 patients, 10 achieved a CR (5 of 20 untreated, 5 of 11 pretreated, 9 of 21 Binet stage B, and 1 of 10 Binet stage C). The median duration of response was 75 weeks. Given this so-far limited success, a recent trial employed repetitive courses of four cycles of weekly rituximab at 375 mg/m² that were given in 6-month intervals in responding patients. By using this maintenance treatment approach in 44 patients, an overall response rate of 58% with 9% CR was obtained (28 patients received one or more additional courses).⁵⁴ There is, however, no evidence from randomized trials available that would support the usefulness of such a maintenance therapy.

A reason for concern regarding the clinical use of rituximab is the prolonged impairment of antibody production, leading to an increased risk of viral and bacterial infections. Pure red blood cell aplasia due to parvovirus B19 infection has been reported after administration of rituximab,⁵⁵ as have acute viral hepatitis B⁵⁶ and bacterial pneumonia.⁵⁷ Nevertheless, this profound suppression of humoral immune responses has recently been recognized as a therapeutic feature that is now successfully exploited in immunosuppressive regimens in autoimmune diseases (see below).

An antibody approach more suitable to B-CLL may come from the revival of the anti-CD52 mAb alemtuzumab (Campath-1H, humanized rat IgG1). CD52 is highly expressed on over 95% of peripheral blood lymphocytes and monocytes and in the majority of T- and B-cell neoplasias. Low-level expression is found on granulocytes, and hematopoietic stem cells are void of CD52. The physiological function of CD52 on these cell types remains so far enigmatic. The mechanism of action of Campath-1 is based on complement activation and ADCC.

Studies performed in the late 1980s showed a rather limited effect of Campath-1 in various B-cell malignancies, depending on the isotype (IgG2a or IgM).⁵⁸ The first two patients with advanced NHL treated with humanized alemtuzumab both showed a PR.⁵⁹ Likewise, 11 of 15 T-prolymphocytic lymphoma (T-PLL) patients treated with alemtuzumab achieved a PR.⁶⁰ In low-grade NHL, a multicenter phase II trial applied alemtuzumab in 50 patients at 30 mg intravenously three times per week over 12 weeks, and showed a CR in only 4% and a PR in 16% of the patients. It became apparent, however, that, apart from fever and chills in 80% of the patients, alemtuzumab therapy is associated with a very significant

risk of hematologic toxicities: 28% of patients showed grade 3–4 neutropenia and 22% grade 3–4 thrombocytopenia. In addition, a long-lasting lymphopenia was induced by alemtuzumab treatment. The latter is the underlying reason for the high rate of severe infectious complications, including viral and fungal infections, with 28% of the patients developing pneumonitis. As in the case of rituximab, this feature is now used in immunosuppressive therapies, and in the control of graft-versus-host disease (GVHD; see below).

Other phase II studies with alemtuzumab showed similar response rates and spectra of severe complications. Especially in B-CLL, higher response rates were observed: 29 patients who had relapsed after an initial response ($n=8$) or were refractory to chemotherapy ($n=21$) were treated with alemtuzumab administered intravenously 30 mg three times a week for a maximum period of 12 weeks. Eleven patients (38%) achieved a PR and one (4%) a CR. Three of 8 patients (38%) with a relapse and 9 of 21 refractory patients (43%) responded to alemtuzumab therapy. CLL cells were rapidly eliminated from blood in 28 of 29 patients (97%). CR in the bone marrow was obtained in 36% and splenomegaly resolved completely in 32%.⁶¹ These results are supported by a more recent phase II trial in CLL first-line therapy.⁶² This phase II study determined the efficacy and safety of alemtuzumab over a prolonged treatment period of 18 weeks in 41 patients with symptomatic B-CLL. Injections were administered subcutaneously three times a week. An overall response rate of 87% (with a CR in 19% and a PR in 68%) was achieved in 38 evaluable patients. CLL cells were cleared from the blood in 95% of patients in a median time of 21 days. CR or nodular PR in the bone marrow was observed in 66% of the patients and most patients achieved this after 18 weeks of treatment. Notably, a 87% overall response rate (with a CR in 29%) was established in the lymph nodes. Transient injection site skin reactions were seen in 90% of patients. Rigor, rash, nausea, dyspnea, and hypotension were, however, rare or absent. Transient grade 4 neutropenia developed in 21% of the patients. Infections were rare, mainly due to cotrimoxazole prophylaxis, but 10% of patients developed cytomegalovirus (CMV) reactivation. Thus, alemtuzumab is highly effective as first-line treatment in patients with B-CLL, but requires caution in view of the impressive immunosuppression by this compound.

More antibodies to come...

In addition to antibodies against CD20 and CD52, a variety of antibodies are currently being developed for the treatment of T- and B-NHL and lymphoid and myeloid leukemias. CD22 is a 135 kDa B-cell-restricted sialoglycoprotein present in the cytoplasm of virtually all B-lineage cells but expressed on the B-cell surface only at mature stages of differentiation. CD22 expression is high in follicular mantle and marginal zone B cells and weak in germinal center B cells. In B-cell malignancies, CD22 expression ranges from 60% to 80%, depending on the histological type and on the assays used. The function of the CD22 molecule is uncertain, although recent studies have suggested roles for the molecule both as a component of the B-cell activation complex and as an adhesion molecule. After binding to antibodies, CD22 is rapidly internalized. This provides a potent costimulatory signal in primary B-cells and proapoptotic signals in neoplastic B cells. In preclinical studies, CD22 has been shown to be an effective target for immunotherapy of B-cell malignancies using either naked, unconjugated or toxin-labeled or radiolabeled mAbs.⁶³ Clinical trials in patients with low- and high-grade NHL are now ongoing with a humanized unconjugated anti-CD22 antibody (epratuzumab) used as single agent or in combination with other mAbs (e.g. rituximab) and/or chemotherapy. Preliminary data from these studies has shown that such approaches are effective and well-tolerated.

Newer antibodies in development as single agents and in combinations include apolizumab (Hu1D10), a humanized antibody against an epitope of HLA-DR, and IDEC-152, a primatized anti-CD23 antibody. BL22, anti-CD22 immunotoxin with impressive activity in hairy cell leukemia, is in phase II trials in CLL as well. Antibodies employed in the treatment of solid tumors are discussed separately (see below).

Immunotoxins

Because of the low intrinsic cytotoxicity of most mAbs, antibody–toxin conjugates (immunotoxins) have been constructed (reviewed in reference 64). Conventional immunotoxins are capable of inducing responses in patients with hematological malignancies, with dose-limiting toxicities being thrombocytopenia, hepatic damage, and especially vascular leak syndrome.⁶⁵ The latter is characterized by an increase in vascular permeability accompanied by extravasation of fluids and proteins and resulting in interstitial edema and organ failure. Manifestations include fluid retention, increase in body weight, peripheral edema, pleural and pericardial effusions, ascites, anasarca, and, in severe forms, signs of pulmonary and cardiovascular failure. Symptoms are highly variable among patients. The pathogenesis of vascular leak syndrome is poorly understood, but involves both direct damage to endothelial cells by the toxin and release of cytokines and of inflammatory mediators by targeted leukocytes that lead to alterations in cell–cell and cell–matrix adhesion and cytoskeletal function of vascular endothelial cells. Vascular leakage is the

major dose-limiting toxicity in immunotoxin therapy and, in some cases, necessitates the cessation of therapy.

Newer immunotoxins contain a recombinant ligand, either the variable domains (Fv) of a mAb or a growth factor, fused to a truncated bacterial toxin. The antibody portion of the immunotoxin is used to focus the toxin specifically to the targeted cell population. The cytotoxic effect of the immunotoxin therefore does not rely on the activation of immune helper mechanisms or of growth-inhibitory or apoptosis-inducing signaling. The mAb is only used as a vehicle to target the toxin to the tumor cell. Conjugates with potent toxins have been produced either by chemical crosslinking or, more recently, by genetically engineered recombinant fusion proteins with scFvs. Genetically engineered immunotoxins have been proven to be more potent as compared with the chemical production procedure. Using a similar approach, toxins have been fused to non-antibody-derived ligands such as cytokines that may be employed to target the toxin to cytokine receptor-expressing tumor cells (e.g. the IL-2R). Recombinant fusion toxins have several potential advantages over conventional immunotoxin chemical conjugates, including (1) a defined toxin–ligand junction; (2) efficient and relatively inexpensive production on a large scale from bacteria; (3) shorter plasma half-lives, which might avoid the diffuse endothelial damage that leads to vascular leak syndrome; and (4) the ability to genetically engineer mutations in the recombinant toxin to increase its potency or lower its non-specific toxicity.

The two major varieties of recombinant fusion toxins are growth factor fusion toxins, containing a growth factor fused to a truncated toxin, and recombinant immunotoxins, containing the Fv domains of an antibody fused to a truncated toxin. In either case, the ligand is used to bind selectively to tumor cells while the toxin kills the target cell following internalization.⁶⁶

The toxins employed in most conjugates are *Diphtheria* toxin, *Pseudomonas* exotoxin, the plant-derived ricin, and, more recently, the bacterial toxin calicheamicin. Most toxins possess domains specific for cell binding (B chain), toxin translocation (B chain), and toxic activity (A chain). Ricin tends to bind via its B chain to galactose carbohydrate moieties expressed on most cell types.⁶⁷ Therefore, to prevent non-specific binding to untargeted tissue, so-called ‘blocked’ ricin is produced in which blocking affinity ligands are attached to the ricin B chain. This has been proven advantageous over the removal of the B chain from the toxin, since the translocation-mediating B-chain moieties and consequently higher biological activity are retained in the complex.

Nanogram quantities of the pure toxin would be lethal to the patient if not bound to a targeting moiety, for example an antibody, an scFv fragment, or a growth factor, to target it directly to a specific tumor cell. This also implies that only mAbs with low cross-reactivity with normal tissues are selected for the generation of immunotoxins.

In contrast to antibody therapy with unconjugated mAbs, it is advantageous in the case of immunotoxins that the target antigen be internalized together with the bound immunotoxin. This allows the toxin component to exert action. In the case of *Diphtheria* toxin and *Pseudomonas* exotoxin, the mode of action is based on inhibition of protein synthesis and ATP depletion through ADP-ribosylation, which inactivates elongation factor 2 (EF2) and turns off the transcriptional machinery of the cell. Similarly, ricin inactivates protein synthesis by disrupting N-terminal glycosylation of 28S-rRNA via the catalytically active A chain. Like *Diphtheria* toxin and *Pseudomonas* exotoxin, ricin thereby inactivates ribosomes by rendering their 60S subunit unable to bind EF2. In contrast, calicheamicin is a member of the enediyne class of antitumor antibiotics, i.e. a ‘small molecule’ and not a protein like the toxins described above. This toxin is therefore discussed below, in the context of drug–antibody conjugates.

Using such compounds in vitro, up to a 5 log₁₀ reduction of tumor cells has been reported. These immunotoxins are efficient at nanomolar concentrations in vitro and in vivo to eliminate malignant cells. In fact, while gram quantities of unlabeled mAbs have often been administered to demonstrate clinical efficacy, milligram quantities of immunotoxins can suffice to eliminate an established tumor in vivo in animal models. A major disadvantage of immunotoxins as compared with unconjugated mAbs or radiolabeled mAbs (see below) is, however, their increased immunogenicity. The macromolecular toxins are of mostly bacterial origin and therefore lead rapidly to the production of neutralizing antibodies, which may also be present prior to therapy due to vaccination (*Diphtheria* toxin) or natural exposure (*Pseudomonas* exotoxin).

Immunotoxins against CD5, CD19, CD22, and CD38 (B-NHL), against CD3, CD5, CD7, and CD25 (T-NHL), and against CD30 (anaplastic large cell NHL and Hodgkin’s disease) have been successfully employed in vitro and in experimental animals in vivo to eliminate malignant cells.⁶⁴ A phase I study of a murine anti-CD22 mAb (RFB4) coupled with deglycosylated ricin A chain (dgA) in 26 patients with relapsed B-NHL showed short-term responses of 30–78 days with 1 CR and 5 PR.⁶⁸ Patients were treated for up to 24 days; vascular leak syndrome was dose-limiting and in 1 patient rhabdomyolysis was encountered. A high percentage (37%) of patients developed antibodies against the murine Ig or the dgA. Animal experiments show that the efficiency of this toxin can be

increased by combination with an anti-CD19 antibody as carrier (HD37-dgA⁶⁹). An anti-CD 19-blocked ricin (anti-B4-blocked ricin) immunotoxin was administered in 12 patients as a 7-day continuous infusion during complete remission after autologous bone marrow transplantation (ABMT) for relapsed B-NHL.⁷⁰ Again, vascular leakage was dose-limiting. Anti-immunotoxin responses developed in 7 patients, but 11 of the 12 patients remained in CR 13–26 months after ABMT. Another phase I trial was conducted with daily bolus injections of the anti-B4-blocked ricin immunotoxin.⁷¹ In this trial, 25 patients were treated with increasing immunotoxin doses for 5 days; the main toxicities were reversible elevation of aminotransferases, thrombocytopenia, and fever. One CR and two PR were observed. Nine patients developed a humoral immune response against the immunotoxin that may be directed against either the antibody component or the toxin itself. Additional adverse side-effects reported in other phase I trials with anti-B4-blocked ricin are fatigue, nausea, hypoalbuminemia, myalgia, dyspnea, and capillary leak syndrome. A later phase II trial in 16 patients with relapsed CD19⁺ NHL, conducted to evaluate the efficacy of anti-B4-blocked ricin when administered at the previously established maximum tolerated dose using a daily bolus for 5 consecutive days, failed to establish the clinical efficacy of this compound. Immunohistochemical analysis of tissue samples provided some insight into the low efficacy and showed poor penetration into lymphoid tissue.³³ To this end, phase II trials were undertaken in which anti-B4-blocked ricin was either combined with aggressive polychemotherapy in 25 patients with low-grade NHL⁷² or as adjuvant therapy to patients in CR after ABMT for B-NHL.⁷³ These trials yielded interesting data regarding the efficacy of such combination regimens, but so far they have not allowed determination of the contribution of the immunotoxin. Nevertheless, such an adjuvant approach might overcome the limitations imposed by the poor tissue penetration. Apart from problems arising from pharmacokinetics, toxic side-effects of the toxins might be the limiting factor in future developments in immunotoxin-based therapeutic strategies. In the case of the dgA-conjugated anti-CD 19 antibody HD37, such adverse effects that may be dose-limiting are vascular leak syndrome, aphasia, rhabdomyolysis, and acrocyanosis with reversible superficial distal digital skin necrosis in the absence of overt evidence of systemic vasculitis.⁷⁴ In fact, a phase I study in 22 patients that employed a combination regimen of dgA conjugated to mAbs directed against CD22 (RFB4-dgA) and CD19 (HD37-dgA) reported two therapy-related fatal complications.⁷⁵ So far, apart from these toxicity profiles no trial data have been published for RFB4-dgA and HD37-dgA that would allow assessment of the clinical efficacy of these interesting compounds in the therapy of B-NHL. Finally, the toxicity of dgA chain containing immunotoxins in patients with NHL is exacerbated by prior radiotherapy, and this may affect the clinical applicability of dgA immunotoxins in pretreated patients.⁷⁶

In contrast, denileukin diftitox (DAB389IL2, Ontak) is a recently US Food and Drug Administration (FDA)-approved growth factor fusion toxin containing human IL-2 and *Diphtheria* toxin and is effective in chemotherapy-resistant cutaneous T-cell lymphoma (CTCL). Denileukin diftitox is an IL-2R-specific ligand fusion protein that may potentially be selective for IL-2R-expressing malignancies. Its activity in the treatment of cutaneous T-cell lymphoma has established the feasibility of utilizing such a targeted therapeutic in disseminated disease with acceptable toxicity. Data from a phase I trial suggest that the definition of activity in other cancer types, including other NHL, is warranted. Denileukin diftitox and its predecessor, DAB(486)IL-2, have shown clinical activity in a variety of diseases, including B-NHL, CTCL, Hodgkin lymphoma, psoriasis, rheumatoid arthritis, and HIV infection. The highest response rates were observed in CTCL, and this became the focus of clinical trials leading to its subsequent approval by the FDA for this disease.⁷⁷ In a recent clinical trial, patients with biopsy-proven CTCL that expressed CD25 were treated with denileukin diftitox administered on 5 consecutive days every 3 weeks for up to eight cycles. Overall, 30% of the 71 patients with CTCL treated with denileukin diftitox had an objective response (20% PR; 10% CR). Adverse events consisted of flu-like symptoms (fever, chills, nausea, and myalgias/artralgias), acute infusion-related events (hypotension, dyspnea, chest pain, and back pain), and a vascular leak syndrome with hypotension, hypoalbuminemia, and edema. In addition, 61% of the patients experienced transient elevations of hepatic aminotransferase levels, with grade 3–4 in 17%. Hypoalbuminemia occurred in 79%, including 15% with grade 3–4 toxicity.⁷⁸

Anti-Tac(Fv)-PE38 (LMB-2) and RFB4(dsFv)-PE38 (BL22) are two recombinant immunotoxins, targeting the CD25 low-affinity IL-2R and CD22, respectively, in which Fvs of mAbs targeting these antigens are fused to truncated *Pseudomonas* exotoxin. BL22 is a recombinant *Pseudomonas* exotoxin-based immunotoxin under development by the US National Cancer Institute (NCI) for the treatment of B-cell malignancies. It is composed of the disulfide-stabilized Fv portion of the anti-CD22 antibody RFB4 genetically fused to a truncated form of *Pseudomonas* exotoxin A. It has entered phase I trials for the treatment of B-NHL.⁷⁹ Both LMB-2 and BL22 have exhibited clinical activity in patients with hematological malignancies, with less vascular leak syndrome and probably less immunogenicity than the larger conventional immunotoxin conjugates. In a phase I trial of LMB-2 in 35 patients with various hematological maligna-

cies, one hairy cell leukemia (HCL) patient achieved a CR, which was ongoing at 20 months. Seven PR were observed in patients with CTCL, HCL, B-CLL, Hodgkin lymphoma, and ATL. Responding patients had 2–5 \log_{10} reductions of circulating malignant cells, improvement in skin lesions, and regression of lymphomatous masses and splenomegaly. All four patients with HCL responded to treatment. Thus, LMB-2 has clinical activity in CD25⁺ hematological malignancies.⁸⁰

Two other immunotoxins, RFT5.dgA (anti-CD25) and Ki-4.dgA (anti-CD30) were assessed in Hodgkin lymphoma regarding their toxicity and clinical efficacy in phase I/II trials. The immunotoxins were constructed by linking the mAbs RFT5 or Ki-4 to dgA. Both immunotoxins showed potent specific activity against Hodgkin lymphoma cells in vitro and in vivo in animal xenotransplant models, and were subsequently evaluated in phase I/II clinical trials in humans. Of the 18 patients treated at the maximum tolerable dose of RFT5.dgA, 17 were evaluable for clinical response and showed 2 PR, 1 minor response (MR), and stable disease (SD) in 5 patients. Of 17 patients treated with Ki-4.dgA, 15 were evaluable for clinical response, and responses included 1 PR, 1 MR, and 2 SD. Toxicities were comparable to those observed in other trials with dgA immunotoxins.⁸¹ It remains, however, to be established whether these compounds overcome the limitations observed with similar dgA immunotoxin constructs directed against CD 19 in B-NHL immunotherapy.

Apart from these hallmark examples, a plethora of new recombinant immunotoxins are currently being engineered and developed to target a variety of hematological and solid tumor antigens. The impression is, however, that the efficacy of immunotoxin constructs is overall lower as compared with that of radiolabeled immunoconjugates. The reasons for this phenomenon may reside in poor tumor penetration, humoral immune responses against the toxin component, and the toxicity profiles of the employed toxins. Exceptions to this rule are, however, conjugates with calicheamicin, as evidenced by the clinical efficacy of gemtuzumab ozogamicin, an anti-CD33–calicheamicin conjugate (see below).

Targeting of anticancer drugs by the use of antibodies

A special form of immunotoxin can be produced by linking cytostatic drugs to mAbs. Since a major advantage of the immunotoxin approach consists, however, in circumventing primary or acquired resistance mechanisms to conventional cytostatic drugs, the clinical efficacy of such a targeting of the classical anticancer compounds remains to be elucidated, especially in view of the well-known resistance mechanisms. In contrast to drug conjugates employing conventional anticancer drugs, gemtuzumab ozogamicin, a conjugate of the bacterial toxin calicheamicin, has been successfully employed in the treatment of myeloid leukemias. Calicheamicin is a naturally occurring hydrophobic enediyne antibiotic that was isolated from *Micromonospora echinospora calichensis*.⁸² It exerts potent antitumor activity and has been shown to induce apoptotic cell death in the picomolar range (Figure 25.9). Calicheamicin binds to the minor groove of the DNA helix, preferentially to the 3' ends of oligopurine tracts, and causes sequence-selective oxidation of deoxyribose and bending of the DNA helix by an induced-fit mechanism of DNA target recognition.⁸³ In addition, calicheamicin and other naturally occurring enediyne antibiotics, including esperamicin, neocarzinostatin, kedarcidin, and dynemicin, constitute a unique class of reactive compounds that can undergo aromatization to produce biradicals. Phosphodiester-bond breakage of DNA was shown, however, to be dispensable for the apoptosis-inducing activity. Furthermore, prevention of apoptosis was observed in analogs that were electronically stabilized to impair aromatic rearrangements and generation of biradicals.⁸⁴ Thus, apart from enforcing a conformational change in DNA structure and the induction of DNA strand breaks, additional signaling events appear to be critically involved in the activation of apoptosis by calicheamicin and its analogs. Notably, calicheamicin induces apoptosis through a p53-independent mechanism, and this may explain part of its impressive clinical activity. Execution of apoptosis then proceeds via the mitochondrial pathway through an entirely Bax-dependent manner that is susceptible to suppression by the anti-apoptotic Bcl-2 and Bcl-x_L.⁸⁵ Conjugates to CD33, which is expressed on more than 90% of myeloid leukemic blasts, are currently being evaluated in the therapy of AML (reviewed in reference 86). In this line, treatment of a patient with the anti-CD33–calicheamicin immunoconjugate gemtuzumab ozogamicin (CDR-grafted humanized P67.6, CMA-676, Mylotarg) led to molecular remission of Philadelphia/*BCR-ABL*⁺ AML.⁸⁷ In vitro data obtained in 122 patients with relapsed AML indicate that gemtuzumab ozogamicin is rapidly and specifically targeted to CD33⁺ cells, followed by internalization and subsequent induction of apoptosis.⁸⁸ After evaluating a series of phase II studies, the US FDA approved gemtuzumab ozogamicin for the treatment of patients with CD33⁺ AML in first relapse who are 60 years of age or older and who are not considered candidates for other types of cytotoxic chemotherapy. Among 277 adult patients with CD33⁺ AML in first relapse, 26% experienced an overall response after gemtuzumab ozogamicin monotherapy.⁸⁹ Despite the fact that myelosuppression, hyperbilirubinemia, and elevated hepatic transaminases were commonly

Figure 25.9 Calicheamicin induces apoptosis via the mitochondrial pathway of apoptosis. BJAB Burkitt-like lymphoma cells (mock or Bcl-x_L transfectants) were incubated in the presence or absence of calicheamicin. (a) Calicheamicin induced apoptosis readily at picomolar concentrations. Apoptosis was determined by flow-cytometric measurement of genomic DNA fragmentation. Percentages of cells with a hypodiploid DNA content are shown. Apoptosis could be inhibited by overexpression of Bcl-x_L, an inhibitor of mitochondrial activation and cytochrome *c* release during apoptosis. (b) Western blot analysis of cytosolic extracts showed that calicheamicin (Ca) induces cytochrome *c* (cyt *c*) release from mitochondria. Induction of cytochrome *c* release by the anthracycline epirubicin (Epi) served as a positive control. Notably, calicheamicin-induced cytochrome *c* release at 100 PM was more pronounced as compared with the conventional anticancer drug epirubicin at 1 μg/ml (1.72 μM). (c) Western blot analysis for caspase cleavage. Calicheamicin induces processing of the initiator caspase-9 and the executioner caspase-3, which are downstream effectors of the mitochondrial death pathway.

observed, the incidences of severe infections and mucositis were relatively low in comparison with conventional chemotherapy. Preliminary reports in pediatric patients also report gemtuzumab ozogamicin to be reasonably well tolerated and to show clinical efficacy.⁹⁰ Data from study regimens combining gemtuzumab ozogamicin and conventional chemotherapy suggest an unusually high remission induction rate in de novo AML patients.⁹¹ More recent data indicate, however, that prior gemtuzumab ozogamicin exposure significantly increases the risk of potentially fatal hepatic veno-occlusive disease in patients who undergo myeloablative allogeneic stem cell transplantation⁹² or additional chemotherapy.⁹³ The underlying pathological mechanism is so far unknown, but appears to be a feature of calicheamicin acting on vascular endothelial cells.

