Because patients in surgery may receive large amounts of citrate, bicarbonate, calcium salts, and fluids, clear discrepancies between total calcium and ionized calcium are common in these patients. In these cases, ionized calcium measurements should be used wherever possible.

CRITICALLY ILL PATIENTS

Part of "20 - Calcium, Magnesium, and Phosphate"

In critically ill patients, including those with sepsis, thermal burns, renal failure, and/or cardiopulmonary insufficiency, hypocalcemia occurs in as many as 70% of cases (19). Sepsis appears to cause hypocalcemia and may correlate with the degree of

hypocalcemia (20). The inflammatory response and mediators of sepsis are involved in reducing ionized calcium concentrations (21).

In patients with hypocalcemia, calcium administration can increase cardiac output and blood pressure (21). A direct relationship has been shown between serum ionized calcium and mean arterial pressure in a study of 112 patients admitted to a medical intensive-care unit (22). While it may seem that correction of hypocalcemia will always benefit cardiovascular status, this is not clearly established. Hypocalcemia may serve as a protective mechanism against cell death during cellular hypoxia. One report suggests that when calcium administration is slowly titrated to no higher than normal concentrations by measurement of blood ionized calcium, adverse side effects were not observed (21).

HYPOMAGNESEMIA

Part of "20 - Calcium, Magnesium, and Phosphate"

Chronic hypomagnesemia has become recognized as a frequent cause of hypocalcemia. There are three proposed mechanisms:

1. Inhibition of transport of PTH across the parathyroid gland membrane (23)
2. Impairment of PTH action at its receptor site on bone (4)
3. Interference with the action of vitamin D (24).

Hypercalcemic Disorders

A flow chart for the evaluation of hypercalcemia is presented in Figure 20.5. While a total calcium results of 3 mmol/L or above virtually always indicates hypercalcemia, a total calcium lower than 3 mmol/L should be confirmed by measurement of ionized calcium, if available. Malignancy and primary hyperparathyroidism are the most common causes of hypercalcemia, accounting for 80% to 90% of cases. Hypercalcemia as a result of malignancy is more common in hospital populations, while primary hyperparathyroidism is more commonly found in the outpatient setting.

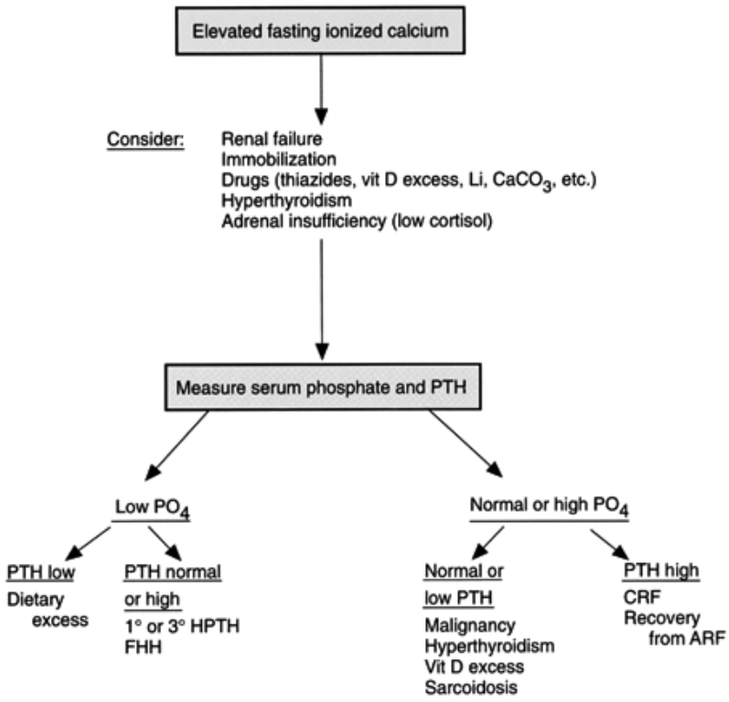

FIGURE 20.5. Evaluation of hypercalcemia. Abbreviations: 1° HPTH, primary hyperparathyroidism; 3° HPTH, tertiary hyperparathyroidism; FHH, familial hypocalciuric hypercalcemia; ARF, acute renal failure; CHF, chronic renal failure.

While hyperparathyroidism refers to excessive secretion of parathyroid hormone, this excess can range from slight to a very large amount. Hyperparathyroidism therefore may either show obvious clinical signs or be asymptomatic. Several studies have shown that, while both total and ionized calcium measurements are elevated in severe hyperparathyroidism, ionized calcium more frequently is elevated in subtle or asymptomatic hyperparathyroidism. Ionized calcium measurements have been reported to be elevated in 90% to 95% of cases of hyperparathyroidism, while total calcium is elevated in 80% to 85% of cases (25). A recent report found that of 60 cases of confirmed hyperparathyroidism, 59 had elevated ionized calcium, while 47 had an elevated corrected total calcium (26).

A new clinical use of PTH measurements has developed from the need to measure PTH rapidly during operations on the parathyroid glands to determine if sufficient parathyroid tissue has been removed to correct hyperparathyroidism (27).

Hypercalcemia is present in up to 20% of various types of malignancy, with calcium measurements sometimes serving as biochemical markers for otherwise inapparent disease (Table 20.1). The increase may be caused by direct lysis of bone by tumor

or by the secretion of PTHRP. PTHRP appears to be expressed in tumors derived from lung, breast, kidney, and many squamous cell carcinomas and T-cell lymphomas (9). PTHRP, being very similar to PTH in its first 13 amino acids, binds to and activates the PTH receptor and mimics the actions of PTH on bone, kidney, and intestine. While measurements of PTHRP ultimately may have clinical diagnostic value (28), they only rarely are used and measurement of PRHRP is available in very few clinical laboratories.

TABLE 20.1. Interpretation of Laboratory Tests in Differentiating Primary Hyperparathyroidism from Malignancy

Test	Favors HPTH	Favors Malignancy
Total Ca (mmol/liter)	<3.13	>3.13
Serum Cl (mmol/liter)	>103	<103
Intact PTH	Elevated	Low or normal
Serum PO_4	N to low	Normal to high
Hematocrit	Normal	Low
Urine Ca	High	Very high
1,25-$(OH)_2$ vitamin D	High	Low
PTHRP	Normal (undetected)	Elevated

PTH, parathyroid hormone; PTHRP, PTH-related peptide.

Although ionized calcium may have slightly higher diagnostic sensitivity, ionized and total calcium measurements have about equal utility in the detection of occult malignancy (29). Carcinoma of the bronchus, breast, urogenital tract, and head and neck area, and multiple myelomas account for 75% of hypercalcemia in malignancy.

Proper Collection and Handling of Samples

Total calcium determinations may be performed on either serum or heparinized plasma. Because anticoagulants such as EDTA and oxalate bind calcium very tightly and interfere with its measurement, even by atomic absorption, they must not be used.

The proper collection of samples for either total or ionized calcium measurements requires both care and appreciation of the problems that can occur. Tourniquet application should be as brief as possible (less than 1 minute) before a specimen is collected: the combined effects of hemoconcentration (causing hyperproteinemia) and localized lactic acid production can alter total calcium by up to 10% (30) and ionized calcium by about 2% to 3% (30, 31). Because loss of CO_2 will increase pH, all samples for ionized calcium measurements must be collected anaerobically. The metabolic activity of cells during storage affects pH and therefore ionized calcium. Although the effects of the lactate anion and the hydrogen cation partly offset each other (31), blood should be centrifuged within 1 hour to prevent acidosis from affecting the ionized calcium concentration (32, 33). While anticoagulated whole blood can be analyzed more rapidly, serum from sealed, evacuated blood collection tubes is satisfactory for ionized calcium if clotting and centrifugation are done within 1 hour. Because of dilutional effects, no liquid heparin products should be used. Heparin also binds a small amount of calcium and tends to lower ionized calcium concentrations. However, if the heparin concentration is less than 30 IU/mL, the interference should be less than 4%. Dry heparin products are available that virtually eliminate the interference by heparin. These products are available either as heparin titrated with small amounts of calcium or zinc ions or as a small amount of heparin dispersed in an inert soluble material. For analysis of calcium in urine, an accurately timed urine collection is preferred. The urine should be acidified with 6 mol HCl/L, with approximately 1 mL of the acid added for each 100 mL of urine.

Methods for Measurement of Total and Ionized Calcium

While atomic absorption spectroscopy remains the reference method for total calcium, accurate measurements require care, both in maintenance and calibration of the instrument and in preparation of samples. In routine testing of serum, many automated analyzers give results that are comparable to atomic absorption. However, for analysis of total calcium in urine and other fluids, atomic absorption still is preferred.

Atomic absorption involves introducing a diluted sample into an air-acetylene flame and measuring the absorption of light at 422.7 nm.

Many automated methods for total calcium measurement are based on the complexometric reaction between calcium and the dye ortho-cresolphthalein complexone, often with 8-hydroxyquinoline added to prevent magnesium interference (33). This methodology was used on the duPont aca, Beckman Astra 8 and Technicon SMAC. Some automated analyzers, including the J and J Vitros and Beckman analyzers use another dye, Arsenazo III.

Ionized calcium is measured using an ion-selective electrode system. These electrodes use membranes impregnated with molecules (ionophores) that selectively, but reversibly, bind calcium ions (35). As calcium ions bind to these membranes, an electric potential develops across the membrane that is related to the ionized calcium concentration. The potential is measured with a sensitive voltmeter in the same way that pH is measured.

Reference Ranges for Calcium

Ionized calcium concentrations can change rapidly during the first 1 to 3 days of life. Following this, they stabilize at relatively high levels with a gradual decline through adolescence. For total calcium, the reference range varies slightly with age. Calcium concentrations are relatively high through adolescence when bone growth is most rapid (see Table 20.2).

TABLE 20.2. Reference Ranges for Calcium[a]

	mmol/liter	mg/dl
Total calcium		
Child	2.20–2.68	8.8–10.7
Adult	2.10–2.55	8.4–10.2
Ionized calcium		
At birth	1.30–1.60	5.2–6.4
Neonate	1.20–1.48	4.8–5.9
Child	1.20–1.38	4.8–5.5
Adult	1.16–1.32	4.6–5.3

[a] Urine reference ranges will vary with diet. Adults on an average diet typically excrete 12 to 75 mmol/day (50 to 300 mg/day).

MAGNESIUM

Biochemistry and Physiology

Awareness of the physiological role and the clinical importance of magnesium has developed relatively recently. The first clinical symptoms of hypomagnesemia were not reported until 1934 by Hirschfelder and Haury. In 1969, Shils reported that magnesium depletion was associated with hypomagnesemia, hypokalemia, and hypocalcemia (36). While hypomagnesemia has been overlooked frequently in the past, there now is a great awareness of the clinical importance of magnesium. This is the result of many articles describing the effects of magnesium on myocardial function and blood pressure (37), the role of magnesium as a calcium-channel–blocking agent (38), the clinical consequences of hypomagnesemia (39), and the implications of magnesium depletion during open-heart surgery (40) and critical care (41).

The clinical importance of magnesium reflects its profound biochemical importance. Magnesium is an essential activator of over 300 enzymes, including those important in glycolysis, gene replication, transcellular ion transport, muscle contraction, and oxidative phosphorylation. In fact, the magnesium complex of adenosine triphosphate (ATP) probably is the true substrate in energy production, rather than ATP alone. It can be said fairly that magnesium is equal in importance to any of the other electrolytes in the body, many of which have been much more intensively studied and are more commonly measured.

Regulation of Magnesium in the Blood

The average dietary intake of magnesium is 10 to 15 mmol/day. Rich sources are green vegetables, meat, grains, and seafood. The small intestine may absorb from 20% to 63% of the dietary magnesium, depending on the need. The overall regulation of body magnesium is controlled largely by the kidney, which can avidly reabsorb magnesium in deficiency states or can readily excrete excess magnesium in overload states. The renal threshold for magnesium is about 0.60 to 0.85 mmol/L. Because this is close to the normal serum concentration, slight excesses of magnesium in serum are excreted rapidly by the kidneys. Because renal magnesium reabsorption competes with reabsorption of calcium in the ascending limb of the loop of Henle, the loss of calcium by diuretics, hypercalcemia, or saline infusion also will cause loss of magnesium (42).

Although magnesium and calcium appear to have several common factors in their regulation, regulation of magnesium is not as well characterized as that of calcium. Parathyroid hormone increases renal reabsorption of magnesium and enhances absorption of magnesium in the intestine. However, for equivalent decreases in ionized calcium and magnesium in blood, changes in ionized calcium have a far greater effect on PTH secretion (7, 43). Paradoxically, chronic or severe acute hypomagnesemia can depress secretion of PTH, one mechanism by which hypomagnesemia can cause hypocalcemia. Aldosterone apparently has the opposite effect of PTH, increasing the renal excretion of magnesium. Insulin appears to increase both intestinal and renal absorption of magnesium, yet also increases intracellular concentrations of magnesium.

Distribution of Magnesium in Tissues and Blood

The human body contains about 1 mol (24 g) of magnesium, with about 50% in the skeleton and relatively high concentrations in skeletal muscle, liver, and myocardium. Magnesium is primarily an intracellular ion, with only about 1% being in the blood and extracellular fluid (44). Magnesium in serum exists as protein-bound (24%), complex-bound (10%), and ionized (66%) forms (data derived from reference 43). Of course, these proportions vary with the concentration of proteins and other anions in blood, and, as with calcium, the extent of binding is affected by blood pH.

Clinical Importance of Magnesium Measurements

Spontaneous hypermagnesemia rarely is observed in clinical practice, with most cases resulting from administration of magnesium-containing antacids, enemas, or parenteral nutrition to patients with renal insufficiency (42). In contrast, hypomagnesemia can arise from a number of causes (45, 46 and 47), which are listed in Table 20.3 (48). Magnesium should be measured during the initial examination of acutely or chronically ill patients, especially those with poor food intake, malabsorption disorders, hypokalemia, or hypocalcemia, and in those taking diuretics (45). Hypomagnesemia has been defined as a serum magnesium of less than 0.75 mmol/L (49). The incidence of hypomagnesemia in hospitalized patients has been reported to be from 5% to 50%, with variations in reference ranges, methods, and populations studied accounting for some of this variation.

TABLE 20.3. Causes of Hypomagnesemia

Skin loss by burns

CRITICAL CARE

Part of "20 - Calcium, Magnesium, and Phosphate"

Magnesium deficiency is found in a large percentage of critically ill patients (50, 51). In patients admitted to intensive care, the presence of hypomagnesemia is associated with an increased mortality rate (52), and may warrant magnesium replacement therapy if serum magnesium is below 0.5 mmol/L (41). In acute-care patients, diagnoses commonly associated with hypomagnesemia include coronary artery disease and coronary bypass surgery, malignancy, chronic obstructive pulmonary disease, and alcoholism. Among chronic diseases, alcoholism, liver disease, and carcinoma were commonly associated with hypomagnesemia (53).

Magnesium was the most common electrolyte abnormality found among pediatric intensive-care unit patients (54). There

also is evidence that ionized magnesium may be decreased in many critically ill pediatric patients who have normal total magnesium concentrations (55).

CARDIAC DISORDERS

Part of "20 - Calcium, Magnesium, and Phosphate"

Magnesium ion plays an important role in energy metabolism, calcium-channel regulation, myocardial contraction, and other cardiac functions. The heart, with its high metabolic activity, is particularly vulnerable to magnesium deficiency, which has been associated with coronary vasospasm, arrhythmias, acute infarction, and sudden death (36, 57). These conditions may arise because hypomagnesemia promotes loss of myocardial potassium and increases the ratio of calcium to magnesium, both of which alter myocardial electrophysiology (58). The extracellular concentration of ionized magnesium apparently controls arterial tone and blood pressure by regulating magnesium-calcium and sodium-calcium exchange sites on the membrane (59) and by modulating the vasoconstrictive effects of hormones such as norepinephrine and angiotensin II: a high magnesium concentration antagonizes their effects, while a low magnesium concentration enhances their activity (60). A reduction of ionized magnesium in the extracellular fluid produces sustained constriction of arterioles and venules, coronary vasospasm, and increases the potency of vasoconstrictive agents.

One of the most important consequences of hypomagnesemia in cardiovascular disease may be that cellular loss of magnesium uncouples oxidative metabolism that, by depleting ATP, leads to disruption of mitochondrial function and structure. Moreover, in congestive heart failure (CHF), cardiac output is diminished and is inadequate for the metabolic needs of tissues. Because deficiencies of magnesium and potassium lead to high blood pressure, causing increased vascular resistance, the problems of diminished cardiac output of CHF are further intensified (59).

An area that has received increasing attention over the years is the use of prophylactic magnesium to minimize complications in both myocardial infarction (61, 62) and after cardiac operations (63).

In patients undergoing surgery with cardiopulmonary bypass, plasma ionized (but not total) magnesium was decreased significantly by 24 hours after bypass (64). Because magnesium promotes vasodilation and inhibits platelet aggregation and adhesion, hypomagnesemia may promote coronary vasoconstriction and thrombosis in the early postoperative period (63). To avoid this, two to four grams of magnesium now are routinely administered after cardiac operations at our institution. Measurements of ionized magnesium may prove to be clinically useful during this therapy.

DRUG EFFECTS ON MAGNESIUM CONCENTRATION

Part of "20 - Calcium, Magnesium, and Phosphate"

Several drugs, including diuretics, gentamicin and other aminoglycoside antibiotics, cisplatin, and cyclosporine increase renal loss of magnesium and result frequently in hypomagnesemia. The loop diuretics, such as furosemide, especially are potent in increasing renal loss of magnesium, while thiazide diuretics usually require chronic use to develop hypomagnesemia (65). Gentamicin inhibits reabsorption of magnesium in the renal tubule. Because hypomagnesemia intensifies the toxic side effects of gentamicin, hypomagnesemia especially should be avoided (66). Cisplatin also is nephrotoxic, and profound hypomagnesemia can be caused by cyclosporine, an immunosuppressant widely used following organ transplantation. Cyclosporine also severely inhibits the renal tubular reabsorption of magnesium in addition to its other side effects, which include hypertension and hepatotoxicity (67).

DIABETES MELLITUS

Part of "20 - Calcium, Magnesium, and Phosphate"

Hypomagnesemia has been reported in from 25% to 75% of patients with diabetes (68). The mechanism of magnesium deficiency appears to be magnesium loss secondary to ketoacidosis and glycosuria (49), along with possible abnormal intracellular-extracellular distributions of magnesium caused by hormonal imbalances. Hypomagnesemia may lead to insulin resistance, diabetic retinopathy, hypertension, cardiovascular disease, increased platelet activity and thrombosis, and decreased PTH and altered vitamin D metabolism. The American Diabetic Association issued a statement about magnesium and diabetes. Among the conclusions were:

1. Hypomagnesemia often results from glycosuria
2. Hypomagnesemia probably does not play a primary role in the pathogenesis of diabetes
3. A strong relationship exists between hypomagnesemia and insulin resistance
4. Magnesium supplements should be given to all patients with documented hypomagnesemia, but not to all patients with diabetes (69).

Acute hypomagnesemia can result from intracellular shifts of magnesium following the administration of glucose or amino acids (46, 47). This effect is pronounced following starvation or insulin treatment for hyperglycemia.

ALCOHOLISM

Part of "20 - Calcium, Magnesium, and Phosphate"

Many studies have found a marked deficiency of total magnesium in chronic alcoholism (70, 71). Both acute and chronic ingestion of alcohol are associated with renal magnesium losses and decreased muscle magnesium content (72). Other factors that may cause hypomagnesemia in alcoholic patients include dietary deficiency, ketosis, vomiting, diarrhea, and hyperaldosteronism. Alcoholic patients may become hypomagnesemic after treatments such as dextrose infusion, which induces insulin secretion and may cause a shift of magnesium back into cells to correct a chronic intracellular magnesium deficiency. A recent report found that both total and ionized magnesium increased after three weeks of abstinence (71). While total magnesium was lower in alcoholics than controls, ionized magnesium was either similar to or decreased relative to controls, depending on the type of ionized magnesium analyzer used.

OTHER DISEASES

Part of "20 - Calcium, Magnesium, and Phosphate"

Because magnesium requirements increase during pregnancy, hypomagnesemia may develop if intake also is not increased. Premature labor and preeclampsia or eclampsia are clearly associated with the development of hypomagnesemia. Treatment with magnesium salts has long been an accepted practice in these conditions, although hypermagnesemia sometimes results from excessive doses. The fetus also may be affected by hypermagnesemia in such cases.

Neonatal seizures occur especially in infants of diabetic mothers, with hypocalcemia and hypomagnesemia being possible causes (18). Hypomagnesemia is common in many critically ill children, with more having decreased ionized magnesium than decreased total magnesium (55).

Magnesium deficiency may be an important risk factor in renal stone formation and other renal calcification (73). Magnesium ion probably inhibits calcification by pairing with anions that would otherwise form insoluble salts with calcium.

Cerebrospinal fluid magnesium, but not serum magnesium, has been found to be significantly lower in acute schizophrenic patients than in schizophrenic patients in remission (74). A similar association of CSF (but not serum) magnesium also has been reported to be a prognostic indicator of the intensity of the neurologic disorder in stroke victims (75).

Patients with Paget's disease who also have hypomagnesemia tend to have more active disease as measured by increased serum alkaline phosphatase and urinary hydroxyproline. Because urinary magnesium is not significantly increased in Paget's disease, the low serum magnesium apparently is caused by increased uptake of magnesium into bone. For these reasons, patients with Paget's disease should increase their intake of magnesium to about 10 mmol per day (76).

Proper Collection and Handling of Samples

The patient should fast before collection of blood. Because of the threefold higher concentration of magnesium in erythrocytes, serum should not remain in contact with the clot for an extended period of time. Hemolyzed samples are not acceptable. The anticoagulants citrate, oxalate, and EDTA bind magnesium tightly and must not be used.

Measurement of Magnesium

While measurement of total magnesium concentrations in serum remains the usual diagnostic test for the detection of magnesium abnormalities, serum concentrations have two limitations. First, about 30% of magnesium is protein bound. Therefore, as with total and ionized calcium, total magnesium may not reflect the physiologically active magnesium. Second, and probably of greater significance, because magnesium is primarily an intracellular ion, serum concentration will not necessarily reflect the status of intracellular magnesium. Even when cellular magnesium is depleted by 20%, serum magnesium concentration may remain normal.

A magnesium load test may detect body depletion of magnesium in patients with a normal concentration in serum. However, a magnesium load test requires over 48 hours to complete. After collecting a baseline 24-hour urine, $MgSO_4$ is administered while another 24-hour urine sample is collected. Individuals with adequate body stores of magnesium will excrete 60% to 80% of the magnesium load within 24 hours, while magnesium-deficient patients excrete less than 50% (42).

Of the numerous methods developed for measurement of magnesium over the years, at least four have accuracy and precision that are acceptable for clinical laboratories (77, 78). These methods are atomic absorption spectroscopy, colorimetric methods using either calmagite or methylthymol blue, and a dry-slide colorimetric method using a formazan dye and a calcium chelator.

Calmagite is a metallochromic derivative of naphthol sulfonic acid that can be used to measure magnesium without deproteinization of the sample. The blue-colored reagent forms a pink magnesium-calmagite complex, with the absorbance measured at around 532 nm. The use of ethylene glycol tetraacetic acid (EGTA) prevents interference by calcium, and cyanide is used to bind heavy metals, preventing them from binding to the dye. The reaction is completed within 60 seconds, which allows the calmagite method to be used on automated analyzers (79).

Methylthymol blue is also widely used for determination of magnesium, with calcium chelators added to increase the specificity. This method is used on the duPont aca, with the absorbance measured at both 510 and 600 nm (79). The dry-slide method uses a multilayered reagent with both a calcium chelator and a magnesium-sensitive formazan dye. The magnesium-formazan complex is measured at 630 nm (78).

The reference method for magnesium measurement is atomic absorption spectroscopy. This method is capable of excellent accuracy and precision (77) in the hands of an experienced operator. Neutron activation analysis with the radioactive isotope magnesium-27 has been proposed as a definitive method (79).

The routine measurement of ionized magnesium now is possible by the development of magnesium ion-selective electrodes. The sensors for these electrodes were developed from studies on over 200 ionophores by the late Dr. Wilhelm Simon and his colleagues (80). Two different companies, each with their own ionophore, have introduced such electrodes that are approved by the Food and Drug Administration (81). Both electrodes also are sensitive to calcium ions, an effect that is corrected for by simultaneous measurement of the calcium ion concentration. Free magnesium has been quantitated as ultrafiltrable magnesium (43, 82). While this may give a reasonable estimate of ionized magnesium in many cases, ultrafiltrable measurements can significantly overestimate the concentration of both ionized magnesium and ionized calcium following administration of citrate (6).

Reference ranges for total magnesium in serum and other fluids are shown in Table 20.4, along with reference ranges for ionized magnesium in blood. Note the slightly different reference ranges for ionized magnesium as determined by the two brands of analyzers currently available (83).

TABLE 20.4. Reference Ranges for Magnesium[a]

	mmol/liter
Total magnesium	
Serum (newborns)	0.50–0.90
Serum (adults)	0.65–1.05
Erythrocytes	1.65–2.65
CSF	1.0–1.40
Urine	1–5 mmol/day
Ionized magnesium (83)	
Blood	0.44–0.60 (AVL analyzer) 0.39–0.64 (Nova analyzer)

[a] Concentrations of magnesium in serum are lower at birth than in older children or adults.

PHOSPHATE

Part of "20 - Calcium, Magnesium, and Phosphate"

Biochemistry and Physiology

Compounds of phosphorus are in all cells and participate in many biochemical processes. The genetic materials deoxiboxynucleic acid (DNA) and ribonucleic acid (RNA) are complex phosphodiesterases. Phosphate is a component of nucleotides, phospholipids, and most coenzymes. The most important reservoirs of biochemical energy are ATP, creatine phosphate, and phosphoenol pyruvate. One explanation for the widespread occurrence of phosphate in biochemical systems is that phosphate has three oxygen radicals. This allows linkage with two other molecules while still leaving one basic oxygen, which can be protonated or can participate in other reactions (84). Inorganic phosphate is important for maintaining adequate cellular stores of compounds such as ATP, and 2,3-DPG (85). Phosphate deficiency can lead to ATP depletion, which ultimately is responsible for many of the clinical symptoms observed in hypophosphatemia.

About 80% of the 700 to 800 grams of phosphate in the body are contained in bone, mostly in the form of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$]. Phosphate in blood is either absorbed from dietary sources or resorbed from bone. Most phosphate is found within cells, and the transport of glucose into cells is accompanied by an influx of phosphate. Intracellular phosphate then is used in the synthesis of phosphorylated compounds (86).

The kidney plays an important role in the regulation of serum phosphate concentration, and the renal reabsorption of phosphate is affected by several factors, including acid-base status, vitamin D, and PTH. PTH inhibits the normal tubular reabsorption of phosphate, increasing loss in the urine and decreasing serum phosphate concentrations. Therefore, PTH can have a dramatic effect on phosphate regulation, because the renal tubules normally reabsorb over 90% of phosphate filtered at the glomerulus.

While PTH lowers serum phosphate, vitamin D increases phosphate concentrations in the blood by promoting both phosphate absorption in the intestine and phosphate reabsorption in the kidney. In fact, phosphate may have a direct effect on parathyroid cells to enhance PTH secretion (87). Growth hormone, which helps regulate skeletal growth, also can affect circulating concentrations of phosphate. With excessive secretion or administration of growth hormone, phosphate concentrations in the blood tend to increase because of decreased renal excretion. However, growth hormone administered together with parathyroid hormone increases renal excretion of phosphate (88).

Although the total concentration of phosphate (expressed as phosphorus) in blood is about 12 mg/dL, most of this is organic phosphate; only about 3 to 4 mg/dL is inorganic phosphate. HPO_4^{2-} and $H_2PO_4^-$ are an important buffer pair; at pH 7.4 inorganic phosphate is about 75% HPO_4^{2-} and 25% $H_2PO_4^-$.

Clinical Interpretation of Phosphate Measurements

Both hyperphosphatemia and hypophosphatemia are seen frequently in clinical medicine, and both conditions are important to recognize. Flow diagrams for the evaluation of hypophosphatemia and hyperphosphatemia are shown in Figure 20.6 and Figure 20.7, respectively.

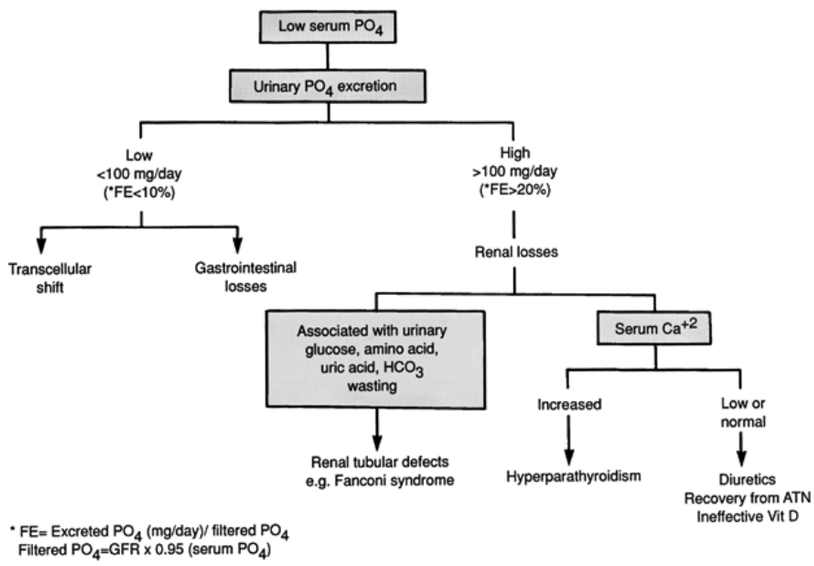

FIGURE 20.6. Evaluation of hypophosphatemia. FE, excreted PO_4 (mg/day/filtered PO_4); Filtered PO_4-GFR × 0.95 (serum PO_4). (From Chernow B. *The pharmacologic approach to the critically ill patient*. 2nd ed. Baltimore: Williams & Wilkins, 1988:629.)

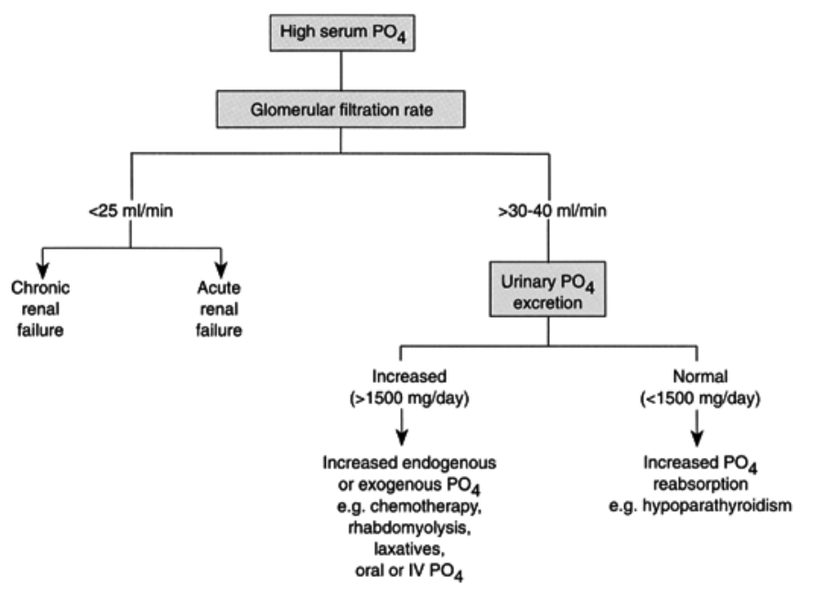

FIGURE 20.7. Evaluation of hyperphosphatemia. (From Chernow B. *The pharmacologic approach to the critically ill patient*. 2nd ed. Baltimore: Williams & Wilkins, 1988:633.)

HYPOPHOSPHATEMIA

Part of "20 - Calcium, Magnesium, and Phosphate"

The incidence of hypophosphatemia in hospitalized patients varies from 2% to 40%, depending on the population studied (89). Severe hypophosphatemia usually results in decreased concentrations of phosphate-containing compounds, such as ATP and membrane phospholipids. These deficiencies in turn are responsible for symptoms of hypophosphatemia, including muscle weakness, respiratory and myocardial insufficiency, and hepatocellular damage (89). Because phosphate is present in nearly all foods, a pure dietary deficiency rarely causes hypophosphatemia. More commonly, hypophosphatemia is caused by renal loss, gastrointestinal malabsorption, or transcellular shifts of phosphate. Mild hypophosphatemia is common in hospitalized patients and usually is not treated, but severe hypophosphatemia (less than 1.0 g/dL or 0.3 mmol/L) requires monitoring and possible replacement therapy. Some causes of hypophosphatemia in hospitalized patients are listed below, by the mechanism of their cause:

1. *Transcellular Shifts*. Because the movement of glucose into cells is accompanied by phosphate, the administration of glucose or insulin will lead to an influx of phosphate into cells that may cause hypophosphatemia. By a complex mechanism involving glycolysis and formation of phosphorylated intermediates in cells, respiratory alkalosis also substantially enhances phosphate uptake by cells (86, 89, 90). Urinary phosphate is usually decreased.
2. *GI losses*. As with many electrolyte disorders, diarrhea and vomiting can diminish GI absorption of phosphate. Because the divalent cations in antacids such as aluminum hydroxide, magnesium hydroxide, or aluminum carbonate bind phosphate and prevent its absorption in the gut, hypophosphatemia often results from chronic excessive use of such antacids (86). Urine phosphate is usually low.
3. *Renal losses*. The causes include: primary hyperparathyroidism, diuretics, hypomagnesemia, or defects in renal tubular absorption of phosphate. Urine phosphate is normal or elevated.

4. *Mixed causes* (86, 90).

   - In diabetic ketoacidosis, the combined effects of acidosis, glycosuria, ketonuria, and insulin therapy deplete phosphate, both by renal loss and cellular uptake. Serum concentrations may decrease rapidly.
   - Acidosis induces mobilization of phosphate from bone and tissues, along with increased renal loss.
   - Alcoholism leads to hypophosphatemia by increasing renal loss and decreasing GI absorption.

   During recovery from thermal burns, phosphate is shifted into cells and secreted into renal tubules, where it is lost in urine.

HYPERPHOSPHATEMIA

Part of "20 - Calcium, Magnesium, and Phosphate"

The most common cause of hyperphosphatemia is decreased phosphate excretion resulting from renal failure. In the early stages of a chronic loss of renal function, the remaining nephrons increase excretion of phosphate. Therefore, severe hyperphosphatemia does not occur until renal disease is well advanced and when the glomerular filtration rate is less than 25 mL/minute. A recent study concluded that a large percentage of longer-term renal dialysis patients have a serum phosphate above 2.1 mmol/L, and that this placed them at an increased risk of death (91). In acute renal failure serum phosphate may rise even more rapidly than urea or creatinine. Consequently, serum phosphate should be monitored in acutely ill patients (88, 89).

Other causes of hyperphosphatemia include increased intake of either phosphate or vitamin D and increased breakdown of cells by severe infections, intensive exercise, or neoplastic diseases. Immature lymphoblasts have about 4 times the phosphate content of mature lymphocytes, so patients with lymphoblastic leukemia may develop hyperphosphatemia. Neonates are especially prone to hyperphosphatemia caused by increased intake because they may not have mature PTH and vitamin D metabolism.

If renal function is normal, a urinary phosphate excretion above 1500 mg/day suggests hyperphosphatemia caused by chemotherapy, rhabdomyolysis, malignant hyperthermia, or excessive administration of phosphate by enema or intravenous route. A urinary phosphate excretion less than 1500 mg/day with normal renal function suggests some form of hypoparathyroidism (89).

Proper Collection and Handling of Samples

Hemolysis will falsely elevate serum phosphate concentrations, and serum should be removed or separated from cells promptly to avoid intracellular loss of phosphate into the plasma or serum phase. Phosphate concentrations will be slightly lower after meals, so the patient should be fasting before the sample is drawn to obtain an accurate baseline level. Intravenous administration of glucose or fructose lowers serum phosphate by promoting the intracellular shift of phosphate.

Methods for Measurement of Serum Phosphate

Since the 1920s, phosphate has been measured by methods in which molybdate reacts with phosphate to form complex molecules of phosphomolybdate. Fiske and Subbarow used a reducing reagent, 1-amino-2-naphthol-4-sulfonic acid (ANS), to form molybdenum blue, a complex polymer with a high molar absorptivity at 660 nm (92). While utilization of the basic reaction of phosphate with molybdate has remained essentially the same through the years, several different reducing agents have been developed. In addition to ANS, agents used have included stannous chloride (with and without hydrazine) and ferrous ammonium sulfate (93).

Simonsen showed that the unreduced phosphomolybdate complex has a high absorptivity at 340 nm, and Daly and Ertingshausen optimized this method for centrifugal analysis (93). Garber and Miller proposed a selected method for phosphate in serum that utilizes protein precipitation with semidine HCl as a reducing agent (94). A dry-slide method for phosphate determination utilizes p-methylaminophenol sulfate as reducing agent while monitoring light reflection at 680 nm (95). Several enzymatic methods for measuring phosphate have been developed (96) but have not been widely used in clinical laboratory practice. Reference ranges for phosphate are shown in Table 20.5.

TABLE 20.5. Reference Ranges for Phosphate[a]

	Serum Phosphate[b]	
	mgp/dL	**mmol/L**
Newborn (1–2 days)	5.5–9.5	1.78–3.07
Infant	4.5–6.5	1.45–2.10
Child	4.5–5.5	1.45–1.78
Adult male	2.3–3.7	0.74–1.20
Adult female	2.8–4.1	0.90–1.32

[a] Serum phosphate concentrations are relatively high at birth, then decline by 3 to 4 days, about the time the parathyroid gland becomes functional. Adults on an average diet should excrete 0.4–1.3 g of phosphorus per day.

[b] Expressed as phosphorus.

Heme Synthesis and Catabolism

György Ábel

Darryl Palmer-Toy

OVERVIEW

Part of "21 - Heme Synthesis and Catabolism"

Scope

Heme is a versatile chemical prosthetic group involved in various essential functions including respiration, detoxification, antimicrobial defense, and second messenger synthesis. Many of the colors of clinical specimens reflect products of heme chemistry: blood, red (heme); urine, yellow (urochrome); bile, yellow-green (bilirubin); and feces, brown (urobilin and mesobilifuscins). Inherited disorders of heme synthesis, collectively known as the porphyrias, are relatively rare. Yet porphyrias often enter the differential diagnosis of various symptoms as a result of the protean manifestations of these disorders. In contrast, inherited or acquired abnormalities of bilirubin excretion frequently are encountered in routine medical practice. This chapter will review disorders of heme synthesis and catabolism, and the role of laboratory tests in the diagnosis of these conditions. Where possible, the molecular basis for the more common biosynthetic defects, associated clinical syndromes, and relevant laboratory assays will be described including diagnostic strategies for the porphyrias and for hyperbilirubinemia. The topic of hemoglobinopathy is discussed elsewhere (Chapter 41).

Heme Biosynthesis

The primary sites of heme synthesis are the bone marrow (about 85% of the total production), and the liver. Figure 21.1 shows the biochemical pathway of heme synthesis, the enzymes involved in the production of each metabolite and the inherited or acquired enzyme deficiencies involved with the particular porphyrias. The first reaction in the synthetic pathway is the condensation of succinyl CoA with glycine catalyzed by the mitochondrial enzyme d-aminolevulinic acid (ALA) synthase, the rate-limiting enzyme of the synthetic pathway. Because this first step of the sequence is rate-limiting, the product ALA and the subsequent intermediary metabolites normally are found only in low, steady-state concentrations in the cells. The concentration of these metabolites in body fluids also is low. Following its synthesis in the mitochondrion, ALA transfers to the cytoplasm. The next step in the pathway is the condensation of two ALA molecules, mediated by ALA dehydratase (porphobilinogen synthase), to form porphobilinogen (PBG). Four PBG molecules then are condensed into hydroxybilane by PBG deaminase (uroporphyrinogen I synthase). Hydroxymethilbilane then is converted to uroporphyrinogen III by uroporphyrinogen III cosynthase. Alternatively, hydroxymethylbilane may convert to uroporphyrinogen I, then to coproporphyrinogen I, using an alternative pathway. Uroporphyrinogen III is converted in the cytosol to coproporphyrinogen III by the fifth enzyme in the pathway, uroporphyrinogen III decarboxylase. This compound then reenters the mitochondrion, where two of the propionic acid groups are decarboxylated and by the enzyme coproporpyrinogen oxidase, resulting in the next metabolite, protoporphyrinogen IX. In the next step, protoporphyrinogen oxidase oxidizes protoporphyrinogen IX by the removal of six hydrogen atoms. The reaction produces porphyrins, which are the oxidized forms of porphyrinogens. In the final step, a Fe^{2+} is incorporated into protoporphyrin IX to form the final product, heme. In the bone marrow, ALA synthase is expressed at higher levels than in the liver where it is repressed by free heme. The enzymes responsible for heme biosynthesis in the bone marrow are regulated in a coordinated fashion. In the liver, ALA synthase is inducible by the same agents that induce the cytochrome P450 enzymes. Because most of the hepatic heme is used in the synthesis of cytochrome P450, the regulation of these enzymes and ALA synthase are coordinated in the liver.

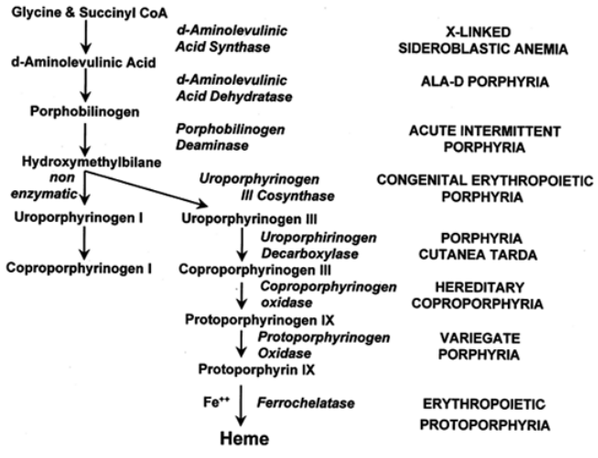

FIGURE 21.1. Heme synthesis: metabolites, enzymes, and the disorders associated with enzyme deficiencies.

THE PORPHYRIAS

Part of "21 - Heme Synthesis and Catabolism"

Porphyrias are diseases resulting from disorders of heme synthesis. The clinical symptoms of different porphyrias significantly overlap, therefore the clinical presentation cannot be used alone to identify the specific disorder. Therefore, the pattern of measured porphyrins and their precursors found in urine, plasma, red blood cells, and feces are used for diagnosis of the particular type of porphyria. Measuring the activity of the enzyme suspected to be deficient and molecular genetic tests are useful adjuncts. The disorders related to the deficiency of each participating enzyme are listed in Figure 21.1. Porphyrias have been classified according to the major clinical manifestations as erythropoietic, hepatic, and hepatoerythropoietic porphyrias (Table 21.1). An alternative classification system divides porphyrias into those with cutaneous or neurological manifestations. Photosensitivity is a key clinical symptom in erythropoietic porphyria, erythropoietic protoporphyria, porphyria cutanea tarda, variegate porphyria, and hepatoerythropoietic

porphyria. Acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria are classified as acute porphyrias because they present with similar abdominal, autonomic, and neuropsychiatric features; whereas porphyria cutanea tarda, erythropoietic protoporphyria, and congenital erythropoietic porphyria are characteristically associated with photosensitivity of the skin, and are classified as “nonacute porphyries.” ALA and PBG, the key metabolites accumulating in acute intermittent porphyria and ALA dehydratase deficiency porphyrias do not produce photosensitization. Consequently, there are no cutaneous symptoms in these disorders (Table 21.2). Most chelated porphyrins, such as heme, are not photosensitizing. In addition, porphyrins chelated to Mg^{2+}, Zn^{2+}, and Cu^{2+} do not show fluorescence and also are not photosensitizing.

TABLE 21.1. CLASSIFICATION OF PORPHYRIAS

Acute Intermittent Porphyria
ALA Dehydratase Deficiency

TABLE 21.2. AMINOLEVULINIC ACID DEHYDRATASE DEFICIENCY PORPHYRIA

Epidemiology:
Very rare, only few patients reported
Autosomal recessive, cDNA showed double heterozygousity was found in cDNA for two independent alleles
Pathophysiology:
Aminolevulinic acid dehydratase deficiency
Clinical presentation:
Symptoms similar to acute intermittent porphyria, no skin lesions
Precipitating factors: stress, ethanol
Laboratory findings:
Erythrocytes: Aminolevulinic acid dehydratase <5% of normal;protoporphyrin elevated
Urine: Aminolevulinic acid, coproporphyrin, uroporphyrin elevated
Differential diagnosis:
Acute intermittent porphyria

ALA Dehydratase Deficiency Porphyria (Porphobilinogen Synthase Deficiency)

ALA synthase is the first and rate-limiting enzyme in the heme biosynthetic pathway. Although this enzyme is not associated with a specific porphyria, the activity of this enzyme is increased in all hepatic porphyrias, leading to an increased excretion of ALA and PBG in the urine.

Homozygous genetic mutations resulting in defects of the second enzyme, ALA dehydratase (ALA-D) manifest in ALA-D

deficiency porphyria, also called “plumboporphyria,” because of the similarity of the finding in this disorder to those observed in lead poisoning. ALA-D deficiency porphyria is a rare disorder with the clinical features of acute porphyrias (Table 21.3). The key laboratory finding is a massive elevation of ALA in the urine with normal urinary PBG excretion. Additional supporting laboratory findings for ALA-D deficiency porphyria are the increased coproporphyrin III in the urine. Laboratory tests for ALA-D deficiency porphyria include urinary ALA, PBG, coproporphyrin isomers, and ALA-D activity in red blood cells.

TABLE 21.3. ACUTE INTERMITTENT PORPHYRIA

Epidemiology:
Autosomal dominant, rarely manifests before puberty, female predominance
Incidence 1.5:100,000, in Lapland 1:1,000
Pathophysiology:
Deficiency of porphobilinogen deaminase
Clinical presentation:
Acute attacks with neurovisceral symptoms, abdominal pain
Skin photosensitivity: absent
Constipation, nausea, muscle weakness – paralysis, bizarre psychotic behavior
Often precipitated by drugs, hormones
Laboratory findings:
Rapid lab tests: Urine darkens to deep red/brown color when exposed to sunlight
Hoesch test or Watson-Schwartz test of urine for porphobilinogen
Urine: Elevated aminolevulinic acid, porphobilinogen, uroporphyrin I
Plasma: Increased porphyrins during attacks
Erythrocytes: Decreased porphobilinogen-deaminase activity, normal porphyrin levels
Feces: Normal or slightly elevated porphyrins
Differential diagnoses:
Variable, may resemble many different diseases, called “little imitator” by Waldenström

Acute Intermittent Porphyria (Porphobilinogen Deaminase Deficiency, Uroporphyrinogen Synthase Deficiency, Hydroxymethylbilane Synthase Deficiency Porphyria, Swedish-Type Porphyria)

The three acute porphyrias are acute intermittent porphyria (AIP), variegate porphyria (VP), and hereditary coproporphyria (HCP), all inherited in an autosomal-dominant manner. Clinically, all of these three disorders present after puberty. Acute intermittent porphyria is a result of four distinct mutants of PBG deaminase. In the most common genotype of AIP, patients have about one half of the normal PBG deaminase. With this genotype, decreased concentrations of PBG deaminase may be found both in patients with clinical disease and in latent carriers of this genetic defect. Most individuals with decreased PBG deaminase activity as a result of this gene defect never develop porphyria. However, they may be at risk if they are exposed to triggering factors, a “second hit.” Attacks are frequently precipitated by a variety of drugs and hormones. Acute attacks of AIP are characterized by abdominal pain, the hallmark symptom of this disorder, constipation, nausea, muscle weakness, paralysis, and bizarre psychotic behavior. Muscle weakness may be severe during a prolonged attack. It is because of the effects of the accumulated metabolites on the peripheral nerves, the nerves in the abdomen, and the central nervous system. The exact mechanism of the symptoms is not well understood. Attacks are more prevalent in women than in men and more often occur during the second half of the menstrual cycle. Attacks can be triggered by oral contraceptives containing synthetic estrogens. Alcohol and various environmental chemicals also are found to have this attack-triggering, porphyrogenic potential. A partial list of porphyrinogenic and “safe” drugs and agents is shown in Table 21.4.

TABLE 21.4. THE “SECOND HIT”: EXAMPLES OF UNSAFE AND SAFE AGENTS AND DRUGS

Unsafe	Safe
Ethanol	Acetaminophen
Anti-epilepsy drugs	Aspirin
Barbiturates	Atropine
Birth control pills	Bromides
Calcium-ch. Blockers	Chloral hydrate
Carbamazepine	Penicillin
Clonazepam	Phenotiazines
Danazol	Narcotic analgesics
Diclofenac	Cimetidine
Ergots	Insulin
Rifampine	Glucocorticoids
Sulfonamides	Streptomycin

The principal laboratory tests in AIP are measurements of ALA and PBG in urine. During acute episodes, the urine may turn dark red/brown from the increased excretion of ALA, PBG, and porphyrins. Excessive PBG in urine is nonenzymatically converted to uroporphyrin I. This process may be slowed by refrigeration and alkalinization of the urine specimen to pH 8–9. The excretion of ALA and PBG usually decreases with clinical improvement. A normal urinary PBG level effectively excludes AIP as a cause for the current symptoms. Most asymptomatic, “latent” heterozygous individuals with PNG deaminase deficiency have normal urinary excretion of ALA and PBG. Therefore, measurement of PBG deaminase in erythrocytes is useful to confirm the diagnosis and screen asymptomatic family members.

Because quantitative tests for ALA and PBG most often are performed in reference laboratories, many hospitals use qualitative screening test methods for PBG. In the Hoesch test, urine is tested with p-dimethylaminobenzaldehyde (Ehrlich's reagent). The specificity of this simple test has been improved in the Watson-Schwartz test with the use of chloroform and n-butanol to remove interfering substances, primarily urobilinogen. Specificity also can be improved by the application of ion-exchange column to remove interfering compounds prior to performing the Ehrlich reaction. Although empirical evidence suggests that the Watson-Schwartz test is suitable for the detection of AIP, the quantitative analysis of a timed urine specimen also is necessary for the definitive diagnosis.

The deficiency of PBG deaminase is detectable in the erythrocytes of most heterozygotes. However, the activity of this enzyme is higher in younger erythrocytes and may increase into the normal range in AIP when erythropoiesis is increased. Thus, a normal result does not necessarily exclude the diagnosis of AIP.

The management of AIP involves high carbohydrate diet, IV glucose and hematin infusions, and the avoidance of the precipitating drugs.

Congenital Erythropoietic Porphyria (Congenital Erythropoietic Porphyria, Congenital Hematoporphyria, Erythropoietic Uroporphyria, Uroporphyrinogen III Cosynthase Deficiency, Hydroxymethylbilane Hydrolase Deficiency, Günther's Disease)

Erythropoietic porphyria (EP) is extremely rare, less than 200 cases have been described (Table 21.5). It is inherited in an autosomal-recessive manner. The enzymatic basis for this disease is the deficiency of uroporphyrinogen III cosynthase. This enzyme catalyzes the synthesis of the asymmetric uroporphyrinogen III molecule. The deficiency of this enzyme leads to the overproduction of uroporphyrinogen I and coproporphyrinogen I, which have no role in heme synthesis. Oxidation of these metabolites to their respective porphyrins, leads to accumulation and excretion of uroporphyrin I (URO I) and coproporphyrin I (COPRO I), beginning during fetal life. The disorder usually is discovered soon after birth because patients excrete unusual red-pigmented urine. Intravascular hemolysis also may occur. Urinary excretion of URO I and COPRO I is extremely high, maybe over 100 times the normal level. Urinary excretion of ALA and PBG is normal. Fecal coproporphyrin also is elevated, with COPRO I as the dominant isomer.

TABLE 21.5. ERYTHROPOIETIC PORPHYRIA

Epidemiology:

Autosomal recessive, very rare (<200 reported cases)

Pathophysiology:

Uroporphyrinogen III cosynthase deficiency

Clinical presentation:

Hemolytic anemia, erythrodontia, splenomegaly, pink-red urine, fluorescent erythrocytes and normoblasts, ulcerations of the eyes

Photosensitivity: marked, early in childhood

Skin reactions: vesicles, bullae, erosions, hypertrichosis, thickened eyebrows and eyelashes, hypermelanosis, skin photosensitivity, later scarring with atrophy, mutilating deformities of hands, ears, face and nose, cicatrizing alopecia

Laboratory findings: Urine: Uroporphyrin I and coproporphyrin I elevated; URO > COPRO

Feces: Coproporphyrin I elevated

Erythrocytes and plasma: Uroporphyrin I and/or zinc protoporphyrin elevated

Plasma: Uroporphyrin I and coproporphyrin I elevated

Enzyme: Uroporphyrinogen III cosynthase decreased, particularly in bone marrow

Differential diagnoses:

Other congenital photodermatoses, hepatic porphyrias

The management of EP includes splenectomy, which may improve hemolysis, the avoidance of exposure to sunlight, and the treatment of secondary skin infections.

Porphyria Cutanea Tarda [Uroporphyrinogen Decarboxylase (UROD) Deficiency Type I: 'Sporadic' Type, and Types II and III: 'Familial' Type Symptomatic Porphyria, Acquired Hepatic Porphyria, Chemical Porphyria]

Porphyria cutanea tarda (PCT) is the most common porphyria, caused by the deficiency of the enzyme uroporphyrinogen decarboxylase (UROD). PCT can be acquired, the onset is often later during life, it is most common in elderly men. The disorder almost occurs in a sporadic manner but cases with familial inheritance also have been described. PCT often is found in association with liver disease, hepatitis C virus infection has been implicated in these disorders in recent years. Alcohol abuse also is among the most common causes. Other diseases, such as uremia, diabetes mellitus, and certain autoimmune disorders also have been found associated with this disorder. For a summary of PCT, see Table 21.6. The activity of UROD is decreased to about half of the normal value. In most cases, this reduced level of activity, however, is sufficient for carrying out the process of heme synthesis. In other cases, the insufficient enzyme activity results in a decreased synthesis of heme and accumulation of the early metabolites of the synthetic pathway. Iron overload and excessive hepatic iron stores often are present. Patients in both sexes with PCT develop cutaneous lesions in areas of the skin exposed to sunlight: the face, dorsa of hands, and forearms, while the legs and feet typically are affected in women.

TABLE 21.6. PORPHYRIA CUTANEA TARDA

Epidemiology:

Essentially an acquired disease, genetic type (mainly autosomal dominant) is also known, the most common porphyria, male predominance

Age of onset is usually third or fourth decade

Hepatitis C virus (HCV) infection and alcohol abuse have been implicated

Pathophysiology: Uroporphyrinogen decarboxylase deficiency

Clinical presentation:

Photosensitivity: Marked, early in childhood, moderate to severe

Skin reactions: Bullae, vesicles, ulcers on light-exposed skin (e.g., on dorsa of hands and feet), increased skin fragility, hyperpigmentation, scarring alopecia

Diabetes mellitus in 25% of patients

Increased liver iron stores and serum iron

Urine may show pink fluorescence

Acute attacks are absent (unlike in variegate porphyria)

Laboratory findings

Urine: Increased uroporphyrin (I > III), coproporphyrin, and 7- carboxylporphyrin III,

Feces: Increased isocoproporphyrins

Erythrocytes: Normal porphyrins

Plasma: Increased 8- and 7-carboxylporphyrins

Enzyme defect: Deficient uroporphyrinogen decarboxylase in liver (type I) and in erythrocytes (type II)

Differential diagnoses: Variegate porphyria, epidermolysis bullosa acquisita

In the acquired form of PCT (type I), the deficiency of UROD occurs both in the hepatocytes and erythrocytes. In the acquired form of the disorder (type II), the enzyme defect is limited to the liver. All forms of PCT manifest with cutaneous symptoms and similar porphyrin profile in urine, feces, and plasma. In PCT, the plasma fluorescence scan exhibits a characteristic porphyrin spectrum that can be described by excessive uroporphyrin and higher carboxylated porphyrins, predominantly 7- and 8-carboxyl porphyrins. Erythrocyte porphyrins are normal, while urinary porphyrins show increased uroporphyrin and heptacarboxyl porphyrin levels.

The possible role of the analysis of UROD activity in PCT is unclear. It generally is accepted that patients with familial PCT have reduced levels of this enzyme in tissues, cultures skin fibroblasts, and erythrocytes. However, most cases are sporadic,

and in the sporadic cases erythrocyte enzyme activities often are normal. Laboratory diagnostic assessment for PCT should include qualitative and quantitative plasma porphyrin analysis, urinary, fecal, and erythrocyte porphyrin measurements.

PCT is considered the most treatable porphyria, its management consists of the avoidance of exposure to direct sunlight, avoidance of ethanol, estrogens, and other precipitating drugs, chemicals such as polycarbonated hydrocarbons, HCl-benzene, and dioxin. Removal of one unit of blood with phlebotomy weekly or biweekly reduces hemoglobin and iron levels. Chloroquine treatment is an alternative option.

Hepatoerythropoietic Porphyria (Hepatoerythrocytic Porphyria)

Hepatoerythropoietic porphyria is a rare disorder associated with a profound deficiency of uroporphyrinogen decarboxylase (Table 21.7). Clinically, the skin manifestations resemble porphyria cutanea tarda and erythropoietic porphyria. The disease typically manifests in childhood, with dark urine and cutaneous symptoms. Plasma of patients with this disorder contain excessive amounts of uroporphyrin, and red blood cells contain excess zinc protoporphyrin. Isocoproporphyrin is the predominant coproporphyrin isomer present in urine and stool. In contrast to porphyria cutanea tarda patients, serum iron is normal in hepatoerythropoietic porphyria. Key laboratory tests are erythrocyte zinc protoporphyrin, urinary porphyrin profile, and urinary coproporphyrin isomers. Uroporphyrinogen decarboxylase activity usually is 5% to 10% of normal. The management of hepatoerythropoietic porphyria includes the avoidance of sunlight, and oral charcoal therapy. Phlebotomy is not indicated.

TABLE 21.7. HEPATOERYTHROPOIETIC PORPHYRIA

Epidemiology:
- Autosomal recessive Extremely rare (<20 cases)
- Early onset, before age 2

Pathophysiology: Uroporphyrinogen decarboxylase deficiency

Clinical presentation:
- Normochromic anemia
- Erythrodontia, pink urine, photosensitivity: marked
- Skin reactions: Vesicles, bullae, erosions, scarring, hyperpigmentation, mutilating scarring deformities of hands, ears, face and nose

Laboratory findings:
- Urine: Elevated uroporphyrinogen I, III and 7-carboxylporphyrine
- Feces: Elevated uroporphyrinogen, coproporphyrin, isocoproporphyrin
- Erythrocytes: Elevated protoporphyrin, usually Zn protoporphyrin
- Enzyme: Markedly decreased uroporphyrinogen decarboxylase
- Serum Fe normal

Differential Diagnoses:
- Erythropoietic porphyria, porphyria cutanea tarda, erythropoietic protoporphyria

TABLE 21.8. HEREDITARY COPROPORPHYRIA

Epidemiology:
- Autosomal dominant
- Age of onset: Any age
- Incidence: Rare (<50 cases reported)

Pathophysiology:
- Deficiency of coproporphyrinogen oxidase

Clinical presentation:
- Neurovisceral symptomatology, similar to AIP
- Precipitating agents: Barbiturates, other drugs
- Photosensitivity: Infrequent
- Skin reactions: Blisters

Laboratory findings:
- Urine: Elevated coproporphyrin III
- Feces: Markedly elevated coproporphyrin III, less elevated protoporphyrin; aminolevulinic acid and porphobilinogen are also elevated during acute attacks
- Enzyme: in fibroblasts, lymphocytes, elevated hepatic ALA-synthase

Differential diagnosis:
- Acute intermittent porphyria, porphyria cutanea tarda

Hereditary Coproporphyria (Idiopathic Coproporphyria, Coproporphyrinogen Oxidase Deficiency)

Hereditary coproporphyria (HCP), an autosomal dominant disorder presents as an acute neurological porphyria, as photosensitivity, or both (Table 21.8). The acute neurological attacks are similar to those in a milder form of AIP. Abdominal pain is the most common symptom. Hepatic function usually is not impaired. The attacks are associated with elevated urine porphobilinogen, and, to a lesser extent, elevated ALA levels. As a result of the enzyme defect, an overproduction of the coproporphyrinogen occurs that inhibits hydroxymethylbilane synthase, resulting in an elevation of porphobilinogen. Coproporphyrin III is elevated in urine and feces. The key laboratory tests are urine porphyrin isomer profile and fecal porphyrin profile. The management of hereditary coproporphyria is similar to the treatment of AIP or VP (carbohydrate rich diet, administration of glucose, hematin, avoidance of precipitating factors).

Variegate Porphyria (South African Type Porphyria, Porphyria Cutanea Tarda Hereditaria, Mixed Porphyria, Protocoproporphyria, Protoporphyrinogen Oxidase Deficiency)

Clinically, VP includes the manifestations of AIP and PCT, which may occur in the same individual (Table 21.9). Most often, patients present with the symptoms of AIP at the first time of discovery. Chronic cutaneous symptoms also are frequently present. Peripheral neuropathy is an important part of the clinical syndrome in many patients. VP is most common among Dutch descendants in South Africa.

TABLE 21.9. VARIEGATE PORPHYRIA

Epidemiology:
- Autosomal dominant
- Age of onset: Usually between 15 and 30 years
- In South Africa: incidence 3/1000, rare elesewhere

Pathophysiology:
- Protoporphyrinogen oxydase deficiency

Clinical presentation:
- Neurovisceral symptomatology similar to AIP
- Photosensitivity and skin lesions: similar to PCT
- Acute attacks similar to AIP precipitated by barbiturates, dapsone, estrogens
- Abdominal pain, nausea, vomiting
- Behavioral changes, seizures, paralysis

Laboratory findings:
- Urine: Elevated aminolevulinic acid, porphobilinogen in acute attacks, normal between attacks
- Feces: Increased protoporphyrin and coproporphyrin (PROTO > COPRO III) and X-porphyrins (ether- acetic acid insoluble porphyrins)
- Enzymatic: Decreased protoporphyrinogen oxydase in fibroblasts, somewhat decreased ferrochelatase; increased hepatic ALA synthetase

Differential diagnosis:
- Porphyria cutanea tarda, hereditary coproporphyria, hepatoerythropoietic porphyria

The primary enzyme defect of protoporphyrinogen oxidase results in excess protoporphyrinogen, which inhibits hydroxymethylbilane synthase giving rise to elevated PBG. Like in AIP, acute attacks are characterized by excretion of large amounts of ALA and PBG, but urinary excretion may occur between attacks as well. Urine coproporphyrin III also is elevated during attacks. In the stool, protoporphyrin, coproporphyrin, and the ether-acid insoluble porphyrins (x-porphyrins) are elevated. The key laboratory tests are urinary PBG and ALA during an attack, fecal porphyrin profile (stool protoporphyrin), and plasma fluorescent scan.

Management of this disorder involves avoidance of precipitating drugs, treatment for neurovisceral symptoms as in AIP, and protection from sunlight.

Erythropoietic Protoporphyria (Erythrohepatic Protoporphyria Protoporphyria, Ferrochelatase Deficiency)

This disease begins early in life and the symptoms vary greatly in severity (Table 21.10). Some individuals may not experience photosensitivity, but most patients are moderately sensitive to sunlight. Symptoms include burning, itching, stinging in light-exposed skin, particularly of the nose, cheeks, and dorsum of the hands. Erythropoietic protoporphyria (EPP) is inherited in an autosomal-dominant manner, and ferrochelatase activity is about half of normal in affected individuals. Excess protoporphyrin is deposited in the skin, resulting in mild photosensitivity starting in childhood. A rare homozygous form of this disorder is accompanied by more serious symptoms. Late onset cases also are known.

TABLE 21.10. ERYTHROPOIETIC PROTOPORPHYRIA

Epidemiology:
Autosomal dominant, variable penetrance
Age of onset: 1–4 years
Pathophysiology:
Ferrochelatase deficiency
Clinical presentation:
Photosensitivity: Mild to severe, onset immediate – within minutes
Pruritus, burning, edema, erythema, urticaria, purpura, rare bullae on nose and hands, waxy scars over nose, hands, erosions, crusts, wrinkling of face, waxy thickening of the knuckles, nose with fine linear scarring
Cholelithiasis, cholestasis, hepatic failure
Anemia: Uncommon
Laboratory findings:
Urine: Normal porphyrins
Feces, erythrocytes and plasma: Elevated protoporphyrin
Erythrocytes show red fluorescence
Enzyme defect: Ferrochelatase deficiency in skin, fibroblasts, liver, and bone marrow
Differential diagnosis:
Congenital erythropoietic porphyria, extreme sunburn, polymorphous light eruption

The laboratory diagnosis of ferrochelatase deficiency can be made by detecting free protoporphyrin in erythrocytes and feces. Plasma protoporphyrins and fecal coproporphyrin also may be increased, and are present in higher concentrations than fecal coproporphyrin. Urine shows normal porphyrin levels and possibly increased coproporphyrin I. The key laboratory tests are free erythrocyte protoporphyrin, plasma porphyrin, plasma fluorescent scan, and fecal porphyrin profile.

In the management of EP, beta-carotene (Solatene) is used for sunburn protection by quenching singlet oxygens and trapping free radicals. Hepatic failure is difficult to manage, liver transplantation has been used successfully.

Erythropoietic Coproporphyria

There are only three published cases of erythropoietic coproporphyria (ECP) known. Photosensitivity associated with this disorder and elevated protoporphyrin and coproporphyrin in red blood cells are the main manifestations of this disorder. Very little is known about this entity.

Lead Poisoning

Lead inhibits two steps in the heme synthetic pathway: ALA dehydratase and ferrochelatase. Consequently, the substrates of these two enzymes, ALA and protoporphyrin accumulate in lead poisoning. In addition, coproporphyrin also is often elevated in urine. Urinary measurement of ALA is a sensitive indicator of lead poisoning. Measurement of protoporphyrins in erythrocytes was until recently an important test for population screening for lead poisoning. Measurement of protoporphyrins, however, is no longer acceptable for the detection of lead poisoning because of its relative insensitivity and lack of specificity.

Secondary Disorders of Porphyrin Metabolism

Various forms of liver disease also can cause increased excretion of porphyrins into the urine, most commonly only coproporphyrin elevations are seen. This also is the case in some patients with hemolytic disease. Rarely, hepatic tumors produce excess porphyrin metabolites.

Protoporphyrins may be elevated because of secondary causes such as disorders involving the system of heme biosynthesis. These disorders include iron deficiency, sideroblastic anemia, secondary polycythemia, and any cause of excessive erythrocyte destruction.

Hereditary tyrosinemia is another disorder related to porphyrin metabolism. Succinylacetone, a metabolite produced during the degradation of tyrosine, inhibits ALA dehydratase, and the patients affected by this disorder develop symptoms resembling AIP.

LABORATORY TESTS FOR PORPHYRIN DISORDERS

Qualitative Methods

If the clinical picture suggests an acute porphyria, the first test should be the measurement of PBG in urine. Increased PBG is the most important biochemical abnormality in urine in AIO, and, during attacks, in VP and HCP. When these disorders are suspected, both PBG and ALA should be measured. These assays help to differentiate AIP, ALA-D porphyria, and lead poisoning. In the latter two, only urine ALA is elevated, while PBG is normal. In cutaneous porphyrias, porphyrins are produced in excessive amounts, VP and HCP both present with photosensitivity and neurovisceral manifestations.

Testing for Porphobilinogen in Urine

The classic method for PBG screening is the Hoesch test in which porphobilinogen is reacted with *p*-dimethyl-aminobenzaldehyde (Ehrlich's reagent) to yield a magenta color at the interface. In the Watson-Schwartz test, the urobilinogen-Ehrlich's reagent complex is removed with butanol into the organic phase, improving the assay's specificity.

Quantitative Measurement of Porphobilinogen

Most quantitative methods employ chromatographic isolation and subsequent reaction with Ehrlich's reagent.

Measurement of Porphyrins in Urine

Because porphyrins exhibit red fluorescence, it often is possible to detect porphyrins in the urine by examination under a Wood's light. Addition of 10% hydrochloric acid enhances fluorescence. Direct spectrophotometric analysis also can be performed. However, these methods are neither sensitive, nor specific. Quantitative methods use solvent extraction from acidified urine followed by fluorimetric or spectrophotometric measurement.

Measurement of d-Aminolevulinic Acid in Urine

Reliable measurement of ALA can be achieved by chromatographic separation from other components, especially from porphobilinogen. The isolated ALA is reacted with acetylacetone to form a pyrrole, which then is reacted with Ehrlich's reagent.

Measurement of Protoporphyrin in Blood

Protoporphyrin can be extracted in the presence of acid, which dissociates zinc from the porphyrin molecule. Thus, the measurement resulting from this method is called “free erythrocyte protoporphyrin.” Direct measurement of protoporphyrin can be achieved from an instrument called a hematofluorometer, which measures zinc-protoporphyrin.

Fecal Porphyrin Analysis

Fecal porphyrin analysis employs repeated acidified organic solvent extraction of porphyrins from the specimen. Then the extracts are centrifuged and prepared for spectrophotometric analysis. Thin-layer chromatography, high-performance liquid chromatography, and capillary electrophoresis also have been used for separation and quantitative analysis of porphyrins.

HEME

Part of "21 - Heme Synthesis and Catabolism"

The role of heme in hemoglobin is discussed in Chapter 41. Other important heme-containing proteins (hemoproteins) include myoglobin, cytochrome P-450, catalase, peroxidase, NO synthetase, Try-pyrrolase, and adenylcyclase.

BILIRUBIN

Part of "21 - Heme Synthesis and Catabolism"

Roughly 1% of a person's red blood cells normally turn over on any given day. This results in the production of 175 to 250 mg of bilirubin daily. Another 75 to 100 mg of bilirubin is derived from ineffective erythropoiesis and the turnover of other hemoproteins. Heme released from these sources is rapidly bound by the serum glycoprotein, hemopexin, and transported to the reticuloendothelial system. If the carrying capacity of hemo-pexin is exceeded, circulating heme binds to albumin to form methemalbumin.

Heme is degraded to biliverdin IX through the microsomal heme oxygenase enzyme complex (HO). This reaction involves cleavage of the α-methene bridge of heme and loss of iron. Also produced is carbon monoxide, long thought to be an incidental side product of heme catabolism, but now recognized as a potent vasodilator. HO is anchored to the endoplasmic reticulum at the cytosolic border. Three isoforms of HO have been identified that are expressed in various tissues. Primarily HO-1 is expressed in the spleen, where most heme is catabolized. HO-1 is a heat-shock protein, inducible by heme and other stimuli: fever, hormones, stress, starvation, and sundry metals and organic compounds. HO-1 is induced in the liver after splenectomy. HO-1 is inhibited by zinc and tin-protoporphyrin. Zinc protoporphorin accumulates when marrow iron stores are low, and this feedback inhibition on heme catabolism may lessen the anemia resulting from iron deficiency.

Biliverdin is highly water-soluble, and would make a logical end product for heme degradation in humans as it serves in birds, reptiles, and amphibians. However, in man, biliverdin is rapidly converted to bilirubin by biliverdin reductase. There is a clear evolutionary trade-off in this extra metabolic step as bilirubin is more hydrophobic than biliverdin. Hydrophobicity allows for transplacental excretion of bilirubin from the fetal to maternal circulation, but bilirubin can selectively deposit in the basal ganglia (kernicterus) if pre- or neonatal hyperbilirubinemia occurs. Both bilirubin and biliverdin are potent free-radical scavengers, but the physiologic significance of this property is unclear. The majority of biliverdin formed in the adult is biliverdin IX_{α}, but biliverdin IX_{β} predominates in the fetus. Four different isoforms of biliverdin reductase, with higher affinities for each

biliverdin IX isomer (biliverdin $IX_{\alpha\text{-}\delta}$), have been identified in the human liver. The hydrophobicity of bilirubin is surprising considering the presence of propionic acid side chain on the B and C rings. However, the cis configuration of the two interring methene bridges leads to intramolecular hydrogen bonding of the acidic groups, rather than solvation. Phototherapy with blue light causes a configurational change in one or both of these methene bridges, leading to more hydrophillic molecules that are excreted readily.

Bilirubin readily binds to albumin, and this complex is transported through the circulation to the liver. Bilirubin is transferred to ligandins within the hepatocyte. Ligandins comprise a family of cytosolic carrier proteins that bind various substrates destined for biochemical modification by the hepatocyte. Ligandin binding prevents the diffusion of these substrates back into the bloodstream. The principal fate of bilirubin is glucuronidation, the conjugation of one or two sugar groups to the propionic acid side chains. Glucoronidation disrupts the intramolecular hydrogen bonds and greatly enhances the solubility of bilirubin. Most bilirubin progresses to the diglucuronide state, in reactions mediated by UDP-glucuronyl transferases (UGTs). Two families of UGTs exist: UGT1, which metabolize bilirubin and phenol; and UGT2, which metabolize steroids. Both families also glucuronidate a number of xenobiotics, and their activities can be modulated by drugs like phenobarbital and hormones like thyroxine and cortisol. Various alleles of the UGTs may predispose individuals to side effects from many common drugs. Characterizing these interactions is the basis for much work in the emerging field of pharmacogenetics.

Conjugated bilirubin is secreted into the bile by the cannicular multispecific organic anion transporter (CMOAT), also known as the multidrug resistance protein (MRP). This protein originally was identified in various tumors during chemotherapy. In the canaliculus, bilirubin mixes with bile salts, phospholipids, and cholesterol to form bile. Bile proceeds first to the gall bladder, where it becomes more concentrated and acidic, and then to the duodenum after mixing with the pancreatic juices. Trace amounts of conjugated bilirubin diffuse out of the hepatocyte, into the circulation, and ultimately into the urine. In contrast, unconjugated bilirubin is protein-bound and does not pass into the urine. Consequently, urine bilirubin reflects the conjugated form and may be elevated in conjugated hyperbilirubinemia.

Urobilinogen

Heme biosynthetic and catabolic pathways are taxonomically widespread, and we are symbiotic in certain aspects of bilirubin metabolism. Many of the heme breakdown products in human bodily fluids and excrement are products of enteric bacterial metabolism. Some bilirubin is deconjugated by bacterial ß-glucuronidases in the terminal ileum and colon, and the unconjugated bilirubin is reabsorbed into the blood stream via the enterohepatic circulation. The remainder of unconjugated bilirubin is reduced to form d-urobilinogen, mesobilirubinogen, and stercobilinogen (collectively known as urobilinogen). A portion of urobilinogen is absorbed via the enterohepatic circulation and finally emerges in the urine. The majority of urobilinogen subsequently is oxidized by bacteria to form the urobilins and excreted in the feces. Urine urobilinogen may be elevated in conditions associated with increased bilirubin production such as hemolytic jaundice.

Laboratory Assays

Bilirubin usually is measured using a red-violet chromogenic reaction with diazotized sulfanilic acid (diazo reaction), on serum, plasma, or urine specimens. The reaction course is biphasic, with a “direct” or rapidly reacting component composed of soluble conjugated bilirubin and bilirubin covalently bound to protein, and an “indirect” or slowly reacting component composed mostly of insoluble, unconjugated bilirubin. Measurements made early in the reaction essentially measure only the direct component, but at least 25% of the conjugated bilirubin is missed. Addition of “accelerators” such as methanol, caffeine, or sodium benzoate enhance the solubility and reaction rate of unconjugated bilirubin, presumably through disruption of intramolecular hydrogen bonds. This allows quantification of the total bilirubin. Indirect bilirubin then can be estimated by subtraction of the direct from the total bilirubin. Typical reference ranges for total and direct bilirubin are 0.3 to 1.2 mg/dL (5 to 20 µM) and <0.3 mg/dL (<5 µM), respectively. Hemoglobin interferes with the reaction, resulting in falsely elevated bilirubin measurements in severe anemia and falsely depressed measurements in hemolyzed specimens. An alternate approach for measuring bilirubin, employs reflectance photometry performed on a patient's skin or on thin films of blood for measurement of either conjugated or unconjugated bilirubin. Bilirubin has an absorption maximum at 455 nm in blood. Unfortunately, oxyhemoglobin also absorbs at this wavelength. However, the oxyhemoglobin component can be estimated from a parallel measurement at 575 nm, so that contribution can be subtracted out. Other substances present in the skin can interfere, and consequently transdermal measurements are only used in newborns. Bilirubin can be measured by HPLC, but this generally is reserved for research purposes.

Urobilinogen is measured routinely as part of dipstick urinalysis through a chromogenic reaction with p-diethylaminobenzaldehyde. Normally, this semiquantitative assessment is calibrated so normal levels of urobilinogen, up to 1 mg/dL of urine, do not register. Urobilinogen is not measured routinely in serum. Formerly, there was some clinical interest in quantifying stool urobilinogen to estimate hemoglobin degradation rates, however, those days are over.

DISORDERS OF BILIRUBIN METABOLISM

Part of "21 - Heme Synthesis and Catabolism"

Disorders of heme catabolism are, for all practical purposes, disorders of bilirubin metabolism. To date, only one case of HO-1 deficiency has been identified, and no human biliverdin reductase mutatations have been described. Although biliverdin levels may become elevated from various hepatic insults, biliverdin itself is excreted readily and apparently is nontoxic. On the other hand, acquired or genetic defects have been identified for most steps in bilirubin uptake, metabolism, and excretion. These defects

lead to hyperbilirubinemia of the unconjugated and/or conjugated type (Table 21.11). When serum bilirubin levels exceed about 2 mg/dL (34 μM), a yellow discoloration of the skin (jaundice) or sclera (icterus) becomes evident. For intrinsically dark-skinned people, inspection of the soles and hands may be necessary to see early jaundice. Only elevated conjugated bilirubin levels will result in patients who report darkening of the urine or yellowing of the urine foam.

TABLE 21.11. DIFFERENTIAL DIAGNOSIS OF JAUNDICE

Unconjugated hyperbilirubinemia
Increased heme catabolism
Hemolytic anemia
Hematoma
Impaired hepatic conjugation
Neonatal jaundice
Gilbert syndrome
Crigler-Najjar syndromes, types I and II
Conjugated hyperbilirubinemia
Impaired hepatic excretion
Hepatocellular disease
Dubin-Johnson syndrome
Rotor syndrome
Posthepatic obstruction

TABLE 21.12. NEONATAL HYPERBILIRUBINEMIA

Epidemiology:
Most, if not all infants
Pathophysiology:
Transient deficiency of UDP glucuronyl transferase – 1
Clinical presentation:
Jaundice, usually more pronounced in upper body
Laboratory findings:
Increased total bilirubin, with initially undetectable direct bilirubin
Transaminases, alkaline phosphatase, albumin, PT and PTT normal
Differential diagnosis:
Hemolytic disease of the newborn

Unconjugated Hyperbilirubinemia

Unconjugated hyperbilirubinemia is diagnosed when total bilirubin is elevated and <20% is direct. This occurs when the amount of unconjugated bilirubin in the blood exceeds the conjugating capacity of the liver: either because the amount of unconjugated bilirubin is especially large, the conjugation capacity of the liver is relatively low, or both.

Large amounts of free heme, and subsequently unconjugated bilirubin may be released into the blood in hemolysis or when hematomas form. As the functional conjugating reserve of the healthy liver is large, total bilirubin levels rarely rise more than two- to fourfold. The diagnosis of hemolysis may be aided by evaluation of the patient's history, complete blood count, and measurement of the serum haptoglobin among other tests. The most common form of unconjugated hyperbilirubinemia is neonatal jaundice (Table 21.12). This transient condition results from inadequate hepatic UGT1 activity, and manifests between days 2 and 5 of life in most newborns. Jaundice at birth suggests other metabolic derangements, as the maternal-fetal circulation protects the newborn from normal heme catabolism. Typically, the level of serum unconjugated bilirubin remains below 5 mg/dL (85 μM), however when levels exceed 20 mg/dL (340 μM) then the developing basal ganglia and other central nervous system structures are susceptible to toxic bilirubin deposition, known as kernicterus. This pigment is grossly evident at autopsy when the brain is sectioned. Brain damage can be severe, and the auditory tracts are particularly susceptible. Hypothyroidism (cretinism) delays the development of UGT1 activity, potentiating kernicterus. Newborns also may have increased hemolysis, particularly if ABO incompatibility exists, which aggravates neonatal jaundice. Certain agents, including chloramphenicol, vitamin K, and perhaps even free fatty acids in mother's milk, may further impair UGT1 activity. Subjective clinical assessment of bilirubin levels frequently is made based on the intensity and distribution of jaundice (which is usually most pronounced over the head and upper body), but these estimates have been shown to be unreliable. Intense visible light phototherapy commonly is employed for infants at risk to covert the unconjugated bilirubin to more soluble forms, as described above. The HO-1 inhibitor, tin-protoporphyrin soon may be used widely to inhibit bilirubin formation in neonatal jaundice.

Three clinically distinct forms of unconjugated hyperbilirubinemia are attributable to mutations in UGT1 (Gilbert's syndrome and Crigler-Najjar syndrome, types I and II). Gilbert's syndrome is defined clinically as the presence of persistent, mild, unconjugated hyperbilirubinemia ranging from 1 to 3.5 mg/dL (17 to 60 μM), and has a prevalence of 5% to 10% (Table 21.13). This level of hyperbilirubinemia is of no physiologic consequence unless the patient is exposed to a heme bolus, as most commonly occurs when the patient has coexisting glucose-6-phophate dehydrogenase deficiency. Psychological or physiologic stress also can exacerbate the jaundice. The severity of neonatal jaundice has been linked to hetero- or homozygosity of common UGT1 alleles that also cause Gilbert syndrome. Often, occult hemolysis must be ruled out in the evaluation of Gilbert syndrome. A helpful diagnostic challenge is to monitor unconjugated bilirubin, which rises after a prolonged fast or caloric restriction in the Gilbert syndrome, but not in the case of occult hemolysis. The uncommon Crigler-Najjar syndrome type II results in higher, but still nontoxic levels of hyperbilirubinemia, ranging from 3. to 20 mg/dL (60 to 340 μM). In both Gilbert syndrome and Crigler-Najjar syndrome type II, there is a relative abundance of monoconjugated bilirubin. UGT1 activity in these patients is inducible by phenobarbital. In contrast, no UGT1 activity is inducible in the rare Crigler-Najjar syndrome type I (see Table 21.14 and Table 21.15). These patients have severe hyperbilirubinemia

over 20 mg/dL (<340 μM), but liver function tests are otherwise normal. These patients generally succumb to kernicterus in childhood. Phototherapy has diminishing value in older children because of their thicker skin, so plasmapheresis or exchange transfusions may be employed to manage these patients.

TABLE 21.13. GILBERT'S SYNDROME

Epidemiology:

~5% of population

Pathophysiology:

Deficiency and or impairment of UDP glucuronyl transferase – 1

Clinical presentation:

Asymptomatic or occasionally with jaundice under stress

Laboratory findings:

Increased total bilirubin < 6 mg/dL, with low direct bilirubin

Transaminase, alkaline phosphatase, albumin, PT and PTT normal

Differential diagnoses:

Acute hepatitis or hepatotoxicity

TABLE 21.14. CRIGLER-NAJJAR SYNDROME TYPE I

Epidemiology:

Rare

Pathophysiology:

Impairment of UDP glucuronyl transferase – 1

Clinical presentation:

Severe jaundice, typically resulting in kernicterus.

Laboratory findings:

Increased total bilirubin above 20 mg/dL, with undetectable direct bilirubin.

Total bilirubin unchanged after phenobarbital ingestion

Transaminase, alkaline phosphatase, albumin, PT and PTT normal.

Differential diagnoses:

Crigler-Najjar syndrome type II

TABLE 21.15. CRIGLER-NAJJAR SYNDROME TYPE II

Epidemiology:

Rare

Pathophysiology:

Deficiency and or impairment of UDP glucuronyl transferase – 1

Clinical presentation:

Mild-moderate jaundice, exacerbated under stress

Laboratory findings:

Increased total bilirubin between 6 and 20 mg/dL, with low to undetectable direct bilirubin

Total bilirubin diminishes after phenobarbital ingestion

Transaminase, alkaline phosphatase, albumin, PT and PTT normal

Differential diagnoses:

Crigler-Najjar type I, Gilbert's syndrome complicated by hemolytic anemia

TABLE 21.16. DUBIN-JOHNSON SYNDROME

Epidemiology:

Rare, except among Sephardic Jews

Pathophysiology:

Impairment of cannicular mixed organic ion transporter

Clinical presentation:

Mild to moderate jaundice, red to brown urine

Laboratory findings:

Increased direct bilirubin ranging from 3–15 mg/dL

Total bilirubin unchanged after phenobarbital ingestion

Urinary coproporphyrin I levels can distinguish heterozygotes from homozygotes

Transaminase, alkaline phosphatase, albumin, PT and PTT normal

Differential diagnosis:

Rotor syndrome

Conjugated Hyperbilirubinemia

Whenever there are defects with hepatic excretion or post-hepatic obstruction, conjugated bilirubin levels generally will rise before unconjugated levels. If more than 50% of the total bilirubin is direct, the condition is termed conjugated hyperbilirubinemia. Clearly, many patients will not fit into either the unconjugated or conjugated hyperbilirubinemia definitions, especially as disease progresses. When conjugated bilirubin is elevated, the urinary bilirubin also may be increased. Hepatocellular diseases and cholestasis also may be accompanied by elevations of alanine and aspartate transaminases and alkaline phosphatase. Relative elevations of the transaminases and alkaline phosphatase are most helpful in distinguishing these etiologies. Typically, hepatocellular disorders produce a disproportionate elevation in transaminases and a slight or modest rise in alkaline phosphate and 5-nucleotidase (hepatocellular pattern) whereas obstructive jaundice (from etiologies such as cholelithiasis, tumors, or other causes) produces a more marked increase in alkaline phosphatase and 5-nucleotidase than in the transaminases (obstructive pattern). Intrahepatic cholestasis usually presents with an obstruction enzyme pattern, but elevated transaminases resembling hepatocellular disease may be observed or in other cases, a mixed enzyme pattern may occur.

Dubin-Johnson syndrome (see Table 21.16) is characterized by persistent, mild, conjugated hyperbilirubinemia ranging from 3 to 15 mg/dL (51 to 255 μM). It is as common as 0.1% in select populations, such as Persian Jews. The condition generally is benign, but stress and oral contraceptive use can exacerbate the jaundice. On autopsy, these patients have black livers resulting from the accumulation of hepatocyte lysosomal pigment, yet other liver function tests are normal. The disorder probably results from mutations in the CMOAT gene. Increasing levels of coproporhyrin I in the urine distinguish hemozygotes from heterozygotes and normals. Another very rare, benign, and unexplained causes of conjugated hyperbilirubinemia is the Rotor syndrome. Lower levels of coproporhyrin I in the urine distinguish Rotor syndrome patients from Dubin-Johnson heterozygotes.

SCOPE OF CLINICAL TOXICOLOGY AND THE ROLE OF THE TOXICOLOGY LABORATORY

Part of "22 - Toxicology"

Clinical toxicology in laboratory medicine can be defined as the analysis of drugs in human biological fluids for the purpose of patient care. The two traditional clinical toxicology services provided by clinical laboratories are therapeutic drug monitoring and emergency toxicology. Therapeutic drug monitoring, which is the measurement of serum drug concentration to aid in optimizing drug therapy, is the topic of another chapter. Emergency toxicology is the accumulation of laboratory data to assist in the diagnosis and treatment of poisonings resulting from self-poisoning, accidental ingestion, or exposure.