A prodrug approach in order to reach higher local anticancer drug concentrations is the mAb-mediated targeting of enzyme–mAb conjugates to tumor cells. These enzymes can produce high local cytotoxic concentrations of otherwise non-toxic compounds. An example of this is the use of horseradish peroxidase to produce high local concentrations of reactive oxygen compounds or the targeting of a prodrug-converting enzyme such as carboxypeptidase G2 or cytosine deaminase.

Radioimmunotherapy

Radiolabeling of mAbs was an early development in immunoassay techniques. Later, it was found that mAbs also allow the specific delivery of high doses of a radiolabel to tumor cells. This can be exploited both for diagnostic immune scintigraphy and for the delivery of therapeutic radiation doses to tumor cells, i.e. radioimmunotherapy (reviewed in reference 94). Thus, radionuclides are an appropriate alternative for targeting cytotoxicity to tumor cells. In contrast to drug or toxin immunoconjugates, radiolabeled mAbs can kill cells that are not in direct contact with the mAb target and there is no need for the labeled mAb to be internalized, as in the case of immunotoxins. The killing of neighboring cells depends largely on the choice of radionuclide, for example the type of emission (α , β , or γ), the isotope half-life, and the energy transfer. The attractive feature of radioimmuno-therapy is the prospect that most normal tissues can be spared from intensive radiation. Therefore, as in

the case of other mAb conjugates, the radionuclide should be linked tightly to the mAb without affecting targeting. Considerable progress has been made in the chemistry of mAb radiolabeling. Some radionuclides (e.g. iodine) can be conjugated directly to the mAb, while others are linked by an intermediary group, such as chelators for radiometals.

Each radionuclide decays at a specific rate and releases particular radioactive emissions. The β decay from iodine-131 (^{131}I) travels a relatively short distance of less than 1 mm. Other β -emitting isotopes, such as yttrium-90 (^{90}Y), have a higher maximum energy and diffuse their radiation effect over a larger distance within tissues, showing path lengths of several millimeters. Moreover, ^{90}Y offers several advantages over ^{131}I , since radiometals such as ^{90}Y are better retained within target cells after cellular internalization of antigen—antibody complexes. Because ^{90}Y is a pure β emitter, large doses can be given safely in an outpatient setting with fewer consequences for medical personnel or patients' families. In contrast, α particles traverse much shorter distances of only 30–90 μm . They nonetheless possess an approximately ten fold higher energy and are often several thousandfold more efficient at a short range than β emitters. A single hit by an α particle to the nucleus is sufficient to kill a cell. This is also true for low-energy electrons such as those emitted by ^{125}I , which deposit their energy over very short distances in the nanometer range (Table 25.5).

Phase I trials in B-NHL demonstrated that conjugates such as ^{131}I -labeled anti-CD20, anti-CD22, anti-CD37, and anti-HLA-DR can induce tumor regression for several months. Toxicities include mainly suppression of hematopoiesis, which can last for several months.^{95–98} The doses of radioactivity that can be delivered to the tumor by 'high-dose' radiolabeled mAbs are in the range of 40–50 Gy, with limited toxicity to bone marrow and other organs. Similar data were obtained with a ^{90}Y -labeled anti-idiotypic mAb in relapsed B-NHL.⁹⁹

Significant PR and CR rates of 50–70% can be achieved by the use of radiolabeled antibodies in relapsed and even chemoresistant NHL patients. Nevertheless, early studies showed that only a few patients receiving such radioimmunotherapeutics as single agents had a disease-free survival longer than 5 years. It was therefore postulated that higher, potentially myeloablative, doses combined with bone marrow or stem cell transplantation might yield a higher rate of CR and longer disease-free survival.¹⁰⁰ It was suggested that such high-dose radioimmunotherapy be applied only in patients with a 'favorable'

Table 25.5 Radionuclides employed for antibody labeling in radioimmunotherapy

Nuclide	Decay	Emission	Half-life	Energy (keV)	Range (mm)
Iodine-131 (^{131}I)	β	β	8.02 d	971	0.8
		γ		364	
Yttrium-90 (^{90}Y)	β	β	64.1 h	2280	2.7

biodistribution. Notably, the majority of patients without bulky disease, small spleen and tumor load below 500 g should show such a favorable distribution in almost all instances. This possible bias in selecting patients with a more favorable prognosis must be considered when interpreting clinical data obtained from patients treated with account taken of favorable/unfavorable biodistribution. Often, such high-dose radioimmunotherapy results in severe, long-lasting myelosuppression and should therefore be combined with (autologous) stem cell support.^{101–103} Depending on the dose, onset of leuko- and thrombocytopenia occurs on day 7–10, with complete aplasia around week 2–3. At this time, remaining radioactivity has dropped to a level that permits reinfusion of bone marrow stem cells (15–20 mCi in the case of ¹³¹I). Using such a protocol, neutrophils recover after 7–10 days, whereas thrombopenia (mostly grade 3) may persist far longer—in some cases for more than 100 days after stem cell transplantation.

The murine ⁹⁰Y-labeled IDEC-Y2B8 anti-CD20 antibody (⁹⁰Y-ibritumomab tiuxetan, Zevalin) was the first radiolabeled antibody to obtain approval from the FDA for non-myeloablative therapy of relapsed or refractory low-grade, follicular, or transformed B-cell lymphoma, including rituximab-refractory transformed NHL.¹⁰⁴ Like ibritumomab tiuxetan, ¹³¹I-tositumomab (B1, Bexxar) is a murine antibody directed against the CD20 antigen expressed on the surface of normal and malignant B lymphocytes. Recently, the FDA has approved ¹³¹I-tositumomab for the treatment of patients with CD20⁺ follicular NHL whose disease is refractory to rituximab and has relapsed following chemotherapy. ¹³¹I-Tositumomab is given according to a patient-specific dosimetric pretherapeutic study, whereas ⁹⁰Y-ibritumomab tiuxetan has been developed in such a manner that this pretherapy dosimetry is not needed, and is administered on a body-weight basis.¹⁰⁵ As with most drugs, there is considerable interpatient variability in the clearance rate (or total body residence time) of radioimmunoconjugates. The clearance rate of ¹³¹I-tositumomab in clinical trials has varied by as much as fivefold. The advantage of radioimmunotherapy with ¹³¹I, which emits both γ rays and β particles, is that by scanning it allows for the determination of the patient-specific total body residence time by the administration of a tracers dose of the radionuclide (i.e. dosimetric dose). By administration of the dosimetric dose, and determination of the patient's residence time (a measure of how long the radionuclide is retained in the body), the patient-specific maximally tolerated therapeutic radiation dose is determined in order to maximize efficacy while minimizing organ and bone marrow toxicity. Both ¹³¹I-tositumomab and ⁹⁰Y-ibritumomab tiuxetan require, however, a pretherapy cold antibody dosing in order to clear peripheral B cells and improve biodistribution of the radiolabeled antibody, i.e. to improve tumor targeting. This is achieved by infusion of unlabeled tositumomab with ¹³¹I-tositumomab and of unlabeled rituximab prior to ⁹⁰Y-ibritumomab tiuxetan. The current ⁹⁰Y-ibritumomab tiuxetan regimen consists of pretreatment with rituximab (250 mg/m² intravenously) on days 1 and 8, then ⁹⁰Y-ibritumomab tiuxetan (0.4 mCi/kg intravenously, with a maximum of 32 mCi) on day 8. An imaging/ dosimetry dose of indium-111 (¹¹¹In)-labelled ibritumomab tiuxetan (5 mCi) may be injected after rituximab (day 1) for dosimetry and imaging purposes.¹⁰⁶

Interestingly, both ⁹⁰Y-ibritumomab tiuxetan and ¹³¹I-tositumomab have shown higher and more durable responses than the 'naked' antibodies, but they also have dose-limiting toxicities, predominantly myelotoxicity. Infusional adverse reactions are minimal for ¹³¹I-tositumomab, as compared with ⁹⁰Y-ibritumomab tiuxetan, and both show minimal non-hematological toxicities, with absence of hair loss or mucositis and generally mild nausea.¹⁰⁷ Because of the usually high release of ¹³¹I from ¹³¹I-tositumomab, thyroid blockage is required. This does not, however, preclude a complication of hypothyroidism even with such blockage. Some patients have shown myelodysplasia after longterm follow-up following ¹³¹I-tositumomab, but they were also heavily pretreated with chemotherapy, which could have contributed to this complication.¹⁰⁸

In the USA, ¹³¹I-tositumomab can now be given in most (but not all) states on an outpatient basis providing that the total effective dose equivalent to another individual from exposure to a treated patient is below 500 mrem.^{109,110} ⁹⁰Y-Ibritumomab tiuxetan and other products using pure β emitters such as ⁹⁰Y can be used throughout the USA on an outpatient basis. Because ⁹⁰Y is a pure β emitter, the ⁹⁰Y-ibritumomab tiuxetan regimen is routinely administered as an outpatient procedure by using plastic shielding during the procedure. Once the radioimmunoconjugate has been administered, the risk of radiation exposure to healthcare workers and family members is minimal. The primary route of biological elimination of ⁹⁰Y-ibritumomab tiuxetan is through the urinary system, with approximately 7% of the total being activity administered being eliminated over the course of 1 week. Standard universal precautions, which should already be in place in healthcare facilities, should be sufficient to prevent radiation exposure to personnel working with patients who have been treated with ⁹⁰Y-ibritumomab tiuxetan. Written radiation safety instructions for patients are not required, but basic instructions to the patient and his or her family may help further minimize the risk of radiation exposure and help alleviate patient and family concerns.¹¹¹

Both products have been studied predominantly as single-cycle therapy. A recent phase II trial in 30 patients with relapsed or refractory NHL yielded an

overall response rate of 83% (37% CR, 6.7% CR unconfirmed, and 40% PR). Of these patients, 83% had a follicular lymphoma and 67% showed bone marrow involvement. Patients had a median of two prior therapies. The Kaplan–Meier estimated median time to progression (TTP) was 9.4 months. In responders, the Kaplan–Meier estimated median TTP was 12.6 months, with 35% of data censored. Toxicity was primarily hematological, transient, and reversible. The incidences of grade 4 neutropenia, thrombocytopenia, and anemia over 33%, 13%, and 3%, respectively. Notably, this regimen was evaluated in patients with mild thrombocytopenia ($100\text{--}149 \times 10^9$ platelets).¹¹² A phase II trial with ^{131}I -tositumomab in 60 patients with chemotherapy-refractory low-grade or transformed low-grade B-NHL demonstrated an overall response in 39 patients (65% CR+PR) after ^{131}I -tositumomab, as compared with 17 patients (28%) achieving a PR or CR after their last chemotherapy. The median duration of response was 6.5 months after ^{131}I -tositumomab, as compared with 3.4 months after the last chemotherapy.¹⁰⁸ A multicenter single-arm study in 40 patients with follicular lymphoma showed efficacy of ^{131}I -tositumomab in patients who were either resistant to or relapsed after rituximab treatment. A total of 29% of the patients had a CR and the median duration of response had not been reached after a follow-up of 25 months. The results of this study were supported by demonstration of durable responses in four other single-arm studies enrolling 190 patients in rituximab-naïve follicular lymphoma, where the overall response rates ranged between 47% and 64% and the median duration of response from 12 to 18 months.¹¹³

Phase II trials have been performed to determine the efficacy of combinations of ^{131}I -tositumomab and CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) chemotherapy in follicular lymphoma: 90 patients with previously untreated, advanced-stage follicular lymphoma underwent six cycles of CHOP followed 4–8 weeks later by ^{131}I -tositumomab. Treatment was well tolerated; reversible myelosuppression was the main adverse event, and was more severe during CHOP chemotherapy than following radioimmunotherapy. The overall response rate to the entire treatment regimen was 90%, including 67% CR (plus unconfirmed CR) and 23% PR. Interestingly, 27 (57%) of those patients who achieved less than a CR following CHOP improved their remission status after ^{131}I -tositumomab. After a median follow-up of 2.3 years, the 2-year progression-free survival rate was estimated at 81%, with a 2-year overall survival rate of 97%.¹¹⁴

There is now evidence that high-dose radioimmunotherapy may be superior to 'conventional' high-dose chemotherapy, both followed by autologous peripheral blood stem cell transplantation (PBSCT). A comparison of 125 high-dose radioimmunotherapy plus PBSCT patients treated with ^{131}I -tositumomab ($n=27$) or conventional high-dose therapy ($n=98$) showed an improved overall and progression free survival for the high-dose radioimmunotherapy group. The estimated 5-year overall and progression-free survival rates were 67% and 48%, respectively, for high-dose radioimmunotherapy and 53% and 29%, respectively, for conventional high-dose therapy. Notably, the 100-day treatment-related mortality rate was 3.7% in the high-dose radioimmunotherapy group and 11% in the conventional high-dose therapy group.¹⁰² Similar data are now available for relapsed mantle zone lymphoma: 16 patients received a median of three prior treatments, and 7 had chemotherapy-resistant disease. Among 11 patients with measurable disease, the CR and overall response rates were 91% and 100%, respectively. The overall survival rate at 3 years from transplantation was estimated at 93%, with a progression-free survival rate of 61%.¹⁰¹

A recent phase III randomized study compared radioimmunotherapy with ^{90}Y -ibritumomab tiuxetan with a control immunotherapy, rituximab, in 143 patients with relapsed or refractory low-grade, follicular, or transformed CD20⁺ NHL. The overall response rate was 80% for the ^{90}Y -ibritumomab tiuxetan group versus 56% for the rituximab group. CR rates were significantly better in the ^{90}Y -ibritumomab tiuxetan, at 30%, as compared with 16% in the rituximab group. An additional 4% achieved an unconfirmed CR in each group. The Kaplan–Meier estimated median duration of response was 14.2 months in the ^{90}Y -ibritumomab tiuxetan group versus 12.1 months in the control group, and the time to progression was 11.2 months versus 10.1 months in all patients. Durable responses of more than 6 months were significantly more frequent for ^{90}Y -ibritumomab tiuxetan radioimmunotherapy, versus 64%, 47% for rituximab. As expected, reversible myelosuppression was the primary toxicity noted with radioimmunotherapy.¹¹⁵

A further study evaluated the response to ^{90}Y -ibritumomab tiuxetan radioimmunotherapy in 54 patients with rituximab-refractory follicular lymphoma. The overall response rate for the 54 patients was 74% (15% CR and 59% PR). The Kaplan–Meier estimated time to progression was 6.8 months (range 1.1–25.9+ months) for all patients and 8.7 months for responders. Adverse events were primarily hematological, with grade 4 neutropenia in 35%, thrombocytopenia in 9%, and anemia in 4% of the patients.¹¹⁵

Finally, radioimmunotherapy with the anti-CD20 ^{131}I -tositumomab in patients with low-grade NHL does not induce loss of acquired humoral immunity against common antigens. Despite a temporary depletion of peripheral blood B cells and a decline in T-cell subpopulations, no reduction in serum immunoglobulin levels was observed. Almost all patients remained seropositive against rubella, mumps,

varicella zoster, measles, and tetanus antigens during a 1 to 2-year follow-up, and no significant reductions in antibody concentrations to tetanus or measles were detected. Thus, acquired humoral immunity against common antigens appears to be preserved despite a temporary depletion of immune cells.¹¹⁶

In analogy to the data obtained with the use of radiolabeled anti-CD20 antibodies, patients with relapsed and chemoresistant Hodgkin lymphoma may benefit from radioimmunotherapy with ¹³¹I- or ⁹⁰Y-labeled antibodies against ferritin.¹¹⁷ Overall, 134 patients with recurrent Hodgkin lymphoma were treated in five different studies with intravenous antiferritin, labeled with ¹³¹I or ¹¹¹In for diagnostic purposes and with ⁹⁰Y for therapeutic purposes. Patients with recurrent, end-stage Hodgkin lymphoma obtained a 60% response rate following ⁹⁰Y-labeled antiferritin. One-half of the therapy responses were complete.¹¹⁸ Complete responders survived significantly longer than partial responders (2 years versus 1 year), and patients with a PR survived longer than patients with progressive disease (1 year versus 4 months). The underlying principle is, however, not tumor cell targeting and tumor-targeted irradiation but rather seems to be related to a sort of unspecific 'internal' total body irradiation. It remains to be established whether better results can be obtained with the use of radiolabeled anti-CD30 monoclonals that are currently in preclinical development.

For diagnosis and treatment of T-cell neoplasias, mainly three target structures are currently being evaluated: CD5, CD7, and CD25. Radiolabeling of the antiCD25 mAb anti-Tac with the β emitter ⁹⁰Y increases efficiency as compared with the unlabeled mAb. In a phase I/II trial, 18 patients received up to eight treatment cycles with 5–15 mCi per infusion.¹¹⁹ Two patients had a CR and 7 a PR. The duration of the responses was 1–33+ months and freedom from progression ranged from 2 to 45+ months, as compared with a median survival time of 9 months in a historical control group of untreated patients. A phase I study in patients with CTCL and B-CLL using a ¹³¹I-labeled T101 anti-CD5 antibody showed a PR in 5 of the 10 treated patients. The median response duration was 23 weeks. One CTCL patient who subsequently received electron-beam irradiation to a residual lesion was disease-free after 6 years.¹²⁰ Notably, rapid antigenic modulation of CD5 on circulating T and B cells was observed and recovery of non-malignant T-cell populations occurred within 2–3 weeks. Interestingly, suppression of normal B-cell populations persisted after 5+ weeks. Anti-CD7 antibodies are still in preclinical development, but show interesting activities both as unlabeled or radiolabeled therapeutics.

Although radioimmunotherapy with radiolabeled intact mAbs has demonstrated efficacy in the treatment of lymphoma, it provides low tumor-to-normal tissue radionuclide target ratios and unwanted prolonged radiation exposure to the bone marrow. To overcome these obstacles, the administration of the radionuclide was separated from that of the antibody by using an anti-IL-2 α antibody scFv-streptavidin fusion protein, followed by radiolabeled biotin to treat lymphoma or leukemia xenografted mice. This pretargeting approach provided extremely rapid and effective tumor targeting and cure of xenotransplanted mice when combined with the β emitter ⁹⁰Y or the α emitter bismuth-213 (²¹³Bi) as radionuclides.¹²¹ The use of such genetically engineered fusion proteins should allow better tumor penetration as compared with conventional anti-CD25 antibodies such as anti-Tac-²¹³Bi conjugates.¹²² Nevertheless, the clinical efficacy of this approach remains to be established.

Like other radiolabeled antibodies against tumor-associated antigens, radiolabeled anti-CD33 antibodies are capable of reducing large tumor burdens. CD33 is a 67 kDa cell surface glycoprotein found on most myeloid leukemia cells and on committed myelomonocytic and erythroid progenitor cells. It is not found on lymphoid or non-hematopoietic cells. So far, three anti-CD33 antibodies have been evaluated in clinical radioimmunotherapy of myeloid leukemias: M195, HuM195, and p67. M195 is a murine monoclonal IgG2a antibody, HuM195 is a humanized antibody constructed by grafting the complementarity determining region of M195 onto the constant region and variable framework of human IgG1. Notably, and in contrast to the murine H195, the humanized HuM195 can mediate the killing of leukemia cells by ADCC. p67 is an anti-CD33 antibody that was tested in the past for efficacy in the radiotherapy of myeloid leukemias. To determine the intrinsic clinical efficacy of such unlabeled antibodies, 50 adult patients with relapsed or refractory AML were randomized to receive HuM195 at a dose of 12 or 36 mg/m² by intravenous infusion over 4 hours on days 1–4 and 15–18. No hepatic, renal, or cardiac toxicities were observed, and other adverse events such as nausea, vomiting, mucositis, and diarrhea were uncommon. In addition, anti-HuM195 responses were not detected. Of 49 evaluable patients, two CR and one PR were observed. Decreases in blast counts ranging from 30% to 74% were seen in nine additional patients. This indicates that HuM195 as a single agent has minimal antileukemic activity in patients with relapsed or refractory AML, with activity being confined to patients with a low burden of disease.¹²³ Such anti-bodies against CD33, however, target not only the AML blasts but also the normal bone marrow. This explains the extensive myelotoxicity of anti-CD33 radioimmunotherapies and is why these mAbs may be employed for myeloablative therapeutic schedules (reviewed in reference 124).