Because of the complexity of the diagnosis and treatment of poisoning and substance abuse, a team effort involving the clinical staff and laboratory personnel is required. In the emergency department, the clinician first makes an assessment based on history and physical examination, and the patient is treated symptomatically to support vital signs and vital functions. Toxicological data, if available at this point, can influence the diagnosis and subsequent treatment of the patient. If the patient is obtunded or comatose, a drug history may not be available. Drug history, even if available, is frequently inaccurate. Hence, an emergency toxicology screen can validate drug history or identify drugs that are not previously suspected. In those cases where specific treatments are effective, expeditious laboratory identification of the toxic agents is invaluable for prompt institution of treatment: for example, the initiation of N-acetylcysteine therapy for acetaminophen overdose, hemoperfusion for massive barbiturate overdose, or administration of ethanol or 4-methylpyrazol for methanol and ethylene glycol poisoning. A drug screen that fails to identify specific toxic agents still is an important laboratory result because it will influence the clinician to evaluate the differential diagnosis and to explore other diagnostic studies to explain the patient's clinical presentation. The determination of serum drug levels can, in some instances, help to gauge the severity of intoxication and prognosis. Ensuing determinations can be useful in monitoring and evaluating the effectiveness of the treatment procedure.

In the last few years, the widespread abuse of illicit drugs has placed additional demands on the health-care system. Consequently, clinical toxicology laboratories have moved beyond their traditional activities and now are routinely performing urine testing of drugs of abuse for other clinical services such as obstetrics for pregnant drug abusers, pediatrics for their newborns, and drug-dependency treatment programs. Such testing usually focuses on a small panel of the most frequently abused drugs such as cocaine, cannabinoids, and the benzodiazepines, rather than the broad-spectrum screening performed in emergency toxicology (1, 2).

Pregnant patients with a chemical dependency, particularly that of cocaine, are at high risk for obstetric complications (3). Urine testing for drugs of abuse provides evidence for the diagnosis of drug dependency and subsequent monitoring of drug use during the course of the pregnancy. For babies born of drug-dependent mothers, there is a higher risk of congenital malformations and neurobehavioral impairment (4). Therefore, early identification of their addiction not only allows better medical care; it will also permit prompt social evaluation and intervention. Urine drug testing is an objective way to identify these infants. However, because urine collection for infants is difficult and drug concentration is low, urine screening probably underestimates the number of babies at risk. Recent data suggested that testing for drugs in meconium and hair can be alternate approaches (5, 6 and 7).

In many localities, the hospital, upon the demonstration of illicit drug in an infant's urine, may be required to report it to a governmental agency. This may trigger a sequence of events that in extreme cases may result in the removal of the infant from the mother's custody. While the mother's family and social environment are important considerations, the confirmed positive urine drug test result frequently is the overriding medical evidence in this contest of custody. In these instances, the clinical toxicology testing has taken on an additional evidentiary role. Therefore, the laboratory must be prepared to defend its data against challenges.

The emphasis on treatment and rehabilitation of chemical dependency has resulted in increased enrollment in drug treatment programs. Many clinical toxicology laboratories now routinely perform urine testing in support of the diagnosis of these patients' chemical dependency (2). Urine testing also is an adjunct to the counseling and management of these patients by monitoring their progress during rehabilitation. Enrollment in drug treatment programs is not always voluntary. A drug-addicted employee may have enrolled because his employer's substance abuse policy mandates that all employees with a drug problem must be rehabilitated as a condition for continued employment. Successful rehabilitation is evidenced in part by negative drug

test results obtained during and after the treatment program. Therefore, although the toxicology laboratory is performing testing for medical reasons, test results ultimately may be used for administrative purposes, and the potential for legal challenge by dismissed employees is real.

Some clinical toxicology laboratories have extended their expertise in drugs of abuse testing into the new arena of workplace drug testing. This is nonmedical testing, and is a departure from the traditional mission of clinical toxicology. The forensic nature and specific requirements of workplace drug testing are discussed at the end of this chapter.

TOXICOLOGY SERVICE

Part of "22 - Toxicology"

Cost constraints and staffing problems limit the kind of toxicology service a laboratory can provide. The laboratory has to design a drug screen that is cost-effective and one that still can meet the basic needs of clinicians. Furthermore, programmatic issues that need to be considered include what drugs comprise a drug screen, which assays should be qualitative or quantitative, what type of sample is required, when the specimen should be obtained, and how much time is involved in completing a drug screen.

Drug Lists

The ideal laboratory will be one that can analyze for any drug the clinician might encounter, and can do so in the shortest turnaround time. In reality, this goal is difficult to achieve. Methodologies for many drugs are not suitable for a clinical toxicology laboratory, either because they require costly and sophisticated instrumentation, or the turnaround time is too long for them to be clinically useful. Even in laboratories blessed with experienced staff and advanced instrumentation, the financial and personnel requirements for performing timely, comprehensive drug screening are prohibitive. Therefore, a drug screen should be one that is designed to detect a shorter list of drugs, the selection of which is based on the prevalence of these drugs in the population served by the emergency department, the clinical usefulness of their early identification, and the ability of the laboratory to perform the analyses within an acceptable turnaround time. This list should be determined jointly by the emergency department and the laboratory. For example, a very basic clinical toxicology service may include screening tests for ethanol, salicylate, acetaminophen, barbiturates, tricyclic antidepressants, digoxin, cocaine, and opiates. In addition, serum iron, carboxyhemoglobin, and methemoglobin usually are analyzed in the clinical chemistry laboratory. Any additional drugs that have a high prevalence in the locality also should be included. The importance of turnaround time for a drug screen is related directly to the impact the results have on patient management. Therefore, these drug tests are recommended to be available on an immediate (stat) basis. With additional resources and expertise, the laboratory may enlarge its service to include other drug assays: e.g., amphetamines, benzodiazepines, phenothiazines, and sedative-hypnotics. The laboratory should encourage clinicians to inquire about drugs that are not on this list and whether the laboratory or a reference laboratory can detect these drugs.

Analytical Approaches

A drug screen is a compromise among rapid turnaround time, analytical specificity, and sensitivity, and it may be a combination of qualitative and quantitative analyses. An initial screen might be a targeted search for a small number of drugs by a series of tests, each of which is specific for a drug or group of drugs (e.g., spot tests or immunoassays). Obviously, this approach is restricted by the availability of specific methodologies. Moreover, the time required for these individual assays is cumulative, and the turnaround time rapidly deteriorates as the number of drug assays increases. If the number of drugs in a screen is to be expanded, a broad-spectrum screen using a methodology such as thin-layer chromatography or gas chromatography can be employed at the expense of lower sensitivity compared to immunoassays.

Specimen Types And Quantitation

The specimens most frequently submitted for analysis are urine, blood, serum/plasma, and gastric fluid. Drug screens in most clinical laboratories are performed on urine. The advantage of urine is that a large volume can be obtained, allowing analysis of drugs in low concentration. Urine, however, contains metabolites, which may complicate identification. For those drugs that are extensively metabolized, the parent drug may not be present; therefore an assay should be chosen that would identify the metabolites that are present in the greatest concentrations. Urine tests are qualitative, as drug concentrations in urine correlate poorly with clinical effects. Blood (and serum or plasma), although limited by sample volume, is the specimen of choice for quantitative analysis of those drugs for which there is correlation between drug level and toxicity. Quantitative tests usually are more time consuming. If knowledge of a specific level does not influence patient management, quantitation should not be performed. Some tests that provide useful quantitative information include those for acetaminophen, alcohols, salicylate, barbiturates, phonation, theophylline, lithium, digoxin, and iron. Quantitative level, however, can be misleading for drugs for which tolerance can develop. For example, a supposedly lethal barbiturate level for a novice user may be well tolerated by a chronic barbiturate abuser. First gastric aspirate, vomitus, or stomach washings are appropriate specimens if they are obtained soon after ingestion and particularly if pill fragments are noted. Analysis of gastric contents offers no advantage over urine or serum and is not recommended. Moreover, drugs that are absorbed rapidly or that are not taken orally will not be detected.

Accuracy

Although much emphasis has been placed on the rapidity with which a drug screen can be performed and reported, the importance of accuracy needs to be addressed (8, 9 and 10). The analytical methods used in performing a drug screen, including colorimetric assays, immunoassays, thin-layer chromatography (TLC), and gas chromatography (GC) do not necessarily give unequivocal identification of a drug. Some assays are group-specific rather than analyte-specific (e.g., an immunoassay for the opiates

rather than morphine). Some chromatographic methods do not separate isomers (e.g., quinine and quinidine by TLC and GC) or closely related drugs (e.g., the tricyclic antidepressants by GC). Hence there is a need for confirmation of a presumptive positive result obtained by the screening test.

Repeat analysis of the presumptive positive specimen using the same screening test method does not constitute confirmation, although it does serve to reduce random error. Confirmation requires testing a new aliquot of the original specimen using a technique, which is based on a different analytical principle and has greater specificity and at least equal sensitivity to that of the initial test. For example, a presumptive positive result obtained by an immunoassay for opiates cannot be confirmed by a second opiate immunoassay; TLC, which can specifically identify the opiate involved, can confirm it.

While confirmation testing is mandatory in forensic toxicology, in clinical toxicology, where rapid turnaround time to support a diagnosis of a suspected drug overdose is required, it is not always possible to meet these requirements. The clinical laboratories routinely report presumptive positives, but interpretation by the clinician is done within the context of both clinical and other laboratory findings. The laboratory, however, should make every attempt to do confirmatory testing whenever possible. The laboratory report must state accurately whether the positive result is a confirmed positive or an unconfirmed (presumptive) positive so that clinicians can properly evaluate toxicology results.

METHODOLOGIES

Part of "22 - Toxicology"

Spot Tests

Spot tests are among the simplest, most rapid, and inexpensive screening tests. Urine or serum is added directly to the reagents either in a test tube or on a white tile or porcelain dish. The formation of a color product indicates the presence of a specific drug, but more often, a class of drugs (e.g., a positive Folin-Ciocalteu test for phenolic compounds). Proper interpretation of a color test should take into account that a range of color is possible (e.g., phenothiazines give red range, blue, or violet colors with the Forrest reagent). Colors may vary depending on the conditions of the test, the amount of substance present, and the presence of other drugs and extraneous material. A positive test should trigger more definitive testing. Examples of spot tests routinely performed in clinical and forensic laboratories are in Table 22.1 (11).

TABLE 22.1. SPOT TESTS[a]

Drug(s)	Test	Comments
Volatiles (U,S)[b]	Dichromate	Alcohols and aldehydes
Salicylates (U,S)	Trinder's	Positive after therapeutic doses
Acetaminophen (U)	Cresol-ammonia	Positive after therapeutic doses
Phenothiazines (U)	FPN	Color and sensitivity vary with Phenothiazine
Imipramine/desipramine trimipramine (U)	Forrest	Interfered by some phenothiazines
Ethchlorvynol (U,S)	Diphenylamine	Good sensitivity and specificity

[b] U, urine; S, serum; FPN, fixed pattern noise.

Immunoassays

The immunoassays most frequently used in clinical laboratories are enzyme immunoassays (EMIT), fluorescence polarization immunoassays (FPIA), cloned enzyme donor immunoassay (CEDIA), and agglutination immunoassay (ONLINE). These assays have sensitivity more than adequate for drug overdose situations, and, being homogeneous assays requiring no preliminary extraction required before analysis, they can give test results rapidly. Moreover, they are automated easily.

A drug screen using immunoassays is a combination of individual tests. Although each individual test is fast, the time required for several accumulates. In addition, the spectrum of drugs that can be detected in such a screen is limited by assay kit availability. The immunoassay kits are designed specifically for use with either urine or serum/plasma. When a kit is used with a different matrix (e.g., using a urine assay to analyze blood), the laboratory needs to validate this modification (12).

In recent years, single-use devices, each of which consist of a panel up to seven or eight drugs, have become the mainstays of urine drug screen for many laboratories (13, 14 and 15). They offer the advantage of near-patient testing with results available in minutes, instead of the much longer turnaround time associated with laboratory-based drug screens. Most of these devices have been designed to meet the needs of workplace drug testing. Therefore, they may only consist of assays for the five drug classes (amphetamine and methamphetamine, cannabinoids, cocaine metabolites, codeine and morphine, and phencyclidine) with cutoffs mandated by the federal drug-testing program.

Most immunoassays are not specific for an analyte (16); many will detect a family of closely related compounds with different degrees of cross-reactivity. For example, the opiates assay will detect morphine, codeine, and related narcotics such as hydromorphone, hydrocodone and oxycodone. Therefore, a positive result will require additional testing (confirmation) to differentiate among members of this family. Workplace urine drug testing has been the driving force behind the development of more specific assays. For example, new amphetamine assays are highly specific for amphetamine and methamphetamine with much lower cross-reactivity with other sympathomimetics such as ephedrine. While this approach is intended to reduce the number of presumptive positives needing gas chromatography-mass spectrometry confirmation, the use of such an assay of limited specificity is less useful in clinical toxicology. The users of immunoassays should be familiar with assay specificities for proper interpretation of test results.

Thin-Layer Chromatography

The simplicity, reliability, and low cost of a TLC system are the reasons why this technique is widely used for drug screening and confirmation. Its selectivity of detection is enhanced through the

use of various stationary and mobile phases, and color development reagents (17). For larger laboratories, the ability to perform simultaneous analyses of several specimens is an advantage.

The disadvantage of TLC is lower sensitivity (usually greater than 1 mg/L) compared with GC or high-performance liquid chromatography (HPLC), although the limits of detection are adequate for a large number of commonly encountered drugs in overdose cases. TLC also has lower resolution compared with GC or HPLC, particularly when small size (10 cm) plates are used. Recent developments in high-performance TLC (HPTLC) have demonstrated improvement in both sensitivity and resolution. Despite the simplicity of TLC procedures, proper interpretation of a TLC chromatogram requires highly skilled and experienced personnel. A commercially available TLC system in kit form facilitates a broad-spectrum TLC screen by providing accelerated development and a systematic color detection scheme (TOXI-LAB, ANSYS Diagnostic, Lake Forest, CA)(18).

Gas Chromatography

GC, particularly when it is used with a capillary column, is a powerful tool for separating a mixture of drugs and it is the method of choice for volatile compounds (e.g., anesthetic gases, organic solvent, alcohols). It is less suitable for compounds of low volatility or those with polar functional groups. Careful choice of chemical derivatives can overcome these problems (19). More problematic are compounds that are thermally unstable (e.g., benzodiazepines). Although a wide choice of stationary phases is available, only a few are used commonly in drug analysis such as the roughly equivalently nonpolar dimethyl silicone phases of SE-30, OV-1, and OV-101, and the relatively more polar phenylmethyl silicone, OV-17. A single column of SE-30 (and its equivalents) or OV-17 can separate most of the drugs of interest, and is therefore sufficient for a drug screen. Separation has been advanced further by the use of capillary columns (20, 21). The higher efficiency of these columns results in tall, narrow peaks that improve detection limits. Among the detectors, the flame ionization detector (FID) responds with good sensitivity to nearly all classes of compounds with excellent linearity over a wide range of concentrations. The nitrogen-phosphorus detector (or NPD) has enhanced response to compounds containing nitrogen and phosphorous. Because most drugs contain nitrogen atoms, NPD particularly is useful for drug analysis and has sensitivity up to 100 times that of a FID. The electron capture detector (ECD) has very high sensitivity for compounds with high affinity for electrons such as those containing halogen, nitro, or carbonyl groups. The selectivity of the ECD and its high sensitivity makes it very useful for drugs such as benzodiazepines and phenothiazines, which are present in very low concentrations. The higher selectivity of this detector, however, makes it unsuitable for drug screening.

The use of a mass spectrometer (MS) as a GC detector provides sensitivity and specificity unsurpassed by other detectors. Mass spectrometry in combination with chromatographic separation is the most effective technique for identification of drugs (22, 23). The mode of ionization most widely used is electron impact (EI), which is the only mode available in the low-cost MS equipment. Because fragmentation can be quite extensive with EI, the molecular ion may not be detectable. Therefore, the molecular weight cannot be deduced. In chemical ionization, softer ionization results in less fragmentation, and a prominent molecular ion or quasi-molecular ion (frequently the base peak) allows molecular weight elucidation. Less fragmentation, however, means less structural information for unambiguous identification. Operation of an MS in the CI mode gives even higher sensitivity than EI, but the best performance will require more critical conditions.

Identification of unknowns by MS can be based on the computer matching of the unknown mass spectrum against those in commercially available mass spectral libraries. Alternatively, a laboratory can build its own library of the most frequently encountered drugs. The main disadvantages of MS—the complexity and cost of the instrumentation—have been addressed by the low-cost bench-top instruments that have been designed for routine analysis, multiple-operators, easy maintenance, and good reliability. These instruments have made GC-MS technologically accessible for many clinical laboratories. Still, GC-MS analysis is relatively costly in terms of equipment, personnel, and required time. It is not cost-effective for screening and is more suitable for confirmation testing. In forensic urine drug testing, confirmation by GC-MS analysis is the standard of practice and is mandated in government-regulated programs.

High-Performance Liquid Chromatography

HPLC is similar to GC in its ability to separate complex mixture of drug compounds and a variety of detectors (spectrophotometric, fluorometric, and electrochemical) that can be used to attain high sensitivity (24). HPLC has the advantage over GC in that polar compounds (e.g. drug metabolites) and those that are thermally labile can be analyzed. Until recently, HPLC has found its place in a toxicology laboratory mostly as an instrument for quantitative analysis of targeted groups of drugs (e.g., tricyclic antidepressants, benzodiazepines, barbiturates) rather than for broad-spectrum drug screen. Structural information helpful for identification of unknown compounds eluting from HPLC can be obtained using a photodiode array detector or mass spectrometer detector. An automated liquid chromatography (LC) system equipped with on-line extraction and analytical columns is available commercially with the capacity to identify more than 900 basic drugs and metabolites based on retention and scanning ultraviolet (UV) data (REMENDi HS, BioRad, Hercules, CA)(25, 26).

Recent improvements in interface design have led to the exciting prospect of LC-MS becoming a viable technology in a toxicology analysis, offering the capability to analyze polar compounds (many drug metabolites are) at pg/mL sensitivity level (27, 28)

An example of a TLC-based comprehensive drug screen is presented in Figure 22.1. The urine TLC screen is supplemented by a spot test for salicylate and four immunoassays. TLC does not adequately detect these analytes because these drugs are recovered poorly from urine extraction (salicylate and benzoylecognine) or present in low concentrations without prior hydrolysis of their conjugated metabolites (opiates and benzodiazepines). Urine that tests positive for one of the drugs

often will be processed for confirmatory testing. Quantitation in serum always is necessary for an alcohol; for some other drugs, serum levels may be informative and quantitation will be performed when indicated

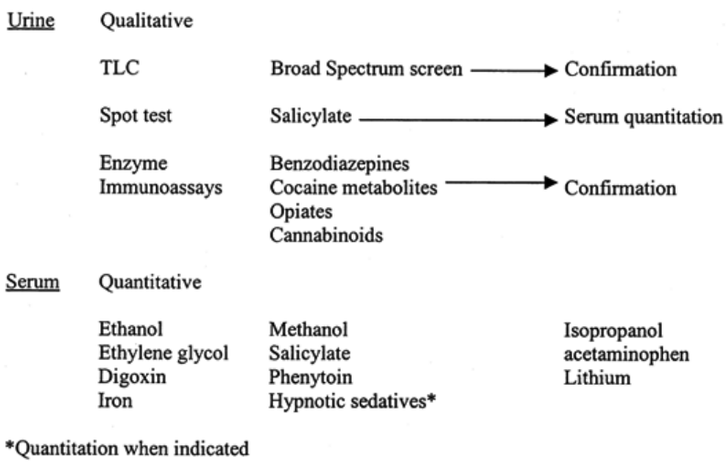

FIGURE 22.1. A thin-layer chromatography based comprehensive drug screen.

CLINICAL TOXICOLOGY OF SELECTED DRUGS

Part of "22 - Toxicology"

Ethanol

Ethanol is the most widely used social drug, and its abuse is one of the most important causes of injury and disease. Recent attempts to combat the problems of driving while under the influence of alcohol (DUI) have placed additional responsibilities on hospitals and clinical laboratories because the results of blood alcohol analyses, although obtained for medical reasons, may be used for legal purposes.

Ethanol usually is consumed in beers (3% to 6% ethanol), wines (10 to 12%), and distilled beverages (40% to 50%). The term “proof” means two times the percent of ethanol by volume. Ethanol is absorbed rapidly, and there is significant intersubject variability in the peak blood-alcohol concentration attained and the time for its achievement because of food intake and physiological variables (29). Ethanol distributes in total body water. Therefore, at equilibrium, ethanol concentration in any tissue or fluid is a function of the water content of that specimen. A plasma/blood ratio of 1.18 (range of 1.10 to 1.35), urine/blood ratio of 1.3, and breath/blood ratio of 2,407 (range of 1,981 to 2,833) have been determined (30, 31).

Ethanol is metabolized mostly by liver alcohol dehydrogenase to acetaldehyde at a rate that follows first-order kinetics at low concentration (less than 20 mg/dL). At higher concentration, metabolism proceeds at zero-order kinetics, which is independent of dose or initial blood-alcohol concentration. The average rate of metabolism is approximately 16 mg/dL/hr for men with significant variability (10 to 25 mg/dL/hr) and may be 10% to 20% lower for women (32). Individuals with high blood-ethanol concentration (greater than 3 g/L) have a rate of metabolism that is higher and more unpredictable (33).

Ethanol is a central nervous system (CNS) depressant. In intolerant subjects, ethanol-induced CNS dysfunction ranges from limited muscular incoordination at blood concentrations less than 50 mg/dL to coma, respiratory failure, and death at 400 mg/dL or higher. It is difficult to interpret blood levels in tolerant subjects; seemingly alert patients with ethanol levels in excess of 600 mg/dL have been reported.

Other diseases such as diabetic ketoacidosis and subdural hematoma can simulate the clinical signs of alcohol intoxication. Blood alcohols are ordered for the investigation of those patients who present with anion gap metabolic acidosis or those who are comatose. Medically, it may be desirable, or necessary, to know the patient's blood alcohol concentration before administrating anesthetics or medications.

Clinical toxicology laboratories are increasingly involved in the collection and analysis of blood for ethanol that subsequently has forensic implications. A set of guidelines has been developed in response to the need for information dealing with various aspects of blood-alcohol analysis (34).

Type of Specimen

Plasma or serum usually is analyzed in clinical laboratories. Most state laws on drinking and driving, however, define alcohol concentration in terms of whole blood. Alcohol concentration in whole blood is lower than in plasma or serum; the frequently used serum/whole blood ratio is 1.18 (34). The analysis of either serum or whole blood yields results with the same clinical significance. However, the difference between serum and whole-blood–ethanol concentration is significant in forensic analysis particularly when a “blood” alcohol result falls in the vicinity of a statutory threshold pertaining to drinking and driving. Conversion of results of alcohol analysis performed on serum or plasma to whole blood using a population mean ratio of 1.18 is discouraged; for legal purposes, it is best to analyze whole blood. Laboratories should identify the specimen type in their reports. Venipuncture sites should be cleansed by nonalcohol-containing disinfectant such as benzalkonium chloride or aqueous povidone-iodine. If analysis will be delayed for a few hours, sodium fluoride at 1% (higher for longer-term storage) is an effective preservative (34).

Urine is not a suitable specimen because blood-alcohol concentration cannot be established with sufficient reliability from

alcohol concentration of a pooled-bladder urine specimen and because of the great variability of the blood:urine ratio.

The use of breath and saliva for ethanol measurement has considerable appeal relative to blood (35, 36). Its advantages are the noninvasive nature of sample collection, the ease of test performance, and rapid turnaround time. Breath-alcohol test is based on Henry's Law, which states that in a closed system under constant temperature, the concentration of a gas above the liquid is proportional to the concentration of the gas dissolved in the liquid. The distribution of the gas in the gas and liquid phases is determined by the partition ratio. In the breath alcohol test, the assumption is that an equilibrium state exists between the alcohol in the blood perfusing the lung and that in the alveolar (breath). If the partition ratio for alcohol is known, blood-alcohol concentration can be determined indirectly by measuring alcohol concentration in breath. In forensic testing, a partition ratio of 2,100 has been adopted and used by measuring devices, although values have been reported to range from 1,981 to 2,833 (31). Careful considerations must be given to developing a quality-assurance program for POCT alcohol tests. Users of clinical breath-alcohol tests can benefit from the collective experience of the forensic community, which has extensive experience in breath-alcohol testing in traffic law enforcement (37).

The advantages of saliva testing are the noninvasive nature of sample collection, ready availability of saliva in sufficient quantity for analysis, and the ease of test performance (36). A device for measuring alcohol in saliva (STC Diagnostics, Bethlehem, PA) is based on enzymatic oxidation of alcohol by alcohol dehydrogenase. Saliva-alcohol results are in good agreement with alcohol concentrations in venous blood and end-expired breath, but insufficient sample volume was found to be a problem with highly intoxicated patients (36).

Analytical Methods

Many methods for alcohol analysis are in use in clinical laboratories (34). They can be grouped into the following categories:

1. Chemical oxidation of ethanol with acid dichromate.

   The reduction of dichromate is proportional to ethanol concentration. This is a nonspecific reaction; other alcohols and paraldehyde (as its metabolite acetaldehyde) also will give positive results. It is used in older breath analyzers.

2. Enzymatic oxidation using alcohol dehydrogenase (ADH).

$$C_2H_5OH + NAD^+ \xrightarrow{ADH} CH_3CHO + NADH + H^+$$

   The extent of interference by methanol and isopropanol depends on the source of ADH and can be minimized by careful choice of assay parameters. Enzymatic methods are simple and the most frequently used methods in clinical laboratories. Laboratories, however, must be prepared to investigate suspected ingestions of alcohols other than ethanol or the co-ingestion of ethanol and another alcohol.

3. Gas chromatography.

   Gas chromatography is the most specific method (38). It yields information on both the identity of the alcohol as well its concentration. For emergency analysis, direct injection of a diluted sample has the advantage that it eliminates the 15- to 30-minute equilibration period required for headspace analysis. The use of an internal standard (e.g., n-propanol) will improve precision.

Concentration Units

Many state laws on drinking and driving define blood-alcohol concentration as percent by weight/volume (% w/v). Clinical laboratories usually report alcohol results in concentration units of milligram alcohol per 100 mL (dL) of blood (or serum). An alcohol concentration of 100 mg/dL is equivalent to 0.1% w/v.

For breath alcohol testing in the clinical setting, the devices should display results in concentration unit of gram of alcohol per 100 mL of blood and not as gram of alcohol per 210 L of breath. Physicians and nurses are accustomed to reviewing medical laboratory test results in concentration units based on 100 mL of blood (or serum).

Methanol and Isopropanol

Methanol and isopropanol are important industrial chemicals that also are available as household items: methanol as a constituent of some antifreeze and windshield washer solutions; isopropanol as a disinfectant (30% to 99.9% solution) or as rubbing alcohol (70% solution). Intoxication with methanol and isopropanol can be from accidental ingestion, industrial exposure, self-poisonings, or as substitutes for ethanol.

Both methanol and isopropanol are absorbed readily following ingestion. They are metabolized by hepatic alcohol dehydrogenase at rates one tenth or less of that for ethanol. Methanol is oxidized to highly toxic formaldehyde and then to formic acid. Formic acid is much more toxic than methanol and accounts for the profound anion gap metabolic acidosis and its ocular toxicity. Formate levels (generally not available in clinical laboratories) are better correlated with poor outcome (39). Methanol toxic symptoms may include inebriation, headache, dizziness, seizure, and coma. Nausea, vomiting, stiff neck, abdominal pain, and malaise also are common complaints. After ingestion, methanol serum level peaks at about 2 hours, but there may be a latent period of about 24 hours when there is a deceiving lack of severe toxic manifestation but during which appropriate treatment is critical (40).

Isopropanol is metabolized to acetone, which accounts for the CNS effects and ketonemia. Toxic manifestations include CNS depression, lethargy, weakness, hypotension, and abdominal pain. Hemorrhagic tracheobronchitis and gastritis are characteristic findings. Clinical laboratory findings include ketonemia, ketonuria, and elevated osmolality. There is no metabolic acidosis. Treatment of isopropanol overdose mainly is supportive and most patients respond well. Patients with very high isopropanol levels (400 to 500 mg/dL) usually are associated with severe hypotension and coma and hemodialysis should be considered (40).

Because the toxicity of methanol is because of ADH-generated toxic metabolites, treatment involves competitive inhibition of ADH with a saturating concentration (100 to 150 mg/dL) of ethanol, the preferred substrate, and allowing the kidneys to eliminate methanol provided adequate urine flow is maintained (40).

Hemodialysis is indicated if methanol level is greater than 25 mg/dL and should be performed until methanol reaches undetectable levels. 4-Methylpyrazol, a specific inhibitor of ADH, is undergoing a clinical trial to assess its efficacy as an antidote for methanol and ethylene glycol poisoning (41).

The method of choice for the identification and measurement of methanol and isopropanol is GC. The GC methods for ethanol generally are also applicable to these two alcohols if acetone is adequately resolved from the alcohols (38). Low methanol levels are seen periodically in alcoholics after binge drinking. Ethanol inhibits methanol metabolism, allowing the accumulation of a small amount of methanol originating from endogeneous production or consumption of fermented beverages. As many as 6% of patients with ethanol levels greater than 100 mg/dL had serum-methanol levels of 4.5 mg/dL or more (42).

The popular enzymatic assay for ethanol will not detect methanol and isopropanol because of the weak enzyme activity when these alcohols are substrates. Toxic serum levels of these osmotically active substances, however, will result in a significant osmolal gap between measured osmolality and calculated serum osmolality, thus allowing the evaluation of an acute situation when specific assays for methanol and isopropanol are not available. A formula to estimate serum osmolality is (43):

[1.86 × Na (mmol/liter) + Glucose (mg/dl)/18 + BUN (mg/dl)/2.8] ÷ 0.93

The calculated osmolality is divided by 0.93 because serum is approximately 93% water. The measured osmolality must be determined by freezing-point depression osmometry (not by using a vapor-pressure osmometer). The expected contribution to measured osmolality of a serum-methanol concentration of 100 mg/dL is 31 mOsm/kg. Ethanol is the most common cause for elevation of serum osmolality. Users of this approach must be aware of its nonspecificity because other alcohols, acetone, and ethylene glycol also can raise serum osmolality if present in sufficient concentration.

Ethylene Glycol

Ethylene glycol is the principal component of antifreeze products and brake fluids. It is absorbed readily in the gastrointestinal tract and is metabolized by oxidization to glycolic acid, glyoxylic acid, and formic acid by alcohol dehydrogenase and glycolic acid oxidase (40). Ethylene glycol itself is only mildly toxic; its metabolites, however, are highly toxic (44). Persistent vomiting, and gradual onset of CNS depression appear within 4 to 8 hours and are accompanied by a large anion gap metabolic acidosis. A common urinalysis finding is the presence of calcium oxalate or hippurate crystals, which can lead to acute renal tubular necrosis developing within 12 hours to 2 days.

Treatment of ethylene-glycol poisoning consists of correction of metabolic acidosis, inhibition of metabolism by ethanol or 4-methylpyrazol, and hemodialysis. Hemodialysis rapidly clears both ethylene glycol and its toxic metabolites from the bloodstream and is recommended for patients who are symptomatic or have blood levels of ethylene glycol greater than 25 mg/dL (40).

There is no easy assay for ethylene glycol, and most clinical laboratories do not provide ethylene glycol analysis. Serum osmolality measurement and the calculation of the osmolal gap can provide a rough approximation of ethylene glycol concentration, but only if ethanol and other alcohols are known to be absent (43).

Early gas chromatographic methods, including those based on direct injection, were plagued by “trailing peaks,” “ghost peaks,” variable recovery, and interference by propylene glycol or 2,3-butandiol (present in serum of some alcoholics) (45). A recent GC procedure has improved precision and accuracy, and also can measure glycolic acid (46).

An enzymatic method is based on the action of glycerol dehydrogenase on ethylene glycol is rapid and easy to perform (47). The enzyme assay will not detect propylene glycol and it is not specific for ethylene glycol; known interfering substances include glycerol and 2,3-butandiol (48). Specimens containing high lactate dehydrogenase activity or lactate level will give false-positive results (49). For laboratories unable to maintain a chromatographic assay for ethylene glycol, the enzyme assay, despite its specificity limitation, is a clinically useful alternative. It has high negative predicative value in eliminating ethylene glycol from the list of etiologies causing unexplained metabolic acidosis.

Acetaminophen

Acetaminophen is an effective analgesic and antipyretic drug that lacks antiinflammatory action. It is available in pure form and also in combination with other drugs such as codeine and propoxyphene. It presents less risk for producing gastrointestinal ulceration and hemorrhage than aspirin and other nonsteroidal antiinflammatory drugs. With the reported link of Reye's syndrome to aspirin use, usage of acetaminophen as an over-the-counter medication has surpassed that of aspirin in recent years. At typical nonprescription doses of 325 to 1,000 mg every 4 hours, acetaminophen is a safe drug. At higher doses, acetaminophen is hepatotoxic, although toxic dosage is variable; liver damage may occur after single doses of 7.5 g or greater in healthy adults or 150 mg/kg in children (50). Individuals on other medications that are hepatotoxic or those who have liver diseases or who are alcoholics, however, will be susceptible to acetaminophen toxic effects at lower doses (51).

Acetaminophen after a therapeutic dose is eliminated mostly as glucuronide or sulfate conjugates. Following overdose, the conjugation pathways are saturated and formation of a highly reactive intermediate (probably N-acetyl-benzoquinoneimine) takes place via the cytochrome P-450 mixed-function oxidase system (52). This metabolite, normally detoxified by endogenous glutathione, reacts with and destroys hepatocytes once glutathione stores are depleted.

Acetaminophen is absorbed rapidly with peak plasma concentration reached within 30 to 120 minutes after therapeutic doses. Delayed peaks may occur with slower gastric emptying following large doses. Clinically, a patient overdosed on acetaminophen may present in four phases (50). In the initial phase, lasting 12 to 24 hours after ingestion, the patient usually exhibits gastrointestinal (GI) irritability, nausea, and vomiting. Some patients may be asymptomatic. During the second phase (24 to 72 hours postingestion) the patient may feel reasonably well while liver function tests prove abnormal. If significant hepatic

necrosis has occurred, the third phase (72 to 96 hours postingestion) is characterized by the sequelae of hepatic necrosis including coagulopathy, jaundice, and encephalopathy. If the patient survives phase 3, complete resolution of hepatic dysfunction will ensue (4 days to 2 weeks).

N-Acetylcysteine is an effective antidote. In the United States, the standard oral regimen consists of a loading dose of 140 mg/kg followed by 17 doses of 70 mg/kg every 4 hours. Treatment is most successful when started within 8 hours of ingestion, and its effectiveness appears to extend to those high-risk patients who are treated as late as 24 hours post ingestion (53). In Canada and Britain, intravenous administration over a 20-hour period is the approved protocol (150 mg/kg loading dose over 15 minutes followed by an additional dose of 50 mg/kg over 4 hours and then 100 mg/kg over 16 hours) (54). A nomogram relating time since ingestion, plasma drug concentration, and risk of hepatotoxicity is used in evaluating the need for *N*-acetylcysteine treatment (Fig. 22.2) (55). The nomogram is for use with acute ingestion only. It cannot be used to assess toxicty resulting from chronic misuse of acetaminophen. Because early treatment is critical to a favorable outcome, and initial plasma-drug concentration is a crucial deciding factor to initiate therapy, prompt and reliable measurement of plasma-acetaminophen level is an important emergency toxicology service. Numerous methods are available for the analysis of acetaminophen. Colorimetric tests such as the cresol-ammonia spot test (11) or the Glynn and Kendal method are fast and sensitive although the Glynn and Kendal method is interfered by salicylates. The colorimetric method based on the prior hydrolysis of acetaminophen and its conjugated metabolites to indophenol is

not recommended because the aforementioned nomogram is based on serum concentration of unconjugatd acetaminophen only (56). HPLC procedures, though simple and rapid, are not as convenient as the FPIA and EMIT methods that are available in most clinical laboratories.

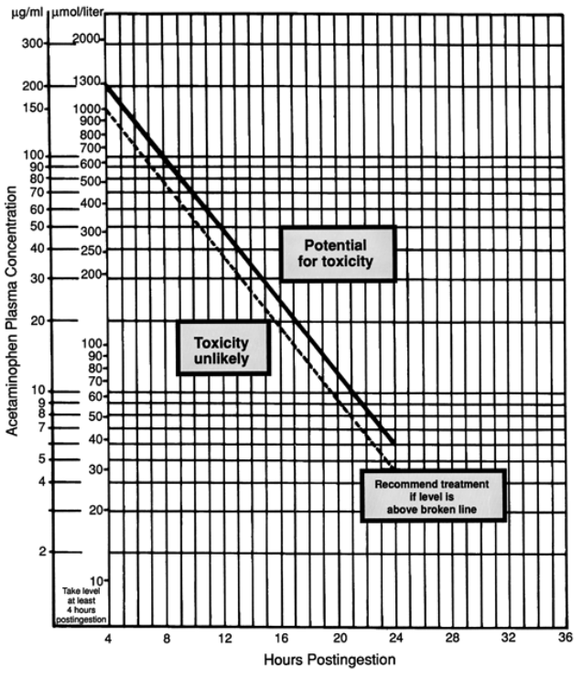

FIGURE 22.2. Nomogram relating acetaminophen plasma concentration, time since ingestion, and risk of toxicity. (Modified from Rumack BH, Matthew H. Acetaminophen poisoning and toxicity. *Pediatrics* 1975;55:871–876.)

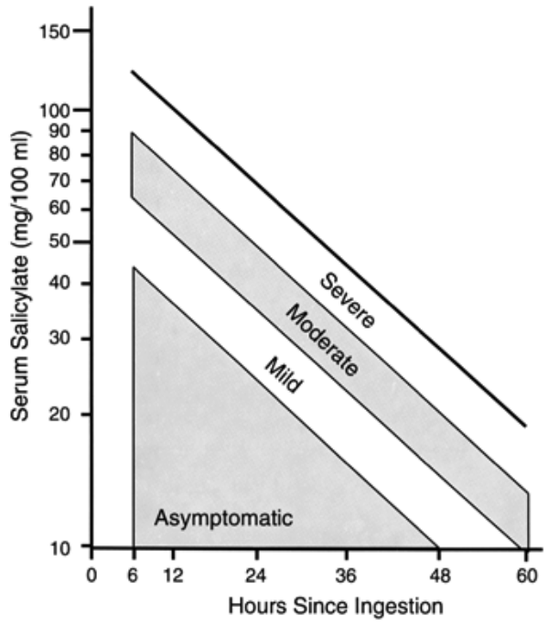

FIGURE 22.3. Nomogram for salicylate poisoning. (From Done AK. Salicylate intoxication. Significance of measurements of salicylate in blood in cases of acute ingestion. *Pediatrics* 1960;26:800–807.)

Salicylates

Salicylate, as one of the least expensive and most widely used drugs, has been the cause of many drug overdose cases, particularly in the very young and the elderly. Salicylate still ranks as a leading cause of childhood poisoning deaths and still is commonly used in self-poisoning by adults (57, 58). Many derivatives of salicylic acid are available commercially; the most important is acetylsalicylic acid (aspirin), which is hydrolyzed rapidly to salicylic acid, and circulates in the blood in the ionized form, salicylate. In serum, salicylate at therapeutic concentration is highly protein bound, and the extent of binding varies with total salicylate concentration. The major metabolic pathways of salicylate conjugation with glycine and with glucuronic acid are saturable. Thus, the half-life of elimination of salicylate as well as the serum level of salicylate will increase disproportionately with increasing dosage (57).

The primary pathophysiological effects of salicylism are complex (59). They include direct stimulation of the respiratory center resulting in hyperventilation, respiratory alkalosis and compensatory excretion of base, uncoupling of oxidative phosphorylation, interference with the Krebs cycle, and accumulation of organic acids leading to metabolic acidosis. In children, respiratory alkalosis is transient and a late-stage dominant metabolic acidosis is common. In adult patients, the most common acid-base disturbance is mixed respiratory alkalosis and metabolic acidosis. Associated with acid-base disturbances are fluid and electrolyte imbalance and dehydration. Other metabolic effects of salicylate toxicity are hyperthermia and impaired glucose metabolism with either hyperglycemia or hypoglycemia. In overdosed patients who are acidemic, the lower blood pH will increase the amount of nonionized salicylate (pKa = 3.0) for transfer into the CNS. Thus, CNS disturbances often accompany those intoxicated patients who are severely acidemic.

The toxic severity after acute ingestion is related to the amount of drug ingested. Ingestion of less than 0.15 g/kg is unlikely to result in toxic symptoms. Mild to moderate toxic reactions can be expected from an ingested dose of 0.15 to 0.39 g/kg and doses more than 0.3 g/kg lead to severe reactions. Ingestion of greater than 0.5 g/kg is potentially lethal. Chronic intoxication or therapeutic overdose is a result of excessive therapeutic administration of salicylate over a period of 12 hours or longer, and zero order kinetics lead to accumulation of salicylate in serum to toxic level (60). Chronic salicylate intoxication is a diagnostic problem particularly among elderly patients because the presenting symptoms often are ascribed to other causes. Thus, the intoxication often goes unrecognized, and as a result, appropriate therapy is delayed. These patients suffer significant morbidity and mortality.

Treatment for salicylate intoxication includes measures to prevent further absorption of salicylate and to correct the metabolic imbalances such as fluid and electrolyte depletion and acid-base disturbances. Alkalization with sodium bicarbonate to enhance the renal elimination of the drug should be considered in adults with serum salicylate level exceeding 50 mg/dL and children with levels greater than 35 mg/dL. If the salicylate level is greater than 100 mg/dL, and the patient is very ill or is unable to eliminate the salicylates, hemodialysis is indicated (59).

The availability of salicylate assay on an emergency basis is critical to confirm the clinical suspicion of acute salicylate intoxication. Diagnosis of chronic salicylate intoxication, particularly in the elderly, is much more difficult without a high degree of suspicion because patients may have become drowsy and confused and are unable to offer a reliable drug history. Therefore, documentation of elevated serum salicylate levels becomes very important in the differential diagnosis (57).

A nomogram (Done's nomogram) (62) has been constructed to facilitate the interpretation of salicylate levels at different intervals after ingestion in order to predict the severity of intoxication (Fig. 22.3). The clinical value of the nomogram is limited because it was based on data from a pediatric population after a single acute ingestion of regular formulation (63). It does not predict the rate of salicylate elimination or future serum salicylate levels and it is not applicable for assessing the severity of chronic salicylate intoxication.

If the ingested salicylate is of an enteric-coated or sustained-released formulation, the absorption of salicylate will be delayed. The diagnosis of salicylate intoxication based on an elevation of serum level on admission can be missed because of delayed absorption (64). If ingestion of enteric-coated or sustained-release salicylate is suspected, the patient must be observed for at least

24 hours, and serum salicylate determination should be repeated. Peak salicylate level may not be attained until 60 to 70 hours postingestion.

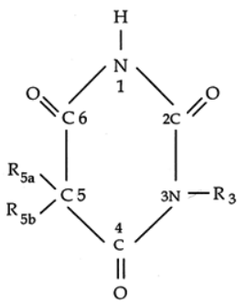
Simple qualitative screening tests such as ferric chloride and Trinder's reagent for urine salicylate are useful for quick confirmation of salicylate overdose if quantitation of serum levels is not available immediately. All positive results should be confirmed using quantitative assays and serum samples (57).

The majority of salicylate assays in use are colorimetric assays based on the reaction of salicylic acid with ferric ion in acid medium to give a purple color complex (56, 57). This simple and rapid reaction is not specific for salicylate; metabolites of salicylate, ketone bodies, catechols such as tyrosine and the catecholamines Ketone bodies and catecholamines frequently are elevated in disease states that are associated with metabolic derangement, such as ketoacidosis and Reye's syndrome. Salicylate concentrations of these patients that are measured by a colorimetric method can be falsely high (65). Colorimetric assays have proven acceptable for the routine clinical use of salicylate levels in the diagnosis of salicylate intoxication. The assay based on Trinder's method (66) is the most commonly used, although newer techniques such as FPIA, HPLC, and enzymatic assay using salicylate hydrolase are available.

A different approach to the measurement of salicylate is the use of the enzyme salicylate hydrolase (EC 1.14.13.1) purified from *Pseudomonas cepacia* (67, 68 and 69). This enzyme, in the presence of reduced nicotinamide adenine dinucleotide (NADH) or reduced nicotinamide adenine dinucleotide phosphate (NADPH), converts salicylate to catechol. Salicylate concentration can be determined by monitoring, photometrically, the consumption of NADH (67) or the formation of catechol (68, 69). Compounds that are known to interfere with the colorimetric assays do not affect the enzymatic methods.

Barbiturates

Barbiturate poisoning either by accident or more often in suicide attempts was a major health problem in the past. It has lessened in recent years because their use as anxiolytics has been replaced by the safer benzodiazepines; medical use of barbiturates now is primarily for treatment of insomnia and convulsive disorders, and as anesthetic and preanesthetic medications. The barbiturates are derivatives of barbituric acid (Fig. 22.4). Pharmacologically, they can be divided broadly into ultra-short (e.g., thiopental), short- to intermediate- (e.g., secobarbital and butalbital), and long-acting groups (e.g., phenobarbital) depending on their duration of action (70). Drug abusers prefer the short- to immediate-acting barbiturates because of the relative rapid onset of action (15 to 40 minutes). Duration of drug action, which may last up to 6 hours, is dependent on lipid solubility. Thus, the short-



Generic (trade) name	R5a	R5a	t1/2(h)	pKa
Methohexital(Brevital)	-CH2-CH=CH2	-C(CH3)-C°CH2-CH3	1-2	7.9
Thiopental(Pentothal)	-CH2-CH3	-CH(CH3)-CH2-CH2-CH3	4-60	7.6
Amobarbital (Amytal)	-CH2-CH3	-CH2-CH2-CH(CH3)2	15-40	7.9
Pentobarbital(Nembutal)	-CH2-CH3	-CH(CH3)-CH2-CH2-CH3	20-30	7.9
Secobarbital(Seconal)	-CH2-CH=CH2	-CH(CH3)-CH2-CH2-CH3	22-29	7.9
Butabarbital(Butisol)	-CH2-CH3	-CH(CH3)-CH2-CH3	34-42	7.9
Butalbital(Fiorinal)	-CH2-CH=CH2	-CH2-CH(CH3)2	35-88	7.6
Phenobarbital(Luminal)	-CH2-CH3	-C6H5	48-144	7.2

R3 = H, except methohexital when R3 = CH3

FIGURE 22.4. Common barbiturates.

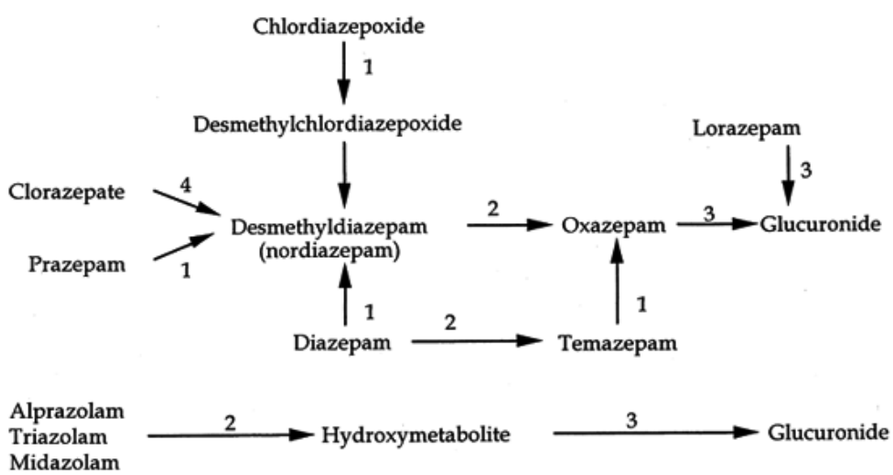


FIGURE 22.5. Major biotransformation pathways of common benzodiazepines. 1, dealkylation; 2, hydroxylation; 3, glucuronidation; 4, decarboxylate.

acting barbiturates have higher lipid solubility, greater potency, and more rapid clearance from the central compartment. In contrast, the long-acting barbiturates have less lipid solubility, lower potency, and much longer half-lives of elimination.

The barbiturates are weak acids with pKa values ranging between 7.2 and 7.9. Hence, at pH 7.4 a barbiturate such as phenobarbital (pK = 7.2) will be about 40% nonionized, whereas secobarbital (pK = 7.9) is 76% nonionized and therefore is more lipid soluble and more rapidly distributed to tissues.

The major actions of the barbiturates are their depressant action on the CNS and cardiovascular system. Acute barbiturate intoxication is characteristically associated with coma and shock; the former must always be differentiated from other forms of coma or CNS injury. Plasma barbiturate levels may be helpful in making a diagnosis, but they are of limited value in predicting the severity of the overdose or the duration of the coma, which are related more closely to brain than plasma barbiturate concentration. In addition, chronic barbiturate users are expected to have higher plasma concentration for any grade of coma because of the tolerance they have developed. Moreover, the depth of coma can be greater than might be expected from plasma concentration if other CNS depressants, such as alcohol, also have been ingested.

Treatment of barbiturate intoxication consists of aggressive support to combat shock and hypoxia in addition to lavage and charcoal treatment. Alkalization of urine to pH 7.5 to 8.0 with sodium bicarbonate will increase the fraction of ionized drug and will enhance excretion in urine. This is helpful for long-acting barbiturates because their principal means of elimination is renal. Alkalization is less effective for short-acting barbiturates because they have higher pKa values, are more highly protein-bound, and they are metabolized primarily by the liver (70).

Immunoassays detect barbiturates as a group and provide rapid results. Barbiturates other than the one used as the assay calibrator may have different cross-reactivities to the assay antibody. For example, an enzyme immunoassay that uses secobarbital as the calibrator will detect the less reactive phenobarbital only at much higher concentrations.

Identification of the specific barbiturate(s) requires chromatographic separation. TLC can effectively separate phenobarbital from other barbiturates, but the short- and intermediate-acting group (amobarbital, butabarbital, butalbital, secobarbital, and pentobarbital)– have similar migration, and identification requires skill and experience (18). Gas chromatography and HPLC methods for identification of the commonly encountered barbiturates are available (71, 72), and mass spectral identification of the barbiturates must be done with care because these drugs are structurally similar and yield similar spectral data (73).

The benzodiazepines are among the most frequently prescribed drugs. They vary in their potency in anxiolytic, hypnotic, muscle relaxant, anticonvulsant, and anesthetic effects. One useful classification of the benzodiazepines is according to their half-lives: long (greater than 24 hour), intermediate-short (5 to 24 hours) and ultra short-acting (less than 5 hours) (Table 22.2). A long-acting benzodiazepine such as diazepam is well suited as an anxiolytic agent, whereas a short-acting benzodiazepine such as triazolam is more appropriate as a hypnotic (70).

TABLE 22.2. COMMON BENZODIAZEPINES

Generic Name	Trade Name	Half-life (hr)
Diazolobenzodiazepines		
Chlordiazepoxide	Librium	6–27
Diazepam	Valium	21–37
Oxazepam	Serax	4–11
Clorazepate	Tranxene	2
Flurazepam	Dalmane	2–3
Lorazepam	Ativan	9–16
Temazepam	Restoril	3–13
Halazepam	Paxipam	14–16
Prazepam	Centrax	1.3
Triazolobenzodiazepines		
Alprazolam	Xanax	10–12
Trialzolam	Halcion	2.6
Midazolam	Versed	1–4

Benzodiazepines also are useful for treating neuromuscular diseases, sleep disorders, seizure, drug withdrawal, and as pre-anesthetic agents. Continuous use has led to tolerance, addiction, dependence, and abuse (74).

All the benzodiazepines are metabolized and cleared by the kidney as glucuronides or sulfates. Many of the metabolites are active, and some benzodiazepines such as clorazepate and flurazepam are considered to be prodrugs (Fig. 22.5). The major biotransformation routes are demethylation (e.g., chlordiazepoxide, temazepam) and hydroxylation (diazepam, nondiazepam).

With the popularity of these drugs, overdose is a frequent occurrence, yet fatalities resulting from benzodiazepines alone are very rare (75). Patients intoxicated with benzodiazepines are sedated and side effects include respiratory depression, weakness, headache, blurred vision, nausea, and diarrhea. Serious intoxication with benzodiazepines usually results from co-ingestion with other CNS depressants (e.g., ethanol). Therefore, in the evaluation of a patient suspected of benzodiazepine intoxication, it is important to investigate if other drugs also have been ingested. Plasma benzodiazepine concentration does not predict the severity of intoxication or outcome. A specific benzodiazepine antagonist, flumazenil, has been reported to effectively reverse benzodiazepine-induced CNS symptoms. Its benefit, however, must be weighed against the risk of precipitating acute benzodiazepine withdrawal, or seizure among patients who also may have taken seizure-causing drugs such as the cyclic antidepressants (76).

Benzodiazepine levels in blood and plasma can be determined by HPLC or GC assays (77, 78). Some benzodiazepines, such as chlordiazepoxide and oxazepam, are heat-labile, and are more suitable for HPLC analysis. GC methods using electron capture or mass spectrometer detection have the best sensitivity capable of detection of triazolo-benzodiazepines at low ng/mL levels, whereas those dependent on FID detection are adequate for drug levels in the high therapeutic or toxic ranges. TLC does not easily detect benzodiazepines without prior acid hydrolysis to form benzophenones, which are strongly fluorescent (79). Specific identification is not possible because different benzodiazepines can form the same benzophenone. Also, some benzodiazepines

(e.g., alprazolam and triazolam) are stable to acid hydrolysis and are not converted to benzophenones.

Commercially available immunoassays for benzodiazepines in urine or serum are designed to detect oxazepam or nordiazepam, metabolites that are common to several benzodiazepines (Fig. 22.5). Immunoassays have sufficient cross-reactivity with many of the newer benzodiazepines to detect therapeutic levels of some (e.g., alprazolam), but only higher levels for others (e.g., triazolam) (78, 80, 81).

Cyclic Antidepressants

The cyclic antidepressants are a major cause of life-threatening drug overdose, and are responsible for more deaths than any other drug classes except the analgesics (58). Drugs in this class of commonly prescribed antidepressants include the tricyclic compounds, such as imipramine, desipramine, trimipramine, amitriptyline, nortriptyline, doxepin, and loxapine, the tetracyclic compounds maprotiline and miaserin, and the bicyclic fluoxetine. Trazadone, a triazolopyridine, and amoxapine, a dibenoxapine, while structurally unrelated to the tricyclic compounds, often are classified or described with them. These cyclic compounds are rapidly absorbed by the GI tract, but absorption may be delayed at higher blood levels as a result of the anticholinergic effect of delayed gastric emptying. The volumes of distribution of these drugs are large (10 to 50 liters/kg) and extent of binding to plasma protein is high (greater than 90%). There is extensive first-pass metabolism, and the major hydroxylated metabolites of the tricyclic and demethylated metabolites of the bi- and tetracyclic compounds are pharmacologically active. The toxic effects of the tricyclic and tetracyclic antidepressants are similar and are mostly related to their anticholinergic and cardiotoxic effects. Anticholinergic effects result in agitation, seizure, coma, and hallucination. Circulatory collapse, serious cardiac arrhythmia, conduction disturbances, and heart block can occur; arrhythmia is the leading cause of death in tricyclic overdoses (82). The toxicity of trazadone differs from that of the tricyclic and tetracyclic antidepressants in that there are no anticholinergic signs or symptoms and the primary manifestations are CNS effects and hypertension. Fluoxetine adverse effects are anxiety, nervousness, and insomnia.

Life-threatening events following a tricyclic overdose usually occur within the first 6 hours of ingestion (83). A patient is at low risk for toxicity if he has not developed the following within 6 hours of ingestion: QRS interval > 100 msec, arrhythmia, altered mental status or seizures, respiratory depression, or hypotension (84).

Tricyclic antidepressant-intoxicated patients who had peak (not admission) serum drug levels greater than 1,000 ng/mL were associated with seizures and ventricular arrhythmias (85). There was no correlation, however, between drug levels and toxic symptoms over a wide range of tricyclic antidepressant levels including those below 1,000 ng/mL and drug levels did not predict severity of symptoms (83). Therefore, measurement of serum tricyclic antidepressant levels, particularly if requested on a “stat” basis, to predict the severity of acute tricyclic antidepressant poisoning is unwarranted.

The tricyclic antidepressants can be detected and identified in urine by TLC or one of the tricylic antidepressant group-specific immunoassays. Because the toxic effects resulting from an overdose of these compounds are so similar, demonstration of the presence of one of these drugs without specific identification often is sufficient for management. Immunoassays (EIA, FPIA) are designed primarily for detection of the major tricyclic antidepressants (imipramine, desipramine, amitriptyline, nortriptyline) but, because of the cross-reactivities of the antibody for other members of the tricyclic antidepressant family, these immunoassays also are capable of detecting other tricyclic antidepressants and metabolites (86). A single-use device designed to test for tricyclic antidepressants and several drugs of abuse has been evaluated for use in the emergency department (13). Although a positive result does not necessarily indicate a toxic concentration of the drug, a negative response will rule out the possibility of an overdose. Quantitative immunoassays (EMIT) for the four major tricyclic antidepressants also are available. These assays require solid-phase extraction from serum or plasma before analysis. Quantitative determination of serum levels is performed best using HPLC (77, 87).

Cyclobenzaprine is prescribed extensively as a muscle relaxant. It is a tricyclic compound, structurally differing from amitriptyline only in having a double bond in the cycloheptane ring. Analytical distinction between the two is difficult—they are indistinguishable in immunoassay cross reactivity and chromatographic

elution on TLC or HPLC. Distinction can be achieved by HPLC using a photo-diode detector to exploit differences in their UV spectra (88) or by careful examination of their different fluorescence characteristics in Stage III of the TOXILAB TLC system (89)

Iron

Iron supplements in various forms of iron salts are readily available and ferrous sulfate, the cheapest and most common iron salt, is involved frequently in overdose. Other iron salts are gluconate, fumarate, succinate, lactate, chloride, ferrocholinate, and glutamate. The elemental iron dose ingested can be calculated from the percentage of elemental iron in the formulation (Table 22.3). Acute iron poisoning is particularly common in the pediatric population, with the majority of the reported exposure occurring in children less than 6 years of age (58).

TABLE 22.3. ELEMENTAL IRON EQUIVALENTS IN IRON SALTS

Salt	% Fe	mg Fe/Tablet[a]
Sulfate	20	65
Gluconate	12	38
Fumarate	33	106
Lactate	19	-
Chloride	28	-
Ferrocholinate	13	-

[a] 325 mg tablet

Fe, iron

In acute iron poisoning, an estimation of the amount of elemental iron is important in assessing potential toxicity. An ingestion of 10 to 20 mg of elemental iron per kilogram of body weight can be associated with toxicity (90). A dose of 20 to 60 mg/kg can pose moderate risk, whereas a dose greater than 60 mg/kg has high risk for serious toxicity.

Five clinical stages of acute iron poisoning have been described. The first stage is the initial postingestion period lasting up to 6 hours. As iron is absorbed in the duodenum and upper small intestine, GI symptoms manifested at this stage are a direct result of the corrosive action of iron; the absence of these symptoms during this period excludes serious injury. During the next stage (latent period) of up to 12 hours, the patient may appear to improve. If the dose ingested is sufficiently large, the patient's condition may progress directly to a third stage (12 to 48 hours postingestion) of systemic toxicity with cardiovascular collapse, seizure, coma, and shock. The fourth stage is hepatic failure 2 to 3 days postingestion. Some patients who survive are still at risk of developing late strictures and some GI tract obstruction (2 to 4 weeks) (90).

Ingestion of iron can be documented by abdominal radiograph, which can reveal radiopaque iron-containing pills prior to dissolution as much as 6 hours or longer after ingestion of adult-strength tablets. Pediatric preparations, which are chewable iron supplements, dissolve rapidly in 30 to 60 minutes and are not always seen (91).

A qualitative test to predict potential for toxicity is the deferoxamine challenge test. A sufficiently large deferoxamine dose (90 mg/kg) is given to bind free iron in plasma and forms the reddish feroxamine complex, which is excreted in urine. The appearance of feroxamine in urine within 4 to 6 hours implies potential toxicity. False-negative results have been reported, and a negative challenge test should not rule out toxicity (92).

Serum iron level usually is determined along with total iron-binding capacity (TIBC). Serum iron levels between 300 and 500 µg/dL are associated with significant GI toxicity. Patients with serum iron levels above 500 µg/dL can exhibit systemic toxicity and shock, and will require chelation therapy. Sampling of blood for determination of serum iron should be on admission and again at 4 to 6 hours postingestion when peak levels are thought to occur.

Theoretically, if the serum iron value is greater than the TIBC, then the free circulating iron is potentially toxic. The use of TIBC is discouraged because of spurious elevation of TIBC following iron poisoning from a laboratory artifact (93).

The management of acute iron poisoning includes removal of residual iron in the GI tract by emesis or lavage and standard support therapy (90). Deferoxamine therapy is used to chelate free serum iron.

Most methods for measuring serum iron levels are based on spectrophotometric measurement of a color complex formed by the chelation of ferrous iron to a dye. Deferoxamine, as a competing chelator, interferes with dye-binding calorimetric assays to give falsely low results (94). Therefore, blood for serum iron levels should be drawn before deferoxamine chelation therapy. Atomic absorption spectroscopy for serum iron levels is not routinely available but is a method that can be used in the presence of deferoxamine.

Cannabinoids

The term cannabinoids denotes a group of more than 60 compounds found in the plant *Cannabis sativa L*. Δ^9-Tetra-hydrocannabinol (THC) is the major psychoactive compound of marijuana.

The effects of THC, when smoked, appear within minutes and seldom last longer than 2 or 3 hours. Oral intake delays the onset of symptoms for 30 minutes to 2 hours but the duration of drug action is longer. The effects of THC are tempered by dose, route of administration, and experience of the user. There usually is a sense of euphoria, an altered perception of time, a keener sense of hearing, and more vivid visual imagery. Both short-term memory and task performance are impaired. Higher doses can induce frank hallucinations, delusions, and paranoid feelings. The most consistent cardiovascular effects are an increase in pulse rate and conjunctival reddening (95).

THC, a lipophilic drug with a large volume of distribution estimated to be about 10 L/kg, is sequested in certain organs such as liver and lung. In man, THC is transformed rapidly first by the hepatic cytochrome P450 enzyme system to 11-hydroxy-Δ^9-THC (11-hydroxy-THC) which then is oxidized by alcohol dehydrogenase to 11-nor-Δ^9-THC-9-carboxylic acid (THCA). 11-hydroxy-THC is a psychoactive metabolite, whereas THCA is devoid of psychoactivity (95).

The primary urinary metabolite is THCA, which exists both as the free acid and glucuronide conjugate. Because of the large tissue storage of THC, continuous reentry of THC from tissues into the central compartment followed by metabolism means

that THCA is excreted into the urine long after a person has stopped using marijuana. The duration of urine samples testing positive is dependent on the dose, metabolism of THC, route and frequency of use, timing of urine collection, quantity of liquid taken prior to specimen collection, and assay cutoff. Generally, infrequent users test positive from 2 to 5 days after each dose when a 20-µg/L cutoff is used, but heavy users have been reported to test positive for over 46 days (96, 97). Thus, a positive urine result indicates only that the subject has been exposed to marijuana hours to weeks before the collection of the urine specimen, and the result cannot be used to estimate the time of exposure. Because of variation in a patient's hydration status, serial tests may see fluctuation of test results between positive and negative. A positive result following a negative one could be a result of residual excretion or dehydration and not reuse of marijuana. Serial determination of urine THCA concentrations normalized to urine creatinine can be helpful in interpretation (98, 99).

Because marijuana is smoked frequently in social situations, it is possible that nonsmokers could inhale a sufficient amount of cannabinoids present in sidestream smoke to produce a positive urine cannabinoids test. Studies have shown that this can occur, but only after exposure to high concentrations of marijuana smoke in a small, unventilated area (100). Such extreme exposure conditions are not encountered in the usual social situations, and with higher cutoffs (e.g., 50 or 100 µg/L) used by many screening assays, the detection of a positive urine from passive inhalation is unlikely (101).

Screening usually is done with immunoassays as they have good sensitivity and they can be automated for batch analysis of large numbers of samples. The popular commercial immunoassays use antibodies to detect THCA, the major urinary metabolite, and many of the other metabolites of THC. These assays, therefore, measure the sum of the immunoreactive THC metabolites. In contrast, the chromatographic assays (TLC, GC, and GC-MS) separate and specifically detect and quantify THCA. The threshold concentrations of these confirmation chromatographic methods usually are set lower than those of the initial tests. For example, in the Federal Workplace Drug Testing Programs, a confirmation threshold of 15 ng/mL is used when the immunoassay cutoff is 50 ng/mL (102).

If a chromatographic assay is used, hydrolysis of the glucuronide metabolites is necessary. TLC has a detection limit as low as 10 µg/L, whereas GC-MS methods, using a deuterated internal standard and selected ion monitoring, can have a limit of quantitation of 5 ng/mL and lower.

Hemp and marijuana both are *Cannabis sativa L*. Hemp, cultivated to produce hemp fiber and seeds for commercial use, generally contains relatively small amount of Δ^{9}-THC. Recently, food products derived from hemp seeds and hemp seed oil have become popular health food items and are easily available on the internet. These products contain varying amount of Δ^{9}-THC (103) and ingestion of these products can lead to positive drug test results for marijuana (104, 105). In one study, volunteers ingested 11 or 22 g of hemp seed oil containing high Δ^{9}-THC concentration (1,500 µg/g of oil). Urine specimens collected were positive for the marijuana test for 6 days with Δ^{9}-THCA concentrations reaching 431 ng/mL by GC-MS analysis. All subjects felt the pyschotropic effects of THC (103).

Opioids

The opioid drugs can be divided into naturally occurring, semi-synthetic, and synthetic groups. The naturally occurring opioids are morphine and codeine, which are derived from the opium poppy, *Papaver somniferum L*. Semi-synthetic opioids include heroin, hydromorphone, oxycodone, and oxymorphone. Synthetic opioids are meperidine, methadone, diphenoxylate, propoxyphene, and the fentanyls. Opioids have similar pharmacological effects and potential for addiction and tolerance; they vary only in their potency for analgesia, duration of action, and extent of abuse (106).

Opioids produce analgesic respiratory depressant, euphoric, and emetic effects. The triad of miosis, coma, and respiratory depression are pathognomonic of opioid poisoning (107). The response to the pure opioid antagonist, naloxone, is both diagnostic and therapeutic for opioid intoxication.

Heroin and methadone are the most frequently abused opioids. In recent years, concomitant use of heroin or methadone with cocaine has been reported. The preferred route of heroin administration is intravenous, although heroin of sufficient purity now is available and is smoked or administered intranasally. Heroin (diacetylmorphine) is deacetylated rapidly to 6-mon-oacetylmorphine (6-MAM) with a half-life of 3 minutes, which then undergoes a second deacetylation step to form morphine (108). Consequently, only 6-MAM and morphine are found in the urine of heroin users (109). Morphine and 6-MAM are equally potent in their opioid effects. Thus, heroin acts as a prodrug for providing the active metabolites, 6-MAM and morphine.

Codeine is rapidly absorbed from an oral dose, with plasma concentration peaking at 1 hour postingestion. It is extensively metabolized to norcodeine, but at least 10% of the dose is transformed to morphine. Most of the dose is excreted in the urine as glucuronide conjugates of codeine, norcodeine, and morphine. Thus, morphine is a metabolite of both heroin and codeine. Consumption of baked goods containing poppy seeds can result in detectable amounts of morphine and codeine in urine (110, 111) because some batches of poppy seeds are contaminated with these opiates. When a urine tests positive for morphine, it becomes important to ascertain whether the morphine comes from codeine in prescription medications, from heroin/morphine abuse, or from poppy-seed ingestion. A set of guidelines has been proposed to help in the interpretation of urine opiates results and the determination of the source of morphine and codeine (111, 112). Test results that can rule out poppy seeds as the sole source for morphine and codeine are: (i) codeine levels greater than 300 ng/mL with a morphine-to-codeine ratio less than 2 (indicative of codeine use); (ii) high levels of morphine (greater than 1 ng/mL) when codeine is undetectable; (iii) total morphine levels exceeding 5,000 ng/mL (indicative of abuse of heroin, morphine, or codeine); (iv) the presence of 6-MAM (a positive indication of heroin use).

To avoid “false-positive” morphine results as a result of poppy-seed ingestion, the Federal Workplace Drug Testing Program has raised the initial and confirmation test thresholds to 2,000 ng/mL of morphine and codeine. In addition, the Program now requires the test for the presence of 6-MAM in urine specimens confirmed to contain morphine (113).

The fentanyls are analgesic-anesthetic drugs that are many times more potent than morphine. Many analogs of fentanyls (3-methyl-, α-methyl-, and parafluoro derivatives) have appeared on the street as “China white” (114). Heroin containing fentanyl is a grave risk to heroin abusers. A standard urine drug screen most likely will fail to detect a fentanyl overdose because fentanyl concentration in urines is very low (µg/L), and the available urine immunoassays for opiates have no reactivity for fentanyls.

Immunoassays are used commonly as preliminary tests for the opiates (morphine and codeine), methadone, and propoxyphene. The synthetic narcotics (dihydrocodone, hydrocodone, hydromorphone, and oxycodone) also are detected by opiates immunoassays, thus necessitating a confirmation test (TLC, HPLC, GC, and GC-MS) that can distinguish between morphine and the other opioids. Conventional TLC has a detection limit of 1 mg/L of free morphine, which makes it suitable for use in overdose cases but not for drug abuse testing.

Cocaine

Cocaine (benzoylmethylecgonine) is an alkaloid extracted from the leaves of the *Erythroxylon coca* plant and purified as the hydrochloride salt (cocaine HCl). It is a powerful CNS stimulant, and in recent years the illicit use of cocaine has increased rapidly.

Cocaine hydrochloride is snorted or administered intravenously. Many cocaine users used to prepare free-base crystals for smoking (“free-basing”) by dissolving cocaine HCl in a solution of baking soda or ammonia, and extracting it with a solvent (ether) that is evaporated, leaving relatively pure cocaine crystals. “Crack” (so named because of the crackling sound made by the crystals when heated) also is a free-base form of cocaine, prepared by precipitation from an alkaline solution. Crack is relatively pure cocaine (80% to 90%), and when heated, is mostly vaporized rather than pyrolyzed. Its low cost and wide availability have worsened the cocaine epidemic.

Cocaine, a powerful CNS stimulant, produces heightened alertness, self-confidence, and an intense feeling of euphoria (rush). These stimulatory effects are followed by depression (crash). It is the positive reinforcement of the rush to escape the crash that leads to chronic cocaine abuse (115). Psychosis, repeated grand mal seizures, and coma are common following acute intoxication. Other clinical manifestations include arrhythmia, myocardial infarction, hypertensive crisis, cerebral vascular accidents, hyperthermia, and respiratory arrest. Spontaneous abortion and *abruptio placentae* are obstetric complications for women who use cocaine during pregnancy (3). Low birth weight and higher risk of congenital malformations, perinatal mortality, and neurobehavioral impairment are common results of a fetus exposed to cocaine in utero (4). Necrosis of the nasal septum from snorting cocaine, lung damage, and pulmonary edema are some of the other complications associated with cocaine use.

Bioavailability of intranasal cocaine is variable (20% to 60%) and appears to be dose dependent. Smoking free-base provides a more effective absorption of cocaine (57% bioavailability) (116), and a rapid peaking in its plasma concentration within 5 minutes. The euphoric effect of smoking cocaine usually lasts for only 20 minutes. Similar results were obtained in subjects given cocaine intravenously. Cocaine is lipid soluble and readily crosses cell membranes and distributes rapidly across the blood-brain barrier and the placenta.

The main routes of metabolism of cocaine are enzymatic and nonenzymatic hydrolysis of the methyl ester giving benzoylecgonine (BE) and enzymatic hydrolysis of the benzoyl group by plasma and liver esterases, yielding ecgonine methyl ester (EME) (117). Further hydrolysis of both of these compounds gives ecgonine. Norcocaine, the product of *N*-demethylation, undergoes similar hydrolysis and is believed to be pharmacologically active, but it is present in very small amounts. The two major metabolites, BE and EME, are excreted into urine in about equal amounts (40% to 50%). Cocaine itself is excreted in very small amounts, less than 1% of the dose in 3 days. Elimination half-lives for BE, EME, and cocaine have been calculated from literature data to be 7.5, 3.6, and 1.5 hours, respectively (118). A pyrolytic product of crack cocaine, anhydroecgonine methyl ester (methylecgonidine, MEG) has been identified and detected in urine, hair, saliva, sweat, and blood of crack smokers, but not in samples obtained form users of cocaine by other routes (119).

A pharmacologically active metabolite, cocaethylene, has been found in cocaine users following concurrent use of cocaine and ethanol (120). Cocaethylene is frequently present in clinical specimens which are positive for benzoylecgonine (121).

Addition of sodium fluoride to inhibit esterase activity and low temperature will stabilize cocaine in blood specimens for long-term storage. The major urine metabolites, BE and EME, are relatively stable.

Immunoassays are popular because they do not require sample pretreatment, and they are fast and easy to perform. Since these assays were designed primarily for use with urine specimens, the target analyte is the major urinary metabolite benzoylecognine (122). Benzoylecognine is not effectively extracted by nonpolar solvents and requires the addition of an alcohol (e.g., ethanol) or chloroform to make the extraction solvent more polar. The resulting extract can be used for various chromatography techniques (TLC, HPLC, GC, and GC-MS). TLC sensitivity is generally at 1 to 2 µg/mL, which is adequate for cocaine overdose cases. Sensitivity has been improved with claimed detection limits of 0.25 µg/mL for use in drug abuse testing (TOXI-LAB). A disadvantage of this TLC procedure is the limited migration of BE away from the origin.

Gas chromatography procedures require derivatization of the carboxylic side group of BE before chromatography (23). Procedures using a flame ionization detector have sensitivity down to 200 µg/mL, which can be enhanced further by the use of a mass-spectrometer detector.

The high specificity and sensitivity of GC/MS assays are utilized routinely for confirmation of BE in urine using deuterated BE as internal standard and selected ion ionization mode.

Ecgonine methyl ester (EME) is a major urinary metabolite of cocaine. Its presence in urine is an indicator of cocaine use is as sensitive and specific as that of BE. The use of EME has the advantage that, unlike BE, it can be easily extracted urine and it has good chromatographic properties in TLC and GC systems (123).

Urine BE levels typically decline rapidly to below the usual 300ng/mL cutoff in 24 to 96 hours since last exposure, but

among long-term, high-dose abusers BE was reportedly detectable after 10 to 22 days (124). Detection times, however, are assay-dependent. In a study of human subjects given 20 mg of cocaine HC1 intravenously, the mean times of detection of the last positive urine specimen (greater than or equal to 300 ng/mL BE) after cocaine administration varied from 16.9 to 52.9 hours, depending on the commercial tests used (TLC, EIA, FPLA, RIA) (122).

Sympathomimetic Drugs

Sympathomimetic drugs mimic the actions of the endogenous neurotransmitters that stimulate the sympathetic nervous system. Sympathomimetic agents include the over-the-counter medications (e.g., ephedrine, pseudoephedrine, and phenylpropanolamine), illegal street drugs (e.g., amphetamines, and methamphetamine, MDMA, and MDA), and herbal preparations (ephedra, Ma Huang). The clinical presentations from these many different agents are the classic sympathomimetic signs and symptoms such as tachycardia, hypertension, diaphoresis, hyperthermia, acute psychosis, and seizures. Poisoning occurs secondary to the use of prescription agents, over-the-counter medications, and illicit drugs. A contemporary scene is the abuse of the designer agents (particularly MDMA or “ecstasy”) at rave dance parties where users have been afflicted with dehydration, hyperthermia, and cardiac arrhythmia (125).

Methamphetamine and amphetamine are strong CNS stimulants, and at low doses produce euphoria, increase alertness, intensified emotions and sense of well being. Because of its ease of manufacturing and ready availability and its longer half-life (10 hours vs. minutes for cocaine), the abuse of methamphetamine has increased in recent years (126). Methamphetamine may be taken orally, intravenously, or by smoking. The smokeable form of methamphetamine has the street name “ice.” Methamphetamine is excreted in the urine largely as the unchanged drug and a small amount (7%) is demethylated to amphetamine. With a pKa of approximately 9.9 for both amphetamine and methamphetamine, elimination of these drugs is highly dependent on urine pH: up to 74% of a dose of amphetamine is excreted unchanged in acidic urine, but only 2% in alkaline urine (30).

The sympathomimetics can be detected by immunoassays. There are many commercially available kits either as reagent packs to be used on automated instruments or single-use devices designed for near-patient testing (15, 16). In choosing which kit to use, one must be familiar with the immunospecificity of the assay and the cutoff used. Most of the products on the market are designed to meet the demand of workplace drug testing for high specificity for methamphetamine and amphetamine, the target drugs of abuse in most testing programs. Assays with low cross reactivity with over-the-counter sympathomimetic amines such as ephedrine or phenylpropanolamine will reduce the need for costly GC-MS confirmation. In the clinical setting, however, it is important to be able to detect other sympathomimetics as well. Emergency department or drug-treatment clinic encounters with designer drugs (MDMA, MDA), prescription (phentermine) or nonprescription (ephedrine, PPA) drugs, and herbal preparations (ephedra) are common.

Specific identification of individual sympathomimetics requires chromatographic assays, typically those based on TLC or GC-MS. In a TLC kit commonly used in many clinical toxicology laboratories, the migration and color characteristics of the sympathomimetics are similar although subtle differences do allow correct identification by expert chromatographers (18). The manufacturer of the kit provides a special (remigration) procedure for detection and differentiation of the common sympathomimetics. The detection limits for the sympathomimetics are in the range of 0.5 to 1.0 (g/mL, which are adequate for testing patients who are suspected of an overdose.

Gas chromatography of the sympathomimetics requires chemical derivatization. The most commonly used with primary and secondary amines include heptafluorobutyric anhydride (HFBA), pentafluoropropionic anhydride (PFPA), trifluoroacetic anhydride (TFAA) and 4-carbethoxyhexfluorobutyryl chloride (4-CB). The methamphetamine artifact has been reported in some specimens when they were used with some of these derivatives (127). The source appeared to be ephedrine, which was in very high concentrations in these specimens. Under the conditions of the assay, a small amount of the ephedrine was converted to methamphetamine. The laboratory should be careful in reporting a positive methamphetamine result in the presence of a high concentration of ephedrine (> 0.1 mg/mL) and when amphetamine, a methamphetamine metabolite, is not detected at ≥200 ng/mL. Various solutions to this problem have been proposed, including lowering the injection port temperature or using a different derivative (128). The most effective solution is the fragmentation of ephedrine and related compounds with periodate treatment (129).

The *d* and *l* enantiomers of methamphetamine have very different CNS stimulant potency. *d*-Methamphetamine is 10 times more powerful as a stimulant, is a controlled substance in the United States, and is a drug of abuse of choice. *l*-methamphetamine has greater peripheral vasoconstrictive action and is used in over-the-counter nasal inhaler (Vicks Inhaler, Procter & Gamble, Cincinnati, OH). All pharmaceutical methamphetamine is the *d* isomer whereas illicitly synthesized methamphetamine can be pure *d*-methamphetamine or racemic methamphetamine. The standard clinical toxicology tests for the amphetamines (TLC, HPLC, or GC-MS) cannot differentiate between the enantiomers. Special chiral derivatizing reagent may be used to convert the isomers into chiral derivatives, which can be separated by standard chromatography (130).

A number of drugs or compounds are metabolized to methamphetamine and/or amphetamine. These include amphetaminil, benzphetamine, clobenzorex, deprenyl, dimethylamphetamine, ethylamphetamine, famprofazone, fencamine, fenethylline, fenproporex, furfenorex, mefenorex, mesocarb, and prenylamine (128). Proper interpretation of positive methamphetamine or amphetamine results must take into account the medication history of the patient.

Date-Rape and Knockout Drugs

The use of drugs to facilitate sexual assault is not new. Ethanol is the most frequently involved drug, being particularly effective when used together with other CNS depressants. Newer drugs

that have been implicated include flunitrazepam and γ-hydroxybutyrate (GHB), although any benzodiazepine is effective, particularly when it is ingested with ethanol (131). These drugs cause the victim to lose consciousness and the ability to make rational decisions. Moreover, perpetrators take advantage of the anterograde amnesia that their victims frequently suffer.

Flunitrazepam (Rohypnol), with street names such as “rooffies,” “rochies,” “rocha,” “rophies,” is not available legally in the United States. It dissolves readily in alcohol and is colorless, odorless, and tasteless. Detection of flunitrazepam in blood or urine is difficult because of the small amount administered (typically 1 to 2 mg) and its extensive metabolism. Documentation of exposure usually is based on the detection of the major metabolite, 7-aminoflunitrazepam. Many of the commercially available immunoassays for benzodiazepines have sufficient cross-reactivity with this metabolite to detect its presence in urine. Definitive confirmation is by GC-MS (132). It is recommended that urine and blood specimens should be collected as soon as possible after the alleged assault and preferably within 24 hours (133).

Gamma-hydroxybutyrate is a naturally occurring product of the metabolism of the neurotransmitter γ-aminobutyric acid (GABA). In the 1980s, it was abused by body builders as a steroid enhancer and was easily available in health-food stores and mail-order outlets until its ban by the Food and Drug Administration in 1990. It continues its popularity as an illicit drug among “rave” party participants for its euphoric and hallucinogenic properties. Gamma-hydroxybutyrate is a CNS depressant and an excessive amount ingested in combination with ethanol can cause profound coma (134, 135). Hence, its implication as a date-rape drug. Gamma butyrolactone (GBL), with a street name of “blue nitro,” and 1,4-butandiol (BD), are converted, *in vivo*, to GHB. In February 2000, GHB, GBL, and BD were added to schedule I of the Control Substance Act.

There is no readily available screening test for GHB. Some laboratories may be able to use their urine organic-acid screen methodologies or specific GC-MS procedures to detect GHB (136, 137).

FORENSIC URINE DRUG TESTING

Part of "22 - Toxicology"

One of the initiatives for achieving a drug-free workplace is to implement urine drug testing programs for job applicants as well as for workers in occupations that are considered critical to public safety and health, e.g., those in nuclear-power plants and the transportation industry. Urinalysis programs remain a controversial approach to dealing with the substance-abuse problem in the workplace. Among the issues being intensely debated are the accuracy of the tests and the reliability of the laboratories conducting them (138, 139).

It is important to appreciate that urine drug testing for the workplace differs from clinical testing in several critical respects (138). For example, workplace drug testing results may be used for administrative purposes such as disciplinary action, dismissal, or denial of employment. Moreover, such test results stand on their own and are interpreted without the usual benefit of the physician-patient relationship or the clinical context in clinical testing. Thus, workplace drug testing must produce definitive test results that are both scientifically and legally defensible, the latter requiring comprehensive documentation to show that the integrity of the specimen has been maintained (chain of custody). This forensic aspect of substance abuse testing usually is unfamiliar to clinical laboratorians.

In addition to standard good laboratory practice, stringent requirements are needed for forensic urine drug testing (FUDT) laboratories. A discussion of these requirements follows.

Laboratory Facility

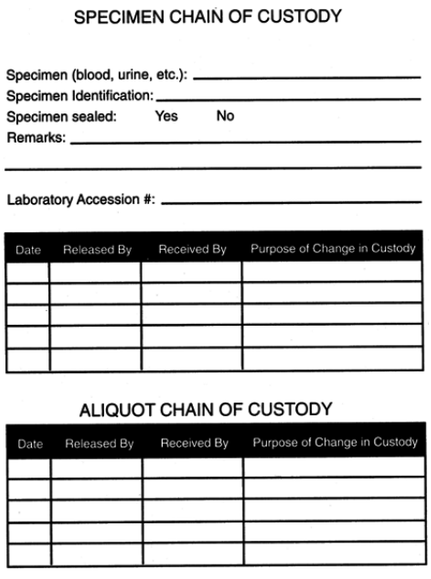
The FUDT laboratory where specimens and records are kept and where analytical work is performed should be separate from areas of clinical activities, and the laboratory should be a limited access area to authorized personnel. The laboratory should have protocols to protect the confidentiality of all records, to ensure the security of computer files relating to FUDT, and to limit computer access to authorized users.

Initial and Confirmation Tests

FUDT is a two-stage process: initial testing followed by confirmatory analysis of the presumptive positive specimens by quantitative GC-MS. Most FUDT programs required the performance of both initial and confirmation tests at the same laboratory site.

Chain-of-Custody Documentation

In FUDT, every urine specimen is treated as evidence. Therefore, there is a need to show proof of integrity of the specimen from specimen collection to its final disposition after analysis is completed. This requires documentation of *what* was done with the specimen (or aliquot), *who* handled the specimen (or aliquot), and *when* it was handled. A sample chain-of-custody form is shown in Figure 22.6.



SPECIMEN CHAIN OF CUSTODY

Specimen (blood, urine, etc.): _____
Specimen Identification: _____
Specimen sealed: Yes No
Remarks: _____
_____

Laboratory Accession #: _____

Date	Released By	Received By	Purpose of Change in Custody

ALIQUOT CHAIN OF CUSTODY

Date	Released By	Received By	Purpose of Change in Custody

FIGURE 22.6. Specimen/aliquot chain-of-custody form.

Because the chain-of-custody procedures are the most challenged aspect of FUDT, they should be an important part of a laboratory's quality assurance program. The chain-of-custody of every specimen must be checked to assure that it has been completed appropriately before certifying results for reporting.

Personnel

The qualifications of a FUDT laboratory director are stringent, requiring training, experience, and expertise in forensic analytical toxicology comparable to that of a diplomat of the American Board of Clinical Chemistry in Toxicological Chemistry or the American Board of Forensic Toxicology.

The forensic aspect of drug testing creates the need for a certifying scientist (CS) that does not exist in clinical laboratories. The CS performs the final review of the entire laboratory process: the chain-of-custody documentation, and standards, blanks and quality-control data of preliminary and confirmation tests before certifying the reports for release.

Accreditation and Licensure

In some states, e.g., New York, FUDT laboratories must meet state regulatory licensure requirements. At the national level there are two certification programs: The College of American Pathologists (CAP) Forensic Urine Drug Testing program and the Department of Health and Human Services (DHHS) National Laboratory Certification Program (NLCP). The federal program is based on a set of guidelines issued by Substance Abuse Mental Health Services Administration (SAMHSA) (102). Certification by this program is required for laboratories engaged in drug testing for the federal government or industries regulated by the Department of Transportation (140). Both programs require acceptable performance in proficiency-testing programs, and laboratories must successfully pass on-site inspection for obtaining and maintaining accreditation or certification.

Trace Elements, Vitamins, and Nutrition

Jane M. Yang

Kent B. Lewandrowski

NUTRITION

Part of "23 - Trace Elements, Vitamins, and Nutrition"

The basic food substances required by humans are carbohydrates, fats, and proteins. These macronutrients must be ingested in appropriate amounts to meet the energy needs of the body, which vary with body size, activity, age, and gender. The presence of illness or trauma may augment daily requirements. Proteins and carbohydrates provide about 4 kcal/g. Fats furnish about 9 kcal/g.