A ¹³¹I-p67 anti-CD33 conjugate was studied in nine patients with advanced AML. Of these patients,

only four had a ‘favorable biodistribution’, defined as a higher dose of radiation delivered to the marrow and spleen than to other organs. These four patients then received therapeutic doses of ^{131}I -p67 (110–330 mCi) together with cyclophosphamide (120 mg/kg) and total body irradiation (12 Gy) as a conditioning regimen for allogeneic BMT. Although the therapy was well tolerated, three of the four patients relapsed.¹²⁵ In view of the short half-life of ^{131}I -p67 in the bone marrow (9–41 hours) and the unfavorable biodistribution in many patients, the further focus of this study group was on the use of an ^{131}I -anti-CD45 radioimmunoconjugate as reviewed elsewhere.¹²⁶ The anti-CD33 murine antibody P67.6 was, however, developed successfully as an immunoconjugate with calicheamicin: gemtuzumab ozogamicin¹²⁷ (see above). Similar problems regarding the half-life of radiolabeled constructs in targeting CD33⁺ blasts in bone marrow were encountered when ^{131}I conjugates of M195 and HuM195 were employed. Moreover, ^{131}I labeling of tyrosine residues in the hypervariable region partially affects antigen binding by M195 and HuM195 anti-CD33 antibodies.¹²⁸ Therefore, and in view of the unfavorably long half-life of ^{131}I , and the need for isolation, current trials employ a ^{90}Y conjugate of HuM195. An early phase I study with a ^{131}I -H195 conjugate in acute promyelocytic leukemia (APL) in relapse showed promising results when combined with differentiation therapy using all-trans-retinoic acid (ATRA).¹²⁹ The median disease-free survival of the 7 patients was 8 months (range 5.5–33 months). The results of this trial compare favorably with those of other regimens for APL in relapse. In a more recent phase I trial, ^{90}Y -HuM195 was studied in patients with relapsed or refractory AML. Nineteen patients were treated with escalating doses of ^{90}Y -HuM195 (0.1–0.3 mCi/kg). Apart from myelosuppression lasting 9–62 days, adverse side-effects were limited to transient low-grade liver function abnormalities, which occurred in 11 of the 19 patients. Up to 56 and 75 Gy were delivered to the marrow and spleen, respectively. Thirteen patients had reductions in bone marrow blasts, and one patient achieved a CR lasting 5 months. All patients treated with 0.3 mCi/kg had hypocellular bone marrow biopsies performed 2 or 4 weeks after treatment, without evidence of leukemia.¹²⁴ These results compare well with those of a phase I/II study where ^{131}I -M195 or ^{131}I -HuM195 were given in combination with busulfan and cyclophosphamide as conditioning for allogeneic BMT in 31 patients with relapsed/refractory AML ($n=16$), accelerated/ myeloblastic CML ($n=14$), or advanced myelodysplastic syndrome (MDS) ($n=1$).¹³⁰ At 59+, 87+, and 90+ months following BMT, three patients with relapsed AML remained in complete remission. This indicates that ^{90}Y -HuM195 might be useful as conditioning before stem cell transplantation, and clinical studies are currently being undertaken to determine the value of such preparative regimens for autologous and non-myeloablative allogeneic stem cell transplantation.

In addition, radiolabeling with ^{213}Bi , an α emitter, can be used in such an adjuvant setting to eliminate minimal residual disease. The advantages of the short-range α emitters versus other radiolabels are shown in Table 25.5. As low as 1 particle per cell may suffice to kill a targeted cell. The combination of this regimen with a consolidation therapy with conventional AML chemotherapy appears promising. To enhance the potency of native HuM195 while avoiding the non-specific cytotoxicity of β -emitting constructs, the α -emitting isotope ^{213}Bi was conjugated with HuM195. Eighteen patients with relapsed and refractory AML leukemia or chronic myelomonocytic leukemia (CMML) were treated with 10–37 MBq/kg ^{213}Bi -HuM195. No significant extramedullary toxicity was seen. All 17 evaluable patients developed myelosuppression, with a median time to recovery of 22 days. Nearly all the ^{213}Bi -HuM195 rapidly localized to and was retained in areas of leukemic involvement, including the bone marrow, liver, and spleen. Absorbed dose ratios between these sites and the whole body were 1000-fold greater than those seen with β -emitting constructs in this antigen system and patient population.¹³¹ Of 15 evaluable patients, 14 (93%) had reductions in circulating blasts, and 14 (78%) of 18 patients had reductions in the percentage of bone marrow blasts.¹³²

Purging strategies

High-dose chemoradiotherapy followed by ABMT or PBSCT has been shown to result in long-term disease-free survival of selected patients with malignant B-NHL. A problem that may affect the clinical outcome of ABMT or PBSCT in NHL is tumor infiltration of the marrow and, as a consequence, contamination of the graft. To prevent reinfusion of residual tumor cells in the transplant, a number of *in vitro* techniques have been developed for ‘purging’ autografts. These include chemoseparation with cytotoxic drugs, use of mAbs in conjunction with complement-mediated lysis, toxin-conjugated mAbs, or immunoconjugates with magnetic particles (Figure 25.10).^{133,134} In B-NHL, murine mAbs against the CD19, CD22, and CD37 antigens have been employed for immunomagnetic purging of B-NHL cells from human bone marrow.¹³⁵ Using a cocktail of these antibodies in combination with indirect labeling via sheep anti-mouse-coated immunomagnetic beads, a more than $5 \log_{10}$ reduction of malignant B cells from bone marrow can be achieved. The concomitant reduction of colony-forming units (CFU) is low, in the range of 20%. In 21 patients with B-NHL (18 low-grade and

Figure 25.10 Immunomagnetic purging of transplants with mAbs. Stem cell preparations can be contaminated with tumor cells. To eliminate the tumor cells from the transplant, these cells can be depleted by staining with mAbs against tumor-associated antigens, (a) Stained cells can be depleted with coated iron beads and are removed from the transplant by magnetic separation, (b) Raster scanning electron microscopy of two antibody-coated magnetic beads bound to a tumor cell.

3 high-grade) treated with high-dose chemotherapy followed by ABMT with purging, CR was achieved in 8 and PR in 6.¹³⁶ A cocktail of anti-CD19, CD20, CD22, CD23, and CD37 was used for purging. After myeloablative treatment with total body irradiation and cyclophosphamide at 200 mg/kg body weight hematopoietic reconstitution was observed after a median of 21.5 days (white cell count $>10^9/l$), 27.5 days (neutrophils $0.5 \times 10^9/l$), and 27 days (platelets $>20 \times 10^9/l$). Using marker genes, a sensitive PCR-based detection of contaminating tumor cells is possible. One of these tumor-specific markers is generated by t(14;18) translocations in B-NHL, leading to fusion of the *bcl-2* gene with the IgH enhancer. Thus, it has been shown that purging can remove virtually all tumor cells down to PCR-negativity of the purged transplant.¹³⁷ The use of magnetic beads proves to be advantageous if compared with the previously employed complement lysis-mediated purging. The latter requires antibody isotypes capable of activating complement, and does not reach the high log rates in purging achieved with immunobeads.

Additional purging efforts have focused on the CD14, CD15, and the CD33 antigens in AML. Anti-CD33 mAbs bind to normal myeloid cells in the marrow and to monocytes in the periphery. In the bone marrow, 20–30% of cells express CD33, including a fraction of metamyelocytes, most myelocytes and promyelocytes, and virtually all myeloblasts. Among the progenitor cells approximately 50% of CFU granulocyte-erythrocyte-macrophage-megakaryocyte (CFU-GEMM), more than 95% of CFU granulocyte-macrophage (CFU-GM), and a variable fraction of burst-forming units erythroid (BFU-E), CFU-E, and CFU megakaryocyte (CFU-Mk) are CD33⁺. The earlier hematopoietic stem cells express CD34 but not CD33, suggesting that CD33 can be used as a target for depletion of CD33⁺ AML cells. Purging of bone marrow for ABMT with anti-CD33 mAbs in AML significantly delays engraftment of the transplant,¹³⁸ as compared with purging allografts with anti-CD10 mAbs in ALL,^{139,140} indicating that CD33⁺ marrow cells are important in the early phase of hematopoietic reconstitution after ABMT. In analogy, a cocktail of CD14 and CD15 mAbs, which do not bind to multilineage progenitor cells, has been used for complement-dependent purging of AML cells in ABMT in a multicenter phase II trial.¹⁴¹ As in anti-CD33 studies, engraftment of purged bone marrow was strongly delayed. This approach can lead to long-term disease-free-survival in about 50% of patients with relapsed AML.

The need for graft purging is nevertheless still controversial. A beneficial effect for marrow purging in ABMT for B-NHL was suggested by Gribben et al¹⁴² in 1991. However, none of the clinical trials performed so far has demonstrated in a controlled way that transplant purging has an effect on relapse rates. The largest patient numbers have been investigated in AML.^{138,141} Nevertheless, most of these strategies failed to significantly improve the outcome of patients in controlled studies. This, together with the purging-related costs, has so far prevented the clinical introduction of purging of bone marrow or stem cell preparations.

Anti-idiotypes and idiotypic vaccination

The idiotypic determinants of surface immunoglobulin (Ig) on B-lymphoma cells were the first tumorspecific antigens to be discovered.¹⁴³ Malignant B cells express an individual B-cell receptor (Ig)

with a unique antigen recognition site (idiotype). Immunization of mice with B-NHL cells led to the generation of anti-idiotypic antibodies (anti-Id) that recognized only the idiotype of the malignant B cell but not the majority of non-malignant B cells of the patient (Figure 25.11). These anti-Ids are to a large extent truly tumor-specific. It was therefore tempting to use these anti-Id mAbs for the therapy of B-cell lymphoma.^{144,145} In contrast to a tumor-associated mAb, e.g. anti-CD20,¹⁴⁶ the normal B-cell pool remains untouched and no immune suppression is to be feared. The disadvantage of this strategy is that an idiotype-specific antibody has to be produced against every individual idiotype. Fortunately, the existence of 'shared idiotypes' was discovered by Levy and coworkers. These are idiotypic determinants on B-lymphoma cells shared by different patients, which can be recognized by one anti-idiotypic mAb. This facilitated the production of anti-idiotypic antibodies, since appropriate anti-idiotypic mAbs for an individ-

Figure 25.11 Idiotypic and anti-idiotypic antibody response against a tumor cell, (a) The individual antigenbinding region of a mAb (idiotype) against a (tumor) antigen (idiotope) can be recognized by the immune system and lead to the formation of anti-idiotypic antibodies. These can mimick the antigen and form a so-called 'Internal' image of the idiotope (i.e. a structure derived from the self immune system). Such anti-idiotypic antibodies are currently being investigated in tumor vaccination studies with the aim of raising a protective immune response against the tumor antigen. (b) In the case of malignant B lymphocytes, anti-idiotypic antibodies can be raised by immunizing mice with tumor cells. These anti-idiotypic mAbs can then be used to induce tumor regression upon injection of a tumor cell-carrying host.

ual patient could be identified by screening a library of existing anti-idiotypes.

So far, only a few patients have been treated using anti-idiotypic antibodies, although the principle was introduced in the early 1980s. A compilation of data from phase I trials shows that anti-idiotypic antibodies alone or in combination with IFN- α induced a CR or PR in 68% of 34 treated patients.^{143,145,147,148} A more favorable response was seen in those patients in whom the anti-Id mAbs induce signal transduction (tyrosine phosphorylation) in malignant B cells.¹⁴⁹ It is conceivable that some anti-Id mAbs bind to the B-cell antigen receptor but do not deliver an activating signal. There are therefore several possible mechanisms for the antitumor effect of these anti-idiotypes. Opsonization of the tumor cell, ADCC, and destruction by complement activation do not appear to be the major mechanisms of tumor cell elimination. In other models, the activation of the antigen receptor of malignant B cells was shown to lead to cell cycle arrest and apoptosis. Figure 25.6 shows the induction of apoptosis in human BL41 Burkitt lymphoma cells by anti-IgM antibodies.^{26,27} Direct signaling for cell cycle arrest or apoptosis is therefore the most probable mechanism of anti-Id action.

In experimental animals or patients treated with anti-Ids, selection of tumor cell subclones with mutated idiotypic determinants has been observed during anti-idiotypic therapy.¹⁵⁰ This may lead to escape from immune recognition. An alternative approach to the direct infusion of anti-idiotypic Ig is to induce a broad antitumor response by active immunization with tumor-derived idiotype vaccines. Vaccination with tumor-derived immunoglobulins leads to polyclonal antibody and T-cell responses. These responses are capable of recognizing multiple antigenic determinants on the individual idiotype, and may thus prevent the escape of tumor cells by idiotype mutations. These anti-idiotype vaccinations can protect experimental animals from tumor cell challenge and can cure animals—even those with established lymphomas. In a long-term follow-up of a phase I study, it was shown that 20 of 41 patients with low-grade B-NHL developed specific anti-idiotypic immunity upon immunization with a tumor-Ig—KLH conjugate.¹⁵¹ The clinical outcome for those patients who mounted a specific immune response was a freedom from progression of 7.9 years, as compared with 1.3 years for those who did not. This suggests that idiotypic vaccination might be a potent tool to improve the treatment of B-NHL. A promising new approach might be the use of idiotypic DNA vaccines. These are simple plasmids containing the variable region sequences of the malignant B-cell Ig. These have been used successfully for vaccination in NHL patients to generate an anti-idiotypic humoral and T-cell response.¹⁵² Nevertheless, no clinical data are yet available regarding the efficacy of this type of

tumor-specific DNA vaccination. A more feasible approach might be the use of dendritic cell (DC) vaccination in which the DC are loaded with tumor-derived Id proteins. The results of two phase I studies in 35 patients have been published.¹⁵³ Among 10 patients with measurable lymphoma, 8 mounted T-cell proliferative anti-Id responses, and 4 had clinical responses (2 CR, 1 PR, and 1 molecular response). Twenty-five additional patients were vaccinated after first chemotherapy, and 15 of 23 (65%) who completed the vaccination schedule mounted T-cell or humoral anti-Id responses. Notably, six patients with disease progression after primary DC vaccination received booster injections of Id-KLH protein, and tumor regression was observed in three of them (two CR and one PR). This suggests clinical efficacy, validation of which in a controlled trial is desirable.

Targeting T cells to tumor cells by using bifunctional antibodies

It is generally accepted that tumor cells can carry tumor-specific antigens. Chromosomal translocations lead to the formation of novel non-self determinants such as the BCR-ABL fusion protein, and point mutations (e.g. in CDK4 as in malignant melanoma) create altered self structures that can be recognized by specific T cells. Theoretically, these tumor-specific antigens can be exploited by tumor vaccination strategies to elicit a tumor-specific T-cell response leading to tumor cell elimination in a fashion comparable to transplant rejection. Nevertheless, T-cell targeting to tumor cells can also be achieved by so-called bispecific antibodies (bsAbs), which form a bridge between the tumor cell and T cells, or other immunological effector cells such as NK cells or monocytes (Figure 25.12). One arm of these bsAbs reacts with the tumor-specific or tumor-associated antigen, while the other arm reacts with a structure on the immune effector cell, mediating both bridging and activation of the cytotoxic machinery. These antibodies can be produced by (1) chemical crosslinking of intact antibodies or F(ab)' fragments, (2) by fusion of two antibody producing hybridomas to 'quadromas' (Figure 25.13), or (3) by recombinant DNA technologies. One strategy to achieve this is to fuse two single-chain antibodies (scFv) to a recombinant bsAb (scFv₂), also termed a 'diabody', by the introduction of an additional linker peptide. Effector cells that may be targeted by bispecific antibodies include T and NK cells and phagocytes such as neutrophils or monocytes/macrophages (Table 25.6). Apart from these cytotoxic effector cells, death receptors such as CD95/Fas have been targeted by bispecific antibodies to allow for specific activation of these killer receptors on the cancer cell without harming non-malignant tissues such as the liver (reviewed in reference 29).

Figure 25.12 Targeting of cytotoxic T lymphocytes (CTL) to tumor cells by bispecific antibodies or chimeric T-cell receptors, (a) CTL capable of recognizing tumor cells have been found in 'Immunogenic' cancers such as malignant melanoma and renal cell carcinoma. The CTL recognize the tumor cell through tumor antigens presented in the groove of mainly MHC class I molecules. This leads to activation of the T-cell receptor (TCR) and signal transduction via the TCR-associated CD3 complex, (b) Monoclonal antibodies against tumor antigens and antibodies against the CD3 complex (in most cases against the CD3 ϵ chain, such as the OKT3 mAb) can be combined to produce a bispecific antibody. Commonly used tumor-associated antigens for bsAbs are CD19, CD20, or CD22 in B-NHL. The bsAb binds with one arm to the tumor-associated antigen and to the CD3 complex with the second arm. This activates the CD3 signaling cascade and T-cell activation independently of the TCR. (c) A novel recombinant DNA technology is under current development, and may lead to rapid progress in tumor immunology: Artificial chimeric TCRs can be produced by fusion of a recombinant single-chain antibody (scFv) to the ζ or γ chain of the CD3 complex. Such cDNAs for chimeric TCR can be introduced into T-cells via retroviral expression vectors. These fusion proteins can lead to efficient signal transduction, T-cell activation, and generation of CTL. The T cells then express the artificial TCR, and have been shown to specifically kill tumor cells.

Figure 25.13 Generation of bispecific Abs (bsAbs). Individual mAb-producing hybridoma cells can be fused to which then produce bsAbs. After selection of bsAb-producing clones, the bsAbs can be purified, for example by high-performance liquid chromatography (HPLC).

Effector	Trigger molecule
T cells	CD3 ϵ chain
NK cells	Fc γ RIII (CD16)
Monocytes/macrophages	Fc γ RI (CD64) Fc α RI (CD89) Fc γ RIIIa (CD16)
Cranulocytes	Fc γ RI (CD64) Fc α RI (CD89)
Death receptors	CD95/Fas TRAIL receptors DR4, DR5

The bridging mediated by such bsAbs mimics specific activation of the immune effector cell. Thus, a bsAb consisting of an anti-CD3 ϵ mAb and an anti-CD19 mAb moiety (CD3 \times CD19) can polyclonally activate T cells in the presence of CD19⁺ B-lymphoma cells by crosslinking of the T-cell receptor (TCR)/CD3 complex.¹⁵⁴ This bypasses the need for specific TCR/MHC/peptide interaction, leading to proliferation of the T cell (which would normally be unreactive against the lymphoma cells) and to the generation of cytotoxic T lymphocytes (CTL). In the presence of the bridging bsAb, these CTL can specifically lyse the B-lymphoma cells (Figure 25.14a). Costimulation via agonistic anti-CD28 mAbs increased the efficiency of CTL generation by mimicking the binding of its physiological ligand, B7.1 (CD80) or B7.2 (CD86).¹⁵⁵ It is generally accepted that this costimulation (signal 2) complements the CD3/TCR-mediated activation signals (signal 1), to allow the induction of a productive immune response. Otherwise, the stimulation by the bsAb alone could lead to induction of T-cell unresponsiveness (anergy) or to an abortive immune response due to deletion of inadequately activated T cells.¹⁵⁵ In an animal model, SCID mice carrying xenotransplanted human Burkitt lymphoma cells could be cured by injection of CD3 \times CD19 bsAb in combination with an anti-CD28 mAb (Figure 25.14). This adequate phoma cell elimination and therapeutic efficacy of the costimulation was a prerequisite for efficient lym-CD3 \times CD19 bsAb.¹⁵⁶ Likewise, a study using a CD3 \times CD30 mAb in combination showed that costimulation via CD28 is a prerequisite for efficient bsAb therapy of lymphoma.¹⁵⁷ The use of CD3 \times CD19 bsAbs in phase I studies in patients with low-grade B-NHL such as CLL leads to T-cell activation in vivo and a strong reduction in the number of the malignant cells. Unfortunately, CLL cell elimination is so far incomplete and, upon cessation of bsAb antibody infusions, the malignant cell pool is rapidly replenished. Additional studies are therefore required to clarify whether higher bsAb doses, repeated injections, and additional costimulation are required to increase the therapeutic efficiency of bsAbs. In this vein, recombinant diabodies generated by genetic fusion of two scFv antibody fragments may circumvent such problems: extremely low doses of the recombinant bsAb were sufficient to efficiently generate a cytolytic T-cell response against lymphoma cells in vitro, even in the absence of a second, costimulatory signal (Figure 25.15, see Plate 5).¹⁵⁸ While this propensity to trigger and mediate cytolytic T-cell responses is impressive, it remains to be clarified whether treatment by the use of these recombinant bs scFv is restricted to high efficacy against the malignant B-cell population without concomitant toxicities such as massive polyclonal T- and B-cell activation leading to cytokine secretion, shock, and vascular leakage syndrome.

Recombinant DNA techniques may also overcome some of the drawbacks of T-cell targeting with bsAbs. Chimeric TCR have been created by fusing scFv molecules recognizing tumor-related antigens to the signal-transducing molecules of the TCR/CD3 complex, for example the γ or ζ chains.¹⁵⁹ These chimeric molecules function as 'surrogate' T-cell receptors and mediate antigen recognition, and are therefore termed T bodies. The intracellular part of the molecule (CD3 γ or ζ chain) then triggers signal transduction cascades, T-cell activation and generation of cytotoxic

Figure 25.14 Bispecific antibodies can bridge between tumor cells and lead to specific lysis by T cells that are otherwise unresponsive for the tumor cell, (a) T cells were polyclonally activated by a CD3 \times CD19 bsAb that links CD19 on the surface of a malignant B cell to the CD3 ϵ chain on a T cell for a 4-day period. T cells received a second, costimulatory signal via an agonistic antibody against CD28. The activated T cells were then incubated with chromium-51 (^{51}Cr)-labeled Raji Burkitt lymphoma cells. Only low alloreactive lysis is observed in the absence of bsAb. Addition of CD3 \times CD19 bsAbs induces tumor cell lysis, even at low effector-to-target (E:T) cell ratios as measured by specific ^{51}Cr release, (b) A CD3 \times CD19 bsAb was employed to inhibit tumor growth of Raji Burkitt lymphoma cells that were xenotransplanted into SCID mice. Subcutaneous injection of tumor cells alone led to rapid tumor growth. Co-injection of polyclonally activated human T cells at an E:T ratio of 1:1 slows down but does not prevent tumor growth. Animals that received the human T cells, CD3 \times CD19 bsAb, and costimulatory anti-CD28 mAb were saved from tumor growth.¹⁵⁶

Figure 25.15 Three-dimensional (3D) structure of a recombinant bispecific single-chain antibody (diabody). An scFv antibody against CD19 was fused by a linker to an scFv against CD3. This diabody construct is highly efficient in activating resting T cells and inducing a CTL response and target cell lysis of CD19 $^+$ malignant B cells.¹⁵⁸ (a) Backbone of the peptide chain, (b) Rendering of the 3D surface structure. Green, V_H of the anti-CD19 scFv; purple, V_L of the anti-CD19 scFv; gray, V_H of the anti-CD3 scFv; light blue, V_L of the anti-CD3 scFv; yellow, linker peptide; orange, His tag; darker blue, Flag tag (employed for detection and purification of the recombinant protein) (see Plate 5).

T cells (Figure 25.12). In vitro experiments are promising, but the clinical relevance remains to be elucidated. Nevertheless, a gene therapy approach to deliver and express these chimeric T-cell receptors in patients' T cells might finally exploit the power of the immune system to eliminate tumors.

Targeting solid tumors

To date, there have been few successful attempts to treat solid tumors with antibodies or immunotoxins. The treatment of solid tumors is more difficult owing to the tight junctions between tumor cells, the high interstitial pressure, and the heterogeneous blood supply. Moreover, a higher rate of HAMA or HACA responses is observed in patients with solid tumors receiving mAb therapy. This may be due to the higher grade of immunocompetence as compared with often immunocompromised lymphoma and leukemia patients.