In addition to water and energy necessities, there also are requirements for nine essential amino acids (lysine, threonine, leucine, isoleucine, methionine, tryptophan, valine, phenylalanine, histidine), one fatty acid, and 13 vitamins and 15 minerals (Table 23.1). Most of the vitamins and minerals are micronutrients, that is, substances required in daily amounts of less than 100 mg.

TABLE 23.1. MACRONUTRIENTS AND MICRONUTRIENTS

Macronutrients	Carbohydrates
	Fats
	Proteins
Micronutrients	Fat-soluble vitamins
	Vitamins A,D,E, and K
	Water-soluble vitamins
	Vitamin B
	Thiamine (B1), riboflavin (B2), niacin, pyridoxine (B6), biotin, pantothenic acid, folic acid, cobalamin (B12),
	Vitamin C
	Minerals
	Sodium, potassium, calcium, magnesium, chloride, phosphorus
	Trace elements
	Iron, zinc, cobalt, copper, manganese, molybdenum, chromium, selenium, fluoride, nickel

Good nutrition is necessary for normal resistance to illness and for optimal recovery from medical and surgical procedures. The U.S. Recommended Daily Allowances (RDAs) serve as dietary guidelines for amounts of nutrients necessary for the maintenance of good nutrition of almost all “healthy people in the United States.” These amounts may not be adequate in hospitalized patients or other special situations.

DISORDERS OF NUTRITION

Part of "23 - Trace Elements, Vitamins, and Nutrition"

Inappropriate nutrition is the single greatest cause of illness in the world today. The majority of the world's population is subject to some degree of malnutrition in either protein, calories, or essential micronutrients. In developing regions of the world, childhood malnutrition is one of the leading contributors to overall disability and death (1). In contrast, obesity is the predominant nutritional disorder in industrialized nations.

Protein-Energy Malnutrition

Protein-energy malnutrition (PEM) [also called protein-calorie malnutrition (PCM)] occurs with inadequate ingestion of protein and/or calories. In developing countries, PEM predominantly affects infants and children who may manifest characteristics of the classic syndromes, kwashiorkor (protein deficiency) and marasmus (predominant energy deficiency). In the United States and other developed nations, PEM typically occurs secondary to other diseases and affects both adults and children.

Although some patients may have deficiencies of vitamins or minerals, the most common nutritional problem in hospitalized patients is PEM. About 40% of all hospitalized patients have some degree of nutritional deficiency, and as many as 15% suffer from clinically significant PEM. In particular, geriatric patients, alcoholic patients, and those with mental or chronic illnesses are at risk for malnutrition. Causes of malnutrition include decreased oral intake (e.g., anorexia, nausea, dysphagia, pain, gastrointestinal obstruction, poor dentition), increased nutrient losses (e.g., malabsorption, diarrhea, bleeding, protein-losing enteropathy), and increased nutrient requirements (e.g. fever, infection, neoplasm, surgery, trauma, burns).

Kwashiorkor

Kwashiorkor is a syndrome caused by severe protein deficiency despite adequate caloric intake, usually in the form of carbohydrates. In countries where kwashiorkor is endemic, the syndrome often occurs in the child subsequent to weaning.

The syndrome is characterized by growth retardation, muscle wasting, edema, swollen abdomen (from hepatomegaly and ascites), anemia, and hair loss. Dry, hyperpigmented lesions affecting the face, extremities, and perineum (“flaky paint” dermititis) also are characteristic. Children with kwashiorkor typically are lethargic and anorectic. Bradycardia, hypothermia, decreased blood pressure, and cardiac failure also may occur.

In kwashiorkor, body weight may be low or normal as a result of edema or anasarca. Unlike marasmus (see below), subcutaneous fat is present (albeit reduced), and increased fat in the liver (steatosis) produces hepatomegaly. An increased susceptibility to infection presumably results from a defective barrier function in the skin and mucous membranes, impaired granulocyte, humoral, and cell-mediated immune functions, and impaired complement activity. Without treatment, kwashiorkor is fatal, and up to 40% die despite medical intervention.

There are no characteristic biochemical findings of this condition. Serum albumin typically is less than 2.8 g/dL. Prealbumin and retinol-binding protein are similarly diminished. Serum

transferrin may be low, normal, or even slightly elevated if there is coexistent iron deficiency. Electrolyte abnormalities are common especially hypokalemia and hypophoshatemia. Anemia usually is normochromic and normocytic.

Marasmus

Marasmus is a condition that develops from deficient calories in the form of both protein and carbohydrate. These patients exhibit wasting of both muscle and fat. In contrast to kwashiorkor where body fat may be normal, subcutaneous fat is extremely depleted in marasmus-affected children. Kwashiorkor dermititis and edema do not occur in marasmus, and the abdomen is not distended. Affected children typically have a good appetite. Serum albumin and other protein markers often are normal.

Secondary PEM

The presentation of secondary forms of PEM varies greatly depending upon the previous nutritional status of the individual and the chronicity of the associated disease. Chronic disease states may produce a marasmus-like malnutrition. These patients who suffer from chronic conditions have gradual muscle wasting. Serum albumin may be normal or low but rarely less than 2.8 g/dL. More acute illnesses such as sepsis, burns, or trauma tend to produce a more kwashiorkor-like presentation. Edema and ascites may occur and serum albumin may diminish to less than 2.8 g/dL. Recognition and diagnosis of secondary PEM may be difficult. (See Nutritional Assessment).

Obesity

Approximately 25% of Americans are overweight, and about 10% are considered severely obese. Many different systems for classifying body fat and weight exist. Ideal body weight often is provided in terms of body height in prepared tables such as the Metropolitan Life Insurance Company tables. Ideal body weight also may be calculated as 100 pounds plus 5 pounds for every inch above 5 feet in height for women and 106 pounds plus 6 pounds for every inch above 5 feet for men. Adjustments should be made for type of body frame.

A simple but somewhat imprecise definition of obesity is a proportion of fat of more than 20% body weight in men and more than 30% in women (see Nutritional Assessement below for body fat measurements). A useful calculation for classification of obesity is the body mass index (BMI) which is calculated as follows: BMI = weight in kilograms/(height in meters)^2 or weight in pounds/(height in inches)^2 × 703.1 (1a).

BMI	
Grade 0	< 25
Grade I	25–29.9
Grade II	30–40
Grade III	> 40

Risk of health-related disorders increases as the BMI exceeds 25. Obesity may initiate or exacerbate certain conditions such as insulin resistance, diabetes mellitus, hypertension, hypertriglyceridemia, cardiovascular disease, chronic hypoxia and other respiratory problems, sleep apnea, thromboembolism, cancer, cholecystitis, and arthritis.

The obvious treatment for obesity is the reduction of calories. For a diet to be effective, an individual must intake a negative caloric balance. Weight loss also is promoted by increased energy utilization. When obesity reaches a crisis situation, surgical intervention may be warranted.

During the early 1990s, combination therapy for weight loss using the two amphetamine agents, fenfluramine and phenteramine, (known as “fen phen”) became widely popular. Despite its clinical effectiveness and commercial success, reports of valvular heart disease resulting from fenfluramine necessitated its withdrawal from the market in 1997. Phenteramine still is available. Typically, amphetamines and other anorectic drugs are utilized only as a short-term adjunctive therapy to diet and exercise because of their potential toxicity, addictive properties, and abuse potential.

NUTRITIONAL SUPPORT AND ASSESSMENT

Part of "23 - Trace Elements, Vitamins, and Nutrition"

In hospitalized patients, untreated PEM is associated with a three-fold increase in morbidity and mortality. PEM impairs the recovery of hospital patients, increases the risk of infection, and delays wound and tissue repair. The benefits of treating malnutrition are potentially great in terms of improved outcome, reduced morbidity, and reduced length of stay. Furthermore, early intervention may be the key to maximizing benefits in hospitalized patients. Identification of malnourished patients and patients at risk for developing PEM involves both thorough clinical evaluation and measurement of laboratory parameters.

Parenteral Nutrition

Nutritional support of the hospitalized patient may take the form of enteral or parenteral feeding. Patients who cannot be fed enterally may be given nutrients through intravenous routes. Parenteral nutrition may be in the form of peripheral parenteral nutrition (PPN) or total parenteral nutrition (TPN).

Parenteral nutrition is indicated for patients who cannot be fed orally or enterally for more than 5 to 7 days. PPN is delivered

through ordinary peripheral vein catheters and may be preferred for short-term support (less than 2 weeks) because TPN requires central venous catheter insertion and thus carries a higher risk of mechanical complications (pneumothorax, great vessel injury, and brachial plexus injury from catheter insertion) and infection. Only solutions of 1,000 mOsm or less are administered as PPN. High osmolarity solutions cannot be administered through peripheral veins because of the occurrence of phlebitis.

Parenteral solutions are composed of amino acids, dextrose, and lipid emulsions. Electrolytes, vitamins, trace minerals, and medications are added as necessary. Complications of parenteral nutrition include thrombosis, infection (focal catheter wound infections, sepsis), hyperglycemia, hypoglycemia, fluid and electrolyte abnormalities, hepatic abnormalities (elevation of liver function tests, steatosis), biliary disease (cholelithiasis, biliary sludge), micronutrient deficiencies (zinc, iron, vitamin B12), and elevation of BUN.

Nutritional Assessment

Selection of patients for nutritional support and monitoring therapy are based largely on clinical assessment and criteria. The cornerstone of nutritional assessment is physical examination and careful history-taking. Anthropomorphic and traditional laboratory parameters may play an ancillary role. Newer laboratory markers may be useful in identifying early malnutrition and in monitoring the effectiveness of nutritional intervention.

Physical Examination

Physical examination provides a number of clues about the general nutritional status of the patient and specific deficiency states. For example, the loss of subcutaneous fat and muscle indicates general nutritional deficiency while various skin, hair, and mucous membrane changes are characteristic of vitamin deficiencies.

A careful nutritional history and dietary evaluation are important components in the assessment of nutritional status. However, this information is not always reliable. A complete and accurate dietary history is difficult to obtain. Furthermore, direct measurement of consumption over a fixed period does not assess the natural diet nor can it be extrapolated over a long timeframe.

Anthropomorphic Measurements

Anthropomorphic measurements include body weight and other dimensions. A body weight less than 85% of ideal usually indicates a nutritional deficiency. Caliper measurements of skinfold thickness at multiple sites (triceps, biceps, subscapular, and suprailiac areas) are used to estimate body fat and to monitor nutritional status changes. Other measurements include abdominal/limb circumference, body density (water immersion or isotope dilution with ^{40}K), electromagnetic conductivity, bioelectric impedance, and computed tomography (CT) scanning. Disadvantages of anthropomorphic measurements include lack of reliability and reproducibility. Some methods are extremely cumbersome and are therefore impractical for routine use.

Laboratory Parameters

Laboratory parameters may be useful in the evaluation of nutritional status. As our understanding of the importance of adequate nutrition increases, improved chemical markers have been sought for new functions. Nutritional markers are needed to detect malnutrition in its early stages, to identify patients mostly likely to benefit from nutritional intervention, and to monitor the effectiveness of nutritional support. Measures of visceral protein status include the serum proteins, albumin, transferrin, prealbumin, and retinol-binding protein (Table 23.2). These proteins are all synthesized in the liver but vary widely with regard to biologic half-life and clinical utility. The ideal biological marker for nutritional status is sensitive to small increments and losses, responds rapidly to these changes, and is not affected by conditions unrelated to nutritional status. To fulfill these requirements, the marker should have a short half-life, small body pool, a rapid synthetic rate and constant catabolic rate. In addition, the marker should not be an acute phase reactant, and it should not be significantly affected by hydration, liver and renal disease, and other states independent of overall nutritional status. Unfortunately, no marker identified to date can fulfill these requirements.

Serum Albumin

Serum albumin is the traditional biochemical marker for protein nutritional status. Levels greater than 3.5 g/dL are considered normal while less than 3.0 g/dL suggests PEM. Albumin measurements are readily available and strongly correlate with morbidity and mortality in hospitalized patients (2, 3). Patients with serum albumin levels of less than 3.5 g/dL have a fourfold increase in postoperative complications and a sixfold increase in mortality (4). A serum albumin of less than 2 g/dL is associated with a 30-day mortality rate of 62% (5). Malnourished patients also have longer hospital stays and increased numbers of infections and other complications (6).

Albumin has a long biological half-life of about 20 days and a large extravascular body pool (7). Consequently, the serum albumin level responds very slowly to nutritional changes. Albumin is an acceptable marker of long-term nutrition and chronic protein deficiency, but it lacks the rapid responsiveness and sensitivity necessary for short-term monitoring (8). Albumin levels often are depressed only in moderate to severe malnutrition. In addition, albumin is nonspecific. Extravascular stores are mobilized during stress and may falsely elevate albumin levels in malnutrition. Depressed albumin occurs in other conditions including liver and renal disease, intravenous fluid use, the acute phase response, and protein-losing states.

Serum Transferrin

Like albumin, serum transferrin has been used for the general assessment of visceral protein status despite suboptimal sensitivity and specificity. Transferrin levels of less than 100 mg/dL, 100 to 150 mg/dL and 150 to 200 mg/dL have been used to identify severe, moderate, and mild protein malnutrition in patients with normal hepatic and renal function. Transferrin's half-life is

TABLE 23.2. SERUM PROTEINS AS NUTRITIONAL MARKERS

Serum Protein	Half-Life	Reference Ranges	Advantages	Disadvantages
Albumin	19 days	>3.5 g/dL is normal < 3.5 g/dL is associated with delayed healing < 3.0 g/dL suggests PEM < 2.5 g/dL is a strong predictor of increased morbidity and mortality in both hospitalized and ambulatory patients < 2.0 g/dL indicates severe PEM and is associated with a 60% 30-day mortality rate	• Established use in assessment of various groups of patients • Marker for chronic protein deficiency • Easy to perform, inexpensive	• Due to its long half-life of 19 days and large body pool, albumin changes too slowly and does not reflect short-term nutritional changes (e.g., feeding after stress remission). Not suitable for monitoring response to nutritional intervention. • Not specific. Conditions independent of nutritional status may lower albumin e.g., cirrhosis, other liver disease, nephrotic syndromes, other renal disease, use of intravenous fluids, overhydration, burns, protein-losing enteropathies. Elevated in dehydration.
Transferrin	8–10 days	>200 mg/dL normal nutritional state 150–200 mg/dL mild nutritional depletion 100–150 mg/dL moderate < 100 mg/dl severe visceral protein depletion	• Shorter half-life and smaller body pool than serum albumin. Hence, earlier response to protein depletion than serum albumin.	• Limited use in monitoring response to nutritional therapy. Response time better than albumin but not rapid enough. • Not specific. Decreased in cirrhosis, protein-losing states, neoplastic disease, use of high concentration antibiotics (tetracycline, cephalosporins, aminoglycosides). Increased with iron deficiency, pregnancy, use of oral contraceptives, and hepatitis.
Prealbumin (transthyretin)	2 days	< 11 mg/dL signifies inadequate nutritional support Rise of less than 2 mg/dL per week indicates inadequate nutritional support or inadequate response	• Very short half-life and small body pool. Rapid response to diminished nutritional intake and nutritional support. • Sensitive indicator of effectiveness of nutritional support. Daily increments of up to 1 mg/dL indicate good visceral protein anabolic response to nutritional support • May be sensitive enough to allow for early assessment and intervention in patients at risk for malnutrition. • Not significantly affected by hydration status. Less affected by liver disease as other markers. More specific. • High tryptophan content and high essential to non-essential amino acid ratio. More accurate marker for nutritional status.	• Some increase in renal failure (but not to the same extent as seen with RBP) • Decreased in cirrhosis
Retinal-binding protein	12 hours		• Shortest half-life and small body pool. Rapidly responds to changes in nutrition. Good for monitoring short-term nutritional changes.	• Increased and unreliable in renal failure. • Unpredictable changes in liver disease.

shorter (8 days) than that of albumin and therefore, transferrin responds sooner than albumin to nutritional changes but not rapidly enough for use in daily monitoring of nutritional therapy. Serial transferrin levels lack sensitivity and cannot detect critical increments and decrements during the course of nutritional therapy (6). Transferrin levels also are not specific to nutritional status. Cirrhosis and protein-losing states will affect all the serum protein markers to some degree, but transferrin has

poorer specificity because of the fact that neoplastic disease and the use of high concentration antibiotics (tetracycline, cephalosporins, aminoglycosides) decrease levels and iron deficiency, pregnancy, hepatitis, and the use of oral contraceptives increase transferring (7).

Prealbumin

Prealbumin (Transthyretin) has a short half-life of 1.9 days and small body pool, and may be the best serum protein for short-term nutritional evaluation (8). Prealbumin is a sensitive and rapidly responsive nutritional marker used both to detect diminished nutritional intake and to monitor the effectiveness of nutritional intervention. Decrements in prealbumin occur in as little as three days following inadequate nutritional intake. Daily increments of prealbumin (up to 1 mg/dL) indicate a positive nitrogen balance reflecting a good visceral protein anabolic response to nutritional support while increments of less than 2 mg/dL per week signify an inadequate response or inadequate level of nutritional support (7, 9).

Prealbumin has a high essential to nonessential amino-acid ratio and high tryptophan content (Tryptophan plays an important role in protein synthesis initiation). Consequently, prealbumin is thought to be an accurate reflection of nutritional status. Furthermore, prealbumin has good specificity compared to that of other serum proteins. Though prealbumin may be diminished in end-stage liver disease, other conditions such as renal disease, dehydration, and overhydration appear to have lesser effect on prealbumin.

Retinol Binding Protein

Retinol binding protein (RBP) has the shortest half-life (12 hours) and thus may be the most sensitive index of protein status and the most rapid marker to respond to nutritional intervention. However, RBP has inferior specificity compared to that of prealbumin (7, 10). In particular, RBP is elevated considerably in patients with renal dysfunction and cannot be used reliably in these patients.

Other Laboratory Markers

For many clinical situations (e.g., preoperatively), a general nutritional assessment may be made by taking only simple body dimensions such as body weight and height and by measuring one or two of the visceral protein markers in Table 23.2. Less common laboratory measurements are discussed below. The use of these markers often is cumbersome and does not yield any additional clinical information. As such, their application is reserved for selected clinical situations and research.

Nitrogen balance is an older parameter that has been used in monitoring malnourished patients as an indicator of adequate nutritional support and anabolism (7). It is the difference between nitrogen intake and nitrogen excretion. In the healthy, well-nourished adult population, the nitrogen balance should approach zero. During periods of decreased intake, stress, or illness, nitrogen losses may exceed intake causing a negative nitrogen balance. With recovery and proper nutritional support, the nitrogen balance should become positive. The nitrogen balance is calculated as follows:

Nitrogen balance = nitrogen intake - nitrogen loss

Nitrogen intake = 24-hour protein intake (grams)/6.25

Nitrogen loss = 24-hour urinary urea nitrogen/total volume + non-urea nitrogen losses

Ninety percent of nitrogen is excreted renally and urinary nitrogen is comprised mostly of urea (80% to 90%). Direct measurement of total urinary nitrogen is technically difficult. The 24-hour measurement of urinary urea nitrogen usually is the only measurement actually made, and a factor of 2.5 g is used to approximate non-urea losses, that is, non-urea urinary nitrogen (ammonia, creatinine, uric acid, and other nitrogen-containing components) and fecal and skin losses which are small.

Somatic muscle mass is catabolized to preserve visceral protein. Because anthropometric measurements often are not practical, **urinary creatinine** excretion (which reflects protein derived from the somatic compartment) has been used to estimate lean body mass (LBM) as shown below where the average of three consecutive 24-hour urine creatinine measurements is used.

LBM (kg) = 7.38 + 0.02909 × creatinine (mg/day)

The **creatinine height index** (CHI) is the ratio of 24-hour urinary creatinine to ideal creatinine excretion based on height, gender, and age. In most men, CHI values of greater than 7.4 mg/cm and 8.4 mg/cm qualify as moderate and severe malnutrition, respectively. The specificity of the CHI is limited by variation because of renal function, dietary protein, exercise, infections, fever, and other parameters that influence creatinine.

Somatic muscle also may be evaluated by 24-hour urinary excretion of **3-methylhistidine**, which is derived from skeletal muscle actinomyosin. Urinary excretion of 3-methylhistidine increases in muscle catabolism. **Urinary amino acid** patterns may denote chronic protein deficiency. Typically, the total amount of urinary amino acids decreases while relative amounts of branched-chain amino acids are diminished and glycine and serine are augmented. Urinary **hydroxyproline** has been used to assess collagen catabolism and maybe other indicator protein status. These measurements (urinary 3-methylhistidine, amino acids, and hydroxyproline) require special methods and are not readily available.

In contrast, **urinary ketones** and **glucose** are measured easily. Their utility in nutritional assessment is limited to certain clinical situations. The presence of ketones in the urine indicates either an inappropriate use of a TPN solution or a starvation state in which fat stores are mobilized for calories. The ability to develop ketosis after a fast is evidence of fat stores.

Excess glucose in the urine may indicate that spilling of TPN fluid through the glomerulus is taking place. The resulting loss of calories, fluids, and electrolytes may hamper the calculation of other nutritional parameters.

Skin sensitivity testing using the intradermal injection of antigens has been used to demonstrate an impaired immune response in states of severe nutritional deficiency. This test is not specific.

VITAMINS

Vitamins are micronutrients that are not endogenously synthesized or are not made in sufficient amounts to meet physiologic requirements. Many vitamins serve as coenzymes in critical biochemical pathways. The water-soluble vitamins include thiamine (B1), riboflavin (B2), niacin, pyridoxine (B6), biotin, pantothenic acid, folic acid, cobalamin (B12), and vitamin C. Vitamins A, D, E, and K are fat-soluble.

Deficiency and toxicity of vitamins is discussed below and summarized in Table 23.3. Inadequate dietary intake or the use of drugs that destroy vitamins may lead to deficiency states. In the case of fat-soluble vitamins, malabsorption as a result of biliary or pancreatic insufficiency is an additional risk factor. Severe toxicity and fatality following vitamin overdose are rare. Fat-soluble vitamins such as vitamins A and D may cause a syndrome of acute toxicity. Typically, excess water-soluble vitamins are excreted in the urine following acute ingestion. On the other hand, chronic toxicity may develop regardless of the vitamin's water solubility. The laboratory evaluation of each vitamin is summarized in Table 23.4.

TABLE 23.3. VITAMINS

Vitamin	Dietary Source	Deficiency State	Risk Groups for Deficiency	Toxic States
Vitamin A	Meat, fat, eggs, dairy products	Night blindness Complete blindness Skin abnormalities with disordered keratinization Impaired skeletal growth, depressed immune function	Alcoholism, hepatic disease, fat malabsorption, pancreatitis, cystic fibrosis Underdeveloped countries–common dietary deficit	Acute toxicity– headache, drowsiness, blurred vision, blurred vision, abdominal pain, nausea, vomiting, weakness Chronic toxicity–alopecia, multiple bone and skin abnormalities, anemia, hepatotoxicity Increased intracranial pressure, bulging fontanelles in newborns Teratogenicity Carotenemia
Vitamin D	Fish, liver, eggs, butter	Defective mineralization of bone resulting in rickets in children and osteomalacia in adults In rickets, hypocalcemia and resulting tetany, growth retardation with skeletal deformities and bone fractures, listlessness, and muscular weakness	Inadequate nutrition or sunlight exposure in winter at northern latitudes, malabsorption due to biliary or pancreatic insufficiency, liver or renal failure Drugs such as phenytoin, phenobarbital, rifampin that increased degradation	Chronic ingestion may cause hypercalcemia (>11 mg/dL)
Vitamin E (tocopherols)	Vegetable oils, egg yolk, liver, milk	Areflexia, gait disturbance, diminished proprioception	Fat malabsorption, abetalipoproteinemia, cholestatic liver disease, diets with high polyunsaturated fat content	Severe toxicity is rare. Vitamin E antagonizes vitamin K so patients on oral anticoagulation therapy may have excess platelet time prolongation. Premature infants given parenteral vitamin K may develop hepatosplenomegaly, ascites and jaundice.
Vitamin K	Green vegetables	Coagulopathy	Malabsorption, poor dietary intake, sterilization of GI tract from long-term oral antibiotics, newborns	
Vitamin B_1 (thiamine)	Milk, grains, yeast	Wet beriberi, dry beriberi, Wernicke's encephalopathy, Korsakoff's syndrome	Alcoholics, chronic dialysis, glucose administration, diets high in milled rice, ingestion of thiaminases (raw foods)	
Vitamin B_2 (riboflavin)	Liver, kidneys, raw milk, eggs, cheese, fish, green vegetables	Glossitis, cheilosis, dermatitis, neuropathy, and anemia	Isolated deficiency is rare	
Niacin	Whole grains, liver, beef, fruit, vegetables, production from tryptophan	Pellagra (dermatitis, dementia, diarrhea, and death)	Milled corn, carcinoid syndrome, Hartnup disease, isoniazid administration	Overdose causes histamine release and flushing, pruritus, nausea, vomiting, and diarrhea. Chronic overdose may cause hepatitis.
Vitamin B_6 (pyridoxine)	Meat, poultry, fish, yeast, seeds, bran	Dermatitis with cleilosis (dry lips) and glossitis, stomatitis, anemia, depression, and confusion. Infants may present with seizures.	Exclusive ingestion of processed foods. Alcoholism. Use of certain drugs such as isoniazid, hydralazine, penicillamine, cycloserine, and theophylline	Chronic overdose may cause peripheral neuropathy with paresthesias, ataxia.
Vitamin C (ascorbic acid)	Citrus fruits, berries, melons, tomatoes, green peppers, leafy vegetables	Scurvy–arthralgia, fatigue, subcutaneous hemorrhage in the gingiva, extremities, joints and nailbeds (splinter hemorrhages), gingivitis, loose teeth, and hyperkerotic, papular skin lesions.	Diet devoid of fruits and vegetables	Increased oxalate Kidney stones, nephropathy
Biotin	Liver, kidney, egg yolk, milk, fish, nuts	Peritoneal dermatitis, conjunctivitis, alopecia, ataxia Developmental delay	In multiple carboxylase deficiency (MDC) or following raw egg white consumption or parenteral nourishment	

TABLE 23.4. LABORATORY EVALUATION OF VITAMIN STATUS

Vitamin	Laboratory Evaluation of Nutritional Status
Vitamin A	Measurement of serum vitamin A is technically complex and requires protein precipitation and extraction steps. High-pressure liquid chromatography (HPLC) is the preferred method for analysis and is able to separate retinyl esters.[16]
	Serum vitamin A levels do not correlate well with liver stores and typically become depressed only in severe deficiency. Elevated levels indicate hypervitaminosis A. Toxicity may also be determined by measuring the retinyl ester fraction of vitamin A by HPLC. Retinyl esters normally account for 5% of total vitamin A. This proportion is elevated to greater than 30% in toxicity.
	Serum carotene is simpler to determine. Serum is denatured and extracted prior to analysis by spectrophotometry or HPLC.[17] Elevated carotene levels confirm carotenemia. Serum carotene may also be used as a screening test for fat malabsorption. Elevated carotene levels may be used to rule out steatorrhea but lower values are not specific.
Vitamin D	The best test for vitamin D status is serum 25-OH vitamin D_3 level by RIA, nephelometry, or HPLC. A fasting specimen is preferred. Normal levels are approximately 10–60 ng/mL.
	Measurement of the 1,25-OH form of vitamin D may be useful in chronic renal failure. This test is less readily available than 25-OH vitamin D. The reference range for 1,25-OH vitamin D is 15–65 pg/mL.
Vitamin E (tocopherols	Measurements of vitamin E and alpha-tocopherol employ saponification, solvent extraction, and separation by HPLC or GC. Blood levels do not correlate with body storage of the vitamin and are not considered useful in the assessment of vitamin E deficiency or toxicity. The ratio of alpha-tocopherol to total plasma lipid may be a better indicator of vitamin E body stores.[25]
Vitamin K	Direct measurements of vitamin K by chromatographic methods is rarely used. Clinically, prothrombin time is used to assess vitamin K status.
Vitamin B_1 (thiamine)	The most reliable indicator of thiamine status is erythrocyte or whole blood transketolase activity.[32] Levels less than 0.6 U/gram hemoglobin suggest deficiency.
	Deficiency is also defined as an increase in transketolase activity of greater than 15% upon in vitro addition of thiamine diphosphate.
Vitamin B_2 (riboflavin)	Blood and urine riboflavin measurements have little clinical value. The best test is red blood cell glutathione reductase activity before and after addition of FAD. An increase of more than 40% indicates a deficiency state. Less than 20% is normal.
Niacin	Niacin status is evaluated by measurement of urine metabolites, N1-methylnicotinamide (NMN) and its pyridone (pyr).[36] Less than 1.2 mg per day of either corresponds to low intake.
Vitamin B_6 (pyridoxine)	Vitamin B6 may be measured by enzyme assay, radioimmunoassay or HPLC methods. Normal levels of pyridoxine and pyridoxal-5′-phosphate (PLP) are 3–30 mcg/L and 5–50 mcg/L, respectively. Levels less than 1 mcg and 3 mcg indicate deficiency.
	The tryptophan loading test may be performed for deficiency screening (40). Urinary xanthurenic acid is measured before and after oral tryptophan loading. Normal is greater than 50 micromol/24 hours.
	Erythrocyte aspartate aminotransferase (eAST) will be increased following addition of vitamin B6. A large difference between unsupplemented and supplemented eAST indicates deficiency.
Vitamin C (ascorbic acid)	Vitamin C is measured by colorimetric, fluorometric, and HPLC methods. Serum ascorbic acid levels of less than 0.2 mg/dL (11 mol/L) suggest deficiency.
	Vitamin C status may also be assessed with two consecutive 24-hour urine measurements of ascorbic acid; one at baseline, the other, after 2 days of 200 mg oral ascorbic acid. Vitamin C deficiency is defined by a concentration of less than 50 mg ascorbic acid in the second 24-hour urine collection
Biotin	Biotin assay not readily available in most settings. Diagnosis of multiple carboxylase deficiency (MCD) requires enzyme studies.

RIA, radioimmuno assay; GC, gas chromatography; FAD, flavin adenine dinucleotide.

Vitamin A

Vitamin A consists of a group of compounds that have the biological action of retinol. The main vitamin A compounds are retinol (vitamin A_1) and 3-dehydroretinol (vitamin A_2). The alcohol, retinol, is the form that is absorbed and delivered to peripheral tissues bound to retinol-binding protein. The aldehyde, retinal, is required for vision. Retinol combines with fatty acids to form body reserves of vitamin A, which are abundant in the liver. When needed by the body, these retinyl esters are hydrolyzed. Recent studies have elucidated the important role that various retinol-binding proteins play in the regulation of vitamin A absorption, transport, storage, and metabolism (11, 12).

Retinol derivatives (called retinoids) include retinal and the ester, retinoic acid, as well as numerous other synthetic forms, which may or may not possess biologic activity. Liver, fat, eggs, and dairy products are good sources of retinoids. Beta-carotene and other carotenoids are precursors of vitamin A and constitute the yellow-orange pigments found in various vegetables such as carrots.

Vitamin A and carotenoids are not soluble in water. For this reason, they cannot be absorbed directly in the gastrointestinal tract but must be coabsorbed with fats as part of the micelles that form in the intestine. Pancreatic enzymes also are required in order to hydrolyze retinol fatty acid esters. Thus, absorption of vitamin A and utilization of body stores depend upon adequate biliary and pancreatic function.

Vitamin A is essential for vision, epithelial differentiation, and mucus secretion. During dark adaption, retinol in the eye is oxidized to retinal and isomerized allowing its interaction with opsin to form rhodopsin. Rhodopsin is the light-sensitive substance which allows night vision.

Deficiency/Toxicity States

Vitamin A deficiency occurs commonly in developing countries and is a leading cause of blindness in the young (13). Other individuals at risk for vitamin A deficiency include those with fat malabsorption, pancreatic disease, cystic fibrosis, hepatic disease, and alcoholism.

Deficiency of vitamin A causes ocular and dermatologic abnormalities. The initial symptom of vitamin A deficiency is night blindness. With severe deficiency, total blindness may occur. Vitamin A deficiency also may present with skin abnormalities caused by disordered keratinization. Impaired skeletal growth, depressed immune function, and increased morbidity from measles also occur.

Acute vitamin A toxicity may occur following overdoses in excess of 500,000 IU and is characterized by drowsiness, irritability, blurred vision, abdominal pain, anorexia, nausea, vomiting, increased intracranial pressure, intense headache, and muscle weakness (14). After several days, skin desquamation occurs. Chronic toxicity may occur from taking only moderately high amounts over extended periods of time. Alopecia, multiple skin and bone abnormalities, anemia and hepatotoxicity occur with chronic over-supplementation (daily doses in excess of 35,000 IU). In children, as little as 1,500 IU (about four times the recommended daily allowance) may cause chronic toxicity. Doses of 25,000 IU or more during early pregnancy may be teratogenic.

There are over 1,000 synthetic retinoid dervatives. Three major ones, retinol, isotretinoin, and etretinate, may be used in the treatment of psoriasis and acne (15). When used systemically, these retinoid compounds may cause ocular and liver toxicity as well as abnormal serum lipid profiles. They are also teratogens. An excess of carotene from a diet high in carotenoid-containing vegetables such as lettuce and carrots may cause an orange discoloration of the skin, which is not harmful but may be misinterpreted as jaundice. Carotenemia does not lead to hypervitaminosis A probably because of regulation of carotene conversion to vitamin A.

Measurement

Measurement of serum vitamin A is technically complex and requires protein precipitation and extraction steps. The Carr-Price method is a colormetic procedure employing antimony trichloride. High-performance liquid chromatography (HPLC) is a preferred method and is able to separate retinyl esters (16).

Serum vitamin A levels do not correlate well with liver stores and typically become depressed only in severe deficiency. Elevated levels indicate hypervitaminosis A. Toxicity also may be determined by measuring the retinyl ester fraction of vitamin A by HPLC. Retinyl esters normally account for 5% of total vitamin A. This proportion is elevated to greater than 30% in toxicity.

The assay for serum carotene is somewhat simpler to perform. Serum is denatured and extracted prior to analysis by spectrophotometry or HPLC (17). Nonetheless, like vitamin A, serum carotene is not a good indicator of vitamin A status, and its utility is limited. Elevated carotene levels confirm carotenemia. Serum carotene also may be used as a screening test for fat malabsorption. Elevated carotene levels may be used to rule out steatorrhea but lower values are not specific.

Vitamin D

Vitamin D is a fat-soluble vitamin involved in mineral homeostasis. In particular, vitamin D plays an important role in osteoblast function, parathyroid hormone release, and intestinal absorption and renal excretion of calcium (18, 19).

Vitamin D refers to both vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol). Most of the vitamin D in the body is vitamin D_3 and a much smaller proportion is vitamin D_2. Fish, liver, eggs, and butter are good sources of vitamin D_3. It also may be endogenously synthesized; Ultraviolet (UV) light catalyzes its formation from 7-dehydrocholesterol in the skin. In contrast, vitamin D_2 derives only from plants. Because the amount of vitamin D obtained from food sources and endogenous synthesis often is insufficient, milk has been fortified with vitamin D in most developed countries. Each quart of milk typically contains 10 mcg (or 400 IU) of vitamin D. Vitamin D supplements may consist of vitamin D_3 or vitamin D_2.

Both vitamin D_3 and vitamin D_2 are inactive and undergo hydroxylation to the weakly potent 25-OH vitamin D in the liver and to the most active form of the vitamin, 1,25-OH vitamin D, in the kidneys.

Clinical Syndromes

In vitamin D deficiency, mineralization of bone is defective resulting in rickets in children and osteomalacia in adults. Rickets is characterized by hypocalcemia, tetany, growth retardation with skeletal deformities and bone fractures, listlessness, and muscular weakness.

Vitamin D deficiency in the adult may occur as a result of inadequate nutrition, inadequate sunlight exposure, residence in

northern latitudes, and malabsorption as a result of biliary or pancreatic insufficiency. Because the active form of the vitamin is dependent upon hydroxylation, hepatic and renal disease also may cause manifestations of deficiency. Chronic use of certain drugs such as phenytoin, phenobarbital, and rifampin will increase hepatic metabolism of 25-OH vitamin D.

Excess supplementation may cause acute hypercalcemia, altered mental status, seizures, renal stones, and metastatic calcifications.

Measurement

The major circulating form of vitamin D is 25-OH vitamin D_3, and the best test for assessment of vitamin D status is the serum 25-OH vitamin D_3 level by radioimmunoassay, immunonephelometry, or HPLC methods (20, 21). A fasting specimen is preferred, and normal levels are approximately 10 to 60 ng/mL. Indications for the measurement of the 1,25-OH form of vitamin D are limited to cases of chronic renal failure where 1-hydroxylation is deficient. This test is less readily available than 25-OH vitamin D, and the reference range for 1,25-OH vitamin D is 15 to 65 pg/mL. The best indicator of toxicity is also serum 25-OH vitamin D_3, because 1,25-OH vitamin D levels may not be elevated. Serum calcium is another important measurement in toxicity and typically exceeds 11 mg/dL.

Vitamin E

Vitamin E includes a group of compounds known as tocopherols and tocotrienols. α-Tocopherol is the most active form. Tocopherols are found ubiquitously in foods. Vegetable oils, egg yolk, liver, and milk are particularly good sources of vitamin E (22).

Vitamin E is a fat-soluble vitamin. The daily requirement is closely related to the dietary intake of polyunsaturated fats. Vitamin E is stored in various tissues, especially adipose.

Vitamin E is an antioxidant and as such neutralizes free radicals in red blood cells, neurons, and other tissues (23). In particular, vitamin E is thought to protect polyunsaturated fatty acids in cell membranes.

Clinical Syndromes

Vitamin E deficiency occurs in premature infants and in children and adults with cystic fibrosis, biliary disease, other causes of malabsorption, and abetalipoproteinemia. Erythrocytes have increased fragility resulting in hemolytic anemia. Another feature of vitamin E deficiency is a progressive neurologic disease with ataxia, areflexia, gait disturbance, and diminished proprioception and vibratory sensation (24).

Unlike the fat-soluble vitamins A and D, vitamin E has not been reported to cause severe toxicity in the general population. Excessive intake may cause gastrointestinal upset, lethargy, and headache. Toxicity does occur in patients on oral anticoagulation therapy because vitamin E can potentiate warfarin compounds by antagonizing vitamin K. Premature infants may develop hepatosplenomegaly with ascites, cholestasis, and thrombocytopenia in response to parenteral vitamin E.

Measurement

Methods for the measurement of vitamin E or α-tocopherol are not readily available and typically employ saponification, solvent extraction, and separation by HPLC or gas chromatography (GC). Blood levels do not correlate with body storage of the vitamin and are not considered useful in the assessment of vitamin E deficiency or toxicity. The ratio of α-tocopherol to total plasma lipid may be a better indicator of vitamin E body stores (25).

Vitamin K

There are a number of different vitamin K compounds chemically known as methylnaphthoquinones. Vitamin K_1 (phylloquinone) is found in green vegetables. Intestinal bacteria produce Vitamin K_2 or menaquinone. The contribution of bacterially produced vitamin K_2 to total vitamin K requirement is not known (26, 27).

Vitamin K is required for the posttranslational gamma-carboxylation of glutamic acid residues in prothrombin, clotting factors VII, IX, and X, and inhibitory proteins C and S (28).

Clinical Syndromes

Vitamin K deficiency is characterized by coagulopathy with prolonged prothrombin time and possible hemorrhagic disease. Deficiency occurs with fat malabsorption or biliary obstruction. Parenteral nutrition and prolonged use of broad-spectrum antibiotics also may produce vitamin K deficiency. Newborns are particularly susceptible because of immature liver function and lack of vitamin K synthesis by gastrointestinal bacteria.

Measurement

A variety of direct measurements are available for vitamin K, involving chromatography or spectrophotometry. However, these methods rarely are used except in research applications and it is usually adequate to rely on the measurement of the prothrombin time to assess the vitamin K status (29).

Vitamin B_1 (Thiamine)

Vitamin B_1 is an essential component of the coenzyme, thiamine pyrophosphate. Thiamine diphosphate is the predominant form of the vitamin.

The vitamin is found in most plant and animal tissues, but the best source is unrefined cereal grains, enriched flour, liver, heart, and kidney. Thiamine is removed from grains during the milling process.

Thiamine is essential for the decarboxylation of keto acids and is therefore important in the Krebs cycle. It also is required for transketolase activity which is essential to carbohydrate metabolism. Thiamine also plays an important role in neurons and myelin lipid maintenance.

Clinical Syndromes

Thiamine deficiency occurs in populations that depend on rice as a staple in their diet. The milling process removes the thiamine-rich outer layers of grains. Thiaminases in other food products such as coffee, tea, fish, shellfish, and raw meat also can

destroy thiamine. Loss of thiamine also may occur with dialysis, diarrhea, and diuretic use. Daily requirements for thiamine are increased by carbohydrate intake and diminished by fat.

Body stores of thiamine are limited, and manifestations of deficiency occur in as little as a week on a deficient diet. Thiamine deficiency occurs in alcoholics, in persons with diets of predominantly milled rice and those containing thiaminases, and in certain other settings such as chronic dialysis and refeeding after starvation. Glucose administration may precipitate clinical deficiency in thiamine-depleted patients or worsen the symptoms of Wernicke's encephalopathy.

Thiamine deficiency affects the cardiovascular and central and peripheral nervous systems. Manifestations of deficiency include wet beriberi, dry beriberi, Wernicke's encephalopathy, and Korsakoff's syndrome. Wet beriberi is characterized by severe edema and congestive heart failure. Dry beriberi is a peripheral neuropathy that is caused by degeneration of myelin sheathes. Typically, distal portions of the extremities are more affected than proximal ends. Findings include both sensory (numbness, tingling, with or without pain) and motor changes.

Ophthalmoplegia, horizontal nystagmus, ataxia, dysarthria, and an acute confusional state are features of Wernicke's encephalopathy. Confusion may progress to coma and death. Untreated Wernicke's has a 17% mortality rate (30). Korsakoff's syndrome is characterized by amnesia, learning impairment, and confabulation, and usually occurs in alcoholic patients weeks after an episode of Wernicke's encephalopathy or as Wernicke's subsides following thiamine administration (31). Remote memory typically is preserved in Korsakoff's syndrome.

Measurement

The most reliable indicator of thiamine status is erythrocyte or whole-blood transketolase activity where values less than 0.6 U/g of hemoglobin are indicative of thiamine deficiency (32). Deficiency also may be defined by an increase in transketolase activity of greater than 15% upon *in vitro* addition of thiamine diphosphate (TDP).

Direct measurement of blood thiamine is performed by HPLC and is not available for routine use. Similarly, urinary thiamine is not of clinical value.

Vitamin B_2 (Riboflavin)

Dietary sources of vitamin B_2 include liver, kidney, heart, eggs, and vegetables. Small amounts are found in cereals. The vitamin is present in raw milk but is eliminated by pasteurization (33).

Riboflavin in the coenzymes flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD) are important in oxidation-reduction reactions. The precursors FMN and FAD are cofactors for electron transport, liver enzyme action, and corticosteroid production.

Clinical Syndromes

Riboflavin deficiency is characterized by glossitis, cheilosis, dermatitis, neuropathy, and anemia. However, these findings are nonspecific, and the syndrome is almost always found in association with other B vitamin deficiencies. Chronic dialysis, phenothiazines, and cyclic antidepressants may increase riboflavin requirements.

Measurement

Blood and urine measurements of riboflavin have little clinical application. The best test for vitamin B_2 nutritional status is the measurement of red blood cell glutathione reductase activity before and after addition of FAD (34). An increase in activity of less than 20% is normal whereas an increase of more than 40% indicates a deficiency state.

Niacin (Nicotinic Acid)

Niacin refers to nicotinic acid and its derivatives. Dietary sources of niacin include whole grains, beef, liver, fruit, and vegetables. Niacin is not an essential dietary requisite for the reason that it can be formed in the body from the amino acid, tryptophan. The daily dietary requirement for niacin is dependent upon tryptophan intake.

Niacin is a basic part of the coenzymes, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are utilized in oxidation-reducation reactions throughout the body.

Clinical Syndromes

Niacin deficiency causes the syndrome known as pellagra. Pellagra is characterized by dermatitis, dementia, diarrhea, and death (the four ‘Ds’). This syndrome generally occurs as a result of dietary deficiency. The dermatologic abnormalities are hyperkeratosis, hyperpigmentation, and desquamation. Mental status changes include fatigue, apathy, confusion, amnesia, hallucination, and psychosis. Diarrhea, glossitis, stomatitis, and vaginitis may occur as a result of mucosal inflammation. Pellagra is a progressive disease, and death may ensue.

Diets composed predominantly of milled corn may lead to niacin deficiency because corn is low in tryptophan and the milling process eliminates bioavailable niacin (35). Widespread supplementation of corn and grain products has diminished the occurrence of niacin deficiency as a result of dietary deficit.

Niacin deficiency may occur secondary to other conditions. Carcinoid neoplasms consume an excessive proportion of tryptophan to make serotonin. Hartnup disease is a renal tubular disorder characterized by massive urinary loss of certain amino acids including tryptophan. By depletion of tryptophan, these conditions may precipitate niacin deficiency. Isoniazid administration also may cause a pellagralike syndrome. Isoniazid inhibits pyridoxine, which is required for the conversion of tryptophan to niacin.

Excessive consumption of niacin has been reported to cause flushing, pruritus, nausea, vomiting, and diarrhea from histamine release. Chronic overdosage may cause hepatotoxicity.

Measurement

Niacin status is evaluated by measurement of principal urinary metabolites, in particular, N1-methylnicotinamide (NMN) and

N1-methyl-2-pyridone-5-carboxamide (pyr) (36). These measurements are made using HPLC (37). Urinary excretion of less than 1.2 mg per day of either NMN or pyr corresponds to low niacin intake. Plasma levels of NMN and pyr are significantly less reliable.

Vitamin B_6 (Pyridoxine)

Vitamin B_6 refers to pyridine derivatives including pyridoxine, pyridoxal, and pyridoxic acid. The phosphorylated forms of these compounds serve as cofactors for various enzymes involved in tryptophan metabolism, lipid and carbohydrate metabolism, and the syntheses of neurotransmitters, niacin, and heme.

Vitamin B_6 is ubiquitous in foods. Meat, poultry, fish, yeast, seeds, wheat germ, and bran are particularly rich in vitamin B_6. Smaller amounts are present in milk, eggs, and certain green vegetables. Vitamin B_6 compounds may be destroyed by heat or other food processing.

Clinical Syndromes

Deficiency of vitamin B_6 is rare but has occurred as a consequence of diets limited to processed food. Severe vitamin B_6 deficiency causes dermatitis with cleilosis (dry lips) and glossitis, stomatitis, sideroblastic anemia, depression, and confusion. Infants may present with colic, irritability, and seizures as a result of infant formulas that are overheated.

A significant number of drugs including isoniazid, levodopa, phenelzine, hydralazine, penicillamine, cycloserine, theophylline, oral contraceptives, and ethanol also may precipitate vitamin B_6 deficiency by increasing its loss and/or inhibiting its functions (38). Supplementation of vitamin B_6 is indicated if sideroblastic anemia develops in alcoholics and in patients taking these drugs. Genetic errors of metabolism such as xanthurenic aciduria, primary cystathioninuria, homocystinuria, and glutamate dehydrogenase deficiency also may respond to increased administration of vitamin B_6.

Chronic excessive vitamin B_6 (daily consumption of > 2 g/day) causes neurotoxicity characterized by ataxia, gait disturbance, tingling, and numbness.

Measurement

Vitamin B_6 measurements in biologic fluids are obtained by enzyme assay, radioimmunoassay, or HPLC methods (39). Vitamin B_6 status may be assessed by the measurement of pyridoxine and/or pyridoxal 5′-phosphate (PLP), the major biologically active form of vitamin B_6. Normal levels are 3 to 30 mcg/L and 5 to 50 mcg/L, respectively. Levels less than 1 mcg and 3 mcg, respectively, indicate deficiency. Total vitamin B_6 levels also may be determined and typically include pyridoxine, PLP, pyridoxal, and pyridoxic acid. In vitamin B_6 deficiency, urine pyridoxic acid levels also may be diminished.

Because tryptophan metabolism is dependent upon vitamin B_6, a functional test of vitamin B_6 may be performed by measuring urinary levels of the tryptophan metabolite, xanthurenic acid, following oral administration of 2 g of tryptophan (tryptophan loading test). With adequate vitamin B_6 status, urinary xanthurenic acid should exceed 50 µmole per 24 hours. Less than 50 µmol implies vitamin B_6 deficiency. Xanthurenic acid measurements are made by spectrophotometry, fluorimetry, and HPLC methods (40).

Vitamin B_6 is an essential cofactor of aspartate aminotransferase, and vitamin B_6 nutritional status also may be assessed by measurement of erythrocyte aspartate aminotransferase activity (eAST) before and after the addition of vitamin B_6. A large difference between the unsupplemented and supplemented activities indicates deficiency (41).

Vitamin C (Ascorbic Acid)

Vitamin C (ascorbic acid) is found abundantly in various foods including citrus fruits, berries, melons, tomatoes, green peppers, and leafy vegetables. The daily requirement for vitamin C is met by consumption of even small amounts of fruit or vegetable. Nonetheless, vitamin C is commonly supplemented.

Vitamin C functions as an antioxidant removing free radicals from the body and maintaining metal ions in a reduced state. It also plays an important role in collagen synthesis. In particular, vitamin C serves as a cofactor for protocollagen hydroxylase. Without hydroxylation, collagen cannot form a triple helix and lacks tensile strength. Deficiency of vitamin C most severely affects collagen rich in proline, which is found in blood vessels. Vitamin C also affects tyrosine metabolism and neutrophil chemotaxis, prevents tetrahydrofolate oxidation, and enhances iron absorption and storage.

Clinical Syndromes

Vitamin C deficiency is rare but may result from a diet completely lacking in citrus fruits and leafy vegetables. The most severe form of deficiency is known as scurvy. Scurvy originally was a disease of sailors in the 19th century who did not have access to fresh foods for long periods of time. It is characterized by arthralgia, fatigue, poor wound healing, gingivitis, loose teeth, hyperkerotic, papular skin lesions, and capillary fragility leading to subcutaneous hemorrhage in the gingiva, extremities, joints, and nailbeds (splinter hemorrhages).

Chronic overdosage of vitamin C may be a cause of uric acid and cystine kidney stones. In susceptible individuals, it clearly is associated with oxalate renal calculi. High levels of vitamin C in the urine will cause false-negatives with some conventional methods of dipstick chemistry (glucose, blood, bilirubin, and nitrite) and with quantitative measurements of oxalate.

Measurement

Vitamin C is measured by colorimetric, fluorometric, and HPLC methods. The colorimetric method utilizes Cu (II) to oxidize serum ascorbic acid to dehydroascorbic acid, which reacts with 2,4-dinitrophenylhydrazine to form hydrazone (red color). Hydrazone is quantitated spectrophotometrically. Serum ascorbic acid levels of less than 0.2 mg/dL (11 mol/L) are suggestive of vitamin C deficiency.

Vitamin C status also may be assessed with two consecutive 24-hour urine measurements of ascorbic acid; one at baseline,

the other, after 2 days of 200-mg oral ascorbic acid. Vitamin C deficiency is defined by a concentration of less than 50 mg ascorbic acid in the second 24-hour urine collection.

Folate and vitamin B_{12} are discussed in the chapters in hematology.

Vitamin H (Biotin)

Biotin is found in liver, kidney, pancreas, egg yolk, milk, fish, and nuts. Most dietary biotin exists in a form bound to lysine (biocytin). Biocytin must be hydrolyzed by the intestinal enzyme, biotinidase, for absorption.

Biotin serves as a coenzyme for carboxylases involved in CO_2 transfer, fatty acid synthesis and oxidation, amino acid metabolism, and in cholesterol metabolism and storage.

Clinical Syndromes

Biotin deficiency is rare but may occur in multiple carboxylase deficiency (MCD) or following prolonged raw egg white consumption or parenteral nutrition. Egg whites contain avidin, which binds biotin, prevents its absorption, and may induce biotin deficiency.

Biotin deficiency is characterized by perioral dermatitis, conjunctivitis, alopecia, and ataxia. In addition, developmental delay and more serious neurologic abnormalities may occur in the setting of MCD where biotin deficiency develops as a result of abnormal biotin metabolism. There are two types of congenital disorders leading to MCD, biotinidase deficiency and holocarboxylase synthetase deficiency (42). Organic aciduria occurs as well as hypotonia, seizures, ataxia, feeding difficulty, rash, and alopecia. The age of onset and severity are variable. Biotinidase deficiency responds to oral biotin therapy if introduced before irreversible neurologic damage. Holocarboxylase synthetase deficiency appears to respond only partially to biotin.

Measurements

Definitive diagnosis of MCD requires studies of biotinidase and holocarbosylase synthetase enzymes. Biotin assays are not readily available in most hospital settings. Biotin can be measured by isotope dilution, enzyme immunoassay, and chemiluminescence techniques (43, 44).

TRACE ELEMENTS

Part of "23 - Trace Elements, Vitamins, and Nutrition"

Some minerals are major constituents of the body such as sodium, potassium, chloride, calcium, magnesium, and phosphorus. These elements are required in relatively large quantities. Other minerals are referred to as trace elements because collectively they constitute less than 1% of total body mass. Essential trace elements are iron, zinc, copper, cobalt, manganese, molybdenum, selenium, nickel, chromium, and fluoride. These elements serve as crucial components of many different tissues and enzyme systems. The importance of silicon, tin, and vanadium in humans is not clear. Elements without any known physiologic role are aluminum, arsenic, cadmium, gold, lead, and mercury. Some of these elements such as arsenic, cadmium, lead, and mercury are collectively referred to as “heavy metals.”

Specimen Collection and Contamination

Trace elements are present in biological samples at quantities on the order of micrograms or nanograms per liter. Metal, rubber, wood, paper, skin, dust, and water in the environment, laboratory, and collection apparatus may contain comparable amounts of trace elements. Thus, trace element analysis is susceptible to external contamination from the environment, collection apparatus and containers, and laboratory. Extreme care are must be taken during specimen collection, processing, and analysis. Rubber stoppers and syringe parts must be avoided, and all needles, syringes, and glass containers should be acid-washed or otherwise treated for metal collection. In particular, chromium and manganese are known to leach from metal needles (falsely elevating levels), and selenium and lead adsorb onto glass tubes over time (falsely lowering values) (45, 46). Aluminum levels may be elevated falsely by contamination from rubber stoppers made of aluminum silicate.

The gold standard technique for trace element analysis is to use a plastic catheter and an all-plastic syringe for blood collection. Also suitable is the use of an evacuated Sherwood Monoject trace element blood collection tube [#8881-307006 for serum or #8881-307022 (EDTA) for whole blood] with a Becton Dickinson #5175 20-gauge stainless steel needle or butterfly needles from Terumo or Abbott (43, 44). Earlier reports of normal or pathologic trace element concentrations (prior to 1971) may not be reliable and there are often notable differences in reference ranges among laboratories. These problems may be explained largely by specimen contamination.

Even in the absence of specimen contamination, interpretation of trace element values can be difficult because these substances are stored in various parts of the body, and the serum or urine level may be a poor reflection of actual body stores. It is important, therefore, to select the appropriate body fluid for measurement.

Analytic Methods

As mentioned, extreme care must be taken in the laboratory to avoid sample contamination. The area for trace metal analysis should be isolated from the main clinical laboratory. Solvents must be reagent-grade in purity. Glassware must be cleaned in acid and thoroughly rinsed with purified water.

Analytical sensitivity is crucial to the accurate determination of trace elements, which may be present in quantities as low as nanograms per liter or nanomoles. Atomic absorption spectrophotometry (AAS) is the most popular method for trace metal measurement. The flame AAS mode is simpler to operate. However, the greater sensitivity of electrothermal (flameless) AAS may be required for certain trace elements.

Emission spectrometry, neutron activation analysis, mass spectrometry, and x-ray fluorescence spectrometry are applicable in principle but require expensive apparatus and expertise. Colorimetry is useful in some cases, and anodic stripping voltametry has limited applications (47, 48).

Hair Analysis

Analysis of metals in hair is available through specialized laboratories. Advantages of hair analysis are ease of sample collection, sample stability, and potential length of detection period. Hair grows at a rate of about 1 cm per month (0.4 mm/day) and depending upon the hair length, it may be possible to obtain a history of several months. Furthermore, by fractionating along the length of the hair shaft and analyzing fractions, the chronicity and nature of exposure (bolus versus continuous) may be determined.

To date, the potential benefits of hair testing have been outweighed by its limitations. External contamination of the hair is the most significant problem. Not all substances may be distributed in the body to the hair shaft, and different sections of hair grow at different rates. Pollutants, industrial fumes, sprays, and chemicals that are externally applied may contain elements and are not representative of *in vivo* exposure. Moreover, hair treatments such as bleaching, coloring, and permanent waving may remove metals from the hair shaft or may contain chemicals that interfere with the detection of metals.

Analysis of metals requires solubilizing hair, a solid matrix, and different laboratory methods are not equivalent. Differences in metal measurements also may be intrinsic to the type of hair depending upon hair color, race, sex, age, and body site. Finally, reference ranges for metals in hair have not been well established. The correlation between hair levels and those in vital affected organs is not known. Interpretation is especially troublesome in cases where values are slightly, but not markedly, elevated. In conclusion, there are insufficient data to support the use of hair samples, and caution is advised in interpretation of the results of hair metal analysis.

Deficiency and toxic states for the essential trace elements are discussed below and summarized in Table 23.5. Laboratory evaluation of trace elements is outlined in Table 23.6.

TABLE 23.5. DEFICIENCY SYNDROMES AND TOXICITY CAUSED BY ESSENTIAL TRACE ELEMENTS

Metal	Deficiency Syndrome	Toxic States
Iron	Hypochromic, microcytic anemia	Hemosiderosis, hemochromatosis
Zinc	Juvenile dwarfism (growth retardation, delayed sexual maturation), hypogonadism, hypogeusia, delayed wound healing, depression, lethargy, defective immunity	Zinc oxide fume inhalation may cause metalfume fever (chest pain, cough, headache, nausea, vomiting, chills, fever, weakness). Zinc chloride inhalation may be fatal.
	Acrodermatitis enteropathica	Chronic oversupplementation may cause sideroblastic anemia
Cobalt	See Vitamin B12 deficiency	Ingestion is cardiotoxic. Cardiomyopathy, polycythemia, and goiter are features of beerdrinker's cardiomyopathy. Potential role in uremic cardiomyopathy. Contact with cobalt fume or dust causes dermatitis, rhinitis, conjunctivitis. Chronic inhalation leads to pulmonary fibrosis.
Copper	Premature infants, patients on TPN or zinc supplementation are at risk for deficiency.	Ingestion of copper or copper salts causes hemolytic anemia, gastroenteritis
	Anemia, neutropenia Osteopenia, bone and joint deformities Hypotonia, psychomotor retardation Skin depigmentation Menke's syndrome (hereditary functional copper deficiency)	Wilson's disease (defective biliary elimination with Cu accumulation in various tissues), Kayser-Fleisher rings, hepatitis, cirrhosis, personality and behavioral changes, cognitive decline
Manganese	No well-defined deficiency syndrome. Impaired growth, decreased reproductive function, ataxia, seizures, skeletal deformities may occur.	Acute dust inhalation may cause metal fume fever. Chronic inhalation may cause psychiatric disorders and Parkinson like signs.
Molybdenum	No well-defined deficiency syndrome Mental retardation, seizures, bilateral lens dislocation, sulfaturia, and thiosulfaturia may occur	Fume inhalation may cause anorexia, weakness, fatigue, headache, myalgia, cough, diarrhea
Chromium	Atherosclerosis, impaired glucose tolerance	Hexavalent chromium compounds (chromium trioxide and chromic acid) are toxic. Ingestion may cause hemorrhagic gastroenteritis, hepatic and renal damage, coagulopathy, and hemolysis. Chronic inhalation of dusts and fumes leads to asthma, pneumoconiosis, and lung cancer. Contact causes dermatitis, skin ulceration, and nasal septum perforation.
Selenium	Cardiomyopathy (Keshan disease), osteoarthritis, skeletal muscular degeneration	Abdominal pain, nausea, vomiting, irritability, paresthesia, hyperreflexia Selenious acid ingestion may be rapidly fatal.
Fluoride		Acute ingestion of more than 5–10 mg/kg of fluoride produces vomiting, abdominal pain, gastrointestinal ulceration and hemorrhage, hypocalcemia, hypomagnesemia, tetany, muscle weakness, respiratory depression, coma, arrhythmias, and death. Chronic overexposure (doses as low as 0.1mg/kg per day for 10 to 20 years) produces mottling and skeletal fluorosis (excess bone calcification, tendon and ligament calcification, and joint fusion.) Hydrogen fluoride causes severe corrosive injury to eyes, nose, mouth, and skin. Inhalation leads to sore throat, cough, bronchospasm, chemical pneumonia, and pulmonary edema.
Nickel	None defined	Dermatitis, eczema, asthma Nickel carbonyl causes severe respiratory and neurologic toxicity.

TPN; total parenteral nutrition.

TABLE 23.6. LABORATORY EVALUATION OF ESSENTIAL TRACE ELEMENT STATUS

Metal	Laboratory Evaluation of Nutritional Status
Iron	Serum iron, total iron-binding capacity, ferritin
Zinc	Zinc measurements are made by atomic absorption spectrometry. Colorimetric methods utilizing dithiazone are obsolete.[84]
	Normal serum zinc is 600–1000 mcg/L. Serum levels only roughly correlate with body burden. Levels become depressed only in moderate and severe deficiency, and early or mild zinc deficiency is detectable.[85]
	Fever, estrogen, and stress may lower blood zinc levels. Hemolysis releases red blood cell carbonic anhydrase and falsely elevates zinc concentration. Contact with rubber parts of syringes and collection tubes must be avoided to prevent contamination.
Cobalt	Cobalt can be measured by atomic absorption spectrometry, flameless atomic absorption spectrometry, and neutron-activation analyses. These assays are difficult to perform, and there is no demonstrated clinical application for these measurements.
Copper	Copper may be identified by a colorimetric method using bathocuproine sulfonate.
	Measurements are made by atomic absorption spectrometry. Ceruloplasmin is determined by nephelometric, spectophotometric, and radial immunodiffusion techniques.
	Serum copper measures total copper (free copper and that bound to ceruloplasmin, albumin, and other proteins). Normal levels are 700–1500 mcg/L. Severe toxicity associated with levels in excess of 5000 mcg/L.[86]
	Whole blood levels may correlate better in toxicity. 24-hour urine copper levels are also elevated in toxicity. Normal daily excretion is 15 to 64 mcg.
	Ceruloplasmin is an acute phase reactant. Both serum copper and ceruloplasmin are elevated in inflammatory conditions, estrogen, and pregnancy. Serum copper may be decreased in nephropathy, malabsorption, valproic acid, ACTH, and glucocorticoids.
Manganese	Atomic absorption spectrometry may be used to measure manganese. Other possible techniques include colorimetry, neutron activation analysis, and emission spectrometry.[87] Normal serum levels are 0.4–0.8 ng/mL. Whole blood levels are higher and may be a better measure of body burden (normal 4–12 ng/mL).
	To evaluate toxicity, 24-hour urine concentration may also be useful (normal 1–10 mcg/L). In random urine, manganese content may be reported per gram creatinine. Exposed individuals typically have elevated blood and urine levels. However, if exposure is remote, signs of chronic toxicity may persist after blood and urine levels have normalized.
Molybdenum	There is no generally accepted method for the measurement of molybdenum in biological fluids.
Chromium	Extreme caution must be taken for accurate measurement of chromium. Stainless steel and all metal must be avoided during specimen collection and analysis.
	Laboratory work should be performed under laminar flow conditions. Methods are isotope ratio mass spectroscopy and graphite furnace atomic absorption spectroscopy.
	The normal range for serum chromium is between 0.05 ng/mL and 0.15 ng/mL.[88]
	Higher reference ranges reported in the past are inaccurate. Serum levels exhibit diurnal variation (higher in the morning, lower post-prandially.) Reports of higher reference ranges of up to 18 ng/mL are erroneous and likely due to sample contamination. Serum levels are elevated in acute exposure but are not helpful in the diagnosis of deficiency. Urinary chromium may also be used as a measure of chromium overexposure.
	Chromium deficiency may be demonstrated by improvement in glucose tolerance after chromium supplementation. A modified glucose tolerance test is used in which fasting, 30-, 60-, 90-, and 120-minute samples are measured.
Selenium	Selenium measurements are made by atomic absorption or fluorometry.
	The normal ranges for serum and whole blood are 50–150 mcg/L and 60–240 mcg/L, respectively. Blood is used in the evaluation of both deficiency and toxicity states.
	Serum levels reflect recent intake. Erythrocyte levels are more indicative of remote exposure. Levels may be lowered in acute illness.[89] Hair levels have been used in the diagnosis of deficiency. Normal 0.2–1.4 mcg/gram.
	Levels may be falsely elevated by use of selenium sulfide shampoo.
	24-hour urine is used to monitor exposure. Normal excretion is 15–150 mcg/L.
	Levels greater than 500 mcg/L are most likely associated with toxicity.
	Red blood cell glutathione peroxidase activity is a useful functional test.
Fluoride	Fluoride is measured by ion-specific electrode. Fluoride measurements are useful in the diagnosis of overexposure. Hypocalcemia and hyperkalemia may also occur.
	Normal range for serum fluoride is 10 to 370 mcg/L. Values of up to 450 mcg/L are seen in red blood cells. The half-life of fluoride is 2–9 hours.
	The reference range for unexposed urine is 0.2–1.9 mg/L. The occupational threshold limit is 4–7 mg/L
	Specimen collection containers for fluoride should be plastic since the silicon in glassware may react with fluoride and form volatile compounds that are lost during analysis.
Nickel	Nickel is measured by electrothermal atomic absorption spectrometry.[90] Care must be taken to avoid specimen contamination. Blood nickel levels are not clinically useful unless drawn within the first few minutes or hours of exposure.
	Normal whole blood and serum levels are 3–7 mcg/L and 1–5 mcg/L, respectively.
	Blood nickel is increased following myocardial infarction, cerebral vascular accidents, and burns and decreased in cirrhosis and uremia.
	Urine nickel levels (8-hour or 24-hour urine) are the best measure of severity of toxicity. They may also be used to monitor occupational exposure in workers and chelation therapy.
	Unexposed urine: 2–10 mcg/L
	Exposure threshold: >25 mcg/L
	Moderate exposure: 100–200 mcg/L
	Severe exposure: >500 mcg/L
	Nickel carbonyl is rapidly metabolized to ionic nickel, and urine nickel is the best indicator of toxicity.

Iron

Iron metabolism, deficiency, and overload syndromes are discussed at length in Chapter 41, Red Blood Cell Disorders.

Zinc

Zinc is an essential cofactor of many enzymes including carboxypeptidases, carbonic anhydrase, alkaline phosphatase, ribonucleic acid (RNA) and deoriboxynucleic acid (DNA) polymerase, and alcohol dehydrogenase. Zinc is found in vegetables, cereals, meat, and fish. The daily adult requirement is 12 to 115 mg. Zinc is absorbed in the duodenum and jejunum by a mechanism shared with other elements. Copper, calcium, phosphate, and the presence of various other dietary substances such as fiber and phytate inhibit zinc absorption. For this reason, zinc in vegetables and cereals that is complexed to phytate is not well absorbed. Zinc is transported in the blood bound to albumin and α_2-macroglobulin. The primary route of elimination is biliary. Normally, only small amounts are excreted in urine. This amount may be augmented with chelation therapy.

Clinical Syndromes

Causes or contributing factors of zinc deficiency include low dietary zinc, high intake of phytates, fiber, calcium or other substances that diminished zinc absorption, chronic malabsorptive syndromes, total parenteral nutrition, and penicillamine therapy (from chelation and excretion of zinc).

Zinc deficiency in children is characterized by anemia, growth retardation or dwarfism, and delayed sexual maturation. Affected adults exhibit anemia, hypogonadism, and poor wound healing. Zinc deficiency also appears to cause keratotic skin lesions, depression, lethargy, diarrhea, hypogeusia (impaired taste), and defective macrophage and T-cell functions.

Acrodermatitis enteropathica or Danbolt's disease is another syndrome of zinc deficiency that is caused by defective intestinal absorption. This autosomal-recessive condition is characterized by progressive bullous, pustular skin lesions, diarrhea, and alopecia.

Zinc toxicity occurs most often by inhalation of zinc oxide fumes (metal fume fever) or by ingestion of zinc salts. Zinc is used in metal alloys and paints and in the metal galvanizing process. Zinc chloride is found in wood-preserving products, astringents, moss killer, and fireproofing materials. Zinc supplementation usually is in the form of zinc gluconate.

Zinc oxide fumes are produced when zinc is heated to high temperatures during the welding or smelting process. Inhalation of these fumes causes a syndrome known as metal fume fever (49). Upon exposure, chest pain and cough occur followed in 4 to 8 hours by fever, chills, headache, nausea, vomiting, myalgias, and weakness. Effects usually last about 24 hours and resolve without treatment. In contrast, inhalation of zinc chloride fumes (chemical smoke) causes severe respiratory symptoms and may be fatal. Ingestion of zinc chloride causes caustic injury to the gastrointestinal tract with nausea, vomiting, epigastric pain, and hematemesis. Central nervous system (CNS) depression and renal dysfunction also may occur.

Side effects of zinc gluconate ingestion for treatment of the common cold are nausea, vomiting, and diarrhea. Long-term zinc may lead to copper deficiency, and excessive supplementation on a chronic basis may cause sideroblastic anemia (50).

Cobalt

The only known function of cobalt is as the metal component of vitamin B_{12}. Cobalt also can substitute for zinc in metalloenzymes, but the significance of this is not clear. The recommended daily allowance for vitamin B_{12} contains 0.13 mcg of cobalt. The average diet contains a surplus of cobalt (about 300 mcg). Cobalt is absorbed readily in the gastrointestinal tract. Renal excretion is the major route of elimination.

Clinical Syndromes

Inadequate cobalt causes vitamin B_{12} deficiency (See Chapter 35, HLA: Structure, Function, and Methodologies).

Cobalt is found in steel alloys of diamond-grinding disks, other industrial tools, and jet engines and in pigments in paints, china, and glass. Most commonly, occupational hazard is associated with the dusts or fumes that are produced during use of cobalt-containing tools. Direct contact with these dusts and fumes causes dermatitis, conjuctivitis, and rhinitis, and chronic inhalation results in pulmonary disorders such as allergic asthma,

interstitial pneumonitis and pulmonary fibrosis. Similarly, dusts and fumes from hard metal, a tungsten carbide-cobalt amalgam, are mucosal irritants.

Cobalt ingestion is associated with cardiotoxicity. Formerly, cobalt was used as a foam stabilizer commonly added to beer. Chronic excessive ingestion of cobalt-containing beer leads to polycythemia, goiter, and heart disease characterized by cardiomyopathy, pericardial effusion, and congestive heart failure (“beer drinker's cardiomyopathy”). The toxicity in these cases may have been exacerbated by concomitant nutritional deficiencies and ethanol. Accumulation of cobalt also occurs in uremic patients and may contribute to uremic cardiomyopathy (51).

Copper

Copper is an intrinsic part of a number of metal enzymes including cytochrome C oxidase, lysyl oxidase (connective tissue cross-linking), tyrosinase (melanin synthesis), dopamine-ß-hydroxylase (cathecholamine synthesis), and superoxide dismutase. The daily adult requirement for copper is about 2 mg. The copper content in food is dependent upon the copper content in the local soil. Shellfish and liver are rich sources of copper.

Copper is absorbed readily from the small intestine by a mechanism shared with zinc. Accordingly, there is a reciprocal relationship between zinc and copper absorption. Copper is stored in the liver and released into blood bound to ceruloplasmin. Most of the copper present in serum is bound tightly to ceruloplasmin. The major route of copper elimination is biliary (80%). Less than 5% is excreted in urine.

Clinical Syndromes

Copper deficiency is characterized by hypochromic anemia, neutropenia, bone and joint deformities, decreased skin pigmentation, and neurologic abnormalities including hypotonia and psychomotor retardation. The anemia is responsive only to copper supplementation and occurs because copper is required for iron incorporation into heme. Premature infants are at risk of developing copper deficiency as are patients with chronic diarrhea and malabsorption states and those on long-term total parenteral nutrition (52). Long-term zinc supplementation also may contribute to copper deficiency.

Menke's kinky hair syndrome (trichopoliodystrophy), a sex-linked, recessive disorder, is characterized by a functional copper deficiency. Its features include *pili torti* (kinky hair), retarded growth development, cerebral degeneration, arterial tortuosity, cardiac rupture, and bone and joint deformities. Serum copper and ceruloplasmin are low, and copper therapy does not cure this disease.

An accumulation of copper occurs in Wilson's disease (hepatolenticular degeneration), an autosomal-recessive disorder. Copper absorption is normal while copper excretion into bile is defective. As a result, excess copper deposits into various tissues including liver, brain, cornea, and kidneys. Clinical manifestations include Kayser-Fleischer corneal rings, hepatitis, cirrhosis, intellectual deterioration, behavioral and personality changes, tremor, dysarthria, and gait disturbance. In most cases, ceruloplasmin is decreased to less than 20 mg/dL. Liver copper is increased to greater than 250 mcg/g dry weight, and daily urinary copper excretion is greater than 100 mcg. Serum copper may be low or normal.

Copper is used widely in electrical wires, cooking utensils, and plumbing pipes. It also is found in common alloys such bronze (tin) and brass (zinc), industrial catalysts, furniture polishes, dyes, glass, and ceramics. Copper sulfate is used as an insecticide, herbicide, fungicide, and algicide commonly used in swimming pools (53). Copper smelters are at risk for inhalation of fine copper dust, which causes metal-fume fever similar to that observed with zinc oxide. Anorexia, nausea, and hepatomegaly also may occur. Copper salts are corrosive agents, and ingestion causes hemolytic anemia, nausea, vomiting, diarrhea, emesis, and abdominal pain. Gastrointestinal bleeding, shock, coma, and death also may occur. Hepatic and renal failure are common later sequelae.

Ingestion of excessive copper supplementation or contaminated water or beverages also may cause symptoms of gastroenteristis and hemolytic anemia. Copper leaching from pipes and containers occurs more with acidic and carbonated liquids. Chronic copper exposure leads to hepatic and CNS abnormalities resembling Wilson's disease. Copper toxicity from ingestion of milk and other liquids stored in brass containers is the likely cause of Indian childhood cirrhosis (ICC) (54).

Manganese

Manganese is an essential cofactor of numerous cellular enzymes including mitochondrial superoxide dismutase. Manganese is absorbed through the small intestine. Efficiency of absorption is low. Absorption and elimination appear to be regulated by the amount of dietary manganese. The major route of elimination is biliary with very little excreted in urine.

Clinical Syndromes

Abnormalities that have been associated with low manganese include impaired growth, skeletal deformities, decreased reproductive function, ataxia, and seizures (55, 56). However, these findings occurred in a small number of isolated cases, and a deficiency syndrome has yet to be well defined.

Manganese is used in various metal alloys, batteries, and ceramics. Acute toxicity in the form of metal fume fever (fever, chills, myalgia) may occur following inhalation of manganese fumes. Long-term inhalation may lead to chronic disability characterized by psychiatric and CNS finding (headache, irritability, personality change, hallucinations, memory loss, compulsive laughing or crying) or neurologic signs resembling Parkinson's disease (akinesia, rigidity, tremor). Liver failure may cause manganese neurotoxicity.

Molybdenum

Molybdenum is an essential component of xanthine oxidase, aldehyde oxidase, and sulfite oxidase.

Clinical Syndromes

There is no well-recognized molybdenum deficiency syndrome. Low molybedum may be associated with mental retardation, seizures, bilateral lens dislocation, sulfaturia, and thiosulfaturia.

Molybdenum is used in welding rods. Fume inhalation may cause anorexia, diarrhea, weakness, fatigue, headache, myalgia, and cough. Toxicity also may develop in areas with high molybdenum content in local soil. Hepatosplenomegaly, renal diseases, and inflammatory arthritis may occur (57).

Chromium

Chromium is required for glucose and lipid metabolism (58). Chromium is a crucial component of glucose tolerance factor (GTF), which potentiates insulin action. Meat and whole-grain foods are rich in chromium. Daily intake of chromium should be about 50 to 300 mcg. Chromium is absorbed in the small intestine. Urinary excretion is the major route of elimination.

Clinical Syndromes

The primary feature of chromium deficiency is hyperglycemia or glucose intolerance. Elevated free fatty acids, accerelated atherosclerosis, peripheral neuropathy, and encephalopathy also may occur in chronic chromium deficiency. Long-term parenteral nutrition is a known cause of deficiency. However, more extensive documentation of chromium deficiency cases has been hindered by the inability to make sensitive and specific chromium measurements. Chromium deficiency may exist frequently in adults with glucose intolerance or insulin resistance diabetes as well as in individuals with general malnutrition. Deficiency is suggested by the improvement of glucose tolerance following chromium supplementation.

Chromium is found in various metal alloys, pigments, dyes, and preservatives. Toxic chromium compounds are used in steel making, electroplating, photography processing, and leather tanning industries. Hexavalent chromium compounds (chromium trioxide and chromic acid) are the most toxic (59, 60). Ingestion of these corrosive agents may cause hemorrhagic gastroenteritis, hepatic and renal damage, coagulopathy, and hemolysis. Chronic inhalation of dusts and fumes may cause asthma, pneumoconiosis, and lung cancer. Contact leads to dermatitis, skin ulceration, and nasal septum perforation. Bivalent and trivalent forms such as chromic oxide and chromic sulfate are relatively insoluble and nontoxic.

Selenium

Selenium is an important antioxidant in the body. It is a component of the enzyme, glutathione peroxidase (61). This enzyme contains four atoms of selenium per molecule and functions to prevent oxidative damage to cells by quenching peroxides. Selenium also is a part of the enzyme, thyroxine-5′-deiodinase, and as such is involved in thyroid hormone metabolism.

Selenium is the least abundant and potentially the most toxic of all the essential elements (62). Seafood, meats, and cereals contain selenium, and daily intake is dependent upon the local soil content of selenium. The recommended daily allowance is 50 to 200 mcg. Selenium is absorbed from the gastrointestinal tract and is excreted readily into urine. The site and mechanism of its absorption are not well known.

Clinical Syndromes

Deficiency of selenium has been linked to cardiomyopathy and skeletal muscular degeneration.

Deficiency occurs in patients on long-term parenteral nutrition and endemically in areas with low selenium content in soil. Keschan disease is a form of dilated cardiomyopathy that affects mostly children in China and has been associated with selenium deficiency (63). Decreased selenium also has been linked to endemic osteoarthritis (Kashin-Beck disease) and skeletal muscle weakness and pain (64).

Selenium salts (sodium selenite, sodium selenate, iron selenide) are used in the electronic, semiconductor, steel, glass, ceramic, and pigment industries (65). Selenium is used also as a dietary supplement (elemental selenium) and as a component of antidandruff shampoo (selenium sulfide). Elemental selenium and selenium sulfide are relatively low in toxicity. Acute overdose of selenium or its salts may cause nausea, vomiting, abdominal pain, fatigue, and irritability. Chronic daily exposure to more than 3 mg of selenium may cause hyperreflexia, paresthesias, alopecia, white striae on the nails, metallic taste, and garlic odor on the breath. Exposure to selenium dusts produces respiratory-tract irritation, epistaxis, and cough.

Selenious acid (H_2SeO_3) is the most toxic form of selenium (66). It is used as a gun bluing agent. As little as 15 mL is potentially fatal. Ingestion causes gastrointestinal burns and erosion, hypersalivation, vomiting, diarrhea, muscle spasm, pulmonary edema, seizure, stupor, and respiratory depression.

Fluoride

Fluoride is absorbed in the small intestine and is incorporated into bone and teeth. Fluoride increases bone density and calcification and prevents tooth decay. Fluoride supplementation of public drinking water for the prevention of dental caries is limited to 1.5 mg per liter. Daily intake of fluoride is dependent upon consumption of fluoridated water and foods prepared with that water.

Clinical Syndromes

Fluoride compounds are widely used as insecticides and rodenticides. Hydrofluoric acid (aqueous hydrogen fluoride) is used to remove rust, to etch glass, and to manufacture semiconductor chips.

Fluoride in pharmacologic doses (15 to 60 mg per day) stimulates osteoblasts and increases trabecular bone mass and has been used to treat post-menopausal osteoporosis (67). Toothpaste usually contains no more than 1 mg fluoride per gram, and the maximum allowable amount of fluoride in a single tube is 260 mg. Approximately 0.05 mg/kg per day is optimal for prevention of tooth decay.

Acute ingestion of more than 5 to 10 mg/kg of fluoride may produce vomiting, abdominal pain, gastrointestinal ulceration and hemorrhage, hypocalcemia, hypomagnesemia, tetany, muscle weakness, respiratory depression, coma, arrhythmias, and death. Contact with hydrogen fluoride can cause severe corrosive injury to eyes, nose, mouth, and skin. Inhalation of the gas leads

to sore throat, cough, bronchospasm, chemical pneumonia, and pulmonary edema. Chronic fluoride overexposure produces discoloration of tooth enamel (mottling) and skeletal fluorosis (excess bone calcification, tendon and ligament calcification, and joint fusion.) Fluorosis occurs with chronic doses as low as 0.1 mg/kg/day for 10 to 20 years.

Nickel

The role of nickel as an essential micronutrient has not been well established. Daily dietary intake of nickel is about 0.3 to 0.6 mg. Nickel is absorbed poorly through the gastrointestinal tract. It is distributed mostly to the kidneys, liver, and lungs. Tissue accumulation is minimal. The primary route of elimination is renal.

Clinical Syndromes

Nickel is used in metal plating, electronic devices, and various metal alloys. Stainless-steel contains about 15% nickel. Nickel is emitted into the environment largely as a result of fuel oil combustion and waste and sewage treatments.

Nickel is a skin, mucous membrane, and respiratory tract irritant. Contact dermatitis, eczema, urticaria, and asthma occur in sensitized individuals. Most stainless-steel and costume jewelry allergies are likely because of nickel. Toxicity of metallic nickel and nickel alloys is low.

Nickel carbonyl is a very toxic form of nickel formed by contact of nickel with carbon monoxide (68). Inhalation exposure occurs in the rubber, electronic parts, battery, and electroplating industries. Immediate symptoms are headache, nausea, dyspnea, dizziness, and chest pain followed in 1 to 5 days by severe pulmonary symptoms (cyanosis, pneumonitis), arrhythmias, weakness, muscle pain, and convulsion.

Metallic nickel and many nickel compounds are probable or known human carcinogens. In particular, nickel sub-sulfide, which is found in refinery dust, causes lung and nasal carcinomas.

Iodine is discussed in Chapter 16, Endocrine Function and Carbohydrates.

NONESSENTIAL TRACE ELEMENTS

Part of "23 - Trace Elements, Vitamins, and Nutrition"

Sources and toxic effects of non-essential trace elements are discussed and presented in Table 23.7.

TABLE 23.7. TOXIC EFFECTS OF NONESSENTIAL TRACE ELEMENTS

Metal	Toxic Effects
Aluminium	Dialysis encephalopathy
	Pulmonary fibrosis following dust inhalation
Arsenic	Organic forms are not toxic.
	Arsine gas inhalation causes hemolysis, abdominal pain, and renal failure
	Acute inorganic arsenic ingestion causes hemorrhagic gastroenteritis, hypotension, shock, death, cold, clammy skin, muscle cramps, delirium, seizure, coma with delayed peripheral neuropathy and Aldrich-Mees' lines.
	Chronic toxicity may cause malaise, anorexia, anemia, gastroenteritis, hepatitis, skin lesions (hyperpigmentation, hyperkeratosis), Aldrich-Mees' lines, and peripheral neuropathy.
	Carcinogenic.
Cadmium	Inhalation produces a chemical pneumonitis.
	Chronic exposure to cadmium causes pulmonary fibrosis, renal failure, and osteomalacia.
Gold	Allergic dermatitis, stomatitis, alopecia, hypersensitivity pneumonitis, drug-induced lupus, bone marrow suppression, hepatitis, colitis, proteinuria, encephalopathy, and neuropathy
Lead	Acute toxicity is characterized by abdominal pain, nausea, vomiting, hepatotoxicity, hemolysis, renal failure, convulsions, and coma.
	Subacute or chronic exposure causes malaise, irritability, anorexia, anemia with basophilic stippling, constipation or diarrhea, other gastrointestinal complaints, renal toxicity, hypertension, and central nervous system manifestations including ataxia, incoordination, headache, diminished concentration, and acute encephalopathy with increased intracranial pressure.
	Chronic exposure in children is associated with low intelligence, decreased growth, diminished hearing, hyperactivity, and aggressive behavior.
	Permanent mental retardation may occur at high lead levels.
Mercury	Elemental mercury inhalation causes gingivitis, tremor, and neuropsychiatric changes (irritability, angry fits, mood lability, memory loss, depression, anxiety), corrosive bronchitis, and acrodynia.
	Inorganic mercury especially mercuric chloride causes hemorrhagic gastroenteritis with esophageal erosions, hematemesis, severe abdominal cramps and renal failure.
	Organic mercury especially methylmercury causes neurotoxicity including memory loss, personality changes, ataxia, paresthesias, motor weakness, dysarthria, hearing loss, and constricted visual fields. Quadraplegia, coma, and death may occur in severe to xicity. Also teratogenic.

Aluminum

Aluminum is the most abundant metal and the third most abundant element (after oxygen and silicon) in the earth's crust. It is found in all human tissues but has no demonstrated biological role. The average daily oral intake ranges from 10 to 100 mg. Food alone usually accounts for no more than 2 to 40 mg of aluminum per day. Use of aluminum food packaging, pans, and utensils can increase markedly aluminum intake. Individuals taking aluminum hydroxide antacids or phosphate-binding therapy may ingest 300 mg or more per day. Only 2% to 6% of ingested aluminum is absorbed (69). Renal excretion is the major route of elimination.

Patients with chronic renal failure and workers with aluminum in the workplace are at risk for developing aluminum toxicity. In renal failure, patients are not able to eliminate aluminum from aluminum-containing agents that are administered in order to lower their serum phosphate (70). Previously, those patients undergoing dialysis were at added risk because of aluminum in the dialysate. A progressive encephalopathy usually occurs after months or years of exposure to aluminum. Common manifestations include speech disturbance (stuttering or stammering), diminished attention and memory, disorientation, visual and auditory hallucinations, paranoia, and suicidal ideation. Microcytic anemia and neuromuscular abnormalities such as tremor, twitching, myoclonus, and immobility also may occur. Excessive amounts of aluminum also may cause osteomalacia and hypercalcemia because aluminum blocks the incorporation of calcium into osteoid. Occupational toxicity is most often a result of inhalation of aluminum dusts, which causes respiratory-tract irritation and leads to pulmonary fibrosis. Aluminum welders and smelters are at particular risk.

High levels of aluminum are found in the neurofibrillary tangles in the hippocampus and cerebral cortex in Alzheimer's disease. However, the causal relationship of aluminum and Alzheimer's disease has not been proven.

Measurement

Measurement of aluminum in body fluids is performed using atomic absorption spectrometry.

Because aluminum is ubiquitous, extreme caution is necessary to avoid specimen contamination in the laboratory.

Blood levels are used widely to monitor dialysis patients (71). Normal nontoxic blood levels are less than 15 mcg/L. Levels greater than 100 mcg/L are considered elevated and may indicate toxicity, but blood levels do not correlate with total body burden or severity of clinical toxicity.

Very little aluminum is excreted in urine and the urinary elimination half-life of aluminum is highly variable. Nevertheless, aluminum measurement in 24-hour urine may be used to monitor occupational exposures and chelation therapy. Hair measurement is not useful.

Arsenic

Arsenic is the second most common heavy metal (after lead) to cause significant poisoning. The toxicity of arsenic depends upon the form of arsenic (72). The most frequent source of arsenic poisoning is pesticides that contain inorganic arsenic compounds. **Organic arsenic** forms are found in seafood and include arsenobetain and arsenocholin. These forms are not toxic. Their half-lives are 4 to 6 hours, and they are completely cleared in urine in 1 to 2 days. **Metallic** arsenic also is nontoxic.

Arsine gas (AsH_3) is the most toxic form of arsenic. It is formed in metal smelting and refining and in the microelectronics industry when metals containing arsenic react with acid. Exposure to as little as 0.05 ppm is considered toxic, and 25 to 50 ppm may be fatal. Arsine gas is a colorless gas with a garlic-like odor. It is well absorbed by inhalation but is noncorrosive and does not cause respiratory symptoms. There is a latent period of up to 24 hours followed by abdominal pain and massive intravascular hemolysis. Secondary renal failure typically occurs in a couple of days.

Inorganic forms of arsenic are toxic. Arsenic trioxide (As_2O_3) is the most common commercial form of arsenic. It and other trivalent forms of arsenic (arsenite) react with free sulfhydryl groups and thereby inhibit important enzymes. Pentavalent arsenic (arseniate) as found in arsenic acid is somewhat less toxic than arsenite because of lesser solubility and is capable of substituting for phosphate and inhibiting mitochondrial oxidative phosphorylation.

Both trivalent and pentavalent forms of arsenic are found in pesticides, insecticides, herbicides, wood preservatives, and certain pigments used in glass manufacturing. Unintentional exposures occur as a result of gardening, boating, and ingestion of water or foods retaining pesticide residues. Smoking of cigarettes of tobacco sprayed with arsenic pesticides also may cause toxicity. Arsenic also may be used to cause intentional poisoning. Because of their high potency and ability to cause rapid death, arsenic compounds are used not infrequently for suicidal and homicidal purposes.

Contact with inorganic arsenic causes skin and mucous membrane irritation. Ingestion usually causes immediate symptoms of hemorrhagic gastroenteritis including nausea, vomiting, hematemesis, and rice water or bloody diarrhea. A garlic odor on the breath is characteristic. Hypotension, shock, and death may ensue. Other features include cold, clammy skin, delirium, encephalopathy, seizure, and lactic acidosis.

Delayed manifestations of acute arsenic poisoning may occur several weeks to months following exposure and include alopecia, hepatotoxicity, and neurologic abnormalities. The delayed peripheral neuropathy involves mostly the lower extremities and is characterized by distal paresthesias, ascending motor weakness, and paralysis. Aldrich-Mees lines, which are transverse striae on nails, occur at about 5 weeks after the exposure.

Chronic arsenic poisoning usually occurs from inhalation of arsenic compounds in the workplace or from ingestion of contaminated food or water (73, 74). Affected individuals may present with nonspecific complaints of fatigue, weakness, irritability, malaise, and anorexia. There may also be a garlic odor on breath, delirium, encephalopathy, seizures, Aldrich—Mees lines, neutropenia, anemia with basophilic stippling, gastroenteritis, hepatomegaly, chronic hepatitis, and cirrhosis. Characteristic skin lesions (pattern of hyperpigmentation and hypopigmentation with hyperkeratosis) typically develop only after years of exposure. Chronic arsenic also may cause a progressive peripheral neuropathy that is characterized by paresthesias or sensory loss with weakness, tremor, fasciculations, and loss of reflexes that occurs

first in the soles of the feet. Debilitating muscle weakness and atrophy may develop. Hoarseness, conjunctivitis, dermatitis, and perforation of the nasal septum may be present as a result of contact with arsenic dusts and fumes.

Arsenic also is a human **carcinogen**. A high incidence of lung cancer and hepatic angiosarcoma in the metal-smelting industry has been attributed to inhalation of dust from arsenic compounds such as arsenic trioxide and sulfide. Skin cancer has been associated with the chronic use of Fowler's solution (1% potassium arsenite) which was used in the first half of the 1900s as a topical agent to treat various skin disorders. Arsenic also may be linked to renal and bladder cancers.

Measurement

Arsenic is measured by atomic absorption spectrometry. An older colorimetric method utilizes silver diethyldithiocarbamate.

The short half-life of arsenic (about 2 to 6 hours) limits its detection period in blood. Blood levels are elevated for only 2 to 4 hours immediately following exposure (75) and are useful only in the first few hours of acute toxicity. Blood levels decline rapidly despite ongoing toxicity and cannot be used reliably in the assessment of chronic toxicity. Normal blood levels are less than 70 mcg/L. Fatal arsenic overdoses have been associated with blood levels ranging from 600 to 3,300 mcg/L (76). However, blood levels are highly variable and do not correlate well with the severity of toxicity.

A 24-hour urine is the most reliable specimen for assessment of arsenic poisoning. In normal, unexposed individuals, arsenic should be less than 50 mcg/L. Levels greater than 200 mcg/L indicate toxicity. Those between 50 and 200 mcg/L are considered borderline. Toxic forms of arsenic should cause elevated urine levels for about 6 to 20 days following exposure. Ingestion of seafood (nontoxic organic arsenic) also will elevate urine levels (200 to 1,700 mcg/L), and abstinence from seafood for 3 days prior to collection is recommended.

Hair measurement often is useful in the investigation of chronic arsenic poisoning because hair may afford a longer detection period. However, external contamination is an important consideration. About 30 hours are required after ingestion for arsenic deposition into hair to take place. Hair arsenic levels are normally less than 1 mcg/g. In chronic poisoning, these levels are elevated to 1-5 mcg/gram or more.

Most screening tests measure total arsenic. Speciation may be necessary to distinguish toxic inorganic arsenic compounds and nontoxic organoarsenicals. Typically, arsenic species are resolved by liquid chromatography or similar technique prior to their individual measurement by atomic absorption. It is important to remember when interpreting results that inorganic arsenic is converted in the body to organic metabolites, monomethylarsonic acid (MMA) and dimethylarsonic acid (DMA), consecutively. Following recent exposure to inorganic arsenic, there will be some MMA and DMA in the urine, and the amount of MMA exceeds that of DMA. In cases of chronic toxicity, DMA is greater than MMA. These differences can sometimes be used to date the exposure.

Cadmium

Cadmium has no physiologic role. Cadmium is poorly absorbed from the gastrointestinal tract. Cadmium has a very long biologic half-life of 10-30 years and is the heavy metal most likely to accumulate in the body. As such, the toxicity of cadmium is of significant public health concern.

Environmental exposures to cadmium in the general population occur through contaminated air, food and water. Cadmium occupational risk is high in nickel cadmium battery manufacturing, metal welding and smelting, and electroplating industries. Cadmium is also used as a pigment and stabilizer in paints and plastics.

Cadmium inhibits enzymes with critical sulfhydryl groups. It also interferes with zinc absorption and the function of zinc metalloenzymes. Cadmium accumulates in the kidneys and effects damage to the renal tubules. This nephrotoxicity is exacerbated in zinc deficiency.

Exposures to cadmium occur by ingestion or inhalation of fumes and dust. Acute inhalation is many times more toxic than ingestion. Inhalation produces a chemical pneumonitis characterized by cough, dyspnea, and chest pain. Pulmonary edema and death from respiratory failure may occur. Ingestion may cause abdominal cramping and diarrhea.

Chronic exposure to cadmium causes pulmonary fibrosis, renal failure, and osteomalacia. In the 1960s, a metals processing plant in Japan released cadmium into the local water which contaminated food products and subsequently caused severe cadmium poisoning called the Itai-Itai or “ouch ouch” disease. Prominent features were osteomalacia, skeletal deformities, and severe leg and back pain probably resulting from calcium and phosphorus disturbances secondary to renal damage (77).

Elevated cadmium has also been linked to hypertension (78). Furthermore, cadmium is a known carcinogen, and cadmium smelters have an increased incidence of lung cancer. Unlike lead and arsenic, cadmium is not a well-established cause of peripheral neuropathy. There is only one known reference that makes this association (79).

Measurements

Because of cadmium's high renal and pulmonary toxicity, exposed workers should be monitored periodically by cadmium measurements, urine β_2-microglobulin, and pulmonary function studies.

Electrothermal atomic absorption spectrometry for the measurement of cadmium in biologic samples has replaced an older dithizone colorimetric method. Special caution to avoid contamination is necessary because of the minute amounts of cadmium in normal blood and urine. Cadmium is highly bound to red cells, and the normal range for whole blood cadmium is 0.5 to 1.0 mcg/L. Cigarette smokers have higher levels, 1.4 to 4.0 mcg/L. Whole-blood measurements greater than 5 mcg/L are potentially toxic. Whole-blood cadmium levels will fall to normal months after last exposure while urine cadmium will remain elevated for longer periods.

For urine measurements, a 24-hour specimen is preferred. Urine cadmium is normally below 1 mcg/L. Values may be expressed

in micrograms per gram creatinine. Levels greater than 5 mcg/g creatinine are associated with irreversible renal damage. Urine β_2-microglobulin is elevated in cadmium-induced renal damage and levels correlate with duration and extent of cadmium exposure. Hair measurements also may be elevated in chronic toxicity. Normal levels are less than 1.0 mcg/gram.

Like other metals, cadmium in the body binds to the protein, metallothionein. Metallothionein appears to have a protective effect against cadmium toxicity. Elevated levels of urine metallothionein appear to correlate with cadmium accumulation. However, this test lacks specificity for cadmium since copper and zinc also will elevate levels.

Gold

Oral methotrexate therapy has largely replace gold therapy in the treatment of rheumatoid arthritis. Gold sodium thiomalate and gold sodium thioglucose both have been employed as a treatment for rheumatoid arthritis. These substances inhibit lysosomal enzymes and thereby reduce inflammation in the joints.

Gold has been associated with allergic dermatitis, stomatitis, alopecia, hypersensitivity pneumonitis, drug-induced lupus, bone-marrow suppression, hepatitis, colitis, proteinuria, encephalopathy, and neuropathy. Severe toxicity occurs in approximately 3% of cases. Because of these concerns, patients receiving gold therapy are monitored by platelet count, urinary protein, and serum aspartate aminotransferase. Gold toxicity does not appear to be dose-dependent. Furthermore, there is no correlation between serum or urine measurements of gold and toxicity or efficacy of therapy (80). Therefore, measurement of gold is almost never performed.

Lead

Lead is the most common heavy metal to cause poisoning and is of particular concern in children. Paints manufactured prior to 1977 contained significant amounts of lead, and buildings covered with these paints continue to be a major source of lead exposure. Toxicity occurs from lead ingested in the form of paint chips or inhaled as dust, debris, or fumes. At risk for lead toxicity are workers in certain industries and children who repeatedly ingest paint chips or lead-contaminated debris. Lead exposure also occurs from consuming plants grown in lead-contaminated soil and water from lead pipes, ceramics, and crystal containers. Other sources of lead are moonshine, certain herbal medications, and older gasoline products. In the 1990s, the Environmental Protection Agency oversaw the removal of tetraethyl lead from gasoline in the United States. Industries associated with significant lead exposure include lead battery manufacturing, ore smelting and refining, torching, soldering, building demolition and renovation, ammunitions and shipbuilding. In children, exposure occurs most commonly by ingestion of lead paint chips, dust, or soil. Industrial exposure generally is because of the inhalation of fumes or dusts.

Lead interferes with membrane integrity, neurotransmitter function, heme synthesis, and mitochondrial oxidative phosphorylation. In particular, lead inhibits the activity of the enzymes, aminolevulinic acid dehydrase, which converts aminolevulinic acid (ALA) to porphobilinogen, and coproporphyrinogen decarboxylase, which converts coproporphyrinogen to protoporphyrin. As a result, urinary ALA and coproporphyrin are elevated. Lead also interferes with incorporation of iron into the tetrapyrrole ring of hemoglobin.

Manifestations

Acute toxicity may be caused by pica, the ingestion of nonfood substances, and is characterized by abdominal pain, nausea, vomiting, hepatotoxicity, hemolysis, renal failure, convulsions, and coma. More commonly, toxicity is subacute or chronic in nature. Features include malaise, irritability, anorexia, anemia with basophilic stippling, constipation or diarrhea, other gastrointestinal complaints, renal toxicity, hypertension, and CNS manifestations including ataxia, incoordination, headache, diminished concentration, and acute encephalopathy with increased intracranial pressure. A peripheral neuropathy characterized by distal motor weakness (called lead palsy) occurs more often in adults than in children and does not appear to be dose-related. Hearing impairment, lead lines (blue lines in gingiva), and a metallic taste are also characteristic of lead toxicity.

The developing CNS is susceptible particularly to lead toxicity. Studies in children have shown that chronic low-level exposure to lead (whole blood levels over 10 mcg/dL) is associated with low intelligence, decreased growth and diminished hearing in children (81). Developmental delay, hyperactivity, and aggressive behavior also are linked to lead, and permanent mental retardation may occur at higher lead levels.

Measurements

Whole blood lead level is the best indicator of lead exposure. Plasma and serum are not appropriate. To avoid contamination, blood should be collected using lead-free syringe and tubes, and venipuncture technique is preferred over capillary blood sampling by fingerstick. Normal whole blood lead levels are less than 20 mcg/dL (1 mcmol/L) in adult urban populations and less than 10 mcg/dL (0.5 mcmol/L) in rural settings. In adults, levels over 40 mcg/dL(2 mcmol/L) are considered toxic, and overt intoxication (acute encephalopathy, lead colic, nephropathy) occurs at levels greater than 100 mcg/dL. All patients with blood level concentrations of 45 mcg/dL (2.2 mcmol/L) or higher should be chelated with cacium EDTA, dimercaprol (BAL), or dimercapto succinic acid (DMSA).

Toxic blood levels in children are significantly lower. During the 1980s, levels in excess of 25 mcg/dL (1.2 mcmol/L) were considered toxic. In 1991, the threshold level was revised downward to 10 mcg/dL (0.48 mcmol/L) (48). Current CDC recommendations for children are listed in Table 23.8.

TABLE 23.8. CENTERS FOR DISEASE CONTROL GUIDELINES FOR EVALUATION OF LEAD POISONING IN CHILDREN (1991)

Class	Blood Lead in mcg/dL	Concentration in mcmol/L	Comments
I	< 10	< 0.5	Not considered to be lead poisoning
II	10–14	0.5–0.7	Many children (or a large proportion of children) with blood lead levels in this range should trigger community-wide childhood lead poisoning prevention activities. Children in this range should be rescreened frequently.
III	15–19	0.7–0.97	Child should receive nutritional and educational interventions and more frequent screening. If the blood lead level persists in this range, environmental investigation and intervention should be done.
III	20–44	1–2.1	Child should receive environmental evaluation, remediation and a medical evaluation. Such a child may need pharmacologic treatment of lead poisoning.
IV	45–69	2.2–3.3	The child will need both medical and environmental intervention, including chelation therapy.
V	> 70	> 3.3	The child should be considered a medical emergency. Medical and environmental intervention must begin immediately.

From Olsen KR, ed. *Poisoning and drug overdose*, 2nd ed. Norwalk, CT: Appleton & Lange, 1994:210–213.

Urinary lead excretion is variable, poor and lacks correlation with CNS effects. Urine levels also will decrease more rapidly than blood levels following untreated exposures. Urine lead measurements are most useful for monitoring chelation therapy. A 24-hour urine collection is indicated and must be done using a lead-free container (e.g., a polyethylene bottle that has been washed with hydrochloric acid). An EDTA challenge test is the measurement of urinary lead excretion (8-hour or 24-hour) following a dose of EDTA (82). This test may be used in children

with levels between 25 and 44 mcg/L; those with high urinary lead levels would be additional candidates for chelation.

Lead measurement is taken using atomic absorption spectrometry or anodic stripping voltametry. Graphite tube flameless atomic absorption methods also have been developed. Measurements should be made without delay because over time, lead in standard solutions and samples will adsorb onto the walls of glass tubes.

In lead toxicity, elevations occur in free erythrocyte protoporphyrin, zinc protoporphyrin, urinary coproporphyrin, and urinary ALA levels as a result of impaired heme synthesis. None of these biochemical markers are specific for lead toxicity. Blood protoporphyrin levels become elevated several weeks following significant lead exposure and also are elevated in iron deficiency. Patients with inborn errors of metabolism also will have elevated urinary coproporphyrin and ALA excretion.

Mercury

Mercury has no known biological function but is a well-recognized toxin. Mercury is found in elemental, organic, and inorganic forms (83). Elemental mercury is used in thermometers, dental amalgams, paints, and chemical industries. It is a liquid that is vaporized readily. Following inhalation, mercury passes through alveoli and diffuses into tissues, notably the CNS, and causes a triad of gingivitis, tremor, and neuropsychiatric changes (irritability, angry fits, mood lability, memory loss, depression, anxiety). Acute inhalation also may cause a corrosive bronchitis. Chronic vapor exposure may cause acrodynia, an idiosyncratic reaction characterized by pain and pink discoloration of the extremities, sweating, anorexia, and insomnia. In contrast, ingestion of elemental mercury does not cause poisoning because gastrointestinal absorption is very poor. A common scenario for poisoning is ironing of clothes that are contaminated with liquid-mercury droplets. Heat from the iron causes mercury vaporization. The presence of multiple dental amalgams has been associated with elevated mercury levels presumably as a result of vaporizing small amounts of mercury during mastication. However, their potential to cause clinical toxicity is controversial.

Inorganic mercury occurs in mercurous (Hg^{+}) and mercuric (Hg^{++}) forms. Formerly, inorganic forms of mercury were used commonly in disinfectants ($HgCl_2$), calomel laxative (Hg_2Cl_2), and hat manufacturing ($HgNO_2$). Exposure more often is by ingestion than through inhalation or dermal exposure. Ingestion of inorganic mercury salts, especially mercuric chloride, can cause hemorrhagic gastroenteritis with esophageal erosions, hematemesis, and severe abdominal cramps. Shock and cardiovascular collapse may ensue. Nephrotic syndrome and renal failure also occur.

Serious mercury toxicity is most commonly caused by organic mercury. Organic mercury compounds are well absorbed gastrointestinally and dermally and are distributed widely in the body. Organic mercury exists in short-chain alkyl (methyl, ethyl), aryl (phenyl) and long-chain forms. Long-chain and aryl mercury compounds have a labile carbon-mercury bond and undergo conversion to inorganic mercury in the body. Short-chain organic mercury compounds are found in contaminated fish, fungicides, and antiseptic products. Bacteria and marine organisms convert inorganic mercury in pollutants to methylmercury, and ingestion of methylmercury-contaminated fish caused an epidemic in Japan during the 1950s known as Minamata disease. Short-chain organic compounds, especially methylmercury, cause neurotoxicity including memory loss, personality changes, ataxia, paresthesias, motor weakness, dysarthria, hearing loss, and constricted visual fields. Quadraplegia, coma, and death may occur in severe toxicity. Methylmercury also is teratogenic and causes mental retardation and cerebral palsy. In contrast to elemental and inorganic mercury, which are primarily renally

excreted, organic mercury is eliminated primarily in feces with less than 10% excreted in urine.

Measurement

Mercury analysis is performed by flameless atomic absorption spectrometry. Whole-blood mercury levels are used to confirm exposure to mercury. Levels less than 2 mcg/dL are considered normal. Levels greater than 35 mcg/dL are considered toxic. Short-chain mercury compounds have high affinity for red blood cells (RBC:plasma ratio of 5:1 to 20:1), which may be used to differentiate them from other mercury forms. Speciation into organic and nonorganic fractions also may be performed to determine the type of mercury exposure.

Urine levels are particularly useful in monitoring chelation therapy. Urine should be collected as a 24-hour collection in an acid-washed container. The urine level also will remain elevated for a longer period of time than blood following exposure. In inorganic mercury poisoning, urine levels of greater than 100 mcg/L are considered elevated. In methylmercury intoxication, urine is not a good index of total body burden because less than 10% is excreted in urine.

Inborn Metabolic Errors

Tina M. Cowan

Miriam G. Blitzer

INTRODUCTION

Part of "24 - Inborn Metabolic Errors"

Human metabolism consists of a large number of interrelated and coordinated biochemical reactions, each of which is governed by the activity of one or more enzymes. Many of these reactions are involved in the degradation of proteins, lipids, and carbohydrates, which are derived either from the ingestion of food or from the normal turnover of endogenous compounds. An *inborn error of metabolism* is defined classically as a genetic defect in which reduced or absent enzyme activity leads to a specific block in a metabolic (usually catabolic) pathway. Such a block can lead to abnormal accumulation of substrate (and often its secondary metabolites) and/or a depletion of downstream intermediates, leading in turn to clinical pathology. Inborn errors typically are categorized by the metabolic pathway that is impaired, and include disorders of amino acid, organic acid, fatty acid, and carbohydrate metabolism. Clinically, most inborn errors of metabolism present with symptoms that could be compatible with more than one category of metabolic disease (e.g., inborn errors of amino acid and organic acid metabolism), or with more than one disease within a single category (e.g., the mucopolysaccharidoses Hunter and Hurler syndromes). A patient's presenting symptoms also can be suggestive of a nongenetic disease (e.g., sepsis, Reye syndrome). Therefore, metabolic disorders must be considered in the differential diagnosis of a wide variety of conditions, and their precise diagnosis is a prerequisite for optimal treatment and effective genetic counseling, including a discussion of the expected prognosis, recurrence risks, availability of heterozygote testing, and prenatal diagnosis.

In addition to the overlap in clinical presentation of many metabolic disorders, a large degree of biochemical heterogeneity exists. Although inborn errors most commonly arise from mutations in the genes encoding metabolic enzymes themselves, they also can be caused by abnormalities in enzymes involved in the synthesis and/or recycling of essential vitamins or cofactors, in proteins involved in the recognition or transport of compounds from one cellular compartment to another, or in proteins involved in the regulation of certain pathways. This underlying complexity can be the source of considerable diagnostic confusion, because a single biochemical abnormality can result from different underlying causes, each of which may be associated with a specific treatment, prognosis, laboratory diagnostic approach, and recurrence risk. Therefore, a basic understanding of the inborn metabolic errors, including their clinical presentation and approach to laboratory diagnosis, is essential for the optimum management of patients and their families.

Finally, recent advances in human molecular genetics are providing new insights into the contribution of molecular heterogeneity [i.e., heterogeneity at the level of the deoxyribonucleic (DNA) itself] to both clinical and biochemical heterogeneity. With increasing frequency, the genes involved in metabolic disorders are being isolated and characterized, and their pathogenic mutations described. This is leading to the increasing availability of DNA-based laboratory testing for some, but not all, of the inborn errors, both to confirm a biochemical diagnosis and to test other family members (including both carrier testing and prenatal diagnosis). In some cases, results of molecular testing are being used to give patients and their families a more accurate assessment of prognosis, and to define optimum management and treatment strategies. Refer to Chapter 7 and Chapter 8 (DNA) for a thorough discussion of the applications and limitations of molecular testing for human disease.

This chapter presents clinical and classic biochemical approaches for the diagnosis and management of patients with inherited metabolic diseases. It is not meant as an exhaustive review, but rather will focus on selected disorders as a means of highlighting clinical and laboratory features that help to distinguish between the many metabolic disorders. A complete listing of human genetic disorders can be found at the Online Mendelian Inheritance in Man (OMIM) website (http://www.ncbi.nlm.nih.gov/Omim/); this useful resource contains diseases cataloged by OMIM number, referenced here in the tables for readers wanting more detailed information. Finally, although specific laboratory tests and approaches will be discussed, detailed protocols will not be given. Refer to the Suggested Readings at the end of the chapter for descriptions of these methods.

METABOLIC DISORDERS

Part of "24 - Inborn Metabolic Errors"

Disorders of Amino Acid Metabolism

Normal Amino Acid Chemistry and Physiology

Amino acids, the fundamental building blocks of proteins, are small molecules with a tetrahedral carbon covalently bound to an amino group, a carboxyl group, a variable (R) group, and a hydrogen atom. R groups are classified as hydrophobic, neutral,

acidic, or basic, and determine the unique chemical properties of the individual amino acids. There are 20 commonly occurring amino acids found in proteins and at least 150 other nonprotein amino acids.

Normal turnover of amino acids occurs through a series of enzymatically controlled steps, the first of which often is a deamination, or removal of the primary amine group, to form the corresponding α-ketoacid. These compounds are metabolized in a step-wise fashion, ultimately entering the tricarboxylic acid (TCA) cycle leading to the formation of adenosine triphosphate (ATP). Several amino acids are intermediates in the urea cycle, the main pathway of ammonia detoxification through the formation of urea. Amino acids also are found as intermediates in the transsulfuration pathway, as well as pathways involved in the generation and utilization of single carbon units.

Free amino acids normally are found in all body fluids, including plasma, urine, cerebrospinal fluid, amniotic fluid, semen, sweat, and tears. Normal levels of amino acids depend to a great extent on the age of the individual, as well as nutritional status and overall health. Circulating plasma amino acids are the products of protein catabolism, and are filtered in the kidneys by the renal glomeruli. Specific amino acids then are reabsorbed in the proximal tubules via specialized transport systems, while others are efficiently excreted in the urine. The pattern of urinary amino acid excretion therefore depends largely on the function of transport mechanisms governing tubular reabsorption.

Alterations in Amino Acid Metabolism

Abnormal concentrations of amino acids in the plasma (aminoacidemias) or urine (aminoacidurias) arise when either the normal degradation or excretion of amino acids is altered1. These disorders are classified as either primary or secondary, depending on the nature of the particular defect.

Primary Disorders of Amino Acids

A primary aminoacidemia results from a mutation in a gene governing the activity of a specific degradative enzyme. The defective enzyme cannot catabolize a particular amino acid, which in turn accumulates. These blocks can also lead to abnormal accumulations of secondary metabolites and to depletions of “downstream” intermediates. Primary aminoacidemias refer solely to metabolic blocks in the first or second step of amino acid catabolism; blocks further downstream, although in the same overall pathway, are classified as organic acidemias and often differ in both clinical presentation and laboratory approach to diagnosis (see below). The vast majority of aminoacidemias follow an autosomal recessive pattern of inheritance.

Clinical findings associated with the primary aminoacidopathies range from severe and life threatening to benign. Examples of the most commonly encountered of these disorders are highlighted below; and a summary of common aminoacidemias is presented in Table 24.1.

Hyperphenylalaninemia Syndromes

Hyperphenylalaninemia is a heterogeneous group of disorders involving either a complete or partial block in the phenylalanine hydroxylase (PH) enzyme system, which converts phenylalanine to tyrosine. Classical phenylketonuria (PKU) involves a virtual absence of PH activity, while some variant forms demonstrate significantly reduced, but not absent, activity. Other variants result from a block in either the recycling or synthesis of tetrahydrobiopterin, the cofactor necessary for PH activity. Specific diagnosis is made on the basis of phenylalanine and/or cofactor levels in plasma; assay of the PH enzyme, a liver-specific protein, usually is not performed. An elevation of phenylalanine and its metabolites and/or a deficiency of tyrosine lead to early, irreversible brain damage and impairment of mature brain function. Clinical consequences include mental retardation, microcephaly, seizures, eczema, and a characteristic musty odor. These symptoms are avoided if dietary restriction of phenylalanine is started within the first weeks to months of life and continued throughout the patient's life. Benign forms of hyperphenylalaninemia also exist in which no treatment is necessary. Finally, maternal PKU is seen in children born to women with untreated hyperphenylalaninemia; prenatal exposure to high concentrations of phenylalanine leads to congenital malformations, microcephaly and mental retardation in patients who themselves have normal levels of phenylalanine.

Hyperphenylalaninemia occurs in approximately 1/12,000 live births, and all states in the United States offer newborn screening for this disorder to identify asymptomatic infants and to institute therapy, if needed, prior to the onset of symptoms. Accurate prenatal diagnosis of PKU and its variants now is available using DNA analysis and family studies in informative families.

Homocystinuria

Excretion of homocysteine in the urine can have a variety of inherited causes. The most common of these is deficient activity of cystathionine-β-synthase, the vitamin B_6- (pyridoxine-) dependent enzyme catalyzing the conversion of homocysteine to cystathionine. This block also leads to secondary hypermethioninemia. Some, but not all, of these patients respond to therapy with pyridoxine. Clinical features include dislocation of the optic lens, skeletal abnormalities including osteoporosis, increased tendency for thromboembolitic events, and variable mental retardation. Homocystinuria with methylmalonic aciduria and hypomethioninemia is caused by defects in the remethylation of homocysteine to methionine, a reaction dependent on the vitamin B_{12} derivative, methylcobalamin (MeCbl). Remethylation defects can arise from: (i) a failure in the metabolic conversion of hydroxycobalamin to MeCbl, (ii) nutritional or intestinal absorption deficiencies of vitamin B_{12}, or (iii) failure to synthesize 5-methyltetrahydrofolate, the cosubstrate in the remethylation reaction (note that methylmalonic aciduria is not seen in this last group). Clinical findings are highly variable, and range from severe, life-threatening illness presenting in infancy, to neuropathy and thrombocytopenia of juvenile or adult onset. Some, but not all, of these patients respond to therapy with vitamin B_{12} or MeCbl.

Nonketotic Hyperglycinemia

Nonketotic hyperglycinemia (NKHG) is a primary disorder of glycine metabolism clinically characterized by neonatal seizures,

TABLE 24.1. PRIMARY DISTURBANCES IN AMINO ACID METABOLISM

Disorder	Clinical Findings	Laboratory Findings	Deficient Enzyme	OMIM entry
Defects in sulfur-containing amino acids:				
Homocystinuria (due to CBS deficiency	Marfanoid features; optic lens dislocation; ±mental retardation, osteoporosis, thromboemboli. Variable responsiveness to pyridoxine (B_6).	↑ homocyst(e)ine in plasma and urine; ↑ methionine in plasma.	Cystationine-ß-synthase (CBS)	236200
Homocystinuria (due to MTR deficiency	Mental retardation, megaloblastic anemia. Autosomal dominant inheritance.	↑ homocyst(e)ine, ↓ methionine in plasma and urine.	N^5-methyl-tetrahydrofolate-homocysteine methyltransferase (methionine synthase)	156570
Homocystinuria (due to MTHFR deficiency)	Mental retardation, thrombosis, proximal muscle weakness. Variable responsiveness to folic acid.	↑ homocyst(e)ine in plasma and urine, normal plasma methionine.	N5,10-methylene-tetrahydrofolate reductase (MTHFR)	236250
Defects in phenylalanine metabolism:				
Phenylketonuria	If untreated, profound mental retardation, microcephaly, seizures, eczema, musty odor. Treatable by dietary restriction of phenylalanine.	↑ phenylalanine (20 mg/dl), ↓ or normal tyrosine in plasma, ↑ phenylpyruvic acid in urine.	Phenylalanine hydroxylase (in liver)	261600
Persistent hyperphenylalaninemia	Normal or near-normal neurological development, dietary restriction often not required.	↑ phenylalanine in plasma; milder than classical PKU.	Phenylalanine hydroxylase (greater residual activity than classical PKU)	261600
Dihydropteridine reductase deficiency	Mental retardation despite phenylalanine restriction, seizures, eczema, hypotonia, dystonic posturing. Treated with dopamine, 5-hydroxytryptophan and carbidopa.	↑ phenylalanine in plasma, abnormal biopterin/neopterin ratio in urine.	Dihydropteridine reductase	261630
Biopterin deficiency	Mental retardation despite phenylalanine restriction, seizures, hypotonia. Treated with dopamine, 5-hydroxytryptophan and carbidopa.	↑ phenylalanine in plasma, ↑ biopterin/neopterin ratio in urine.	Dihydrobiopterin synthetase	261640
Defects in tyrosine metabolism:				
Tyrosinemia Type I (hepatorenal form)	Hepatomegaly, jaundice, hepatic failure, vomiting, bleeding abnormalities, renal Fanconi syndrome, cabbagelike odor, liver cancer. Treated with NTBC or liver transplant.	↑ tyrosine in plasma, generalized aminoaciduria. ↑ succinylacetone in urine.	Fumarylaceto-acetase	276700
Tyrosinemia Type II	Progressive mental retardation, palmar and plantar hyperkeratosis and keratitis. Treated with diet restricted in phenylalanine and tyrosine.	↑ tyrosine in plasma, ↑ urine organic acids including 4-OH-phenylacetic, 4-OH-phenyllactic and N-acetyltyrosine.	Tyrosine transaminase	276600
Tyrosinemia Type III	Mild mental retardation, acute intermittent ataxia, no liver dysfunction.	↑ tyrosine in plasma.	4-hydroxyphenyl-pyruvate dioxygenase	276710
Other amino acid disorders:				
Nonketotic hyperglycinemia	Neonatal seizures (hypsarrhythmia), absent corpus callosum, death in infancy common.	↑ glycine in CSF, urine and plasma, ↑ ratio of CSF [gly] to plasma [gly].	Glycine cleavage system (in liver); four genetically distinct subunits	238300 238310 238330 238331
Hyperornithinemia (gyrate atrophy of choroid and retina)	Progressive chorioretinal degeneration, myopia, night-blindness, loss of peripheral vision in 1st decade, blindness by 3rd or 4th decade.	↑ ornithine in plasma, urine and CSF.	Ornithine aminotransferase	258870

neurological deterioration, and death in infancy or early childhood. Patients who survive have uncontrollable seizures and are severely mentally retarded. Diagnosis is based on abnormal elevations of glycine in all fluids, particularly cerebrospinal fluid (CSF). A ratio of CSF glycine/plasma glycine in the range of 0.2 or above is considered diagnostic (normal ratio less than or equal to 0.02). Because abnormal elevations of glycine also are seen in many of the organic acidurias, a complete workup must include urinary organic acid analysis. Ketones are characteristically absent in NKHG but often are present in the organic acidurias with secondary hyperglycinemia. There is no successful treatment for altering the outcome of NKHG, although sodium benzoate and dextromethorphan are sometimes used in attempts to lower glycine levels and improve neurological function. Confirmation of the diagnosis is available through enzyme assay of biopsied liver tissue, and prenatal diagnosis is performed following chorionic villus sampling, but not amniocentesis.

Urea Cycle Defects

The urea cycle is central to the excretion of nitrogen via conversion of ammonia to urea, and is also involved in the synthesis of arginine. The urea cycle defects (see Table 24.2) represent disruptions in the five different enzymatically controlled steps in the pathway. All are inherited as autosomal recessive disorders except ornithine transcarbamylase (OTC) deficiency, which is X-linked. Although considerable clinical and genetic heterogeneity exists, the typical and most severe presentation occurs at 1 to 3 days of life with progressive lethargy, hypothermia, and apnea accompanied by profound hyperammonemia (often in the range of 600 to 1,200 µg/dL). Later-onset forms can include episodes of vomiting, abnormal mental status, and hyperammonemia, as well as developmental delay and poor growth. Patients in this latter group often have enzyme activity that is reduced but not entirely absent. Laboratory studies leading to the diagnosis of a urea cycle defect include plasma and urine amino acids and urine organic acids, including orotic acid. The specific pattern of metabolites that are elevated indicates the point at which the pathway is impaired (see Table 24.2). Confirmation of the diagnosis can be performed by enzyme assay in either liver tissue (for arginino succinate synthetase, arginino succinic lyase, or arginase deficiencies) or in blood cells (for ornithine transcarbamylase (OTC) and carbamyl phosphate synthetase (CPS) deficiencies.) Ten percent to 15% of OTC mutations are large deletions involving all or part of the OTC gene; there also is considerable molecular heterogeneity among the other urea cycle disorders. Treatment of the urea cycle defects includes a protein-restricted diet, as well the administration of various agents (e.g., sodium benzoate, sodium phenylacetate, and arginine) aimed at enhancing the excretion of excess nitrogenous compounds.

TABLE 24.2. UREA CYCLE DEFECTS

Enzyme Defect/ Disorder	Clinical Findings	Laboratory Findings	OMIM entry
Carbamylphosphate synthetase I (CPSI) deficiency	Mental retardation, failure to thrive, seizures, vomiting, encephalopathy, coma. Neonatal lethal and late-onset forms.	Hyperammonemia. ↑ plasma glutamine, alanine, glycine and lysine, ↓ to normal citrulline and arginine. Generalized aminoaciduria. Deficient CPSI activity in liver.	237300
Ornithine transcarbamylase (OTC) deficiency	X-linked inheritance. Clinically indistinguishable from CPSI deficiency. Males typically die in infancy; variable expression in females.	Hyperammonemia. ↑ orotic acid in plasma and urine. ↑ plasma glutamine, glycine and alanine. Deficient OTC activity in liver.	311250
Argininosuccinate synthetase (AS) deficiency (citrullinemia)	Neonatal form: hypertonicity, vomiting, seizures, mental retardation, coma, death. Subacute form: mental retardation and ataxia in older children. Exacerbations with vomiting and encephalopathy.	Hyperammonemia. ↑ citrulline and glutamine in plasma and urine. ↓ plasma arginine. Deficient AS activity in liver, fibroblasts and lymphocytes.	215700
Argininosuccinic acid lyase (ASL) deficiency (arginino-succinic aciduria)	Failure to thrive, seizures, coma, mental retardation, early death. Milder forms in older children include ataxia, trichorrhexis nodosa and hepatomegaly. Exacerbations with vomiting and encephalopathy.	Hyperammonemia. ↑ argininosuccinic acid in plasma and urine. ↑ plasma glutamine, glycine, alanine and citrulline. Deficient ASL activity in erythrocytes and fibroblasts.	207900
Argininase (ARGI) deficiency (argininemia)	Spasticity, ataxia, seizures, vomiting, hepatomegaly, mental retardation. Exacerbations with vomiting and encephalopathy.	Moderate hyperammonemia. ↑ arginine in CSF, plasma and urine. Orotic aciduria during exacerbations. Deficient ARGI activity in erythrocytes, leukocytes and liver.	207800

Clinically Benign Aminoacidemias

In certain instances abnormal elevations of amino acids do not lead to any predictable pattern of clinical findings, and any symptoms that are present are coincidental to, but not caused by, the metabolic disturbance. Such conditions are thought to include histidinemia, sarcosinemia, prolinemia, and hydroxyprolinemia. Therefore, caution must be exercised in attributing specific clinical findings to abnormal elevations in amino acids.

Secondary Disorders of Amino Acids

Secondary changes in amino acid concentrations result from a physiologic disturbance not directly involving the primary

metabolic pathways themselves. These include transport and absorption defects, changes secondary to prematurity, kidney and/or liver failure, starvation, overfeeding, fever, organic acidemia, hyperammonemia, and interference from drugs and their metabolites. A partial list of secondary amino acid disturbances is given in Table 24.3. Some of these disorders have significant clinical consequences, such as failure to thrive in lysinuric protein intolerance or renal stones in cystinuria. Other secondary changes in amino acids can be indicators of other clinical problems, such as generalized aminoaciduria in renal tubular dysfunction and hypertyrosinemia in liver failure. A wide variety of medications can also lead to secondary changes in amino acid profile. Those most commonly encountered include antibiotics, antiseizure medications (e.g., valproate leading to hyperglycinuria and hyperglycinemia) and contrast dyes given for diagnostic imaging procedures. Because of the large number of situations that potentially can confound the interpretation of an altered amino acid profile, it is important that the laboratory be made aware of any pertinent clinical information, including relevant physical and routine laboratory findings, drug history, and diet and nutritional status.

TABLE 24.3. TRANSPORT DEFECTS LEADING TO SECONDARY AMINOACIDURIA

Disorder	Clinical Findings	Laboratory Findings	Primary Defect	OMIM entry
Cystinuria type I	Nephrolithiasis, renal complications, variable mental retardation in some patients.	↑ excretion of cystine, lysine, ornithine and arginine.	Mutations in SLC3A1 amino acid transporter gene; impaired transport of dibasic amino acids in renal tubules and intestinal mucosa.	220100
Lysinuric Protein Intolerance (dibasic aminoaciduria II)	Failure to thrive, periods of nausea and vomiting, aversion to protein-rich foods.	↑ excretion of lysine, arginine and ornithine; low levels in plasma. Intermittent hyperammonemia.	Mutations in SLC7A7 amino acid transporter gene; impaired transport of lysine, arginine and ornithine in intestinal epithelia and renal tubules.	222700
Hartnup disorder	Intermittent and variable photosensitivity, motor abnormalities, psychotic behavior. Some patients respond to nicotinamide; others show spontaneous remission.	Characteristic aminoaciduria of the monoamino-monocarboxylic group.	Impaired transport of neutral amino acids by intestinal mucosa and renal tubules.	234500
Lowe syndrome (oculocerebrorenal syndrome)	Renal tubular damage, congenital cataracts, hypotonia, hyporeflexia and psychomotor retardation. X-linked recessive inheritance.	Generalized aminoaciduria, proteinuria, phosphaturia, renal tubular acidosis.	Mutations in OCRL1 gene leading to deficiency of phosphatidyl-inositol 4,5-bisphosphate 5-phosphatase.	309000

Laboratory Investigations of Aminoacidemias

Amino acid analysis should be undertaken in any patient (i) who presents with life-threatening illness in the neonatal period, particularly if the illness coincides with the introduction of protein into the diet; (ii) with unexplained mental retardation or developmental delay, particularly if the patient was noted to be neurologically normal early in life and/or if there is a family history of a similarly affected sibling; or (iii) with unexplained systemic findings that could be compatible with one of the aminoacidopathies. Note that abnormalities in amino acid concentration often depend on protein intake, such that important clues may be missed if the patient was restricted from protein prior to sample collection. It is therefore imperative that specimens be collected immediately prior to altering the diet or giving medication.

The specimens evaluated most frequently are plasma, urine, and, less often, CSF. The analysis of amino acids in newborns and young infants is most efficiently and accurately done in plasma. Evaluation of newborn urine can be relatively unreliable and uninformative, because the sample often is dilute and may contain interfering drug metabolites (e.g., antibiotics given because of a clinical picture resembling sepsis). Furthermore, the immature renal reabsorption systems of premature infants can lead to secondary changes in urinary amino acid profile that can mask a primary abnormality. For older children and adults, analysis of urine is a relatively reliable screening approach, although valuable information is also gained by evaluating plasma. The most appropriate specimen(s) for analysis is frequently dictated by the clinical presentation of the patient.

Urine Spot Tests

A variety of simple urinary screening tests have been developed for patients suspected of having a metabolic defect. While these tests have the advantage of being rapid and relatively inexpensive to perform, they are limited in both sensitivity and specificity. However, especially when results of several tests are taken together, these “spot tests” can give useful clues that a more extensive metabolic workup may be warranted. The most commonly used spot tests for amino acid disorders include the ferric chloride test for PKU and tyrosinemia, the nitroprusside-cyanide test for cystinuria and homocystinuria, and the silver-nitroprusside test for homocystinuria.

Thin-Layer Chromatography

More precise information about amino acid composition is gained by chromatographic separation of amino acids by thin-layer chromatography (usually on cellulose or silica) in either one or two dimensions. This technique can be applied using either plasma or urine; urine amounts usually are standardized against creatinine concentration. Samples are subjected to acid precipitation prior to chromatography, such that only free amino acids are analyzed. Amino acids are visualized with a stain such as ninhydrin, which reacts with primary amine groups of all compounds, including those of amino acids (for this reason, many drugs also give rise to seemingly abnormal bands). The resulting pattern is interpreted by comparing the position, color and intensity of the bands with the pattern of normal, age-matched controls. This semi-quantitative approach to amino acid analysis is useful for detecting relatively large changes in amino acid concentration, such as those resulting from generalized aminoaciduria, hyperglycinuria, or phenylketonuria. Many of the more subtle changes may be missed by this method, and are much more accurately assessed by quantitative amino acid analysis using liquid column chromatography.

Quantitative Amino Acid Analysis

The most accurate method of assessing amino acid abnormalities is quantitative amino acid analysis. Modern systems are fully automated high-pressure liquid chromatography analyzers. In a typical setup, amino acids are separated on a single ion-exchange column using a gradient of elution buffers of increasing pH and ionic strength, reacted with ninhydrin, and then detected spectrophotometrically. The resulting peaks then are integrated, quantified, and compared to normal, age-matched controls. The entire analysis takes less than three hours per specimen, with the most sophisticated systems resolving at least 40 different amino acids. Because of the ease of operation and accuracy of results, some laboratories with automated systems routinely offer quantitative amino acid analysis in lieu of spot tests and thin layer chromatography.

Disorders of Organic Acid Metabolism

Normal Organic Acid Structure and Function

Organic acids are carboxylic acids that contain a variety of functional groups, but do not contain the primary amine group of amino acids. (This implies that organic acids will not be stained by ninhydrin, and will therefore not be detected by standard methods of amino acid chromatography.) Organic acids are metabolic intermediates from a variety of pathways including the metabolism of amino acids, fatty acids, carbohydrates, and steroids. Organic acids also are derived from the diet (e.g., benzoic acid, a common food preservative), a wide variety of drugs, as products of bacterial metabolism in the gut, or as contaminants from plastic urine containers, lotions, or other exogenous sources.

Disorders of Organic Acid Metabolism

Primary disorders of organic acid metabolism occur as a result of an enzymatic block in a metabolic pathway, leading to the abnormal accumulation of organic acid intermediates in the blood and urine. As with the majority of inborn errors of metabolism, the block can be from a mutation in a gene either encoding the degradative enzyme itself, or an enzyme involved in the synthesis or utilization of a cofactor required for enzyme activity. There currently are 50 to 60 known disorders of organic acid metabolism and their variants, most following an autosomal recessive mode of inheritance.

Organic Acidurias Arising from Blocks in Amino Acid Metabolism

The endpoint of amino acid metabolism is the generation of carbon skeletons and acetyl-CoA, which enter the TCA cycle for reutilization or energy production. Organic acidurias arising from blocks in amino acid metabolism most often involve the degradative pathways of valine, leucine, isoleucine (the branched-chain amino acids) or lysine; the specific pattern of accumulating intermediates gives important diagnostic information about which pathway is affected. Analysis of urinary organic acids is therefore an important step in pinpointing the specific metabolic block. For many, definitive diagnosis is confirmed by demonstrating deficient enzyme activity, most often in peripheral leukocytes or cultured skin fibroblasts. Table 24.4 outlines the more commonly encountered organic acidurias arising from amino acid metabolism.

Clinical findings tend to be overlapping and nonspecific. The typical course involves acute, life-threatening illness in the neonatal period, with altered mental status (e.g., lethargy, hypotonia, coma), tachypnea, and vomiting. Symptoms usually are not seen until after the first protein feeding. A less severe form includes failure to thrive and vomiting beginning during the first year of life, progressive psychomotor delay, and episodes of ketoacidosis and neurological deterioration exacerbated by infection, immunization, or other metabolic stress. Finally, some patients may experience onset of symptoms only after the first year of life, with episodes of ketoacidosis and neurological deterioration following a minor infection, often accompanied by lethargy, seizures, or coma. Organic acidurias also may be accompanied by unusual odors caused by the accumulation of organic compounds. Because of the nonspecific clinical findings, a definitive diagnosis only can be made through evaluation of urinary organic acid profile, most often with gas chromatography and mass spectrometry, but recently also with tandem mass spectrometry.

The accumulation of abnormal organic acid metabolites and their coenzyme A derivatives also leads to secondary laboratory findings giving strong indications that an underlying organic aciduria is present. These include metabolic acidosis (including ketosis and lactic acidosis), hypoglycemia, hyperglycinuria, hyperammonemia and carnitine deficiency. An abnormal accumulation of acylcarnitine derivatives is also often seen. Abnormal metabolites may only be elevated during acute illness, and levels can return to normal between episodes.

Maple Syrup Urine Disease

Maple Syrup Urine Disease (MSUD), or branched-chain ketoaciduria, is a heterogeneous group of disorders resulting from defects in branched-chain α-ketoacid dehydrogenase. This multienzyme complex is common to the catabolic pathways of the

branched-chain α-keto acids (BCKA) derived from valine, leucine, and isoleucine. The classic MSUD phenotype occurs in neonates or young infants, and includes apnea, poor feeding, lethargy, profound ketoacidosis, and coma possibly leading to death. The urine often has a sweet smell resembling maple syrup. Intermediate, intermittent, and thiamine-dependent forms of branched-chain ketoaciduria also exist with variable onset and outcomes; clinical heterogeneity may be a reflection of molecular heterogeneity. The abnormal accumulation of BCKA in MSUD leads to secondary elevations of branched-chain amino acids, which are readily detectable in plasma by amino acid analysis; a characteristic, abnormal pattern of urinary organic acid excretion also is seen. Alloisoleucine, a transamination product of the ketoacid of isoleucine, can be identified by amino acid analysis and is essentially pathognomonic for MSUD. Treatment of classical MSUD is accomplished with dietary restriction of the branched-chain amino acids. Confirmation of diagnosis by assay of enzyme activity can be performed.

TABLE 24.4. ORGANIC ACIDURIAS ARISING FROM DEFECTS IN AMINO ACID METABOLISM

Disorder	Clinical Findings	Laboratory Findings	Primary Enzyme Deficiency	OMIM entry
Disorders of leucine metabolism:				
Isovaleric acidemia	Neonatal presentation: poor feeding, vomiting, ketoacidosis, coma, "sweaty feet" odor. Chronic course: exacerbations with encephalopathy and mental retardation.	Severe metabolic acidosis, ↑ lactate and pyruvate. ↑ isovalerylglycine and 3-hydroxyisovaleric acid in urine; pancytopenia.	Isovaleryl-CoA dehydrogenase	243500
3-Hydroxy-3-methylglutaric acidemia	Hepatomegaly, lethargy, coma. Exacerbations with a Reye syndrome-like presentation.	Metabolic acidosis, nonketotic hypoglycemia, hyperammonemia, carnitine deficiency. ↑ 3-hydroxy-3-methylglutaric, 3-methyl-glutaconic, 3-hydroxy-isovaleric, 3-methylglutaric acids in urine.	3-hydroxy-3-methylglutaryl-CoA lyase (HMG CoA lyase)	246450
3-methylcrotonyl-glycinuria	Hypotonia, muscular atrophy, variable seizures and mental retardation. Some patients respond to treatment with biotin.	↑ 3-methylcrotonylglycine and 3-hydroxyisovaleric acid in urine.	3-methyl-crotonyl-CoA carboxylase	210200
Disorders of isoleucine and valine metabolism:				
ß-methyl-acetoaceticaciduria (3-oxothiolase deficiency)	Failure to thrive, encephalopathy, mental retardation.	Ketoacidosis, variable hyperammonemia. ↑ 2-methyl-3-hydroxyburic and methylaceto-acetic acids and tiglyglycine in urine.	Mitochondrial ß-ketothiolase	203750
Propionic acidemia	Acute presentation with lethargy, vomiting and seizures. Chronic presentation with episodic vomiting, failure to thrive and mental retardation. Some patients respond to treatment with biotin.	Ketoacidosis, hypoglycemia, hyperammonemia, neutropenia, ↑ glycine in plasma and urine. ↑ 3-hydroxypropionic and methylcitric acids in urine.	Propionyl-CoA carboxylase (two genetically distinct subunits)	232000 232050
Methylmalonic acidemia (*mut* group)	Acute presentation with lethargy, vomiting and seizures. Chronic presentation with episodic vomiting, failure to thrive and mental retardation. Some patients respond to treatment with B_{12}.	Ketoacidosis, hypoglycemia, hyperammonemia, neutropenia, thrombo-cytopenia, ↑ glycine in plasma and urine. ↑ methyl-malonic, methylcitric, and lactic acids in urine.	Methylmalonyl-CoA mutase	251000
Methylmalonic acidemia (*cblA* and *cblB* groups)	Variable presentation ranging from benign to severe. Vomiting, hypotonia, failure to thrive, seizures. Responsive to treatment with B_{12}	Intermittent ketoacidosis, hypoglycemia, hyper-ammonemia, neutropenia, thrombocytopenia, ↑ glycine in plasma and urine. ↑ methylmalonic, methylcitric, and lactic acids in urine.	Defective synthesis of adenosyl-cobalamin	251100 251110
Methylmalonic acidemia (*cblC* and *cblD* groups)	Severe CNS dysfunction including psychosis and mental retardation, pulmonary thromboemboli; skeletal, eye and cardiac abnormalities.	Megaloblastic anemia. ↑ methylmalonic acid in urine. ↑ homocysteine and cystathionine in urine and plasma, ↓ methionine in plasma.	Defective synthesis of methyl- and adenosyl-cobalamin	277400 277410
Multiple carboxylase deficiency	Seizures, skin rash, alopecia, developmental delay, hypotonia; abnormal urinary odor.	Lactic acidosis; ↑ urine ß-methylcrotonylglycine and 3-hydroxyisovaleric acids.	Holocarboxylase synthetase (early onset form); Biotinidase (later onset form)	253253 260270
Maple syrup urine disease (branched-chain ketoaciduria)	Four clinical variants, ranging from severe to mild. Mental retardation, cerebellar ataxia, CNS deterioration, seizures; maple syrup odor. Some patients respond to treatment with thiamine.	Acidosis, hypoglycemia, ketonuria. ↑ urine 2-oxo-isocaproic, 2-oxo-3-methyl-valeric and 2-oxoisovaleric acids. ↑ branched chain amino acids (valine, leucine, isoleucine) in blood and urine.	Branched-chain α-ketoacid dehydrogenase complex (four genetically distinct subunits)	248600 248610 248611 246900
Disorders of lysine and tryptophan metabolism:				
Ketoadipic aciduria	Neonatal collodion skin, retarded development, hypotonia.	Acidosis. ↑ urine 2-ketoadipic, 2-ketoglutaric and 2-aminoadipic acids.	Unknown; possibly deficient activity of 2-oxoadipic acid dehydrogenase	245130
Glutaric acidemia type I	Dystonia, choreoathetosis, macrocephaly, encephalopathy. Progressive dystonic palsy.	Acidosis, hypoglycemia. ↑ urine glutaric, 3-hydroxyglutaric and glutaconic acids. Carnitine deficiency.	Glutaryl-CoA dehydrogenase	231670

Isovaleric Acidemia

Isovaleric acidemia results from a deficiency in isovaleryl-CoA dehydrogenase, the enzyme that converts isovaleryl-CoA to 3-methylcrotonyl-CoA in the degradative pathway of leucine. Roughly half of patients have the neonatal form of this disorder, similar in presentation to neonatal MSUD, with acute episodes of severe metabolic acidosis and ketosis, vomiting and coma often leading to death. A chronic intermittent form also exists, with acidotic episodes often involving neutropenia, thrombocytopenia, or pancytopenia. An abnormal "sweaty feet" odor often is present during acute episodes. The major abnormal urinary organic acid detected by gas chromatography is the glycine conjugate of isovaleric acid, isovalerylglycine; diagnosis is confirmed by demonstration of absent or severely reduced activity of isovaleryl-CoA dehydrogenase in cultured fibroblasts. Normal growth and development can be seen in patients treated with moderate protein restriction, and carnitine and glycine supplementation.

Other Organic Acidurias from Altered Amino Acid Metabolism

A variety of other organic acidurias are clinically indistinguishable from MSUD or isovaleric acidemia and are differentiated solely by organic-acid profile. These include propionic aciduria, methylmalonic aciduria, and several others (see Table 24.4 and Table 24.5). Therefore, urinary organic acid analysis by gas chromatography/mass spectrometry and/or tandem mass spectrometry is an essential step in diagnosing the individual metabolic defects in patients presenting with symptoms compatible with one of these disorders.

TABLE 24.5. ORGANIC ACIDURIAS ARISING FROM DEFECTS IN FATTY ACID METABOLISM

Disorder	Clinical Findings	Laboratory Findings	Primary Enzyme Deficiency	OMIM entry
Short-chain acyl-CoA dehydrogenase (SCAD) deficiency	Neonatal presentation: acidosis, skeletal muscle weakness, failure to thrive, seizures; Chronic course: lipid-storage myopathy in adulthood	↑ urine ethylmalonic acid; low-normal carnitine with increased acylcarnitine fraction. No hypoglycemia as in MCAD or LCAD deficiency	Short-chain acyl-CoA dehydrogenase	201470
Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency	Lethargy, coma of variable age of onset, sometimes leading to sudden death; fatty changes in liver; exacerbations with metabolic stress (e.g., infection).	Hypoketotic hypoglycemia (intermittent), secondary carnitine deficiency. ↑ urine adipic, suberic, sebacic acids, hexanoylglycine and phenylpropionylglycine.	Medium-chain acyl-CoA dehydrogenase	201450
Long-chain acyl-CoA dehydrogenase (LCAD) deficiency	Hypotonia, hepatomegaly, cardiomegaly, cardiorespiratory arrest	Hypoketotic hypoglycemia, secondary carnitine deficiency. ↑ dicarboxylic and 3-hydroxydicarboxylic acids in urine.	Long-chain acyl-CoA dehydrogenase	201460
Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency	Cardiomyopathy, skeletal myopathy, Reye-like picture, unexplained sudden death. Associated with acute fatty liver of pregnancy and HELLP syndrome in mothers of affected fetuses	Hypoketotic hypoglycemia, elevated liver enzymes, lactic aciduria. ↑ 3-hydroxy-dicarboxylic acids in urine. Single base pair substitution accounts for nearly 90% of subunit A mutations	Long-chain 3-hydroxyacyl-CoA de-hydrogenase (Mitochondrial trifunctional protein, subunit A or B)	600890 143450
Glutaric acidemia type I (multiple acyl-CoA dehydrogenase [MAD] deficiency)	Neonatal hypotonia, jaundice, coma, frequently death; "sweaty feet" odor, polycystic kidneys, hepatomegaly, facial dysmorphism	↑ glutaric, lactic, ethylmalonic, butyric, isobutyric, 2-methyl-butyric, and isovaleric acids. Generalized aminoaciduria	Electron transfer flavoprotein (two subunits) or electron transfer flavoprotein dehydrogenase	231680 130410 231675
Carnitine palmitoyl-transferase II (CPT2) deficiency	Neonatal form: cardiac arrhythmia and sudden death; adult form: exercise intolerance, myoglobinuria	Hypoketotic hypoglycemia, high plasma creatine kinase, ↓ plasma total and free carnitine, ↑ lipids and long-chain acylcarnitines	Carnitine palmitoyl-transferase II	600649

Organic Acidurias Arising from Blocks in Fatty Acid Metabolism

Fatty acid oxidation is an important source of energy in heart and skeletal muscle, and occurs in all tissues except brain. The endpoint of normal fatty acid ß-oxidation is the formation of acetyl-CoA and ketone bodies. Following the entry of fatty acids into the cell, these molecules are activated to their acyl-CoA esters, and subsequently linked to carnitine via the action of carnitine palmitoyl transferase (CPT) 1. Fatty acylcarnitines then are translocated across the inner mitochondrial membrane, and then reconverted to their fatty acyl-CoA derivatives by CPT 2 prior to entry into the ß-oxidation cycle. Sequential rounds of fatty-acyl CoA dehydrogenation are catalyzed by long-, medium- and short-chain acyl-CoA dehydrogenases (LCAD, MCAD and SCAD, respectively). Genetic defects in each of these enzymes have been described, as well as defects in their common cofactor, electron transfer flavoprotein (ETF), leading to a deficiency of all three enzymes (a condition called multiple acyl-CoA dehydrogenase deficiency, or glutaric aciduria type II). Defects in fatty acid oxidation also arise because of systemic carnitine deficiency caused by a variety of genetic and nongenetic factors. Patterns of abnormal fatty acid metabolites seen on urinary organic acid analysis give important clues about which enzyme(s) may be defective; definitive diagnosis through enzyme assay in leukocytes or cultured fibroblasts is possible in most cases. Genetic defects in fatty acid metabolism are outlined in Table 24.5.

Medium-Chain Acyl CoA Dehydrogenase (MCAD) Deficiency

Medium-chain acyl CoA dehydrogenase (MCAD) is an enzyme involved in the oxidation of medium-chain (C_6 to C_8) fatty

acids. Its deficiency leads to a disorder of variable clinical severity and age of onset, characterized by episodes of vomiting, lethargy, and profound hypoglycemia accompanied by low ketones, brought on by fasting or other forms of stress. The initial presentation typically occurs within the first 2 years of life and can include hepatomegaly and fatty infiltration of hepatocytes. Patients with MCAD deficiency have been misdiagnosed as having Reye syndrome or, because the initial presentation may be as extreme as sudden death, sudden infant death syndrome (SIDS). Recent studies have suggested that MCAD deficiency may be a significant contributor to cases of SIDS (Bennett et al. 1990). Accumulation of medium-chain fatty acids leads to elevated excretion of medium chain dicarboxylic acids (adipic, suberic, and sebacic acids) in urine, which can be detected by gas chromatography. More detailed studies, including urinary acylglycine and acylcarnitine profiles, also are available for the efficient workup of patients. A specific DNA mutation, designated G985, is seen in roughly 90% of white MCAD patients. Diagnosis is confirmed by demonstrating decreased MCAD activity in cultured fibroblasts and/or the presence of the G985 mutation by DNA analysis. Treatment involves maintaining adequate caloric intake, and chances for favorable outcome appear to be excellent. Although the exact incidence of this disease is unknown, the frequency of heterozygotes may be as high as 1/100.

Systemic L-Carnitine Deficiency

Primary systemic carnitine deficiency results from inherited defects in the active transport of carnitine in the kidney and small intestine, leading to increased urinary loss of carnitine. Secondary deficiencies result from the abnormal accumulation of acyl-CoA compounds, such as those accumulating in many of the organic acidurias involving amino acid or fatty acid metabolism. Acyl-CoA derivatives readily bind to free carnitine to form acylcarnitines, which are efficiently excreted in the urine. This leads to a secondary decrease in circulating free and total carnitine, and an increase in urinary acylcarnitines. Clinical abnormalities associated with carnitine deficiency itself resemble those of Reye syndrome, including hepatic dysfunction, encephalopathy, hypoglycemia, and hyperammonemia. There also may be signs of muscle dysfunction, including cardiomyopathy. There are no known defects in the synthesis or degradation of carnitine itself. Treatment of carnitine deficiency is by supplementation with L-carnitine, with good outcome in many cases.

Laboratory Investigations of Organic Acidurias

Organic acids are excreted effectively by the kidneys and concentrated in the urine. For this reason, organic acids are most accurately measured in urine rather than blood. Patients presenting with clinical indications of an organic aciduria, especially neonates or young infants, also should be evaluated for plasma amino acids, because several of the aminoacidemias can present with similar findings. In addition, plasma and urine carnitine levels should be determined. A complete metabolic workup also should include the following routine studies: blood lactate and pyruvate, complete blood count and differential, ammonia, glucose, electrolytes, ketones, and pH, and urine-reducing substances and ketones. Because metabolic abnormalities often are not detectable once the patient has been stabilized, it is imperative that all studies be ordered at the time of acute illness, and not after the more likely possibilities (e.g., sepsis, poisoning, starvation) have been ruled out.

Urine Spot Tests

As for the aminoacidemias, a variety of simple spot tests have been developed that can give indications that an organic aciduria may be present. Although the limitations in sensitivity and specificity of these tests must be recognized, results can provide important clues that a more extensive metabolic workup is warranted. The most commonly used spot tests for the organic acidurias are the dinitrophenylhydrazine (DNPH) test for ketoaciduria, Clinitest (Ames) for urine-reducing substances, ferric-chloride test for aromatic organic acids, and the methylmalonic acid spot test for methylmalonic aciduria.

Gas Chromatography and Mass Spectrometry

The general procedure for organic acid analysis involves the acidic extraction of urine organic acids, followed by derivitization (alteration of chemical structure such that compounds are suitable for chromatography) and separation by gas chromatography (GC). Creatinine is used as a reference for urine concentration. Extraction of organic acids typically is done using a combination of organic solvents such as ethyl acetate and/or ether. Oximization, or replacement of the keto groups of α-ketoacids with oxime groups, can be done prior to extraction to decrease artifacts introduced by the solvents. Following extraction, the organic acids are converted to their trimethylsilyl derivatives and separated by GC. The separated organic acids are identified by comparing their retention times with those of known, individual, organic acids. This semi-quantitative method is the one most often employed for routine screening for organic acid disorders.

Any suspected abnormalities detected by GC should be confirmed by mass spectrometry (GC/MS) to provide positive identification of organic acids. This analysis gives rise to a characteristic mass/charge ratio for each ionizable species. Computer programs compare the resulting mass spectra to libraries containing mass spectra of known compounds.

Further Studies of Organic Acidurias

Specialized methods recently have been developed for the detailed evaluation of patients suspected of having certain organic acid defects. Tandem mass spectrometry (MS-MS) is a highly sensitive technique used for the identification and quantitation of urinary acylcarnitines and other metabolites, such as those accumulating in patients with MCAD deficiency and other inborn errors of amino acid and organic acid metabolism. Alternatively, the stable-isotope dilution measurement of urinary glycine conjugates also identifies compounds accumulating in patients with a fatty-acid oxidation disorder, particularly n-hexanoylglycine, 3-phenylpropionylglycine, and suberylglycine in MCAD deficiency. Although once performed in only a small number of specialized laboratories, these rapid and sensitive tests are being used with increasing frequency in the workup of patients suspected of having a metabolic disorder.

Disorders of Carbohydrate Metabolism

Disorders of Galactose Metabolism

Classical Galactosemia

Classical galactosemia is an autosomal recessive disorder caused by deficient activity of galactose-1-phosphate uridyltransferase (transferase, or GALT) such that galactose-1-P (Gal-1-P) and UDP-glucose cannot be converted to UDP-galactose and glucose-1-P. The resulting clinical signs and symptoms usually appear within a few days following milk ingestion, and include failure to thrive, vomiting, and diarrhea and liver dysfunction presenting as jaundice and/or hepatomegaly. Cataracts resulting from punctate lesions on the lens nucleus can be present within a few days of life. Galactosuria, generalized aminoaciduria, proteinuria, and hyperchloremic acidosis are commonly present. There is an increased susceptibility to infection, particularly by *Escherichia coli*, and an increased frequency of death from *E. coli* sepsis is seen in affected infants. If left untreated, irreversible mental retardation will develop. At the DNA level, a single base pair substitution in the transferase gene, designated Q188R, has been shown to account for approximately 67% of classical galactosemia mutations. A simple polymerase chain reaction- (PCR) based assay can be performed to confirm this genotype; other mutations have been described in patients using direct DNA sequencing or other mutation scanning approaches.

Many of the clinical symptoms appear to be reversible and/or avoidable by early diagnosis and dietary restriction of galactose by avoidance of lactose ingestion. Liver abnormalities resolve, weight gain ensues, and the aminoaciduria, proteinuria, and galactosuria decrease. In general, the cataracts will regress, and if not extensive at the outset, do not result in impaired vision. Mental retardation is not severe, but is irreversible. Long-term studies have shown that intelligence quotient (IQ) scores often are somewhat lower in treated patients than in their unaffected siblings. In addition, there may be some specific learning disorders involving spatial relationships and mathematics, as well as an increased incidence of attention deficit and behavioral problems, even in patients under strict dietary control. A high incidence of ovarian failure and hypergonadotropic hypogonadism is seen in female patients, including those that have been well managed by dietary therapy; however, pregnancies have occurred in several patients. No abnormalities have been reported in male gonadal tissue.

Because galactosemia is a treatable disease that can be diagnosed prior to the onset of symptoms, most states screen for this disorder in newborn infants using dried blood specimens.

Measurements of galactose and/or gal-1-P levels by microbiological assays or transferase activity (by enzyme activity or bacterial inhibition assays) are employed routinely. The finding of nonglucose-reducing substances in urine by Clinitest strengthens the suspicion of galactosemia. [Caution must be stressed because many hospital laboratories test only for glucose, such as with glucose oxidase test (Clinistix), and therefore do not detect elevated galactose.] When abnormal screening results are found, diagnostic tests are performed for quantitative determinations of red-cell transferase activity and gal-1-P; absence of enzyme activity accompanied by elevated levels of gal-1-P, indicates the need for immediate implementation of dietary therapy.

Transferase Variants

The implementation of large-scale newborn screening for galactosemia led to the identification of infants with abnormally low, but not absent levels of transferase activity. The subsequent workup of these patients has resulted in the characterization of a number of variants of the transferase enzyme. These classifications are based on characteristic alterations in the electrophoretic migration pattern of the enzyme. The most common is the Duarte variant, which is identified by two distinct electrophoretic bands that migrate faster than the single band seen in normal individuals. Patients homozygous for the Duarte allele have roughly 50% of normal red cell transferase activity, and Duarte/normal heterozygotes have about 75% normal activity. Patients who carry both the Duarte and classical galactosemia alleles have approximately 25% normal activity, and can have elevated gal-1-P levels, which may warrant dietary galactose restriction for the first year or two of life. At the DNA level, a single nucleotide substitution, designated N314D, underlies the Duarte biochemical phenotype, and can be detected by a PCR-based assay. Other, less-frequently encountered transferase alleles also have been described.

Other Genetic Causes of Elevated Galactose

Galactokinase and UDP-gal-4-epimerase (epimerase) deficiencies are two other inherited enzyme defects in the galactose utilization pathway that can result in elevations of galactose or gal-1-P. Galactokinase deficiency results in the inability to convert galactose to gal-1-P, in turn leading to elevations of galactose and its byproduct, galactitol, in blood and urine. The clinical findings of galactokinase deficiency are cataracts and pseudotumor cerebri, both of which can occur very early in infancy. Patients can be identified by the newborn screening tests for classical galactosemia as having elevated galactose levels but normal transferase activity. Definitive diagnosis is based on demonstration of deficient galactokinase activity in red cells. This disorder occurs much less frequently than classical galactosemia: estimates from newborn screening suggest a frequency of about 1/250,000.

Patients with epimerase deficiency can be identified by newborn screening as having elevated red cell gal-1-P but normal transferase activity. Epimerase activity is deficient in red cells and leukocytes but is thought to be normal in other tissues. This condition typically is clinically benign, and appears to be more common among African Americans. Several patients with systemic, rather than isolated red cell, epimerase deficiency have presented with symptoms similar to classical galactosemia.

Glycogen Storage Disorders

Glycogen, the principal storage form of carbohydrate in animals, is present in virtually all cells in varying concentrations. It is composed of glucose molecules linked to form a polymeric, highly branched structure. Glycogen is synthesized from glucose via a series of enzymatic steps, and is degraded by a phosphorylase, causing the stepwise cleavage of glucose (yielding glucose-1-phosphate), with other enzymes cleaving the branched linkages.

The glycogen storage disorders (GSDs) are caused by defects in the enzymes involved in glycogen synthesis and degradation. Some present mainly with liver or muscle involvement, while others have a more generalized picture. The hepatic forms are most common and are characterized by growth retardation, hepatomegaly, and fasting hypoglycemia. Other forms primarily affecting muscle usually have no liver involvement, but may present with fatigue and muscle weakness. It is the combination of clinical, biochemical, and pathological findings that must be considered in the differential diagnosis of these diagnoses. Details of the GSDs are delineated in Table 24.6.

GSD Type I (von Gierke Disease)

This disorder is caused by deficient activity of glucose-6-phosphatase, a liver enzyme that normally converts glucose-6-phosphate to glucose. This results in severe hypoglycemia and lactic acidosis (with no ketosis) that can be life threatening. Neonates often present with hepatomegaly at birth, which continue to increase in size. There is a protruding abdomen from hepatomegaly (but no splenomegaly), short stature, and a characteristic doll-like facial appearance. There is no neurological involvement. Laboratory findings include hyperuricemia, hypertriglyceridemia, and bleeding tendencies from deficient platelet adhesiveness. Progressive renal dysfunction is a frequent complication in older patients. In the second decade, a significant incidence of adenomatous nodules in the liver develops, but cirrhosis does not occur. There are several clinical variants of GSD I, caused by different genetic mutations. Definitive diagnosis is made by assaying enzyme activity in liver, but the diagnosis usually is first inferred from the clinical findings, laboratory values, and functional tests. These include glucagon or epinephrine challenges where there is little or no rise in glucose but a large increase in lactate. Dietary treatment focuses on preventing hypoglycemia and controlling the lactic acidosis. Management strategies involve frequent feedings along with nocturnal nasogastric infusion of high glucose-containing formula.

GSD Type II (Pompe Disease)

GSD type II is a lysosomal storage disorder caused by deficient activity of the enzyme acid α-glucosidase (acid maltase). The infantile form presents during the first few months of life with muscle hypotonia, macroglossia, cardiomegaly, and hypertrophic muscles. The liver is normal in function but progressively increases in size. Hypoglycemia and ketosis are not present. Infants usually die within the first year of life from cardiac failure. The juvenile or adult forms typically present with delay and/or difficulty in walking and progress much more slowly than the infantile form. Muscle weakness can develop even in the third or fourth decade, appearing as chronic myopathy. GSD

TABLE 24.6. GLYCOGEN STORAGE DISORDERS (GSD)

Disorder	Clinical Findings	Laboratory Findings	Deficient Enzyme	OMIM entry
GSD Type I (Von Gierke disease) GSD types Ia, Ib, and Ic	Typically presents in infancy, hepatomegaly, short stature, life-threatening hypoglycemia and lactic acidosis; renal dysfunction in older patients. Three different genetic types with similar phenotypes.	Hypoglycemia, Hyperuricemia, lactic acidemia, hyperlipidemia, metabolic acidosis.	*Type IA*: Glucose-6-phosphatse *Type Ib*: glucose-6-phosphate translocase *Type Ic*: glucose-6-phosphate translocase	232200 232220 232240
GSD Type II (Pompe disease)	Classic form presents in infancy. Hypotonia, macroglossia, cardiomegaly, hepatomegaly; death in first year. Later onset forms occur.	No hypoglycemia or acidosis. Abnormal enzyme activity.	Acid α-glucosidase (acid maltase)	232300
GSD Type III (Forbes disease; Limit dextrinosis)	Hepatomegaly, similar to GSD I but milder. Several biochemical subtypes.	Mild hyperuricemia, lactic acidosis, hypoglycemia.	Glycogen debrancher enzyme; amylo-1,6-glucosidase	232400
GSD Type IV (Andersen disease)	Rare disorder. Failure to thrive, early development of cirrhosis with liver failure, death by age 5 years.	Hypoglycemia, abnormal enzyme activity.	Brancher enzyme; amylo(1,4 to 1,6) transglucosidase deficiency	232500
GSD Type V (McArdle disease)	Presents in early adulthood with muscle cramps following exercise. Significant genetic heterogeneity.	Myoglobinuria common, increased serum creatine kinase.	Muscle glycogen phosphorylase	232600
GSD Type VI (Hers disease)	Growth retardation, significant hepatomegaly, normal heart and skeletal muscle; good prognosis	Mild hypoglycemia and ketosis.	Liver glycogen phosphorylase	232700
GSD VII (Tarui disease)	Very rare. Muscle cramps and weakness with exertion.	Myoglobinuria with extreme exertion.	Muscle phospho-fructokinase	232800
GSD VIII	Mild disease. Hepatomegaly, growth retardation. X-linked inheritance.	Hypercholesterolemia, hypertriglyceridemia, fasting hyperketosis.	Liver phosphorylase kinase	306000

type II is diagnosed by measuring a-glucosidase activity in leukocytes or fibroblasts.

GSD Type III (Limit Dextrinosis or Forbes Disease)

GSD type III is caused by deficient activity of the debrancher enzyme (amylo-1,6-glucosidase) resulting in the accumulation of limit dextrin, a polysaccharide derived from the breakdown of glycogen that has short outer branches. The clinical picture is similar to, but milder than, GSD type I, with hepatomegaly as the predominant feature. The clinical and metabolic abnormalities usually decrease at puberty, while muscle and heart involvement may become more pronounced in adulthood. As with most genetic disorders, there are several biochemical subtypes of GSD type III. The disorder can be diagnosed by measuring activity of the debrancher enzyme in liver, leukocytes, or fibroblasts. Management is similar to, but not as demanding as, that for type GSD type I.

GSD Type IV (Andersen Disease)

GSD type IV is a rare disorder in which patients appear normal at birth, but present with hepatosplenomegaly, progressive failure to thrive, hypotonia, and muscle atrophy within the first several months of life. Cirrhosis develops and death occurs usually by the age of 5 years. GSD type IV is caused by deficient activity of the brancher enzyme [amylo(1,4 to 1,6) transglucosidase], resulting in the accumulation of structurally abnormal glycogen. The enzyme deficiency can be demonstrated in liver or fibroblasts.

GSD Type V (McArdle Disease)

GSD type V is caused by complete deficiency of muscle glycogen phosphorylase enzyme. Characteristically, patients present in their third or fourth decade with muscle cramps following vigorous exercise. Myoglobinuria commonly is seen. Serum creatine kinase can be elevated at rest and increases dramatically following exercise. There is significant clinical and molecular heterogeneity between patients that complicates the identification of these patients. Diagnosis can be confirmed by demonstrating deficient phosphorylase activity in a muscle biopsy.

GSD Type VI (Hers Disease)

In contrast to GSD type V, this disorder is caused by a deficiency in liver glycogen phosphorylase activity. The disease is characterized by significant hepatomegaly in childhood that resolves before puberty, as well as mild hypoglycemia, hypotonia, motor and growth delay. There is no heart involvement. Diagnosis is made by enzyme analysis in liver or leukocytes. Patients with GSD type VI have a primary defect in the liver phosphorylase gene.

GSD Type VII (Tarui Disease)

GSD type VII is the rarest of the GSDs and the most severe of the muscle glycogenoses. It is caused by a deficiency of muscle phosphofructokinase.

Clinically, GSD type VII presents in a similar fashion to but more severe than GSD type V, with onset usually in childhood. There is an increased reticulocyte count; red cells are affected, causing hemolytic anemia. Diagnosis is made by measuring phosphofructokinase activity in leukocytes or fibroblasts.

GSD Type VIII

This disorder is one of the most common of the GSDs and one of the mildest. Unlike all others, it is inherited in an X-linked recessive manner. Clinically, patients present with hepatomegaly, growth retardation, along with hypercholesterolemia, triglyceridemia, and fasting ketosis. Most adult patients are asymptomatic, as symptoms gradually disappear with age. Over the years, this disorder has been classified as GSD types VIa or IX. Patients have low liver phosphorylase activity, as seen in type VI, but in this case liver phosphorylase kinase activity also is deficient and is the primary defect.

Disorders Of Fructose Metabolism

Fructose is the predominant sugar in honey, vegetables, and fruit, and is a component of the disaccharide, sucrose, one of the most common sweeteners in food, medications, and infant formula. Fructose metabolism occurs mainly in the liver, kidney, and small intestine. The clinical consequences of metabolic blocks in fructose metabolism range from life-threatening to benign.

Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) is an autosomal recessive disorder that presents with symptoms including failure to thrive, poor eating, vomiting, jaundice and hepatomegaly, hypoglycemia, generalized aminoaciduria, and proteinuria. Symptoms appear only following ingestion of fructose or sucrose and can be so severe as to be life threatening. Because there is no fructose in breast milk, breast-fed infants with HFI do not experience symptoms until weaning or the introduction of fruits and vegetables into the diet.

HFI is caused by deficient activity of fructose-1,6-bisphosphate aldolase (aldolase B), which normally catalyzes the conversion of fructose-1-phosphate to D-glyceraldehyde and di-hydroxyacetone phosphate. Its absence leads to an abnormal accumulation of fructose-1-phosphate in liver, kidney, and small intestine, resulting in hyperuricemia, lactic acidosis, and hypoglycemia. The diagnosis of HFI is suspected in patients with clinical findings described above and fructosuria following fructose ingestion. Although enzymatic studies can be performed using liver tissue, the diagnosis usually is made by demonstrating hypoglycemia and hypophosphatemia following an intravenous fructose load. The complete elimination of fructose and sucrose from the diet results in normal physical growth and development. Interestingly, some affected individuals learn to selectively avoid fructose-containing foods.

Fructose-1,6-bisphosphatase deficiency

Fructose-1,6-bisphosphatase catalyzes the conversion of fructose-1,6-bisphosphate to fructose-6-phosphate and inorganic phosphate. Because this enzyme plays an important role in gluconeogenesis, its deficiency leads to lactic acidemia once liver glycogen stores are depleted. Symptoms are similar to those seen for many of the organic acidurias, with severe metabolic acidosis, hypotonia, apnea, and hypoglycemia usually appearing within the first week of life. These patients do not develop an aversion to fructose, and there is no renal tubular dysfunction or liver abnormality, as seen in HFI. Outcome is good with appropriate dietary management.

Essential Fructosuria

This is a benign condition usually identified by elevated reducing substances following routine urinalysis. Essential fructosuria is caused by a deficiency in hepatic fructokinase activity, the enzyme that catalyzes the conversion of fructose to fructose-1-phosphate. No clinical or pathological findings have been reported.

MITOCHONDRIAL MYOPATHIES

Part of "24 - Inborn Metabolic Errors"

The mitochondrial myopathies are a diverse group of disorders involving abnormalities in the normal function of mitochondria. These important organelles contain metabolic pathways critical to energy metabolism and the production of ATP, and their deficiencies lead to a wide range of clinical abnormalities, predominately affecting muscle, brain, and heart tissue. Muscle biopsy often reveals “ragged red fibers,” or abnormal mitochondrial morphology visualized by special staining. Lactic acidosis also is commonly present.

Some of the mitochondrial enzymes are encoded by mitochondrial DNA, and their deficiencies follow a maternal pattern of inheritance. These disorders encompass a wide range of clinical variability stemming from a phenomenon called heteroplasmy, or variability in the proportion of mutant to normal mitochondria, both within and between tissues. Examples in this category include MERRF (mitochondrial encephalopathy and ragged red fibers) and MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes), for which specific mitochondrial DNA mutations have been identified. Another group of mitochondrial disorders arises from mutations encoded by nuclear genes, with most inherited as autosomal recessive traits. This includes disorders of pyruvate metabolism (e.g., pyruvate dehydrogenase deficiency), as well as the tricarboxylic acid cycle (α-ketoglutaric dehydrogenase deficiency) and electron transport chain (complex I deficiency).

Screening tests for the mitochondrial myopathies include blood lactate and pyruvate, free and total carnitine, plasma amino acids, and urine organic acids. More definitive testing involves direct assay of specific enzymes from either skin or muscle biopsy, and/or molecular studies of mitochondrial DNA.

PEROXISOMAL DISORDERS

Part of "24 - Inborn Metabolic Errors"

Peroxisomes are organelles that perform a variety of anabolic and catabolic functions, such as the metabolism of very-long-chain fatty acids and the synthesis of plasmalogens. One group of peroxisomal disorders, including Zellweger syndrome, arises from

inherited defects in peroxisomal biogenesis leading to deficiencies of multiple peroxisomal enzymes. Although there is a spectrum of clinical severity, patients typically have profound hypotonia, dysmorphic features, hepatomegaly, and renal cysts, with death occurring in infancy. Laboratory findings supporting the diagnosis of a biogenesis defect include abnormal levels of very-long-chain fatty acids, pipecholic acid and phytanic acid, reflecting the deficiency of multiple peroxisomal enzymes. There is no known treatment for this group of disorders.

In addition to the biogenesis defects, there are an increasing number of disorders involving the deficiency of a single peroxisomal enzyme. Included in this category is X-linked adrenoleukodystrophy, a childhood-onset illness in which affected boys suffer a rapidly downhill course of progressive neurological deterioration and death. Plasma very-long-chain fatty acids are abnormally elevated, but other peroxisomal metabolites are normal. Results of experimental treatment protocols with bone marrow transplantation and dietary supplementation are cautiously optimistic.

Disorders of Lysosomal Storage

Lysosomes are single-membrane bound, acidic organelles that contain degradative hydrolases involved in the normal turnover of macromolecules. Lysosomal storage disorders result from deficient activity of a particular lysosomal enzyme or enzymes, leading to the abnormal accumulation of macromolecular substrates and ultimately to clinical pathology. Deficient enzyme activity can be caused by a mutation in a gene encoding the degradative enzyme itself, an activator protein required for proper enzyme function, or a protein involved in the synthesis and processing of the enzyme.

The general clinical course for the lysosomal storage disorders is one of regression. Patients most often appear normal at birth and begin to experience symptoms in late infancy or early childhood (although neonatal-, juvenile- and adult-onset variants of many of these disorders are known). Symptoms can include progressive loss of developmental milestones, psychomotor retardation and variable visceral involvement, usually leading to early death. The variation in symptoms between the different disorders is explained in part by the different tissue distributions of the various substrates. For example, many of the sphingolipids are components of brain and other nervous tissue; therefore, enzymatic defects in sphingolipid catabolism often lead to mental retardation and other neurological involvement. Significant clinical variability also is seen within the various groups of disorders, and the specific clinical phenotype is, to a large extent, determined by the molecular mutation(s) present in a given patient.

Mucopolysaccharidoses

The mucopolysaccharides are a heterogeneous group of macromolecules predominantly involved in the structural integrity of the extracellular matrix. They consist of unbranched polysaccharide chains containing both acidic and amino sugars and also are referred to as acidic mucopolysaccharides, glycosaminoglycans, or, when linked to protein, proteoglycans. There is varied tissue distribution for the different mucopolysaccharides: keratan sulfate is found predominantly in cartilage, cornea, and intervertebral discs; dermatan sulfate is found in heart, blood vessels, and skin; and heparan sulfate is a component of lung, arteries, and cell surfaces in general.

Mucopolysaccharidoses (MPS) are disorders resulting from defects in the stepwise degradation of mucopolysaccharides from enzymatic blocks at various points in the catabolic pathways of keratan, heparan, or dermatan sulfate. Although clinically heterogeneous, the MPS are generally characterized by a chronic progressive course, organomegaly (including hepatomegaly and splenomegaly), dysostosis multiplex, and coarsening of facial features. Profound mental retardation is seen in types IH, II, and III (Hurler, Hunter, and Sanfilippo syndromes), but normal intelligence is retained in types IS, IV, and VI (Scheie, Morquio, and Maroteaux-Lamy syndromes). Morquio syndrome also is characterized by distinctive skeletal abnormalities arising from abnormal storage of keratan sulfate. Treatment of the MPS disorders has been attempted by both enzyme replacement and bone marrow transplant, with mixed results. Outcome may be better for those disorders lacking neurological findings, and significant research using animal models and modern molecular approaches are currently underway. There are at least 10 different known enzyme deficiencies leading to abnormal mucopolysaccharide storage, including four genetically distinct deficiencies leading to Sanfilippo syndrome and two leading to Morquio syndrome. All of the MPS are inherited in an autosomal-recessive manner except Hunter syndrome, which is X-linked. A complete list of the MPS and their subtypes is given in Table 24.7.