The most promising data so far come from the use of antibodies to block growth factor signaling. Therapeutic targets for this approach are the epidermal growth factor (EGF) receptors, i.e. EGFR itself and homologs such as the HER2/*neu* receptor (Figure 25.16). The concept of using a mAb directed against EGFR was first proposed in the 1980s as a means to block the receptor from its activating ligands, transforming growth factor α (TGF- α) and EGF, thereby preventing the cascade of tyrosine kinase activation and mitogenic signal transduction in tumor cells. This led to the development of a human–murine chimeric antibody, cetuximab (C225, IMC-225), which binds with a 10-fold higher affinity than the natural ligands without delivering an activating signal and induces downregulation of the inactivated receptor.¹⁶⁰ Cetuximab thereby induces cell cycle arrest in G₁, presumably through induction of the cyclin-dependent kinase inhibitor p27, which inhibits the cyclin-dependent kinase cdk2. Moreover, expression of apoptosis-inducing proteins is induced, and inhibitors of angiogenesis and metastasis-associated metalloproteinases are downregulated.¹⁶¹ Finally, ADCC and complement lysis add to the inhibitory effects of cetuximab. Several phase I and phase I/II trials showed good tolerability and only a low rate of adverse reactions, with 4% of the patients developing detectable HACA, an acneiform rash in

Figure 25.16 Targeting of epidermal growth factor (EGF) receptor (EGFR) signaling by antibodies and small molecules. Ligand binding of EGF or transforming growth factor α (TGF- α) to the EGFR triggers activation of the receptor tyrosine kinase (RTK) activity of the EGFR, leading to recruitment of adapter molecules (Grb2 and SOS) that mediate activation of the p21^{Ras} pathway. This results in activation of MARK and PI3/Akt kinase signaling, which turn on proliferation and inhibit apoptosis. Blocking of ligand binding to the EGFR by the anti-EGFR mAb cetuximab blocks ligand binding and abrogates ligand-induced EGFR signaling. Similarly, the anti-HER2/*neu* antibody trastuzumab interferes with HER2/*neu* signaling and crosstalk with the EGFR. These antibodies therefore inhibit proliferation of EGFR+ or HER2/*neu*⁺ tumor cells and sensitize these cells for apoptosis. Similarly, small-molecule kinase inhibitors may interfere with signaling, inhibit proliferation, and abrogate survival signals. Examples are gefitinib (ZD1983, Iressa), an EGFR RTK inhibitor, and the various inhibitors of p21^{Ras} farnesylation.

9%, and anaphylactic reactions in 2%, managed successfully by standard therapies. Notably, other trials reported severe skin toxicities when combining cetuximab with paclitaxel. In combination with radiotherapy in 15 patients with head and neck cancer, a 100% overall response was found: 13 patients had a CR and 2 a PR. Even though radiochemotherapy already yields a high rate of CR in head and neck cancer, these results for cetuximab are better than those for historic controls of a 50–60% CR rate.¹⁶² Another trial in head and neck cancer showed a 67% CR rate when cetuximab was combined with cisplatin.¹⁶³ Phase III trials are now underway to validate the efficacy of radiation or cisplatin in combination with cetuximab. Trials in other carcinomas, including colorectal and pancreatic carcinoma, showed activity in advanced and chemorefractory patients when cetuximab was combined with irinotecan/5-fluorouracil or gemcitabine. Trials are currently being performed to evaluate the efficacy in first-line therapy. Additional antibodies against EGFR—ICR62, EMD55900, and ABX-EGF, a fully humanized antibody—are now in preclinical and clinical development. Moreover, MDX-447, a bsAb against EGFR and FcR γ 1 (CD64), has entered clinical trials. From 36 evaluable patients with various clinically advanced carcinomas, 9 showed stabilization of the disease for 3–6 months upon therapy with MDX-447.¹⁶⁴ Other constructs currently being evaluated in phase I trials aim at targeting of cytotoxic T lymphocytes by anti-EGFR \times CD3 bsAbs in combination with costimulation by a second bsAb against CD28. It remains to be established if these antibodies compare favorably against the novel smallmolecule EGFR kinase inhibitors such as gefitinib (ZD1839, Iressa) and erlotinib (OSI-774, Tarceva).

HER2/*neu*, also known as c-ErbB2, is expressed by breast, ovarian, gastric, and prostate tumors of subsets of patients with these disorders. HER2/*neu*, the product of the proto-oncogene c-erbB2, is a 185 kDa transmembrane receptor with protein tyrosine kinase activity that is a member of the EGFR family. This receptor is modestly expressed in normal adult tissues; however, it is strongly associated with epithelial solid malignancies and is overexpressed in approximately 25–35% of human gastric, lung, prostate, and breast carcinomas. HER2/*neu* overexpression is found in approximately 10% of breast carcinomas and is inversely related to estrogen receptor expression; it is correlated with poor prognosis. Antibodies directed against HER2/*neu* were developed in the mid to late 1980s.^{165,166} Trastuzumab (Herceptin), a humanized IgG1 mAb that contains human framework constant immunoglobulin regions associated with the complementarity-determining regions of the murine antibody 4D5, is now employed clinically. Trastuzumab was shown to be effective when administered as a single agent in HER2/*neu*-overexpressing breast cancer when administered weekly in a phase II trial.¹⁶⁷ Moreover, it was shown to enhance the antitumor activity of paclitaxel and doxorubicin when studied in mice bearing HER2/*neu*-overexpressing human breast cancer xenografts.¹⁶⁸ In fact, trastuzumab shows clinical synergy when combined with anthracyclines such as doxorubicin in patients with metastatic breast cancer.¹⁶⁹

In another approach, attempts were made to treat micrometastasis in a neoadjuvant setting with the mAb edrecolomab (17–1 A, Panorex) directed against the EpCAM antigen, a pan-epithelial cell marker. Initial reports from a phase II trial showed impressive improvement of overall survival when edrecolomab was given in an adjuvant setting.¹⁷⁰ The mode of action depends on ADCC and complement lysis as an immune effector mechanism. Nevertheless, these data could not be confirmed in a large phase III trial, and this led to the discontinuation of this compound. Interestingly, edrecolomab was shown to sensitize carcinoma cells for chemotherapy, much like trastuzumab. In the adjuvant therapy of breast cancer, a reduction of EpCAM⁺ disseminated tumor cells was achieved by sequential immunochemotherapy plus edrecolomab.¹⁷¹ A phase I study showed moderate toxicity of combined edrecolomab and capecitabine in 27 patients with advanced or metastatic adenocarcinoma. Of the 18 patients evaluable for response, 1 had a CR and 2 a PR. Nine patients had disease stabilization lasting a median of 17.5 weeks (range 14.5–28+).¹⁷² A fully humanized IgG1 antibody against EpCAM, MT201, is now under preclinical development and shows improved immune effector mechanisms.¹⁷³ It remains to be seen whether, in view of the data obtained with edrecolomab, any therapeutic benefit may derive from such novel anti-EpCAM antibodies or even edrecolomab alone or in combination with other cancer treatment modalities.

Immune suppression by antibody therapy

Suppression of B-cellular immune responses

The potency of antibodies to suppress humoral immune responses became evident when rituximab entered clinical use. Patients receiving this or other antibodies that eliminate neoplastic B cells show a profound and long-lasting depletion of non-malignant B cells from peripheral and lymphoid tissues. The good therapeutic efficacy, coupled with limited toxicity (consisting primarily of infusion-related events), has led to the recent use of this agent for the treatment of autoimmune disorders, with the aim of interfering with or, at best, abolishing autoantibody production. In fact, several case reports and phase I studies indicate that rituximab can be applied successfully for the therapy of autoimmune hemolytic anemia (AIHA) and mixed cryoglobuline-

mia (MC). Nevertheless, considering the type of autoantibody responsible for hemolysis, it appears that a better response can be achieved in patients with cold-agglutinin disease, as compared with warm autoantibody AIHA.^{174,175}

A combination of rituximab, cyclophosphamide, and dexamethasone was applied in eight CLL patients with steroid-refractory AIHA. All eight achieved a remission of their AIHA. The median pretreatment hemoglobin level was 8.3 g/dl, and this increased post treatment to 14.3 g/dl. Five of the eight patients converted to Coombs negativity with this treatment regimen. The median duration of response was 13 months (range 7–23 months), and retreatment was also effective in achieving a response on relapse of AIHA.¹⁷⁶ In pediatric AIHA, 15 children were given rituximab. All patients had previously received two or more courses of immunosuppressive therapy; two patients had undergone splenectomy. After completing treatment, all children received intravenous immunoglobulin for 6 months. Treatment was well tolerated. With a median follow-up of 13 months, 13 patients (87%) responded, whereas 2 showed no improvement. Median hemoglobin levels increased significantly from 7.7 g/dl to a 2-month post-treatment level of 11.8 g/dl, with a concomitant decrease in reticulocyte count. An increase in platelet count was observed in patients with concomitant thrombocytopenia (Evans syndrome). Three responder patients relapsed 7, 8, and 10 months after rituximab infusion, respectively. Notably, all three again achieved disease remission upon a second course of rituximab. These results indicate that rituximab alone or rituximab-based combination regimens are highly effective treatment modalities for steroid-refractory AIHA.¹⁷⁷

Likewise, 20 patients with MC and hepatitis C virus (HCV)-positive chronic active liver disease, resistant to IFN- α therapy received a 'standard' regimen of 375 mg/m² rituximab intravenously once a week for 4 consecutive weeks. Of the 20 patients, 16 (80%) showed a CR, characterized by a rapid improvement of clinical signs (disappearance of purpura and weakness arthralgia and improvement of peripheral neuropathy) and a decline in cryocrit. CR was associated with a significant reduction of rheumatoid factor (RF) activity and anti-HCV antibody titers. Decline of IgG anti-HCV titers in the cryoprecipitates was usually associated with a favorable response, and no differences in the dynamics of B-cell depletion and recovery were found between responders and non-responders. No severe side-effects were reported. Molecular monitoring of the B-cell response revealed disappearance, i.e. deletion of peripheral clones, in the responders. Nevertheless, rituximab had a clearly negative impact on hepatitis C viremia; HCV RNA increased approximately twice the baseline levels in the responders, whereas it remained much the same in the non-responders. Of 16 responders, 12 (75%) remained in remission throughout the follow-up. These results indicate that rituximab has clinical and biological activity in patients with HCV-associated MC. The long-term consequences of the increased viremia in the responders must, however, be clarified before this treatment modality may enter clinical routine.¹⁷⁸ Similar data were reported in a parallel study in 15 patients with HCV-associated MC.¹⁷⁹

Additional disorders where rituximab has shown activity in suppression of disease activity are autoimmune thrombocytopenias, some patients with rheumatoid arthritis,¹⁸⁰ and other autoimmune disorders (reviewed in reference 181). Compared with the other immunosuppressive agents used for the treatment of antibody-mediated autoimmune disorders, rituximab presents the advantage of inducing selective B-cell immunosuppression, sparing cellular immunity mediated by T cells and NK cells. Moreover, the specific impairment of antibody production can be easily corrected by prophylactic intravenous immunoglobulin administration, which allows maintenance of normal IgG levels for the whole period of B-cell depletion.

Suppression of T-cell responses

Acute and chronic graft-versus-host disease (GVHD) remain major obstacles to successful allogeneic hematopoietic stem cell transplantation, contributing substantially to morbidity and non-relapse mortality. Better understanding of the immunopathophysiology of GVHD has identified a number of targets for intervention that provide a more rational and probably also more effective approach as compared with antithymocyte immunoglobulin. Among newly developed agents suitable for the prevention and treatment of GVHD, several mAbs have shown promising results. Those currently available, such as infliximab against TNF- α and anti-IFN- γ , are capable of blocking the action of these effector cytokines. Antibodies directed against activated T cells, including anti-CD25 (daclizumab), humanized engineered non-FcR-binding anti-CD3 IgG2 (visilizumab¹⁸²), and ABX-CBL, an IgM murine mAb binding to CD147/basigin, a signaling receptor for cyclophilin B,¹⁸³ may offer more specificity than the more broadly acting pan-T-cell-depleting agents, and show promising results in the treatment of steroid-resistant acute GVHD.¹⁸⁴ Antibody targeting of the T-cell activation-associated antigen CD147 prevents TCR stimulation-dependent reorganization and clustering of membrane microdomains. Triggering CD147 induces a displacement of the GPI-anchored coreceptors CD48 and CD59 from such microdomains in human T lymphocytes. This perturbation of microdomains is accompanied by a selective inhibition of TCR-mediated T-cell proliferation.¹⁸⁵ Daclizumab binds to the IL-2R α chain (see below)

and interferes with IL-2 signaling, which is critically involved in the maintenance of T-cell responses. In contrast, antibodies against the CD3 signaling complex such as visilizumab or muromonab activate signaling functions of the TCR signal transduction machinery that, in the absence of adequate costimulatory signals, lead to apoptosis and T-cell deletion or T-cell anergy.^{155,156} In addition, these antibodies exert immune effector functions such as ADCC and complement lysis.

Notably, such T-cell depletion approaches carry the risk of reducing graft-versus-tumor effects and of increasing susceptibility to virus reactivation, but offer significant benefits in terms of reduced mortality and morbidity from GVHD. Finally, the clinical investigation of antibodies to adhesion molecules (such as LFA-1) or distal effector mechanisms (such as CD95/FasL or TNF- α) may offer another level of specificity. Alemtuzumab (Campath-1H) has been used successfully for the prevention of acute GVHD. Two protocols are currently favored: (1) simple addition of alemtuzumab to the stem cell infusion¹⁸⁷ and (2) administration *in vivo* prior to the transplant—especially in the context of non-myeloablative conditioning regimens.¹⁸⁸ Both of these give excellent control of GVHD with minimal graft rejection (reviewed in references 189 and 190).

Apart from their application in the prevention or treatment of GVHD, these antibodies have been employed successfully in the treatment of allograft rejection in organ transplantation.¹⁹¹ Additional applications include the treatment of autoimmune diseases. T-cell activation and cellular immune responses in these disease conditions are modulated by IL-2 through binding to IL-2R. Three forms of the receptor are recognized based on IL-2 binding affinity. The high-affinity receptor is heterotrimer composed of α , β , and γ polypeptide chains. The α chain—also known as the TAG (T-cell activation) antigen or CD25—is a unique subunit of the IL-2R (IL-2 α). Together with the β -chain it forms the high affinity IL-2R (IL-2R). Resting T cells express few IL-2R α ; however, when activated, the expression of IL-2R α rapidly increases. Humanized antiTAC (daclizumab) has been shown to reduce the incidence of renal and cardiac allograft rejection,¹⁹¹ as well as decreasing the severity of GVHD in patients undergoing HLA-matched allogeneic BMT.^{184,189} In addition, anti-CD25 IL-2R antibody therapy with daclizumab, given intravenously with intervals of up to 4 weeks, instead of standard immunosuppressive therapy, appeared to prevent the expression of severe sight-threatening autoimmune uveitis in 8 of 10 patients treated over a 12-month period, with noted improvements in visual acuity.¹⁹² Notably, antibodies against the IL-2R β chain, which is shared between the high-affinity IL-2R and IL-15R, have yielded similarly potent immunosuppressive activities in preclinical models *in vitro* and *in vivo*.

The Anti-CD3 ϵ -chain murine mAb muromonab (OKT3) has been employed in the past to deplete T cells from allogeneic grafts and to suppress T-cell responses *in vivo* both in GVHD and in organ transplant rejection. Nevertheless, the reports on its clinical efficacy are mixed, which may be due to the intrinsic T-cell stimulatory property of this antibody. Early data seem to indicate that these limitations do not apply in the case of HuM291, a humanized murine IgG2 mAb against the human CD3 complex. This antibody has undergone preclinical and clinical testing for various indications, where it was noted to profoundly deplete normal circulating T cells. It is now under consideration for clinical testing against CD3⁺ T-NHL. In chimpanzee studies, HuM291 induced virtually complete peripheral blood T-cell depletion as early as 6 hours after administration. T-cell counts increased as the HuM291 concentration in the circulation declined, indicating that the T-cell depletion in these animals was reversible. A multiple dose-escalation study of HuM291 given intravenously to renal transplant patients experiencing acute rejection was performed in 14 patients. Profound T-cell depletion was achieved, and its extent and duration appeared to be dose-dependent, with the highest dose leading to T-cell counts below 100 cells/mm³ for 14 to 28 days. A multicenter study evaluating the safety and pharmacology of HuM291 administered as a single subcutaneous injection to patients with mild or moderate psoriasis has now begun.

Like 'naked' antibodies, immunotoxins and radioimmunotherapeutics have entered clinical trials aiming at immune suppression. With regard to the immunotoxin denileukin difitox (DAB(389)IL-2 Ontak), the potential to target the high-affinity IL-2R supports the development of this agent in transplantation and in autoimmune diseases. Denileukin difitox has so far been examined in clinical trials of psoriasis and rheumatoid arthritis and has shown promising results.

Additional promising target structures include the CD40 ligand (GD154) or other costimulatory ligands and the inhibitory ligand CTLA4. In preclinical models, the administration of a fusion protein genetically engineered by linking CTLA4 and the Fc part of IgG (CTLA4-Ig) can prolong the survival of allogeneic BMT recipient mice, although this effect was not complete. CTLA4-Ig blocks the interaction of CD28 on T cells and B7 molecules on antigen-presenting cells (APC) in this setting. In addition, an anti-CD154 mAb, which can interfere with the interaction of CD 154 on T cells and CD40 on APC, can induce long-term graft survival in such a murine model.^{193,194} It is noteworthy that the combined administration of CTLA4-Ig and an anti-CD40L mAb can prevent allograft rejection in

primates. Moreover, clinical data indicate that blockade of the CD40/CD154 pathway enhances T-cell-depleted allogeneic bone marrow engraftment under non-myceloablative and irradiation-free conditioning therapy.¹⁹⁵

Side-effects and nursing techniques

The most distressing problem of intravenous mAb therapy is the possibility of severe allergic reactions. These include fever, chills, and rigors, and usually occur during the first 30 minutes of the mAb infusion. This acute risk increases with repeated injections. In contrast to these early reactions, fever that develops late in therapy (hours to days after injection) may be due to the development of HAMA. Continuation of infusion in the latter case can lead to symptoms such as facial palsy, hypotension, and acute renal tubular necrosis. The rapidity of dose administration appears to relate to the severity of symptoms. Thus, an infusion for 4–6 hours both decreases the severity of the reaction and allows discontinuation of the infusion rapidly enough in the case of hypersensitivity as compared with bolus intravenous injection. Prolonged infusion may also be associated with a decrease in pulmonary problems such as dyspnea and respiratory obstruction. Throat tightness, cough, dyspnea, stridor, or chest pain are early indicators of hypersensitivity, and should always lead to immediate discontinuation of the infusion. Tumor lysis and the formation of circulating immune complexes due to HAMA or shed tumor antigens may lead to immune deposits, complement activation, and, in most cases, transient renal damage and elevation of serum creatinine. Premedication with antipyretics may help prevent fever, while chills and rigor usually respond well to low-dose opiates. Medications to be administered in case of more severe hypersensitivity include intravenous H₁ and H₂ histamine receptor antagonists, high-dose intravenous steroids, and hydration. It has been reported that, upon rapid relief of symptoms, the infusion may be continued slowly without the occurrence of additional hypersensitivity reactions.

In the case of immunotoxins, in contrast, the sideeffects can be severe, and their systemic toxicity is a dose-limiting factor in clinical use. Unfortunately, despite the use of different toxins, there is substantial overlap with regard to toxicity profiles. The most commonly observed side-effect is capillary leak syndrome, most probably due to non-specific endothelial range from simple weight gain and moderate periphdamage. As in cytokine therapy with IL-2, this can eral edema to severe hypotension, pleural effusion, and lung edema. Fever, myalgia, and anorexia are frequently observed. Neurological disorders such as aphasia have been described, as have liver toxicity and severe rhabdomyolysis.

Conclusions and future directions

Despite the scarcity of cancer-specific antigens, mAbs have been demonstrated to be more or less selective anticancer agents. Nevertheless, the complexity and variety of human cancers dictate so far that no single agent or approach is sufficient to cure the disease. Each cancer type and stage may require a different agent or a combination of modalities. Several unlabeled mAbs and, recently, radiolabeled antibodies have shown promising results in clinical phase II and III studies. It is now mandatory to evaluate whether the increases in complete remissions and the so-far observed prolongation of disease-free survival are sustained and move forward cancer therapy. Disappointing results in the past are in part due to an excess of tumor burden: minimal residual disease appears therefore to be a most promising target for mAb therapy in the near future. A list of ongoing clinical trials for monoclonal antibody serotherapy in cancer can be accessed at the cancer.gov server of the US National Cancer Institute (<http://cancer.gov/cancerinformation>).

In conclusion, it is clear that mAbs are still far from being the ‘magic bullet’ that Paul Ehrlich dreamed of. They nonetheless provide novel therapeutic approaches that contribute to the steady—if slow—improvement in the treatment of leukemias, lymphomas, and an array of other malignancies.

T-cell-mediated immunotherapy of cancer

Rienk Offringa, Rene EM Toes, Maaïke E Rensing, Marloes LH de Bruijn, and Cornelis JM Melief

Immunotherapy of cancer

The mere fact that tumors can develop and progress in cancer patients indicates that the tumor cells have apparently escaped the attention of—or at least destruction by—the patients' immune systems. In the past, this notion has led to the suggestion that tumor cells may lack antigenic structures. At present, as a result of extensive experimental research using both murine tumor models and material from human cancer patients, it has become clear that many tumors do express an aberrant repertoire of antigenic determinants that can, in principle, be recognized by the immune system.^{1,2} Furthermore, work, especially with murine tumor models, has indicated several ways in which the immune system can be stimulated or redirected to destroy tumor cells.^{3,4}

Attempts to develop immunotherapeutic approaches for the treatment of cancer have mainly focused on three arms of the immune system:⁵

- natural killer (NK) cells and lymphokine-activated killer (LAK) cells;
- T cells;
- antibodies.

Of these effector mechanisms, NK and LAK cells are relatively easily induced, stimulation with lymphokines (especially interleukin (IL)-2) usually sufficing. The other side of the coin is the poor specificity of the immune effector cells obtained, as well as the severe side-effects elicited by most lymphokines when administered systemically to patients.^{6,7} The induction of antigen-specific immunity requires more detailed knowledge of the target molecules exhibited by the tumor cells and of the methods by which immunity against these targets can be induced. Although these factors make the induction of antigen-specific antitumor immunity far more challenging, the superior selectivity of such effector mechanisms makes it worth the trouble. Both antibodies and T lymphocytes have been found to be capable of specifically recognizing and eliminating tumor cells.^{2,4,8–11} The spread of antibodies, however, depends strongly on the vascularization of the tumor tissue,¹² whereas T lymphocytes have the capacity to migrate through tissues and in this manner to track down their targets, even if these targets are located outside the bloodstream or in multiple sites of the body. This property makes T lymphocytes especially valuable in the fight against solid tumors and metastasizing tumors. In fact, T cells possess most of the desirable properties of a 'magic bullet', the highly effective and specific anti-tumor agent that represents the ultimate goal of cancer research. In this chapter, we shall therefore focus on the antitumor T-cell response and on various approaches that can be employed to activate or redirect this immune response.

The approaches used to activate and/or redirect the T-cell immune response can be subdivided into two categories:

- *adoptive immunotherapy*, involving the generation of the desired tumor-reactive T cells outside the patient (usually in vitro), followed by transfer of the resulting effector cells to the patient;
- *active immunotherapy*, involving the administration of vaccines and/or lymphokines to the tumorbearing host with the objective of reprogramming the host's immune system.