TABLE 24.7. MUCOPOLYSACCHARIDOSES (MPS)

Disorder	Clinical Findings	Laboratory Findings	Deficient Enzyme	OMIM entry
Hurler syndrome (MPS IH)	Onset 6–8 months. Severe mental and motor regression, coarse facial features, early corneal clouding, cardiac insufficiency, stiff joints, protuberant abdomen, deafness, dysostosis	Urinary excretion of dermatan and heparan sulfate.	α-L-iduronidase	252800
Scheie syndrome (MPS IS)	Milder variant of type IH. Late corneal clouding, stiff joints, and cardiac insufficiency. Normal intelligence. Shortened life expectancy.	Same as type IH.	α-L-iduronidase	252800
Hunter syndrome (MPS II)	Onset in infancy and childhood. Mental and motor regression, dwarfing, coarse facial features, progressive deafness, stiff joints, hepatomegaly, no corneal clouding. Mlld to severe clinical forms. X-linked.	Urinary excretion of dermatan and heparan sulfate.	Iduronate sulfatase	309900
Sanfilippo syndrome (MPS III) Types A-D	Onset in first few years of life. Progressive mental retardation, severe behavioral disturbances, hirsutism, moderate dwarfing, joint stiffness, moderate organomegaly. Four genetically distinct forms, distinguishable by enzyme assay.	Variable urinary excretion of heparan sulfate.	*Type A*: Heparan sulfate sulfatase *Type B*: N-acetyl-alpha-D-glucosaminidase *Type C*: Acetyl CoA:α-glucosaminide-*N*-acetyltransferase *Type D*: N-acetylglucosamine 6-sulfatase	252900 252920 252930 252940
Morquio syndrome A (MPS IV A)	Onset 12–18 months. Severe progressive skeletal changes, corneal clouding, progressive deafness, odontoid hypoplasia, cervical myelopathy. Usually normal intelligence.	Variable urinary excretion of keratan sulfate.	Galactosamine-6-sulfatase	253000
Morquio syndrome B (MPS IV B)	Onset in childhood. Milder form of Morquio A. Bone changes, corneal clouding, hypoplastic odontoid.	Variable urinary excretion of keratan sulfate.	ß-galactosidase	253010
Maroteaux-Lamy syndrome (MPS VI)	Onset 2–3 years. Growth retardation, coarse facial features, corneal clouding, dysostosis multiplex, cardiac failure, normal intelligence. Mild to severe clinical forms.	Urinary excretion of dermatan sulfate.	arylsulfatase B (N-acetylgalactosamine-4-sulfatase)	253200
Sly syndrome (MPS VII)	Onset in infancy and childhood. coarse facies ± mental retardation, hepatosplenomegaly and dysostosis multiplex	Urinary excretion of dermatan and heparan sulfate.	ß-glucuronidase	253220

MPS patients characteristically excrete mucopolysaccharides in their urine; the specific pattern gives an indication of the site of the enzymatic defect. The preliminary workup of a patient suspected of having an MPS therefore includes a urinary screening test for abnormal mucopolysaccharides, including thin-layer chromatography or electrophoresis to identify the specific macromolecular species. Such screening tests are subject to false negatives, particularly for Sanfilippo syndrome; if clinical findings are suggestive of an MPS, further workup is warranted even with negative screening results. Histological changes include large, empty-appearing vacuoles, inclusions resembling zebra bodies, and metachromatic granules (seen upon staining with a cationic dye such as Alcian blue) that are lysosomes distended by stored material. Definitive diagnosis of a specific disorder is based on the demonstration of deficient enzyme activity in leukocytes or cultured fibroblasts.

Prenatal diagnosis is possible for all of the MPS by enzyme assay on chorionic villus tissue or cultured amniocytes. Heterozygotes have roughly half of normal enzyme activity, and so carrier testing for these disorders is feasible. Care must be taken when interpreting results of carrier testing for Hunter syndrome because of the influence of X chromosome inactivation on enzyme activity. Testing for mutations at the DNA levels can be performed provided that the specific mutation is known (i.e., has been identified in an affected family member).

Oligosaccharidoses

Oligosaccharides, or the carbohydrate portion of glycoproteins, consist of 10 to 20 sugar residues with a characteristic branched structure. These molecules play an integral role in determining

the specificity of protein structure, function and antigenicity, and are found throughout the body. The group of disorders known as the oligosaccharidoses arises from enzymatic defects in the stepwise degradation of N-linked oligosaccharides. This degradation normally occurs by the action of (i) a series of exoglycosidases acting in sequential fashion at the nonreducing termini, and (ii) aspartylglycosaminidase, which cleaves the bond between asparagine and the adjacent sugar, N-acetylglucosamine. Defects in each of the degradative steps are known, and are summarized in Table 24.8. All oligosaccharide storage disorders follow an autosomal-recessive pattern of inheritance.

TABLE 24.8. OLIGOSACCHARIDOSES

Disorder	Clinical Findings	Laboratory Findings	Deficient Enzyme	OMIM entry
Fucosidosis	Onset at 1 year. Coarse facies, growth retardation, dysostosis multiplex and severe psychomotor regression. Variants with milder presentations with angiokeratomas and psychomotor retardation have been described.	↑ sweat electrolytes in most patients. Urinary excretion of fucosyl-rich oligosaccharides.	α-fucosidase	230000
α-Mannosidosis	Onset during infancy. Rapid progression of psychomotor and mental retardation, facial coarsening, dysostosis multiplex, marked hepatosplenomegaly and death between 3–10 years. Milder clinical variants have been described.	Vacuolated lymphocytes. Urinary excretion of mannose-rich oligosaccharides.	α-mannosidase	248500
ß-Mannosidosis	Milder than α-mannosidosis. Variable mental retardation, facial coarsening, hepatosplenomegaly and bone disease.	Urinary excretion of a characteristic mannose-containing disaccharide.	ß-mannosidase	248510
Aspartylglycosaminuria	Onset in first few years of life. Angiokeratoma, severe mental retardation, cardiomyopathy, coarse facial feature, recurrent infections	Aspartylglycosaminuria.	Aspartylglucosaminidase	208400
Sialidosis (Mucolipidosis I) Types I and II	Type I: Onset in childhood. Myoclonus, ocular cherry-red spots, decreased visual acuity, gait abnormalities, normal intelligence. Type II: Dysmorphic findings, hepatosplenomegaly, dysostosis multiplex, coarse facies, and dwarfism. Clinical variants with congenital or juvenile onset have been described.	Urinary excretion of sialyloligosaccharides.	Neuraminidase I (sialidase)	256550

Clinically, the oligosaccharidoses are similar to the MPS, with a chronic progressive course, often following a period of normal growth and development. Specific findings can include mental retardation, facial coarsening, hepatosplenomegaly, cataracts or corneal opacities, and hearing loss. There are clinical subtypes for each of the oligosaccharidoses, representing a broad range of variability in both age of onset and severity of symptoms, and probably resulting from specific molecular mutations.

Abnormal urinary oligosaccharide excretion is seen in patients with an oligosaccharidosis, as well as in some patients with mucolipidosis, sphingolipidosis, or glycogen storage disease. The

diagnostic approach for patients suspected of having an oligosaccharidosis therefore begins with screening for abnormal urinary oligosaccharides by thin-layer chromatography; these results are used as a guideline for proceeding with specific diagnostic enzyme assays in leukocytes or cultured fibroblasts. Because of the clinical overlap between the MPS and oligosaccharidoses, the MPS should be considered in the differential diagnoses and workup of these patients. Prenatal diagnosis and carrier detection are possible for all of the oligosaccharidoses.

Sphingolipidoses

The sphingolipids comprise a heterogeneous group of macromolecules containing the fatty alcohol sphingosine, which is linked covalently to a fatty-acid side chain to form ceramide. Sphingolipids can be divided into different subclasses based on chemical modifications of ceramide: glycolipids (or glycosphingolipids) result from the linkage of ceramide to one or more sugar residues; cerebrosides from the linkage of ceramide to a single sugar residue; sulfatides (or sulfolipids) from a cerebroside containing a sulfate group; and sphingomyelin from ceramide linked to phosphocholine. In addition, the gangliosides are a complex group of glycolipids containing one or more negatively charged sialic acid (N-acetylneuraminic acid) residues. The sphingolipids are distributed throughout the body as structural components of plasma membranes, and many are particularly abundant in brain and other nervous tissue. Table 24.9 summarizes the known genetic defects of sphingolipid catabolism. All follow an autosomal recessive pattern of inheritance except Fabry disease, which is X-linked. Diagnosis is made directly from results of enzyme assays ordered on the basis of clinical, laboratory, and histological findings.

Although there is clinical overlap between the different disorders, it is useful to distinguish between those with a progressive neurodegenerative course and those characterized by more severe visceral involvement. The sphingolipidoses characterized by progressive psychomotor deterioration include metachromatic leukodystrophy, Krabbé disease (globoid-cell leukodystrophy), G_{M1} gangliosidosis, and G_{M2} gangliosidosis (including Tay-Sachs disease and Sandhoff disease). These disorders usually are

TABLE 24.9. SPHINGOLIPIDOSES

Disorder	Clinical Findings	Laboratory Findings	Deficient Enzyme	OMIM entry
G_{M1} Gangliosidosis Type I	Infantile onset. Rapid mental and motor regression. Seizures to decerebrate state, blindness, coarse facies, macrocephaly, cherry-red spots, macroglossia, hepatosplenomegaly, dysostosis multiplex; death 1–2 years.	Foamy histiocytes in bone marrow.	Acidic ß-galactosidase (ß-galactosidase-1)	230500
Type II	Juvenile onset. Slower progression than type I. May present with ataxia, seizures, strabismus, loss of speech; death 3–10 years.	Same as in type I.	Acidic ß-galactosidase (ß-galactosidase-1)	230600
Type III	Adult onset. Progressive cerebellar dysarthria with spasticity and ataxia, angiokeratoma.	Same as in type I.	Acidic ß-galactosidase (ß-galactosidase-1)	230650
G_{M2} Gangliosidosis				
Tay-Sachs disease	Onset 3–6 months. Exaggerated startle reaction. Seizures, mental and motor deterioration, blindness, doll-like facies, cherry-red spots, macrocephaly; death by 3–4 years.	Deficient activity of hexosaminidase A in serum, leukocytes and fibroblasts.	Hexosaminidase A	272800
Sandhoff disease	Clinically indistinguishable from Tay-Sachs.	Deficient activity of hexosaminidase A and B in leukocytes and fibroblasts.	Hexosaminidase A+B	268800
Juvenile G_{M2} gangliosidosis	Onset 2–6 years. Ataxia, progressive spasticity, seizures, late blindness; death by 5–15 years	Same as in Tay-Sachs disease.	Hexosaminidase A	272800
Adult (chronic) G_{M2} gangliosidosis	Progressive deterioration of gait and postures, muscle weakness and wasting, and ataxia. Gradual loss of motor and intellectual milestones.	Same as in Tay-Sachs disease.	Hexosaminidase A	272800
Metachromatic leukodystrophy				
Late infantile form	Onset 6–24 months. Rapid neurological regression, gait disturbance, blindness, peripheral neuropathy and quadriparesis.	Elevated CSF protein, decreased nerve conduction velocity.	Arylsulfatase A (cerebroside sulfatase)	250100
Juvenile form	Onset 5–10 years. Mental regression, gait disturbance, blindness, peripheral neuropathy loss of speech, quadriparesis.	Same as above.	Arylsulfatase A (cerebroside sulfatase)	250100
Adult form	Onset mid-teens-60 years. Dementia, symptoms similar to juvenile form.	Same as above.	Arylsulfatase A (cerebroside sulfatase)	250100
Krabbe disease (globoid cell leukodystrophy)	Onset 3–6 months. Irritability progressing to severe mental and motor deterioration. Infantile encephalopathy, hypertonicity, blindness, cherry-red spots, deafness, peripheral neuropathy; death by 12–18 months.	Elevated CSF protein, decreased nerve conduction velocity.	Galactocerebroside ß-galactosidase	245200
Fabry disease	X-linked inheritance. Pain and paresthesia in extremities, whorl-like corneal dystrophy, angiokeratoma, cardiovascular angiectasis and renal failure.	Proteinuria, increased globotriaosylceramide in plasma or urinary sediment.	α-Galactosidase A	301500
Gaucher disease				
Type I (chronic nonneuropathic; adult form; visceral form)	Onset in childhood or later. Most patients are Ashkenazi Jews (incidence 1:2,500). Hepatosplenomegaly, episodic bone pain, hypersplenism and pulmonary infiltrates.	Typical “Gaucher” foam cells in bone marrow, thrombocytopenia, anemia.	Acidic ß-glucosidase (glucocerebrosidase)	230800
Type II (acute neuronopathic)	Onset birth-18 months. Rapid progressive neurological regression with seizures, hypertonicity, spasticity and hepatosplenomegaly; death by 12 months.	Same as above.	Acidic ß-glucosidase (glucocerebrosidase)	230900
Type III (subacute neuronopathic)	Similar to type II. Symptoms may appear early in life, but their progression is slower.	Same as above.	Acidic ß-glucosidase (glucocerebrosidase)	231000
Niemann-Pick disease				
Type A (acute neuronopathic form; classic infantile)	More common in Ashkenazi Jews. Onset in infancy. Rapidly progressive neurological regression, cherry-red spots, hepatosplenomegaly; death by 3 years.	Foam cells in bone marrows.	Sphingomyelinase	257200
Type B (chronic, visceral form)	More common in Ashkenazi Jews. Onset in infancy or childhood. Only the visceral findings of type A.	Same as above.	Sphingomyelinase	257200
Type C (chronic neuronopathic form)	Onset usually after 2 years. Spasticity, seizures hepatosplenomegaly, loss of mental and motor skills; death before age 20 years. Clinically heterogeneous.	Foamy macrophages in marrow; low HDL, LDL and ApoA1.	Mutant NPC protein leading to block in cholesterol esterification. Sphingomyelinase not deficient.	257220
Type D (Nova Scotia variant)	Onset 2–4 years. Resembles type C with a protracted course and neurological abnormalities.	Foam cells in spleen and lymph nodes.	Mutation allelic to Type C	257250
Type E (Adult form, nonneuropathic form)	Adult onset. Hepatosplenomegaly. No neurologic difficulties.	Foam cells in marrow.	Sphingomyelinase.	257200

CSF, cerebrospinal fluid; HDL, high-density lipoprotein; LDL low-density lipoprotein.

considered in the evaluation of patients with clinical findings suggestive of neurodegenerative disease.

The sphingolipidoses characterized by more severe visceral involvement include Gaucher disease and Niemann-Pick disease. Both of these diseases are characterized by hepatosplenomegaly and variable neurological involvement. Histopathological changes represent lysosomes swollen with stored material: Gaucher disease is typified by the presence of Gaucher cells, and Niemann-Pick by foamy histiocytes. More rarely encountered disorders such as Farber disease and acid lipase deficiency are discussed elsewhere (see Suggested Readings); Pompe disease (glycogen storage disease type II) is discussed elsewhere in this chapter.

Tay-Sachs Disease (TSD) Carrier Testing

Treatment strategies for the sphingolipidoses are aimed at prevention rather than cure. This involves the identification of at-risk couples (i.e., both partners are carriers for the same disorder), who can then make informed decisions regarding their reproductive future. This approach is well suited for TSD, which is found at a significantly increased frequency among Ashkenazi Jewish individuals, as well as a subset of French Canadians. There is roughly a ten-fold increase in heterozygote frequency among these groups compared to the general population, making it feasible to conduct screening programs aimed at identifying TSD carriers.

The assay for TSD carrier detection is routinely performed using serum, although certain medications (particularly oral contraceptives) and medical conditions (pregnancy, liver disease) can interfere with the serum assay. In these cases, evaluation of enzyme activity in leukocytes usually yields reliable results. Carriers of Sandhoff disease also will be detected by this assay in either tissue. Some laboratories offer confirmation of Tay-Sachs carrier status by DNA testing; three specific mutations account for roughly 93% of mutant alleles among Ashkenazi Jews.

Recently, testing for Tay-Sachs carriers has been extended to include molecular testing for other disorders occurring at a higher frequency among Ashkenazi Jews. These panels also may include carrier testing for Canavan disease, cystic fibrosis, Niemann-Pick disease Type A, and Gaucher disease, all of which are performed by DNA analysis for population-specific mutations.

Mucolipidoses (ML)

These disorders are so named because they share clinical features of both the MPS and sphingolipidoses. Mucolipidoses I and IV

represent deficiencies in sialidase (neuraminidase) activity specific for glycoproteins and gangliosides, respectively. ML-II (I-cell disease) and ML-III (pseudo-Hurler polydystrophy) are single gene disorders characterized biochemically by deficient intracellular activity of multiple lysosomal enzymes involved in the degradation of mucopolysaccharides, oligosaccharides and sphingolipidoses, leading to abnormal storage of these compounds. The primary defect for both disorders is deficient activity of N-acetylglucosaminyl-1-phosphotransferase, the enzyme necessary for normal intracellular targeting of lysosomal enzymes. As a result, the enzymes are secreted extracellularly. The distinction between ML-II and ML-III is made on clinical grounds, with ML-II patients being much more severely affected. Biochemical diagnosis is made by demonstrating low intracellular activity of several lysosomal enzymes together with abnormally high activity outside cells (serum or culture medium). Diagnosis can be confirmed by demonstration of deficient phosphotransferase activity.

NEWBORN SCREENING

Part of "24 - Inborn Metabolic Errors"

Screening for genetic disorders falls into three categories: (i) neonatal screening, or the identification of infants with treatable metabolic disorders prior to the onset of clinical symptoms; (ii) prenatal screening, or the identification prior to birth of fetuses with certain genetic disorders; (iii) and carrier screening, or the identification of phenotypically normal individuals who are heterozygous for a particular mutation and therefore at risk of having affected offspring. There are numerous issues that must be addressed in determining which disorders are amenable to population screening. This section focuses on neonatal screening and the disorders typically included in these programs.

Newborn screening first became feasible in 1961, with the development of the Guthrie bacterial inhibition assay for measuring phenylalanine in dried blood specimens. The purpose of this test was to identify infants at risk for PKU prior to the onset of symptoms, so that dietary management could be instituted and serious clinical sequelae avoided. PKU screening has subsequently been instituted throughout the Unites States and other countries, and has also been expanded to include other metabolic and nonmetabolic disorders.

At least three aspects of PKU render this disorder amenable to newborn screening. First, untreated PKU leads to severe clinical symptoms, including mental retardation. Secondly, dietary management prevents the mental retardation, provided the treatment is begun early. Finally, PKU can be detected in the newborn period as an elevation of blood phenylalanine in affected individuals. Newborns now are screened prior to discharge from the hospital at 1 to 3 days of age; some states retest at 2 weeks of age to assure that all infants have ingested sufficient protein for the screen to identify an affected infant. The most effective screening programs are those in which all newborns are tested.

Many general issues also must be considered in the establishment of an optimal screening test. The test must be simple and inexpensive to perform, as well as reliable, reproducible, and accurate. Ethical, legal, and economic considerations also determine the appropriateness of a given test, including the estimation of both the adverse and advantageous consequences of the proposed screening. These are determined in part by the frequency of the disorder in the population, as well as by the number of affected individuals who will be successfully identified. In addition, the practicality and cost of preventive treatment must be considered and constantly reevaluated in the context of advances being made in biomedical technology. Finally, the test sensitivity (the proportion of people with the disease whose results are positive) and specificity (the proportion without the disease whose results are negative) must be balanced for each screening test, thereby minimizing the number of false negative results while holding false positive cases to an acceptably low number, which for newborn screening is to accomplish no false negatives.

Many of the newborn screening tests rely on the detection of abnormally elevated blood metabolites that accumulate as a consequence of a particular metabolic block. These include the tests for PKU, homocystinuria, and tyrosinemia. In contrast, other metabolic disorders are instead identified by the deficient activity of a specific enzyme, rather than the accumulation of substrate. These include the screening tests for biotinidase deficiency and the Beutler test for classical galactosemia (i.e., assay of gal-1-P uridyltransferase activity by the Beutler test). For these disorders in which enzyme activity itself is measured from the dried newborn blood spot, the accuracy of the test is independent of both dietary intake and in most cases clinical status of the infant.

The recent application of tandem mass spectrometry techniques to newborn screening has significantly increased the number of metabolic disorders potentially detectable by newborn screening, as well as decreased the number of false positives and negatives. At this time, only a few states utilize this technology, although this number will certainly grow in the future. Several resources are available with excellent summaries of newborn screening principles and procedures (see Suggested Readings).

SUGGESTED READINGS

Comprehensive metabolic testing and other genetics services are available at many major medical centers throughout the world; a number of excellent on-line resources are accessible from:

http://www.ncbi.nlm.nih.gov/Omim/ The Online Mendelian Inheritance in Man (OMIM) website contains a complete listing of human genetic disorders catalogued by OMIM number.

http://www.geneclinics.org/ GeneClinics is a clinical information resource relating genetic testing to the diagnosis, management, and genetic counseling of individuals and families with specific inherited disorders.

http://www.genetests.org/servlet/access GeneTests, providing current genetic testing information for families and healthcare providers.

25
Point-of-Care Testing

Elizabeth Lee-Lewandrowski

Kent B. Lewandrowski

INTRODUCTION

Part of "25 - Point-of-Care Testing"

Point-of-care testing (POCT) is an emerging concept in laboratory medicine and has attracted considerable interest in the medical literature. Recent experience has revealed a variety of applications for these new technologies in hospitals, outpatient clinics, and home-care settings (1). Diagnostics manufacturers continue to invest significant resources in developing point-of-care (POC) technologies creating new opportunities to redesign the delivery of laboratory services. Some of the current uses of POCT have been discussed in other chapters in this book. In this chapter, the discussion will focus on general concepts relating to key issues relevant to medical, operational, and regulatory concerns. No attempt will be made to review the current literature on individual POCT technologies. For a more in-depth discussion of POCT applications, see the excellent presentation in reference 1.

POINT-OF-CARE TESTING: A HISTORICAL PERSPECTIVE

Part of "25 - Point-of-Care Testing"

Point-of-care testing (also called bedside or near-patient testing) has been defined by Price and Hicks as “all testing not undertaken in a central laboratory… that is undertaken close to the patient, with the result leading to a possible change in the care of that patient” (1). According to the Joint Commission on Accreditation of Healthcare Organizations, POCT is differentiated from central-laboratory testing in that it does not require a physical laboratory; that is, the laboratory exists at each point-of-care. The specimen is obtained, the test performed, and the result reviewed where care is provided. Despite various attempts, a rigorous definition of POCT is somewhat elusive, if not artificial. However, differentiating POCT from central laboratory testing is a useful concept from the management perspective because it involves testing by nonlaboratory personnel using specialized technologies adapted for near-patient bedside applications.

POCT had its beginnings many decades ago when physicians performed testing in hospital laboratories with or without the aid of a technologist. An archaic example of POCT was the practice of tasting a patient's urine to detect the presence of glycosuria indicative of diabetes mellitus. In the traditional academic medical center, the task of performing laboratory testing fell to the junior resident or intern house officer. The menu of laboratory tests was small, the available technology limited, and regulatory and medical-legal issues were of little concern. Subsequently, hospitals established clinical laboratories capable of performing an increasing diversity of tests. With the use of automated technology, the volume of testing also increased markedly. Over time, medical technology evolved into a formal profession complete with undergraduate and graduate training programs and a system of certification examinations designed to ensure competency. For many years, POCT remained unrecognized and limited to a few selected types of tests such as fecal occult blood testing, physician performed microscopy, and urinalysis. Under the traditional fee-for-service system of reimbursement, there was little incentive for doctors to evaluate and treat patients rapidly or to expedite noncritical laboratory testing. This mentality began to change as managed care became an increasingly important force influencing the medical reimbursement system. Efficient cost-effective management of patients now is essential to quality medical care and in many cases to the financial success of the provider. This shifting landscape has resulted in a reassessment of the role of the clinical laboratory and of the opportunities afforded by point-of-care testing.

POINT-OF-CARE TESTING: GENERAL CONCEPTS

Part of "25 - Point-of-Care Testing"

For the clinical pathologist responsible for providing laboratory services, there are three options for performing a test as shown in Table 25.1. These include reference laboratories, hospital laboratories, or testing at the POC. Reference laboratories include national commercial operations such as Quest Diagnostics and Laboratory Corporation of America. These laboratories boast a large test menu and a significant economy of scale owing to the volume of testing performed. Economy of scale translates into a low unit cost (although charges may be much greater). The major disadvantage of reference laboratories lies in the fact that their remote location results in long turnaround times that may be inappropriate for some types of testing. At the opposite end of the spectrum is POCT. In the case of POCT, the available menu is limited and the economy of scale is minimal because tests are performed one at a time. Consequently, the unit cost of POCT tends to be higher than other alternatives. However, the turn around time for POCT is usually only a few minutes. The hospital laboratory presents another option. On the one hand, some hospital laboratories have grown to impressive size with large

menus, automated instrumentation, and significant economy of scale. In this respect, hospital laboratories may resemble regional reference operations. On the other hand, many laboratories have set up STAT laboratories and urgent-care facilities with pneumatic tube transport systems to facilitate rapid transport and short turnaround time. These STAT laboratories provide a reasonable alternative to POCT in many applications, and may offer some cost and quality advantages. The needs of each institution for laboratory testing are highly variable depending on geography, available infrastructure, logistics, the type of medical services, patient acuity, reimbursement, regulatory requirements, and a variety of other factors. The three options for providing laboratory testing (reference laboratories, hospital laboratories, and POCT) compete to serve the needs of the patient and physician. Many solutions therefore are possible depending on a number of complex and at times contradictory factors. In the final analysis, most hospitals utilize all three options to a greater or lesser degree.

TABLE 25.1. OPTIONS FOR PROVIDING LABORATORY SERVICES

	Reference Laboratory	Hospital Laboratory	Point-of-Care
Menu	+++	++	+
Economy of Scale	+++	++	+
Turnaround Time	+	++	+++

Enthusiasm concerning the opportunities provided by POCT to achieve rapid turnaround time has resulted in substantial and continued investment in POCT technologies by the diagnostics industry. At the same time, hospitals are learning how to manage POCT performed by nonlaboratory personnel using interdisciplinary teams composed of the laboratory, nursing, and hospital administration. Consequently, the opportunities to implement successful POCT programs have been expanding as technology has improved progressively (Table 25.2). However, POCT continues to present major challenges including issues of cost, medical necessity, analytical quality, the performance of tests by nonlaboratory personnel, the impact of POCT on hospital operations, and regulatory concerns.

TABLE 25.2. MAJOR TRENDS IN THE EVOLUTION OF POINT-OF-CARE TESTING

- Expanding menu
- Consolidated platforms
- Improved analytical technologies
- Improved data management systems
- Product-line orientation of major suppliers
- Improved management of POCT using multidisciplinary teams

TABLE 25.3. EXAMPLES OF TESTS AVAILABLE AT THE POINT-OF-CARE

Chemistry
- Glucose
- Blood gases and electrolytes
- Cholesterol
- Cardiac markers
- Urinalysis
- Urea nitrogen
- Creatinine
- Ionized calcium
- Drugs of abuse
- Pregnancy testing

Hematology:
- Prothrombin time
- Partial thromboplastin time
- Activated clotting time
- Blood count

Microbiology:
- Physician performed microscopy
- Rapid group A Strep testing
- H. pylori testing
- Influenza testing
- Sexually transmitted diseases

Other:
- Fecal occult blood
- Gastric occult blood

Menu For Point-of-Care Testing

The menu of tests available at the POC has grown rapidly as shown in Table 25.3 to include many of the commonly performed tests in the chemistry, hematology, and microbiology laboratories. Some of these tests are performed on instrument-read quantitative systems with electronic data management capability (e.g., bedside glucose testing, blood gases, and electrolytes) while others utilize visually read devices (noninstrumented tests) producing a semiquantitative result (dipstick urinalysis) or a simple positive-negative result (*Helicobacter pylori* serology, fecal occult blood, pregnancy testing). As the menu of tests available at the POC has expanded, some manufacturers are consolidating multiple tests on a single platform. For example, devices are available that can perform blood gases, electrolytes, blood-urea nitrogen, creatinine, ionized calcium, glucose, activated clotting time, and other tests on a single hand-held device. As a consequence, most of the test menu required for emergency-department and acute-care applications now can be performed at the POC. The future will inevitably produce further expansion of the test menu and consolidation of platforms. It is reasonable to predict that most of the high volume and critical turnaround-time-dependent tests eventually will be available at the POC and that the majority of the conventional laboratory test volume will not necessarily be performed in the central laboratory. Where testing will ultimately be performed may depend on many variables, but lack of available technology will not be a limiting factor.

Utility Of POCT

POCT may be used in a variety of applications as shown in Table 25.4. These include patient screening, diagnosis, medical management, and management of patients. Medical management refers to testing performed for the purpose of managing a clinical condition such as bedside capillary glucose testing to maintain glycemic control in diabetic patients. In contrast, management of patients refers to testing performed to assist in managing the patient within the hospital. For example, cardiac markers may be used in conjunction with clinical data to triage patients to one of several different types of hospital beds such as an observation

unit, a general medical unit, or intensive-care setting. The decision is more related to hospital operations than medical issues with the aim being to provide the most cost-effective and clinically appropriate setting in which to care for the patient. In all of the above applications, the key to the selection of POCT versus the central laboratory is the priority of rapid turnaround time over other considerations. Although the unit cost of POCT tends to be higher than central-laboratory testing, when the total cost of care is considered, POCT may in some cases prove to be more cost effective.

TABLE 25.4. CLINICAL UTILITY OF POINT-OF-CARE TESTING: SOME EXAMPLES

Screening: Fecal occult blood, cholesterol, capillary blood glucose testing for diabetic screen at a health fair
Diagnosis: Pregnancy testing, cardiac marker, rapid Strep A
Medical Management: Bedside glucose testing, gastric occult blood, blood gases, electrolytes, activated clotting time
Management Of Patients: Cardiac markers used to triage patients to an observation unit versus an inpatient medical unit, urine pregnancy screen as a pre-radiology test in a trauma unit
Home Use: Patient Self Monitoring: Capillary glucose testing, ovulation testing

A growing application for POCT is home testing used for patient self-monitoring. Self-monitoring by diabetic patients using hand-held over-the-counter glucose meters has become an accepted standard of care. Capillary blood-glucose testing has radically improved the ability of diabetic patients to maintain glycemic control compared to obsolete methods such as urine glucose testing using dipstick methods. In the future, noninvasive and continuous glucose monitoring devices will become available further enhancing the ability of the patient to manage their condition and reducing the discomfort of obtaining specimens using the fingerstick method. A number of other tests now are available for home use including urine pregnancy testing, ovulation monitoring kits, fecal occult blood, and drug-screening kits using hair specimens to name just a few. Patient self-monitoring of anticoagulation testing using simple hand-held devices has become available, but remains controversial. Home testing using over-the-counter kits presents a radical departure from the traditional method of obtaining laboratory test results in that the patient, not the physician, chooses the test and interprets the result. The future of home testing remains uncertain and presents many challenges to the traditional approach endorsed by the medical establishment.

Analytical Performance

Many studies have reported on the analytical performance of testing devices at the POC. Evaluations on the performance of these technologies must take into account the capabilities of the devices under controlled conditions as compared to the performance of testing in actual practice in the hands of nonlaboratory personnel (2). Many POC devices are not as accurate or precise as testing performed in the clinical laboratory by skilled medical technologists. There are several reasons for this including limitations imposed by the capabilities of the technologies themselves and operator-related errors in the preanalytical and analytical phases of testing. Some early POC devices exhibited significant issues with analytical performance. In many cases improved engineering has reduced operator errors and improved the precision and accuracy of POCT devices. When evaluating a laboratory or POCT device, it is important to be aware of the limits of performance necessary for the clinical care of the patient. POCT systems do not necessarily need to be as accurate or precise as testing performed in the clinical laboratory provided the performance characteristics of the system are sufficient for the clinical application. For example, bedside glucose testing is widely used for the management of patients with diabetes as an aid to direct therapy (3). These technologies have revolutionized the care of the diabetic patient and have facilitated the ability of patients to maintain tight glycemic control. Most of these devices are only accurate to within +/- 10% to 15% of a reference value, but this level of performance is adequate for the clinical application. In contrast, laboratory-based glucose measurements using reference methods are considerably more accurate, but the turnaround time typically is too long for hospitalized patients and is hopelessly inadequate for outpatient or home-use settings. A different situation occurs in the diagnosis of diabetes mellitus. In this application, accurate reproducible results are essential to reliably classify patients and avoid over- or under-diagnosis. POC devices are not sufficiently reliable for use in this application and laboratory-based measurements are strongly preferred. In contrast, POCT glucose meters have been used in public-health applications to screen populations for diabetes mellitus. Individuals that test positive on the screen then are referred for follow up visits and formal laboratory testing. Thus the analytical performance of a given technology must be understood in terms of how the device will be used in clinical practice rather than a dogmatic adherence to the doctrine that greater accuracy or precision is itself the desired endpoint. This does not mean that all POC technologies are “good enough” for clinical application rather that these technologies must be evaluated in the context in which they will be used. Some devices currently available and approved by the Food and Drug Administration are not necessarily reliable. Therefore, the laboratory should assist other medical professionals in evaluating and validating POCT devices. Various parameters should be addressed when validating a new technology for laboratory testing (Table 25.5). The extent of the validation should at a minimum fulfill basic regulatory requirements. Beyond this, the validation should be extensive enough to ensure the reliability of the technology in clinical practice. This may require judgment and considerable expertise and represents one area where the laboratory can be particularly helpful in supporting the POCT program. Two caveats to consider when evaluating POCT technologies is how the devices

compare to tests offered in the clinical laboratory and what differences in sample types may be encountered. For example, the laboratory may offer troponin T for the evaluation of patients with chest pain whereas most POCT systems use troponin I. Reference ranges for the same tests (e.g., two troponin I methods) may be different, resulting in confusion among physicians. Finally, most POCT systems use urine or whole blood whereas central laboratories use plasma or serum. Implementing POCT therefore may necessitate careful consideration of many factors unique to the individual site and requires close communication with the clinical staff.

TABLE 25.5. FACTORS TO CONSIDER IN THE VALIDATION OF POINT-OF-CARE TECHNOLOGIES

- Ease of use, ease of training
- Data management
- Accuracy
- Precision
- Reference ranges
- Interferences
- Crossover studies to existing methods
- Quality control frequency and ranges
- Sample selection

MANAGEMENT OF POINT-OF-CARE IN THE HOSPITAL

Part of "25 - Point-of-Care Testing"

Traditionally, POCT was unregulated and consequently little effort was made by hospitals to establish an approach to managing these technologies. Predictably, issues concerning the quality of test results became apparent (2) resulting in the establishment of regulatory requirements (see below) that have been enforced by hospital accreditation organizations. Failure to comply with regulatory mandates may have major consequences. The need to address regulatory requirements combined with rapid expansion of POCT technologies has resulted in a concerted effort by institutions to manage POCT as a formal hospital program.

The first step in developing a strategy to manage POCT involves setting up an interdisciplinary POC management team, including the laboratory, physicians, and nurses (4). The POC team has the responsibility of determining the test menu, selecting technologies, establishing policies and procedures, ensuring training and regulatory compliance, and providing advisory assistance to the end users of POC technologies. Establishing a POC team requires financial support from the institution. At Massachusetts General Hospital nearly $100,000 is spent on salary support for the POCT management team. This figure does not include the cost of office and laboratory space, consumables and office supplies, administrative overhead, and other nonsalary expenses. Once a POC team has been established, a management structure must be put in place to ensure that the team has the authority to implement new initiatives and to perform corrective action where necessary. Figure 25.1 shows the management structure for POCT at the Massachusetts General Hospital. Oversight of POCT is the responsibility of the Point-of-Care Steering Committee, which includes the chief of pathology, the director and program manager of POCT, the chief medical officer for the hospital, the vice president of ancillary services, and the associate director of nursing. This committee provides high-level oversight and has interdisciplinary authority to mandate compliance with the POC program. Beneath the steering committee is the Point-of-Care Management Team, composed of a medical director, a laboratory program manager, a nurse manager, and a medical technologist. The POC management team is responsible for direct oversight of POCT, determining medical need, selecting technologies, establishing policies and procedures, overseeing regulatory compliance and quality assurance, and ensuring that individuals performing POCT have been adequately trained. The POC management team also ensures that each site performing POCT has assigned a medical director and a manager who are responsible for supervising testing activity, ensuring regulatory compliance, and serving as a liaison to the POC management team. In this system, responsibility is placed with the end user. The POC management team serves in a consulting role and coordinates the POC program throughout the institution. However, responsibility for compliance rests with the individual testing site, not the laboratory or administration.

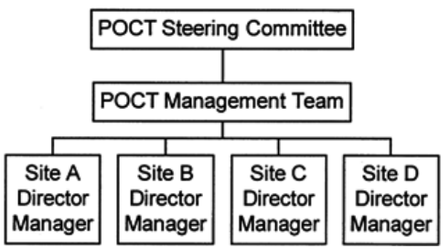

FIGURE 25.1. Management structure for point-of-care testing at the Massachusetts General Hospital: circa 1999.

The first task of the POC management team is to assess what testing is being performed in the institution. This may include a combination of e-mail surveys and site visits to inspect testing areas and interview staff. Many types of tests may be discovered that were unknown to the POCT team. In a number of cases, we discovered POCT during site inspections that were not reported during e-mail surveys. This is particularly true for manual POC tests such as fecal and gastric occult blood, various urinalysis products, and urine pregnancy testing.

The next step is to assess the medical need for each POC test and determine which technologies are most appropriate for the intended application. This requires interviews with physicians or nurses and is best performed by the POCT medical director. Questions to be considered when assessing medical need include assessing why the site is performing POCT, what turnaround time is required both from a medical perspective and from the perspective of unit operations, and finally what analytical performance is acceptable for the intended application.

The next task is to develop policies and procedures. This includes establishing a quality control and quality assurance program to ensure regulatory compliance and to maintain quality testing. A corrective action plan to remedy ongoing deficiencies is essential to the success of the program. In some cases, this may require mandates to discontinue testing in noncompliant sites. The corrective action plan is particularly important for manual POCT where auditing of quality control and quality assurance activities is more difficult than for instrumented tests because of the necessity of maintaining manual records. In contrast, oversight of instrumented tests can be facilitated by electronic data management systems and therefore requires less onsite assessment of compliance. The key to successful corrective action is to ensure that the POC team has the authority to make decisions concerning the suitability of testing on any given site. When a site is found to be noncompliant, an effort should be made to educate the personnel who are performing tests as to the necessary requirements for compliance with the program. If remedial action is not successful, consideration should be given to removing

testing when compliance cannot be achieved with the quality assurance program. One recommendation to ensure the authority of the POCT management team is to have an institutional policy whereby the POCT team controls the Clinical Laboratory Improvement Amendment (CLIA) certificates (see below) for all testing sites.

Once a POCT program has been established, the team should begin a continuous process-improvement effort designed to enhance the efficiency and ease of compliance with the program. This requires ongoing site inspections, continuing education, and may involve implementing new technologies, consolidation of technologies, and in some cases, elimination of POC tests that do not meet quality standards. For example, our site inspections revealed that a number of urinalysis dipstick products were being used in our hospital for a variety of applications. These include screening for hematuria and urine pH on oncology units, monitoring hydration status in pediatric patients and those with diabetes insipidus, and general urinalysis applications. Each product required its own policy and procedure, quality control, training, and competency assessment programs. First, the medical need for each type of test was studied to ensure that the application was appropriate and that the technologies performed at an acceptable level for the intended application. For example, pH paper to measure urine pH had not been validated and was eliminated. Owing to the availability of multiple products, maintaining compliance with the POC program was extremely difficult for users of urinalysis test strips because there were too many different products, standards for performance were not established, and some of the applications were inappropriate. The management decision was to consolidate all of these technologies to a single urinalysis strip and to establish one set of policies and procedures, training, and quality control. This radically simplified the management of POC urinalysis testing in our institution.

REGULATORY ISSUES

Part of "25 - Point-of-Care Testing"

Regulatory issues that pertain to POCT include requirements mandated by the CLIA 88, and subsequently by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), the College of American Pathologists (CAP), and in some localities, state or other organizational requirements. Prior to these regulations, there were few guidelines for POCT. Predictably, major concerns regarding test quality, operator competency, and management of test results became apparent. Regulations imposed by CLIA 88 divide POC tests into two categories, CLIA-waived and nonwaived tests, the latter including moderate and highly complex subtypes. Waived tests are defined as tests that use simple accurate methods that make the possibility of errors unlikely or pose no significant risk of harm if performed incorrectly (5). Examples of CLIA waived tests are shown in Table 25.6. According to CLIA 88, all laboratory testing with the exception of waived tests are subject to certain basic requirements for quality control, patient records, and quality assurance (Table 25.7). Waived tests are exempt from these regulations, but are still subject to guidelines imposed by the JCAHO or the CAP. These requirements have evolved over time reflecting the need to make guidelines concerning POCT realistic and practical. In the past, both the JCAHO and the CAP imposed requirements that were arbitrary at best and were unachievable in many situations. Regulatory guidelines continue to evolve as accreditation agencies learn what guidelines promote practical, high quality POCT versus those that are superfluous.

TABLE 25.6. EXAMPLES OF CLINICAL LABORATORY IMPROVEMENT AMENDMENT WAIVED POINT-OF-CARE TESTS

- Dipstick urinalysis (but not microscopic analysis)
- Dipstick microalbumin
- Bedside glucose testing (if the device is FDA approved for home use)
- H pylori serology (selected kits)
- Fecal occult blood
- Hemoglobin (copper sulfate or Hemocue)
- Spun hematocrit
- Urine pregnancy testing
- Ovulation test kits
- Sedimentation rate (nonautomated)
- Group A strep antigen (selected kits)

TABLE 25.7. SUMMARY OF REQUIREMENTS FOR NON-WAIVED TESTING MANDATED BY THE CLINICAL LABORATORY IMPROVEMENT AMENDMENTS OF 1988 (CLIA 88) (3)

- Testing covered under appropriate CLIA 88 certificate
- Personnel requirements: Specific training requirements for director, technical consultant, clinical consultant and testing personnel
- Proficiency testing standards
- Patient test management standards: Specimen collection, handling, reporting, records
- Quality control standards: Including procedure manuals, per-formance verification, equipment maintenance, calibration, specific quality control, and corrective action
- Quality assurance: Systems established to monitor quality (pranalytic, analytic, postanalytic) and assessment of staff competency.

In order to perform testing, all sites must be covered under a CLIA 88 certificate. Different types of certificates are available including a waived testing certificate, a provider performed microscopy (PPMP) certificate and a certificate for moderate and high complexity testing. Waived tests are not covered under federal law concerning personnel or testing requirements. However, both the JCAHO and CAP have instituted standards for waived tests as part of the hospital/laboratory accreditation process. The standards of the JCAHO and the CAP differ somewhat and in some facilities there also may be state requirements as well. An excellent review of the perspective of the JCAHO concerning requirements for POCT is provided in reference 6 and of requirements mandated by CLIA 88 in reference 7. Further details may be obtained directly from the JCAHO or CAP.

PERSPECTIVES ON COST

Part of "25 - Point-of-Care Testing"

Conventional wisdom concerning the cost of POCT is that testing performed at the bedside is more expensive on a unit-cost basis than testing performed in the clinical laboratory where the

economy of scale is typically higher. For example, in one study at a Veterans Affairs medical center, the cost of bedside capillary glucose testing was reported to be 3.6 times more expensive ($11.50 per tests versus $3.10) than testing performed in the clinical laboratory. Other studies have shown that POCT is not invariably more expensive than testing performed in the clinical laboratory depending on test volume, technology, program management, and other factors (8). In another example, Bailey et al. reported an institutional savings of $392,336 with a reduction in unit cost from $15.33 per panel to $8.03 following institution-wide implementation of POCT for blood gases and electrolytes (9). Despite a growing literature on this subject, a determination of the actual cost of POC testing versus the central laboratory remains an enigma. Other factors besides unit cost also must be considered such as the impact of reduced turnaround time on the time to diagnosis and overall cost of care, issues of workflow on clinical units, impact on test utilization, and benefits to patient outcomes to name only a few. Collectively, these factors are too complex to be understood solely in terms of unit cost. Kost has pointed out that “there is no adequate generalization. Cost effectiveness analysis, consideration of marginal costs of competing alternatives, and other means of economic assessment must be individualized to the institution and setting.” Lacking clear consensus in the literature, the decision of whether to implement POCT versus using a central laboratory will depend on a number of features unique to the individual hospital or care unit. Lacking reliable outcomes data in the literature, the approach will be in part intuitive and may require trial and error to arrive at a satisfactory solution.

THE FUTURE OF POCT: POSSIBLE SCENARIOS

Part of "25 - Point-of-Care Testing"

Technological improvements in POCT devices have resulted in greater ease of use, improved analytical performance, and lower unit cost because of the development of less expensive, more efficient platforms. Many hospitals have learned to manage POCT successfully and to improve compliance with regulatory guidelines. As the menu available at the POC expands and platforms are consolidated into multianalyte systems, new opportunities to exploit these technologies will be possible. Currently, the rate-limiting factor for most POCT programs is the ability to manage quality control and patient data in an efficient reliable manner. Also, problematic is the fact that many technologies cannot be integrated electronically (including both instrumented and noninstrumented tests) into a turnkey POC solution. Until these challenges are overcome, POCT will be limited to specialized applications in selected settings.

Assuming further improvements in POCT technology, various scenarios are possible. At one end of the extreme, virtually all turnaround-time-dependent tests could be moved out of the central laboratory to the bedside where immediate test results would be available to providers of clinical care. At the opposite end of the spectrum, POCT may remain only a minor component of total testing volume because of limitations imposed by cost, technology, and system management. The most likely outcome probably will lie between these two extremes with continued growth in POCT and expansion of the menu. Each institution will seek its own solutions depending on its unique circumstances resulting in a limitless number of permutations. Clearly, POCT will challenge laboratory professionals for many years to come.

26
Tumor Markers

Morton K. Schwartz

The use of cancer markers goes back more than 150 years. In 1847, Sir Henry Bence-Jones described a protein in urine that could be identified by its unique thermal properties. It becomes slightly opaque when cooled. When citric acid is added, it effervesces, assumes a reddish hue, and becomes quite clear, but as it cools it becomes opaque. This protein, known as “Bence-Jones protein” or, as Sir Henry Bence-Jones described it, “hydrated deutoxide of albumen,” served as a definitive diagnostic test for myeloma for 100 years. With the introduction, first of electrophoresis and then of immunological procedures, the Bence-Jones protein was identified as the light chain of immunoglobulin G (IgG). These techniques allowed the identification of IgG light chains in the urine of some individuals who did not exhibit Bence-Jones protein or have myeloma (1).

Another early application of testing in cancer was by Sir Michael Foster who in 1867 reported the presence of amylase in blood from patients, and proposed the use of urinary amylase as a marker for cancer of the pancreas. As more information was obtained about the pathology and physiology of the pancreas, it was realized that pancreatic cancer originates in the ductal cells and not in the acinar tissue, which produces amylase. Amylase elevations therefore were only significant in cancers with a large tumor burden, which impinged on acinar tissue (2). Other early markers include acid phosphatase (prostate cancer), alkaline phosphatase (bone cancer), catechols (pheochromocytoma and neuroblastoma), 5-hydroxyindole acetic acid (carcinoid), and pituitary gonadotrophins (choriocarcinoma). These markers are still in use, but the techniques for their measurement all have been improved and both their sensitivity and accuracy increased (3).

DEFINITIONS

Part of "26 - Tumor Markers"

It was not until the invention of the radioimmunoassay and its application in immunoassays permitting quantitative assay of nanogram concentrations of protein that the term “tumor marker” was introduced and became a part of the everyday laboratory vocabulary. Tumor markers originally were defined as substances that can be measured quantitatively by immunochemical means in tissue or body fluids to identify the presence of a cancer and possibly the organ where it resides, to establish the extent of tumor burden before treatment, to predict prognosis, and to monitor the response to therapy. This definition now must be modified to include markers in solid tissue that can be identified semiquantitatively or quantitatively by immunochemical staining, cell sorting, or molecular diagnostic techniques as well as substances released from the cell (usually from the surface membrane) and found circulating in body fluids, where they can be measured by a variety of techniques. The range of molecules that now are classified as tumor markers is considerable, including tumor-associated antigens, nuclear and specific proteins, enzymes, isoenzymes, genes, oncogenes and their products. The performance of tumor markers in the United States requires use of a Food and Drug Administration (FDA) approved assay (4, 5). At Memorial Sloan Kettering Cancer Center, this volume has increased dramatically every year. The three tumor markers with the most remarkable growth are CEA, which has increased from 10,925 tests in 1987 to 22,125 in 1999; PSA from 569 tests in 1987 to 23,693 in 1999; and CA15-3 from 0 in 1987 to 14,661 in 1999. CA125 has increased in that time from 1,246 to 7,185, but AFP and hCG have remained constant at about 3,500 tests. In 1999, free PSA and CA19-9 were introduced.

Clinical application of tumor markers requires an understanding of the epidemiological and analytical definitions of sensitivity and specificity and the importance of prevalence. In addition, we must appreciate the analytic limitations of the assay and be aware of preanalytical and postanalytical effects on the marker. Epidemiological sensitivity is the percentage of true positives. Specificity is the percentage of true normals. The positive predictive value is a percentage of the true positives compared to positive values. The negative predictive value is the true negatives compared to all negatives. The efficiency of the test is the true negatives and true positives divided by the number of tested individuals.

Prevalence of the disease plays an important role in the use of a marker for cancer detection. In a test with 95% sensitivity and specificity, the predictive value would be only 16.2% when the prevalence was 1%, 50% when the prevalence was 5%, and 95% when the prevalence was 50%. Analytical sensitivity can be defined as the lowest detectable amount of marker measured by the method in use, while analytical specificity reflects the extent of exogenous material interferences in the assay (4, 5).

It also is of extreme importance to note that observed values in the same specimen measured by different methods may be different and these values cannot be used interchangeably. These differences may be as a result of poor calibration, differing antibody

specificities, variation in quoted reference ranges, and assay robustness. Robustness is related to hook effects, linearity, and the possible presence in the patient's serum of human antimouse antibody (HAMA). This is becoming more important as cancer patients in larger and larger numbers are treated with monoclonal antibodies of mouse origin (6).

Carcinoembryonic Antigen (CEA)

When first described, CEA fulfilled all the requirements of an ideal tumor marker. It apparently was elevated in almost all patients with colorectal cancer, but was normal after successful removal of the tumor. 30 years later, it now is well-understood that CEA is elevated in all solid-tissue tumors, not only those of the colon or rectum and is elevated in only 4% of patients with early stage diseases compared to 65% of patients with distant metastases (4). Following successful therapy, elevations of CEA may fall and subsequent elevations suggest recurrence. These elevations may be seen months, if not years, before there is clinical evidence of disease. It is important to understand that elevations will not be seen in about 30% of individuals with recurrent metastatic disease. In two patients with equally progressive disease, a crescendolike rise in serum CEA concentration may be seen in one patient while little or no increase is observed for the other. This probably reflects the pathology of the tumor. Well-differentiated tumors produce CEA while those that are undifferentiated or poorly differentiated produce little, if any. In patients with metastatic gastric cancer, CEA elevations never were observed over a period of 1 year in individuals with undifferentiated cancers, whereas there was a mean rise of more than 20 times the pretreatment level in patients with highly differentiated tumors. It certainly would make interpretation of CEA data more understandable and useful if the pathology of the tumor was reported with CEA values (7).

During therapeutic monitoring, it is important to understand the significance of changes in CEA values. There is no definition of a meaningful decrease or increase of CEA. In general, a 25% to 35% change has been termed significant. Four patterns of change of serum CEA values may be observed. Two patterns are expected: an uninterrupted rise in patients who do not respond to treatment, and a fall in those who do. There are two other patterns. In patients who are responding to treatment, there may be a surge in CEA for weeks posttreatment, followed by the conventional fall. In others, there may be an immediate but sustained fall in serum CEA and then the rise that indicates lack of response. It is apparent that if CEA is to be used in evaluating response to therapy, an understanding of these kinetics is essential (7, 8).

An expert panel of the American Society of Clinical Oncology (ASCO) has concluded that CEA cannot be used for screening for colon-rectal cancer, but preoperative CEA may assist staging and surgical treatment planning. The panel also concluded that CEA elevations detect recurrence earlier than other techniques and CEA monitoring should be done at the start of treatment and then every 2 to 3 months thereafter (9). CEA also has been found to be useful in monitoring cancer of the breast, ovary, and pancreas. Elevated CEA values are useful prognostic indicators (4).

CA19-9

CA19-9 is the marker most useful in adenocarcinoma of the pancreas. It is more sensitive (70% to 95%) and specific (72%) than CEA (40% to 60% and 70% respectively). Combined measurement of both markers does not significantly augment the sensitivity of the test. CA19-9 is not elevated in islet cell carcinoma of the pancreas. The value of CA19-9 is obscured by the fact that benign conditions such as acute or chronic pancreatitis or cholelethiasis may cause elevations. CA19-9 may be useful in monitoring patients who are receiving treatment. Many other markers have been studied in patients with pancreatic cancer, but none has the sensitivity or specificity of CA19-9. Of considerable interest is that CA19-9 is only found in the serum of individuals who secrete Lewis antigen. It is not found in serum of nonsecretors (10).

CA72-4

CA72-4 is a glycoprotein with a molecular weight of 220,000 to 400,000. It is clearly different from CEA, CA19-9, or other glycoprotein tumor markers. Although elevated in serum of patients with many different gastrointestinal cancers and only rarely in benign gastrointestinal diseases, it is more sensitive and specific than any other marker in gastric cancer. In one study, it was clearly shown that it is inferior to CA19-9 in pancreatic cancer (22% versus 82%) and to CEA in colorectal cancer (32% versus 58%). In gastric cancer, it identified 59% of the patients compared to 52% with CA19-9 and 25% with CEA. When combined with CA19-9, 70% of the gastric cancer patients were identified (11).

Alpha Feto Protein (AFP)

AFP has been used for more than 30 years in screening for hepatocellular cancer (HCC) and in diagnosis and monitoring of patients with germ-cell tumors. When screening for HCC, a disease of great importance in sub-Saharan Africa and Southeast Asia where hepatitis B and hepatitis C are endemic, the sensitivity of the assay is important. In an early study with an immunodiffusion method, 39 of 56 patients with HCC were detected and there were no false positives. When a radioimmunoassay was used in these same specimens, 49 of the 56 patients were detected but there were so many false positives that screening was not practical. The solution is either use of a less sensitive method or an increase in the cut-off to eliminate the false positive. When monitoring germ-cell tumors, particularly embryonal testicular cancer, the most sensitive method available is needed because successful therapy is defined as a return of the marker to no detectable level (12, 13).

In China, there have been widespread AFP screening programs in high-risk areas to detect HCC. Between 1971 and 1976, 1,967,511 persons were screened in Shanghai and 3,090 cases were detected (15.3 cases/100,000). In Qidong Province between 1976 and 1992, there were 499 cases identified in the 1,310,871 persons tested (38.1 cases/100,000). If only those individuals with liver diseases were considered, AFP detected 253 cases of HCC in 76,600 persons in Shanghai (330 cases/

100,000) and 48 cases in 4,875 persons (98.6 cases/100,000) in Qidong. In these studies, the 3- to 4-year survival of detected and treated patients was 57.1% and the 2-year survival, 69%. In a limited study of 3,454 hepatitis B antigen-positive patients, there were 31 HCC cases (897 cases/100,000).

When a highly sensitive AFP method was used, normal levels were seen in all of 450 normal individuals, in 98.2% of 564 patients who were hepatitis-B antigen positive and in 96.4% of 536 patients with nonmalignant disease or other cancers. With this method, elevations were seen in 23/28 (82%) HCC patients from Africa who were hepatitis-B antigen positive and in 45/57 (79%) hepatitis-B antigen positive HCC patients from the Far East. Abnormal values were observed in 38% of 16 HCC patients who were hepatitis-B antigen negative (14).

Although individuals with cirrhosis are at high risk for HCC, studies have suggested that AFP screening is not useful in detecting cirrhotic patients who will develop HCC (15). In addition to screening, AFP is of use in monitoring patients with HCC. The concentrations rise and fall, reflecting the course of the disease, and may be reflective of recurrence before any other clinical or diagnostic indication.

AFP is an important marker in germ-cell tumors, but only when used in conjunction with the ß-subunit of choriogonadotropin (ß-hCG) (16). The AFP observed in HCC is of liver origin and the AFP in germ-cell tumors originates in the yolk sac. It may be possible to differentiate the liver form of AFP from yolk-sac AFP by their different affinities for lentil lectins. Lectin binding of the AFP in HCC has been documented whereas the yolk-sac form does not react. This difference has been exploited for more precise identification of the source of AFP elevations.

Chorionic Gonadotropin (hCG) and its Beta Subunit (ßhCG)

hCG, which is produced by the syncytiotrophoblast cell after trophoblastic differentiation has been used for more than 50 years in the diagnosis and monitoring of trophoblastic cancers such as choriocarcinoma and hydatidiform mole. An elevation is essential for the confirmation of diagnosis, and changes in the concentrations clearly reflect the success or failure of therapy. AFP is not elevated in these cancers (16).

In nonseminomatous germ-cell tumors of the testes, a combination of AFP and hCG — more particular the ß subunit of hCG (ß-hCG)— are essential for the management of the patient. Presumably because of the heterogeneity of the cancer cell, it is essential to measure both ß-hCG and AFP when monitoring embryonal testicular cancer. Successful therapy is indicated by a fall of the elevated markers to normal. A rise in one or the other or both suggests recurrence, usually before there is clinical evidence of metastases. Very often during an exacerbation, only one of the markers will become elevated (16).

AFP and ß-hCG have been used to predict therapeutic response and to evaluate prognosis of testicular cancer. If the serum concentrations fall to 50% of the pretreatment value during a biostatistically defined period [7 days for AFP and 3 days for (hCG)], there is much poorer prognosis. In individuals with longer fall-off periods, the 9-year survival was 29% compared to 84% in men with a shorter fall off. A multivariate equation has been established that uses the concentration of ß-hCG, the activity of serum lactate dehydrogenase, and the number of metastatic sites to predict whether conventional therapy will be effective. Neither AFP nor CEA offered additional help. When this equation was used, the prediction of those who will respond is >90% accurate, but unfortunately, the equation properly predicts only approximately 50% of those men who do not respond (17, 18).

CA-125

CA-125 has been observed in the blood of patients with ovarian cancer but also is elevated in a variety of cancers (uterus, pancreas, liver, lung, and a variety of benign diseases). The assay is only approved by the FDA for monitoring second-look operations in women who have been treated for ovarian cancer. Elevations of CA-125 may be seen in many nonmalignant conditions. These include pregnancy, menstruation, ovarian cysts, endometriosis, and peritoneal or pleural inflammation. Because of the elevations in benign conditions and because CA-125 elevations are related to tumor burden, CA-125 cannot be used for early diagnosis (19).

However, CA-125 is an important marker because elevations after treatment suggest presence of residual tumor, and second-look exploratory surgery probably is unwarranted. In a literature survey, elevations were seen in all but one of 500 women with residual tumor prior to further treatment. About 50% of women with normal serum concentrations of CA-125 after treatment still had residual tumor. An elevated CA-125 is highly suggestive of residual tumor, but a normal value should not give a false sense of security that the tumor has been removed completely. It now is accepted to describe responses or recurrences when the only indication of a change in the patient's condition is the CA-125 (20).

CA-125 may be a prognostic predictor. In women in whom the fall of serum CA-125 after therapy followed a half-life of five days, prognosis was much better than in women in whom it did not. Eighty percent of women who experienced a return to normal CA-125 values within 30 days after therapy survived for more than 5 years, compared to only 10% of women who did not achieve normal values in this time.

It has been proposed that use of an algorithm and sequential CA-125 results may make it possible to use CA-125 for early detection (21). If the logarithm of CA-125 concentrations is plotted against time (taking two annual specimens initially and then after the first elevation, a further specimen every 3 months), the slope of the line becomes predictive. In a study of 1,855 women in the “training set” (the data used to develop the algorithm) and an additional 1,840 women in the validation set, the sensitivity for the early diagnosis was 83%, the specificity 99.8%, and the positive predictive value 16% (a value that exceeds the 10% expected in a screening program). Prospective clinical studies now are required to establish the true utility of this algorithm.

There is controversy over the role of CA-125 in screening and there is general agreement that single CA-125 values cannot be used for this purpose. Increases of CA-125 are observed in approximately 50% of patients with mucinous early (stage I or II) cancer and to a much lesser extent in women with nonmucinous

disease. A retrospective study was carried out with retrospective specimens obtained from the Norwegian Janus Serum Bank (specimens from 39,300 women collected in 1974 to 1986). Of these, 105 women developed ovarian cancer 1 to 143 months after the specimen was collected. The cancer patients were compared with 323 matched normal controls randomly selected from the bank. Fifty percent of the 105 women with ovarian cancer had abnormal CA-125 values as many as 18 months before diagnosis; 7% (23) of the control women had elevated CA-125 values. Twenty-five percent of the cancer patients had increased CA-125 levels 60 months before, compared with only 0.9% in the controls. The conclusion of this study was that CA-125 is useful in screening (22). In another study of 915 women without clinical symptoms, 36 had elevated CA-125 values; none had ovarian cancer but many had benign gynecological problems. Four who did not have an increased CA-125 died of nonovarian neoplasms. In screening of 1,010 asymptomatic postmenopausal women with CA-125, 43 abnormalities were observed. Abnormal pelvic examinations were seen in 28, over half related to fibroids or cysts. Thirteen women had abnormal ultrasound patterns; in the 12 who consented to laparotomy, one cancer was established.

In a study of 1,082 asymptomatic women over age 40, abnormal CA-125 values were found in 36. Additional specimens were collected and repeat assays were performed on those with the increases. A doubling of the value was considered a true positive. One of the 1,082 women had a clinically confirmed stage II ovarian cancer, diagnosed 21 months after the last specimen was collected. The incidence of detection in this study (1 in 1,082) would be 93 cases/100,000 screened, compared with the reported clinical incidence of ovarian cancer of 42.2 cases/100,000 (23). Evaluation of these screening studies suggests that if CA-125 is the only criterion; 30 laparotromies would be performed to confirm each ovarian cancer. Screening asymptomatic women in the United States by pelvic ultrasonography and CA-125 would cost 45 billion dollars. In women with operable pelvic masses, CA-125 can be very valuable. In a large study of women in Scandinavia, the sensitivity of CA-125 was 87% and the specificity 88%. The prevalence was 50% and the positive predictive value 88% (24).

Prostate-Specific Antigen (PSA)

The tumor marker that has received the most public attention over the past few years is prostate-specific antigen (PSA). PSA is prostate-tissue specific but not prostate-cancer specific. Elevations (PSA >4.0 µg/L) are seen in about 40% of men with early prostate cancer, 70% of men with more advanced cancer, and in 20% of men with benign prostatic hypertrophy (BPH). After surgical removal of the prostate, the PSA in serum falls with a half-life of 3.2 ± 0.6 days. Following radiation therapy the fall-off is much greater, and the half-life approaches 2 to 6 months (25).

PSA originally was approved by the FDA for monitoring therapy. In men whose cancer has successfully responded to treatment, serum PSA will reach very low (nondetectable) levels. A subsequent elevation to very low levels suggests recurrence. At 0.4 µg/L each of 16 men studied had recurrent disease. In another study, using a “super-sensitive” method with a reported minimum detection level of 0.025 µg/L, a rise to 0.04 µg/L was related to recurrence (26). The problem with the “super-sensitive” method is that many other tissues elaborate small amounts of PSA and if this assay is used in screening, it could conceivably create a large number of false positives (27).

In addition to monitoring, preoperative PSA values may be important prognostic markers and may be useful in influencing clinical decisions about orders for bone scans. Only three of 561 men with PSA <10 µg/L and only one of 467 patients with PSA <8.0 µg/L had an abnormal bone scan. These investigators concluded that when serum PSA is <10 µg/L bone scans are not necessary. It was estimated that if this criterion were used, 50,000 patients each year in the United States would not require radionuclide bone scans, which would represent a savings of $30 million (28).

The FDA recently has approved the use of PSA for screening. This use in screening for prostate cancer is supported by a large body of data suggesting that 60% to 70% of men with PSA values >10 µg/L will have biopsy-proven cancer. The problem in initiating large-scale screening programs is their cost and the fact that at autopsy, the large majority of men will have cancer cells in their prostates even though only 2% to 3% of these men will ever have a clinically significant prostate cancer. An absolute marker is not yet available to establish which prostate cancer will be clinically meaningful (29).

In an early study, 1,600 men who did not have urologic symptoms were compared to a control group of 200 men with urologic symptoms. In men with PSA values between 4.1 and 9.9 µg/L, 22% of the study group had biopsy-proven prostate cancer compared with 26% in the control group. In men with PSA values >10 µg/L, 64% of the screened population had biopsy-proven cancer compared with 64% in the control group (30). Other studies have found that the combination of digital rectal examination (DRE) and PSA detects 70% of cancers, compared with only 24% in individuals with abnormal DRE and normal PSA. DRE and PSA complement each other, and their combined use has been recommended (31).

The most compelling argument for the use of PSA in screening is a retrospective study of serum specimens collected over a 20-year period at a geriatric institution. In men who did have demonstrable cancer, there was an age-related small linear incremental increase in PSA over time. In men with BPH, the increase was still linear, but the slope was somewhat higher. In men who developed cancer, the rate of increase was exponential. In men with malignant disease, the exponential rise was much more rapid than those with localized cancer. Elevations preceded clinical evidence of prostate cancer by many years. It is conceivable that mathematical consideration of several PSA values collected over time may permit prediction of the eventual development of localized or malignant prostate cancer (32).

We now know a great many things about the physiology and pathology of PSA (33, 34, 35, 36 and 37). There is a physiologic variation of PSA concentrations in sequential specimens drawn over a short period of time. It was suggested that a meaningful change between successive specimens is ±30%. Hormone therapy (finasteride) may reduce PSA concentrations by as much as 50% without any effect on the cancer (36). Men with low endogenous

testosterone concentrations also may have low PSA values, and normal values may occur in such men even if they have prostate cancer. PSA values are age-related, young men having lower reference ranges and older men higher values. At age 70, the upper limit of the reference range is 6.5 µg/L. Black males have higher values than white males. Exercise may affect the values. In men who spent 30 minutes on an ergometer bicycle, there were elevations to twice the preexercise level.

Free and Complexed PSA

The question has been raised as to how PSA measurements can be used more effectively in the management of men with prostate cancer and made more accurate in distinguishing between benign disease and cancer. PSA exists in serum primarily as three forms. One form is complexed to the protease inhibitor α l-antichymotryspin, a second to α-2 macroglobulin and the remainder is noncomplexed (free PSA). The total PSA is presumably the free and the antichymotrypsin-bound form because the α-2 macroglobulin form is not immunoreactive. One proposed approach is to use the ratio between free and total PSA. In an original report, it was found that if the ratio was greater than 0.154, benign disease was present, and if it was lower, the patient suffered from cancer. With this cutoff, 93% of men with BPH were identified. Various cut-offs have been proposed and there is continuing controversy over the role of the ratio in the management of patients. When a cutoff of 0.197 was used, the sensitivity was 84.1% and the specificity was 46.8%. In another study, free and total PSA were studied in 773 men of whom 379 had histologically confirmed prostate cancer and 394 had benign prostatic hypertrophy. All had PSA levels between 4.0 µg/L and 10 µg/L. The normal/abnormal cutoff for free PSA was established emperically as that required to maintain 95% sensitivity for detection of prostate cancer in the prostate cancer patients. A 0.25 free PSA/total PSA ratio was determined and with it 95% of the cancers in the BPH patients were found. The procedure probably avoided 20% of unnecessary biopsies. The cancers in men with greater ratios than 0.25 were usually older men with less-aggressive tumors (38, 39, 40). Recently it has become possible to measure the complexed PSA by itself. With this technique, it has been found that in combination with total PSA, it may be possible to stratify men with total PSA between 2 to 4 µg/L (41).

Efforts have been made to use algorithms to improve the sensitivity of PSA testing, and to improve discrimination between prostate cancer and BPH, to define the aggressiveness of the malignancy and to establish whether a prostate cancer has extended beyond the capsule. Many of the equations include PSA, staging, histology and other nonlaboratory parameters. One proposed equation employs age and PSA, prostatic-acid phosphatase (PAP), and creatine phosphokinase (CPK) isoenzymes. With this equation, the sensitivity was 85.3% in Stage T2 cancers and 66.12% in BPH. It is claimed that the algorithm can double or triple the sensitivity of serum PSA. Seventeen of 28 patients (61%) with early stage cancer and 93 of 94 (99%) of men with more advanced cancer was identified. It should be emphasized that the computer program for these algorithms is proprietary. The important point is that neither CPK isoenzymes, total CPK, or PAP alone are useful markers in detecting prostate cancer (42).

Acid Phosphatase

Acid phosphatase is one of the oldest cancer markers and has been used for more than 50 years in monitoring patients with prostate cancer. Elevations are seen in about 80% of men with bone metastases but in 20% or less of men with localized cancer. In a study of 80 patients with stage D prostate cancer, abnormal levels of PSA were seen in 76% of the men compared to elevations of prostatic acid phosphatase in 49%. The conclusion of the authors is that PSA is more sensitive and more useful than acid phosphatase and will be elevated in patients with smaller tumors (43). In our experience, there is a small subset of patients who do not show clinically related PSA levels who have acid phosphatase levels that reflect the clinical course. We continue to offer PAP assay.

Human Kallikrein-2 (hK2)

PSA is a kallikrein (hK-1). Another form hK-2 also is elevated in prostate cancer. Both are serine proteases, but have different biochemical and catalytic properties. In a study of 324 men, 159 of whom had prostate cancer, mean hK-2 levels and the ratio of hK-2 to free PSA were significantly higher than in serum from control subjects. The conclusion was that in men with elevated PSA, those with high hK-2 have a 5- to 8-fold increase in risk for prostate cancer. hk-2 may be a useful adjunct to PSA in selective patients with elevated PSA who require a biopsy (44).

Breast Antigen (CA15-3, BR27.29)

Circulating breast cancer antigens are used in monitoring therapy and recurrence. These antigens are all high-molecular-weight glycoproteins (mucins) coded by the MUC-II gene and expressed on the ductal cell surface of most glandular epithelia. Although many of these markers have been studied in the United States, only two (CA15-3 and BR27.29) are approved by the FDA and only for monitoring. The antibody configurations in the assays are slightly different, and different numerical results may be obtained. Elevations are directly related to stage. In one study of CA15-3, 9% of women with stage I disease and 19% of those with stage II disease had elevations in serum marker concentrations, as compared to 38% in women with stage III cancer and 75% with stage IV. Similar distributions were observed with BR27.29 assay. The detection rate in early-stage disease may be improved with automated methods, which are more precise at low concentrations. The major application of the markers is in monitoring disease progression and response to therapy. The efficiency for identifying progression during therapy was >90% with a lead time of 35 days, and about 85% during follow-up, with a lead time of 75 days. In a study of BR27.29, all patients who experienced a regression of disease had a falling breast cancer antigen value, those with stable disease had values that did not change, and 94% of women with progressive disease showed an increase (45, 46). In a summary of the literature, it was found that of 1,672 patients with breast cancer, there were 352 who

had recurrences. Of these, 235 (67%) had elevations in the breast antigen before or at the time of recurrence. In 1,320 patients without recurrence, 92% had normal values. The mean lead-time from marker elevation to clinical diagnosis of relapse ranged from 2 to 90 months (47).

The ASCO panel, which made CEA recommendations, also reviewed breast cancer markers. The panel recommended hormone receptor assays be used in management, but concluded that present data are insufficient to recommend CA15-3 or BR27.29 for screening, diagnosis, staging, or surveillance following primary treatment. An increasing CA15-3 or BR27.29 level can detect recurrence following primary treatment, but the clinical benefit is not established. Present data are insufficient to recommend routine use of CA15-3 or BR27.29 alone for monitoring response to treatment, but in the absence of readily measurable disease, a rising CA15-3 or BR27.29 concentration may be used to suggest treatment failure (9).

The ASCO recommendations are based on the panel's view that insufficient clinical data are available to support use of serum markers as treatment indicators in breast cancer. One study contradicts the opinion and demonstrates the effectiveness of serum CEA and CA15-3 in management of breast cancer. In a series of lymph-node-positive, high-risk breast cancer patients who had a rise in either marker to the 97th percentile of normal, a rigorous conventional search for metastases was made. Women in whom metastases was not found were randomized to receive chemotherapy or no therapy. In the no-therapy group, the median time to metastases was 4 months, and the median survival 12 months. In the treatment group, the median time to metastases was 24 months and the median survival was 60 months (48).

These markers are not useful in screening because their presence in the serum is related to the extent of tumor burden and the stage of the cancer nor are they useful prognostic markers. However, tissue analysis of markers in primary surgical specimens can provide useful information and practical information concerning prognosis-total survival, disease-free survival, and risk of recurrence. In addition to the well-established estrogen and progesterone receptor assays, these tests include Cathepsin D, HER-2/neu oncogenes, epidermal growth factor and urokinase-type plasminogen activator antigens. With these markers, it may be possible on the day of biopsy or surgery to identify the subset of women with negative lymph nodes and small tumors who will have an early recurrence of cancer (49, 50 and 51).

HER-2/neu

More than a decade ago, the neu oncogene found in rats was reported to encode an epidermal growth factor receptor-related protein with a molecular weight of 185Kd (p185) (52). The human homologue of the rat neu oncogene has been referred to as C-erb-B-2 or HER-2/neu. It is closely related to the epidermal growth factor receptor (C-erb-1). The HER-2/neu gene is amplified in a variety of epithelial-cell tumors. Most attention has been paid to this amplification in breast cancer and the increases in the protein product. Immunohistochemistry studies have shown that normal epithelial cells have approximately 100,000 molecules of p185 per cell whereas in human epithelial tumors, such as breast cancer, the number of molecules may be elevated as much as 30- to 45-fold. The HER-2/neu protein is composed of the cytoplasmic domain, the transmembrane domain, and the extracellular domain. The C-terminal or cytoplasmic end of the molecule is a region containing 580 amino acids and demonstrates tyrosine kinase activity. The extracellular portion of the molecule is heavily glycosylated and constitutes the ligand-binding domain. It is shed from the cell surface by proteolytic cleavage and released into culture supernatants as well as into the circulation of both normal individuals and patients with cancers of epithelial origin. The intact native molecule found in epithelial cells has been widely reported to be an 185Kd protein. Reports now have confirmed the original report in 1989 that the extracellular domain of HER-2/neu is approximately 105Kd with a range from 97-115Kd. Breast cancer patients with HER-2/neu positive tumors (identified by immunohistochemistry) in their primary tumors have been shown to have a poor prognosis with shorter disease-free and overall survival than patients who do not express HER-2/neu. Many reports suggest that patients with HER-2/neu-positive primary tumors should be monitored for elevated serum HER-2/neu levels as a means of detecting early recurrence. In addition elevated levels of serum HER-2/neu correlate with the presence of metastatic disease and poor prognosis and may be valuable in predicting response to various forms of therapy. Combining HER-2/neu serum measurements with other tumor markers (CEA and/or CA15-3) may improve the sensitivity of detection of recurrence (53, 54 and 55).

In our studies of serum HER-2/neu, the specificity in normal women was 100% and those with benign disease 95%. In women with breast cancer, the sensitivity was 1.7% in stage I disease, 3.0% in stage II disease and 35.5% in stage V. There were 56 elevations in 285 women with breast cancer (19.7%). HER-2/neu was monitored over time in patients with metastatic breast cancer who were receiving therapy. All patients had a pretherapy serum specimen and four post-therapy specimens. The tissue HER-2/neu and hormone receptor status was known for all patients. The tissue HER-2/neu was positive in seven patients, of whom five received Herceptin (Genentech, Inc., San Francisco, California) and Taxol (Bristol-Myers Squibb). One patient received only Taxol and one only Adriamycin (Pharmacia Inc., Kalamazoo, Michigan). In six of these seven patients, the pretherapy HER-2/neu was elevated. In five of these patients, there was a rapid fall in HER-2/neu following therapy and lower levels of HER-2/neu were reflective of a response to therapy. There did not seem to be a relationship between serum HER-2/neu levels and hormone-receptor status. A combination of serum HER-2/neu, CA15-3 and CEA allowed a more precise evaluation of response to therapy. The one patient in whom the pretherapy HER-2/neu was not elevated had bone metastases and initially progressive disease. After receiving Herceptin and Taxol, the HER-2/neu remained within normal limits. The patient remained stable for several months and then experienced a recurrence and the therapy was changed to Adriamycin. The HER-2/neu remained in the normal range of five separate occasions between November 1998 and June 1999, but the CA15-3, which remained at about 45 U/mL until the clinical progression, then rose to more than 100 U/mL. The serum CEA also was within normal limits for the entire study. None of these patients

were studied sufficiently long to see if serum HER-2/neu would reflect escape from therapy and a recurrence.

In four patients, tissue HER-2/neu was negative. Only one of these patients received Herceptin and Taxol. One other patient received Taxol alone, one adriamycin, one Tamoxifin, and one a combination of cytoxan and adriamycin. In none of these patients was the preoperative HER-2/neu level elevated, nor did the marker reflect the clinical course of the patient. Of considerable interest is that in two of these patients, CEA was much more indicative of the course of the patient than either HER-2/neu or CA15-3.

There are many other studies related to the prognostic significance of tissue HER-2/neu and possible role of serum HER-2/neu. Numerous workers have shown that the expression of tissue HER-2/neu is related to poor prognosis and predicts the subset of women who will respond to Herceptin therapy. CA15-3, CEA, and HER-2/neu were compared in 200 patients with primary breast cancer who were followed up to 2.5 years. At recurrence, 32.6% of the patients had an elevation of HER-2/neu. This was the first marker elevated in 18.6 of the women whereas CA15-3 was the first indicator in 18% and CEA in 20%. Elevations were seen in 8 of 10 women who expressed HER-2/neu, but in only 1 of 30 women who did not express the oncogene in their tissue. In another study, serum HER-2/neu was measured in 50 controls, 112 patients with benign breast disease and 45 patients with no evidence of breast cancer after therapy. None of these women had elevations. Elevations were seen in 38.5% of patients with liver cirrhosis and in 26.5 of patients with primary liver cancer as well as in 7% of women with local-regional breast cancer and 41.5% of women with metastatic breast cancer. Elevations also were seen in 6 of 28 women with ovarian cancer, 3 of 14 of those with colorectal cancer. Elevations also were seen in 11.5% of patients with localized lung cancer and 16% of those with metastatic disease. Elevations were seen in 22% of men with prostate cancer and 11% of gastric cancer patients. These studies suggest the use of HER-2/neu in other cancers as well as breast cancer and the possible interference in both noncancer- and cancer-related liver disease (56).

In 35 patients receiving fractionated paclitaxel therapy, 10 had HER-2/neu levels above 15 ng/mL (the positive/negative cutoff) (54). The overall therapy-induced remission rate was 36%, but 62% in the women with normal HER-2/neu levels. Sequential changes of the serum HER-2/neu were similar to those of the breast antigen CA27.29, but the HER-2/neu seemed to be more sensitive and reflective of clinical changes. Serum HER-2/neu was measured in 300 patients with metastatic breast cancer who received aromatase inhibitors during therapy. Fifty-eight of these women had elevated serum HER-2/neu values. The clinical response rate was 40.9% in the 242 patients who had “normal” concentrations of HER-2/neu and only 20.7% in the 58 women with elevations. In a retrospective study of 200 women who had received tamoxifen, there was no statistical relationship between HER-2/neu levels and clinical response. Pretherapy HER-2/neu levels did not predict response rates to chemotherapy. Elevations were observed in 10 of 22 women with metastatic breast cancer, but the levels neither predicted response nor reflected therapeutic response (57, 58).

In a study of 42 women with primary breast cancer and 62 patients with stage IV breast cancer, elevated values of serum HER-2/neu were seen in six of the 42 primary cancer patients (14.2%) but in 92.8% of the women who expressed HER-2/neu in their tissues and in 8.2% of women who did not express the oncogene. Serum concentrations were correlated to tumor size and node involvement. In the women with stage IV disease, 27 of 62 (45.5%) had elevations. There was a correlation with CA15-3 as well as to hormone receptor status. Elevations of serum HER-2/neu were found in 32 of 94 patients (34%) with metastatic breast cancer. Low values were a powerful indicator of response to antiestrogen therapy. Three of 32 women with elevated levels responded to therapy compared to 35 of 62 with nonelevated values. In women with elevated values, there was a shorter time to progression. Regardless of other predictive factors, elevated HER-2/neu levels indicated a lack of response to hormonal therapy. Serum HER-2/neu levels before chemotherapy were found to correlate with the number of positive nodes, but there was no correlation to age, receptor, or disease status. After nodal status, the most significant variable in predicting disease-free survival was a low level of HER-2/neu (57, 58).

Cathepsin D

Cathepsin D is measured in tissue but although reported present in serum, assays in serum have not been found to be clinically useful. Breast tissue cathepsin D may be an important prognostic indicator of recurrence, disease-free, and overall survival. However, there is controversy over its use for this purpose and the conflicting reports may be a result of methodology differences. Assays have been developed for a variety of different portions of the protein molecule (50).

Total cathepsin D was studied in 738 primary tumors. High levels were associated with peritumoral vascular invasion, high-grade infiltrating duct cancers, tumors >2 cm in size, and metastases in auxiliary lymph nodes. There was low activity in *in-situ* carcinomas and there was no correlation to menopausal or hormone receptor status. With the same method, but with a cut-off of 60 pmol/mg cytosol protein, an additive prognostic value for cathepsin D with c-erb-B-2 and C-myc oncogenes were observed. There was no correlation to node invasiveness, hormone receptor, tumor grades, or the menopausal status of the patients. In a study of 267 patients, a cut-off of 31 ng/mL cytosol protein was used and it was concluded that cathepsin D is the best prognostic marker for predicting disease-free survival in women with breast cancer and that pS2 is the best marker for predicting overall survival.

Multivariate analysis was used in a study of 710 primary breast cancers. The cathepsin D values ranged from 2.8 to 531 pmol/mg cytosol protein with a mean value of 59 ± 40 pmol/mg. Cathepsin D correlated with hormone receptors and weakly to pS2. There was no relationship to age, menopausal status, tumor size, or differentiation. Higher concentrations of cathepsin D were observed in tissue from lymph-node-positive patients. There was a positive correlation with relapse-free survival ($p = 0.001$) but not with overall survival. In 155 women with cathepsin D values <30 pmol/mg cytosol protein, the survival was 63 ± 5 months; whereas in 189 women with values >70 pmol/mg cytosol protein,

it was 42 ± 4 months. Many workers agree that cathepsin D is a potentially important prognostic marker in breast cancer but its clinical application awaits clearer definition. High cytosolic cathepsin D concentrations are an indicator of poor prognosis in breast cancer. Cathepsin D concentrations are independent of other prognostic markers (59, 60 and 61).

In studies with a commercially available immunoradiometric kit for measurement of the cathepsin D, a cut-off was established at 40 nmol/mg cytosol protein in primary breast cancer tissue. The median follow-up was 48 months in women with low concentrations of cathepsin D and 45 months in women with high concentrations. Patients with high concentrations had significantly shorter disease-free interval ($P<0.05$) and overall survival ($P<0.01$). Women with high concentrations of cathepsin D and low concentrations of estrogen receptor protein had highly significant shorter disease-free intervals ($P<0.01$). Women with high concentrations of cathepsin D and low concentrations of estrogen receptor protein had highly significant shorter disease-free intervals ($P<0.001$) and overall survival ($P<0.001$) when compared to women with high concentrations of estrogen receptor protein but low enzyme concentrations.

Cathepsin B

Serum and urine cathepsin B were reported to be significantly higher in patients with distant metastases from a variety of cancers than in control noncancer patients or cancer patients without distant metastases. Successful treatment resulted in a fall in the cathepsin B to control values. In lung cancer, the expression of tissue cathepsin B was an independent factor associated with death from the disease. Survival rate was significantly poorer in these individuals. In another study in 65 normal/malignant matched lung tissue samples, the cancerous tissue had 4.6 times the cathepsin B concentration. There was no correlation to cell type, tumor stage, or cell differentiation. Increased activity was related to shorter survival. In colon-rectal cancer tissue, cathepsin B was 1.4 times higher in activity than in normal mucosa, but elevations in cancer tissue only were observed in patients with early stage disease. There was no correlation with clinical or pathology prognostic indicators. With a monospecific polyclonal antibody raised against human liver cathepsin B, it was observed that there is a significant correlation to survival in patients with advanced colon cancer, who demonstrated a low immunohistochemical expression of the enzyme. In 41 patients with advanced cancer, 21 exhibited a high expression, 17 exhibited a low expression, and three were negative. In 28 patients with early stage disease, six were negative and 17 demonstrated a low immunohistochemical expression of the enzyme. In 41 patients with advanced cancer, 21 exhibited a high expression, 17 exhibited a low expression, and three were negative. In 28 patients with early stage disease, six were negative, 17 had normal tissues, and 17 from those benign adenomas were negative (50).

Urokinase Plasminogen Activator (uPA) and Plasminogen Activator Inhibitor

uPA activator is a serine protease involved in cancer invasion and metastases. It is an independent prognostic factor in breast cancer and when observed in high concentrations in breast tissue, is an indicator of shortened disease-free survival and overall survival (49).

Enzymes as Tumor Markers

Many of the markers already discussed are enzymes (acid phophatase, prostate specific antigen, human kallikrein, urokinase plasminogen activator, cathepsin D and B). However, many other enzymes are valid markers, some of which have been used for decades and are still of clinical relevance.

Alkaline Phosphatase (ALP)

Serum alkaline phosphatase (43) is elevated in patients with primary bone cancer as well as in individuals with cancer metastatic to bone. Elevations are greater in persons with osteoblastic bone lesions than in patients with osteolytic disease. In osteoblastic disease, serum levels can be as much as 40-fold the upper reference level. Because the majority of metastatic bone lesions in breast cancer are osteolytic and in prostate cancer osteoblastic, elevations of ALP in prostate cancer usually are much higher than in breast cancer. Serum levels reflect regression and progression, but there may be a paradoxical rise in ALP during the early phase of disease regression, presumably reflecting an attempt to repair the damaged bone.

Alkaline phosphatase exists in forms that are organ related; primarily intentine, bone, liver, and placenta. These can be differentiated by specific inhibitors, differences in electrophoretic mobility, heat denaturation, and immunochemical techniques. In establishing whether an elevated ALP is related to bone, liver, or both, traditional isoenzyme measurements have not been too useful when there is minimal involvement of either bone or liver. This is primarily because of similarity and overlap between the bone- and liver-derived enzymes, which are in fact differently glycosylated forms of the same protein. However, it has been demonstrated that wheat-germ lectin preferentially reacts with the bone enzyme and permits excellent differentiation and quantitation of bone and liver alkaline phosphatases. More recently, monoclonal antibodies that can discriminate between the isoforms have been introduced.

The bone alkaline phosphatase measured immunochemically has been successfully used to monitor metastases to bone and differentiate bone verses liver-elevated serum alkaline phosphatase levels.

Lactate Dehydrogenase (LDH)

The role of LDH (62) in algorithms already has been discussed. Serum levels of total LDH have been found useful in hematologic cancers. Patients with lymphoma have been stratified based on LDH levels and remission rates are related to this level.

Neuron-Specific Enolase

Neuron-specific enolase (63) is the γγ isoenzyme of the glycolytic enzyme enolase. Enolase exists as three dimeric subunits γ, β, α, which give rise to five isoenzymes: αα, ββ, γγ, αβ, and αγ. The

γγ isomer (NSE) is the predominant form in brain. In serum, it is a specific marker for the family or neuroendocrine tumors referred to as the amine precursor uptake decarboxylase (APUD) tumors. These include neuroblastoma, medullary carcinoma of the thyroid, and small-cell carcinoma of the lung (SCCL). Elevations initially were observed in 90% of patients with neuroblastoma, primarily those with extensive disease, and in 70% of patients with SCCL. Ninety percent of individuals with extensive SCCL have NSE elevations compared with only 40% of patients with limited disease. In another study, elevations were not found in normal persons or in patients with non-small-cell lung cancer, but in 72% of patients with SCCL before treatment — 90% of patients with extensive disease, and 65% of those with limited disease. In a survey of the literature, elevations were reported in 103 of 169 (61%) patients with limited-stage disease and in 204 of 231 (88%) of those with extensive-stage disease. The authors of these various studies used cutoff values ranging from 7.5 µg/L to 20 µg/L. Neuron-specific enolase is useful in monitoring patients. Falls reflect response to successful therapy and subsequent elevations reflect an exacerbation. Longitudinal studies in 23 patients receiving chemotherapy indicated an excellent correlation between disease state and enzyme concentration. In 25 of 29 patients, regression was accompanied by elevations of NSE activity.

CONCLUSION

Part of "26 - Tumor Markers"

Circulating and tissue-tumor markers have been proposed as clinically useful in screening, diagnosis, prediction of prognosis, and patient management. In screening, the marker should merely answer the question as to whether a cancer is present or not. The use of markers in diagnosis should aid in confirmation of the cancer and also provide information on how severe or extensive the malignancy is (staging). In prognosis, the marker should assist in predicting the aggressiveness of the tumor. The most significant and accepted use of markers is in assistance in the therapeutic management of the cancer patient. In this case, there are two questions the marker can help to answer: (i), what is the prognosis before therapeutic intervention; and (ii), what is the probability of success of specific therapy.

Marker levels may suggest a need for a change in therapy or for additional therapy and provide lead-time for initiation of new or more aggressive therapy. They also may provide assistance in early assessment of clinical trials. It must be emphasized that markers may not be elevated in some patients with extensive and progressive tumors. The important point is that a positive marker may be very meaningful from a clinical point of view, but a negative marker should never create a false sense of security that tumor is not present or is not progressing. Another problem in the use of tumor markers in the United States is FDA approval. Non-FDA–approved diagnostic tests usually are not reimbursable by third-party payers.

Although tumor markers can provide information on regression or progression of disease, the question arises whether the costs of the assay, and more importantly, the cost of other diagnostic procedures triggered by positive marker results, are justifiable in the treatment of ultimately incurable disease and what level of intervention is acceptable among false positives. The acceptance or rejection of these costs is related to the individual's definition of cost effectiveness. Is cost effective the expenditure of whatever is necessary to achieve the best possible result for the patient, or is it taking the most economical course consistent with good medical practice? The nihilist will say that marker assays are not useful or necessary until absolute therapy is available. I contend that markers provide clinically useful information and whenever there is even the remotest possibility of altering the clinical course in a positive way, they should be included in the treatment plan (64).

Section Chief

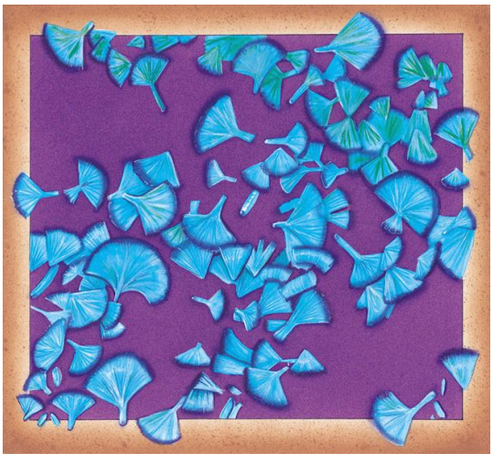

Figure.

27. Synovial, Pleural, and Peritoneal Fluids

28. Urine

Medical microscopy can be defined as the discipline of clinical laboratory medicines that deals with the examination of body fluids other than blood, using macroscopic, physiochemical, and microscopic techniques. The term “microscopy” therefore is a misnomer, because the modern clinical laboratory performs many other important nonmicroscopic examinations on specimens. However, the old terminology has remained and serves a purpose in distinguishing analyses performed on body fluids from those performed on blood.

Urine is the most frequently examined body fluid, but other fluids such as joint, pleural, peritoneal, cerebrospinal, amniotic, seminal, and ocular also receive a fair degree of attention, especially in larger laboratories. Most often, when examination of a particular fluid includes microbiological examination with culture or requires cytologic appraisal, all or a portion of the fluid sample is sent to the appropriate laboratory for that specific analysis.

The urine reagent strip, a 20th century invention, has all but replaced complicated individual chemical analyses for the determination of the presence of various bodily products in urine. Estimations of glucose albumin, hemoglobin, and bile levels, for example, as well as the determination of physical properties such as pH and osmolality, all can be accomplished using a dipstick methodology. Advances in the analysis of urine are constantly being achieved, especially in the area of immunodiagnostic testing. Abnormal products of body metabolism may be expected to be found in the various fluids of the body, and fluid, especially urine, is more easily obtained than tissue. Medical microscopy and the physiochemical examination of body fluids therefore will continue to be an important source for obtaining information to assist in diagnosis and patient care.

Synovial, Pleural, and Peritoneal Fluids

Jonathan L. Curry

Hesham M. Amin

Karl S. Theil

The synovial cavity is a space between diarthrodial joints, containing fluid formed by the synovial membrane. The synovial membrane covers the surface of the joint space except the contact surfaces of articular cartilage and menisci. This membrane is composed of a fibrillar interstitial matrix of collagen and glycosaminoglycans containing loosely interdigitating synovial cells, one to three cell layers thick (1). Unlike usual epithelial cells, synovial cells do not have desmosomal junctions, and there is no basement membrane between the synovial lining and subsynovial tissue. Nerves, lymphatics, and capillaries with fenestrated endothelial cells also are located in synovial tissue (Fig. 27.1).

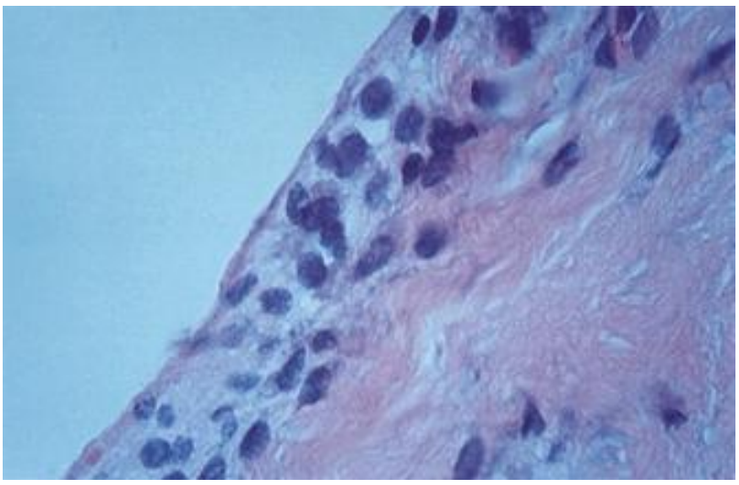

FIGURE 27.1. Synovial membrane from a normal knee joint shows joint space, synovial membrane composed of synovial cells embedded in a loose connective tissue stroma overlying dense collagen (hematoxylin and eosin).

Synovial fluid is colorless to light yellow and highly viscous. It acts as a lubricant and source of nutrients for articular cartilage in diarthrodial joints. It also is an ultrafiltrate of plasma, containing trace amounts of nonplasma proteins, lipids, hyaluronic acid, and high-molecular-weight proteins such as fibrinogen, $\alpha_2$macroglobulin, β_2-macroglobulin, and β_1-lipoprotein. Normal synovial fluid does not clot. The paucity of high-molecular-weight proteins in the ultrafiltrate may be related to endothelial permeability in synovial capillaries, charge interactions in the synovial matrix, and metabolism of proteins by synovial cells (2). Lubricin, a protein produced by synovial cells, appears to aid in lubricating cartilage-cartilage interaction (3). Hyaluronic acid, a high-molecular-weight glycosaminoglycan, is secreted by synovial cells and increases the viscosity of synovial fluid (4).

Synovial fluid analysis provides critical diagnostic information in the evaluation of patients with joint disease. There are several causes of arthritis that can be categorized broadly into infectious, crystal-induced, inflammatory, noninflammatory, and hemorrhagic. Synovial fluid analysis allows for distinction between the types of arthritis, narrowing the differential diagnosis and allowing early initiation of treatment.

Synovial fluid analysis may include macroscopic, microscopic, microbiologic, and chemical assessment. Fluid volume, color, clarity, and viscosity are observed. Total red blood cell count (RBC) and total white blood cell count (WBC) with differential are obtained. A wet preparation is viewed using compensated polarized microscopy to search for crystals or other abnormalities. Microbiological studies include Gram strain and culture. The value of additional studies, such as glucose, protein, and lactate dehydrogenase, is less certain (5).

Disease States Associated with Significant Changes in Synovial Fluid

Trauma

Acute trauma to a joint may result from a variety of causes. Hemorrhage is the most frequent consequence of trauma. Acute hemorrhage is characterized by frank blood. Evidence of previous bleeding may be inferred by finding hemosiderin-laden macrophages or erythrophagocytosis.

Septic Arthritis

Bacterial infections are the most common cause of septic arthritis. Early diagnosis of septic arthritis is important to prevent rapid destruction of the joint by proteolytic enzymes released from neutrophils. Bacteria most frequently reach the joint space by hematogenous spread across the synovial membrane. The synovial membrane is quite vascular and lacks a basement membrane and intercellular bridges; these features facilitate the spread of bacteria into the joint. Direct inoculation through trauma, contiguous wound extension, arthroscopy, or surgery is a less frequent mechanism for septic arthritis. All bacteremic patients are at risk to develop septic arthritis; however, most patients with bacteremia do not develop septic arthritis. Host interactions with the infecting organism modify the likelihood of developing a septic joint: immunologic defects, impaired defense mechanisms, trauma, and joint damage from surgery or chronic inflammation all increase the risk (6).

Neisseria gonorrhoeae is the most common cause of septic arthritis in young adults, especially in women. Gonococcal arthritis may be mimicked by disseminated meningococcal infections, so culture identification of the organism is critical. Nongonococcal septic arthritis in adults is most often a result of *Staphylococcus aureus*, followed by group A *Streptococcus* species, Gram-negative bacilli (*Escherichia coli, Salmonella* species, *Pseudomonas aeruginosa*), *Streptococcus pneumoniae*, and *Staphylococcus epidermidis*. The Gram-negative bacilli tend to occur in patients

with impaired resistance to infection, intravenous drug abuse, or underlying infections of the urinary, biliary, or intestinal tracts (7). *Haemophilus influenzae* and *Streptococcus pyogenes* are the most frequent isolates in neonates and children, respectively (7).

A variety of other organisms also can cause septic arthritis and may not be detected unless special cultures are initiated (8). Tuberculous arthritis may be the result of underlying osteomyelitis. The most common organism is Mycobacterium tuberculosis. Culture of a synovial biopsy specimen may be necessary to establish a diagnosis. Fungal arthritis may be a result of any of the deep-tissue, invasive fungi, including histoplasmosis, *Candida* species, coccidiodomycosis, blastomycosis, aspergillosis, and sporotrichosis. Actinomycosis and nocardiosis also are causes of septic arthritis. *Mycoplasma pneumoniae* has been isolated from the synovial fluid of patients with atypical pneumonia on rare occasions (9).

Viral arthritis can develop as a primary manifestation of the virus itself or as a complication related to immune-complex deposition. Viral causes of arthritis include coxsackieviruses, hepatitis B virus, lymphocytic choriomeningitis virus, mumps, parvovirus (10), rubella, and varicella (7). Diagnosis is established through serology rather than culture of synovial fluid. Although there is no evidence that human immunodeficiency virus (HIV) causes an arthritic process directly, HIV has been isolated from synovial fluid (11, 12). HIV antigen p24 has been demonstrated in synovial fluid when peripheral blood was negative for the antigen (13).

Crystal-Induced Arthritis

Monosodium urate (MSU) and calcium pyrophosphate dihydrate (CPPD) are the two most common crystals encountered in synovial fluid, and are associated with disorders termed gout and CPPD deposition disease, respectively. While joint manifestations of both disorders may be clinically indistinguishable, treatment is different. Other crystals, including calcium hydroxyapatite and calcium oxalate, usually are associated with osteoarthritis.

Gout is a multisystem disorder characterized by hyperuricemia (14). The clinical spectrum of hyperuricemia varies from asymptomatic to fullblown gout with arthritis; crystalline deposits of MSU (tophi) in and around joints, soft tissues, and renal interstitium; and nephrolithiasis. Gout is primarily a male disease, with the highest incidence in the fifth decade. Gouty arthritis usually is monoarticular at first, exquisitely painful, and characterized by granulomas containing MSU crystals within neutrophils or macrophages. Joints of the lower extremity (instep, ankle, heel, knee) are most commonly involved; wrists, fingers, and elbows also may be affected. The diagnosis of gouty arthritis is established by demonstrating MSU crystals in synovial fluid by compensated polarized microscopy. Over 95% of patients with acute gout have demonstrable crystals. Treatment is directed toward relieving the acute attack with antiinflammatory agents in the short term and lowering serum uric acid in the long term. MSU crystals can persist in synovial fluid for months in patients following treatment, even when the WBC is only slightly elevated (15).

CPPD deposition disease is most common in the elderly. The cause of crystal deposition is unknown but may be associated with age-related changes in cartilage, because many patients have preexisting joint damage. Clinical presentations vary from asymptomatic to subacute, acute, or chronic arthritis. The most common joint affected is the knee; the wrist, shoulder, elbow, ankle, and hand also may be involved. Acute attacks (pseudogout) may be precipitated by trauma, infection, joint surgery, or even walking (16). The definitive diagnosis of pseudogout is based on identification of characteristic CPPD crystals by compensated polarizing microscopy of synovial fluid. Nonsteroidal antiinflammatory drugs are the mainstay of treatment.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a multisystem disorder of unknown cause characterized by chronic synovial inflammation (17). Although the disease has a varied course from patient to patient, the potential for joint destruction and deformity is a major cause of morbidity. RA affects approximately 1% of the population, and women are three times more frequently affected than men. Most patients develop the disease between the ages of 35 and 50. Joints typically are affected in a symmetrical fashion, with the hands (especially proximal interphalangeal and metacarpophalangeal joints), wrists, knees, and feet most commonly involved. Signs and symptoms include joint pain aggravated by movement, and generalized stiffness greatest after periods of inactivity (“morning stiffness”).

Pathological examination of rheumatoid joints shows hypertrophy and hyperplasia of synovial fining cells, edema, vascular proliferation, and infiltration of synovium by macrophages and T lymphocytes. The release of immune mediators and chemotaxins in the synovium causes an acute inflammatory response in the synovial fluid. Proliferation of the inflammatory synovium gradually results in destruction of articular cartilage and limitation of movement as a result of pain. Clinical diagnostic criteria are well established (18).

Laboratory Evaluation

Specimen Collection

The techniques for physical examination and needle aspiration of joint fluid are outlined in textbooks of rheumatology and orthopaedics (19, 20 and 21). The sample should be collected in a sterile, plastic, disposable syringe using aseptic technique. Care should be taken to ensure that a sterile joint is not iatrogenically contaminated with bacteria from a local infection in adjacent soft tissue or from bacteremia (21). The syringe may be moistened with sodium heparin (22) (25 U/mL synovial fluid). Lithium heparin, oxalate, and powdered ethylenediaminetetraacetic acid (EDTA) should be avoided because artifacts that confound crystal analysis may result (22, 23 and 24).

The specimen is dispensed into three sterile tubes: 5 to 10 mL in a heparinized tube for microbiological studies, 5 mL in a tube containing heparin or liquid EDTA for microscopic examination, and the remainder in a nonanticoagulated tube for other studies. If lesser amounts are obtained, fluid still may be examined. Only several drops are necessary for a wet mount, leukocyte count and differential, and bacteriologic studies (25). When selecting studies on limited amounts of fluid, examinations for crystals and for microorganisms (Gram stain and culture) should receive top priority (Table 27.1).

Gross Examination

Gross examination of joint fluid is the first step in establishing a differential diagnosis of arthritis. While a precise diagnosis rarely is made from gross examination alone, a careful look at the fluid can provide valuable clues to underlying pathology.

Volume

Normal joints contain very small amounts of fluid; the normal knee joint — the largest synovial joint — contains from a few drops to as much as 4 mL. There is sufficient fluid to coat synovial surfaces and little more, thus making it difficult to sample fluid from a normal joint. Increased amounts of fluid can be seen in conditions causing edema such as myxedema, congestive heart failure, or anasarca. High-dose corticosteroid therapy may be associated with transient, asymptomatic, noninflammatory effusions (26). Difficulty in obtaining fluid from an obvious effusion may occur because of rice bodies, thick fibrin exudates, or loculations that prevent aspiration.

Viscosity

Normal joint fluid is viscous because of a high concentration of hyaluronate. An estimate of viscosity can be made by watching the fluid “string” as it is expressed from a syringe, or by suspending a drop between a glass slide and the tip of a glass rod. Normal fluid will stretch to a string of 1 to 2 inches in length, having a viscosity like egg white (Fig. 27.2). A watery consistency indicates low viscosity, and usually is associated with inflammation. Enzymes released by inflammatory cells, primarily neutrophils, degrade hyaluronate, and visibly reduce the joint fluid viscosity. Low viscosity often is caused by inflammation; however, edema or a sudden effusion after trauma can decrease viscosity by dilution in the absence of inflammation. Very viscous fluids can be seen in hypothyroidism and in fluid aspirated from ganglia. More precise quantification of viscosity generally is not necessary.

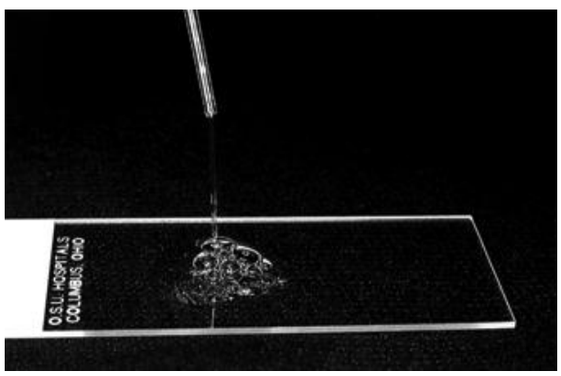

FIGURE 27.2. The viscosity of synovial fluid is demonstrated by the “string test” — the normally viscous synovial fluid forms a thin strand between the pipette tip and the surface of the slide.

The mucin clot test is a qualitative test used to estimate the degree of polymerization of hyaluronic acid. Both protein and hyaluronate are required for a mucin clot to form (27). The supernatant from a centrifuged specimen is transferred to a clean glass tube. A few drops of glacial acetic acid are layered gently on the surface of the fluid. As the acid settles to the bottom of the tube, a dense white precipitate (clot) of protein hyaluronate forms. The quality of the clot is graded as “good,” “fair,” or “poor.” A “good” clot will remain intact even when the tube is shaken; a “poor” clot resembles a few formed shreds in a turbid solution (Fig. 27.3). An alternate method is to prepare a 1:4 solution of joint fluid and 2% acetic acid. The solution is mixed and examined for the presence of a mucin clot. The quality of the clot is graded as just described. The cause of poor mucin clot formation is uncertain. The quality of the mucin clot is not solely

related to the fluid leukocyte count and the percentage of neutrophils; abnormal synovial cell metabolism resulting in production of altered forms of hyaluronate also may be a factor (28).

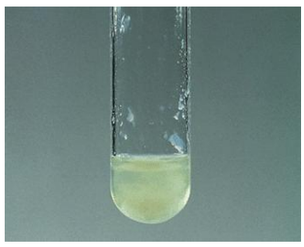

FIGURE 27.3. Poor mucin clot formation is marked by friable, poorly formed shreds.

Synovial fluid is metachromatic if stained with 0.2% aqueous toluidine blue. This feature can help identify synovial fluid if there is doubt whether the joint or soft tissue has been aspirated (dry tap). To perform the metachromatic stain test, spot a filter paper with a drop of fluid. Use a drop of normal saline as a control. After drying, add a few drops of toluidine blue. A positive reaction is marked by a color change to purple when the control spot remains blue (Fig. 27.4). This procedure may be misleading if the fluid has come in contact with heparin, because heparin also is metachromatic with toluidine blue (24).

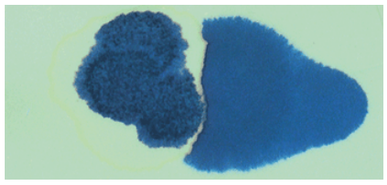

FIGURE 27.4. Metachromatic stain test illustrates metachromasia of normal synovial fluid. Toluidine blue stained synovial fluid (left) is purple. Compare with toluidine blue alone (right).

Clot Formation

Normal joint fluid does not clot because it lacks high-molecular-weight coagulation proteins, including fibrinogen, prothrombin, factors V and VII, antithrombin, and tissue thromboplastin (29). The absence of a clot can help distinguish a truly bloody effusion from a traumatic aspiration or inflammatory effusion.

Clarity

Normal joint fluid is transparent. Because erythrocytes and leukocytes may settle out in the collection tube after aspiration, it is important to ensure that the fluid is well mixed before assessing clarity. If newsprint cannot be read easily through it, the fluid is designated cloudy or opaque. Cloudy fluids may reflect an increase in cellular or protein components, and usually are a result of inflammation. Rice bodies, products of degenerating, fibrin-infiltrated synovial membrane, may appear as flecks resembling polished white rice. Flecks of dark particles resembling ground pepper may be a clue to ochronosis (30). Black or gray pigmented debris from metal or plastic fragments after prosthetic surgery has been described (31). Cholesterol crystals can give an oily quality to the fluid.

Color

Normal synovial fluid is colorless to light yellow. Grossly bloody fluid can be seen in a variety of conditions listed in Table 27.2. Streaks of blood, or the appearance of blood at the beginning of aspiration that decreases as aspiration continues, suggests a traumatic tap. Examination of the supernatant of centrifuged fluid may help distinguish true hemorrhage from a traumatic tap: if the supernatant is xanthochromic, blood probably has been present for sometime. Comparison of the hematocrit of the fluid with the venous hematocrit can help resolve the question of whether venous blood (acute bleed) or a hemorrhagic effusion is present. Noninflammatory fluids generally are yellow or straw-colored. Massive numbers of crystals can make the fluid appear opalescent. Cream-colored to off-white fluids usually contain pus with or without crystals. Various bacterial pigments in septic arthritides may discolor fluid. Milky white or chylous effusions typically are related to chronic arthritis or lymphatic obstruction secondary to filariasis, but can be seen following trauma and pancreatitis (32, 33). The presence of free-floating fat droplets suggests trauma with or without fracture. Golden cloudy fluids may contain cholesterol crystals. A gray fluid has been attributed to a retained bullet fragment (34).

Cell Counting

In addition to the macroscopic examination, the leukocyte count is critically important in classifying joint fluids as noninflammatory, inflammatory, or septic. The total leukocyte count and percentage

of neutrophils are good discriminators between inflammatory and noninflammatory disease (5). Normal synovial fluids are paucicellular; most studies indicate that a WBC of less than 0.1 × 10^9/L (100/μL) is normal (35), with an upper limit of less than 0.2 × 10^9/L (200/μL) being generally accepted (Table 27.3) (24). RBCs are valuable in distinguishing frank blood from a hemorrhagic effusion.

TABLE 27.3. NORMAL JOINT FLUID WBC AND DIFFERENTIAL VALUES

Item	Mean	Range
WBC (× 10^9/liter)	0.063	0.013–0.180
Differential count (%)		
Neutrophils	7	0–25
Lymphocytes	24	0–78
Monocytes	48	0–71
Histiocytes	10	0–26
Synovial lining cells	4	0–12

From McCarty DJ. Synovial fluid. In: McCarty DJ, ed. *Arthritis and allied conditions: a textbook of rheumatology*. 11th ed. Philadelphia: Lea & Febiger, 1989: 70.

WBC, white blood cells.

The total cell count is obtained using a hemacytometer chamber viewed with a standard light or phase-contrast microscope. The count should be performed promptly to minimize the effects of cell clumping and cell death, which can decrease the total leukocyte and neutrophil counts within several hours (36). The presence of clots should be noted as a sign of spuriously low cell counts. The fluid should be well mixed to avoid cell sedimentation before counting. In contrast to other body fluids, normal saline (0.9 N) rather than acetic acid must be used as a diluent to avoid clogging of the pipette and consequent cell entrapment by a protein clot. Staining with 0.1% methylene blue dye aids in identifying leukocytes if a phase-contrast microscope is not available. Hypotonic saline (0.3 N) can be employed to lyse erythrocytes when performing a total leukocyte count. If the fluid is too viscous to permit dilution and cell counting, 0.05% hyaluronidase in phosphate buffer may be added as a diluent (24); however, leukocyte counts are said to be slightly higher in hyaluronidase-treated fluids (37).

In the absence of a hemacytometer chamber, counting leukocytes per highpower (400 x) microscopic field (HPF) can make a rough estimate of the leukocyte count in undiluted fluid. When a WBC of less than 2/HPF is noted, the chamber count frequently shows less than 1,000 cells/μL. In cases where the WBC is higher than 2/HPF, chamber counts should be done to ensure accuracy (38). Electronic counters have been used as a substitute for manual counts, but they are subject to counting errors if debris, lipid droplets, or proteinaceous material are mistaken for leukocytes (39).

Microscopic Examination

The microscopic examination includes analysis of a wet preparation, leukocyte differential count, cytologic evaluation using stained slides, and crystal examination using compensated polarized microscopy.

Wet Preparation

A wet preparation is made for immediate examination by placing a drop of fresh, well-mixed fluid onto the center of a clean glass slide. The drop of fluid is covered with a coverslip, the edges of which may be sealed with nail polish to prevent drying. Examine the center of the coverslipped area for white blood cells, red blood cells, crystals, and other materials. Be careful to avoid artifacts introduced during slide preparation, such as paper fibrils or drying artifacts near the nail polish seal. The wet preparation may reveal crystals that cannot otherwise be seen after routine fixation with alcohol and staining with Wright's stain. Examination of the sediment following centrifugation can help concentrate cellular material and crystals, especially in the clear fluids. Addition of a drop of synovial fluid to special slides coated with dry methylene blue and cresyl violet offers promise as a rapid supravital stain (40).

Light Microscopy

Air-dried Wright-stained cytocentrifuge preparations are used for cellular differential counts. In the absence of a cytocentrifuge, smears of the centrifuged sediment are acceptable, provided there is no delay in processing the sample and the smears are as thin as possible. Thick smears may have a bluish background from heparin or mucopolysaccharides in the fluid, which can prevent cytoplasmic spreading and make examination difficult (24).

Normal cellular elements found in synovial fluid (Table 27.3) include monocytes, lymphocytes, histiocytes, neutrophils, and synovial lining cells or synoviocytes (Fig. 27.5). The appearance of blood cells in Wright-stained preparations is identical to that of peripheral blood. The predominant cell type is a monocyte. Phagocytic vacuoles help identify histiocytes, but the distinction from monocytes is not always clear-cut. Occasional lymphocytes may show reactive changes, including larger nuclear size, nuclear indentations, and a small nucleolus, but the majority are small with round nuclei similar to those in peripheral blood. Synovial lining cells resemble mesothelial cells and do not have diagnostic significance. A few red blood cells are almost always present in joint effusions.

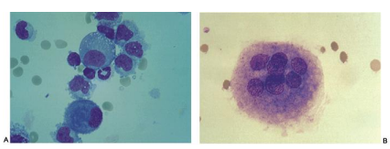

FIGURE 27.5. A: Normal cellular elements found in synovial fluid include neutrophils, lymphocytes, monocytes, histiocytes, and synovial lining cells. A few red blood cells are almost always present in joint effusions (Wright-Giemsa). **B:** Synovial lining cells may be multinucleate (Wright-Giemsa).

Abnormal cellular elements can suggest a specific diagnosis in some cases. *Erythrophagocytosis* by macrophages indicates previous hemorrhage (Fig. 27.6). *Hemosiderin* pigment and *hematoidin crystals* are breakdown products of hemoglobin, and are seen after hemorrhage. Hematoidin crystals are golden yellow, refractile, rhomboidal crystals that may be seen intracellularly or extracellularly. Cartilage cells, or their fragments, are not normally present in synovial fluid and are recognized as individual cells with deep purple cytoplasm and small nuclei surrounded by halos (Fig. 27.7). Cartilage may be seen following trauma or in osteoarthritis. Iron-laden chondrocytes can point to a diagnosis of hemochromatosis. Yellow chondrocytes are described in ochronosis (41). *Ragocytes* or *RA cells* are neutrophils containing refractile round cytoplasmic inclusions and are best seen in wet preparations using phase-contrast microscopy. These cells frequently are found in inflammatory effusions and are not diagnostic of a specific disorder. The inclusions represent phagocytosed immunoglobulin, immune complexes, DNA particles, rheumatoid factor, fibrin, and antinuclear factor (25). Lupus

erythematosus (LE) cells are neutrophils that contain a phagocytized homogenized nuclei (Fig. 27.8). While LE cells may be present in the synovial fluid of patients with systemic lupus erythematosus (SLE), even when peripheral blood LE preparations are negative (24), they are not diagnostic. LE cells also have been described in rheumatoid arthritis (42), and their absence does not exclude a diagnosis of SLE. LE cells should be distinguished from *tart cells*, which are neutrophils or macrophages containing a phagocytized nucleus that retains some chromatin detail (Fig. 27.9). Tart cells are a nonspecific finding without diagnostic significance. So-called *Reiter's cells* are macrophages containing one or more phagocytized neutrophils (Fig. 27.10). They are not diagnostic of Reiter's syndrome, and can be found in a variety of inflammatory effusions.

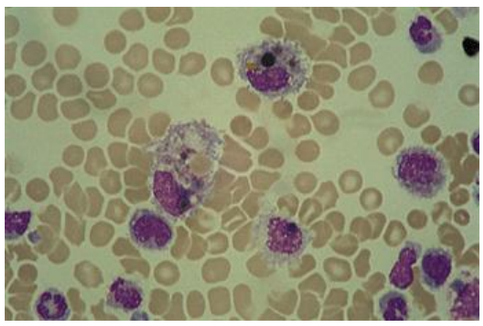

FIGURE 27.6. Indicators of previous hemorrhage in synovial fluid include erythrophagocytosis by a macrophage (center) and breakdown products of hemoglobin, including hemosiderin pigment (brown) and hematoidin crystal (yellow) in macrophage (top) (Wright-Giemsa).

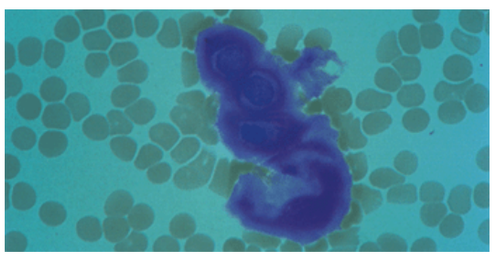

FIGURE 27.7. Cartilage is recognized by its deep purple cytoplasm and nucleus in a lacuna. Chrondrocytes also may be seen as single cells rather than the cluster shown here (Wright-Giemsa).

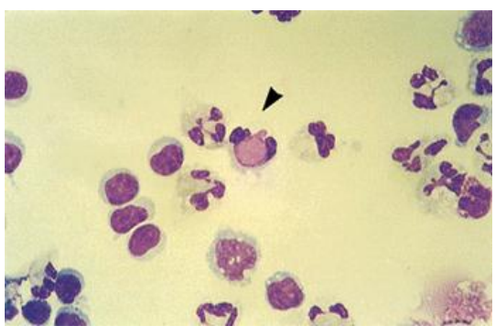

FIGURE 27.8. LE cell (arrow) is a neutrophil containing a phagocytized homogeneous nucleus (Wright-Giemsa).

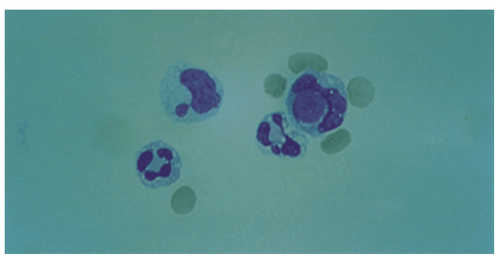

FIGURE 27.9. Tart cell is a macrophage containing a phagocytized nucleus that retains some nuclear detail (Wright-Giemsa).

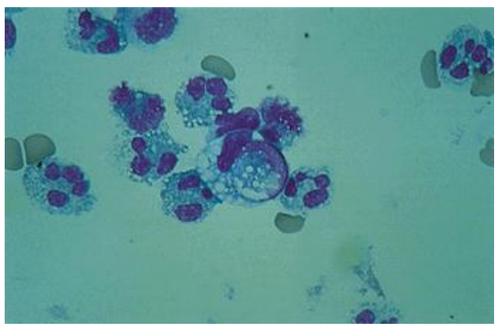

FIGURE 27.10. Rieter's cell (*center*) is a macrophage that has phagocytosed one or more neutrophils. This finding is not specific for Reiter's syndrome.

Lipid-laden macrophages (Fig. 27.11) may be seen in traumatic arthritis as a late finding (43), in chronic arthritis with chylous effusion, and in pancreatitis (33). The lipid in chronic arthritis probably originates from a breakdown of cells damaged by inflammation. Lipid may appear as extracellular or intracellular isotropic fat globules or as anisotropic lipid droplets that show “Maltese cross” birefringence under polarized light. Oil red O or Sudan black B fat stains may be used to identify lipid material.

Prominent intracellular and extracellular *lipid microspherules* or lipid liquid crystals may be observed under polarized microscopy as small Maltese crosses (44, 45). They are of uncertain origin and have been seen in pigmented villonodular synovitis (46) and chronic arthritis (47). The role of the microspherules in the pathogenesis of the arthritis remains to be determined.

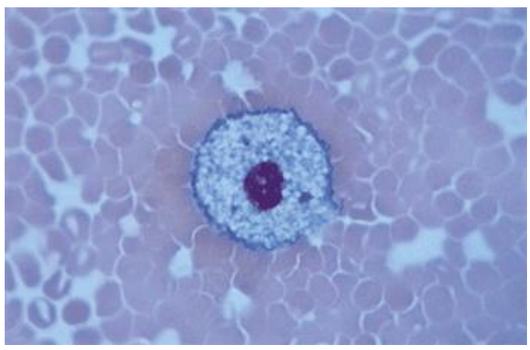

FIGURE 27.11. Lipid-laden macrophage in synovial fluid (Wright-Giemsa).

Eosinophils are not found in normal synovial fluid, and are uncommon in pathological fluids. Increased eosinophils (more than 2% of the leukocytes) are noted in a variety of disorders listed in Table 27.4 (48). *Charcot-Leyden crystals* are elongated, diamond-shaped crystals of lysolecithinase from eosinophils that stain pink or purple with Wright stain (Fig. 27.12). They have been noted in conditions associated with chronic eosinophilia, but their appearance in joint fluid is very rare. Charcot-Leyden crystals have been described in a patient with an allergic reaction following intraarticular injection of steroids (49) and also in a patient with chronic myelogenous leukemia (50). *Mast cells* (Fig. 27.13) have been identified in small numbers in synovial fluid, with variable quantities observed in patients with diverse disorders, including ankylosing spondylitis, Reiter's disease, psoriatic arthritis, and enteropathic arthritis (51). Mast cells have been observed in greatly increased numbers in patients with systemic mastocytosis (52).

Sickled erythrocytes may provide a clue to an underlying sickle disease, trait, combination SC or S-thalassemia (53, 54). The

presence of sickled cells does not necessarily indicate that the hemoglobinopathy is responsible for the joint pathology. *Platelets* may be found in synovial fluid of patients with osteoarthritis and rheumatoid arthritis (55, 56). Marrow spicules are a clue to fracture with involvement of joint (57).

Although they are rare, primary and metastatic malignancies can involve the joint space, and the malignant cells can be recognized on microscopic examination. *Non-Hodgkin's lymphoma* (58), *Hodgkin's lymphoma* (59), blast transformation of chronic myeloid leukemia (60, 61), *acute lymphocytic leukemia* (62, 63 and 64), adult T-cell leukemia (62), *acute myelomonocytic leukemia*(65), *chronic lymphocytic leukemia* (66, 67), metastatic squamous carcinoma (68, 69), and *adenocarcinoma* (70, 71) have been described.

Collagen can be seen to advantage by lowering the microscope condenser. Under polarized light, collagen is weakly birefringent. *Amyloid* appears as amorphous deposits that are green and weakly birefringent when stained with Congo red and viewed under polarized light. Identification of amyloid in synovial fluid correlates well with synovial biopsy findings, so biopsy may be avoided in patients with positive fluid findings (72, 73). Rarely, fragments from metal or polymer prostheses can be seen (31, 74).

Some medications and radiographic contrast media can affect the leukocyte differential count. One study found significantly lower numbers of lymphocytes in patients with rheumatoid arthritis treated with nonsteroidal antiinflammatory drugs (NSAIDs) plus methotrexate, gold, or hydroxychloroquine than in those receiving NSAIDs alone (75). Injection of ionic contrast media with epinephrine was associated with a leukocytosis, whereas no inflammatory changes were noted after injection of nonionic contrast media (76).

Polarized Microscopy

A polarizing light microscope is equipped with two polarizing filters that have fixed axis of light transmission: the polarizer is located over the light source, and the analyzer is between the stage and the observer's eye. For crystal analysis, a first-order red compensator is placed between the polarizer and the analyzer for compensated polarized microscopy. Phase-contrast optics may be added to improve the visibility of cytoplasmic granularity.

To view crystals in a wet preparation or stained smear, the polarizing filters should have their axes of transmission oriented perpendicular (90°) to each other so that light transmitted by the polarizer will not be transmitted by the analyzer. The background of the field is pitch black when the polarizer and analyzer are oriented at 90°. If a birefringent crystal is placed between the polarizer and analyzer, polarized light entering the crystal is refracted into two rays (perpendicular to each other), nonparallel to the plane of the entering light. Refracted light shifted to the plane of the analyzer passes through and the crystal appears as a white object on a dark background. Only birefringent materials behave this way in polarized light.

Birefringence is a property of materials that have two optical axes (biaxial). The optical axis of an object is the path through which light is transmitted unrefracted. Plane polarized light entering a birefringent object out of alignment with the optical axis is refracted into two rays. The one that deviates the greatest degree from the optical axis is designated the slow ray, whereas the fast ray deviates the smallest degree (Fig. 27.14). The exiting rays, by virtue of traveling at different velocities through the object, are out of phase with each other. The difference in the degree of refraction between the fast and slow ray, along with the thickness of the object, determines the strength of birefringence. Not all crystals are birefringent, and not all birefringent objects are crystals.

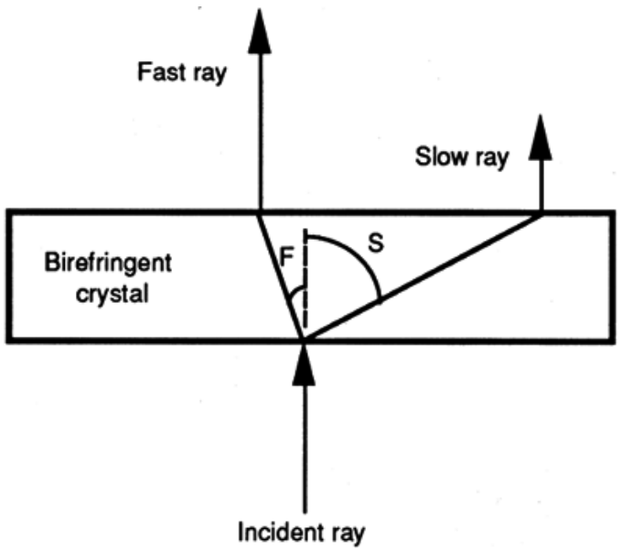

FIGURE 27.14. Light entering a birefringent crystal is refracted into fast and slow rays that are mutually perpendicular. The fast ray has the lesser degree of deviation from the optical axis of the crystal. (Modified from Gatter RA. Use of the compensated polarizing microscope. *Clin Rheum Dis* 1977;3:91–103. Used with permission.)

A compensator, depending on its birefringence and thickness, selectively retards the transmission of a particular wavelength of light. Compensators are named based on the color of light transmitted. Thus, a red compensator orientated 45° to the polarizer will selectively retard the transmission of green light (540 to 575 nm), and the transmitted light from the compensator through the analyzer appears red or rose-colored. The orientation of the slow ray (axis) of the compensator is marked for proper alignment. Most are fixed in the 45° position with respect to the polarizer and analyzer.

Crystals are classified optically as positively or negatively birefringent depending on the orientation of the fast and slow refractive rays to the optical axes of the crystal. The optical axes of biaxial crystals correspond with the physical length of the crystal,

and cross obliquely in the center of the crystal. By definition, when the fast ray of the crystal bisects the acute angle of the optical axes, the crystal is termed negatively birefringent. When the slow ray of the crystal bisects the acute angle of the optical axes, the crystal is termed positively birefringent (Fig. 27.15).

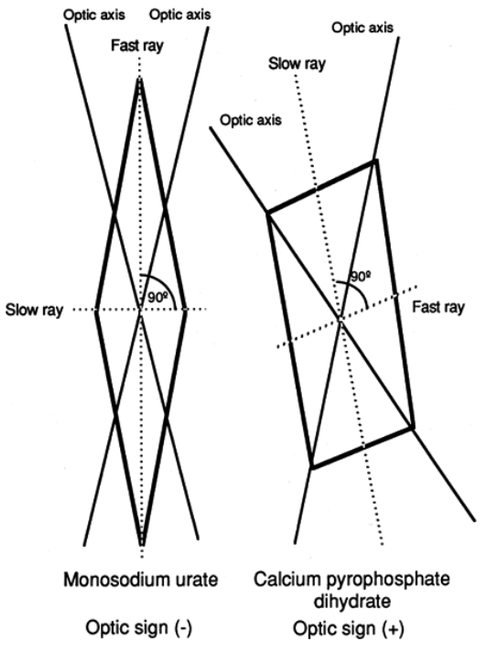

FIGURE 27.15. The optical sign of biaxial crystals is determined by the relationship of the fast and slow axes to the optical axis of the crystal. If the fast axis of the crystal bisects the acute angle of the optical axis, the crystal is optically negative. If the slow axis of the crystal bisects the acute angle of the optical axis, the crystal is optically positive. (Modified from Gatter RA. Use of the compensated polarizing microscope. *Clin Rheum Dis* 1977;3:91-103. Used with permission.)

Rays of light passing through the crystals cannot be seen; therefore, the physical orientation and color of the crystal compared with a known crystal determine birefringence. A birefringent crystal produces interference colors by adding to or subtracting from the incident ray when that ray is oriented parallel to the slow ray (axis) of the compensator. The wavelength of emitted light is shifted higher, to blue, if the slow ray of the crystal is parallel to the slow axis of the compensator, and is shifted lower, to yellow, if the fast ray of the crystal is parallel to the slow axis of the compensator. The colors are described with respect to the wavelength of the red compensator and represent the sum of the wavelengths produced by the compensator and crystal when both are placed between two polarizing filters. As seen in Figure 27.16, blue and yellow are spectrally equidistant from the red of the red compensator and reflect the additive or subtractive effect of the crystal on the red wavelength. The color of the crystal when its long dimension is parallel to the slow axis of the compensator defines the direction of the crystal's slow axis. A crystal that appears blue when its long dimension is parallel to the slow axis of the compensator (the slow ray bisects the acute angle of the optical axes) is positively birefringent. A crystal that appears yellow when its long dimension is parallel to the slow axis of the compensator, and its slow ray oriented perpendicular to the long dimension of the crystal (the fast ray bisects the acute angle of optical axes) is negatively birefringent. Several reviews provide detailed discussions of polarized microscopy (21, 77, 78 and 79).

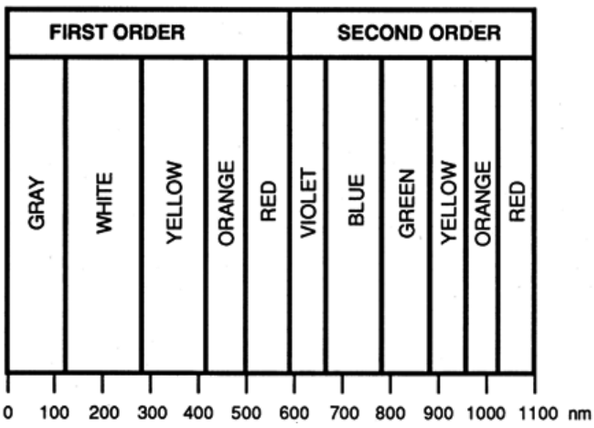

FIGURE 27.16. Orders and colors resulting from the use of compensators in a polarized light system theoretically from 0 to 1,100 nm. Yellow and blue are spectrally equidistant from the red of a red compensator. (From Gatter RA. Use of the compensated polarizing microscope. *Clin Rheum Dis* 1977;3:91-103. Used with permission.)

Weakly birefringent crystals may be difficult to see if the light is not properly adjusted; too bright a background can “overexpose” the crystals; too little light makes the already weak birefringence too weak to see. The slide should be screened under high power even if no crystals are noted under low power, with the knowledge that light microscopy alone cannot definitively exclude the presence of crystals (25, 80). Estimate the number of crystals as few, moderate, or many, and note their location as intracellular, extracellular, or both. Next, with a crystal in view, insert the red compensator. Align the long dimension of the crystal with the slow axis of the compensator, using a rotating stage or by rotating the slide, and note the color and shape of the crystal. Remember that more than one type of crystal may be present (81). Unidentifiable crystals may be subjected to x-ray diffraction, electron microscopy, or other esoteric tests when the crystals are suspected to be responsible for the joint complaint (21).

Monosodium urate (MSU) crystals are needle-shaped, 5 to 20 μm long, and strongly negatively birefringent (Fig. 27.17). MSU crystals may be located intracellularly or extracellularly (25). When the long axis of the crystal is oriented parallel to the slow axis of the red compensator, the crystal is bright yellow (Fig. 27.18 and Fig. 27.19). Rotating the axis of the compensator by 90° causes the crystal to change to blue. These crystals usually are easy to see under low power with polarized light; occasionally, microcrystals 1 to 2 μm in length may only be present requiring high-power examination for detection (82). MSU crystals can be provisionally recognized by their size and color in Wright-stained preparations in the absence of a polarizing microscope

(Fig. 27.17) (83). Rarely, spherules of MSU are present, which may be difficult to recognize as urate (84).

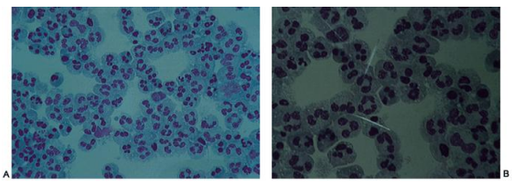

FIGURE 27.17. A: Synovial fluid with acute inflammation and monosodium urate crystals. The needle-shaped crystals are more difficult to recognize without polarized microscopy (Wright-Giemsa). **B:** Monosodium urate crystals observed with polarized light are clearly visible and brightly birefringent.

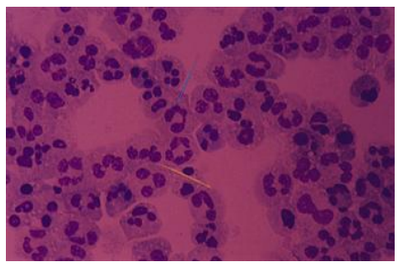

FIGURE 27.18. Monosodium urate crystals observed with compensated polarized light. The slow axis of the compensator is oriented parallel to the long axis of the yellow crystal.

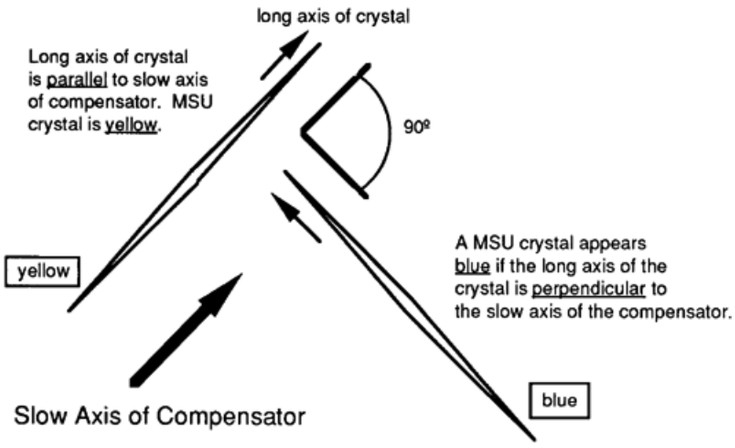

FIGURE 27.19. Polarization characteristics of monosodium urate crystals.

Calcium pyrophosphate dihydrate (CPPD) crystals are round to rhomboidal-shaped, 1 to 20 µm in length, and up to 4 µm in width. These weakly positive birefringent crystals (Fig. 27.20) often are more difficult to see than MSU crystals. CPPD crystals can be intracellular or extracellular. CPPD crystals have polarization characteristics opposite those of MSU (Fig. 27.21). When the long axis of the crystal is oriented parallel to the slow axis of the compensator, the crystal appears blue (Fig. 27.22). Rotating the axis of the compensator by 90° will cause the crystal to turn yellow. When CPPD crystals are nearly square, it can be difficult to locate the long dimension for orientation.

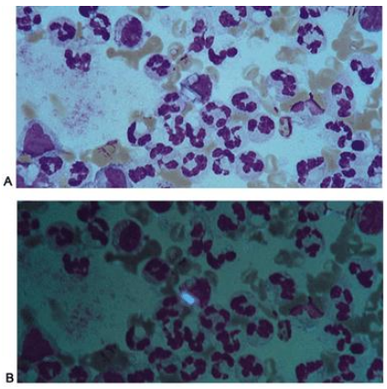

FIGURE 27.20. A: Synovial fluid with acute inflammation and calcium pyrophosphate dihydrate crystals. The rhomboidal intracellular crystals (center) are characteristic (Wright-Giemsa). **B:** Calcium pyrophosphate dehydrate crystals observed with polarized light show weak birefringence.

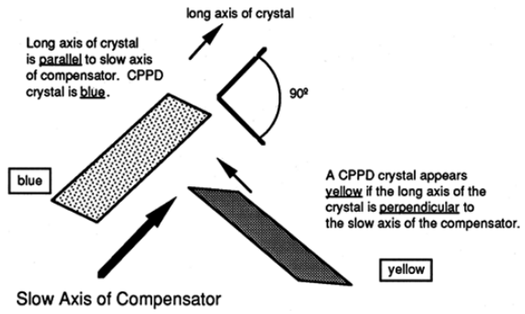

FIGURE 27.21. Polarization characteristics of calcium pyrophosphate dehydrate crystals.

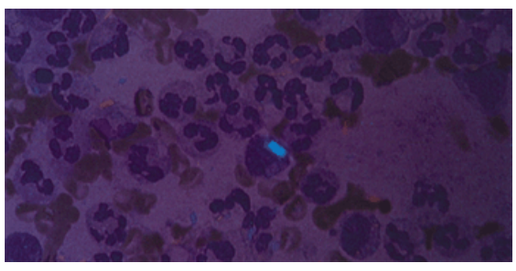

FIGURE 27.22. Calcium pyrophosphate dihydrate crystals observed with compensated polarized light. The slow axis of the compensator is oriented parallel to the long axis of the blue crystal.

Cholesterol crystals usually appear as large, flat rhomboidal plates and have notched corners. They are strongly positively birefringent, especially when stacked on top of one another. Negatively birefringent, needle-shaped forms have been described

that resemble MSU (85). Cholesterol crystals are never phagocytosed (25), and have no known etiologic role in the pathogenesis of arthritis. Both rhomboidal and needle-shaped forms can be seen in the same specimen.

Basic calcium phosphate (BCP) crystals, including hydroxyapatite and calcium phosphates, are ultramicroscopic in size and can be diagnosed as individual crystals only with transmission electron microscopy. Under the light microscope, these crystals appear as spheroidal clumps that vary from 1 to 50 µm in diameter (25). BCP crystals usually are not birefringent unless they are oriented along a common axis. Alizarin red S, a stain for calcium salts, has been used to identify clumps of crystals within cells, though its value as a screening test for these crystals has been questioned (80).

Corticosteroid crystals can mimic the morphology and polarization characteristics of MSU. Triamcinolone hexacetonide may be seen following intraarticular steroid injection therapy, and can persist in synovial fluid for months. These crystals are 10 to 20 µm in length, rectangular to needle-shaped, and negatively birefringent, and can be phagocytized by neutrophils. In contrast to MSU, they have ragged edges (25). Other steroid crystals can have different shapes and be positively birefringent (21). Steroid crystals may dissolve in alcoholic fixatives, making examination of a wet preparation mandatory for their identification.

Calcium oxalate (CO) crystals are bipyramidal, 1 to 2 µm in size, and positively birefringent. *Lithium heparin* crystals resemble CPPD, are 2 to 5 µm in length, and are positively birefringent (88). Other crystalline objects have been described in synovial fluid, including cryoprotein, immunoglobulin (86), and *aluminum phosphate* (87). Additionally, *metal fragments* from prostheses also have been reported in synovial fluid (31).

Artifacts frequently are seen during compensated polarized microscopy. These include *dust* and *dirt*, *paper fibers*, and *talc*. Careful evaluation of the optical sign of the crystal with the compensator, and comparison of polarized and conventional light microscopic appearance can help differentiate artifacts from true crystals. Artifacts may not be in the same plane of focus as cellular

material on the slide. When polarized, starch granules are brightly birefringent spherules and have a characteristic “Maltese cross” appearance (Fig. 27.23).

FIGURE 27.23. A: Starch observed under polarized light shows typical “Maltese cross” appearance. **B:** Starch viewed under polarized light with red compensator.

Chemical Examination

Chemical tests of synovial fluid generally contribute little to establishing a clinical diagnosis. Normal values for synovial fluid are shown in Table 27.5. Of the analytes, joint fluid protein, glucose, and uric acid may be requested in the usual clinical laboratory setting. Other tests, including lipids (89), enzymes, lactate, hyaluronidase, and ferritin, are more often performed in research studies. These are reviewed in several texts (21, 22, 23 and 24, 25). If viscosity presents a problem in clinical analyzers, the fluid can be sonicated or pretreated with hyaluronidase. Analyzers built to analyze serum may not perform as well with synovial fluid (90).

TABLE 27.5. NORMAL JOINT FLUID CHEMICAL VALUES[a]

Item	Range	Mean
pH	7.3–7.43	7.38
Total protein (g/dl)	1.2–3.0	1.8
Albumin (%)	56–63	60
Globulin (%)	37–44	40
Hyaluronate (g/dl)		0.3

[a] From McCarty DJ. Synovial fluid. In: McCarty DJ, ed. *Arthritis and allied conditions: a textbook of rheumatology*, 11th ed. Philadelphia: Lea & Febiger, 1989: 70.

Historically, low synovial fluid glucose has been used to differentiate infectious from inflammatory effusions. Synovial fluid and plasma specimens should be collected at the same time in tubes containing fluoride to minimize cellular metabolism of glucose *in vitro*. Joint fluid glucose equilibrates with serum levels after 6 to 8 hours; fasting levels are most reliable. In noninflammatory effusions, there is a glucose difference of less than 10 mg/dL between serum and joint fluid. With increasing inflammation, glucose levels in joint fluid fall. Infections should be considered when fluid glucose is less than 20 mg/dL (91). The large variation in glucose concentration in inflammatory and infectious disorders minimizes the usefulness of this test. Low glucose levels have been noted with CPPD in the absence of infection (92).

Measurement of synovial fluid protein does not distinguish transudates from exudates as in serous effusions. Increases in protein concentration above 2.5 g/dL are not normal, and concentrations above 4.5 g/dL often are associated with inflammation (27). Unfortunately, the protein concentration does not provide a specific diagnosis and is not of practical clinical value.

Urate is not concentrated within joints, and joint levels mirror serum levels (93). Therefore, there is little need to measure synovial fluid uric acid.

Synovial levels of pentosidine, ectonucleotide pyrophosphohydrolase, and YKL-40 are newer markers that can be measured in assessment of rheumatoid and osteoid arthritis and disease activity; however, their clinical utility has yet to be fully exploited (98, 99 and 100).

Immunologic Examination

There are few immunologic tests performed on synovial fluid that are helpful in establishing a clinical diagnosis. Many studies pertain to rheumatoid arthritis. Normal synovial fluid *immunoglobulin* concentrations are about 10% that of serum. Synovial fluid immunoglobulins in rheumatoid arthritis typically are increased and are derived both from peripheral blood and also local synthesis by plasma cells in the synovium. IgG, IgA, and IgM all are produced as part of the inflammatory response, and at least a portion of the IgM and IgG has *rheumatoid factor* activity. In most cases, the synovial rheumatoid factor titer is similar to the serum titer, but cases have been reported in which serum is negative in the presence of a positive synovial titer. Rheumatoid factors are unique to rheumatoid arthritis, and increased disease activity in RA may correlate with increased synovial fluid levels of pentosidine (25, 98).

Measurements of total hemolytic complement activity (CH_{50}) in synovial fluid need to be correlated with serum levels. The CH_{50} level is low in normal joints, and parallels serum CH_{50} in diseased joints with altered protein permeability. In the absence of local consumption, the CH_{50} is 33% to 50% of the serum value (25). A significant decrease in synovial fluid complement compared with peripheral blood levels correlates with activation by local immune complexes, and is a usual finding in RA. However, similar patterns may be seen in septic arthritis and gout (94). Decreases in both serum and synovial complement may be found in systemic lupus erythematosus. In general, because the levels do not permit separation of similar entities, complement levels are not of diagnostic assistance (95).

Microbiological Examination

Microbiological examination includes Gram stain of fluid smears and culture for microorganisms. While the Gram stain provides an immediate diagnosis when bacteria are visualized, its sensitivity is inadequate to detect all bacterial infections. Negative smears are not uncommon in gonococcal arthritis and in patients who have been treated with antibiotics before arthrocentesis (7). Thus, cultures should be initiated whenever a joint infection is a possibility.

Rapid analysis of fungal or bacterial antigens by latex agglutination or counterimmunoelectrophoresis, examination of metabolites by gas chromatography, and *Limulus* lysate assay for bacterial endotoxin are all applicable to synovial fluid samples.

Clinical Correlation

Based on the gross examination, WBC, and differential, most fluids can be classified into one of several categories (Table 27.6) Examples of disorders representative of each category are shown in Table 27.7. Synovial fluid findings often are nonspecific, and interpretation must be done in the appropriate clinical context. Algorithms for evaluation of synovial fluid microscopy have been proposed and evaluated (97).

TABLE 27.6. CLASSIFICATION OF SYNOVIAL EFFUSIONS

Gross Examination	Normal	Noninflammatory (Group I)	Inflammatory (Group II)	Septic (Group III)	Crystal (Group IV)	Hemorrhagic (Group V)
Volume (mL) (knee)	<3.5	Often >3.5	Often >3.5	Often >3.5	Often >3.5	Often >3.5
Viscosity	High	High	Low	Variable	Variable	Variable
Color	Colorless to straw	Straw to yellow	Yellow Cloudy	Yellow-white Cloudy	Yellow Cloudy	Red Xanthochromic
Routine laboratory examination						
WBC (mm^3)	<200	200–2,000	2,000–75,000	Often 100,000	2,000 to 75,000	50–10,000
PMN leukocytes (%)	<25	<25	>50 often	>75[b]	>50 often	<50
Crystals present	No	No	No	No	Yes	No
Culture	Negative	Negative	Negative	Often positive	Negative	Negative
Mucin clot	Firm	Firm	Friable	Friable	Friable	
Glucose (AM fasting)	Nearly equal to blood	Nearly equal to blood	<50 mg% lower to blood	>50 mg% lower to blood	>50 mg% lower to blood	Nearly equal to blood

Chicago: ASCP Press, 1986:134.

WBC and %PMN leukocytes will be less if organism is less virulent or partially treated.

WBC, white blood cells; PMN, polymorphonuclear neutrophils.

TABLE 27.7. DIFFERENTIAL DIAGNOSIS BY JOINT FLUID GROUPS

Group I Noninflammatory	Group II Inflammatory	Group III Septic	Group IV Crystal-induced	Group V Hemorrhagic
Osteoarthrosis Traumatic arthritis Osteochondritis dissecans Osteochondromatosis Neuropathic osteoarthropathy Pigmented villonodular tenosynovitis	Rheumatoid arthritis Lupus erythematosus Reiter's syndrome Ankylosing spondylitis Regional eneritis Ulcerative colitis Psoriasis	Bacterial Mycobacterial Fungal	Gout CPPD crystal deposition disease Apatite-associated arthropathy	Traumatic arthritis Hemophiliac arthropathy Anticoagulation Pigmented villonodular tenosynovitis Neuropathic osteoarthropathy Synovial hemangioma

From Kjeldsberg CR, Knight JA. *Body fluids; laboratory examination of amniotic, cerebrospinal, seminal, serous, and synovial fluids*, 2nd ed. Chicago: ASCP Press, 1986:133

CPPD, calcium pyrophosphate dihydrate.

The highest WBCs and neutrophils count is found in septic arthritis. WBCs typically are in the 50,000/μL range, but vary from 150/μL to greater than 100,000/μL (27, 96). Neutrophils generally account for more than 90% of the differential count. Previous treatment or diagnostic procedures may modify the WBCs and percentage of neutrophils. Finding more than 80% neutrophils in a joint fluid should prompt a search for bacteria no matter what the WBC. Definitive diagnosis is established when an organism is cultured from the fluid or synovium. When organisms are identified on Gram stain, a presumptive diagnosis can be made. However, a negative Gram stain does not exclude infection. Gram-stained smears are positive in 75% of patients with staphylococcal infections and in 50% of those with Gram-negative bacilli. However, less than 25% of patients with gonococcal arthritis will have organisms on gram stain (6).

Cell counts and percentage of neutrophils in joint fluid in

septic arthritis overlap with those of crystal induced arthritis. WBCs in crystal-related arthritis range from less than 100/µL to greater than 100,000/µL with approximately 80% neutrophils (range: 2 to 100) (27). Identification of the characteristic crystal will establish a diagnosis. Both CPPD and MSU can occur in the same joint.

Inflammatory, noncrystal, nonseptic arthritis is characterized by more than 50% neutrophils and WBCs ranging from 2,000/µL to greater than 100,000/µL. This group is largely diagnosed by the exclusion of crystals and organisms. A specific diagnosis is not always possible from joint fluid analysis alone.

A WBC of less than 2,000/µL distinguishes noninflammatory from inflammatory disorders. This number is clearly not absolute, because there is much overlap between diagnostic categories. Most noninflammatory fluids will have variable numbers of neutrophils, lymphocytes, monocytes, and synovial cells. Fluid analysis alone usually will not provide a specific diagnosis.

Macroscopic examination of the fluid may help distinguish traumatic aspiration from hemarthrosis. A xanthochromic or dark red-brown supernatant after centrifugation of a bloody fluid favors hemarthrosis. Comparison of WBC/RBC ratios in fluid and peripheral blood also may be helpful.

PLEURAL FLUID

Part of "27 - Synovial, Pleural, and Peritoneal Fluids"

The pleural fluid is normally present in small amounts (1–10 mL) in the potential space between the visceral and parietal layers of the pleura. Several factors affect the production of pleural fluid from the capillaries of the parietal pleura. These factors include plasma oncotic pressure, capillary hydrostatic pressure, and capillary permeability. The pleural fluid is drained via vascular channels in the visceral pleura. Increased production or decreased removal will lead to accumulation of the pleural fluid (pleural effusion), which sometimes has significant clinical consequences.

Pleural effusions generally are classified into transudates or exudates. Examples of causes of transudative pleural effusions include congestive heart failure, nephrotic syndrome, and liver cirrhosis. Iatrogenic transudates may occur with misplacement of central venous lines into the pleural space. Exudative effusions usually are products of infectious or malignant processes.

Specimen

Specimens should be collected in heparinized containers (1,000 units of heparin/100 mL fluid). If cell counts are required, an EDTA tube should be added. Fresh specimens may be stored up to 48 hours in the refrigerator before processing. Optimal requirements for pH measurements include collection under anaerobic conditions in heparin, on ice. Exposure of the specimen to air causes elimination of carbon dioxide and, subsequently, a false increase in pH.

Laboratory Evaluation

The aim of evaluating the pleural fluid in the laboratory is to help in establishing a diagnosis. This generally can be achieved by differentiating transudative from exudative effusions, identifying infectious agents, and recognizing malignant involvement.

Transudates usually are clear and odorless, while exudates generally are turbid or cloudy. Infections also lead to characteristic odors of exudative pleural fluids. According to Light et al., pleural fluid is considered an exudate if at least one of the following criteria are established: pleural fluid protein greater than 0.5 of plasma protein, pleural fluid lactate dehydrogenase (LDH) greater than 0.6 of plasma LDH, or pleural fluid LDH greater than two thirds of the plasma upper limit of normal (>200 U/mL) (101). These criteria, however, were arbitrarily established, and pleural fluids with borderline values should be considered exudates.

Bloody pleural effusions usually result from trauma, malignancy, or infarction. A traumatic tap, however, should be excluded. Bloody or turbid fluids should be centrifuged. If the supernatant is still turbid, a chylous or pseudochylous effusion is present. Clear supernatant indicates that turbidity was a result of the presence of cellular elements.

Microscopic evaluation of the pleural fluid includes a cell count. Smears are prepared and stained with Romanowsky's stain for a differential count (102). Centrifugation or filtration should be performed before preparing the smears to warrant optimum cellular yield. Normal and most of the transudative pleural fluids typically contain less than 1,000 cells/µL of which less than 25% are neutrophils, and no red blood cells. The presence of more than 100,000 red blood cells/µL implicates an etiology of trauma, malignancy, or pulmonary infarct. White blood cell count should be interpreted with caution. Pleural fluids generally are considered exudative when more than 1,000 white blood cells/µL are present. This conclusion, however, should be examined carefully as exudates may include smaller numbers of white blood cells.

The different types of cells present in the pleural fluid should be identified, as the presence or increase of certain cellular population usually is associated with specific disease processes. For example, neutrophils predominate in acute inflammations such as bacterial pneumonia (parapneumonic effusions), lymphocytes in viral infection and tuberculosis, and eosinophils in hypersensitivity and drug reactions. It also is important to recognize the mesothelial cells, which are commonly present in inflammatory processes. Reactive mesothelial cells must be differentiated from malignant cells. Such a process sometimes necessitates the use of a panel of immunohistochemical stains (24). The two most common malignant tumors causing pleural effusion are lung and breast. If malignant effusion is suspected, cellblocks also must be prepared.

Lymphocytes may prevail in pleural effusions from patients with lymphoproliferative disorders. Morphologic differentiation of reactive and malignant lymphocytes can be significantly difficult and other ancillary studies must be undertaken, including flow cytometric analysis and immunohistochemical staining. The presence of blasts in the pleural fluid also may necessitate similar studies to establish and confirm the diagnosis.

Chemical and immunologic analyses of pleural fluids include measurements of pH, protein, triglycerides, cholesterol, glucose, lactate, enzymes, tumor markers, rheumatoid factor, and antinuclear antibody titer. The change in the normal, established levels

of some of these analytes sometimes is helpful to establish a diagnosis. For example, pH decreases in parapneumonic effusion (103). A decrease in glucose concentration (<60 mg/dL) is associated with purulent, parapneumonic effusions. Also, low levels of glucose may confirm a diagnosis of rheumatoid pleuritis. An increase in amylase of more than 1.5 times its serum levels occurs in pancreatitis and its complications (104). Levels of LDH are expected to increase in inflammatory conditions. Carcinoembryonic antigen in the pleural fluid increases with pulmonary adenocarcinoma (24). Mesotheliomas, on the other side, were found not to cause such an increase.

Efficient microbiologic evaluation of pleural fluids requires aerobic, anaerobic, and mycobacterial culturing. Gram's and acid fast smears often are desirable. *Staphylococcus aureus*, gram-negative bacilli, and anaerobic organisms are commonly identified in parapneumonic effusions. Diagnosis of tuberculous pleural effusion is important because tuberculous effusions tend to resolve spontaneously over a few weeks. Thereafter, patients frequently present with active pulmonary or extrapulmonary tuberculosis. The sensitivity, however, of pleural fluid culture for mycobacteria is only 30% (105). Therefore, a pleural biopsy is considered an essential diagnostic tool. In fact, histopathologic evaluation of the pleural biopsy is diagnostic in almost 80% of cases and cultures of the specimen are positive in 85% of the cases. Combining histopathologic evaluation and culture of pleural biopsy increases the sensitivity to more than 90%.

PERITONEAL FLUID

Part of "27 - Synovial, Pleural, and Peritoneal Fluids"

The space between the parietal and visceral peritoneal membranes normally is occupied by 10 mL of clear, pale yellow, serous fluid that provides lubrication. Ascites develops from a disruption of the homeostatic forces that control the movement of fluid across the peritoneal membranes and represents an excess state of total-body sodium and water. Ascitic fluid is an ultrafiltrate of plasma. Accumulations are categorized into transudates or exudates. Transudates are the result of increased capillary hydrostatic pressure or decreased plasma oncotic pressure and are commonly seen in congestive heart failure, hepatic cirrhosis, and hypoproteinemia. In contrast, exudates arise from conditions that cause increased capillary permeability or decreased lymphatic resorption, including infections, malignancies, trauma, and pancreatitis.

Specimen

A diagnostic paracentesis contains 50–100 mL of peritoneal fluid (106). Total RBC and WBC with differential, cellular, and microbiological examination and chemical analysis are conducted routinely (107). Peritoneal lavage (PL) is performed if an inadequate amount of fluid is isolated and abdominal trauma, acute pancreatitis, or acute peritonitis is suspected. The specimen should be aliquoted at the time of paracentesis or PL into several EDTA tubes for cell counts, differential, and cellular evaluation, and into heparinized containers for chemical analysis. Fluid should be placed into sterile containers for microbiological assessment. A sample should be collected in Roswell Park Memorial Institute medium (RPMI) for flow cytometric analysis if a hematopoietic neoplasm is suspected. The samples should be transported on ice and analyzed immediately; however, they may be stored in 4°C for 24 hours (108). When clinically indicated, blood specimens should be collected in serum and EDTA tubes for comparative analyses.

Laboratory Evaluation

Peritoneal fluid should appear pale, clear, and not exceed 100 mL in volume (107). Bloody, cloudy, greenish, or milky fluids all are abnormal and may be seen in traumatic, infectious, neoplastic, inflammatory, or chylous processes. Blood caused by a traumatic tap generally diminishes during fluid collection. Clear fluids that exceed 100 mL in volume also are abnormal.

Chemistry

Ascitic fluid is differentiated into transudate or exudate. Transudate is clear, colorless, and low in protein. There are few cellular elements and the specific gravity is low. Exudate, a protein-rich fluid, is composed of more cells and solid material. Exudate may clot if fibrinogen leaked through the vasculature. Depending on the pathogenic process, exudates can be categorized further into catarrhal, fibrinous, hemorrhagic, purulent, or serous. Traditionally, total protein, ascites/serum total protein ratio, ascites lactic dehydrogenase (LD) concentration, or ascites/serum LDH ratio should be measured to differentiate transudate from exudate. The diagnostic accuracy of traditional laboratory tests used to differentiate exudate from transudate has been challenged. Serum/ascites albumin gradient (SAAG), an alternative biochemical diagnostic criterion, is more accurate. SAAG accurately differentiated transudate from exudate in 98% of tested samples, compared to 52%–80% when tested by traditional methods (109). An ascitic SAAG >1.1 g/dL is characteristic of a transudate. In contrast, a SAAG <1.1 g/dL is indicative of an exudate (106).

The presence of any quantity of amylase in ascitic fluid is abnormal and reflects an increase in serum levels (107). Pancreatitis or a gastrointestinal tract defect (perforated peptic ulcer or necrotic bowel) may cause amylase to appear in ascitic fluid. Samples that are lipemic or collected in oxalate or citrate containers may exhibit falsely low amylase results (110).

In malignant effusions, levels of peritoneal fluid LD are greater than those of serum. However, LD activity in peritoneal fluid is less than its activity in plasma activity (107).

Lactate, ammonia, glucose, and lipid analyses lack sensitivity and specificity and should be correlated with additional tests.

Tuberculous peritonitis may be differentiated from sterile cirrhotic ascites by measurement of ascitic fluid pH, lactate, gamma interferon (γ-IFN), and adenosine deaminase activity (ADA) (111, 112). γ-IFN values of 3.2 U/mL detected tuberculous peritonitis with a sensitivity of 93% and a specificity of 98%. ADA activity showed a sensitivity and specificity of 93% at values > 30 U/L in tuberculous peritonitis (112); however, the sensitivity decreased to 30% in cirrhotic patients with tuberculous peritonitis in the United States where tuberculosis is uncommon and cirrhosis is common (113).

The sensitivity of tumor marker tests is low making them

most useful for the monitoring of oncologic disease. Increased carcinoembryonic antigen (CEA) values are seen in many primary gastrointestinal, lung, and breast cancers. Gynecologic malignancies (ovary, fallopian tube, or endometrial carcinomas) commonly have increased levels of CA 125. The CA 125 is most useful in identifying recurrence of a primary ovarian tumor (114).

A multivariate analysis model, using five measurements [total protein, LDH, tumor necrosis factor-α (TNF-α), C4, and haptoglobin], currently is being developed to discriminate between benign and malignant ascites. Cross validation showed that 70% of unknown cases were classified correctly with this model (115).

Microscopic Examination

The total cell count of normal peritoneal fluid is <500 cells/L. Mesothelial cells, red blood cells, and white blood cells, including monocytic phagocytes, polymorphonuclear leukocytes, and lymphocytes can be found in normal fluid. The percentage of polymorphonuclear leukocyte in normal peritoneal fluid should not exceed 25% of the total cell count (116).

Total erythrocyte count >100,000 cells/μL is virtually diagnostic of hemoperitoneum (117). The total leukocyte count in ascitic fluid varies with the disease state. A polymorphonuclear leukocyte count greater than 250 cells/μL is indicative of spontaneous bacterial peritonitis (118).

Cytospin slides of malignant ascites may demonstrate a monomorphous population of abnormal cells with an increased nuclear to cytoplasmic ratio, and hyperchromatic nuclei with prominent nucleoli.

Microbiologic Examination

Cloudy or blood stained fluids, or those exhibiting increased numbers of polymorphonuclear cells, should be stained for microorganisms. The sensitivity of gram- or acid-fast bacillus stains is low, and culture of ascitic fluid is routinely performed. Direct inoculation of ascitic fluid into blood culture bottles enhances identification of bacterial organisms by 50% compared to routine cultures (119).

Urine

Meryl H. Haber

Patrick C. J. Ward

Examination of urine as an aid in diagnosis has long been an important part of medical practice. Ancient physicians recognized various colors of urine and associated these changes with prognosis (1). With the advent of the microscope, microscopy of various substances, fluids, organs, tissues, and cells became a commonly applied procedure, with great reliance being placed on it for diagnosis. Frequently performed by well-educated physicians, “uroscopy” was also performed by untrained charlatans, called “pisse-mongers” or “pisse-prophets.” The unrestricted proliferation of these quacks finally led, in England in the 17th century, to the enactment of regulations and licensure laws, which protected the public from these individuals (2).

The modern microscope was first applied to the analysis of urine by Golding Bird in the mid-19th century. Bird, in his masterful textbook on urine published in 1842 (3), described certain elements in the sediment that are now commonly diagnosed; crystals and casts were correctly identified and named and were also accurately illustrated with engravings. Richard Bright, working at the same hospital as Bird (Guy's Hospital, London), in 1827, correctly recognized the presence of “red corpuscles” in the urine in a series of patients with severe renal disease, although apparently he did not identify them microscopically (4).

Present-day microscopy is very different from that used by Bird in the 19th century. Although the fundamentals of bright-field microscopy were in use then, the advent of the binocular microscope with better optics and the development of planar and apochromatic lenses has facilitated recognition of various elements. Analysis of urine exemplifies the use of modern microscopic techniques; here, phase-contrast microscopy, polarized microscopy, and interference-contrast microscopy have provided enhanced images that ultimately improve the accuracy of reporting. Staining the elements in a body fluid, whether urine or any other fluid, has become an accepted procedure, often with considerable enhancement of cell identification (5).

Aside from the microscopic techniques performed in the modern clinical laboratory, body fluids may also undergo a variety of physicochemical evaluations. Medical science has come a long way from the ancient and medieval “pisse-prophets” who used visual examination of the urine almost exclusively to diagnose and prognosticate. The advent of the science of chemistry introduced distillation, which was made part of the uroscopy ritual. Various substances were added to the distillation flask or “urine vesicle,” and these, in turn, often produced changes in urine color and precipitation of proteins, which caused lines or bands to form at various levels in the distillation flask. The flask was frequently molded into a human-like shape and contained an alembic “nose.” If a band formed, a marking on the vesicle flask could be established, which would then represent a portion of the human form of the flask (e.g., a band across the abdominal region of the flask). The location of the band would then be interpreted by the physician as indicating the seat of the patient's disease—in this example, the umbilicus (1). This crude application of chemistry to urinalysis was the beginning of modern urine chemistry. Rapid advances in chemistry have occurred during the past 300 years. Many substances were specifically identified in urine (sugar, uric acid), and these tests became available and were subsequently applied to other body fluids. Now chemical analysis is performed routinely, and the most advanced of techniques are utilized, including spectrophotometry, gas chromatography, and a variety of immunologic methods.

The urine reagent strip, a 20th-century invention, has all but replaced complicated individual chemical analyses for the determination of various bodily products in urine. Estimations of glucose, albumin, hemoglobin, and bile, for example, as well as the determination of physical properties such as pH and osmolality, can all be accomplished using dipstick methodology. Advances in the analysis of urine are continually being made, especially in the area of immunodiagnostic testing. Abnormal products of body metabolism may be expected to be found in the various fluids of the body, and these (especially urine) are more easily obtained than tissue. Medical microscopy and the physicochemical examination of body fluids will therefore continue to be an important source of information to assist in diagnosis and patient care.

QUALITY ASSURANCE IN URINALYSIS

Part of "28 - Urine"

Urinalysis, although more frequently performed than any other laboratory test, often does not receive the same quality assurance (QA) attention that is given to other common tests. When conducting a urinalysis, it is important to ensure that the results are accurate, reproducible, and precise (6). Standards of performance and QA procedures must be adopted and applied in the urinalysis laboratory; these measures may be followed with a minimal amount of inconvenience in the modern well-equipped

laboratory, but they should be described and documented appropriately (7,8). The procedure for the performance of a routine urinalysis has several parts; each is discussed separately to delineate major issues of QA. Ordinarily, the attending physician or house-staff officer writes an order for a urinalysis; a nurse, clerk, or other individual then completes a request form.

Urinalysis Request Form

The request form itself should be readily recognized and easy to complete. The use of color coding and bold labeling on the form is helpful. Space should be available for patient information, including name, gender, age, race, identification number (whether an outpatient or inpatient), the reason for ordering the test (i.e., chief complaint, symptoms and clinical impression, surgery), any medications, the time and date of collection, and how the specimen was obtained (e.g., midstream, catheter, aspiration). The form may also serve for reporting the results. If so, ample space should be included for this purpose. Conversely, if the report form is separate, it should have a design similar to that of the request form as far as the color coding and patient information are concerned.

Equipment and Supplies

An overriding consideration when performing a urinalysis is the possibility that the specimen contains an infectious organism that may be transmitted to the technologist. Thus, the test itself, as well as the design of all supplies and equipment used in its performance, must ensure protection for the person performing the test; universal precautions must be adhered to in the handling of all specimens.

Equipment needed for the performance of a routine urinalysis generally consists of a microscope, a centrifuge, and a refractometer. In higher volume laboratories, some of the physicochemical procedures (e.g., dipstick) may be automated or semiautomated, and appropriate instruments necessary for this automation must be available. High-quality work necessitates the use of modern equipment with known performance characteristics.

The microscope should be modern and binocular and have an adjustable condenser with a built-in light source (8). The lenses should be of high quality and should consist of at least three magnifications: low and high power and oil immersion. A lower power scanning lens can be added and often is of value in assessing the general characteristics of the urine sample and in determining whether the field being examined is representative of the entire specimen. The microscope should be kept clean and properly aligned at all times.

Bright-field microscopy is the microscopic technique most frequently used for examination of urine sediment. Tungsten-filament light is transmitted through an adjustable condenser to produce parallel rays of light, so-called Köhler illumination. It is important to be able to reduce the level of light to enhance contrast because many sediment elements have a low refractive index and are difficult to see. High contrast is provided by stopping down the iris diaphragm and lowering the condenser to the level at which the elements are best seen. Light is transmitted through the sediment, and whatever elements are present are observed through the eyepiece lenses (usually 10×). For the most accurate and reproducible results of a sediment examination, it is important that the same microscope be used daily; significant variations in element counts may occur if different microscopes are used. For example, if one observer uses a microscope with wide-field 10× eyepieces and another with ordinary 10× eyepieces, there will be a discrepancy in counts because the field of view is significantly greater with wide-field eyepieces.

The best microscopic lenses are plano to provide a “flat” field of view. Lenses without chromatic aberration are called apochromatic lenses. Some manufacturers produce a lens (the planapo lens) that gives both a flat field and essentially no chromatic abnormalities; this type of lens is usually more expensive and not essential for ordinary everyday work.

Polarized microscopy is a simple and inexpensive addition to the bright-field microscope. All specimens that demonstrate abnormalities, whether macroscopically, chemically, or microscopically, should be examined using two polarizing lenses, a polarizer and an analyzer. The polarizer is inserted between the condenser and the microscopic slide, and the analyzer between the slide and the eyepiece. Particular substances, such as crystals and some lipids, have the peculiar property of being *birefringent* or *anisotropic* (also known as doubly refractile). Through polarized microscopy, objects that have this property are easily observed; objects that do not show birefringence are totally obscured from the field of view. Cholesterol esters, present in the nephrotic syndrome when there is lipiduria, demonstrate a “Maltese cross” pattern in the urine; these same lipids may be entirely missed or misdiagnosed if polarization is not applied to the sediment. Enhancement of ordinary polarization with the use of retardation plates may be helpful in crystal identification. These plates are inserted into the light path to change the path of light vibration. Most commonly used in a first-order red plate, which is useful in distinguishing urate from calcium pyrophosphate crystals, especially in joint fluids. Plates made of mica may be similarly employed.

Phase-contrast microscopy is a technique that has proved to be very useful in examination of the urinary sediment. Phase-contrast microscopy utilizes a special microscope condenser that produces parallel and in-phase light rays, causing the peaks and troughs of the light to be in synchrony. As these waves pass through an object, the wave becomes asynchronous and out of phase. Elements viewed in this manner appear to have a white “halo” around them, greatly enhancing observation and facilitating diagnosis. Phase-contrast microscopy equipment is available from nearly every optical product manufacturer at relatively modest cost and should be standard equipment in the urinalysis laboratory.

Interference-contrast microscopy (ICM) is a valuable microscopic technique that provides a three-dimensional or “shadow-cast” image of the element under study (9). This is accomplished by inserting a pair of beam-splitting prisms in the light path (Nomarski interference), one to actually divide the light and reorient it into phased and perpendicular waves of light (a reference beam and an object beam), and the second to recombine the light *after* it has passed through the element. As the object beam courses through the specimen, both its amplitude and phase are altered;

however, the reference wave does not pass through the element and thus no change occurs in its amplitude or phase. When these two light waves are recombined by passing through the second Nomarski prism, the image of the object appears to be three-dimensional when viewed through the eyepieces of the microscope. ICM is of particular value in teaching because of the ease in demonstrating fine points of structure. The cost of ICM equipment is somewhat high, and therefore it is difficult to justify in most routine laboratories where the urinalysis microscope is used exclusively for patient care.

The *centrifuge*, necessary for sediment concentration for microscopic evaluation, must be calibrated to provide a constant relative centrifugal force (RCF) of 400 (8). Spinning the urine for 5 minutes will provide sediment in which there are no artifacts. Neither the exact time of centrifugation nor the RCF is “set in stone”; each laboratory must determine for itself which settings to use and be certain to check that exactly the same time and RCF are applied to each urine specimen every time. Regular periodic maintenance and calibration checks of the centrifuge are essential to ensure a standardized procedure that will eliminate variations in results.

Refractometers measure the total solids (TS) in a solution by comparing the refractive index of the specimen with water: solids dissolved in urine change the refractive index in proportion to their concentration (10). These instruments are operated with ease and provide a quantitative estimate of the specific gravity using a single drop of urine. Most commercially available refractometers are temperature corrected and have replaced the older (and far less accurate) urinometers (or hydrometers) for the measurement of specific gravity. Reference solutions with known quantities of dissolved substances, such as salt, are prepared to check the calibration of refractometers. Water is used as a standard and is given a value of 1.00. Calibration should be done frequently and at least daily in high-volume laboratories (8).

Osmolality, although not usually tested in the urinalysis laboratory when a routine urinalysis is requested, is a measurement of the number of particles in a solution. Instruments employed to measure osmolality are based on the principle that when a solution is frozen, or vaporized, the point at which this occurs is proportional to the number of particles present. This relationship may not always be a direct one because larger molecules, such as protein, affect the proportionality more than simple molecules, such as sodium chloride. The measurement of urine osmolality is a valuable test when estimating the kidney's concentrating ability, as in the case of possible tubular disease or in the calculation of free water clearance (11). Reference solutions, both high and low, should be utilized at frequent intervals in the testing procedure for instrument calibration to ensure precision and accuracy. Instruments that measure osmolality are complex and need to be treated with the utmost care, always making certain that the manufacturer's instructions are followed exactly.

The supplies used in routine urinalysis should be disposable (7,8). These include a specimen collection system consisting of a collection container and cover, a graduated centrifuge tube with a leakproof cap, labels, and disposable microscopic slides containing a constant-volume chamber for sediment quantitation. Reagent strips are available from a number of different suppliers and can be obtained with several configurations of tests. Most, however, include the following physicochemical tests: pH, hemoglobin, glucose, protein, bilirubin, urobilinogen, ketone bodies, and nitrites. Other commonly available pads test for leukocyte esterase and measure specific gravity (10). Each of these tests is discussed separately in a later section of this chapter.

It is important to conclude this section with a brief comment about reporting. No matter how accurate and precise a procedure may be, or how relevant the results, if one is not consistent in the method of reporting, misinterpretations may result (8). It is therefore incumbent on the laboratory to standardize reporting and to be certain that whoever is performing the test uses the same terminology and identical criteria for the identification of elements. A procedures manual should contain diagnostic criteria and specific definitions; all personnel performing the test should use these criteria. A definition of what constitutes normal urine should be included. Separate mention should be given to abnormal values, and those that should prompt a telephone call to the attending physician, the so-called “panic values,” should be defined.

MACROSCOPIC, PHYSICOCHEMICAL URINALYSIS

Part of "28 - Urine"

Physical Examination of Urine

An adult human produces 1 to 2 L of urine every 24 hours. The urine is formed in the kidney and contains predominantly water in which are admixed mostly urea and salts, especially sodium chloride (11). The amount of solute is directly related to the amount and kind of ingested foods and fluids. Urea is predominantly a byproduct of protein metabolites. Numerous other dissolved constituents are also found in urine, including sugars, bile, other electrolytes such as potassium, products of protein metabolism such as nucleic acids, hormones and their metabolites, vitamins, and some trace metals.

The routine macroscopic, physical, and chemical examination of urine includes appearance, dipstick testing, and measurement of specific gravity (8,10). Normally, urine is pale yellow and has an ammoniacal odor. This odor increases significantly when the urine has been allowed to stand for any length of time and is primarily owing to the release of nitrogenous compounds from bacterial action. The urine is more deeply pigmented as its concentration increases.

Physical Urinalysis

Appearance

When freshly voided, normal urine should be clear and pale yellow to amber in color. Many ingested foods, dyes, or pharmaceuticals may produce a color change. The normal yellow color is owing to the presence of urochrome pigment, a product of hemoglobin metabolism. Color intensity may vary and depends on the concentration of the urine; in highly concentrated urine such as in the early morning, the colors may be more vivid.