Active immunotherapy has the obvious advantage that no manipulation of immune effector cells of the patient outside the body is required. Although in vitro culture conditions can be easily created for the growth and expansion of human lymphocytes, it is far more complicated to create a setting in which T cells are obtained that exhibit the desired antigen-specificity and reactivity. On the other hand, the feasibility of active immunotherapy depends strongly on the state of the patient's immune system. As a result of poor general health status, tumor-mediated immunosuppression, and/or the immunosuppressive effects of conventional chemo- or radiotherapy, the condi-

tion of a patient's immune system may not be sufficient for the induction of an immune response against even the most optimal vaccine.

Cytokines; genetically engineered tumor cells

Selective induction of antitumor T-cell immunity is supported by knowledge of the repertoire of tumor-associated peptides that are presented to the T-cell immune system in the context of major histocompatibility complex (MHC) molecules. Unfortunately, identification of tumor-associated antigens, both in general and in the case of a given patient, is very time-consuming. Using basically two approaches, this laborious process can be circumvented:

- (i) by cytokine treatment;
- (ii) by vaccination with genetically engineered tumor cells.

Cancer patients can be treated by systemic or, in the case of certain solid tumors, local administration of lymphokines that are known to stimulate the T-cell immune response in a non-specific fashion. The lymphokines that have been used most frequently, in both experimental and clinical settings, are IL-2 and interferons.^{6,13,14} The major action of IL-2 is to strongly enhance the activity and proliferation of T cells, whereas interferons act through elevation of the antigen processing and MHC expression on (amongst others) tumor cells and through T-cell activation. As already implied by the mode of action of these lymphokines, the effects of lymphokine therapy are non-specific, causing activation of the immune system in general rather than of the antitumor immune response. Furthermore, systemically administered lymphokines cause pleiotropic effects such as severe toxicity.¹³

Following these considerations, vaccination protocols were developed involving genetically engineered tumor cells that produce lymphokines. This approach in principle combines three desired features:

- (i) the presence of an antigenic stimulus without the need to know the identity of the relevant tumor-associated antigens;
- (ii) the local and temporary presence of T-cell stimulatory lymphokines;
- (iii) especially in the case of interferon-producing tumor vaccines, the increased antigen-presenting capacity of the tumor cells.

One of the first examples of successful vaccination with modified tumor cells involved *IL-2* gene-modified tumor cells. This approach, when tested in murine tumor models, did not involve toxicity and induced strong protective antitumor immunity, which in some cases not only prevented tumor growth but could also lead to destruction of existing tumors.^{15,16} A wide variety of cytokines have been tested similarly, including interferon (IFN)- γ , IL-4, and granulocyte-macrophage colony-stimulating factor (GM-CSF).¹⁷ Although for most lymphokines cases have been described where lymphokine gene-transduced tumor cells could be used as an effective antitumor vaccine, the efficacy of a given lymphokine appears to depend strongly on the experimental setting. An important parameter in this setting is the antigenicity of the tumor that is to be genetically modified. Tumor cells that present sufficient levels of immunogenic, MHC-bound peptides at their surface are more likely to constitute an effective vaccine after, for instance, *IL-2* gene transduction, whereas tumor cells exhibiting very low MHC expression may especially benefit from *IFN- γ* gene transduction, which in an autocrine fashion promotes antigen presentation by the tumor cells. Tumor cells genetically engineered to secrete GM-CSF have the advantage of promoting induction of antitumor immunity through cross-priming, involving the recruitment of professional antigen-presenting cells (APC) of host origin.¹⁷ Professional APC such as dendritic cells (DC) express high levels of class I and II MHC antigens.^{18,19} Consequently, also in the case of class II-negative tumors, the involvement of professional APC will result in the presentation of tumor-derived antigenic peptides in the context of both class I and class II MHC, causing the concerted activation of both cytotoxic T lymphocyte (CTL)-mediated and T-helper cell (Th)-mediated immunity. Moreover, professional APC express on their surfaces various molecules that can provide costimulatory signals to T cells when bound by their corresponding receptors on the T-cell surface. The most prominent costimulatory molecules are B7.1 and B7.2, which, through interaction with the CD28 molecules on T cells, can provide a strong costimulatory impulse to antigen-triggered T cells.²⁰⁻²² The importance of B7-mediated costimulation has been well illustrated by the observation that *B7* gene transduction can significantly increase the immunogenicity of tumor cells.²³⁻²⁵ The first interpretation of such experiments was that coexpression on the tumor cell surface of MHC-bound antigen and B7 led to direct priming of T cells without the intervention of professional APC. More recent data, however, have indicated that, also in the case of vaccination with gene-transduced cells, cross-priming by host APC constitutes a major mechanism of immune activation.²⁶⁻²⁹ The important role of host APC-mediated cross-priming points to a clear advantage of vaccination with (genetically engineered) tumor cells: there is no absolute need for the tumor cell vaccine to be autologous. Partly MHC-matched and completely allogeneic tumors as well as tumors that fail to express MHC, can be used as an effective antitumor vaccine, provided that the non-autologous tumor and the tumor in the patient share the relevant tumor-associated antigens.³⁰⁻³² Especially in the case of tumor types that are known to express a tumor-related repertoire

of antigens (e.g. melanomas),² this advantage may allow the development of 'off-the-shelf' tumor cell vaccines that can be applied to a significant fraction of patients suffering from these types of cancer.

Peptide-based vaccines for the induction of antitumor T-cell immunity

The promising results obtained with different vaccines consisting of genetically engineered tumor cells indicate that this approach will be valuable for the induction of antitumor T-cell immunity against at least certain types of tumors. However, naturally arising tumors are rarely good APC. Although certain tumors arise preferentially in immunosuppressed individuals, most types of cancer develop in immunocompetent hosts and therefore in the face of a functional immune system. In cases where insufficient antigen processing, MHC expression, or costimulation are the limiting factors, genetic modification through transduction of the appropriate gene can be employed to provide the cells with sufficient antigenpresenting capacity to induce an effective antitumor response. However, when the level of tumor-associated antigens is the limiting factor, genetic engineering as described above is not likely to result in an effective vaccine.³³ In that case, a vaccine is required that harbors increased doses of the relevant tumor antigens. This can be valid for vaccination against virus-induced tumors, which, owing to immunoselection, may express only modest levels of the viral oncogene products and may even have switched off the expression of viral genes not required for transformation, but is especially relevant with respect to the induction of T-cell immunity against tumor-associated self-antigens. As many of the latter antigens are also expressed by certain normal somatic cells, the T-cell immune system is likely to exhibit at least partial tolerance against such antigens.³⁴ Vaccination with sufficient amounts of the appropriate antigens may in such cases be required to alleviate the absence of antitumor T-cell reactivity.

Elucidation of the three-dimensional structure of the MHC-antigen complex³⁵ pointed towards new directions for the development of vaccines for the induction of specific T-cell immunity. Since the antigens presented in the context of the MHC molecules are peptides of limited length, this opens the possibility of developing vaccines composed of selected synthetic peptides. The development of such molecularly defined vaccines is further supported by the rapidly increasing knowledge of the repertoire of proteins that are aberrantly expressed by certain types of tumors.^{1,2} Moreover, peptide-binding motifs are available for many MHC molecules, and can be used to predict the peptides within the primary sequence of a tumor-associated antigen that are most likely to bind to the MHC molecules concerned.^{36,37} The actual binding of selected peptides to the MHC can subsequently be measured by means of several different peptide-binding assays.³⁸⁻⁴¹ Based on these binding assays, a new assay was developed that measures the stability of the MHC-peptide complexes.⁴² Since the stability of these complexes was shown to correlate the more accurately with the immunogenicity of peptides than binding affinity as measured by other assays, the stability assay constitutes a valuable new step in the selection of immunogenic peptides.⁴³

Further improvement in epitope prediction comes from *in vitro* proteasomal cleavage analysis of long peptides containing high-affinity MHC class I-binding sequences.⁴⁴ It was found that for proper MHC class I processing and cell surface presentation of antigen sequences, precise proteasomal cleavage of the C termini of the epitopes is required. Because of this requirement, approximately 70% of all high-affinity MHC class I-binding sequences never make it to the cell surface, because of the lack of such a cleavage site.

The efficacy of peptide-based vaccines for the induction of protective T-cell responses was first demonstrated in virus-infected mice. Vaccination with selected class I MHC-binding peptides from lymphocytic choriomeningitis virus (LCMV) and Sendai virus, emulsified in incomplete Freund's adjuvant (IFA) and injected subcutaneously, was shown to induce a vigorous peptide-specific CTL response that protected the mice against a lethal challenge with the virus concerned.^{45,46} Similarly, the peptide vaccination approach was applied in a murine tumor model featuring human papillomavirus 16 (HPV16)-transformed cells. To identify the CTL epitopes presented by these tumor cells, the HPV16 E6 and E7 oncoproteins were screened for peptides that bound with high affinity to the relevant class I MHC molecules. The peptides selected were subsequently tested for their capacity to induce protective immunity against a tumorigenic dose of the HPV16-transformed cells. One of the HPV16 E7-derived peptides was shown to elicit strong peptide- and tumor-specific T-cell immunity, preventing the outgrowth of HPV16-induced tumors.⁴⁷ Encouraged by the efficacy of peptide vaccination in this murine tumor model, an HPV16 peptide epitope vaccine was developed for use in patients suffering from HLA-A*0201⁺ HPV16⁺ cervical carcinomas. The combination of HLA-A*0201 and HPV16 was chosen because of the frequent occurrence of HLA-A*0201 in the human population (40%) and of HPV16 DNA in cervical carcinomas (60%). Peptides derived from HPV16 E6 and E7 were selected for their capacity to bind to HLA-A*0201 and to reproducibly induce peptide-specific T-cell immunity in both HLA-A*0201-transgenic mice and human HLA-A*0201⁺ peripheral blood mononuclear cell (PBMC)

cultures.^{39,48,49} A vaccine consisting of the two most immunogenic HPV16 E7-derived peptides in combination with a pan-HLA-DR-binding T-helper peptide (PADRE), emulsified in an IFA-like adjuvant, was subsequently tested in HLA-A*201⁺, HPV16⁺ cervical carcinoma patients in a phase I/II clinical trial. None of the patients suffered from serious side-effects following repeated injection of the peptide vaccine, whereas several patients, who were selected on the basis of recurrent or residual cervical carcinoma unresponsive to conventional treatment, have displayed stable disease for over 1 year. Although the effects of vaccination on HPV16-specific T-cell immunity await further evaluation, measurement of the pre-existing CTL immunity against one of the selected HPV16 E7-derived peptides in HLA-A*0201⁺ HPV16⁺ cervical cancer patients has shown that such CTL memory can be observed in a minority of these patients, whereas the majority showed influenza-specific CTL memory.⁴⁹ These data suggest that natural CTL responses against HPV16 can occur in patients, but are apparently insufficient in these cases (since these patients suffer from cervical carcinoma) and even absent from the majority of such patients. These findings support the notion that the induction of HPV16-specific T-cell immunity in these patients constitutes a valuable strategy for the immunotherapy of cervical cancer. Similarly, several melanoma patients have been vaccinated with an HLA-A1-binding peptide that is derived from the MAGE-3 melanoma-associated antigen. Although also in these patients clear-cut effects of vaccination on the antigen-specific T-cell response have not yet been documented, striking tumor regression in a small number of patients indicates that peptide-based antitumor vaccines may indeed be effective in inducing antitumor T-cell immunity in certain cases.⁵⁰

In another report, melanoma patients were vaccinated with a gp 100 melanocyte differentiation antigenic peptide, modified at one amino-acid position for enhanced HLA-A2 binding. Again the results were promising in a proportion of patients, with 13 out of 41 patients achieving objective anti-cancer responses.⁵¹

Various other groups have reported beneficial effects of vaccination with MHC class I-binding peptides in patients with metastatic melanoma.⁵²⁻⁵⁴ The problem with this approach is that, clinically, most patients, even those with ostensibly complete remissions, eventually relapse. Moreover, as argued below, vaccination with exact MHC class I-binding peptides is far from optimal.

Optimal antigen presentation; dendritic cells

Although murine models have shown the potency of peptide-based vaccines, experiments with these models have also revealed alarming limitations. For instance, repetitive and systemic intraperitoneal injections of mice with high doses of an immunogenic exact MHC class I-binding LCMV peptide in IFA, which at low doses induced protective immunity, caused suppression rather than induction of peptidespecific CTL immunity.⁵⁵ Furthermore, in a murine tumor model featuring adenovirus type 5 (Ad5)-transformed cells, vaccination with exact MHC class I-binding Ad5-derived tumor-specific peptides was shown to abrogate the peptide-specific CTL response, leading to enhanced tumor growth in the vaccinated mice.^{56,57} Importantly, in contrast to the LCMV model, the adverse effect of Ad5 peptide vaccination on T-cell immunity was observed at peptide doses and with a mode of antigen delivery that in the case of other peptides (LCMV, Sendai, and HPV16 E7) was shown to induce protective CTL immunity. To explain what might go wrong in the case of vaccination with the Ad5 peptides, it is important to consider the mechanism by which soluble exact MHC class I-binding peptides, when injected into mice, modulate the T-cell immune response. The subcutaneously injected peptides in IFA form a depot from which the peptides diffuse throughout the body. Here, they bind to available MHC molecules on the surfaces of somatic cells. Most of these cells, although expressing the appropriate MHC molecules, lack the rich repertoire of costimulatory molecules present on professional APC. At moderate levels of peptide presentation, antigenic trigger and costimulation are still in balance, causing appropriate activation of the relevant T cells. However, at excessive peptide doses, as for instance in the case of the LCMV model,⁵⁵ the antigenic stimulus may greatly exceed the costimulatory capacity of the peptide-presenting somatic cells. As a result, the T cells become inappropriately stimulated, causing them to undergo programmed, activation-induced cell death (apoptosis) or to enter a state of unresponsiveness (anergy). In accordance with this notion, evidence was found that especially the Ad5 peptides, when injected subcutaneously in IFA, spread rapidly throughout the body.^{56,57} In this setting, even modest doses of such peptides are likely to cause excessive peptide presentation and therefore inactivation of the peptide-specific T cells. The relevance of the context of antigen presentation, rather than the peptide itself, to the outcome of peptide vaccination is further supported by the observation that the same Ad5 peptides, when loaded *ex vivo* onto autologous dendritic cells (DC), did serve as an effective vaccine for the induction of protective antitumor immunity.⁵⁸

The inadequacy of exact MHC class I-binding peptides as vaccines was recently also demonstrated in a murine study in which the vaccine potency of exact MHC class I-binding peptides was compared with that of long peptides incorporating both MHC class I and class II epitopes in therapy of established

HPV16-induced murine tumors. Only a long peptide containing an immunodominant HPV16 E7 MHC class I epitope in addition to a class II epitope coadministered with CpG, a powerful Toll-like receptor 9 (TLR9) agonist, was capable of tumor eradication in 80% of mice with established palpable tumors, whereas the exact MHC class I-binding peptide alone admixed with CpG was completely ineffective.⁵⁹ These results correlated with CTL response inductions by these vaccine formulations, a markedly stronger CTL response being observed with the long peptide vaccine. The CpG interacts with TLR9 on DC, causing activation of the DC to robust and powerful APC. Even in the absence of CpG, long peptides (32–35 amino acids long), containing both MHC class I and class II epitopes, induce a powerful CTL response after only two vaccinations.⁵⁹ In this case, DC become activated due to CD40L upregulation on activated CD4⁺ T cells interacting with CD40 on DC, causing DC activation.⁶⁰

The formidable antigen-presenting capacity of DC has also been illustrated by experiments in various murine vaccination models. DC loaded ex vivo either with synthetic peptides or with unfractionated acid-eluted tumor peptides were shown to elicit protective antitumor T-cell immunity that not only prevented development of tumors but in some cases also resulted in the regression of pre-existing tumors.^{61–64} Consequently, the efficacy of DC in the induction of T-cell immunity both in vitro and in vivo against human tumors is the subject of intensive studies. Peptideloaded autologous DC were shown to serve as effective stimulator cells for the induction of peptide-specific CTL responses in human PMBC cultures.^{60,65} Four patients suffering from B-cell lymphoma were vaccinated with autologous DC that had been pulsed ex vivo with tumor-specific idiotype immunoglobulin protein, followed by booster immunizations with these proteins in the absence of DC. All patients developed cellular antitumor responses, whereas tumor regressions were observed in three of the patients.⁶⁶ Taken together, there is no doubt that DC will serve as a valuable component in vaccines. A major point that needs further study, however, concerns the source of DC that is to be used and the protocols that are to be employed for isolation and expansion. DC can be isolated from a limited quantity of peripheral blood, or from the CD34⁺ fraction of human bone marrow, and expanded in vitro with a culture protocol involving stimulation with GM-CSF and IL-4.^{67–70} However, the yield of DC and their phenotype and antigen-presenting capacity, as well as the stability of this phenotype, are still not well controlled, calling for better-defined culture conditions.^{71,72} For proper evaluation of the value of DC vaccination in cancer patients, both clinical and immunological criteria should be defined. Examples of rigorously controlled studies are to be found in references 73–75. A recent discussion of the future of cancer vaccination with ex vivo activated DC can be found in reference 76. Proper DC activation and quality control of DC preparations administered to patients is of the utmost importance. Improperly activated DC are more likely to tolerize than to vaccinate.⁷⁷

Genetically engineered, molecularly defined vaccines

Notwithstanding the increased immuno stimulatory capacity of peptide-loaded DC in comparison with free peptide in adjuvant, peptide-based vaccines are intrinsically limited by the fact that they will comprise only a select set of peptides that bind to certain MHC molecules, although part of this disadvantage can be circumvented by the use of long peptides. Clearly, vaccines that harbor or encode entire tumor-associated antigens can, in principle, be the source of a greater variety of immunogenic peptides. When designing a vaccine covering an entire antigen, one is left basically with two options: a recombinant protein encoded by a dedicated gene construct in, for instance, *Escherichia coli* or baculovirus expression systems, or a gene construct that, when introduced into the recipient, can encode the proteins of choice at the site of injection.

Experience is accumulating with both types of vaccines. Injection of various recombinant proteins was shown to induce specific T-cell immunity that protected against virus infection or tumor growth.^{78–80} Furthermore, vaccination of mice with purified HPV16 E7 protein, synthesized in *E. coli*, has been shown to protect mice against a subsequent challenge with a tumorigenic dose of HPV16-transformed cells, and this protection was accompanied by the presence of HPV16 E7-specific CTL immunity.^{81,82} Like peptide-based vaccines, whole protein-based vaccines can probably be improved through modifications that promote presentation of the resulting immunogenic peptides by professional APC such as DC. This goal can be reached by in vitro incubation of DC preparations with the protein(s) of choice, followed by injection of the protein-pulsed DC. A vaccination trial involving injection of B-cell lymphoma patients with autologous DC that have been pulsed with lymphoma-specific immunoglobulin preparations is in fact based on this principle.⁶⁶ Alternatively, proteins can be targeted for uptake by DC in vitro (and probably in vivo) by attaching mannose groups to these proteins. Mannosylated proteins are taken up not only through macropinocytosis, but also through endocytosis via the mannose receptor that is expressed at high levels on DC.⁸³

Over the past few years, an enormous body of work has been done with respect to the efficacy of vaccines

comprising genes. As a DNA construct is the starting point of virtually all recombinant vaccines, the simplest method of vaccination involves injection of the DNA construct itself. In fact, DNA vaccination using gene constructs encoding tumor antigens and/or lymphokines has been shown to elicit strong T-cell responses against tumor-associated antigens in several model systems.^{84–87} In most cases, DNA vaccination involves intramuscular or intradermal injection of DNA. The intradermal route was generally found to be more efficient—most likely as a result of the higher numbers of professional APC in the skin.^{87–89} DNA vaccination requires uptake of naked DNA by somatic cells, and can therefore be regarded as *in vivo* DNA transfection. Conceivably, the efficiency with which these cells take up DNA is limited, since most somatic cells are highly differentiated and non-proliferative. Attempts to increase DNA uptake have involved the injection of muscle regeneration drugs, which have been reported to facilitate the uptake and transcription of the DNA.⁹⁰ Alternatively, DNA constructs can be transferred (mostly intradermally) using the gene-gun technology, which utilizes an adjustable shock wave that accelerates DNA-coated gold particles into target cells or tissues. Compared with other gene-delivery methods, the gene-gun technique can achieve up to 100-fold higher gene expression levels, conceivably as a result of the fact that this technology leads to delivery of the DNA at the intracellular level.^{91,92} This may overcome a potential problem with DNA vaccination, namely the fact that naked DNA is highly sensitive to degradation by ubiquitous nucleases. This problem is even more pronounced with respect to vaccination protocols employing extremely nuclease-sensitive RNA molecules. Packaging of these nucleic acids into liposomes constitutes an alternative way to shield these molecules from destruction by nuclease activity.

Instead of such ‘artificial wrappings’, recombinant viruses can be used to transfer the gene(s) of interest. Many viruses are capable of eliciting powerful and lifelong immunity. Moreover, viruses can be regarded as nature’s own gene-transduction tool; the capsid shields the nucleic acids from nucleases and functions as an efficient carrier for gene transduction, sometimes even in a cell-specific manner. Finally, a wealth of information is available about the topography of the genomes of various viruses and about sites into which foreign sequences of considerable length can be introduced. Most research on experimental virus-based antitumor vaccines has been performed with recombinant vaccinia virus (rVac).^{93–95} For example, rVac encoding HPV16 E7 were shown to elicit strong E7-specific T-cell immunity in vaccinated rodents.^{81,96,97} An rVac vaccine encoding the E6 and E7 proteins of HPV16 and HPV18 has been used to vaccinate cervical carcinoma patients in a phase I/II clinical trial.⁹⁸ Other viruses that have received much attention as potential tools for vaccination are recombinant human adenoviruses (rAd) and recombinant canarypox and fowlpox viruses.^{99,100} A recombinant fowlpox virus encoding the model tumor antigen b-gal was shown to inhibit tumor development when injected into mice bearing b-gal-expressing tumors.¹⁰¹ A recombinant canarypox vaccine (ALVAC) expressing the tumor-associated antigen p53 has been shown to protect mice from a challenge with highly tumorigenic mutant-p53-overexpressing tumor cells.¹⁰² Interestingly, the tumor protection was equally effective regardless of whether the virus encoded mutant or wild-type p53, indicating that the protective immune response was apparently directed against wild-type p53-derived epitopes and that immunization with such virus-based vaccines apparently works well in inducing immunity against self-proteins. Indeed, in a phase I study of tumor vaccination in patients with colorectal cancer, ALVAC-p53, containing the entire human wild-type p53 sequence, was capable of inducing T-helper 1 type T-cell responses characterized by IFN- γ production.^{103,104} Similar canarypox vector constructs encoding the tumor-associated antigens epithelial cellular adhesion molecule (Ep-CAM) or MAGE-3 were also shown to induce specific T-cell responses to these antigens.^{105,106} Similarly, rAd encoding tumor-associated antigens were shown to induce protective antitumor immunity in murine tumor models.^{107,108}

The first promising results obtained with recombinant virus vaccines have boosted the development of a great variety of these vaccines. Optimization of the processing and presentation of the virus-encoded immunogens to T cells has received considerable attention. To optimize presentation of peptide antigens for recognition by class II-restricted T cells, viruses have been made that encode the HPV16 E7 protein fused to a lysosomal-associated membrane protein, LAMP-1, which reroutes the antigens to the MHC class II pathway.^{97,109} Indeed, LAMP-1 targeting of the E7 protein increases the efficiency with which the vaccine induces T-helper as well as CTL responses. As a role for the ubiquitin-mediated proteolytic pathway has been postulated in the proteasome-mediated degradation of proteins into antigenic peptide fragments, modifications of the gene product that promote ubiquitinylation may also constitute a way to increase processing and presentation of the relevant peptide epitopes. For instance, the rate of MHC class I presentation of b-gal was found to be enhanced when this antigenic protein contained an acidic or basic N terminus that was conjugated to a ubiquitin subunit.¹¹⁰ Alternatively, recombinant viruses have been made that contain minigenes encoding antigenic peptides preceded by an N-terminal ER-insertion sequence, bypassing the requirements for both proteolysis and transport of the antigenic peptides.^{93,94} Finally, rAd have been made

carrying synthetic genes that encode polypeptides consisting of antigenic peptides alternated by short spacer sequences to allow processing of the polypeptide into the proper peptides. A single rAd vaccine encoding a 'string-of-beads' arrangement of immunogenic peptides derived from the HPV16 E7 as well as the Ad5 E1A and E1B oncoproteins was shown to elicit strong, REM-protective T-cell immunity against both HPV16- and Ad5-induced tumors in mice.¹¹¹ The ability to induce T-cell responses against oncoprotein-derived peptides through immunization with such poly-epitope rAd offers a clear advantage over immunization strategies in which the vaccine carries functional oncogenes, in that it largely eliminates the risk of introduction of functional oncogenes into infected cells and thereby of transformation of these cells. Note that oncoproteins especially are attractive targets for immunotherapy of cancer, since their expression is generally required for tumor growth, making the development of tumor variants lacking these antigens unlikely.