Abnormal color of urine occurs in the normal state and as well as in some diseases. Various foods, such as carrots and beets, produce abnormally colored orange to red urine. Although color by

itself is not a particularly sensitive indicator of abnormality, any variation from the normal should be investigated and the specific cause determined. Some conditions may be associated with abnormally colored urine, for example, hemoglobinuria (red), melanin (black), bile pigments (green), chyluria (white), and porphyria (red-purple). In addition, some dyes and pharmaceuticals and some food colorings are notorious for discoloring urine. Specific examples are phenolphthalein (red), methylene blue (blue), and pyridium (yellow-orange) (11).

Normal urine is not always clear, especially after refrigeration. Urate and phosphate crystals often form a cloudy precipitate when urine is subjected to low temperatures. Simply rewarming the urine to room temperature will frequently cause the crystals to dissolve and the urine to become clear again. Urine contaminated with seminal fluid or vaginal secretions and mucus may be cloudy. Clear urine that has been permitted to stand at room temperature for any length of time may become cloudy because of bacterial growth. Turbid urine is commonly associated with abnormal conditions, especially hematuria, leukocyturia, and bacteriuria. Chyluria, or the appearance of lymph in the urine causing cloudiness, is an extremely rare complication of blockage of the lymph passages with the production of a fistula and flow of the lymph into the urinary outflow tract.

Odor

Normal urine has a distinct and easily recognized odor, albeit ill defined. Upon standing, the same urine acquires a pungent ammoniacal odor caused by the action of bacteria and the release of ammonia. Food, such as asparagus, gives the urine a distinct odor promptly after eating. The odor of urine is given little importance in clinical diagnosis, but if an unusual odor is recognized during analysis, it too should be reported. Foul-smelling odors may be associated with urinary tract infections and “fruity” odors with diabetes mellitus when ketones are present.

Collection of Urine

An early-morning, freshly voided specimen is preferred. This should be a clean-catch midstream voided urine (8). The patient is instructed to cleanse the area surrounding his or her urethra using a mild soap and water solution and then to urinate into a clean (not necessarily sterile) collection container that is properly labeled, free of interfering chemicals, can be capped, and is leakproof.

The specimen should be transported to the urinalysis laboratory promptly and examined within 2 hours of voiding (12). Although refrigeration of the specimen is not necessary owing to frequent precipitation of urate or phosphate crystals, in some instances it is preferable to allow the urine to stand at room temperature. The addition of antibacterial agents such as formaldehyde or thymol crystals to the urine to prevent bacterial growth is not advised because these substances interfere with the chemical evaluation.

Once received in the laboratory, the urine is decanted into a graduated centrifuge tube and centrifuged to obtain sediment for evaluation. Transfer pipettes and microscopic slides, preferably with graduated, consistent-volume chambers, are desirable for use. None of the materials mentioned should be reused.

A most important concept in the analysis of urine must be that QA that ensures consistency and accuracy of results (6,7 and 8). Basically, this concept is one of careful control and consistency in every step of the urinalysis procedure to ensure that each and every urine sample is treated and examined in exactly the same manner, and the results obtained are compared with nonsamples to ensure that when and if a discrepancy occurs, corrective action will be taken.

Equipment such as microscopes, centrifuges, reagent strip readers, and refractometer all need to be clean, calibrated, and frequently checked to provide consistency and accuracy in evaluations. The reader is referred to NCCLS Document GP16-P for guidelines with regard to routine urinalysis (8).

Chemical Urinalysis

The performance of a routine physicochemical urinalysis has evolved into a sophisticated, but easily performed, procedure mainly owing to the advent of urine dipsticks (10). These are plastic strips on which are attached a series of chemically impregnated absorbent pads. Each pad contains chemicals that react with a substance in the urine, producing a color change in the pad. This color change is then compared with a series of known standards so that any reaction seen in the patient's urine may be evaluated and quantified. This methodology is simple and easily taught, is rapid, and provides a means of analysis that, although not without some drawbacks, offers an inexpensive and highly useful assessment of several urinary constituents. Most of the available dipsticks contain pads for determination of pH, hemoglobin, glucose, protein, urinary ketones, bilirubin, urobilinogen, and nitrites (13). Other available pad tests, depending on the manufacturer, measure specific gravity and leukocyte esterase (14).

Along with the bottle containing the dipsticks, each manufacturer provides an insert that describes in detail the proper use of the product. Care must be taken to follow these directions exactly. Before using the sticks, one must be certain that they are not outdated and that they have been stored in their original container at the recommended temperature. The bottle should remain unopened until the dipsticks are required for use. The strips should be removed from the container only a few at a time and, once opened, the container should be closed tightly for storage of the remaining dipsticks until further need (8).

In use, the dipstick is immersed into the urine by a rapid, deliberate motion and is then removed. During removal, the edge of the stick is guided over the lip of the urine container, usually a centrifuge tube, to allow excess urine to run off the stick and flow back into the container. Each manufacturer provides a time sequence for the interpretation of each test pad; it is important to follow these instructions because the color reactions on the pads change with prolonged exposure. As pad colors are compared with a colored comparison chart provided by the manufacturer, test results are recorded by the observer. For accurate interpretation, lighting conditions should be good and should simulate daylight. Visual reading of the pads is subject to variation from observer to observer; automated strip readers have improved this variability.

QA procedures need to be employed during the chemical analysis of urine (6). This is performed by utilizing solutions with known concentrations of the analytes being tested for on the dipstick. When spurious or unexpected results are obtained in any patient or if a trend toward abnormal results occurs, the source of potential error must be determined and corrected. Confirmatory testing is performed on the urine sample on occasion. In such instances, it may be desirable to obtain results that exceed those provided by the semiquantitative methodology of the dipstick (8). Confirmatory tests are available for essentially all urine dipstick pads.

Some substances may produce interference with the reaction on the dipstick pad. Many of these are well known and consist of pharmaceutical products, various foodstuffs, and dyes (10,11). In addition, particular physicochemical changes in the urine may interfere with the pad's color reaction and can result in inaccurate false-positive or false-negative readings. As an example, bilirubin, when exposed to light, breaks down and a false-negative reaction on the dipstick pad occurs if the urine has been exposed to direct light for long periods. An excellent example of an interfering substance is ascorbic acid (vitamin C), which is frequently taken in high concentrations in the belief that it affords better overall health and prevents the common cold. This substance is excreted by the kidneys and, when present in the urine, may obscure the dipstick pad for hemoglobin, giving a false-negative reaction. It is of primary importance to provide the laboratory with a good clinical history before the performance of a urinalysis to ensure useful clinical correlations and consistent and accurate interpretations.

Glucose

Glucose is one of a variety of reducing substances that may be present in the urine, but from a clinical standpoint, it is the most important one. Small amounts of glucose may normally be present in the urine, especially after ingesting foods or beverages that have a high concentration (11). Glucose is freely filtered by the glomerulus and almost entirely reabsorbed by the renal tubules, so that under normal circumstances little is found in the urine. *Glycosuria* is defined as the presence of detectable glucose in the urine. This generally occurs when blood levels of glucose exceed 180 mg/dL. At these levels, with similar concentrations occurring in the glomerular filtrate, the renal threshold for glucose is exceeded, and any glucose that exceeds this concentration cannot be reabsorbed by the renal tubules and is excreted in the urine. The renal threshold is not an absolute number and varies somewhat from individual to individual, in the range of 160 to 200 mg/dL.

Diabetes mellitus, a common clinical condition in which serum concentrations of glucose may reach very high levels, is frequently diagnosed and monitored by the detection of glucose in the urine. Elevated blood levels of glucose lead to similarly elevated levels in the glomerular filtrate, which then exceed the renal threshold for glucose, and glycosuria results. Glucose may be found in the urine in conditions other than diabetes; these affect the central nervous system (stroke, neoplasms), kidneys (uremia), endocrine system (overproduction of adrenocorticotropic hormone), and liver (glycogen storage disease) or may be related to general metabolic problems, such as starvation and obesity (10,11,15). Some pharmaceutical agents, such as diuretics and birth control pills, may also cause glycosuria.

Although glucose may be measured in various ways, the dipstick method employs an enzymatic methodology (10). This method takes advantage of the specific reaction of the enzyme glucose oxidase, which catalyzes the conversion of glucose to gluconic acid and hydrogen peroxide. A second enzyme, peroxidase, promotes the reaction of the H_2O_2 generated with a chromogen (iodine complex) to form a brown oxidized compound. The chromogen varies with the manufacturer, as does the sensitivity (10,13).

$$\text{Glucose} + O_2 \xrightarrow{\text{glucose oxidase}} \text{Gluconic acid} + H_2O_2$$

$$H_2O_2 + \text{Chromogen} \xrightarrow{\text{peroxidase}} \text{Oxidized colored chromogen} + H_2O$$

Color charts are provided with the dipsticks to enable semiquantitative determination of the amount of glucose present in the specimen. Reporting is commonly given in a 1+ to 4+ format, which may then be equated to concentrations ranging from approximately 100 to 2,000 mg/dL. Sensitivity of the various dipsticks varies with the manufacturer but is usually in the range of 50 to 100 mg/dL. Reagent strip testing for glucose has problems because at the higher concentrations (i.e., 1 to 2 g/dL), color differences in the pads are more difficult to interpret.

Reducing substances, especially other sugars, do not give a positive dipstick test because the method, which utilizes glucose oxidase, is specific for glucose. However, false-positive reactions may occur if the urine container used is not disposable and strong oxidizing detergents remain from prior washings (11,15). False-negative results may result when any part of the chemical reaction is interfered with, such as when high doses of aspirin or ascorbic acid are present in the urine and these compounds, both reducing agents, prevent the formation of the chromogen by preventing its oxidation by H_2O_2. One other relatively frequent cause of false-negative results is glucose being metabolized by bacteria when the urine sample has been allowed to stand for any length of time after voiding.

A second method for the measurement of reducing sugars, including glucose, in urine is by means of the copper reduction test (Benedict's reaction) (Table 28.1). This test is performed by

adding urine to a tablet composed of copper sulfate, sodium citrate, sodium carbonate, and sodium hydroxide (Clinitest, Bayer Corp., Consumer Division, Morristown, NJ, U.S.A.) (10). The cupric ion ($CuSO_4$), in the presence of a base (NaOH), reacts with reducing substances in the urine to produce cuprous ions plus heat. Depending on the amount of sugar present, a color change occurs that can then be compared with reference charts to quantitate the reaction. This test is performed by simply adding urine and water to a test tube containing a Clinitest tablet, waiting a short amount of time for the chemical reaction to occur (the solution boils with heat liberation and color development; the bottom of the test tube should not be touched), and then quantitating the amount of sugar present by comparing the color of the reactants with a color chart. The manufacturer's directions should be followed in their entirety; accuracy is related to adding the correct amounts of urine and water as well as to the timing of the reaction and the development of color.

TABLE 28.1. COMPARISON OF THE REACTIONS OF GLUCOSE OXIDASE COPPER SULFATE TESTS FOR URINE SUGARS

Substance	Dipstick	Copper Sulfate Tablet
Glucose	Positive	Positive
Other reducing sugars	Negative	Positive
Pharmaceutical agents	Negative	Some false positives
Detergent contaminants (peroxide or strong oxidants)	False positive	Negative

Reducing sugars other than glucose are infrequently seen in urine but are sometimes discovered in a pediatric population. They may be overlooked unless careful attention is paid to the possibility of their existence. This is accomplished by means of testing each pediatric patient's urine with Clinitest or by using another similar nonenzyme-specific methodology. This copper sulfate method will detect the presence of all reducing sugars, some of which may not be glucose. To verify the presence of a nonglucose-reducing sugar, comparisons should be made with dipstick results from the same patient; if the sugar is not glucose, the dipstick test is negative. Thin-layer chromatography may be utilized in the specific identification of nonglucose-reducing sugars when inherited inborn metabolic diseases of sugar metabolism are considered.

Galactosemia, an inborn error of metabolism, must be screened for using the copper sulfate methodology. The use of a dipstick will not discern galactose. Lactase deficiency in the infant results in lactosuria; early diagnosis is of importance because failure to thrive and intestinal damage may result if ordinary milk, which contains lactose, is not removed from the diet. Sucrase deficiency, less common than lactase deficiency, also results in mellituria (sucrosuria), which can be diagnosed using a Clinitest tablet. Symptoms are similar to those seen in lactosuria. Other sugars that may be present in the urine are fructose and pentose. Fructosuria and pentosuria are infrequent causes of nonglucose mellituria.

Protein

Relatively small quantities of protein are normally excreted in the urine, usually no more than 100 to 150 mg/day (16,17). Normal urine volume is between 1,000 and 1,500 mL/day; thus, the expected protein concentration in a normal sample is in the range of 8 to 10 mg/dL (10,15). The predominant protein present in the urine is albumin, which is filtered by the glomerulus and is not reabsorbed by the tubules; albumin accounts for less than 30 mg/day in normal urine. The other main source of urinary protein is the renal tubules, especially the distal tubules. These tubules account for the other two thirds of urine protein excretion, and of this portion, approximately one half is Tamm-Horsfall mucoprotein (THM), which is secreted by the distal tubular epithelium and collecting ducts and is of importance in the formation of urinary casts. Small quantities of other urinary proteins come from filtered low molecular weight proteins of the blood plasma that are not reabsorbed by the tubules, microglobulins from renal tubular epithelial (RTE) cells, and prostatic and vaginal secretions (16).

Proteinuria, defined as increased protein in the urine, is a frequent finding in intrinsic diseases of the kidney and urinary tract. Proteinuria, often associated with urine sediment abnormalities, frequently serves as a basis for the diagnosis of intrinsic renal disease (16). Albumin is most often the predominant protein excreted in excess in urine in disease states and may account for as much as 80% to 90% of the total protein present. In multiple myeloma, a neoplastic condition affecting plasma cells, large quantities of a low molecular weight globulin (Bence Jones protein) may be present in the urine, replacing albumin as the predominant protein. The presence of substantial amounts of albumin in the urine of a patient with known myeloma may be indicative of evolving amyloidosis. Proteinuria may accompany generalized non-urinary tract conditions such as hemorrhage, systemic infections, heart failure, dehydration, and starvation.

Normal persons may excrete abnormal quantities of protein, mainly albumin, in some situations such as during strenuous physical exercise (18), pregnancy, exposure to extreme cold, and psychological stress.

Orthostatic proteinuria is a condition mainly found in adolescents and young adults in which increased quantities of protein are found in the urine when the patient is in a vertical position; the proteinuria disappears when the patient is resting horizontally (15). Pressure on the renal veins when standing is thought to be the cause of this condition, and it frequently disappears with increasing age. Testing the first urine specimen of the morning for protein and comparing the result with that obtained from a specimen collected later in the day after physical activity will usually provide the correct diagnosis and may eliminate the need for a more elaborate workup.

Dipstick screening for protein is designed to differentiate between what is considered a random normal amount (i.e., less than 10 mg/dL) in a given urine sample, preferably an early-morning specimen, and quantities that exceed these norms. One reason for the early-morning collection of urine is that samples of urine obtained after eating or drinking may produce false-negative dipstick tests for protein because of the dilutional effects of food and water. Whenever unsuspected proteinuria is found, confirmatory tests for protein are essential because a diagnosis of proteinuria carries with it considerable clinical importance (8). Any diagnosis of proteinuria should be verified and substantiated. Clinically, proteinuria is considered mild (less than 0.5 g/day), moderate (0.5 to 4 g/day), or severe (more than 4 g/day) (10). Most patients with intrinsic renal disease such as acute glomerulonephritis or pyelonephritis present with moderate proteinuria, but patients with the nephrotic syndrome commonly excrete more than 4 g of protein daily in the urine.

Quantitative protein concentrations can be determined by setting up standards containing measured amounts of protein and comparing the precipitation obtained on an unknown urine

sample with these standards using a nephelometer or spectrophotometer. Immunoassays have recently been employed for the accurate determination of urinary protein content (16). In practice, a qualitative estimation of protein is initially made by comparing the degree of precipitation (i.e., turbidity) with a set of standard tubes containing known concentrations of protein. This reaction may be classified as 1 to 4+ or may be quantified as milligrams per deciliter. A trace reaction is one in which there is perceptible, but minimal turbidity (approximately 20 mg/dL); a 1+ reaction (approximately 50 mg/dL) shows definite turbidity, but no white precipitation granules; in a 2+ reaction (approximately 250 mg/dL), granules and turbidity are seen; a 3+ reaction (approximately 500 mg/dL) demonstrates granules and flocculation; in a 4+ reaction (more than 1 g/dL), large clumps of white precipitate are seen.

Present-day dipsticks for the determination of urine protein use a colorimetric methodology based on the concept of “the protein error of indicators.” This method uses a physicochemical property of protein that causes particular indicators (e.g., tetrabromophenol blue) to change color in the presence of varying concentrations of protein when the pH is kept constant (the dipstick pad is impregnated with buffers kept at a pH of approximately 3). This method provides a rapid means of testing for protein, but one that is somewhat difficult to interpret when low concentrations of protein are encountered, generally in the trace to 1+ range. This difficulty is caused by subtle color changes that occur in the indicators in this range (i.e., yellowish tan). As protein levels increase, the colors become more intense and easier to interpret (i.e., green and blue). Results are read as trace and 1+ to 4+. A dipstick trace reaction corresponds to approximately 15 to 30 mg/dL of protein, whereas a 4+ reaction corresponds to more than 2 g/dL.

Standard dipsticks are most sensitive to albumin. They may completely fail to detect other proteins such as globulins, hemoglobin, myoglobin, and Bence Jones protein. The presence of such proteins must be confirmed by other methods, notably (and most simply) by the sulfosalicylic acid test (11).

Bence Jones protein is found in the urine in approximately one half of patients with multiple myeloma; it may also be present in malignant lymphoma and macroglobulinemia (15,19). Reagent strip testing for Bence Jones protein often is not reflective of the type or amount of protein present in the urine because they are globulins, and the protein pad may even show a completely negative result (10) unless there is accompanying albuminuria. Urine electrophoresis or immunoelectrophoresis is the procedure of choice for recognizing this protein (16), but other tests may also prove helpful, especially as screening tests, because of the peculiar solubility properties of Bence Jones protein.

When gradual heat in a water bath is applied to a test tube of urine containing Bence Jones protein, precipitation occurs between 40° and 60°C. However, if the heat is continued by putting the tube in boiling water, precipitated Bence Jones protein will redissolve at approximately 100°C after a few minutes. Cooling the tube reverses the process, so a precipitate will reform at 40° to 60°C and will redissolve when the temperature falls below 40°C (13). Severe proteinuria in myeloma, if left untreated, often produces renal tubule injury (myeloma kidney), which may lead to clinical manifestations of the nephrotic syndrome and to renal failure. If large amounts of protein other than Bence Jones protein are present in urine, they may interfere with the heat test. Filtering the urine after boiling it and heating it to 100°C and then cooling it to room temperature will remove these interfering substances.

Clinically, it is often valuable to know the total amount of protein excreted in the urine in 24 hours (16). A single urine sample is not sufficient to provide this information; therefore, a 24-hour sample must be collected. Chemicals that cause no interference with the tests for protein are added to the urine collection bag to preserve the specimen. At the end of the timed collection period, the urine is analyzed for its protein content using a precipitation test (i.e., sulfosalicylic acid turbidity). The results are reported as milligrams of protein per deciliter and, depending on the total volume of urine voided, the amount of protein excreted by the kidneys in a given day, can easily be calculated.

Microalbuminuria

The normal excretion of albumin in urine is less than 30 mg/day. Albumin levels greater than 30 mg/day may be present while total urinary protein levels remain normal, i.e., less than 150 mg/day. The commonly used dipstick is negative until total protein excretion is greater than 300 to 500 mg/day. The term microalbuminuria describes levels ranging from 30 to 299 mg/day (20). Hence, microalbuminuria may be present in a dipstick-silent range. Detection of small increments in albumin excretion is of critical importance in that it portends irreversible glomerular injury both in insulin and non-insulin-dependent diabetes. The sulfosalicylic acid test may exhibit trace positivity in this dipstick-silent range of albuminuria but is unreliable for this purpose.

Trace positivity with the sulfosalicylic acid test should then lead to confirmatory testing for microalbuminuria. This is usually performed by nephelometry, an immunoturbidimetric method that provides an accurate measurement of albumin. Because the rate of albumin excretion is in question, a timed collection of urine is required.

An alternative to this confirmatory procedure is the measurement of a urinary albumin:creatinine ratio in a first-voided morning urine (21). Microalbuminuria by this method is interpreted as 30 to 300 mg/g of creatine. The test is also commonly performed on a random “grab” urine specimen. A recently described reagent strip device (dipstick) for quantitation of the urinary albumin: creatinine ratio (Clinitek, Bayer, Newbury, UK) appears promising (22).

It is generally accepted that diabetics should be screened for microalbuminuria 8 to12 years postdiagnosis and yearly thereafter. Detection of microalbuminuria in diabetics, whether insulin dependent or not, should provoke intervention with a view to preventing or slowing down the progression of glomerular disease (21,23).

Microalbuminuria is also encountered in middle-aged nondiabetic patients with major cardiovascular risk factors such as hypertension, weight gain, and increased plasma cholesterol. These factors may be associated with microalbuminuria independently of each other (20).

Blood

Hematuria, defined as increased numbers of red blood cells (RBCs) in the urine, is an important indicator of diseases involving the genitourinary tract. Normal urine may contain as many as five RBCs/μL. Increased numbers of erythrocytes may come from a variety of sources, including the kidneys, ureters, bladder, urethra, prostate gland, and uterus and vagina. Erythrocytes may be found intact or they may lyse and release their contained hemoglobin into the urine, resulting in *hemoglobinuria*. Frank bleeding into the urine causes a reddish discoloration, but fewer RBCs or less hemoglobin in the urine (i.e., occult bleeding) have been described by some patients as a "smoky" urine. Normally, there are small numbers of RBCs in the urine sediment, but these are not detectable using dipstick methodology.

There are many causes of hematuria (19). Among the more common are bladder and kidney tumors, trauma to the kidneys, glomerulonephritis, pyelonephritis, renal calculi, and bleeding disorders related to anticoagulant use. Hemoglobinuria, however, is far less common. It may be associated with trauma or transfusion reactions and is seen in severe burns or poisonings. Myoglobinuria, the presence of myoglobin in the urine, is found on occasion after severe physical exercise or in trauma where muscle fiber necrosis has occurred. Myoglobin gives a positive dipstick reaction for hemoglobin, and therefore the distinction between myoglobinuria, which indicates rhabdomyolysis, and hemoglobinuria must be made using other tests (15). Myoglobinuria should be considered when the dipstick pad is positive for hemoglobin, but microscopic analysis of the sediment does not show RBCs.

Dipstick testing for hemoglobin is based on the property of hemoglobin to catalyze the oxidation of a chromogen because of the release of the RBC enzyme hemoglobin peroxidase (10). Various manufacturers use different chromogens that, when catalyzed by hemoglobin peroxide in the presence of an organic peroxidase buffer, form a green to dark blue chromogen.

$$H_2O_2 + \text{chromogen} \xrightarrow{\text{Hemoglobin peroxidase}} \text{colored chromogen} + H_2O$$

Reagent strip pads for hemoglobin are impregnated with the benzidine chromogen and buffered organic peroxide. If hemoglobin is present in the urine, the hemoglobin peroxidase catalyzes the reaction shown above so that a color develops on the pad. This colored pad can then be compared with color charts for a semiquantitative determination of the amount of hemoglobin present. The readings are 1+ to 3+ and indicate trace, small, moderate, and large amounts of blood. Intact RBCs are lysed when they come in contact with the pad, resulting in a speckled pattern. In most urine containing blood, intact RBCs, as well as free hemoglobin from lysed RBCs, combine to provide the positive reaction on the strip.

Hemoglobin dipstick testing, especially for microscopic hematuria, has been very effective (24). However, there are well-known interfering substances that must be considered whenever the clinical history or the sediment examination does not substantiate the results of the dipstick test. Interference by ascorbic acid (vitamin C) is a prime example of this. False-negative reaction errors can be avoided if a careful clinical history is taken and a check is made for the presence of vitamin C in the urine (13). Other methods used to detect hemoglobin when interfering substances are present include direct chemical analysis using a spectrophotometer or by use of another dipstick with a hemoglobin pad that does not produce false-negative results for hemoglobin in the presence of ascorbic acid.

pH

The kidneys, along with the lungs, are prime regulators of acid-base balance. Depending on the foods ingested, the state of health or disease, lung and renal function, medications being used, and a host of other issues, urine pH may vary from 4.5 to 8. pH is a measure of the hydrogen ion content of the urine. Acid urine, by definition, has a pH less than 7, whereas the pH of alkaline urine is greater than 7. The usual finding in freshly voided samples from normal patients is acidic urine with pH between 5 and 6. If fresh urine is allowed to stand at room temperature before analysis, the pH will change from acid to alkaline owing to the growth of bacteria and the breakdown of urea in the urine with the liberation of ammonia. The kidneys constantly regulate acid-base balance and tend to conserve various ions, especially sodium. This process is accomplished primarily by sodium reabsorption in the renal tubules with concomitant excretion of ammonium and hydrogenic ions (25). In metabolic acidosis such as occurs in diabetes, for example, the urine is acidic; in metabolic alkalosis, the urine is alkaline. Control of the urine pH becomes important in the treatment of certain diseases, such as renal stone formation and bacterial infections of the urinary tract. Maintaining alkaline urine provides a more effective environment for some antibiotic agents, and drugs that keep the urine alkaline therefore assist in the use of these agents. Renal calculi may form from soluble inorganic ions, and by controlling pH, the formation may be slowed or prevented (i.e., uric acid stones tend to develop in acid urine and calcium carbonate stones in alkaline urine).

Measurement of urine pH is facilitated by dipstick methodology and comparison with a color chart (26). Confirmatory testing may be performed with a pH meter, but this is usually not necessary. The pH pad is impregnated with two indicators, methyl red and bromthymol blue, which change color when immersed in urine. Two indicators are usually used to provide a broad range of color change, orange-green-blue. QA checks of pH dipsticks should be made regularly with known solutions (7,8).

Ketone Bodies

Ketonuria, or the presence of ketone bodies in the urine, occurs in conditions in which there is incomplete metabolism of fat. In normal metabolism, the body completely metabolizes fat to carbon dioxide and water. However, in disease conditions such as diabetes, especially when poorly controlled, the supply of carbohydrate

is ineffectually utilized, more energy from fat is required, and fat is frequently broken down as an energy source, with the products of fat metabolism appearing in the blood (ketosis) and urine (ketonuria). These intermediary products, which are formed in the liver, are called ketone bodies; they are acetoacetic acid, acetone, and betahydroxybutyric acid (15). The latter two are derivatives of acetoacetic acid. Nearly 80% of the ketone bodies found in the urine are betahydroxybutyric acid, with acetone accounting for only 2% and acetoacetic acid making up the remainder (10). Ketones are excreted in the urine along with basic ions, depleting the body of its anions and producing acidosis.

Diabetes is the most common disease in which ketosis and ketoacidosis are found, but there are many other conditions in which ketosis also occurs. Among the most important on a worldwide basis is starvation, but in the United States, ketosis is also produced in acute dieting. Under this condition, the body begins to break down its own fat surplus, which results in the production of ketone bodies. Other conditions in which ketones are found in the urine are anorexia nervosa, prolonged vomiting, and in several gastrointestinal diseases.

Dipstick testing for ketone bodies is based on the principle that both acetone and acetoacetic acid react with sodium nitroprusside in an alkaline buffer medium to produce a purple complex (Legal's test). Betahydroxybutyric acid does not react. When the color is fully developed, it is compared with a color chart to determine the amount present; the test is interpreted as trace (5 mg/dL) to 4+ (more than 100 mg/dL) (purple color) (10). Acetoacetic acid is the most sensitive reactant, and because the proportions of the three ketone bodies are similar in ketotic states, it is not clinically important that betahydroxybutyric acid is not measured.

Certain dyes, such as phthaleins, may produce a red color on the test pad. However, this color is different from the violet-purple of acetoacetic acid and should not be confused with it. Similarly, phenylketones may give an orange-red color that may be misinterpreted as a positive dipstick reaction. If the urine stands too long before analysis, there is a potential for ketones to be broken down by bacterial action and give a false-negative reaction. Specific chemical tests are available to measure individual ketone bodies, but these are rarely used today because they have little clinical importance.

Reagent tablet tests exist for the determination of urinary ketones and can also be used on serum samples (10). These tablets are sometimes used to follow the course of strict dieting or when the concentration of acetoacetic acid is so high that dilution is required for accurate estimation. In using this product (Acetest Reagent, Bayer), lactose is added to the other reactants on the test strip to provide enhanced color differentiation.

Bilirubin

Bilirubinuria, the presence of bilirubin in the urine, is an important early indicator of liver dysfunction and of intrinsic or extrinsic biliary obstruction. Bilirubinuria may be diagnosed before clinical jaundice appears. Bilirubin is formed from the breakdown of RBC hemoglobin. It attaches to albumin (indirect or unconjugated bilirubin) and is carried to the liver to be processed by the hepatocyte into a water-soluble form (direct or conjugated bilirubin). Unconjugated bilirubin is water insoluble and cannot be excreted by the kidneys because of its albumin binding and the fact that albumin is not generally filtered by the glomerulus. Conjugated bilirubin, on the other hand, is excreted in the urine because of its water solubility and ease of transport across the glomerular basement membrane (GBM). In normal circumstances, conjugated bilirubin never reaches the kidneys; it is entirely secreted into the bile after conjugation as bilirubin diglucuronide and then into the intestines, where it is broken down by bacteria into urobilinogen. In pathologic conditions, however, such as bile duct obstruction or hepatitis, conjugated bilirubin enters the bloodstream owing to very high concentrations of processed bilirubin and is then found in the urine because of its water solubility and ease of passage across the GBM (15).

Small quantities of conjugated bilirubin are normally present in urine (approximately 0.02 mg/dL), but concentrations this low are not detectable using ordinary dipstick methodology. Unconjugated bilirubin is not normally found in the urine. A crude but rapid method for the determination of bilirubin in urine is often performed by house-staff officers when they want a quick answer to the question of whether a patient is jaundiced. Because conjugated bilirubin is water soluble, vigorous shaking of the test tube containing the suspect urine will produce a yellow foam if increased quantities of bilirubin are present, whereas if the urine contains normal amounts of bilirubin, the foam will be white.

Methodology for the semiquantitative determination of conjugated bilirubin in the urine depends on the color produced by the reaction of a diazotized aniline dye and bilirubin; a purplish azobilirubin compound develops. Ictotest Reagent tablets (Bayer), utilizing similar diazotized dyes, are available for use to confirm dipstick results and are more sensitive than the dipstick pads and less affected by interfering substances (10). The exact aniline dye used in dipsticks varies with the manufacturer. Results are interpreted as negative to 1+ (small amounts of bilirubin) to 3+ (large amounts of bilirubin).

It is of considerable importance that the urine be tested for bilirubin immediately after voiding because bilirubin is unstable and breaks down rapidly, especially after exposure to light; prolonged exposure to room air will also cause the dipstick pad reaction to become negative owing to oxidation of the bilirubin to biliverdin, a substance that is nonreactive to the diazo dyes. False-negative results are obtained on the bilirubin pad when the tested urine contains large quantities of ascorbic acid (vitamin C) or nitrites (released because of bacterial growth).

Urobilinogen

Urobilinogen is also a product of hemoglobin metabolism and is formed with the degradation of bilirubin in bacteria in the intestine. Approximately one half of the urobilinogen is excreted in the feces and the other half is reabsorbed into the circulation from the intestines. This reabsorbed urobilinogen is then filtered by the kidneys and appears in the urine if increased in amount. In normal persons, only small amounts of urobilirubin are excreted in the urine daily, usually less than 4 mg; a random urine

sample contains 0.1 to 1 mg/dL. Serum and urine urobilinogen levels increase when there is increased bilirubin production. This may occur in severe liver disease such as cirrhosis or hepatitis (the liver cannot remove reabsorbed urobilinogen from the blood) and in hemolytic disorders (excess urobilinogen is produced in the intestines because of excessive bilirubin production and the liver cannot handle it all). Blockage of the biliary system, such as occurs in ampullary carcinoma or with gallstones in the common bile duct, does not lead to an increase in urine urobilinogen levels because bilirubin never reaches the intestinal tract where it can be broken down into urobilinogen.

The dipstick method for the detection of urobilinogen (Multistix, Bayer, Newbury, UK) makes use of the Ehrlich reaction; when urobilinogen is mixed with dimethylaminobenzaldehyde in an acid buffer, a tan to orange colored compound is formed (10)]. Using the Ehrlich reactants, some compounds other than urobilinogen (i.e., porphobilinogen, sulfonamides, and aminosalicylic acid) also produce a colored reaction and, if present, cause false-positive results. A relatively new and more specific method for the detection of urobilinogen utilizes a stable diazonium salt (4-methoxybenzenediazonium fluoborate) in an acid buffer. With the Chemstrip dipstick (Roche Diagnostics, Indianapolis, IN), a red azo dye color is produced when urobilinogen is present in excess (27). After the dipstick is immersed in urine, the color produced is compared with a color chart to interpret the urobilinogen concentration. No color development on the pad suggests that a normal amount of urobilinogen is present in the specimen (i.e., less than 1 mg/dL); development of significant color implies an abnormal concentration of urobilinogen in the urine. Compounds other than urobilinogen do not produce color on the pad.

False-negative results for urobilinogen can be obtained whenever the urine is allowed to remain in daylight for extended periods after voiding, as the urobilinogen breaks down. If formaldehyde is used as a urine preservative, it will inhibit the reaction and produce a false-negative result. Pharmaceuticals that contain azo dyes may mask the colors of the urobilinogen pad and lead to erroneous interpretations. Finally, the Ehrlich reaction may be inhibited by high concentrations of nitrites, a product of bacterial metabolism (11,28).

Determination of the presence of excess urobilinogen in urine in a jaundiced patient may be of primary importance in differentiating between obstruction of the biliary tract or upper intestines and hepatic or hemolytic disease. If the upper bowel or common bile duct is obstructed, bilirubin does not reach the intestines and urobilinogen is not produced and therefore is not found in the urine. Conversely, in the same conditions, bilirubin is greatly elevated in both serum and urine, and the bilirubin test pad will show a positive result.

Nitrite

This test provides an effective and rapid method for screening urine for the presence of a bacterial infection (29). The test is based on the principle that most bacteria found in urine have the ability to reduce urine nitrate, a plentiful constituent of urine, to nitrite. These organisms include *Escherichia coli*, *Klebsiella*, *Proteus*, *Staphylococcus*, and *Pseudomonas*, to mention a few that are frequent causes of urinary tract infections. The determination of clinical bacteriuria, is of major significance when culture shows the presence of more than 105 colonies per milliliter. Bacterial infections of the urinary tract are usually accompanied by the presence of large numbers of white blood cells (WBCs) in the urine, most often neutrophils. Occasionally, urinary tract infection may demonstrate no clinical symptoms; in these asymptomatic individuals, the urine examination is of prime importance in diagnosis and in the prevention of long-term complications, especially in the kidneys. Urine nitrite determinations are not designed to replace culture as a means of identification of specific organisms or to replace sediment examination to determine whether the bacterium is a contaminant. However, the nitrite test does serve as a valuable screening tool, along with the leukocyte esterase dipstick test, in defining whether a urinary tract infection is present (30). Concomitant negative dipstick results from both tests provide a predictive value of greater than 95% that culture for urinary tract infection will be negative (10).

The chemical basis of the nitrite reaction is that in an acid environment, nitrite reacts with an aromatic amine (sulfanilamide or *p*-arsanilic acid) to form a colored diazonium salt that in turn reacts with a hydroxybenzoquinoline to provide a pink color (Griess reaction). A positive reaction occurs when the bacterial content is greater than 10^5/mL. It is imperative that fresh urine samples are used when this test is interpreted to eliminate the possibility that the nitrate has been produced by bacterial contamination. First-voided morning specimens are best for detecting bacteruria. If bacterial infection is present in the urinary tract, a single dipstick test will be positive in 80% to 90% of patients when the first morning specimen is promptly examined (10). The nitrite test is qualitative, and any shade of pink produced is considered a positive result and indicative of bacterial infection of the urinary tract.

Negative test results for nitrite are found when the particular species of bacteria does not reduce nitrate in the urine. Therefore, a negative dipstick result when the patient is suspected of having an infection of the urinary tract should always be verified by urine culture and/or microscopy of the sediment. Fortunately, most bacteria that cause infections of the urinary tract are gram negative and are nitrite forming. However, yeasts and a significant number of non-nitrite-producing, gram-positive cocci may cause infections of the urinary tract and produce a negative nitrite dipstick reaction. False-negative results can also be caused by the presence of high levels of ascorbic acid and urobilinogen in the urine (27). Adequacy of diet, especially in vegetables, to allow sufficient nitrates to be formed is essential to the proper interpretation of this test. A diet deficient in vegetables may lead to erroneously false-negative dipstick reactions in urinary tract infections. Antibiotic agents may inhibit the growth of bacteria, even if present, and a false-negative test result is reported. False-positive results are obtained when various dyes, such as pyridium, discolor the strip test pad pink or red.

Leukocyte Esterase

Leukocyturia or *pyuria* is a valuable indicator of the presence of urinary tract inflammation (31,32). The relatively recent advent of an enzymatic test for the presence of leukocyte esterase has

provided a simple means for the detection of increased numbers of WBCs in the urine (27). Neutrophils are nearly always present in infections and inflammations of the kidneys and lower urinary tract. They are nearly always associated with bacterial infections and are thus found in the urine in these conditions in elevated numbers. WBCs are normally present in a centrifuged urinary sediment in relatively small numbers, usually fewer than five per high-power field (hpf). Counts of WBCs of more than 10 per hpf may be considered abnormal and should be investigated further (25). Pyelonephritis, cystitis, urethritis, renal calculi, interstitial nephritis, and glomerulonephritis all give rise to leukocyturia. On close examination, the WBCs are predominantly polymorphonuclear neutrophils (PMNs), although a scattering of other WBC types may be seen. Until the initiation of the leukocyte esterase test, the presence of leukocyturia was verified by microscopic analysis of the sediment (33).

The leukocyte esterase test is based on the release of the enzyme leukocyte esterase from neutrophils, on the ability of this enzyme to split an ester and form a pyrrole. Depending on the test, the pyrrole either reacts with a diazo compound to form a colored azo dye (Multistix) or becomes oxidized to form an indigo dye that then reacts with a diazo salt to form a colored reaction within 2 minutes (Chemstrip) (10,27). The color produced depends on the number of PMNs present in the urine. The sensitivity of the dipstick test has been adjusted to provide a negative reaction when fewer than five WBCs per hpf are present and a trace when there are from five to 15 WBCs per hpf. False-positive results are usually not seen, except when oxidizing agents have been mistakenly added to the urine container. Cells other than leukocytes that may be present in the urine, such as RBCs, epithelial cells, and bacteria, do not contain the leukocyte esterase enzyme in their cytoplasm and cannot produce a positive strip reaction. However, large numbers of eosinophils or a heavy infestation of the vaginal parasite *Trichomonas vaginalis* may provide sufficient esterase to give a false-positive result (10). False-negative results are found when there are high levels of vitamin C, oxidizing agents, formalin, or albumin in the urine (27). Mention should be made of the fact that the leukocyte esterase test may occasionally be positive even when neutrophils cannot be demonstrated in the urinary sediment. This may be owing to lysis of neutrophils in the urine before microscopic examination and release of their cytoplasmic contents. If such a circumstance occurs, a repeat of the urinalysis using a freshly voided specimen will usually reveal many intact WBCs in the sediment.

Specific Gravity

Waste product excretion and reabsorption of vital chemicals are two of the most important functions of the kidneys (25). A measure of their reabsorptive capacity provides a valuable test of renal function, and estimation of urine specific gravity provides just such a measurement. The specific gravity of a liquid provides an estimation of the density of the solid substances dissolved in it. As a measure of density, specific gravity varies according to the size and number of the particles present in the liquid. The specific gravity of urine is a useful indicator of the ability of the renal tubules to concentrate or dilute the urine. Normally functioning kidneys are able to alter the specific gravity of urine in a range of 1.003 to 1.035; early-morning urine specimens are usually more concentrated than random samples taken at various times during the day and tend to have specific gravity readings higher than 1.020, whereas urine voided at other times during the day, especially after ingestion of water and food, are lower. A specific gravity of more than 1.025 in a random urine sample serves as reasonably good evidence that the concentrating ability is preserved. Specific gravity may be at the upper end of the normal scale (i.e., greater than 1.025) in patients with congestive heart failure, severe liver disease, dehydration and vomiting, and diarrhea who have experienced severe water loss. Kidneys lose their concentrating abilities in severe end-stage renal disease; in these cases, the urine may have a “fixed” specific gravity near 1.010. Low values are also obtained in diabetes insipidus, in which antidiuretic hormone excretion is compromised.

The refractometer, which is temperature corrected, is the most accurate and widely used instrument for the estimation of urine specific gravity (6,7 and 8). It measures the amount of dissolved substances in a liquid by measuring the refractive index of the liquid. This task is performed by comparing the velocity of light in air with the velocity of light in the urine. Increases in the concentration of dissolved substances in a solution change the velocity of light penetrating the solution and therefore the angle of the light as it enters a prism. This angle is then converted to specific gravity by the use of standard scales. The most important advantages of the refractometer over the urinometer is that it can provide an accurate measurement of specific gravity with only a few drops of urine and that the instruments in current use are temperature corrected, facilitating standardization. When large amounts of protein or glucose are present in the urine, certain corrections are necessary to ensure accuracy because of the significantly increased density of the solution. Maintaining the refractometer requires little more than cleaning the glass prism and cover after each use (quality control procedures are considered elsewhere in this chapter).

Specific gravity can be estimated with a dipstick available from one manufacturer (Multistix, Ames Company, Elkhart, IN, U.S.A.) (10). This colorimetric method provides a fast and convenient way to estimate the specific gravity of urine without using a refractometer (34). Specific gravity estimation by dipstick is an indirect method in that it measures only ionized particles in urine. It is based on the principle that a change in ionic concentration of a solution initiates a change in the dissociation constant (pK) of pretreated polyelectrolytes (polymethylvinyl ether/maleic acid) embedded in the dipstick pad. This change is then detectable by the use of a pH indicator dye (bromthymol blue). The polyelectrolyte is sensitive to the electrolyte ions in solution in the urine; when these ions increase in number, the pK of the dipstick pad is decreased, thus reducing the pH. This pH change is reflected by a change in the color of the indicator on the dipstick pad, i.e., the indicator, bromthymol blue, changes from blue to yellowish-green (more acidic), and this transformation is directly related to specific gravity.

Another method to assess specific gravity is by the use of the “falling drop” procedure. This method is useful for equipment that automates the reading of dipsticks (e.g., Yellow IRIS, International Remote Imaging Systems, Chatsworth, CA); it is a more specific measure of specific gravity than the one provided

by refractometry. A water-immiscible silicon oil that has a predetermined constant specific gravity is utilized (10). As the urine drops in a carefully designed column filled with this oil, the time it takes for a urine drop to fall a given distance is determined; the falling time is accurately measured by electronic means and is then directly converted to specific gravity units.

Ascorbic Acid

Vitamin C is a frequently administered pharmaceutical that often interferes with several of the usual dipstick reactions (e.g., glucose, bilirubin, leukocyte esterase, hemoglobin, and nitrite). For this reason, it became important to develop a convenient means of testing for its presence in the urine so that if interference was suspected, alternate testing for specific substances could be initiated. Erroneous results should be suspected when a microscopic sediment evaluation shows RBCs but the dipstick is negative for hemoglobin. The various dipstick reactions are based on the powerful reducing property of vitamin C and the change in indicator dye color when this reduction occurs (10).

Phenylpyruvic Acid

It is clinically important to determine whether phenylpyruvic acid is present in the urine of very young infants because its presence is diagnostic of phenylketonuria (PKU) (15). PKU is an inherited metabolic disease in which there is absence of an enzyme, phenylalanine hydroxylase, that is necessary for the conversion of phenylalanine, present in milk, to tyrosine. In the absence of this enzyme, metabolites of phenylalanine, such as phenylpyruvic acid, accumulate and cause brain damage. Treatment is dietary with removal of foods and milk containing phenylalanine. If undiagnosed and untreated, PKU results in permanent brain damage and mental insufficiency, thus early diagnosis by screening urine for phenylpyruvic acid is an important preventive measure. Strip testing is available for the detection of phenylpyruvic acid (Phenstix) and when present, phenylpyruvic acid reacts with a buffered ferric ion solution on the strip to form a bluish-green reaction; the color develops in 30 seconds and is compared with a color chart for an estimate of the concentration of phenylpyruvic acid (10).

Miscellaneous Tests

Several other tests may be performed on urine samples using various technologies (10,11,15). Melanin may be present in the urine in metastatic malignant melanoma, and several different methods for its detection are available. Serotonin, a metabolite of tryptophan, is found in the urine of some patients with tumors of argentaffin cells (carcinoid tumors). Testing urine for its metabolite, 5-hydroxyindoleacetic acid, is a valuable means of diagnosing this condition. In porphyria, a group of inherited enzyme-deficient diseases of hemoglobin metabolism, intermediary metabolic products may appear in the urine. Specific methods for the detection of these products (i.e., porphobilinogen, uroporphyrin, and coproporphyrin) are available and should be utilized when a clinical diagnosis of one of the porphyrias is suspected because of the presence of such symptoms as skin lesions, photosensitivity, recurrent acute abdominal pain, neurologic symptoms, or urine that changes color in light.

MICROSCOPIC URINALYSIS

Part of "28 - Urine"

A microscopic evaluation of the urinary sediment often produces valuable information that provides the clinician with a more specific diagnosis or an assessment of therapy that could not otherwise be obtained if only a physicochemical examination of the urine were performed (35). Recent controversy concerning the cost efficiency of the microscopic part of the urinalysis procedure has centered on the relatively low rate of positive results from sediments in which the chemical examination was negative (33,36,37,38). Without debating this issue, it should be the responsibility of each laboratory to establish its own guidelines for urine analysis that include when to perform a microscopic evaluation; these guidelines should be based on sound scientific evidence (8). As a general “well-population” screening procedure, urine microscopics are not particularly cost effective; conversely, in a hospitalized population, especially in patients on urology or general medical wards, this part of the examination has been shown to be very valuable.

The microscopic urinalysis procedure is quite simple and requires little additional equipment other than what is ordinarily found in any well-equipped laboratory, i.e., a calibrated centrifuge, a modern, clean binocular microscope, and a means of ensuring that strict QA procedures are followed (7). There is no substitute for experience and training on the part of the technologist or physician for accurate sediment evaluation (35). Constituents in the sediment can be varied, and accurate interpretation often depends on previous experience. Some have advocated not centrifuging the urine when doing a microscopic examination (a common practice in England), this author does not. Centrifugation of 10 or 12 mL of urine at a constant time of 5 minutes and a relative centrifugal force (RCF) of 400 to 500 is standard practice in the United States (11,25). The sediment is produced at the bottom of the centrifuge tube. Several commercial products offer a system for processing urine to obtain a sediment; these all yield a constant volume of sediment admixed with urine so that an aliquot may be decanted and then viewed with a microscope (25). As an example, if the initial volume of urine is 12 mL and the volume of the sediment remaining after decanting the supernatant urine is 1 mL, the resulting concentration of the sediment is 12:1. If a specific system is utilized, the use of one in which the concentrated sediment is pipetted into a constant-volume chamber on a microscopic slide is highly recommended. In such instances, this procedure ensures that the volume of the concentrated urine observed in the chamber will be constant from patient to patient and from day to day—an important consideration in QA (6). Because constant volumes of urine are used, when sediment elements are recognized, these can be quantitated on a volume basis (i.e., numbers per milliliter) rather than as numbers per microscopic field. Before the advent of constant-volume slide chambers, the usual procedure for microscopic examination of the urine was to place a drop of the concentrated centrifuged urine sediment onto a glass microscopic slide and observe it with a microscope. Great discrepancies

could be found in the quantitation of the elements because of the variability of the size of the urine drop and the weight of the coverslip. The use of a standardized system for this examination permits much greater consistency in the reporting of results.

Centrifugation at an RCF of 400 to 500 for 5 minutes produces a concentrated sediment in which all elements present may be easily found and are not artifactually distorted by compacting during centrifugation (8). Because most modern centrifuges can be adjusted for revolutions per minutes (rpm) but not for RCF, the following formula, which takes into consideration the radius of the centrifuge head, is used.

$RCF = 1.118 \times 10^{-3} \times \text{radius of centrifuge head (in cm} \times \text{rpm}^2)$

Normal Urinary Sediment

Recognition of sediment elements depends on having a "good eye," knowing what should be present in normal urine, and being able to define accurately and contrast the normal with the potentially abnormal. The appearance of some particles or elements in the urine may be normal. These can be blood cells, cells lining the urinary tract, mucous secretions of glands, cylindrical proteinaceous particles that have formed in the nephron (casts), crystals that have formed in the urine, and foreign cells (e.g., spermatozoa in a woman), microorganisms, or contaminants (Table 28.2) (13,25,35). Each of these constituents is discussed separately.

TABLE 28.2. CONSTITUENTS OF NORMAL URINE SEDIMENT

Cells	Crystals	Casts	Other
Blood cells	Acid urine	Hyaline	Mucus
Red	Amorphous	Granular	Sperm
White	Uric acid		Microorganisms
Epithelial cells	Neutral urine		Bacteria
Squamous	Calcium oxalate		Fungi
Urothelial	Hippuric acid		Contaminants
Renal tubular	Alkaline urine		Fibers
	Triple phosphate		Pollen
	Ammonium biurate		
	Calcium carbonate		

Blood Cells

Erythrocytes (RBCs) and leukocytes (WBCs) may be found in small numbers in the normal sediment. Both of these cells may pass through the glomerulus and enter the urinary flow. Quantitation of these cells over a period of time, such as 12 hours, is rarely performed today because of the great variation in cellular excretion from person to person and the difficulties associated with the collection of the urine and the counting technique (Addis count; a hemocytometer counting chamber is utilized) (39). A disease-free individual may eliminate as many as 750,000 RBCs and 1,750,000 WBCs in 12 hours.

RBCs

In urine sediment obtained from a disease-free person, small quantities of erythrocytes may be present (Fig. 28.1); these vary in number from none per hpf to as many as five per hpf (35). The usual normal sediment will contain an occasional RBC per every other field; counts greater than five per hpf should be thoroughly investigated and an explanation for the hematuria sought. Microscopically, the RBCs appear similar to those found in the peripheral blood, i.e., biconcave disks that have a pale faint orange color confirming their hemoglobin content (Fig. 28.2). In hypertonic urine, RBCs may be crenated and in hypotonic urine they may swell, become spherical, and, in time, burst, leaving only the cell membrane or "ghost" visible. Small globules of oil may simulate the appearance of RBCs. The oil is frequently from the skin of the microscopist. Oil droplets may be differentiated from RBCs based on varying size, absence of hemoglobin, and a spherical rather than biconcave disk shape.

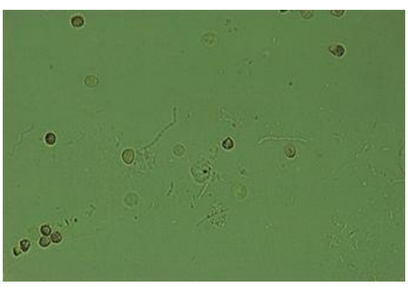

FIGURE 28.1. Red blood cells (RBCs) and bacteria in urine sediment. This field contains a scattering of RBCs and bacillary forms. This is slightly more than the usual number of RBCs one would expect to find in a high-power field and would generally warrant further investigation. Two leukocytes are also present in the center of the field. (Bright-field microscopy, ×160.)

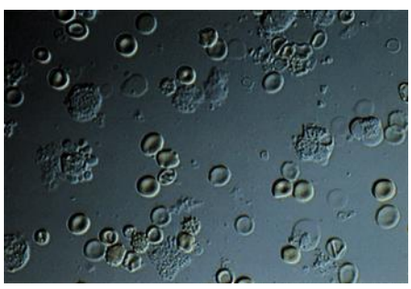

FIGURE 28.2. Polymorphonuclear neutrophils and red blood cells (RBCs) in urine. This unstained photomicrograph vividly demonstrates the biconcavity of RBCs and the multilobed nuclei and granular cytoplasm of the neutrophils. A few RBCs are crenated. (Interference-contrast microscopy, ×200.)

WBCs

WBCs are frequently found in the normal urine sediment, but are few and should not exceed five per hpf (13,25). Although all

the WBC types that appear in the peripheral blood may also be found in urine (i.e., lymphocyte, monocyte, eosinophil), the most common cell present is the PMN. In fact, it is unusual to find any leukocyte other than a PMN in a normal person's sediment. PMNs have a phagocytic function, are actively motile, and move by means of ameboid action with the extension of pseudopods. Leukocytes measure 10 to 20 µm in diameter, with lymphocytes being on the lower end of that range and PMNs at the upper. PMNs are readily recognized in urine because of their multisegmented nuclei and their granular cytoplasm in which brownian movement is often noted.

Staining the sediment enables the observer to identify PMNs more readily because the multilobed nucleus is clearly apparent and confusion with nonleukocytic cells, such as RTE cells, is less likely. Differential staining with Wright's or Giemsa stain provides an accurate means of identifying the various other leukocytes, such as lymphocytes and eosinophils (35). This becomes important when there is an increase in WBCs but is unnecessary in the normal sediment evaluation.

Epithelial Cells

Normal urine contains three main varieties of epithelial cells: renal tubular, transitional (urothelial), and squamous (35). These cells provide the lining for the urinary tract and comprise the tubules of the nephron. Table 28.3 lists some differentiating features of each type of epithelial cell.

TABLE 28.3. EPITHELIAL CELLS OF URINE

	Renal Tubular	Urothelial	Squamous
Origin	Nephron	Renal pelvis, ureter, bladder, proximal urethra	Terminal urethra vagina
Size (µm)	15–25	20–30	30–50
Shape	Polyhedral	Polyhedral, “tadpole”, spherical	Flattened
Other	Microvilli if from proximal tubule		

Renal Tubular Epithelial Cells

RTE cells are infrequently present in the urine sediment in the normal person (zero to one per five hpf). When observed, they are usually single but may also be found in pairs. If a microvillus border is present, their origin can be presumed to be the proximal tubule. Specific immunohistochemical identification may be made, when warranted, by means of acid phosphatase staining, because the RTE cells have a high intracellular content of this enzyme (35). Their shape is most often polyhedral, but they may also be somewhat flat, indicating that they originate from the loop of Henle. Their nucleus is usually eccentric but may be central; it is spherical with nucleoli readily apparent if there are no autolytic changes. In some disease states, primarily those that affect the tubular portions of the nephron, the number of RTE cells in the sediment may be significantly increased.

RTE cells are normally found in the urine because of the constant process of tubular cell renewal and regeneration. In a renal biopsy, tubular lining cells show frequent mitotic activity; the older cells are sloughed into the urine flow and may then be seen in the sediment after having been replaced by the newly fashioned cell. This type of cell regeneration occurs in the most proximal, rather than the distal, nephron.

Transitional Epithelial Cells

These cells (also called urothelial cells) constitute the lining epithelium for a large portion of the urinary tract and are frequently present in the sediment (zero to one per hpf) owing to their high turnover rate. Transitional epithelium is stratified and ordinarily several cell layers thick. Only the most superficial cells are found in the urine and these take three main shapes: spherical (Fig. 28.3), polyhedral, and “tadpole.” Transitional cells have the peculiar characteristic of being able to absorb water and thus swell to as much as two times their original size when they acquire a spherical contour (25). Polyhedrally shaped transitional cells may present difficulties in differentiation from RTE cells if they have no microvillus surface and have a central rather than an eccentric nucleus. The cytoplasm of transitional cells does not contain large quantities of acid phosphatases. Tadpole-shaped urothelial cells are frequently observed in urine. They probably derive from the mid-stratification layers of the transitional epithelium (13). Tadpole transitional cells appear in groups or pairs, as well as singly. Their nucleus is usually central, and they have a fusiform-shaped cytoplasm. Transitional cells increase in number in the urine in certain inflammatory conditions affecting the urinary tract.

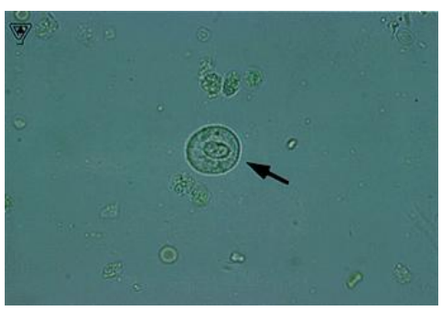

FIGURE 28.3. Transitional cell (*arrow*) and occasional red and white blood cells in urine. Note the spherical shape and central nucleus of this cell. (Bright-field microscopy, ×160.) (From the College of American Pathologists, with permission.)

Squamous Epithelial Cells

Squamous epithelial cells are the easiest of all the epithelial cells to recognize in urine because they are large, flat, and frequently encountered (Fig. 28.4). In a well-collected midstream “clean-catch” specimen, there should be few of them (i.e., fewer than one per hpf). Numerous squamous cells in urine from a female patient usually indicate vaginal contamination. Squamous epithelium normally lines the terminal third of the urethra in both men and women, and it is also the epithelium that lines the vagina. Clean-catch urine collection is more difficult to achieve in women than in men, and contamination with vaginal fluid

and cells is common, especially when the patient has not been instructed previously on how to collect the specimen properly (8).

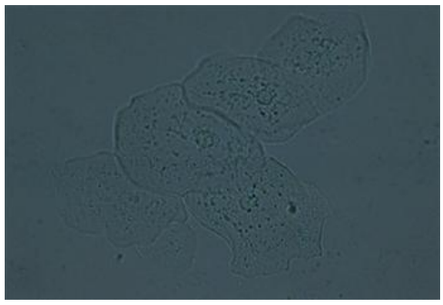

FIGURE 28.4. A group of squamous epithelial cells in urine. The cells are large and flat and have some granules in their cytoplasm. The central nucleus is approximately the size of a large lymphocyte. (Bright-field microscopy, ×160.)

Crystals

Finding crystalline forms in urine sediment is common if the urine has been allowed to stand after voiding, but this finding is infrequent in fresh urine. The formation of crystals is related to the concentration of various salts in the urine, which, in turn, is related to the patient's metabolic state, diet, and fluid intake as well as to the effects of the changes that occur in the urine after voiding (i.e., changes in pH and temperature, which change the solubility of salts in the urine and promote crystal formation). Because the kidneys play a major role in metabolite excretion and the maintenance of homeostasis, the end products of metabolism are found in high concentrations in the urine, and these tend to precipitate and form crystals (10). The pH of normal urine varies from acid to alkaline, and some crystals are associated with an acid pH, whereas others may be more commonly found in alkaline urine (25). There are relatively few crystals associated with a normal state, and the student is well advised to become aware of their various morphologic forms and characteristics. Most normally occurring crystals have little if any pathologic significance. The more common varieties are described here. In a later section of this chapter, several types of abnormal crystals are considered.

Uric Acid Crystals

Uric acid, a metabolic product of protein breakdown, is present in the urine in high concentrations and commonly produces a wide assortment of crystalline structures. Amorphous urates may be described as granular, birefringent, colorless to pale yellow crystals without a particular microscopic structure; they appear as fine granules when observed with the 10× or 40× microscopic objectives (Fig. 28.5). These crystals frequently develop when urine has been refrigerated, and they may be so plentiful that they obscure any other sediment elements present. When urine is prepared for microscopic examination, these crystals are noted as the compacted “pink button” of sediment at the bottom of the centrifuge tube. Most amorphous urates dissolve when alkali is added to the sediment or when the urine is warmed (to at least room temperature) after refrigeration.

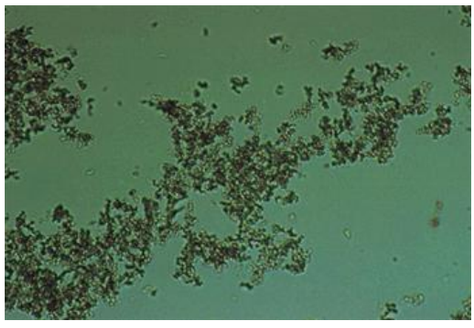

FIGURE 28.5. Amorphous urate crystals in urine. (Bright-field microscopy, ×160.) (From the College of American Pathologists, with permission.)

Uric acid crystals are among the most pleomorphic of all urine crystals; they assume a variety of forms, including rods, cubes (Fig. 28.6), rosettes, six-sided plates, rhombi, and a whetstone shape. They are strongly birefringent and vary greatly in size. Uric acid crystals are soluble in alkaline solutions and insoluble in acid (15). They are colorless to pale yellow to pinkish brown. Uric acid crystals have been associated with renal stones, but their presence in the urine in the normal person is so common that this association has little if any clinical significance.

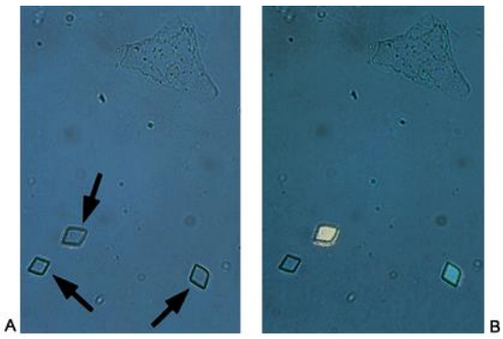

FIGURE 28.6. Uric acid crystals (*arrows*) and squamous cell. In this view, the urate crystals are rhomboid **(a)** and display anisotropism under polarized light **(B)**. (Bright-field microscopy and polarization, ×80.) (From the College of American Pathologists, with permission.)

Other urate salts may form crystals in the urine, i.e., sodium and potassium urates. These can be seen as colorless, needle-shaped crystals and brownish spherules, respectively. Addition of a drop of glacial acetic acid to a wet mount exhibiting the latter spheroids results in their transformation into more usual rhombic and whetstone plates.

Calcium Oxalate

Calcium oxalate crystals are the next most frequently observed in both acid and neutral urine (Fig. 28.7). The most common variant of this crystal is the dihydrate form, a colorless, octahedral crystal with the appearance of an envelope (35). Crystals of this type are found in abundance in the urine of otherwise normal individuals, especially after ingestion of ascorbic acid in large doses or foods rich in oxalic acid such as tomatoes or asparagus. Also intermittently encountered in otherwise normal urine are monohydrate forms, which appear elliptical or dumbbell shaped depending on whether viewed flat or on edge (Fig. 28.8).

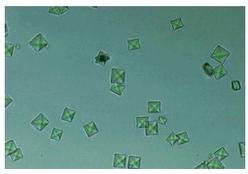

FIGURE 28.7. Calcium oxalate crystals, dihydrate forms. Their square shape and "star," "envelopelike" appearance are characteristic. (Bright-field microscopy, ×160.)

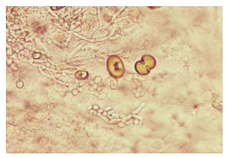

FIGURE 28.8. Bile-stained, calcium oxalate crystals, monohydrate forms. Note oval appearance when lying flat, dumbbell shape when on edge. From urine of severely jaundice patient. (Bright-field microscopy, ×160.)

Hippuric Acid Crystals

Although they are not often diagnosed in urine, hippuric acid crystals are also associated with a neutral pH. These crystals are usually seen as colorless, elongate prisms with pyramidal ends; they may also be thin and needlelike. They are birefringent and associated with diets high in fruits and vegetables that contain large quantities of benzoic acid (10,11).

Amorphous Phosphate Crystals

Crystals derived from phosphates are the most frequently observed crystals associated with alkaline urine. The most common of these is the amorphous phosphate crystal. Microscopically, these cannot be distinguished from amorphous urate crystals present in acid urine. They are fine, granular, birefringent crystals that produce a white precipitate in the bottom of the centrifuge tube. They may also obscure other sediment elements because they are often formed in large quantities.

Triple Phosphate Crystals

Triple phosphate (ammonium-magnesium phosphate) crystals are birefringent crystals that assume a "coffin-lid" appearance (Fig. 28.9). They are usually colorless and birefringent and vary greatly in size. The crystals may also be found in neutral urine and are soluble in acetic acid.

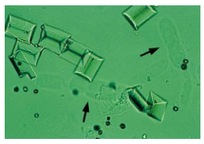

FIGURE 28.9. Triple phosphate crystals in urine. Hyaline casts (*arrows*) are seen in the background. (Bright-field microscopy, ×160.) (From the College of American Pathologists, with permission.)

Occasionally found in otherwise typically alkaline urine are "star" forms or large polyhedral clear plates resembling the shapes of U.S. states (40).

Ammonium Biurate Crystals

Ammonium biurate crystals have a peculiar crablike or "thorn apple" shape (Fig. 28.10). They are yellowish brown and often demonstrate radial or concentric striations in central spheres with radiating "arms" or spicules. They are usually found in urine with a neutral pH and are soluble in sodium hydroxide. They are rarely encountered in normal urine.

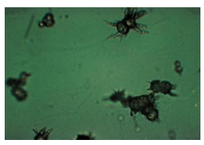

FIGURE 28.10. Ammonium biurate crystals in urine. These "crab-shaped," spiculated crystals are characteristic and are associated with alkaline urine. (Bright-field microscopy, ×400.) (From the College of American Pathologists, with permission.)

Calcium Carbonate Crystals

Calcium carbonate crystals are small spherules of dumbbell-shaped birefringent crystals found in alkaline urine (Fig. 28.11). Because of their small size, they are often mistaken for bacteria. A ready means of differentiation is by the use of polarization, since bacteria are not birefringent. These crystals dissolve in acetic acid and, in the process, effervesce.

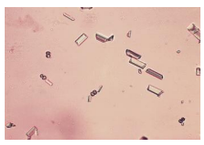

FIGURE 28.11. Dumbbell-shaped calcium carbonate crystals shown here with small triple phosphate crystals (Bright-field microscopy, ×160).

Casts

Urine casts are defined as cylindrical microscopic structures that form in the distal nephron and occur in the urine in both health and disease (41). These "cylinders" are composed primarily of a

kidney-specific protein that is produced only in the distal tubule and collecting duct of the nephron (THM) (42,43). As THM is excreted by the cells lining the distal tubules and collecting ducts, events occur in the glomerular filtrate in the lumen of the nephron that induce this soluble protein to become insoluble and to form thin, proteinaceous bands that may then coalesce or be molded into a cast. The cast formed represents an exact model of the shape of the lumen of the renal tubule in which it originated, much as a mold of gelatin assumes the exact shape of the container in which the liquid gelatin is placed. In experimental studies, changes in particular physical factors are necessary to induce soluble THM to become fibrillar. These include changes in urine flow, ionic strength, concentration, salinity, and pH of the glomerular filtrate. It is likely that in both normal and disease states, similar changes occur in human urine, especially in physiologic stress, which induces previously soluble THM to become insoluble and to form fibrils, which then coalesce into casts.

The classification of renal casts is simple and based on morphologic appearance (Table 28.4) (41). In the normal state, only two varieties of casts appear in the urinary sediment: hyaline casts and granular casts (18). Any additional cast forms must be considered “abnormal” and are most often associated with generalized metabolic or intrinsic renal diseases. Each cast type is discussed separately in detail. Casts, in contrast to cells, are quantitated in the sediment as number per low-power microscopic field (lpf).

TABLE 28.4. CLASSIFICATION OF URINARY CASTS

Acellular Casts	Cellular Casts
Normal	Normal
Hyaline	None
Granular	None
Abnormal	Abnormal
Hyaline	RBCs
Granular	WBCs
Waxy	Epithelial (RTE)
Pigment	Fatty/oval fat bodies
Fatty	Bacterial/fungal

RBC, red blood cells; WBC, white blood cells; RTE, renal tubular epithelial.

In the normal person, the presence of small numbers of hyaline or granular casts in the urine is a frequent occurrence and does not ordinarily present diagnostic difficulty or necessarily imply renal disease. The microscopist usually scans the sediment using the 10× objective, and occasionally casts are found, somewhere on the order of one or two per 10 lpf. These two forms of casts have a low refractive index and are therefore somewhat difficult to see with the ordinary light microscope unless the contrast is enhanced. Stopping down the iris diaphragm on the condenser while lowering it and keeping the light intensity the same will produce the optimal contrast for this observation. A quick scan of the entire microscopic slide will reveal whether any casts are present and their numbers; subsequent specific identification can be made using the 10× or 40× lens.

Hyaline Cast

This is the most frequently observed cast in the urine. It is typically translucent and somewhat difficult to see because of its low refractive index. Careful inspection reveals a smooth outer perimeter and a matrix that is most often smooth but may be wavy (Fig. 28.12) (44). Occasional granular inclusions may be present in the matrix, and sometimes a cell or two may also be seen. The cast may have one end that, instead of being curved, is drawn out into a “tail” or point. In the past, these casts with tails were called *cylindroids*; this term is considered antiquated and is not commonly used today (Fig. 28.13).

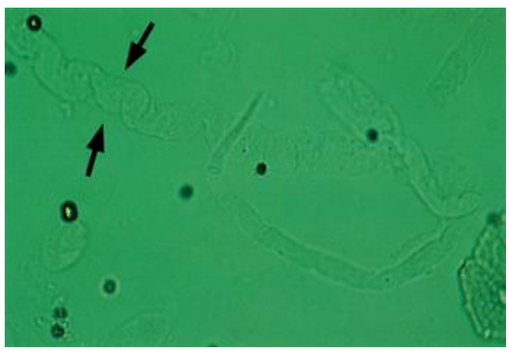

FIGURE 28.12. Hyaline casts. These translucent, colorless proteinaceous structures (*arrows*) are frequently found in normal urine sediment. Their low refractive index makes them difficult to discern using ordinary bright-field microscopy (× 100). (From the College of American Pathologists, with permission.)

FIGURE 28.13. Urine cylindroid, a hyaline cast with a tail. The term cylindroid is antiquated. (Interference-contrast microscopy, × 160.)

Staining the sediment or using phase microscopy (45) is very helpful in the identification and quantitation of all casts but is especially useful for hyaline casts in particular; with ordinary bright-field microscopy and an unstained sediment sample, hyaline casts are somewhat difficult to find.

The effects of stress and strenuous physical exercise on the production and appearance of hyaline casts (also granular casts) in the urine have been well documented (18). Running a mile race or participating in a vigorous physical sport may induce the production of a large number of these casts (46). Stressful emotional situations, such as having to take an examination, can invoke the same phenomenon. Despite obsolescence of the term

cylindroids, the term *cylindruria* lives on. It simply connotes increased numbers of casts in urine. When a patient has undergone physical or emotional stress within the previous 24 hours, cylindruria should not be considered pathologic. In such instances, the urine reverts to a normal state within 24 to 48 hours if the stressful situation or the physical exercise has stopped (18).

Granular Cast

This cast may also be observed in increased numbers in the urine if the patient has been involved in an emotionally stressful situation or has undergone recent strenuous physical exercise (18,35). Compared with hyaline casts, granular casts are found in a ratio of approximately four hyaline to each granular. On removal of the stress or ending the exercise, the number of granular casts in the urine returns to normal within 24 to 48 hours. The reasons for the increased production of these casts in stress or exercise are unknown. Also unknown is the reason why granular casts sometimes appear in the urine of patients on diets rich in carbohydrates.

Granular casts have a higher refractive index than do hyaline casts and are therefore easier to find. They are also cylindrical, although some may have "tails," and have a smooth, well-defined perimeter. Generally, in the normal person, granules covering the cast surface are small and regular (Fig. 28.14). The origin of these granules in the normal person appears to be, at least in part, intracellular lysosomal particles that are expelled into the urine as metabolic products of the renal tubular epithelium (44,47). When in the urinary flow, the lysosomal granules are incorporated into a preformed hyaline cast matrix and thereby transform a previously smooth-surfaced hyaline cast into a granular cast.

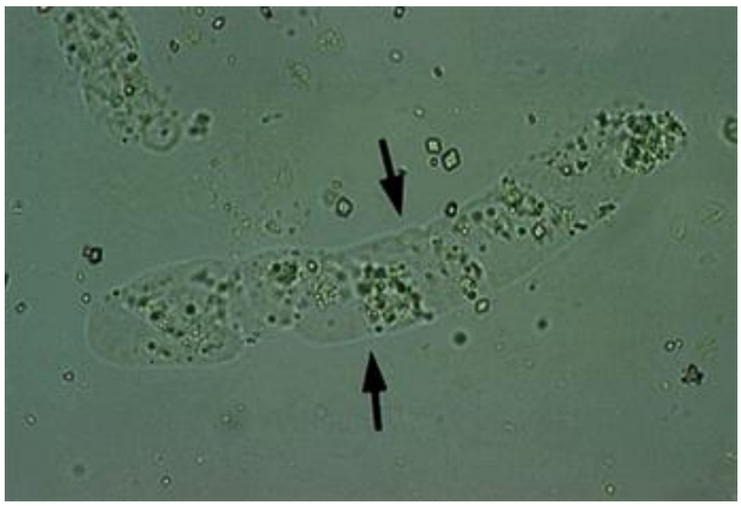

FIGURE 28.14. Granular cast. This type of cast is fundamentally a hyaline cast to which granules have attached along its surface. In the example shown here (*arrows*), the granules do not cover the entire surface of the cast but are relatively evenly dispersed. (Bright-field microscopy, ×160.) (From the College of American Pathologists, with permission.)

Mucus

It is thought that various glands that line the genitourinary tract, such as those in the prostatic urethra and urinary bladder, secrete this mucopolysaccharide into the urine. In addition, recent immunologic studies showed that at least some of the mucus present in the urine is in fact THP, a specific immunoprotein secreted exclusively into the nephron by the distal tubule and collecting duct lining cells (43). The clinical significance of THP in the urine is unknown. When large quantities of mucus are present in the sediment, vaginal secretions may contaminate the specimen.

Mucus is a low-density substance that is often difficult to see unless sufficient contrast has been obtained with the microscope. It appears as thin, fibrillar, wavy, fiberlike bands or lines across the field that have no particular form or shape (Fig. 28.15). The inexperienced observer may sometimes confuse mucus with a hyaline cast because of coalescence of the individual ribbons into what may at first glance appear as a cylindrical object. Mucus has a low refractive index and is not birefringent. Sometimes cells or microorganisms may get caught in it.

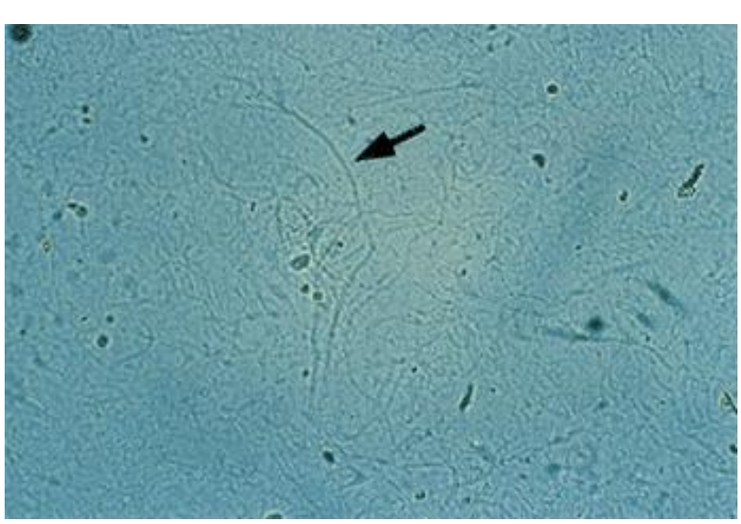

FIGURE 28.15. Mucus threads in urine. Thin, fibrillar mucus is a common feature of urine sediment and should not be confused with cast structures because these threads do not acquire a cylindrical form. (Bright-field microscopy, ×112.) (From the College of American Pathologists, with permission.)

Microorganisms

Bacteria (Fig. 28.1) and occasionally yeast (Fig. 28.16) are often found in what is considered normal urine (48). Theoretically, at

least, microorganisms should not be part of the normal sediment. However, they are commonly found in normal urine because collection of the sample is performed without the use of adequate or effective precautionary techniques that would ensure that no (or few) organisms contaminate the specimen. Additionally, collection systems frequently used to collect and transport the urine for examination are not sterile and may also serve as a source of microbiological contamination.

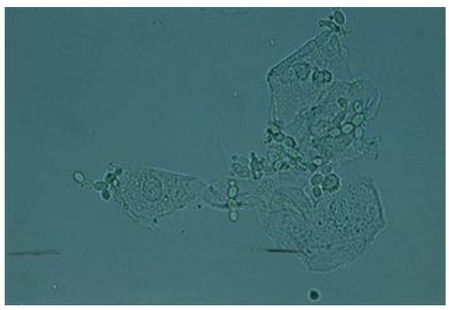

FIGURE 28.16. Budding yeast forms and squames in urine. When not accompanied by leukocytes, yeast forms are most likely growing contaminants, rather than pathogenic. They appear as spherical to elliptical transparent microorganisms approximately the same size as a red blood cell, with which they may be confused. (Bright-field microscopy, ×160.)

Urine is an excellent culture medium in which microorganisms grow with great rapidity. Therefore, when bacteria or yeast forms are present in the sediment and are unaccompanied by PMNs, they are most likely the result of contamination of the specimen. The bacteria may be either cocci or bacilli; yeasts often show budding but no hyphae.

Having stated that normal urine should ordinarily be sterile, one qualifying statement may be made: bacteria normally inhabit the distal urethra. Therefore, should a sample consist of the first part of the voided specimen, rather than a midstream collection, one might expect to find a few bacterial forms in the sediment. This occurrence is more common in women than men because a urine sample obtained from a female patient is more likely to be contaminated than one received from a male patient.

Spermatozoa

Spermatozoa are frequently found in male urine but may also be present in female urine (Fig. 28.17). Because urine is naturally spermicidal, the sperm are usually nonmotile when found, except when ejaculation and/or intercourse occurred very recently. The presence or absence of spermatozoa in the urine of a woman has been used as evidence in rape cases but is not a reliable determinant of the actual time of the rape.

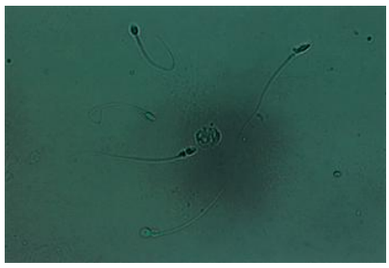

FIGURE 28.17. Spermatozoa. Several sperm are present around the neutrophil in the center of the field. Sperm can normally be found in urine from both men and women. (Bright-field microscopy, ×200.)

Contaminants and Artifacts

Contaminants, especially fibers, appear in abundance in urine sediments. The importance of the correct recognition of these substances, fibers (Fig. 28.18), pollen grains, plant cells, starch granules (Fig. 28.19), or other substances, is that they must not be mistaken for actual constituents of the sediment and result in an incorrect diagnosis. To avoid these errors, it is important to keep in mind the following: (a) most fibers and other contaminants have a high refractive index and are easily seen, whereas most actual constituents of the sediment are much more difficult to detect; (b) many artifacts and contaminants are far larger than any sediment element and can be differentiated by size alone; and (c) plant and synthetic fibers nearly always show birefringence with polarized light (Fig. 28.18), whereas urine casts do not (except fatty casts, which do not look like fibers). In general, the best and most effective means of avoiding a misdiagnosis owing to a contaminant is to be certain about the appearance of and the ways to identify normal sediment elements. If what is seen does not fit the normal pattern, the structure is either abnormal or a contaminant.

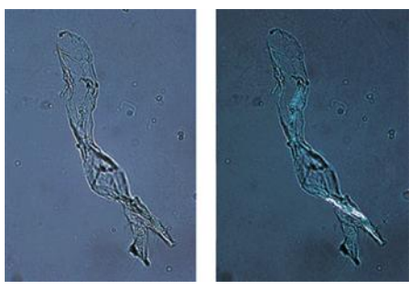

FIGURE 28.18. Fiber in urine. Fiber artifacts are frequently present in urine sediment and should not be confused with “real” elements that may be pathologic. Polarization will usually reveal their true characteristic as they display anisotropism. (Bright-field microscopy and polarization, ×80.) (Reproduced by permission from the College of American Pathologists.)

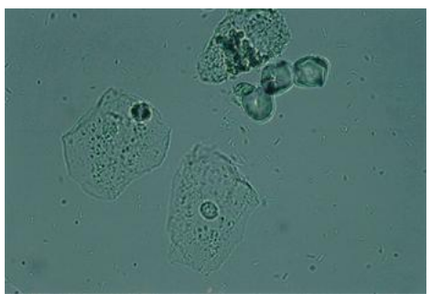

FIGURE 28.19. Starch granules in urine. These highly refractile, irregularly shaped, dense granules are easily identified in urine and are commonly found because starch is the material used to powder latex gloves and to dry the skin (i.e., baby powder). They are birefringent. In this field, three squamous cells and bacteria are also present. (Bright-field microscopy, ×160.)

Abnormal Urinary Sediment

When the normal contents of urinary sediment can be recognized, it is not particularly difficult to identify deviation from normal and make a diagnosis of abnormal. Most frequently, abnormal sediment is defined by an *increase* in the number of cells or casts present, not by an alteration in the type of cell or cast. However, different sediment elements are found in the urine in various disease states, and each of these is discussed in this section (Table 28.5). It should be noted again that there are often subtle differences between normal and abnormal, and when these differences depend on quantitative or semiquantitative measurements, as in cell and cast counting, the examiner must be especially careful to produce results that are consistent, accurate, and reproducible.

TABLE 28.5. CONSTITUENTS OF ABNORMAL URINE SEDIMENT

Cells	Crystals	Casts	Other
Blood cells	Acid urine	Acellular	Parasites
Red	Bilirubin	Hyaline	
White	Cholesterol	Granular	
Epithelial cells	Cystine	Waxy	
Renal tubular	Leucine	Fatty	
Oval fat bodies	Tyrosine	Cellular	
	Hemoglobin	RBCs	
	Drug-related	WBCs	
		Bacterial	
		Epithelial	
		Crystal	

RBCs, red blood cells; WBCs, white blood cells.

Blood Cells

Erythrocytes and leukocytes are increased in number in urine in many diseases. The patient may report having “smoky” urine if hematuria is present or of having a foul-smelling, “white” urine if pyuria is the cause. In each instance, a careful examination of the sediment is needed with a quantitation of the number and type of blood cells present. RBCs or WBCs in quantities greater than five per hpf should be considered abnormal (35).

RBCs

Hematuria accompanies many clinical conditions (Fig. 28.20). However, the most frequent cause is not pathologic but represents contamination of the urine with menstrual blood. One of the first questions to ask when hematuria is encountered in an adult premenopausal female is whether she is having her period. A subsequent urinalysis, when the urine has been collected after appropriate patient instruction and preparation, will produce a normal number of red blood cells in the sediment if menstrual contamination is the cause of the hematuria.

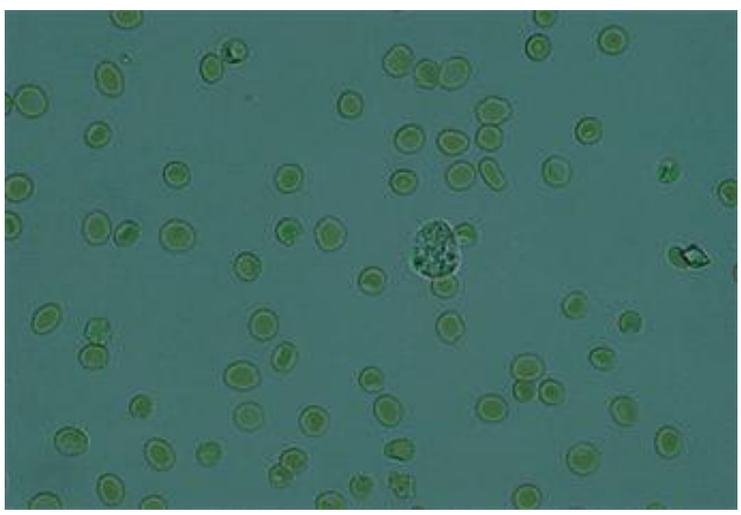

FIGURE 28.20. Hematuria. This field shows a large number of red blood cells (RBCs) accompanied by one polymorphonuclear neutrophil in the sediment. Note that the RBCs appear to be regularly shaped, biconcave disks. (Bright-field microscopy, ×160.)

Another common cause of hematuria is related to exercise. Contact sports such as football, boxing, wrestling, and ice hockey may cause trauma to the kidney or bladder and induce

hematuria. This is usually self-limited and disappears after a day or 2. The terms *pseudoathletic nephritis* and *sports anemia*, coined in the 1950s, have been used to describe the findings in patients with hematuria, and sometimes hemoglobinuria, after strenuous physical exercise (49,50). Before it was recognized that this was an unusual, but not pathologic, response to exercise, many dollars were spent on medical workups of patients presenting with these symptoms. It has been shown that the hematuria in these patients is induced by the stress of the exercise and/or the trauma associated with the constant pounding of bladder urine against the bladder wall, irritating and traumatizing the lining to the point that bleeding into the urine occurs. In addition, the continual pounding of the feet of runners against the pavement causes the RBCs in the foot capillaries to be crushed and rupture, thus releasing their hemoglobin into the circulation where it is then cleared by the kidneys and found in the urine. Abatement of the exercise in these cases produces normal urine within 48 hours.

Medical causes of hematuria include glomerulonephritis, pyelonephritis, cystitis, and neoplasms of the kidney and urinary tract, among others. The hematuria may be microscopic, usually less than 20 RBCs per hpf to gross or macroscopic, more than 50 RBCs per hpf. In bladder or renal cell carcinoma, microscopic hematuria is often an early and important finding that is manifested during a routine laboratory workup in an asymptomatic patient.

Dysmorphic erythrocytes have been described when the hematuria originates in the kidneys (51). These deformed RBCs become an important indicator of intraglomerular hemorrhage and are often overlooked by the inexperienced observer. When dysmorphic RBCs are seen, they are easily recognized. Dysmorphic RBCs have been bent out of shape and into peculiar angles but are not disrupted. In other instances, dysmorphic red cells exhibit one or more budding excrescences such that some manifest a “Mickey Mouse” configuration (Fig. 28.21a and Fig. 28.22). The peculiar contortions of the red cells are thought to be caused by squeezing through a damaged GBM.

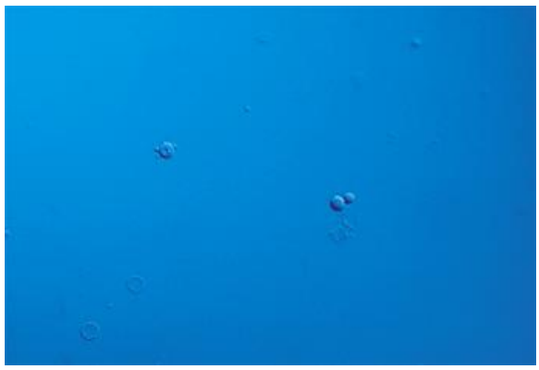

FIGURE 28.21. Dysmorphic erythrocytes in urine sediment, interference-contrast microscopy (×160). Two red blood cells (RBCs) are shown in the center of the field. Each is markedly deformed with buds projecting from their surfaces. In one of the RBCs, the buds are small, whereas in the other RBC, a single bud can be seen.

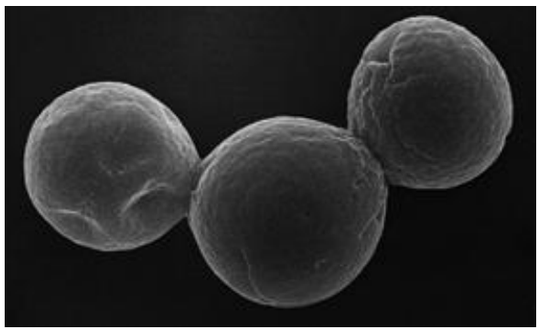

FIGURE 28.22. Scanning electron micrograph of a dysmorphic erythrocyte in urine (“Mickey Mouse” cell) (×7,200).