In addition to the design of the antigen-encoding gene, the presence of additional genes encoding immunostimulatory lymphokines or costimulatory molecules is likely to improve the efficacy of the vaccine. This is illustrated by the enhanced immunogenicity of rVAC-based vaccines that, in addition to the antigen, encoded either IL-2 or B7-1.^{112,113}

Transfer of in vitro expanded tumor-reactive T lymphocytes

Active immunotherapy relies on triggering the host immune response in vivo. Although appropriate vaccine formulations are likely to elicit the desired immune responses in healthy individuals and in cancer patients at an early stage of the disease, this approach may come too late for patients who have advanced stages of cancer and/or have already undergone conventional cytostatic treatment. In the latter cases, the poor state of the patient's immune system requires adoptive immunotherapy—the transfer of ready-made effector mechanisms to the patient. In murine tumor models, this approach has been shown to cause regression of large established tumors. For instance, large established Ad5-induced tumors can be eradicated by adoptive transfer of in vitro expanded Ad5-specific CTL.^{114,115} Since the CTL were administered intravenously, whereas the tumors were located at a subcutaneous site, these results indicate that the CTL are apparently capable of tracking down the tumor cells and that in vitro culture did not affect this homing capacity. Importantly, however, the CTL only succeed in eradicating the tumors when IL-2 is given simultaneously, as a subcutaneous depot in IFA. Although this does not cause major side-effects in mice, systemic administration of IL-2 in humans is very troublesome. Adoptive immunotherapy in humans will therefore benefit greatly from approaches to provide the CTL more physiologically with a mitogenic stimulus. In fact, the most physiological solution is represented by Th cells. The therapeutic efficacies of Th and CTL against viruses and tumors have been investigated in different murine models. For instance, in mice suffering from Rauscher murine leukemia virus-induced disease, it was shown that Rauscher-specific CD4⁺ and CD8⁺ cells only gave partial resistance, whereas a combined transfer resulted in complete protection against these tumors.¹¹⁶

Although in the human situation highly defined and purified Th and CTL populations against tumors are not yet available, adoptive transfer of less well-characterized effector populations is being tested in a clinical setting. For instance, the only curative treatment for chronic myeloid leukemia (CML) is currently allogeneic bone marrow transplantation (BMT). Of the patients treated by BMT, approximately 20% show leukemia recurrence. Full remission in such patients can subsequently be achieved by adoptive immunotherapy involving the infusion of viable buffy coat cells from the marrow donor. The beneficial effect of both BMT and buffy coat transfusion is intimately connected with the antileukemic activity of transplanted T cells.^{117–125} Unfortunately, the effectiveness of this treatment is compromised by the fact that in many cases the donor-type T cells, in addition to the graft-versusleukemia (GVL) response, exhibit graft-versus-host (GVH) activity. Increased knowledge of the identity of the leukemia-associated antigens, in combination with culture techniques that can be used to selectively expand the GVL-reactive T-cell population, are needed for improvement of the specificity of this antileukemic treatment. In vitro restimulation of donor-derived lymphocytes with DC generated from peripheral blood cells of patients with CML was shown to result in T-cell populations that exhibited vigorous cytotoxic activity against CML cells while showing low reactivity against MHC-matched normal bone marrow cells.¹²⁶ The bone marrow can serve as an alternative source for such DC. Culturing of CD34⁺ cells purified from the bone marrow of CML patients in the presence of GM-CSF, IL-4, and tumor necrosis factor (TNF)- α was shown to result in DC-enriched cell suspensions in which the DC expressed the *BCR-ABL* gene.¹²⁷ This implies that such DC should be capable of presenting peptides derived from the BCR-ABL fusion region in their class I and/or class II MHC molecules, and could be used for the induction of T-cell responses against this tumor-associated junctional amino-acid sequence.¹²⁸ Similarly, immunotherapeutic protocols for the treatment of Epstein-Barr virus (EBV)-induced B-cell lymphoma have been developed, involving the adoptive transfer of donor-derived, EBV-specific CTL.^{129,130}

Another source of tumor-specific T cells in humans is constituted by patient-derived lymphocytes.

Melanoma-reactive CTL have been isolated and expanded in vitro from PBMC, draining lymph nodes, and tumor-infiltrating lymphocytes (TIL). In selected cases, adoptive transfer of TIL cultures together with IL-2 resulted in the regression of metastatic melanoma.¹³¹

Recently, partial tumor regressions were seen in 6 out of 13 patients with metastatic melanoma who were treated with a non-myeloablative conditioning regimen, causing lymphodepletion, in combination with ex vivo expanded tumor-reactive T cells containing mainly T cells directed against melanocyte differentiation antigens. Many of these patients also developed autoimmune vitiligo. The lymphodepletion may have deleted suppressor T-cell populations, as well have allowed better expansion of tumorreactive T cells.¹³²

A third source of tumor-reactive T cells is the blood of HLA-typed healthy donors. Through stimulation of human PBMC cultures with selected tumor-associated peptide epitopes, CTL cultures have been obtained that exhibit peptide-specific reactivity as well as reactivity against tumor cells presenting the relevant MHC-peptide complex. As with induction of T-cell immunity in vivo (see above), induction of bona fide T-cell immunity in vitro depends strongly on proper antigen presentation, sufficient costimulation, and the appropriate cytokines. At present, DC appear to provide the best context for antigenic stimulation of T cells in vitro.^{64,65,76}

Conclusions

Clearly, modulation of the tumor-reactive T-cell response constitutes a highly promising approach for the immunotherapy of cancer. Depending on the tumor type and the clinical situation, the desired T-cell response can be elicited either through vaccination of the patient or through stimulation and expansion of patient- or donor-derived T-cell populations in vitro, followed by adoptive transfer of these T cells into the patient. In both cases, the successful induction of effective, tumor-reactive T-cell immunity will depend on accurate knowledge of the relevant tumor-associated T-cell epitopes and of the costimulatory signals required for appropriate T-cell activation. Considering the rate at which our insight into these aspects of the T-cell immune response is increasing, it is conceivable that within the foreseeable future effective immunotherapeutic modalities will indeed become available against at least certain types of cancer.

Interference with signaling pathways in malignant disease

Asim Khwaja

Introduction

All normal cells are influenced by changes in their environment. The decision to move, to die, or to divide depends on extracellular factors, including a variety of cytokines and matrix proteins. Although some hormones may pass through the plasma membrane and interact directly with nuclear receptors, the majority of these factors affect the cell by interacting with external surface receptors that span the membrane—following ligand binding, a message is transmitted via dedicated signaling molecules inside the cell to the appropriate components of the cellular machinery. The molecules involved in transducing these messages form signaling modules, which often have complex relationships with each other.

The formation of cancer in humans is thought to involve a process whereby the sequential acquisition of genetic change in a number of key cellular pathways results in malignancy. Thus, many cancers share a number of attributes that set them apart from their normal counterparts: they may be independent of the normal requirement for external growth factors and less sensitive to signals that normally inhibit growth; they are often less susceptible to apoptosis and can proliferate without limits; in many instances, tumors stimulate the formation of new blood vessels and are also able to spread to sites distant from their origin.^{1,2} Many of these changes in cellular behavior can be attributed to abnormalities in the biochemical pathways that are normally involved in signal transduction. An increasing number of abnormalities in signaling components have been identified, and these may either be relatively tumor-specific, for example mutations in the Flt3 tyrosine kinase receptor in AML,³ or they may be found in a variety of malignancies, such as activating mutations in Ras proteins. Normal mechanisms of signal transduction are discussed in Chapter 3. This chapter will outline some of the abnormalities in signaling pathways that are found in hematological malignancies (Table 27.1) and will focus on approaches in the development of therapies that are targeted to these abnormalities.

Abnormal tyrosine kinase signaling

Tyrosine kinases are normally activated in response to growth factor signaling, and this is often the earliest biochemical event that follows cytokine-receptor binding.⁴ As discussed in Chapter 3, a number of growth factor receptors have intrinsic tyrosine kinase activity, for example c-Kit (the stem cell factor receptor) and Flt3, whereas other receptors utilize cytoplasmic tyrosine kinases, in particular of the Janus (JAK) and Src families. Tyrosine kinases are involved in the development of hematological malignancies in several ways: first, by mutation of receptor tyrosine kinases resulting in their constitutive activation, for example c-Kit in mast cell disorders⁵ and Flt3 in acute myeloid leukemia (AML);⁶ second, as components of fusion genes resulting from chromosomal translocation, for example BCR–ABL in chronic myeloid leukemia (CML) and acute lymphoblastic leukemia (ALL) and TEL–PDGFR in chronic myelomonocytic leukemia (CMML);⁷ third, tyrosine kinases may be activated by overexpression or by the, inappropriate, autocrine or paracrine production of growth factors. In addition, tumor cells may secrete factors such as vascular endothelial growth factor (VEGF) that stimulate tyrosine kinase activity in normal host cells resulting in new blood vessel formation.

Mutations in receptor tyrosine kinases

There are approximately 90 known protein tyrosine kinases (TK) in the human genome, of which two-thirds are receptor TK (RTK).⁴ Signaling via RTK is normally a result of ligand-induced dimerization—

Table 27.1 Constitutive activation of signaling pathways in hematological malignancies; inhibitors that have in vitro and/or clinical inhibitory activity are listed

Abnormal pathway	Genetic alteration	Disease	Inhibitor(s)
Receptor tyrosine kinases			
c-Kit	Point mutations (eg D816)	AML, mastocytosis	SU6577
Flt3	Point mutations (eg D835) Internal tandem duplication	AML AML	PKC412, SU11248, CT53518, CEP701
PDCFR α	Fusion with FIP1L1 interstitial deletion 4q12	Hypereosinophilic syndrome	Imatinib, PKC412
PDGFR β	Fusion with <i>ETV6 (TEL)</i> t(5;12)	CMML	imatinib
FGFR1	Fusion with <i>ZNF198</i> t(8; 13) Fusion with <i>BCR</i> t(8;22)	Stem cell MPD CML	SU6668, SU5402
FGFR3	Overexpression t(4;14)	Myeloma	
ALK	Fusion with <i>NPM</i> t(2;5)	Anaplastic NHL	
TRK	Fusion of <i>TRKC</i> with <i>ETV6</i> t(12;15) Activating deletion of <i>TRKA</i> 1q21	AML AML	CEP751
Cytoplasmic tyrosine kinases			
ABL	Fusion with <i>BCR</i> t(9; 22) Fusion with <i>ETV6</i> t(9;12)	CML, ALL CML, AML	Imatinib
ARG	Fusion with <i>ETV6</i> t(1;12)	AML	Imatinib
JAK2	Fusion with <i>ETV6</i> t(9;12)	ALL, atypical CML	AG490
Syk	Fusion with <i>ETV6</i> t(9;12)	MDS	BAY61–3606, piceatannol
Ras pathway			
Ras	Point mutations N- and Ki- <i>ras</i>	AML, CMML, JMML	Farnesyltransferase inhibitors
NF1	Loss, point mutation	JMML	Farnesyltransferase inhibitors
NF κB pathway			
	Activated by Tax (HTLV-I) Activated by EBV <i>c-REL</i> amplification 2p14 <i>BCL 10</i> amplification t(1;14)	ATLL Hodgkin lymphoma, Burkitt lymphoma DLBCL MALT lymphoma	Proteasomal inhibitor PS341/bortezomib, SPC839 (IKK-2 inhibitor), aspirin
PI3K pathway			
	Loss/mutation of <i>PTEN</i> Activated tyrosine kinases, Ras	Lymphoma, myeloma Various	LY294002, wortmannin (PI3K inhibitors) RAD001, CCI779 (mTOR inhibitors)
<small>PDGFR, platelet-derived growth factor receptor; FGFR, fibroblast growth factor receptor; ALK, anaplastic lymphoma kinase; PI3K, phosphatidylinositol 3'-kinase; AML, acute myeloid leukemia; CMML, chronic myelomonocytic leukemia; MPD, myeloproliferative disorder; CML, chronic myeloid leukemia; NHL, non-Hodgkin lymphoma; ALL, acute lymphoblastic leukemia; MDS, myelodysplastic syndrome; JMML, juvenile myelomonocytic leukemia; ATLL, adult T-cell leukemia/lymphoma; DLBCL, diffuse large B-cell lymphoma.</small>			

this results in phosphorylation in *trans* by the dimeric partner in a region known as the activation loop, which in the resting state occludes the active site of the kinase in *cis* and prevents substrate and/or ATP access. This phosphorylation leads to repositioning of the activation loop away from the active site and allows substrate to gain access.⁴ The importance of this mechanism in preventing unwarranted activation of RTK is underscored by the fact that point mutations in the activation loop result in constitutive kinase activation and are found in a variety of hematological tumors, such as c-Kit in AML and mast cell disorders and Flt3 in AML (see below). In addition to the role of the activation loop in regulating kinase activity, the juxtamembrane region has also been implicated in autoinhibition. Crystal structural studies of the EphB2 TK suggest that the unphosphorylated juxtamembrane domain can interact with part of the kinase domain, resulting in catalytic repression.⁴ This inhibition is relieved by phosphorylation of the juxtamembrane region after initial kinase activation following ligand binding. Oncogenic mutations can also affect this region, most notably in AML by internal tandem duplications of the *flt3* gene, and this is thought to relieve the normal constraints imposed by the juxtamembrane domain on catalytic activity.

c-Kit

The c-Kit protein (CD117) is the receptor for stem cell factor (SCF, Steel factor), and is normally expressed on hematopoietic stem and progenitor cells (Figure 27.1). Expression is usually downregulated with maturation and differentiation, except in mast cell

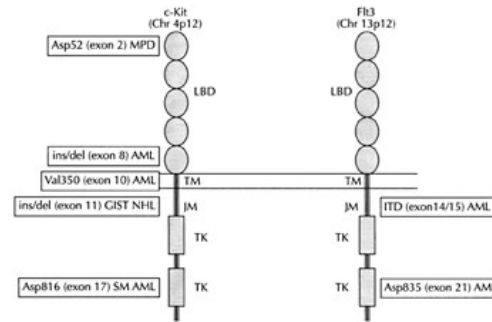

Figure 27.1 Schematic representation of the c-Kit and Flt3 receptor tyrosine kinases. Sites of described mutations are shown. LBD, ligand-binding domain; TM, transmembrane domain; JM, juxtamembrane domain; TK, tyrosine kinase domain; MPD, myeloproliferative disorder; AML, acute myeloid leukemia; GIST, gastrointestinal stromal tumor; NHL, non-Hodgkin lymphoma; SM, systemic mastocytosis; ITD, internal tandem duplication.

development. Mutations in *c-kit* have been described in a number of hematological and related disorders. These are predominantly of three types: point mutations in the activation loop (exon 17) found in mast cell disorders, AML, and sinonasal lymphomas; mutations and in-frame insertions/deletions in the regulatory juxtamembrane region (exon 11), which are typically found in gastrointestinal stromal tumors (GIST); and mutations in the extracellular ligand-binding domain (exon 8), found in AML (reviewed in reference 8).

In systemic mastocytosis, virtually all adult patients are reported to have point mutations in the activation loop, mainly at aspartate 816.⁹ Systemic mastocytosis is associated with myeloid malignancies, in particular with AML and advanced myelodysplastic syndrome (MDS), classified as systemic mastocytosis with associated clonal hematological non-mast-cell lineage disease (SM-AHNMD).¹⁰ The underlying mechanism of this association is not clear: it has been reported that the D816 mutation was present in the abnormal mast cells but not the leukemia cells in a patient with AML¹¹ but also that the mutation was present in both mast cells and myelomonocytic cells in a patient with associated CMML.¹² Studies in patients with indolent mastocytosis (without an associated hematological disorder) and the *c-kit* D816V mutation have utilized immunophenotype-based separation of mast cells, T and B lymphocytes, and monocytes to address which cell types were derived from the same clone. In the majority of cases, significant numbers of B lymphocytes and monocytes also have the D816V mutation, but T lymphocytes are usually not involved.^{13,14} This is reminiscent of results obtained in recognized myeloproliferative stem cell disorders such as CML, and suggests that mastocytosis could be considered as part of this spectrum of disorders. Presumably, further genetic abnormalities are acquired in the stem/progenitor cells of some individuals, resulting in the development of more aggressive myeloid malignancy. A recent report of seven patients with SM-AHNMD showed two patients to have AML with t(8;21), two to have AML/refractory anemia with excess blasts 1 (RAEB-1) with chromosome 5 deletions, and one AML patient with an 11q23 abnormality.¹⁵ t(8;21) in association with systemic mastocytosis has also been reported by others, and although numbers are small outcome does not appear to be favorable as in standard t(8;21)-positive AML.

In AML, *c-kit* mutations are found most frequently in patients with associated inv(16) and t(8; 21) abnormalities.⁸ These translocations result in the expression of the fusion genes *CBFβ-MYH11* and *AML1-ETO* respectively—CBFβ and AML1 both belong to the core binding factor (CBF) family, and this group of leukemias, which carries a relatively good prognosis, is known as CBF-AML.¹⁶ Beghini and colleagues¹⁷ showed in a small study that a high proportion of CBF-AML patients had a *c-kit* D816 mutation, and have also suggested that this may be associated with mast cell differentiation and high presenting white count. Reilly's group¹⁸ has shown in a study of 110 patients with CBF-AML that 9% have a D816 mutation but that an additional 19% (predominantly those with inv(16)) have a D419 mutation. Overall, nearly 32% of patients with inv(16) had a *c-kit* mutation, compared with 13% with t(8;21). Although the D816 mutations have been shown to be constitutively active, this has not been demonstrated for the extracellular domain D419 abnormality.

Flt3

The Flt3 receptor is expressed on hematopoietic stem and progenitor cells and is an important regulator of hematopoiesis (Figure 27.1). Mutations of *flt3* are largely restricted to patients with AML and comprise two main types: the internal tandem duplication

(ITD) and the D835 point mutation.¹⁹ The more common abnormality results from in-frame duplication of 12–204 DNA base pairs of the intracellular juxtamembrane region of the receptor. This ITD is found in about 25% of adult AML cases (under the age of 60 years),²⁰ with a lower incidence (about 12%) in children.²¹ Mutation detection is relatively simple, requiring a single polymerase chain reaction (PCR) step. The presence of an *flt3* ITD is associated with a high white count and, in most series, with a higher relapse rate. ITD are more common in patients with promyelocytic leukemia, especially the variant kind, and less common in those with CBF abnormalities or complex karyotypes.¹⁹ The mutant receptor is constitutively active, resulting in ligand-independent stimulation of the phosphatidylinositol 3'-kinase (PI3K), MAPK, and STAT5 pathways.^{22,23} Expression of *flt3*-ITD can transform factor-dependent hematopoietic cell lines to growth factor independence.²³ When *flt3*-ITD is expressed in a murine progenitor transplant model, it induces an aggressive myeloproliferative disorder (rather than AML).²⁴ Expression of *flt3*-ITD into stem cells from a *PML-RAR α* transgenic mouse leads to the accelerated development of promyelocytic AML, which is still all-trans-retinoic acid (ATRA)-sensitive.²⁵ This suggests that *flt3*-ITD, which is commonly found in AML M3, can cooperate with *PML-RAR α* in the development of overt leukemia. In about 10% of patients who present with *flt3*-ITD, and in whom the mutation is undetectable in remission, the mutation is not present at clinical relapse.²⁶ This indicates, at least in a subset of cases, that the *flt3*-ITD is a secondary phenomenon that is not required for maintenance of the leukemic phenotype. In addition to *flt3*-ITD, about 8% of AML cases have a D835 mutation.¹⁹ This residue in the activation loop is at a homologous site to *c-kit* D816, and its point mutation results in constitutive activation of *flt3*. Therefore, in adult AML, about a third of all patients have an activating mutation in *flt3*, making this the single most frequently mutated known gene in this disease.

Chromosomal translocations resulting in constitutive tyrosine kinase activation

A number of translocations known to generate constitutively active tyrosine kinases are found in hematological malignancies, of which the most intensely studied is the t(9;22) resulting in the generation of *BCR-ABL* in CML and ALL.

BCR-ABL

The t(9; 22) translocation fuses *BCR* genetic sequences upstream to those encoding c-ABL, resulting in a sequence that encodes for one of three *BCR-ABL* fusion proteins: p185 associated with ALL, p210 associated with CML, and p230 associated with a more indolent chronic neutrophilic leukemia.^{27,28} ABL is a tyrosine kinase with important functions in regulation of the cell cycle and apoptosis, in particular in response to DNA damage and in interactions with the actin cytoskeleton. The *BCR-ABL* fusion proteins have markedly increased tyrosine kinase activity compared with ABL and lead to inappropriate autophosphorylation and phosphorylation of many substrates.²⁹ There is constitutive activation of several signaling pathways, with activation of the Ras and PI3K pathways believed to be critical in maintaining the abnormal phenotype.^{30,31} The adapter proteins Grb2 and Crkl probably play an important role in maintaining prolonged activation of signaling pathways that are normally only transiently activated in cells following growth factor stimulation.^{32,33} In addition, activation of the transcription factors NF- κ B, c-Jun, and c-Myc have all been implicated in *BCR-ABL*-mediated transformation.⁷ There is some debate as to whether *BCR-ABL* has a significant anti-apoptotic effect. Cell lines overexpressing the fusion protein are usually factor-independent, but some groups have not detected such an effect in cells taken from patients with CML.^{34–36} In addition, evidence from patients treated with the ABL kinase inhibitor imatinib suggests that total eradication of *BCR-ABL* progenitors does not occur³⁷—this may be because inhibition of ABL kinase activity does not trigger apoptosis of leukemia progenitors but results in negation of their proliferative advantage over normal cells, allowing non-CML cells to repopulate the blood and marrow.³⁸

Transgenic mice expressing p210^{*BCR-ABL*} usually develop lymphoid malignancies, but the expression of *BCR-ABL* by retroviral transduction in a murine bone marrow transplantation model can lead to the generation of a CML-like disorder.^{39,40} Tenen's group⁴¹ has generated a conditional transgenic mouse model expressing p210 regulated by tetracycline administration. These animals rapidly develop a precursor B-cell leukemia akin to Ph-positive human ALL that regresses on readministration of tetracycline (which turns off *BCR-ABL* expression). *ABL* is also involved in fusion with *TEL* (*ETV6*) in the t(9;12), which is an uncommon translocation but has been reported in CML, AML, and ALL.⁴²

PDGFR β

Platelet-derived growth factor receptor β (PDGFR β) is a receptor tyrosine kinase normally expressed on mesenchymal cells and involved in proliferation and migration. It is located on chromosome 5q33, and in hematological malignancies is predominantly involved in the pathophysiology of CMML. A number of fusion partners have been described, the most common being *TEL* (*ETV6*). The *TEL-PDGFR β* fusion protein is the product of the t(5;12) translocation and fuses *TEL* to the intracytoplasmic domain of PDGFR β .^{43,44} *TEL* is able to dimerize via its

helix–loop–helix domain, and this leads to constitutive activation of the intrinsic tyrosine kinase activity of the cytoplasmic portion of PDGFR β . The other reported partners also have dimerization capability, and all result in constitutive kinase activity. TEL–PDGFR β has been shown to be capable of transforming interleukin-3 (IL-3)-dependent cell lines to factor independence. The intracytoplasmic domain of PDGFR β is known to transduce a variety of signals, including activation of Src, Ras, PI3K, and phospholipase C (PLC).⁴⁵ A myeloproliferative disease can be induced in a *TEL–PDGFR β* transgenic model.⁴⁶

PDGFR α

Gilliland and colleagues⁴⁷ have recently described a recurring translocation involving PDGFR α found in a high proportion of patients with hypereosinophilic syndrome (HES). This condition, which is typified by eosinophilia of unknown cause with associated tissue damage, has been ill-understood up to now. It has been suggested that patients with clonal eosinophilia should be classified as having a chronic eosinophilic leukemia.⁴⁸ The presence of an interstitial deletion on chromosome 4q12 in one patient with HES resulted in the identification of the fusion of a novel gene *Fip-1-like 1 (FIPIL1)* to the intracytoplasmic portion of PDGFR α . The *FIPIL1–PDGFR α* fusion (which is usually undetectable by conventional cytogenetic analysis) was subsequently found in 9 of 16 patients with HES—the protein has constitutive activation of tyrosine kinase activity and can render hematopoietic cells factor-independent.⁴⁷ PDGFR α kinase activity is exquisitely sensitive to the ABL inhibitor imatinib, which has been used to successfully manage HES (see below). The presence of a clonal abnormality in patients previously thought to have non-clonal disease indicates that we need to rethink our view of HES as a clinical entity.

FGFR1

The gene for fibroblast growth factor receptor 1 (*FGFR1*) is located on chromosome 8p11 and is fused to a number of partners, most commonly *ZNF198*, in a myeloproliferative disorder (MPD) known as the 8p11 myeloproliferative syndrome (EMS).⁴⁹ Patients with this syndrome present with a Ph-negative MPD with marked bone marrow and blood eosinophilia. In addition, the majority of patients have an associated non-Hodgkin lymphoma, which is usually of T-cell origin. The same cytogenetic abnormality is found in the MPD cells as in the lymphoma, suggesting that the initial genetic change takes place in a pluripotent stem cell. The disease usually rapidly evolves to a blastic acute leukemia phase, which is commonly of myeloid phenotype⁴⁹ although cases transforming to B-ALL have also been reported.⁵⁰ *FGFR1* is also involved in the variant t(8;22), which results in a fusion with the *BCR* gene and presents as CML.⁵¹ FGFR inhibitors have been described, but there are no clinical reports of their use in hematological disorders with specific translocations.⁵²

ALK

Anaplastic lymphoma kinase (ALK) is a tyrosine kinase receptor that is normally expressed in a developmentally restricted way in the central nervous system.⁵³ The ligand for ALK is pleiotropin,⁵⁴ and ALK was originally identified in the t(2; 5) translocation in anaplastic large cell lymphoma.⁵⁵ In this translocation, the N-terminal 117 amino acid residues of the nucleolar protein nucleophosmin (NPM) are joined to the entire intracytoplasmic domain of ALK. This fusion is sufficient to transform fibroblasts, and retrovirally mediated transduction of *NPM–ALK* into mouse bone marrow leads to B-lineage large cell lymphoma.⁵⁶ The NPM segment is required for oligomerization of the fusion protein, which leads to activation of ALK kinase activity.^{57,58} Other partners for ALK have also been described, all of which contain multimerization domains in what is a recurring theme in RTK fusion proteins.⁵⁹ NPM-ALK expression results in the activation of multiple signaling pathways, of which PI3K and STAT5 have been postulated as being critical for malignant transformation.^{60–62}

JAK2

The JAK family of cytosolic tyrosine kinases are critical for hematopoiesis but are rare partners in translocation events in hematopoietic malignancies. Fusion of *TEL (ETV6)* to *JAK2* has been reported in ALL and a case of atypical CML in transformation.^{63,64} In many cases of AML and ALL, constitutive activation of JAKs and various STAT proteins (signal transducers and activators of transcription) has been reported.^{65–67} The mechanism by which this activation takes place is unclear, but could involve autocrine production of stimulatory cytokines such as granulocytemacrophage colony-stimulating factor (GM-CSF)^{68,69} and IL-6.⁷⁰

Inappropriate activation of downstream signaling proteins

A number of signaling modules are activated by cytokines following initial stimulation of tyrosine kinase activity. These pathways can also be activated by activating mutations of positive regulators or deletion of negative regulators, and may be useful targets for therapeutic intervention.

Ras

Many different physiological processes are regulated by guanine nucleotide-binding proteins that act as

molecular switches. Conformational changes as a result of binding GTP enable these proteins to interact with target enzymes (also known as effectors). The interaction is limited by the intrinsic GTPase activity of the protein (converting bound GTP to GDP), which may be enhanced by catalytic mechanisms involving GTPase activating proteins (GAPs). There are two broad classes of such proteins: heterotrimeric G-proteins, which are classically associated with hormone receptors, and members of the Ras superfamily (also known as small GTPases), which are monomeric proteins of about 20–25 kDa in size.⁷¹ The Ras superfamily includes subfamilies that are involved in related processes. The Ras subfamily is mainly involved in cell survival, growth, and differentiation; the Rho subfamily in cytoskeletal organization; the Rab subfamily in vesicular transport; the Ran subfamily in nuclear protein and RNA transport; and the Arf subfamily predominantly in membrane trafficking.⁷²

Four alleles of *ras* have been described: Harvey (H), Kirsten (Ki) A and B, and neuroblastoma (N). Knockout studies have shown that H-Ras and N-Ras, either alone or in combination, are not required for normal mouse development whereas loss of Ki-Ras results in embryonic death (reviewed in reference 73). The reasons for this difference are not fully understood, but are most likely due to the ubiquitous expression of Ki-Ras. Ras is activated in response to a large number of stimuli, including growth factors and extracellular matrix-integrin interactions. Ras proteins are switched to the ‘on’ GTP-bound state by the positive action of guanine nucleotide exchange factors,⁷⁴ of which the best characterized is the son-of-sevenless (SOS) protein, or, less frequently, by the inhibition of GAPs such as p120^{Ras-GAP}⁷⁵ and neurofibromin (NF1) (Figure 27.2). Point mutations at conserved residues in Ras that lead to constitutive activation by maintaining it in the GTP-bound state are found at a high frequency in human malignancies.⁷³ In hematopoietic tumors, mutations are found mainly in N-ras and Ki-ras.

For full biological activity, H-Ras must undergo post-translational modification by prenylation, resulting in its association with cellular membranes (reviewed in reference 76). The critical first step in this process is the covalent attachment of a farnesyl (15-carbon chain) group to cysteine 186 at the C-terminal end of the protein. The terminal three amino acids are then cleaved by a specific protease and the C terminus is methylated. The final modification step required for effective membrane localization is palmitoylation (covalent attachment of a 16-carbon moiety) at the C-terminal region. H-, Ki-, and N-Ras all undergo farnesylation, but only Ki-Ras is not additionally palmitoylated. Rather it relies on a cluster of C-terminal basic residues that interact with acidic phospholipids on the inner leaflet of the plasma membrane. Other members of the Ras superfamily, such as Rho, are not farnesylated but undergo geranylgeranylation (addition of a 20-carbon chain). These processes are catalyzed by specific enzymes: farnesyltransferase, geranylgeranyltransferases, prenyl protein-specific proteases, etc.

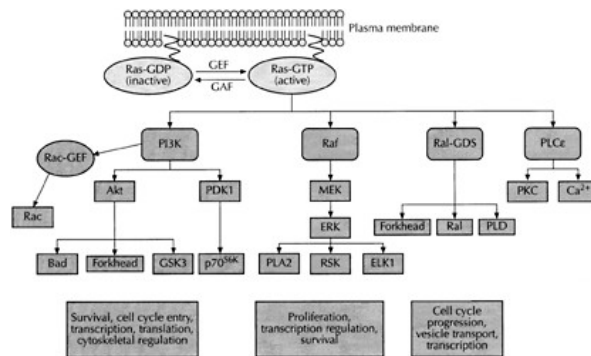

Figure 27.2 Activation of the Ras signaling pathway regulates a number of cellular functions. Ras at the plasma membrane is activated in response to a GEF (guanine nucleotide exchange factor) and is inactivated by a GAP (GTPase-activating protein). GTP-bound Ras interacts with a number of effectors, including phosphatidylinositol 3'-kinase (PI3K), Raf, Ral-guanine nucleotide dissociation stimulator (Ral-GDS) and phospholipase C ϵ (PLC ϵ).

Ras targets

Activation of Ras proteins has been shown to be involved in the control of cell proliferation, survival, differentiation and movement (Figure 27.2). The first Ras target or effector to be described was the serine/threonine kinase Raf-1.⁷⁷ Raf-1 and the related B-Raf and A-Raf proteins sit at the head of a signaling pathway that results in the activation of the ERK type of MAPK (mitogen-activated protein kinases) and subsequently in transcriptional activation.⁷⁸ Activation of ERKs can also regulate non-nuclear substrates such as phospholipase A2 (PLA2) and myosin light-chain kinase (MLCK).^{79,80} The duration of activation of the ERK pathway can play an important part in dictating the cellular response. Prolonged ERK activation was shown originally to result in neuronal cell differentiation rather than proliferation,⁸¹ and thrombopoietin (TPO) may function in a similar way to regulate megakaryocyte maturation.⁸² Although many of the biological effects of Ras were initially attributed to the activation of Raf, it has since become clear that other important effectors exist, including PI3K, Ral-GDS and phospholipase C ϵ (PLC ϵ). The best characterized of these is the catalytic subunit of the PI3K,⁸³ and it is clear that, at least in some cell types, this activity is important for the anti-apoptotic⁸⁴ and cytoskeletal effects of Ras.⁸⁵ Importantly, the full effects of oncogenic Ras in promoting malignant transformation are probably reliant on cooperation between the various effectors.

Ras mutations

Point mutations at codons 12, 13, and 61 are commonly found in AML and in MDS, most often in CMML. Interestingly, Ras mutations rarely coexist with oncogenic tyrosine kinase mutations such as Flt3, TEL-PDGFR β and BCR-ABL. Constitutively active tyrosine kinases result in the activation of normal cellular Ras, and the rarity of coexisting mutations suggest that the Ras pathway is sufficient in many malignancies to provide similar transforming signals as active tyrosine kinases. In AML and other hematological malignancies, mutations are usually found in N-ras and less commonly in Ki-ras. These mutations result in a greatly reduced ability to hydrolyze GTP, resulting in a molecule that is always in the 'on' position. Although the incidence of *ras* mutations varies greatly between published series, overall it is approximately 20% in AML.⁸⁶⁻⁸⁹ The presence of activating ras mutations in myeloid leukemia has been known of for some time, but the biological significance of this feature is not clear. In one study, AML colonies taken from cases with N-ras mutations grown in vitro were examined and it was shown that the proportion of colonies containing no mutant allele ranged from 5% to 57%.⁹⁰ This suggests that ras mutations are post-initiation events in AML and may contribute to the outgrowth of more malignant subclones. In hematopoietic cell lines, the expression of activated Ras usually confers growth factor independence, but data from primary AML samples are lacking. Published data are not clear on whether the presence of an activating ras mutation is associated with an adverse outcome.

ras mutations are frequently found in myeloma, but there is some dispute about the true rate of abnormality.⁹¹ One large series found activating mutations in 39% of samples examined.⁹² In some reports, this has coincided with more advanced disease, ras mutations being found at very high frequency in plasma cell leukemias.⁹³ Although the introduction of oncogenic ras into myeloma cell lines can lead to a reduction in factor dependence and inhibition of apoptosis,⁹⁴ whether this is true in cases with ('natural') ras mutations is unclear.

Recently, activating mutations in the B-raf gene have been found at high frequency in human tumors, in particular in melanomas and colon carcinoma.⁹⁵ Although comprehensive large-scale screens of primary tissue in hematological malignancies have not been reported, no mutations have been found in myeloma/plasma cell lines or in selected cases of AML.^{96,97}

JMML and NF1

Neurofibromin, the product of the *NF1* gene, is a GAP for Ras and is important in some cell types for converting Ras to the inactive GDP-bound state. Infants and children with neurofibromatosis type I (NF1) have a markedly increased risk of developing myeloid malignancies such as juvenile myelomonocytic leukemia (JMML), monosomy 7 syndrome/MDS, and AML.⁹⁸ ras point mutations are often found in JMML patients without NF1 syndrome, but not in JMML patients with NF1 syndrome.^{99,100} In NF1 patients with leukemia, there is frequent loss of heterozygosity of *NF1*, with retention of the mutant allele.¹⁰¹ Loss of NF1 GAP activity is responsible for increased levels of Ras-GTP, with a hypersensitive response to GM-CSF.^{102,103} Hematopoietic reconstitution of mice with *NF1*-deficient stem cells results in a myeloproliferative syndrome akin to JMML. Therefore, it appears that overactivation of the Ras signaling pathway is important in the development of myeloid malignancy in individuals with NF1.

PI3K

Phosphoinositides phosphorylated on the 3'-hydroxyl group of the inositol ring are transiently found in many cell types stimulated with growth factors and in cells transformed by a variety of oncogenes. The enzymatic activity responsible for this is termed PI3K, and was originally purified as a

heterodimer composed of an 85 kDa regulatory and a 110 kDa catalytic subunit.¹⁰⁴ Subsequent investigation has shown that there is a family of such kinases, but for the purposes of this chapter we will focus on the canonical pathway. The major lipid products of growth factor-stimulated PI3K are derived from the phosphorylation of phosphatidylinositol 4,5-bisphosphate—this yields first phosphatidylinositol 3,4,5-trisphosphate (PIP₃) and then, by the action of inositol 5'-phosphatases, phosphatidylinositol 3,4,-bisphosphate.¹⁰⁵ PIP₃ has been implicated in the subsequent activation of several targets, including the Rho family GTP-binding protein Rac, the serine kinase Akt/PKB, and certain atypical members of the PKC family (reviewed in reference 106). The active lipid products are downregulated predominantly by the action of the PTEN (phosphatase and tensin homolog) phosphatase, which acts to remove the 3'-phosphate from the inositol phospholipids. In addition, Src homology 2 domain-containing inositol 5'-phosphatase (SHIP), which removes the 5'-phosphate from PIP₃, is also involved in the control of PI3K signaling.¹⁰⁷ PI3K activity has been shown to be involved in many diverse physiological processes, including cell proliferation, cytoskeletal rearrangements and chemotaxis, the oxidative burst of phagocytic cells, cell survival, and glucose transport.¹⁰⁶

PI3K is involved in malignant change in a variety of tumors, as is most clearly shown by the loss of the *PTEN* gene, which acts as a tumor suppressor.^{108,109} This is fairly common in tumors such as prostate and pancreatic cancers and in glioblastomas. Loss of *PTEN* is, however, uncommon in lymphomas and myeloid leukemias.^{110–112} Activation of the PI3K targets Akt and p70^{S6K} is commonly seen in leukemia and myeloma—as this pathway can be activated by tyrosine kinases and by Ras, it is possible that in the majority of cases there is no evolutionary pressure within the tumor cells for the loss of *PTEN*, but further studies would be needed to confirm this.

NFκB

Nuclear factor κB refers to a group of closely related protein dimers that bind to a common DNA sequence motif (reviewed in reference 113). There are five family members, which fall into two classes: those that do not require proteolytic processing (RELA/p65, c-REL, and RELB) and those that are processed to generate p50 and p52 proteins (NFκB1/p105 and NFκB2/p100). These two groups form dimers, of which the most common is p50^{RELA}. In the canonical NFκB pathway, dimers composed of RELA, c-REL, and p50 are restrained in the cytoplasm by association with an inhibitor of κB proteins (IκB). Triggering of the pathway, commonly by cytokines and in response to infection, results in phosphorylation of IκB, which targets this protein for ubiquitination and subsequent degradation by the proteasome. The liberated NFκB dimers can now translocate to the nucleus, where they induce the transcription of a number of targets—these include genes that regulate the immune system, inflammation, apoptosis, and proliferation. It is thought that NFκB may be one of the links between chronic inflammation and the development of malignant change, such as is seen in infections with *Helicobacter pylori*.

NFκB has been shown to be activated in a variety of hematological malignancies, in particular those affecting lymphoid tissues. As its targets include apoptosis regulators such as the BCL2 family members BFL1/A1 and BCL-X_L and cellular inhibitors of apoptosis (IAP) as well as D- and G-type cyclins, it is an attractive candidate for mediating many of the key features of malignancy.¹¹⁴ NFκB is directly activated by the Tax oncoprotein of HTLV-I, which is implicated in the development of T-cell leukemia.¹¹⁵ The c-REL locus at 2p14 is frequently amplified in diffuse large B-cell lymphomas.¹¹⁶ Epstein–Barr virus (EBV), which is implicated in the development of Burkitt lymphoma, some cases of Hodgkin lymphoma, and lymphoproliferative disorders in immunocompromised patients, can activate NFκB via latent membrane protein 1 (LMP1) and EBV nuclear antigen 2 (EBNA2).¹¹³ In MALT lymphomas associated with t(1;14), a truncated BCL10 is amplified by translocation and leads to activation of NFκB.¹¹⁷ In addition, the t(11;18) translocation associated with MALT lymphomas that are less sensitive to *H. pylori* eradication results in the formation of a fusion protein AP12-MALT1 that activates NFκB.¹¹⁸ The NFκB pathway may be important in the pathophysiology of *BCR*–*ABL*-induced disease,¹¹⁹ and has been found to be constitutively active in a high proportion of AML cells, including the most primitive CD34+CD38- fraction believed to include leukemia-initiating cells.¹²⁰

Signaling components as therapeutic targets

Hematologists have been using signal transduction-directed therapy for some years. Cyclosporin A suppresses the immune system by inhibiting a key Ca²⁺/calmodulin-dependent protein phosphatase known as PP2B or calcineurin. In addition, rapamycin, which is also used as an immunosuppressant, inhibits the protein kinase mTOR (target of rapamycin), which plays a crucial role in T-cell proliferation signaling. The identification of aberrant or overactive signaling pathways in hematopoietic malignancies has raised the possibility of interfering with these pathways in a targeted manner for therapeutic purposes.

For many years, it was felt that blocking signal transduction pathways for treating malignancy would be

ineffective for a number of reasons. As human tumor development is thought to be the result of multiple genetic changes within a cell, targeting a single signaling pathway was predicted to be futile. However, it appears that tumors may become ‘addicted’ to certain oncogenic pathways and that the inactivation, even transiently, of these pathways can trigger cell death or differentiation.¹²¹ The evidence for this largely comes from transgenic murine models of tumor development using regulatable oncogenes. Most frequently, these are controlled by tetracycline, which can be added or withdrawn from the mouse diet to assess the effects of turning on and then switching off an oncogene. For example, Felsher and Bishop showed that transgenic mice expressing *myc* developed T-cell and myeloid leukemias and that these regressed on switching off *myc* due to the induction of cell cycle arrest, differentiation, and apoptosis (reviewed in reference 122). Similar results have been obtained with *BCR-ABL* transgenic mice,⁴¹ and it appears that even brief inactivation of the oncogene may be sufficient to trigger tumor regression. Clearly, these tumor models do not accurately reproduce the development of tumors in humans, but they do suggest that inactivation of signaling pathways may be beneficial in some malignancies. In addition, it appears that some hematological disorders, in particular chronic myeloproliferative disorders such as CML, may not be the result of multiple genetic changes but develop as a consequence of activating mutations or translocations of tyrosine kinases. As is shown in more detail below, such malignancies appear to respond to blockade of the single dysregulated signaling pathway.

Another theoretical worry with signal transduction inhibitors has been that many of the pathways involved, such as Ras and PI3K, are critical for the function of normal cells. Downward⁷³ has postulated that as tumor cells often have high levels of anti-apoptotic signaling activity, this may allow the cell to accumulate and tolerate other genetic changes that would normally be deleterious (such as DNA damage due to loss of cell cycle control). Therefore, inhibition of the dysregulated survival pathway, on which the tumor cell is now reliant, could lead to cell death due to the accumulated active death signals that the cell has previously been able to withstand. Normal cell counterparts in this model would be more able to tolerate blockade of the pathway as they have lower intrinsic levels of death signals. However, the issue of the extent to which a therapeutic window is present and if toxicity to normal tissues is acceptable may have to be empirically assessed for each pathway.

Finally with signaling inhibitors, the issue of specificity has also been raised. In particular, many agents that block kinase activity do so by competing for ATP binding—this region of kinases is highly conserved and it had been felt by many that specific inhibitors would be near impossible to develop. However, we now know that a number of ATP-competitive inhibitors also make contacts with regions of the kinase that are not directly involved in ATP binding and that this can confer some specificity as these areas are less conserved. In addition, as is illustrated by the use of imatinib in the treatment of CML, inhibitors that are not completely specific for their target may still be extremely valuable drugs. This realization, and the clinical success of imatinib, has resulted in virtually all large pharmaceutical and biotechnology companies having major programs in the area of signal transduction inhibition.

Tyrosine kinase inhibitors

BCR-ABL-positive leukemias

The results of clinical studies with the ABL inhibitor imatinib (CGP57148, STI571, Gleevec/Glivec) is considered in detail in Chapters 32 and 41. This section will review the mechanism by which imatinib acts, briefly consider the results obtained in CML and ALL, and discuss problems of resistance.

Druker and colleagues¹²³ were the first to show in the mid 1990s that the ATP-competitive compound STI571 (later named imatinib) could inhibit ABL kinases at low micromolar concentrations. It inhibited the growth of cell lines expressing BCR-ABL in vitro and inhibited tumor formation using similar cells in syngeneic mice. At low concentrations, it inhibited CML colony growth in semisolid assays with much less of an effect on progenitors from normal individuals. Extensive profiling has shown that imatinib is relatively selective for ABL—additional kinases that are inhibited are ARG (a close relative of ABL), c-Kit, and both PDGFR α and β .¹²⁴ Crystal structure analysis of the ABL-imatinib complex has shown that imatinib binds to ABL when it is in an inactive conformation and presumably locks it in this state, preventing it from becoming activated and then transferring phosphates to target proteins.^{125,126} This may partly explain some of the selectivity of imatinib, as inactive kinase conformations are thought to be structurally more varied than active ones.

The clinical results with imatinib in chronic phase CML have been dramatic from the outset, and the drug is now licensed for use in this disease. Doses of 400 mg/day and above have been associated with very high hematological and cytogenetic response rates.¹²⁷ It is not clear if imatinib exerts its effects by selectively inducing apoptosis in BCR-ABL-positive cells or by decreasing the proliferative advantage of the malignant clone (or indeed both). There is a large body of in vitro data showing that BCR-ABL-positive cells undergo apoptosis in response to imatinib, but these experiments mostly involve cells that have been engineered to be dependent on the fusion protein for survival and proliferation. It is possible to isolate quiescent phenotypically primitive (CD34⁺)

BCR–ABL–positive cells from patients with CML in chronic phase that are resistant to the effects of imatinib³⁸—this suggests that ABL inhibitors may not be able to induce apoptosis of all leukemic progenitors. The clinical responses to imatinib in chronic phase CML have been durable and contrast with results seen in patients with blast crisis of CML or with relapsed Ph–positive ALL.¹²⁸ Although there is a significant response to single-agent imatinib in these patients, this is typically of short duration but may be useful as preparation for more aggressive therapy or as part of a combination with cytotoxic drugs.

Soon after the trials with imatinib were initiated, it became apparent that clinical resistance was a problem in advanced disease (reviewed in reference 129). There are a number of potential mechanisms by which this could occur. First, there may be binding proteins in the plasma that become upregulated and reduce the amount of available intracellular imatinib. It has been suggested that increased levels of $\alpha 1$ acid glycoprotein may mediate this,¹³⁰ but the evidence is not conclusive.¹³¹ Second, further genetic abnormalities could develop within the leukemia cells that render them resistant to the effects of imatinib (clonal evolution). Additional chromosomal aberrations have been described in a significant proportion of patients with imatinib resistance by Hochaus et al,¹³² but it is not clear if these render the cells less sensitive to the effects of the drug. Third, gene amplification of *BCR–ABL* could result in cells that are resistant to the effects of imatinib if there is a threshold level of kinase activity that is sufficient to confer a biological advantage to the leukemia clone. Amplification was initially shown to be a factor in imatinib resistance of leukemia cell lines and has been detected in a proportion of patients.^{132–134} In some instances, the clone with amplified *BCR–ABL* has been shown to decline if drug is temporarily withdrawn. Finally, resistance could develop as a result of mutations within *BCR–ABL* that lead to decreased binding of imatinib. The first report of such a mutation indicated a high frequency of C–to–T change at nucleotide 1091 resulting in the alteration of a threonine at position 315 to isoleucine (T315I).¹³⁴ This mutation retains kinase activity and is resistant to imatinib *in vitro*. Analysis of the crystal structure complex of ABL and imatinib shows that position 315 is a key residue for imatinib binding. A number of further mutations have now been described and it has been shown that in some patients these are already present at low levels prior to the initiation of imatinib therapy.^{129,135–137}

The problems with resistance to imatinib monotherapy are likely to become increasingly significant as more patients are treated for longer periods. One approach to circumvent resistance would be to use structurally unrelated ABL kinase inhibitors either to treat patients who are resistant to imatinib or in combination at the initiation of therapy. For example, the drug PD166326 will inhibit the imatinib-resistant E255K BCR–ABL mutant.¹³⁸ However, neither PD166236 nor another inhibitor PD180970 effectively inhibit the common T315I mutant.¹³⁹ Alternative approaches may be to target BCR–ABL using other drugs such as geldanamycin, which reduces BCR–ABL protein levels by inhibiting the function of the molecular chaperone and heat-shock protein Hsp90.¹⁴⁰ Other avenues that are being tested are to combine imatinib with drugs that work in a non–ABL–targeted fashion such as cytotoxic agents (e.g. cytarabine), interferon- α , and farnesyltransferase inhibitors (see below).

Hyper eosinophilic syndrome and mast cell disease

The effectiveness of imatinib in HES was first described in a case report in 2001¹⁴¹ and this has been followed by further reports showing high response rates at low doses (100–200 mg/day).^{142–145} In a number of patients, this is due to dysregulation of the PDGFR α receptor as a result of fusion to the *FIP1L1* gene⁴⁷ (see above), but a significant number of responders do not have this or any other detectable molecular abnormalities. Gilliland and colleagues^{47,146} reported the development of imatinib resistance in one of their cohort of patients due to a point mutation, echoing the problems seen in BCR–ABL–mediated disease. This mutant was still sensitive to an alternative kinase inhibitor, PKC412.^{47,146}

The common c-Kit mutation found in mast cell disease (D816V) is insensitive to imatinib.¹⁴⁷ However, there may be patients with systemic mast cell disease who respond to this drug,¹⁴⁸ and it has been postulated that this could be due to the inhibition of wildtype c-Kit or of another unidentified kinase.

Fit3 mutant leukemia

There are a number of compounds that are in early clinical trials for mutant Flt3–positive AML, including PKC412 (Novartis), SU11248 (Sugen), CEP701 (Cephalon) and CT53518 (Millenium).¹⁴⁹ They all inhibit other kinases in addition to Flt3 and have demonstrable activity against *flt3*–ITD–positive cell lines *in vitro* and in animal models.^{150–152} So far, results from clinical studies have only been presented orally and in abstract form and show a modest response rate in AML with single-agent therapy. It is possible that significant beneficial effects of Flt3 inhibitors would be seen in combination with conventional cytotoxic agents.

Inhibitors of Ras

Several compounds have been identified that effectively inhibit Ras farnesylation.¹⁵³ The rationale for their development was to inhibit Ras targeting to the plasma membrane and thereby suppress oncogenic Ras–mediated tumor growth. This would have to be

achieved without toxicity to cells expressing normal Ras and without adversely affecting the function of other farnesylated proteins such as nuclear lamins and rhodopsin. Considering the importance of Ras to myriad normal cell functions, this approach required that cells expressing activated Ras would be more sensitive to Ras inhibition, a view supported by some experimental data. In tumor models, a CAAX peptidomimetic was shown to cause regression of tumors generated in MMTV-v-H-ras transgenic mice.¹⁵⁴ However, the majority of human malignancies bear Ki- or N-ras mutations. It has been shown that Ki-Ras is much less sensitive to FTase inhibitors (FTI) than is H-Ras;⁷³ in addition in cells treated with FTI, both Ki- and N-Ras (but not H-Ras) can undergo alternative modification by geranylgeranylation and thereby remain associated with the membrane fraction.¹⁵⁵ This may help to explain the relative lack of toxicity of these compounds on normal cells, but also raises questions about their use in human cancer. Furthermore, data derived from a Ras-transformed fibroblast experimental system suggests that the effects of FTI is dependent on inhibition of RhoB function, which presumably acts downstream of Ras.^{156,157} FTI have also been shown to inhibit growth of tumor cells that do not express mutant Ras.¹⁵⁸

The most extensive clinical experience of Ras inhibition in hematological malignancies is with the oral agent R115777 (Tipifarnib, Janssen),¹⁵⁹ which is a non-peptidomimetic FTI.^{160,161} Treatment of 35 adults with poor-risk acute leukemia showed only two complete remissions but some clinical response in 29% of patients.¹⁶² None of the patients had *ras* mutations, emphasizing the fact that FTI, although designed with a rational target, may be exerting their effects in ways that were not previously predicted. Activity in pancreatic cancer, where *ras* mutations are virtually universal, emphasizes this point, as no responses were seen to single-agent therapy.¹⁶³ A further study with R115777 has shown activity in CML, albeit transient, a low response rate in myeloma, and modest activity in myelofibrosis.¹⁶⁴ The number of patients who have been treated with R115777 are still small, and further studies, utilizing combinations with conventional cytotoxics in AML and perhaps with ABL kinase inhibitors in CML, are awaited.

Proteasomal inhibitors

The proteasome is a multicomponent complex found in all cell types that is involved in protein degradation, in particular of proteins that have been modified by ubiquitination.¹⁶⁵ These include cell cycle-regulatory components, p53, cytokine receptors, and the NF κ B inhibitor I κ B. In vitro studies show that tumor cells in general have high proteasomal activity and have a greater propensity to undergo cell cycle arrest or apoptosis in response to inhibitors compared with normal counterparts.¹⁶⁶ This is likely to be multifactorial due to the reduced breakdown of a variety of proteins. The boronic acid dipeptide bortezomib (PS-341)¹⁶⁷ is a proteasomal inhibitor that is most advanced in its clinical evaluation in hematological malignancies and solid tumors.^{168,169} A phase I study¹⁷⁰ showed significant activity in patients with plasma cell dyscrasias where significant in vitro effects had previously been found.¹⁷¹ A subsequent phase II trial in nearly 200 patients with relapsed, refractory myeloma showed a response rate of 35%, with 10% having a complete or near-complete response.¹⁷² Two-thirds of the patients had previously had a stem cell transplant and 83% had received thalidomide. Bortezomib has to be given intravenously, but was well tolerated in this group of patients with advanced disease and will be evaluated as antimyeloma therapy earlier in the course of the disease. Further studies in Waldenström's macroglobulinemia and non-Hodgkin lymphomas are also under way.

Raf/MEK, PI3K and mTOR inhibitors

A number of tumors show increased MAPK activity. In some malignancies, for example melanoma, this is a consequence of activating mutations in Raf itself (B-Raf),⁹⁵ but more frequently increased activity is probably due to activation of upstream regulators such as tyrosine kinases and Ras. Two compounds targeting this pathway are in clinical development—the Raf inhibitor BAY 43-9006¹⁷³ and the MEK (MAPK/ERK kinase, MAPKK) inhibitor CI-1040¹⁷⁴—but there are no results as yet in hematological malignancies.

A number of in vitro studies using the PI3K inhibitors LY294002 and wortmannin have shown that blockade of this pathway may have activity in a wide variety of tumors.¹⁷⁵ However, there have been concerns that the involvement of PI3K in the survival and proliferation of normal cells would result in excessive toxicity. Attention has now switched to developing isoform-specific PI3K inhibitors—there may be differential activation of α , β , γ , and δ isoforms in abnormal cells compared with normal tissues, and inhibitors that selectively target each isoform may be valuable. In addition, there is evidence that inhibiting one of the downstream targets of the PI3K pathway known as mTOR (mammalian target of rapamycin) may inhibit tumor cell proliferation.¹⁷⁶ There are a number of trials with inhibitors related to rapamycin (CCI-779 and RAD001)^{177,178} currently running, but detailed results are not as yet available.

Conclusions

Enormous advances have been made, and are continuing to be made, in understanding signal transduction

pathways in normal and malignant cells. It is likely that in the next decade an increasing number of compounds targeted to specific abnormalities in signaling pathways in malignant cells will be identified. A coordinated combination of laboratory and clinical research will be needed to evaluate whether this approach of rational drug development will result in clinically useful agents.

Gene transfer in leukemia and related disorders

Martin Pulè and Malcolm Brenner

Introduction

Two broad strategies of gene transfer are used in the treatment of leukemia and lymphoma. First, the tumor itself can be genetically modified. That is, tumor cells can be transduced with genes that 'repair' major functional defects, with a toxic gene that destroys the tumor cell, or with genes that express molecules that trigger an immune response against the tumor cell. Second, the host can be modified, so that T cells are redirected and their antitumor activity augmented, with suicide genes introduced to terminate potentially harmful immune reactions. Moreover, the drug sensitivity of normal host tissues can be decreased by delivering cytotoxic drug-resistance genes to sensitive tissues, thereby increasing the therapeutic index of chemotherapy. Host cells may also be transduced with marker genes, not for a direct therapeutic benefit, but merely as a means to follow their behavior and persistence.

Clinical studies of gene therapy must show that the potential benefits outweigh the potential risks; hence, most protocols for the treatment of malignant diseases are open only to patients with a poor prognosis, in whom the risk-to-benefit ratio is most likely to be favorable. It must be emphasized that these patients are ultimately not likely to prove the most suitable group for gene therapy. Instead, many of the approaches to be described in this chapter will probably be most valuable for the eradication of minimal residual disease remaining after conventional therapies.

Methods for gene delivery

Table 28.1 summarizes the properties of the common types of virus-based gene-therapy vector.

Retroviral vectors

In a typical retro viral vector,¹ the structural and replicative genes (*gag*, *pol*, and *env*) are replaced by one or more genes of interest, driven either by the retroviral promoter in the 5' long-terminal repeat (LTR) or by an internal promoter. Currently, only oncoretrovirus-based vectors have clinical applications in cancer. The retroviral constructs are made in cell lines in which the missing retroviral genes are present in *trans* and thus reproduce and package a vector that is not replication-competent (illustrated in Figure 28.1, see Plate 6). Retroviral vectors have a wide target cell range, and the genetic information they convey is integrated into the host cell DNA. Because the transferred gene not only survives for the entire lifespan of the transduced cell, but is also present in that cell's progeny, these vectors are ideal for transferring genes into rapidly dividing cell populations, such as leukemic or normal lymphocytes or for gene therapy targeting hematopoietic stem cells (HSC). Provided that replication-competent virus is absent, the vector preparations appear to be non-toxic. Oncoretroviral vectors have several disadvantages. Expression of the transferred gene requires genomic integration by the virus (hence a population of dividing cells) so that the efficiency of transfer to many cell types may be low.² Such vectors are not well suited for *in vivo* use because they are generally unstable in complement and cannot be targeted to specific cell types. More recently, murine retroviruses were linked to leukemia induction in two children receiving corrective therapy for X-linked severe combined immunodeficiency (X-SCID) caused by defects in the common γ chain for lymphoid cytokine receptors. The leukemia appears to have been generated by insertional mutagenesis due to retroviral integration. While these events have clearly dampened enthusiasm for the use of murine retroviruses to correct immunodeficiency states, many hundreds of patients have received retrovirally transduced normal or malignant hematopoietic cells without any ill effects similar to those in the two SCID patients. This issue is discussed further in the section below on gene therapy as a cause of leukemia.

Table 28.1 Main gene-therapy vectors in clinical use

Vector	Vector genome	Packaging limit (kb)	Tropism	Immune response	Genome in transduced cells	Advantages	Disadvantages
Retrovirus	RNA	8	Only dividing cells	Weak	Integrated	Integrating, hence results in persisting gene transfer in daughter cells	Integration may cause oncogenesis
Lentivirus	RNA	8	Wide	Weak	Integrated	As retrovirus but can transduce non-dividing cells also	More complex to generate than retrovirus; integration may cause oncogenesis
HSV1	dsDNA	40–150	Strong for neurons	Strong	Episomal	Large packaging capacity	Inflammatory response; only transient transgene expression in most cell types
AAV	ssDNA	<5	Serotype dependent	Weak	Episomal and integrated	Simple and have capacity to integrate. Multiple serotypes	Small packaging limit
Adenovirus	dsDNA	8–30	Wide	Strong	Episomal	Very efficient transduction of nearly all cell types	Only transient expression; potent immune response to capsid

HSV1, herpes simplex virus 1; AAV, adeno-associated virus; dsDNA, double-stranded DNA; ssDNA, single-stranded DNA.

Lentiviruses

Lentiviral vectors, which also have been evaluated for their clinical utility,³ can transduce hematopoietic progenitors⁴ and primary acute lymphoblastic leukemia (ALL) cells,⁵ and may be more effective than murine retroviruses in targeting primitive HSC such as those with a CD34⁺CD38⁻ phenotype.⁶ Despite their ability to infect and replicate in non-mitotic cells, lentiviruses pose several technical problems that must be overcome before clinical applications are feasible. For example, the toxicity of some HIV proteins has made the generation of stable packaging cells difficult.⁷ There are also safety concerns with these vectors. In particular, the use of HIV-derived vector systems raises the possibility that wild-type HIV may be generated during vector production. Newer (third-generation) lentiviruses have self-inactivating features, and are likely to become the first vector of this type to be used clinically. As of mid 2004, the first protocols specifying lentiviral vectors have been approved.

Adenoviruses

Adenoviruses infect a wide range of cell types and, unlike retroviruses, can transfer genes into non-dividing cells. Most adenoviral vectors are E1 (early protein) deletion mutants and therefore are not replication-competent.^{8,9} Early genes in the E3 region can also be deleted to increase the 'space' for insertion of new genes.⁸ These vectors are reasonably stable in vivo and can be used to infect cells in situ. Examples include gene transfer into respiratory epithelium (the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene in cystic fibrosis⁸) or liver (genes encoding factor VIII and factor IX in hemophilia A or B¹⁰). However, adenoviral vectors are generally non-integrating, so that the gene products are expressed from episomal DNA. Since the episome is often lost after cell division and can be inactivated or lost even in a non-dividing cell, adenoviral vectors are unsuited for any application that requires long-term expression in a rapidly turning-over cell population or transfer into a stem cell and expression in that cell's progeny. Another limitation is that most adenoviral vectors elicit immune responses against the viral proteins themselves, which often prevents readministration of the vector. More significantly, cellular and humoral immune responses may be generated against low levels of adenoviral proteins, expressed even when cells are transduced by defective viruses. These responses

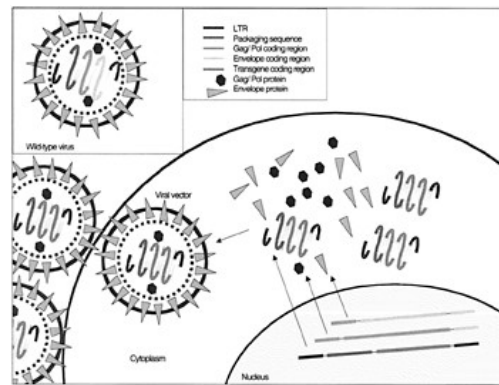

Figure 28.1 Creation of a replication incompetent retroviral vector with a split packaging cell line. Wild-type retrovirus is shown in inset upper-left corner. Virus is composed of gag/pol and env proteins and a RNA genome. This genome codes for gag/pol and env proteins, hence upon infecting a host cell, all retroviral elements can be generated and virus can replicate. Split packaging line provides coding regions for gag/pol and env elements in trans. Coding region for our transgene (red) is preceded by a packaging signal (blue). Packaging signal has been removed from gag/pol and envelope coding regions. Hence virus is assembled as normal but our transgene replaces usual genome. Upon infecting a cell, our transgene is expressed but no gag/pol or env can be generated, and virus cannot replicate. For replication competent virus to be generated, packaging sequence, gag/pol and env elements would have to coincidentally recombine. (See Plate 6)

may destroy the target cell or simply downregulate expression of the transgene along with other virus-associated proteins. In addition, the entry of adenoviruses into many cell types will trigger innate immunity, with the release of cytokines, such as interleukin-8 (IL-8), which induce a non-specific but potentially highly destructive local inflammatory response.¹¹ Although these immunostimulatory attributes may render adenoviruses inherently unsuited for chronic application in diseases such as hemophilia A or B, they may be an asset when one intends to prepare a tumor vaccine (see below), emphasizing the importance of matching a vector's characteristics to its intended use. Aside from issues of immunostimulation, there are also concerns about recombination with endogenous adenoviruses, potentially leading to the release of novel variants into the environment. Finally, the wide host cell range of adenoviral vectors could hinder in vivo targeting to a specific cell type.

Adeno-associated viruses (AAV)

As members of the *Parvoviridae* genus *Dependovirus*,¹² AAV typically depend upon coinfection with a helper virus, such as adenovirus, for efficient replication in the productive phase. The most unique feature of an AAV, however, is the latent phase of its life cycle. When the virus infects a permissive cell in the absence of helper virus, it achieves stable latency without obvious consequences for the host cell. In this phase, the viral genome can assume a number of integrated and episomal forms, but the predominant form in AAV2 latency in human cells appears to be a tandem head-to-tail integration within a region of chromosome 19 that has been termed the AAVSI site.

In their native form, AAV consist of only 145 nucleotides at each end of the genome and two internal genes: *rep* and *cap*. Recombinant AAV vectors are generated by replacing *rep* and *cap* with the transgene of interest and retaining the ITR sequences. Providing permissive cells with *rep*, *cap*, and adenovirus helper functions ensures replication and packaging of these vectors. Plasmids can now be used to supply the genes needed for helper functions, enabling difficulties in generating a packaging line with stably integrated *cap* and *rep* to be overcome.¹³ A recombinant herpesvirus that supplies *rep*, *cap*, and helper genes has also been generated.¹⁴ In parallel with methods for

producing AAV, purification techniques have also improved.¹⁵

The first rAAV2 vector developed for clinical studies was *CFTR*. In several phase I and phase II studies of cystic fibrosis patients,^{15–18} safe, long-term, dose-dependent gene transfer was achieved with this vector, although lung inflammation continues to be an intrinsic barrier to successful gene therapy in this disease.

AAV vectors may also be useful in cancer gene therapy, for example, to transduce myeloma cells to express *B7.1* and *B7.2*¹⁹ genes to generate a tumor vaccine. Selective killing of hepatocellular carcinoma cells by transfer of the herpes simplex virus 1 thymidine kinase gene (*HSV-tk*) by AAV has been reported in a mouse model.²⁰

Whereas some of the major advantages of AAV vectors include stable integration, long-term expression, and ability to infect dividing and non-dividing cells, the major limitations include variations in AAV infectivity among different cell types and the small size of the recombinant genome that can be packaged. Future improvements are likely to include methods to retarget these vectors and increase the packaging size. The availability of multiple AAV serotypes with different tropisms may also increase their value.

Liposomes/other physical methods

Among physical methods of gene transfer, cationic liposome/DNA complexes^{21,22} have been tested most often in patients. These complexes fuse with the cell membrane and enter the endosomal uptake pathway; DNA released from the endosomes may then pass through the nuclear membrane and be expressed. The main advantage of liposomes is that they are non-toxic and can be given repeatedly. In some cell types, high levels of gene transfer have been obtained by this method,²² and successful systemic administration has also been reported in large animal models.²³ However, the DNA transferred by liposomes does not integrate the genome, and despite the incorporation of a variety of ligands into the liposome–DNA complex,²⁴ the ability to target these vectors is still quite limited. More recently, successful gene transfer in vivo has been reported with use of a bio-ballistic (‘gene gun’) technique in which DNA coated onto colloidal gold particles is driven at high velocity by gas pressure into the cell.²⁵ Improved methods of electroporation may also be valuable for transducing normal and malignant hematopoietic progenitor cells with sufficient efficiency to allow therapeutic application.²⁶

Other vectors