WBCs

Leukocytes in the sediment in numbers greater than five per hpf are considered pathologic. This number is not absolute and may vary from laboratory to laboratory, depending on the established normal values. Norms for WBCs in urine may be slightly higher for females. WBCs appear in increased numbers in the urine primarily when an inflammatory process affects the urinary tract. Pyuria is a common finding in cystitis, urethritis, and pyelonephritis. The white cells are predominantly PMNs, but careful study has shown that lymphocytes, monocytes, and eosinophils may also be present (Fig. 28.23). PMNs are actively motile. They enter the urine in the kidney or in the remainder of the urinary tract by actively migrating to the site of the inflammatory process moving through the GBM or tubular basement membrane (TBM) in the kidney or across the lining epithelium of the renal pelvis, ureter, bladder, or urethra (35).

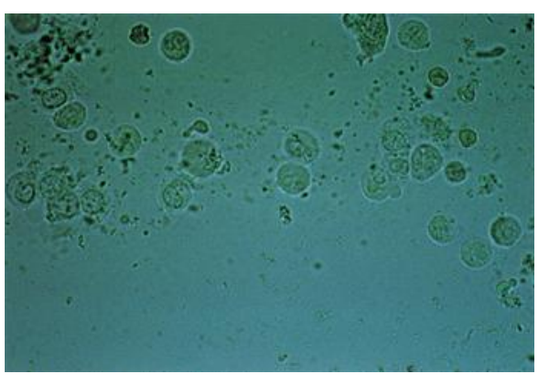

FIGURE 28.23. Polymorphonuclear neutrophils (PMNs) in urine. Across the center of the photomicrograph are many white blood cells; most are PMNs, but there are occasional mononuclear forms as well. Bacteria and a few erythrocytes are present in the background. (Bright-field microscopy, ×160.)

Phase microscopy greatly facilitates the recognition of PMNs because their characteristic spherical shape, granular cytoplasm in which brownian motion is often evident, and multilobed nuclei are readily seen (Fig. 28.24) (38). PMNs are actively phagocytic and serve the body well in protective functions as destroyers of microorganisms and as scavengers and destroyers of microorganisms (Fig. 28.25). “Glitter” cells are PMNs in which

the intracytoplasmic vacuoles are large and in motion and appear to be twinkling when observed in the fresh state. Supravital staining of urine (e.g., Sternheimer-Malbin) provides a means of specific identification of PMNs because their granules and individual nuclear lobes are prominently displayed (5).

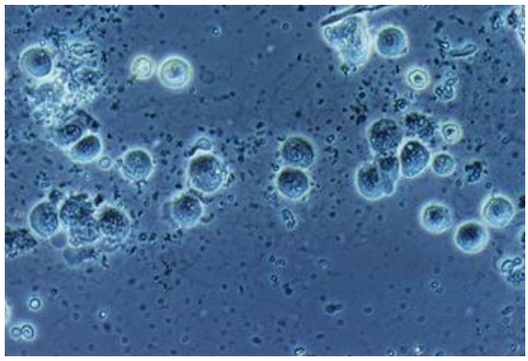

FIGURE 28.24. Phase microscopy (×160) of leukocytes in urine. This photomicrograph represents the same field as seen in Fig. 28.23. Here, the cytoplasmic granules in the polymorphonuclear neutrophils and the multilobed nuclei are prominent.

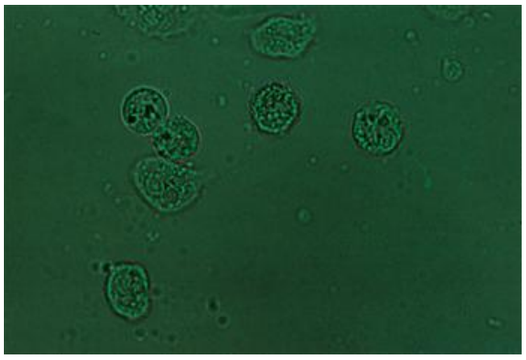

FIGURE 28.25. Glitter cells. These polymorphonuclear neutrophils (PMNs) display amoeboid motion. PMNs may show active motility, as is seen in the large cell near the center of the field. They do this by extending pseudopods from their cytoplasm. (Bright-field microscopy, ×250.)

In interstitial nephritis, an infrequent condition associated with allergic reactions to therapeutic agents, eosinophils are often present in the sediment in greatly increased numbers (52,53). Eosinophils may not be readily identified without the use of special stains, such as Wright's or Giemsa, or a specific stain for eosinophils (Hansel's stain). Eosinophiluria was recently reported to be associated with atheroembolic renal disease, a condition in which renal emboli occur in patients with severe atherosclerosis of the aorta (54).

Epithelial Cells

Epithelial cells may occur in the urine sediment in increased numbers in pathologic conditions. For practical purposes, only the presence of increased numbers of RTE cells is of clinical significance. However, it is important to recognize that large numbers of squamous cells are generally a sign of contamination of the specimen by vaginal fluid, whereas an increased number of transitional cells, if not accompanied by PMNs, most often indicates that some type of medical manipulative procedure involving the urethra and/or bladder was recently performed, such as catheterization.

RTE Cells

RTE cells are increased in the urine when there has been damage to the renal tubules and these cells are sloughed. This increased sloughing is most often accompanied by cylindruria, especially the presence of RTE casts in the urine. The specific etiologies for increased numbers of RTE cells in the urine are varied and multiple; renal tubular necrosis (55) heavy metal poisoning, cytomegaloviral, renal transplantation (56), aminoglycoside nephrotoxicity (57), and renal vein thrombosis are among the more common causes. Tubular lining cells are 15 to 25 µm in diameter and are usually polyhedral and contain an eccentric single nucleus that is approximately the size of a mature lymphocyte; they must be differentiated from similar-appearing transitional cells, which can be a difficult task.

Generalized viral diseases, such as viral hepatitis and cytomegaloviral disease, tend to affect the RTE cells and cause their sloughing (35,58). Common diseases, such as the common cold and measles, produce similar damage to the RTE cells, resulting in large numbers being sloughed into the urine. Tubular lining cells are active metabolically and may show bile staining because bilirubin is actively excreted by the kidney when the patient is jaundiced and has severe liver disease. Heavy metals such as lead, bismuth, antimony, and mercury, when ingested in toxic amounts, produce tubular cell death, resulting in increased numbers of these cells in the sediment. Lead toxicity induces an acid-fast inclusion body to form in some RTE cells, which, if recognized in the sediment, is of great diagnostic assistance in the identification of the clinical problem. Viruses may also induce the formation of inclusion bodies in RTE cells, best demonstrated in herpes, cytomegaloviral disease, and measles.

Oval Fat Bodies

Oval fat bodies (OFBs) (Fig. 28.26) are RTE cells in which globules of lipid have become visible (35). These deformed cells are frequently associated with a nephrotic syndrome but may be seen in various diseases that affect the tubule portion of the nephron. The lipid globules vary in size, are usually spherical, and, because cholesterol is a major component (rather than neutral fat), demonstrate anisotropic properties (Fig. 28.26) by showing a Maltese cross pattern (59). OFBs may occur singly or in pairs or groups.

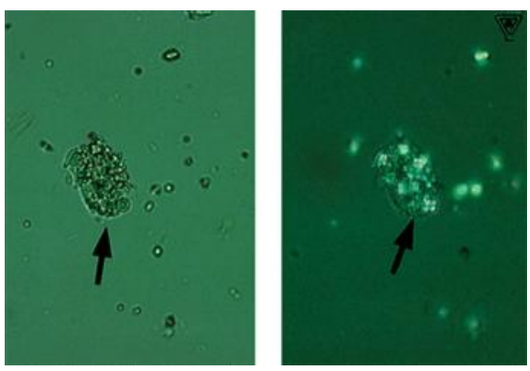

FIGURE 28.26. Oval fat bodies in urine. This renal tubule epithelial cell contains spherical globules of lipid (*arrow*), which, when polarized **(right)**, show a Maltese cross pattern. (Bright-field microscopy and polarization, ×160.) (From the College of American Pathologists, with permission.)

Transitional Epithelial Cells

These cells are rarely of pathologic significance unless there are large numbers present; even then, the usual etiology is that the patient has undergone a recent urinary tract procedure, such as a cystoscopy. In these circumstances, the cells may be observed in groups because of traumatic removal of the epithelium during the procedure. Inflammatory conditions of the bladder and urethra,

in particular, may give rise to increased numbers of urothelial cells in the sediment. However, they are usually accompanied by large numbers of PMNs because inflammation causes a degeneration and sloughing of transitional lining cells of the bladder or urethra. The morphology of these cells is as previously described, and most assume either spherical or caudate shapes. On occasion, irregular forms of transitional cells are observed in the sediment. Some of these cells may be larger than normal and irregularly shaped and have huge and irregular nuclei. Because bladder cancer is relatively common and may be suspected, an additional sediment sample should be obtained for submission to the cytology laboratory for analysis (60,61).

Squamous Epithelial Cells

The presence of large numbers of squamous cells in the urine usually represents contamination from vaginal contents. If accompanied by many bacteria, this is especially true. In patients with rectovesical or rectovaginal fistulas, many squamous cells may be seen in conjunction with fecal matter and bacteria. One form of squamous cell that has recently been identified is the “clue” cell. It has been shown that this cell, a squamous cell with bacillary forms adhering to its surface, is a frequent finding in bacterial vaginosis, an inflammatory condition of the vagina caused by the bacillus *Gardnerella vaginalis* (25). Clue cells should be diagnosed and reported when present (Fig. 28.27).

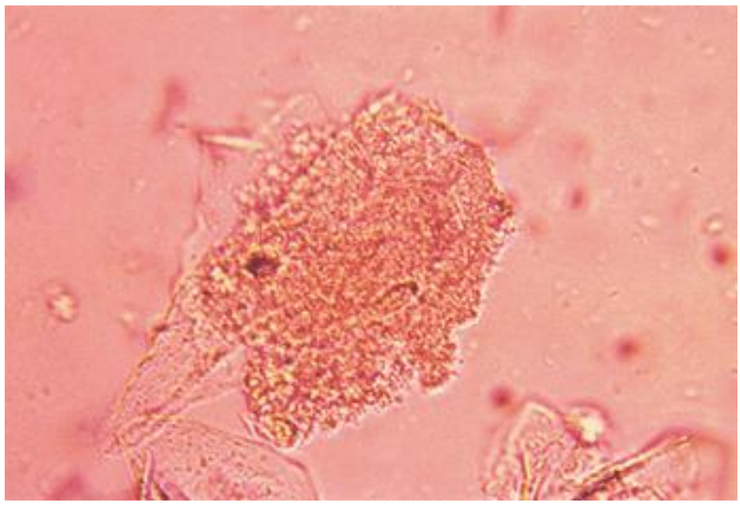

FIGURE 28.27. Clue cell. Note adherent surface bacteria (×160).

Abnormal Crystals

Of primary importance in the recognition of abnormal crystals is the fact that they are found only in urine of acid or neutral pH. For definitive crystal diagnosis, chemical analysis is performed. A few of the more frequently seen varieties are discussed in detail.

Cystine

These crystals are usually flat, six-sided plates that are clear and colorless (Fig. 28.28) (35). The sides of the hexagon are not necessarily equal in length. Polarization demonstrates a negative birefringent pattern (62). Sometimes, in very fresh urine, the hexagonal shapes are incomplete, and aberrations of these forms may be observed. The crystals may be layered or joined. They may be distinguished from six-sided uric acid crystals in most instances by the fact that in the latter, two of the opposing sides are clearly elongated. Although both cystine and uric acid crystals are soluble in ammonia water, only cystine crystals are soluble in dilute hydrochloric acid.

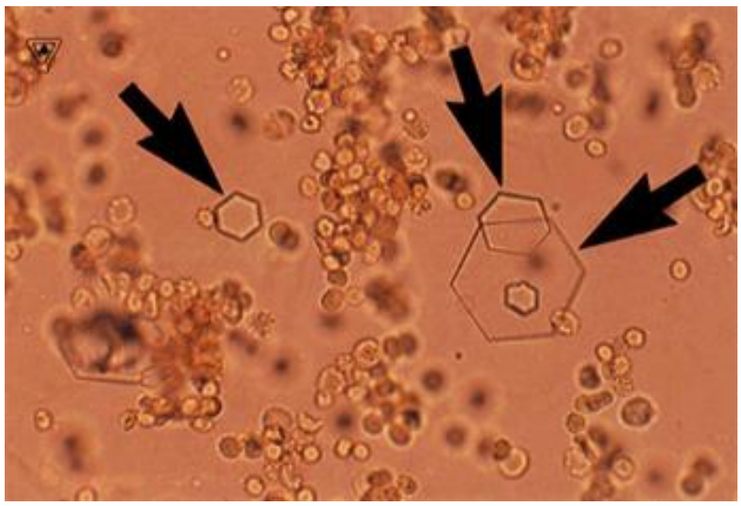

FIGURE 28.28. Cystine crystals in urine (*arrows*). These are flat, colorless, hexagonal crystals. Numerous red blood cells are present in the background. (Wright's stain, bright-field microscopy, ×400.) (From the College of American Pathologists, with permission.)

Cystine crystals appear in the urine in an inherited disorder that prevents the reabsorption of the amino acid cystine by the epithelial cells of the nephron and causes cystinuria. This disease is one of the more common inherited diseases and is expressed equally in each gender as an autosomal-recessive trait. Cystinuria also occurs in diseases affecting the liver (Wilson's disease) and in other diseases of the renal tubules.

Cholesterol

These crystals are most frequently found after refrigeration of the urine; lipid appears in globular form in urine at body temperature but crystallizes on refrigeration. Cholesterol crystals are large, flat, colorless thin plates that assume rectangular shapes of various diameters (Fig. 28.29) (35). One peculiar feature is that

the crystals often show a “staircase” pattern or contain an indentation of one or more of the corners of the rectangular plate. They are birefringent and often overlap or appear together (Fig. 28.30).

FIGURE 28.29. Cholesterol crystals in urine. These colorless, flat plates are characteristic because of their rectangular shape and “staircase” patterns. In the background are many red blood cells and an occasional leukocyte. Some of the red cells demonstrate dysmorphic shapes. (Bright-field microscopy, ×160.)

FIGURE 28.30. Cholesterol crystals, polarized (same as Fig. 28.29). These crystals are anisotropic and often overlap. (Polarization, ×160.)

Cholesterol crystals are occasionally found in the urine sediment of patients with lipoid nephrosis, membranous glomerulonephritis, polycystic renal disease, or the nephrotic syndrome (edema, lipiduria, lipidemia, and hypercholesterolemia). In lymphatic obstruction caused by neoplasms or parasitic disease (filariasis), chyluria may be a consequence if the dilated lymphatics rupture into the kidney or urinary tract.

Leucine

Leucine crystals are rarely found in the urine sediment. They appear as spheroids with a central nidus surrounded by concentric bands with apparent radiations originating from the center and crossing the bands (35) (Fig. 28.31). They are brownish yellow and highly refractile and show birefringence. Patients with severe liver disease, such as fulminant hepatitis and advanced cirrhosis, as well as patients with congenital metabolic conditions, such as maple sugar urine disease, excrete these crystals in their urine. They may occur in association with tyrosine crystals. Microscopically, they should not be confused with prostatic concretions or pollen grains, and if there is doubt, chemical testing of the urine for leucine is warranted.

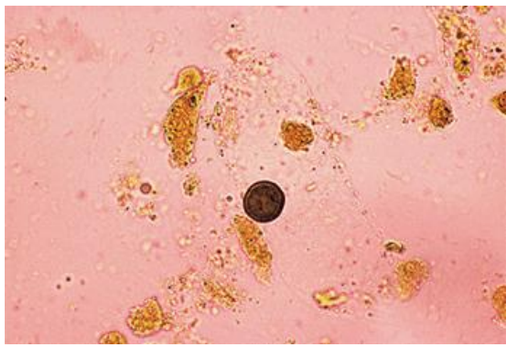

FIGURE 28.31. Leucine crystal in urine of patient with advanced liver disease. Note both radial striations and concentric rings. (×160).

Tyrosine

This crystal is one of the most difficult to see because of its relatively low refractive index; it is birefringent. Tyrosine crystals occur as fine, delicate, colorless or pale yellow elongated needles that may appear singly or in clusters or sheaves (Fig. 28.32). Microscopically, the sheaves look like they have a black central focus, which is a useful point in diagnosis. Tyrosine crystals in the urine are uncommon, even in severe liver disease.

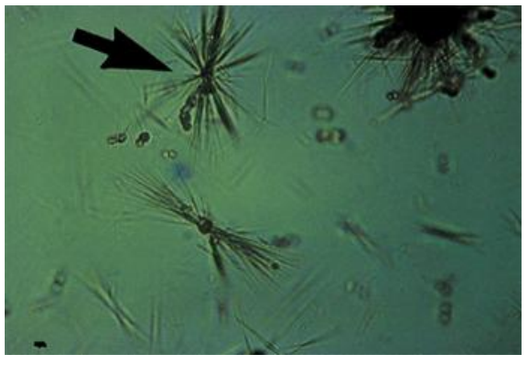

FIGURE 28.32. Tyrosine crystals in urine. These fine needlelike crystals commonly occur in clusters or sheaves. The black central focus depicted in the photomicrograph (*arrow*) is a useful characteristic for diagnosis. (Bright-field microscopy, ×320.) (From the College of American Pathologists, with permission.)

Bilirubin

This brownish red crystal appears in the sediment as amorphous granular material or as short needles. It may be difficult to distinguish from amorphous urates or phosphates without confirmatory chemical testing. For these crystals to form, high levels of

direct-reacting bilirubin need to be reached in the blood and urine, usually as a result of obstructive jaundice (Fig. 28.33).

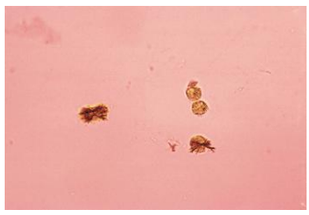

FIGURE 28.33. Brownish yellow bilirubin crystals attached to free renal tubular cells or neutrophils. Urine of patient with advanced metastatic liver disease. Crystals form a sheaf in left cluster (×200).

Hemoglobin

Granules of hemoglobin and hemosiderin may be found in the urine sediment on occasion. When concentrations of hemoglobin in the urine are excessive, as in massive hematuria with RBC lysis or in severe hemolytic anemia and crush syndrome after trauma, hemoglobin crystals form and appear as tiny, refractile, reddish brown, amorphous granules. These may be difficult to distinguish microscopically from other granular crystals, and chemical testing along with staining for hemoglobin (e.g., Prussian blue) may be required.

Pharmaceutical Agents

Many pharmaceutical products may, on occasion, produce urinary crystals. Perhaps the most common of these are the dyes associated with radiologic visualization of the urinary tract (i.e., meglumine diatrizoate, Hypaque, and Renografin). These crystals produced by these dyes are colorless crystals and highly refractile and assume needlelike or elongated rectangular shapes with indented or notched ends. The urine specific gravity is frequently more than 1.040 in patients with these crystals (10). A careful history will reveal the true origin of the crystal.

Ampicillin

The crystal produced in the urine by this drug is an elongated, needlelike, colorless crystal that is found in acid urine. It may be difficult to distinguish from radiographic dye crystals, and a history aids in making a correct diagnosis.

Sulfa Drugs

Now that most sulfanilamide drugs manufactured are water soluble, finding their crystalline products in the urine is uncommon but does occur infrequently. Sulfadiazine is the most commonly found. The urine is acid, with the pH usually less than 6. The sulfa crystals each assume various needlelike shapes, are birefringent, and are most often seen as bundles of brownish yellow “sheaves of wheat” formations with eccentric binding (Fig. 28.34). A lignin test confirms their presence.

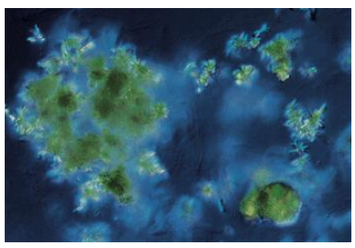

FIGURE 28.34. Sulfadiazine crystals. Sulfa drugs manufactured today are water soluble, and finding sulfa crystals in urine is unusual. (Interference-contrast microscopy, ×250.)

Indinavir

Among the growing numbers of crystallized drugs or drug metabolites detected in urine are those occurring in some patients treated with antiviral agents such as indinavir (63,64). These crystals are readily identified by bright-field, polarized, phase, and interference microscopy (Fig. 28.35A,Fig. 28.35B). Crystalluria tend to be accompanied by significant numbers of neutrophils and by fewer mononuclear cells, particularly lymphocytes and possibly histiocytes. Crystals are elongated with squared or slightly angular ends. They may be intracellular in as many as 5% to 10% of neutrophils and mononuclear cells.

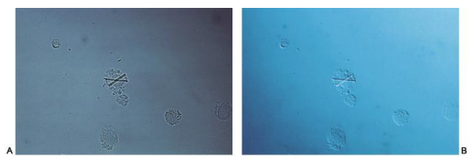

FIGURE 28.35. Indinavir crystals in leukocyte in the urine sediment. Patient with acquired immunodeficiency syndrome. **A:** Bright-field microscopy; **B:** interference-contrast microscopy (×160). These crystals are birefringent and can easily be seen using polarized light. They occur extracellularly as well as intracellularly in the urine.

Finding indinavir crystals in the urinary sediment is not an unexpected complication of therapy with this compound. The solubility of indinavir depends in part on the acidity of the urine, i.e., the lower the pH, the more soluble the medication. From the physical standpoint, it is reasonable to assume that the sharp angular ends of these crystals irritate RTE cells, resulting in an inflammatory reaction. Cells participating in this reaction, mostly neutrophils, migrate into the urine as it flows through tubular lumina, thus producing pyuria without bacteruria.

The birefringent properties of indinavir crystals are distinct from those of ordinary uric acid crystals, even though there is some morphologic similarity. Indinavir crystals are weakly birefringent and do not have the properties of urate crystals, which appear blue when a red retardant filter is used. The crystals may be found inside PMNs and appear to cause their demise when ingested. In addition, many crystals are extracellular.

Abnormal Casts

Both hyaline and granular casts are commonly found in the urine sediment of patients with renal disease. Both of these cast forms were discussed previously and were associated with the “normal” state, but there are some morphologic variations that are worthy of comment. All other casts are abnormal, for all practical purposes, and each is discussed in detail.

Casts originate in the distal tubules and collecting ducts of the kidney and are molds of the tubular lumen; therefore, a damaged nephron may have an abnormal tubular lining epithelium that

may be atrophic, degenerating, necrotic, or absent, which results in a dilated lumen (41). In such instances of nephron damage, casts form that represent this pathologic dilation by being wider than normal, i.e., broad casts (Fig. 28.36). Although the evaluation is subjective, the uroscopist is quickly able to recognize broad casts because they may be as much as five or six times wider than ordinary casts. A large number of broad casts present in a sediment is representative of considerable tubular alteration and nephron injury, and for this reason, they have also been called “renal failure casts.”

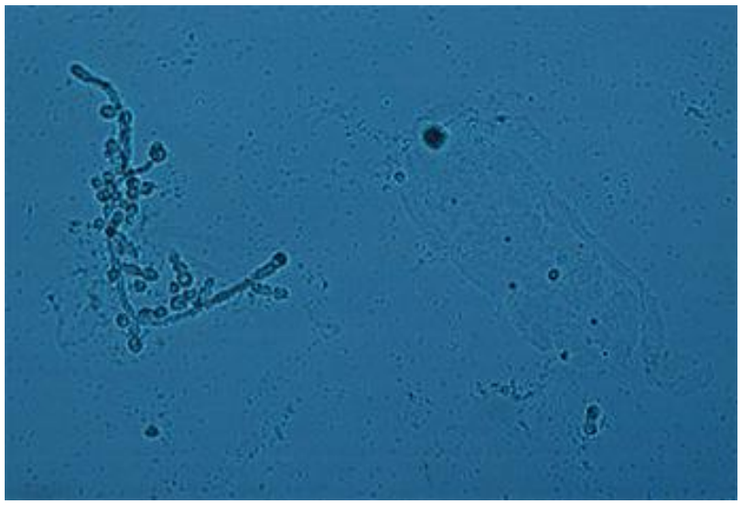

FIGURE 28.36. Broad hyaline cast. When looking at this cast, it is easy to determine that it has a greater breadth than any cast associated with a “normal” state (cf. Fig. 28.12 and Fig. 28.13). The cast depicted here shows some disruption at one end. The background contains budding yeast and hyphae, as well as a bacterium. (Bright-field microscopy, ×100.)

Damage to either the glomerular or tubular portions of the nephron may give rise to products in the sediment not normally found there, some of which may then become incorporated into casts (35). These products may be present in the glomerular filtrate (e.g., fat, hemoglobin, myoglobin, RBCs, WBCs) or may be directly related to tubular damage or destruction (e.g., epithelial cells or cell products). Conversely, casts are produced only when the environment in the renal tubule is appropriate for their formation. Although this is a little understood phenomenon, it is known that alterations in urine flow, pH, and ionic strength of the glomerular filtrate and sufficient concentration of THP are all necessary for the production of these casts (25).

Hyaline Casts

In disease states, hyaline casts may increase significantly in number in the sediment, but their morphologic appearances are not different than what is associated with the normal, except where broad forms are noted (Fig. 28.36). Broad hyaline cast forms are usually an indication of some serious intrinsic renal abnormality and require further clinical and laboratory investigation. Generally, in disease states, increased numbers of hyaline casts are found in conjunction with other sediment or chemical abnormalities, such as the presence of additional cast types and/or proteinuria. It is uncommon to find only large numbers of hyaline casts in the urine in a disease state.

Granular Casts

Large numbers of granular casts are rarely seen in the sediment in health, but this is not an infrequent finding in various diseases. These casts may be small or large or broad. The granules may be diffusely scattered over the entire cast surface (Fig. 28.37) or may be concentrated in one or more sections of the cast. Granule size has long been a topic of discussion. In the normal person, the granules are most often small and regular, and the casts are considered to be finely granular (44). Finely granular casts are also found in diseased urine. Conversely, in diseases in which there has been considerable cellular damage and death (e.g., acute tubular necrosis), the granules may be large and vary greatly in shape and size, and the resulting casts are called coarsely granular (Fig. 28.38). The difference between fine and coarse granules is somewhat subjective, and there is little reason to make this distinction in reports. Cellular destruction leads to the formation of granules that vary in size; when these granules are incorporated into a cast, the resulting granular cast is readily recognized. In

some granular casts, cell wall remnants are observed. Because of this fact, the concept arose that some preexisting cellular casts degenerate during their transit through the nephron and evolve into granular casts. In turn, some granular casts continue this evolution and become waxy casts.

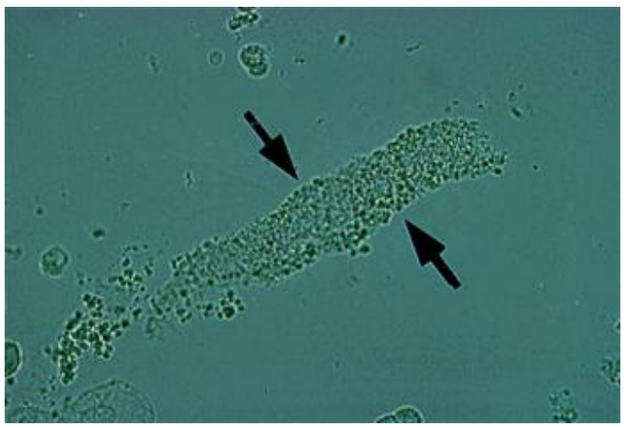

FIGURE 28.37. Granular cast. This cast (*arrows*) is composed of a diffuse scattering of fine granules over its entire surface (bright-field microscopy, ×160.) (From the College of American Pathologists, with permission.)

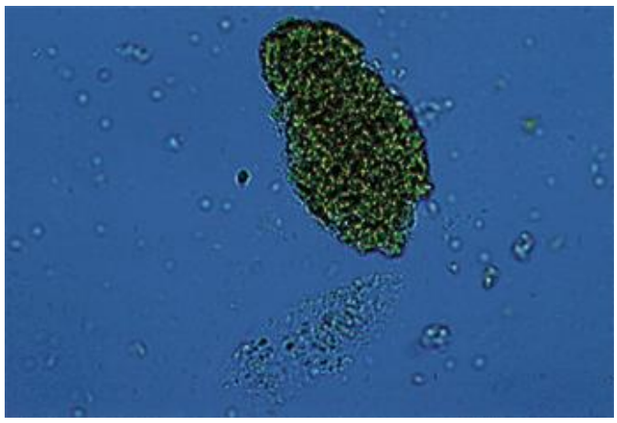

FIGURE 28.38. Broad coarsely granular cast. This cast from a jaundiced patient has adsorbed the bile pigment in the urine. The granules composing it are irregularly shaped and far larger than those seen in the cast in Fig. 28.29. A second, less obvious granular cast is also present in this photomicrograph, just below the broad granular cast initially described. (Bright-field microscopy, ×100.)

Waxy Casts

Morphologically, waxy casts are the most easily recognized of all urinary casts. This is owing to their high refractility, characteristic shape, and peculiar “tallow-wax” surface appearance. Classically, waxy casts appear as cylinders with ends that appear to have been sharply cut or broken off (not rounded) and whose sides are notched (Fig. 28.39) (11,35). Their surface is smooth, for the most part, but may contain a few granules or an occasional cell or cell membrane.

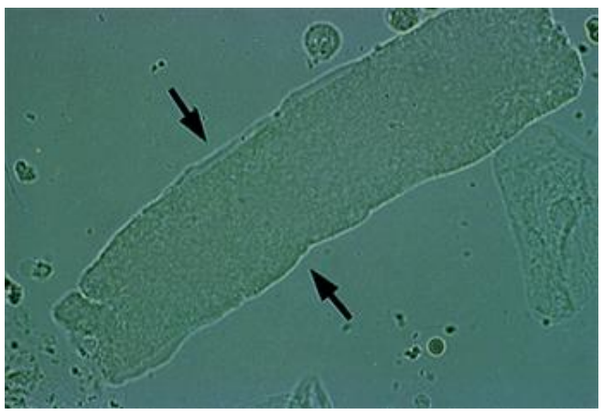

FIGURE 28.39. Waxy cast (*arrows*). This cast presents the typical appearance of a waxy cast in the urine. It has sharp, angular, squared-off ends and an irregularly notched margin. Its surface is relatively smooth and looks like it has a “tallow-wax” consistency. (Bright-field microscopy, ×160.) (From the College of American Pathologists, with permission.)

The origin of waxy casts is not clear, and scanning electron microscopy provides little in the way of solution (44). On electron microscopic study, the surface of a waxy cast is composed of what probably is a typical proteinaceous material (most likely derived from cells) that coats the cast. Waxy casts often appear as broad casts; finding large numbers of waxy casts in the sediment portends a poor prognosis and is often associated with severe nephron destruction, oliguria, and renal failure.

Pigment Casts

Mention should be made of a variety of cast that contains one of the pigments or abnormal products excreted in the urine. These pigments are most commonly bilirubin, hemoglobin, or myoglobin. Melanin pigment casts also occur but are rarely present in melanuria, a complication of malignant melanoma that has metastasized. Pigment casts are usually hyaline or waxy but appear as though stained when in fact no sediment stain has been applied (Fig. 28.40). Some pigments can be differentially stained (i.e., hemoglobin). In multiple myeloma, a neoplastic disease of plasma cells, Bence Jones protein may be excreted by the kidneys

in large quantities (see Protein section under Chemical Urinalysis section, earlier in this chapter), and casts composed of this low molecular weight protein may form and be found in the urine.

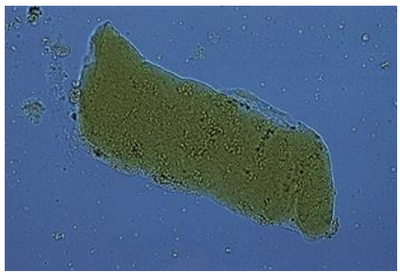

FIGURE 28.40. Waxy cast, bile-stained (pigment cast). This broad cast has a relatively smooth-appearing surface with blunt ends and notched sides. Bile has been absorbed by its matrix to give it a greenish surface appearance. (Bright-field microscopy, ×160.)

Fatty Casts

Lipid may be present in a cast in two forms: either as free globules or within cells. Cholesterol and cholesterol esters demonstrate anisotropism and can be seen with the use of a polarizing microscope (Fig. 28.41). It is observed as having a Maltese cross pattern (35,59). Conversely, neutral fats and triglycerides do not have this anisotropic property but can be stained with Sudan III or oil red O dye.

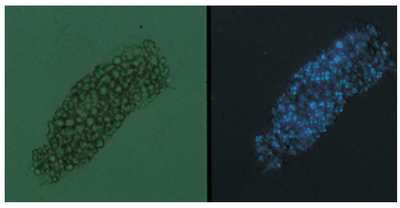

FIGURE 28.41. Fatty cast. This cast contains multiple different-sized lipid globules that, when subjected to polarized light, are anisotropic and display a Maltese cross pattern (*right*). (Bright-field microscopy and polarization, ×160.) (From the College of American Pathologists, with permission.)

Whether the fat is contained within cells (OFBs) or is present as free lipid spherules on the cast surface, accurate recognition is essential. Fatty casts are associated with renal diseases that affect both tubules and glomeruli. These casts are most commonly associated with the nephrotic syndrome but are also present in diseases in which there is severe tubular damage, such as heavy metal poisoning. Fatty casts may form as a result of glomerular injury, which causes a leakage of serum lipids into the glomerular filtrate. The newly formed fatty globules are either absorbed by the tubular epithelium with the formation of OFBs or become a component of the cast by adhering to its surface.

Fatty casts are easily confused with RBC casts because of the globular nature of the free lipid. Careful observation assists in distinguishing them because the lipid globules are of varying size, spherical, and have a rather pale golden brown color. Simple polarization reveals a Maltese cross pattern of the globules. RBC casts, however, are not anisotropic, contain reddish brown RBCs of uniform size, and are in the typical nonspherical, biconcave disk shape.

Crystal Casts

These casts are infrequently present in the urine sediment and may be a helpful indicator of renal obstruction. In obstruction when casts form, precipitation of various crystals occurs in the nephron, and these crystals become incorporated into the cast matrix (Fig. 28.42). The basic crystal cast has a hyaline matrix. Crystal casts might contain uric acid, calcium oxalate, and, rarely, sulfadiazine. Because all these crystals are anisotropic, simple polarization of the cast should demonstrate their true nature if there is any doubt about their diagnosis (Fig. 28.43). It is important to distinguish crystal casts from crystalline pseudocasts (compacted amorphous urate or phosphate crystals assuming a cylindrical castlike shape) because crystal casts may be associated with pathologic conditions, whereas pseudocasts have no clinical significance.

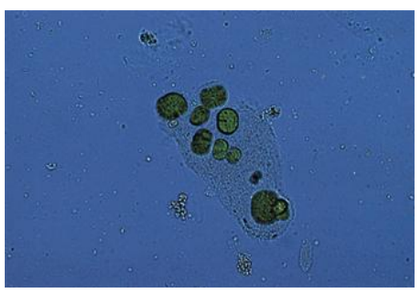

FIGURE 28.42. Crystal casts in urine. Note that the crystals are irregularly scattered over the hyaline cast matrix, which shows fine granularity. This urine sediment sample was from a liver transplant patient who was severely jaundiced. (Bright-field microscopy, ×100.)

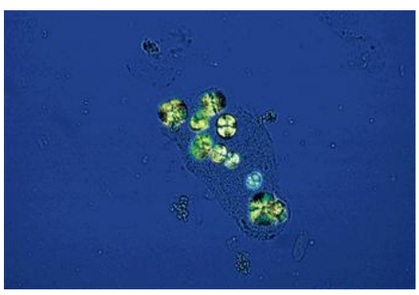

FIGURE 28.43. Crystal cast, polarized. The same cast shown in Fig. 28.42 is depicted under polarized light. The crystals in the cast show anisotropic properties that enable them to be distinguished. These casts may be associated with renal obstruction. (Polarization, ×1,003.)

RBC Casts

RBC casts are among the most diagnostically important of all elements in the urine sediment; their presence usually indicates glomerular injury (i.e., acute glomerulonephritis, IgA nephropathy, lupus erythematosus nephropathy) (65,66). RBC casts can also be found, but far less frequently, in disease states that do not primarily involve glomeruli (i.e., pyelonephritis and renal infarction). RBCs enter the urinary flow via two major mechanisms: they either pass through the GBM, a transglomerular route, or they cross the TBM, a transtubular route (41). Both mechanisms are of importance in the formation of RBC casts. When serious glomerular injury occurs, as in acute poststreptococcal glomerulonephritis, the GBM is damaged and increased numbers of RBCs transgress it; some of these RBCs become incorporated

into a preexisting cast matrix and form a RBC cast. A similar mechanism occurs in instances of transtubular bleeding. Here, the TBM is damaged, as in renal infarction or pyelonephritis, and RBCs leak across it and into the urine flow, to become incorporated into the cast (Fig. 28.44).

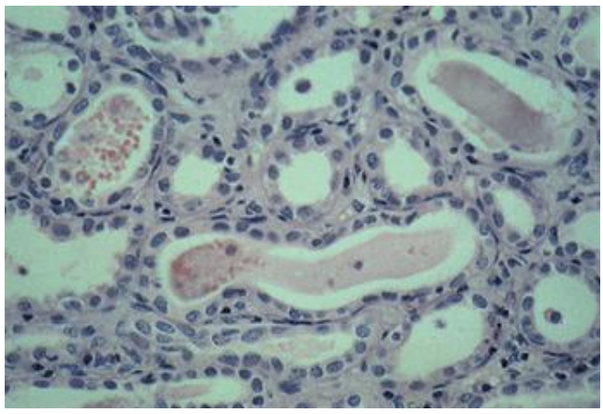

FIGURE 28.44. Red blood cell casts forming in the distal nephron. This histologic section shows three casts in tubular lumina. Two of the casts contain red blood cells, whereas the third is purely hyaline. (Hematoxylin and eosin, ×100.)

A RBC cast is basically a hyaline cast to which RBCs adhere. Scanning electron micrography of this cast type demonstrates that the RBCs are attached to the matrix by means of thin fibrils, presumably in part THP, which serve as a kind of glue to attach the cells to the cast surface. The RBCs apparently attach after the cast has been formed in the distal tubule or collecting duct.

Recognition of RBC casts requires careful microscopic observation because they may be confused with other cast forms such as fatty casts. The RBCs in the cast may be sparse, with only a few present in any one area, or they may be closely packed so that the underlying cast matrix can hardly be seen (Fig. 28.45). The RBCs themselves may be intact, thereby facilitating a diagnosis, but they frequently show degeneration and disruption. If the disruption is severe enough, one may be left with only RBC membranes and brownish red hemoglobin pigment in the cast; these are named blood or hemoglobin casts. To diagnose a RBC cast, the cast surface should contain sufficient numbers of RBCs, or their disrupted membranes, so that no doubt exists regarding the specific diagnosis. Often, RBCs within the cast will show dysmorphism, and appear in twisted and irregular shapes (51). In most patients with RBC casts, proteinuria and hematuria are seen concurrently in the chemical evaluation and the urine sediment surrounding the casts contains free-floating RBCs.

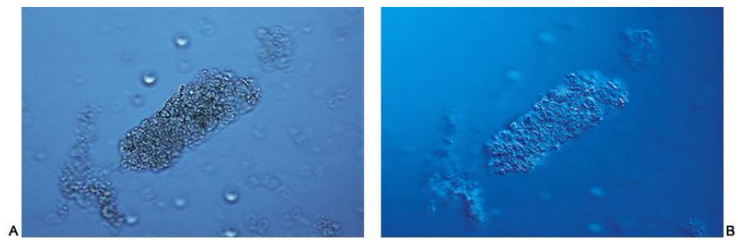

FIGURE 28.45. Erythrocyte casts in urine sediment. **A:** Bright-field microscopy; **B:** interference-contrast microscopy. The red blood cell cast is composed almost entirely of red blood cells. These are mostly intact, but a few have indistinct cell membranes. A few others show dysmorphic alterations (×160).

WBC Casts

WBC casts in the urine usually indicate that an inflammatory process is occurring in the kidney, most frequently involving the interstitium in pyelonephritis and interstitial nephritis. WBCs migrate to the affected region of the kidney and then across the TBM, where they enter the urine flow and become incorporated into the cast matrix. These WBCs are secured to the hyaline matrix by means of fibrillar protein bands, similar to those found in RBC casts (44). Glomerular damage that induces an immune response and the subsequent chemotactic attraction of leukocytes to the site of injury also cause WBC casts to form (i.e., lupus nephritis).

WBC casts may be difficult to recognize accurately because of the possibility of confusion with RTE cell casts. The white cells occupying the cast surface are most often neutrophils (PMNs) (Fig. 28.46). These cells measure approximately 20 μm across and can be identified by their multilobed nuclei and granular cytoplasm. However, neutrophils in these casts are frequently disrupted, fragmented, or undergoing degeneration, and the individual nuclear lobes may be difficult to distinguish. Phase-contrast or interference-contrast microscopy or differential staining may assist in making the distinction between leukocytes and RTE cells.

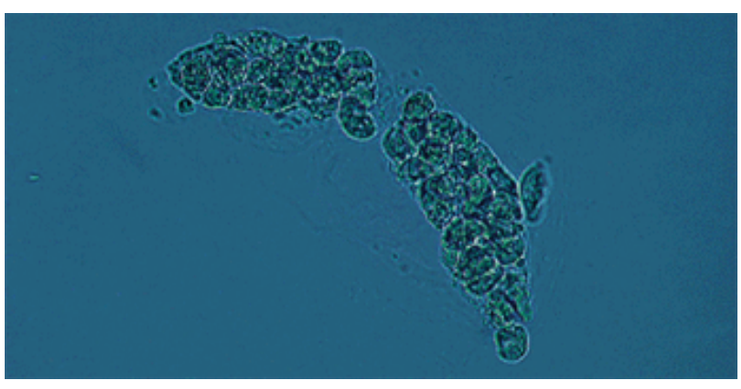

FIGURE 28.46. White blood cell cast. The cast depicted in the photomicrograph is a hyaline cast to which polymorphonuclear neutrophils have adhered. The leukocytes on the cast surface show a granular cytoplasm and multilobed nuclei. (Bright-field microscopy, ×160.)

Lymphocytes and eosinophils may occasionally be found in WBC casts. Lymphocytes, being much smaller cells than neutrophils (12 μm) and having a large central nucleus, are easily recognized. Eosinophils, conversely, may present diagnostic difficulties unless Giemsa or Hansel stain is applied. The authors have never observed a pure eosinophil cast in interstitial nephritis but have noted occasional eosinophils in WBC casts in this disease.

RTE Cell Casts

RTE cell casts are cellular casts composed of RTE that has been sloughed off. Tubular lining cells are easily affected by various poisons, especially the heavy metals such as lead and mercury, ethylene glycol (antifreeze), and viruses (cytomegalovirus and hepatitis) and are also sensitive to alterations in blood flow in instances of prolonged shock and in renal transplantation. In these examples, the RTE cells are caused to exfoliate. If hyaline casts are forming in the distal portions of the nephron, the cells become attached to the cast matrix and form a RTE cell cast (44).

RTE cell casts are sometimes difficult to distinguish from WBC casts because the two cell types are of approximately the same size (20 μm). One means of accurate identification is to look for a single large central nucleus in the cell (Fig. 28.47). In contrast, neutrophils have a smaller nucleus with multiple lobes. Both cell types have intracytoplasmic granules, although those in RTE cells are usually less prominent than those in neutrophils. When the RTE cells begin to degenerate, their cell and nuclear membranes become permeable and the cytoplasmic granules may leak into the surrounding cast matrix, giving a granular appearance. The tendency for microscopists to incorrectly diagnose RTE cell casts as WBC casts is pervasive because WBC casts are far more common than RTE cell casts. This mistake should and can be avoided by careful observation of the cells that make up the cast.

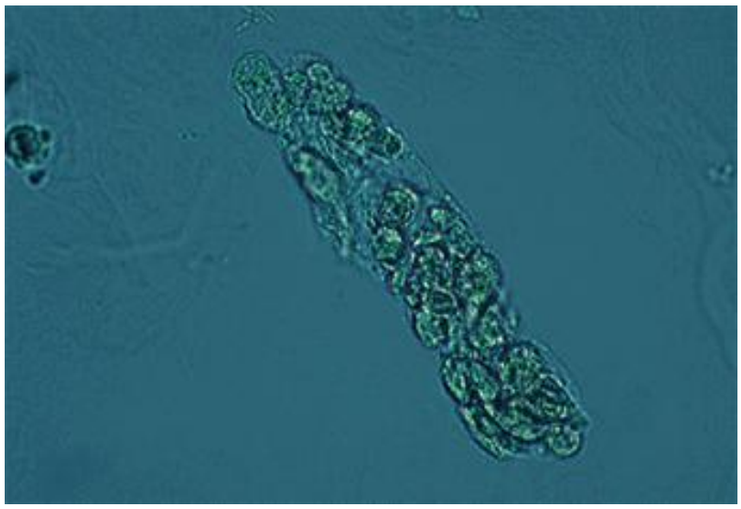

FIGURE 28.47. Renal tubular epithelial (RTE) cell cast. The basic matrix of this cast is hyaline and RTE cells coat its surface. The cells are large (approximately 20 μm) and have a large central nucleus. Their cytoplasm contains far fewer granules than do PMNs and the single nucleus distinguishes their character. They may present difficulty in differentiation from white blood cell casts. Mucous strands are present in the background. (Bright-field microscopy, ×160.)

OFB Casts

In diseases that cause severe degeneration and necrosis of RTE cells, such as heavy metal poisoning or acute tubular necrosis, the intracellular lipids become visible and the resulting sloughed OFBs are incorporated into a cast. These are truly RTE cell casts but have been designated OFB casts because of the peculiar appearance of the damaged epithelial cells and their visible and anisotropic intracytoplasmic lipid droplets. The lipid may be cholesterol or cholesterol esters, in which case it demonstrates anisotropism in a typical Maltese cross pattern, or it may consist of neutral fats and triglycerides, which can be differentially stained with Sudan III or oil red O dye. The fat globules within the RTE cells are of varying size and are usually spherical but may be somewhat irregular. If the RTE cell has a disrupted membrane, the fat droplets may leak out into the surrounding cast matrix.

Bacterial/Fungal Casts

The recognition that microorganisms could be included within the cast matrix is an observation that has often been overlooked in routine urinalysis (67). Bacterial forms, being as small as they are, are frequently not diagnosed within a cast because they appear as granules, and a granular cast is diagnosed when ordinary bright-field microscopy is used in analysis. In studies of women with acute pyelonephritis, WBC casts were often present in the urine and it became apparent that some of the granules within these WBC casts were in fact bacteria. Scanning electron microscopy studies verified this conclusion (Fig. 28.48). It is therefore

important to analyze carefully all abnormal sediments that contain granular or WBC casts and to look for bacterial and/or fungal forms in these casts. This analysis is significantly aided by using a phase-contrast or interference-contrast microscope or by staining with Sternheimer-Malbin Sedi-Stain; in either instance, bacilli will be readily identifiable.

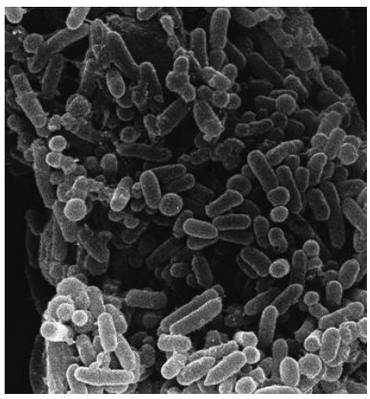

FIGURE 28.48. Bacterial cast. Numerous bacillary forms completely occupy the cast surface. (Scanning electron microscopy, ×5,000.)

It is important to recognize bacterial and fungal casts because their presence is pathognomonic for acute kidney infections (67). Bacterial forms are generally scattered throughout the entire cast matrix and are bound to its surface by bands of fibrillar protein, probably THP. WBCs are often admixed with the bacteria or fungi. Pure bacterial casts are uncommon. Fungal casts are being diagnosed more frequently today because of the recent increase in transplantation surgery and the extensive use of chemotherapeutic and immunosuppressive agents in these patients and in the many patients with malignant neoplasms. Patients with a decreased immune response are more susceptible to various infectious diseases, especially bacterial and fungal (e.g., acquired immunodeficiency syndrome). Fungal forms are somewhat easier to recognize in casts than are bacteria because of their larger size. Yeasts are often budding and, on occasion, even hyphae may be found in the cast.

Parasites

Parasitic organisms are rarely present in the urinary sediment (35). In the United States, the eggs of *Enterobius vermicularis* (pinworm) are occasionally found, especially in children. They result from fecal contamination (Fig. 28.49). The female worm lays her eggs in the perirectal region, and during urine collection, they may be carried into the urine collection bottle, especially if the collection is not performed under supervised and controlled conditions and the genital area has been inadequately cleaned. Other parasites, such as pubic lice and fleas, may be present in the sediment as contaminants when proper collection procedures have not been followed.

FIGURE 28.49. Pinworm egg from urine of 11-year-old girl. One side of the long axis is always more curved than the other.

The single parasite that inhabits the urinary tract (bladder) as part of its life cycle is *Schistosoma hematobium*. The egg of this parasite is difficult to see with ordinary microscopic techniques, as it is clear and colorless. It has a characteristic terminal spine or spike and an elliptical shape. Schistosoma eggs measure approximately 150 µm in length and 60 µm in diameter. A particular species of snail is necessary for the maturation of this organism, which, fortunately, is not present in the United States. In other parts of the world, especially Africa and Egypt, however, schistosomiasis or genitourinary bilharziasis is a significant public health problem, and the finding of these parasitic eggs in urine is not unusual.

Trichomonas vaginalis is the most frequently encountered parasite in urine sediment in the United States and is usually a contaminant from the vagina. This organism typically inhabits the male and female distal urethra, the vagina, and, rarely, the prostate gland. These flagellated protozoans are actively motile in freshly voided urine and have a characteristic appearance. The body measures 10 to 30 µm in length and typically has an undulating membrane running approximately half its length; there are four anterior flagella (Fig. 28.50). The inexperienced observer may easily misdiagnose these organisms as neutrophils because they usually occur in the presence of PMNs and are approximately the same size. Careful scrutiny must be given to the sediment to detect their motility, elliptical shape, and flagella.

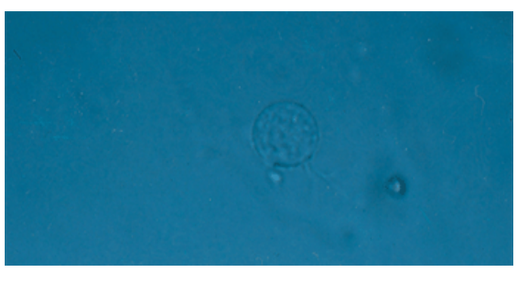

FIGURE 28.50. *Trichomonas vaginalis* in urine. Note the flagella and the spherical character of this parasite. These organisms are easily misdiagnosed as white blood cells. (Bright-field microscopy, ×400.)

Artifacts

As previously discussed, the ability to distinguish between actual urinary constituents and artifactual or contaminant material that may appear in the sediment is of primary importance in sediment

analysis. The experienced observer will have little difficulty in making this distinction and will use the microscopic tools of polarization, phase contrast, and staining to this end. Fibers, precipitated stains, oil droplets, and scratches will frequently be observed and should not be confused with, or misdiagnosed as, abnormal elements (Fig. 28.51 and Fig. 28.52).

FIGURE 28.51. Fiber artifact in urine. This fiber from a disposable diaper may be easily confused with a waxy cast as it has some of the same morphologic features. A clear distinction may be made using polarized microscopy (cf. Fig. 28.52). Red and occasional white blood cells are present in the background. (Bright-field microscopy, ×160.)

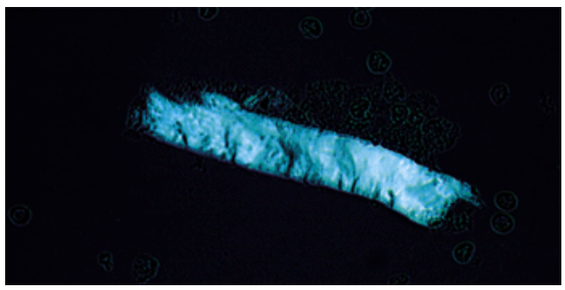

FIGURE 28.52. Fiber artifact in urine, polarized. Note the birefringence of the fiber. Waxy casts do not display anisotropism, and therefore any misdiagnosis of this fiber as a waxy cast should be prevented. (Polarization, ×160.)

SUMMARY

Part of "28 - Urine"

Microscopic evaluation of urine sediment is often a valuable diagnostic part of “routine” urinalysis. It provides a means of evaluating the urine or confirming an abnormal physicochemical finding, which is clinically useful. For this part of the urine examination to be most effective, however, a regularly employed standardized approach must be followed. Whether a laboratory purchases one of the many commercially available systems or develops one of its own, the results of performing the microscopic examination by doing the same thing to each urine sample every time a urinalysis is ordered will undoubtedly pay dividends in the long run by producing more accurate and reliable results. Table 28.6 presents an approach to the performance of urine microscopic examination after the urine has been prepared for sediment evaluation.

TABLE 28.6. METHODOLOGY IN PERFORMING A URINE MICROSCOPIC EXAMINATION

View concentrated sediment with low-power objective (100 ×)
Observe sediment for cells, casts, and crystals
Count casts as number per low-power field
Search for any other type of abnormality (i.e., yeast, parasites)
Polarize sediment to look for lipid (i.e., cholesterol)
If any part of physicochemical examination is abnormal, or
If urine is cloudy, or
If increased numbers of cells or casts are present, then
View sediment under high power (400 ×)
Identify *all types* of cells present
Count blood cells as numbers per high-power field
Count renal tubular epithelial cells as number per high-power field
Identify all types of casts present; specify type
If casts are increased in number then:
Normal vs. abnormal
If abnormal, acellular vs. cellular
Identify crystals present; determine whether
Normal or
Abnormal (only in acid or neutral urine)
Identify any microorganisms, bacteria, fungi, or parasites
Produce report and sign

33 The Chromosome Breakage Syndromes: Clinical Features, Cytogenetics, and Molecular Genetics

34 Solid Tumor Cytogenetics

Clinical cytogenetics was born in 1959 with the description of trisomy 21 in Down's syndrome, monosomy X in Turner's syndrome, and XXY in Klinefelter's syndrome. The field came of age in 1970 with the introduction of chromosome-banding techniques. Cytogenetics is maturing further today because of the rapid development of fluorescence-labeled DNA probes that can mark whole chromosomes, centromere regions, or specific genes of interest. Thus, chromosome analysis has become a major independent discipline in clinical pathology, and an ever-increasing number of medical centers and reference laboratories have a cytogenetics laboratory. Most clinical cytogenetics laboratories have experienced dramatic growth throughout the 1980s, and that growth continued into the 1990s. The importance of cytogenetics will continue to expand with the wider application of new technologies such as maternal serum screening in pregnancy, cytogenetic analysis of solid cancers, *in situ* hybridization of DNA probes, and chromosome painting.

Throughout this section, the authors offer critical technical information related to the preparation of specimens for karyotype analysis, such as the fine points of cell culture for analysis of hematologic malignancy, and the problem of confined chorionic mosaicism in the interpretation of prenatal diagnostic results. Newer concepts and insights into understanding the molecular genetic effects of cytogenetic abnormalities are detailed, such as genomic imprinting in Prader-Willi and Angelman syndromes, amplification of short “nonsense repeats” in fragile X syndrome, the molecular genetic defects associated with the inherited chromosome instability syndromes, and alterations involving oncogenes and tumor-suppressor genes in cancer and leukemia.

HISTORY OF HUMAN CYTOGENETICS

Part of "29 - Basic Cytogenetics"

The initial discoveries leading to the discipline of human cytogenetics occurred in the early 1950s, but their advent was based on a period of technical development starting at the turn of the century. The understanding of human chromosome behavior is based on chromosome methodology and an understanding of aberrations gained from plant and insect cytogenetics, supplemented by methods developed in studying animal tumors and tissue cultures (1).

The early studies of human chromosomes from the 1890s to the 1920s used testicular tissue to observe the meiotic divisions occurring in gametogenesis. The tissue, obtained from recently executed criminals, was fixed immediately postmortem and usually was sectioned. The chromosome counts varied widely, but the work of Winiwarter in 1912 established chromosome counts of 47 in spermatogonia and 48 in oogonia and an XX/XO sex-determining mechanism. T. S. Painter confirmed Winiwarter's work in 1923 and established the human chromosome number to be 48 but disagreed with the sex-determining mechanism, considering it to be XX/XY.

Further progress required tissue culture technology and methodology for handling mitotic cells, not the least of which was the discovery by T. C. Hsu in 1952 of the usefulness of hypotonic pretreatment of tissue culture cells before fixation to disperse the metaphase chromosomes.

Among the methods derived from plant cytogenetics was the use of agents that interfered with the organization of tubulin into the mitotic apparatus. Blakeslee and Avery used the alkaloid colchicine for this purpose and prepared plant chromosomes by a technique involving squashing the cells under a coverglass with gentle pressure. Another plant cytogeneticist, Albert Levan, in John Biesle's tissue culture laboratory, was the first to combine the colchicine and hypotonic pretreatments to obtain chromosome preparations of metaphases from tissue cultures.

In 1956, Levan and Tjio (2) used the same methodology on tissue cultures of human embryonic cells and found the chromosome number of these mitotic cells to be 46 rather than the previously accepted 48. The work was shortly thereafter confirmed by Ford and Hamerton, who observed 23 sets of paired chromosomes or bivalents in squash preparations of human male meiosis.

After the correct normal chromosome number was established, the identification of chromosome abnormalities soon followed. Jerome Lejeune in 1959 described trisomy of a small chromosome in Down-syndrome, and in rapid succession, sex chromosome abnormalities occurring in already described syndromes were identified: 45,X in Turner-syndrome by Ford and co-workers in 1959, 47,XXY in Klinefelter-syndrome, and 47,XXX by Jacobs and associates in the same year. The two other viable trisomic syndromes described, trisomy 13 by Patau and trisomy 18 by Edwards, were described the following year.

Some of these investigators used tissue cultures of skin biopsies and others used bone marrow preparations, but the squash methodology was in use until Rothfels and Simonivitch discovered that rapid air drying on slides of drops of fixed cells resulted in spreading of the metaphases. The culmination of this series of technical advances occurred when Peter Nowell in 1960 discovered that cultures of leukocytes that had been separated from red blood cells using phytohemagglutinin, an extract of the broad bean, were stimulated to divide in culture. This technique, still used today, provided a readily available source of dividing cells and led to the identification of many chromosome abnormalities.

The rapid progress of cytogenetics during these few years required that a common system of nomenclature for the chromosomes be developed, and a series of conferences involving the major investigators in cytogenetics was convened. The first conference, in Denver in 1960, resulted in a system with which to group the chromosomes based on relative length, arm ratio, and centromeric index and proposed a standard system of nomenclature of the groups using a numerical designation, i.e., chromosomes 1–3,4,5,6–12 (Fig. 29.1 and Fig. 29.2). The London Conference in 1963 further described the system and added letters to the groups, A to G plus the sex chromosomes. The meeting in Chicago in 1966 adopted a shorthand system for describing human chromosome abnormalities.

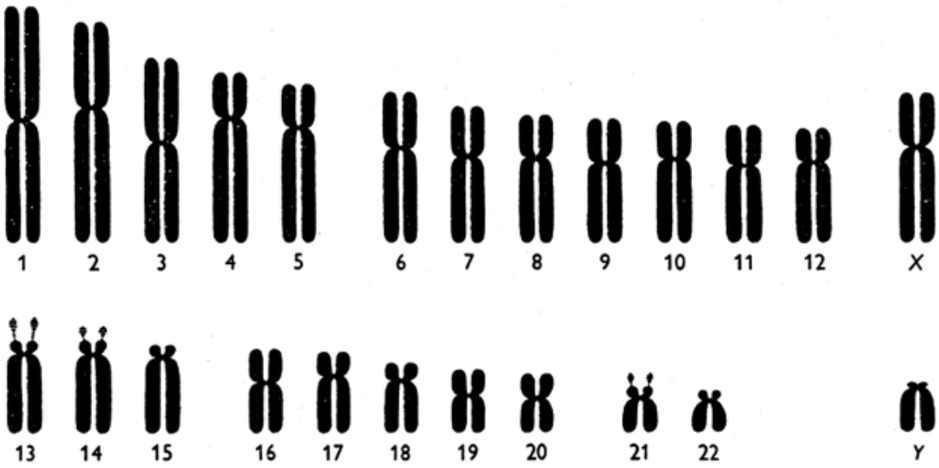

FIGURE 29.1. Idiogram drawn from standard measurements of human chromosomes from the 1960 Denver conference. (From Editorial comments, *Ann Hum Genet* 1960;24:319, with permission.)

Chromosome No.	Relative length				Centromere index			
	A	B	C	D	A	B	C	D

FIGURE 29.2. Relative length and arm ratios of human chromosomes. A, B, C, and D represent different data sets. Sets B, C, and D were identified by Q banding and stained with orcein or Giemsa 9. Set A is the Denver-London data not preidentified by Q banding. The relative length of each chromosome is the length of the chromosome compared with the length of the haploid (1N) set of chromosomes. There are two ways to designate the centromere position: the arm ratio, which is the length of the longer arm relative to the shorter one, and the centromere index, the ratio of the length of the shorter arm to the total length of the chromosome. (From Harden DG, Klinger HP, An international system for human cytogenetic nomenclature. In: Harden DG, Klinger HP, eds. Birth Defects: Original Article Series, vol. 21. New York: March of Dimes Birth Defects Foundation, 1985. Basel, Switzerland: Karger, 1985:114, with permission.)

Although many chromosome abnormalities were described by 1966, the abnormalities were relatively easily visualized—gains or losses of whole chromosomes or easily observed deletions or rearrangements. Some chromosomes could not be readily differentiated from each other; a few were separable by autoradiographic methods based on differences in the completion of replication of similarly appearing chromosomes. Caspersson in 1970 used a fluorescing dye, quinacrine mustard, to stain human chromosomes and was able to demonstrate a different pattern of fluorescence for each of the 22 pairs of autosomes and

the X and Y chromosomes. Each chromosome could now be defined by a specific pattern of light and dark bands, and the banding pattern was shown to be reproduced by other staining techniques using Giemsa stain or other fluorescent dyes. This technique permitted identification of further rearrangements, deletions, duplications, and inversions not previously recognized. The Paris Conference of 1971 addressed the identification of individual chromosomes, regions, and bands and detailed a method of describing structural changes using the banding nomenclature. All the nomenclature was consolidated in the International System for Human Cytogenetic Nomenclature (ISCN) in 1978 (see Chapter 30, Table 26.1) (3).

The major change in the subsequent years was the use of prophase and prometaphase chromosomes to obtain a greater number of recognizable bands, which permitted recognition of even more subtle abnormalities. This was achieved by Yunis, who synchronized the dividing cells to obtain the early stages of division in sufficient quantity to make them useful.

The description of the prophase chromosomes—the size, width, and number of bands at different levels of band resolution—was incorporated into the ISCN in 1981 in *An International System for Human Cytogenetic Nomenclature—High Resolution Banding 1981*; some further revisions were made in 1985 (Fig. 29.3).

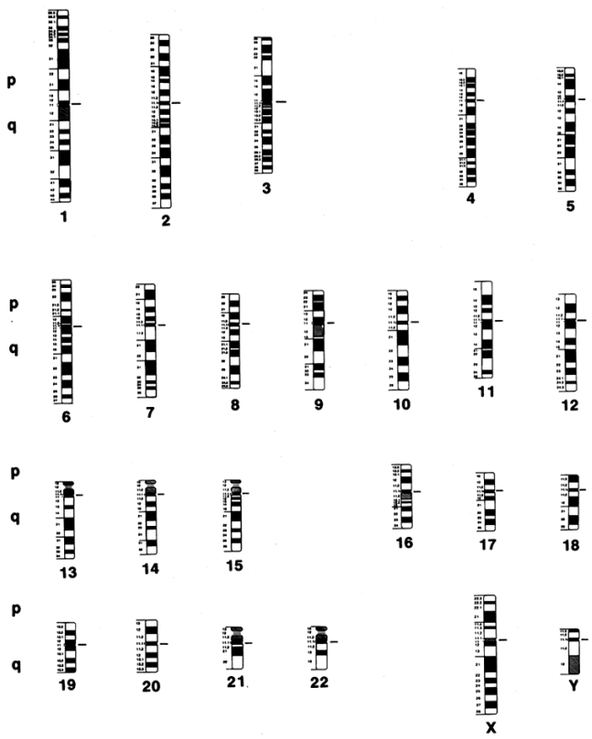

FIGURE 29.3. Diagram showing G-banding pattern of normal human chromosomes at 400-band level. (Adapted from Harden DG, Klinger HP. An international system for human cytogenetic nomenclature. Harden DG, Klinger, HP (eds), In: Harden DG, Klinger HP, eds. *Birth Defects: Original Article Series*, Vol. 21. New York: March of Dimes Birth Defects Foundation, 1985.)

In 1991, recognizing the complexity of describing acquired abnormalities with the current nomenclature, the Study Committee on Human Cytogenetic Nomenclature established new guidelines specific for describing abnormalities encountered in cancer cytogenetics (3a).

The most recent advance in cytogenetics has been the advent of molecular cytogenetics, in which techniques of molecular biology are applied to cytogenetic preparations. These procedures include *in situ* hybridization for localizing DNA probes to specific chromosomes and bands. Radioactive probes labeled with tritiated thymidine were initially used, followed by procedures utilizing immunologic reactions coupled with staining of the product with a fluorescent dye (immunofluorescence). These techniques were useful for both gene localization and the identification of fragments or rearrangements in dividing and nondividing cells.

The greatest advances, however, have involved the utilization of fluorescence *in situ* hybridization (FISH) using a variety of probes labeled with biotin and visualized by fluorochrome staining or probes directly labeled with fluorochromes in conjunction with fluorescence microscopy. This method permits staining of individual chromosomes or regions of chromosomes and allows identification of specific chromosome rearrangements in either metaphase or interphase cells.

As in previous years, an updated version of the ISCN was published in 1995 (4) that addressed the new guidelines that were developed to describe the utilization of FISH. These guidelines proposed an entirely new nomenclature to incorporate this new technology.

Cytogenetics has now become an integral part of the gene mapping attempts and has a wide application to medical questions regarding the relationships between such chromosome abnormalities as infertility, miscarriage, birth defects, mental retardation, and cancer.

CHROMOSOME STRUCTURE

Part of "29 - Basic Cytogenetics"

Studies of chromosomes of a variety of organisms have led to the conclusion that the chromosome is composed of a single continuous DNA fiber in each chromatid (i.e., one of the two daughter strands of a replicated chromosome). The basic subunit is a 10-nm fiber that has been described after digestion by micrococcal nuclease as the “nucleosome”—the familiar “beads-on-a-string” structure, the core particle of which contains 145 bp of DNA helix coiled around an octomer of histones H2a, H2b, H3, and H4 (Fig. 29.4). Adjacent nucleosomes are separated by

DNA linkers of varying length associated with H1 histone, which stabilizes the structure (Fig. 29.5). This fibril is in turn compacted into a 30-nm thick fibril that undergoes further condensation to form the metaphase chromosome. Observations of higher chromosome structure derived from whole-mount or histone-depletion electron microscopy give different perspectives of chromosome architecture (Fig. 29.6) and have resulted in several models of chromosome structure (5).

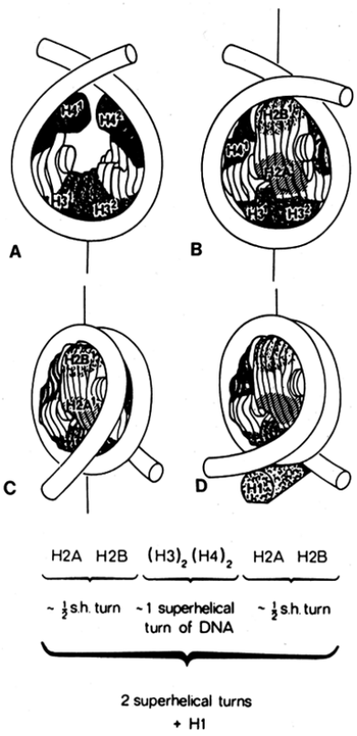

FIGURE 29.4. Assembly of nucleosome core particle from its constituents. (From Richmond TJ, Finch JT, Klug A. Studies of nucleosome structure. *Cold Spring Harb Symp* 1982; 47:493–501, with permission.)

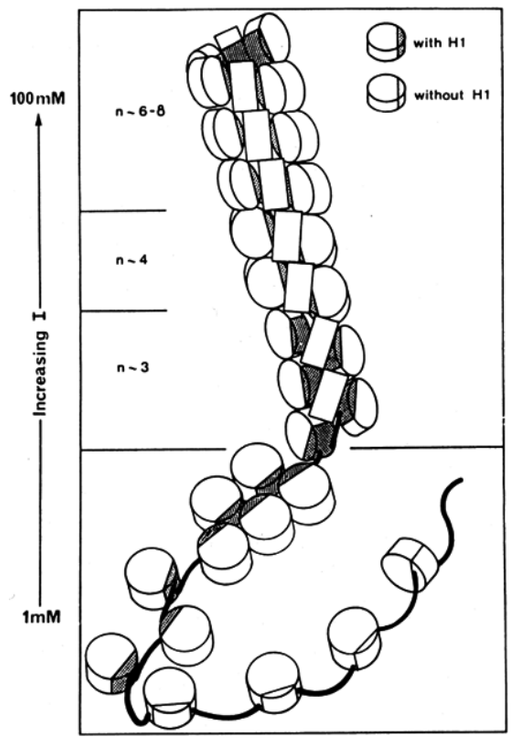

FIGURE 29.5. Idealized drawing of the solenoid structure of a chromosome showing the open zigzag of nucleosomes that form the solenoid. (From Thoma F, Koller TH, Klieg A. *J Cell Biol* 1979;83:403–427, with permission.)

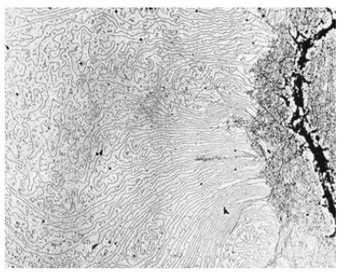

FIGURE 29.6. Electron micrograph of histone-depleted chromosomes shows the organization of the DNA in loops. The chromosome scaffold is to the left with loops extending outward from the scaffold. (From Paulson JR. Scaffolding and radial loops, the structural organization of metaphase chromosomes. In: Adolph KW, ed. *Chromosomes and chromatin, volume III*. Boca Raton, FL: CRC Press, 1988:3–36, with permission.)

When chromosomes are digested to remove most of the histones, leaving only protein and DNA and observed by electron microscopy after spreading, a loose fibrillar protein structure extending through the chromatids and surrounded by a halo of loops of DNA is revealed. These observations have suggested a chromosome structure in which radial loops of DNA are supported by a cytoskeleton or scaffold of fibrillar protein (Fig. 29.7).

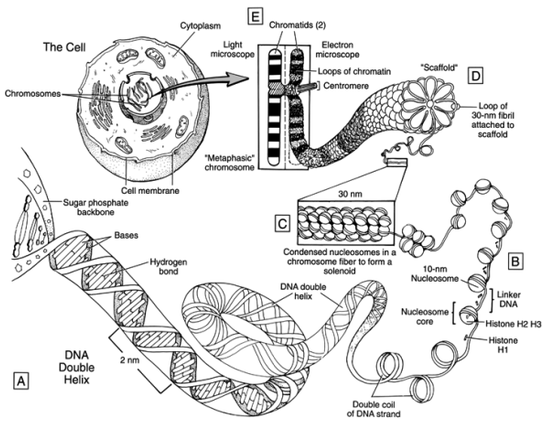

FIGURE 29.7. Model of chromosome structure shows the hierarchy of coiling and looping in the DNA helix **(a)**, nucleosomal 10-nm fiber **(B)**, 30-nm solenoidal fiber **(C)**, the looping of the 30-nm fibers and their attachment to the chromosome scaffold **(d)**, and the chromosome as seen on electron microscopy **(E)**.

Another model derived from whole-mount electron microscopy and light microscopy observations of coiled chromatids suggests that the chromosome is based on a successive series of helical coils of the 30-nm fiber to form a super solenoid, which eventually results in a coiled metaphase chromatid of approximately 1,000 nm in width. All these structures require some degree of compaction of the 10-nm DNA fiber into the condensed chromatin that is visualized at mitotic or meiotic division. The current concept of the chromosome is that the solenoid and looping conformations are both present in the chromosome. The solenoidal structure is the 30-nm fibril that is attached to a scaffoldlike matrix in loops. The whole structure undergoes a higher order of condensation by further coiling as the chromosome shortens in progress toward metaphase (6,7).

Specialized Regions of Chromosomes

The Telomere

The ends of the chromosomes, the telomeres (Fig. 29.8), have several important functions in the cells. The concept of the telomere is based on the observation that when chromosomes are broken by radiography or other means, the broken ends will fuse to each other, but not to unbroken ends. Telomeres protect the ends of the chromosomes from degradation and from becoming involved in end-to-end fusions and allowing complete replication of the end of the chromosome. Telomeres at the end of chromosomes enable cells to distinguish chromosome ends from breaks in DNA. This is essential as unrepaired chromosomes with breaks will cause the cell to become arrested at a checkpoint. Telomeres at the ends of chromosomes allow the cells to pass through the checkpoint. Telomeres also guide localization of the chromosomes within the nucleus as they have the tendency to be positioned near each other (telomere association) and with the nuclear membrane in meiosis and, on occasion, in mitotic prophase.

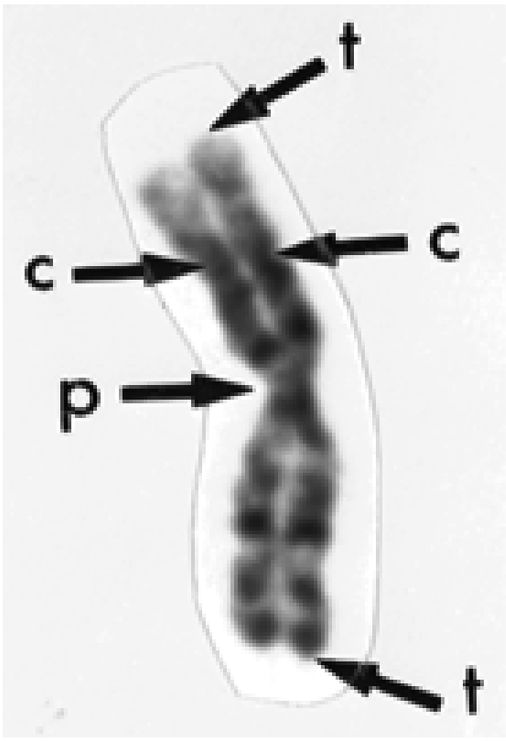

FIGURE 29.8. Each chromosome at metaphase is composed of two chromatids (*c*), each of which has a single continuous strand of DNA extending from end to end. Each chromatid has a centromere, which is located in a constriction, the primary constriction (*p*), and at each end each chromatid is capped by a telomere (*t*).

There is a considerable amount of telomeric DNA [approximately 15 kilobase (kb)] within the cells that is regulated in both species- and cell-specific ways. Additionally, although the telomeres are composed of simple sequences (see below), small changes

can be catastrophic (e.g., division failure). Therefore, it has been hypothesized that telomeres have additional functions including regulation of gene expression, and control over cell division, cell senescence, and neoplastic proliferation. The lack of telomerase will cause the chromosomes to shorten, thereby exposing active genes and eventually leading to cell death. Telomerase activity will immortalize cells, but its mere presence does not confer immortality, indicating that its relationship with cancer is more involved.

The structure of telomeres must account for the characteristics described above as well as for the means of replication of the terminus of a linear DNA molecule. Studies of telomeres have used organisms with many short chromosomes, such as *Tetrahymena* and yeast, to permit purification and molecular analysis of the chromosome ends. The *Tetrahymena* telomere has thus been found to contain 1,500 to 6,000 tandem repeats of the nucleotide sequence TTAGGG. This structure has been found in organisms as widely separated as birds and reptiles, as well as

yeast and other microorganisms. The repeating sequence TTAGGG also occurs at the termini of human chromosomes as well (Fig. 29.9) (8). These tandemly repeated DNA sequences are conserved among vertebrates; however, the number of repeats will vary from 500 to 300. In humans, the telomeres in germ line cells are significantly longer than in the somatic tissue cells. The homology of base sequences in the telomeres can account for telomere association of homologous and nonhomologous chromosomes. In cases in which telomere association persists to metaphase, it is possible that an endonuclease involved in replication has failed to function.

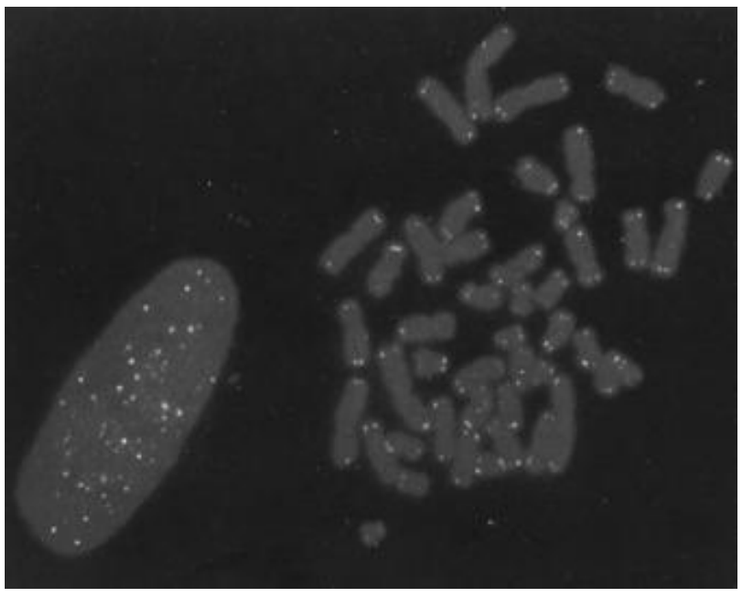

FIGURE 29.9. Telomeres of chromosomes shown after *in situ* hybridization with biotin-labeled repetitive telomeric sequences to metaphase chromosomes. (From Moyis RK, Buckingham JM, Cran LS et al. A highly conserved repetitive DNA sequence (TTAGGG), present at the telomeres of human chromosomes. *Proc Natl Acad Sci U S A* 1988;85:6622–6626, with permission.)

There is telomere-associated DNA (TAS) located immediately internal to the terminal telomeric DNA. Both the telomeres and TAS are dynamic structures that are subjected to both deletion and amplification, apparently involving homologous recombination. Internal to the TAS are unique subtelomeric sequences, which are unique among all the chromosome arms. These are the sequences utilized for the FISH subtelomeric probes (as described below).

There are special problems in replicating the ends of the DNA strand, namely, the requirement of a DNA polymerase to have both a template to copy and a primer to extend because polynucleotide synthesis can proceed in only one direction (from 5′ to 3′). The 3′ ends of the strands cannot be replicated because there is no more DNA left on which to synthesize the RNA primer. How then does the telomere replicate?

An unusual telomerase that functions as a special reverse transcriptase has been found in*Tetrahymena*. The RNA of the telomerase provides its own template for the synthesis of the telomeric repeats that are added on during replication of the ends of the chromosome. A similar telomerase has been identified in human and mouse cells, suggesting that the *Tetrahymena* system may be present in all cells. It has been shown that human telomerase contains a RNA subunit of approximately 450 nucleotides with no sequence homology to any of the lower eukaryotic telomerase RNA components. Proteins act with the RNA template to maintain telomerase. In humans, two important proteins have been identified: TRF1 and TRF2 (9,10). Both of these proteins bind to the TTAGGG repeat and are localized to the telomere of human metaphase chromosomes and are present throughout the cell cycle. TRF1 functions as a suppressor of telomere elongation as overexpression of TRF1 leads to telomere shortening. However, a mutation will lead to a dominant-negative effect and telomere elongation. TRF2 prevents end-to-end fusion and contributes to maintenance of correct structure of telomeres. Overexpression of this protein has no effect; however, expression of a deleted TRF2 protein leads to rapid growth, senescence, and fusion of telomeres (11,12 and 13).

The Centromere

The centromere, the region of the chromosome also referred to as the primary constriction, divides the chromosome into arms (Fig. 29.8). The centromere may be in the middle of the chromosome, resulting in a metacentric chromosome, may be asymmetrically placed on the chromosome to give a submetacentric and/or acrocentric chromosome, or may be at the end of a chromosome in a telocentric chromosome. The centromere is composed primarily of repetitive DNA and associated with the kinetochore (see below) (14).

The centromere of a chromosome has several important functions: (a) it is essential for chromosome attachment to the spindle apparatus, (b) it is essential for the proper segregation of the chromosomes in both mitosis and meiosis, and (c) it serves as a point of attachment for both sister chromatids. As indicated above, the centromere contains repetitive DNA. One important class of tandemly repeated centromeric DNA, which constitutes one component of the functional centromere, is the alpha-satellite DNA family. The amount of this DNA is extremely variable between centromeres, consisting of anywhere from 200 kb to greater than 5,000 kb. The alpha- satellite DNA is located at the primary constriction, and these repeats comprise approximately 3% to 5% of the genome. The basic unit of the alpha-satellite DNA is a 171-bp monomer, which is repeated anywhere from 100 to 1,000 times. Although the monomers between different chromosomes are similar, the sequence may vary by as much as 10% to 40%. This allows the development of specific DNA probes for FISH to detect individual centromeres. It has been hypothesized that alpha-satellite DNA is necessary for centromeric function. A 17-bp of alpha-satellite DNA is recognized by centromere protein B (CENP-B). These CENP-B boxes are regularly distributed at high frequency in the alpha-satellite DNA and analogous to other boxes in other species. Additionally, when alpha-satellite DNA has been introduced to cell lines, this DNA confers centromeric activity. In opposition to these findings, there have now been several reports of chromosomes with no detectable DNA or CENP-B but which normally segregate in cells, suggesting that alpha-satellite is necessary for a functioning centromere (15,16).

The kinetochore is a specialized proteinaceous structure located on either side of and closely associated with the centromere. This centromere/kinetochore complex consists of the kinetochore, heterochromatin, and associated proteins. It is the location

for the mechanochemical motor components of chromosome movement in mitosis. This complex has three structural domains: (a) inner pairing domain, containing proteins and DNA; (b) central domain, consisting of heterochromatin; and (c) outermost domain (kinetochore), containing the kinetochore structure, associated proteins, and chromatin. This outermost domain is the primary point of spindle attachment.

The kinetochore functions as the region of attachment of the subunits of the spindle apparatus, the microtubules, to the DNA of the chromosome during division. As indicated previously, the kinetochore of a mammalian chromosome is a multilayered disk that stains with heavy metals; when visualized by electron microscopy, it appears to have a trilaminar structure composed of an outer plate of condensed fibrillar or granular material 40 nm thick that contains DNA (Fig. 29.10). The kinetochore microtubules appear to terminate in this outer plate. Beneath this is a middle and more electron-translucent 30-nm thick layer that appears to be loosely aggregated and fibrillar in nature. The inner layer, also composed of DNA, is similar in thickness to the outer layer and approximates the underlying chromatin. In addition to the DNA and RNA contained in the kinetochore, there are specific proteins associated with the outer and inner kinetochore plates (17).

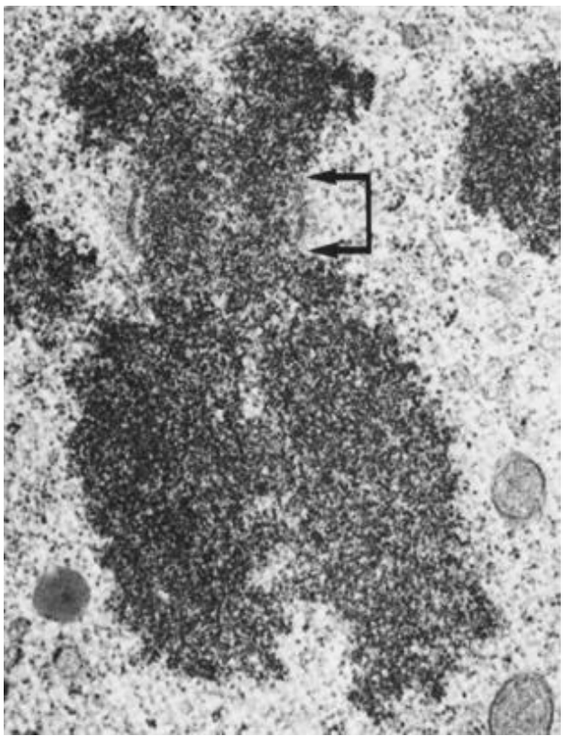

FIGURE 29.10. An electron micrograph of a thin section of a mouse chromosome shows the primary constriction (*arrows*) and the kinetochore, which appears along the lateral surface of the constriction. (From Rattner JB. In: Adolph KW, ed. *Chromosomes and chromatin, vol II*. Boca Raton, FL: CRC Press, 1988:29–49, with permission.)

Patients with autoimmune diseases, such as scleroderma and CREST syndrome, have antibodies that react with these CENPs. These CENPs consist of several different species, all located at the centromere/kinetochore complex. CENP-C, the CliPs (chromatio linking proteins) and Inceps (inner centromere proteins) are localized to the inner pairing domain, CENP-A and CENP-B to the central domain, and CENP-E, and CENP-F to the outermost domain. CENP-B was the first centromeric protein to be isolated and cloned. As described above, its main function is an interaction and binding with alpha-satellite DNA and is conserved among vertebrates. There is a variation in intensity of CENP-B, based on the amount of satellite DNA present. CENP-C has a direct role in kinetochore structure and activity. It is directed only at the active centromere, whereas CENP-B can be also found at inactive centromeres. CENP-C is necessary for both kinetochore assembly and establishment of stable chromosome attachment to the spindle. CENP-E is a unique motor protein. It is associated with microtubule and chromosome movement. Similar to CENP-C, it is localized to only the active centromere. CENP-A is a centromere-specific histone H3 homolog, which is located at the inner plate of the kinetochore. Similar to CENP-C and CENP-E, it is associated with only an active centromere. CENP-A is important in the construction of the nucleosome core particles (18,19).

Heterochromatin

As described previously, a major component of the centromeric region is constitutive heterochromatin (repetitive DNA). First described by Heitz in 1928, heterochromatin is chromatin that remains condensed telophase and remains visible during interphase. This out-of-phase or allocyclic behavior of heterochromatin is also reflected in its DNA synthesis, which occurs late in the replication of the chromosome. Two types of heterochromatin may be differentiated.

The first type, constitutive heterochromatin, contains DNA that is not transcribable and is located mainly at centromeric and telomeric sites, although in some organisms, its location is not limited to these regions. In human chromosomes, constitutive or c-heterochromatin is centromeric in all the chromosomes, with additional paracentromeric areas in chromosomes 1, 9, and 16. It makes up much of the long arm of the Y chromosome and may be readily demonstrated by C banding (described later in this chapter). The second type of heterochromatin, facultative heterochromatin, is composed of transcribable DNA that has been inactivated and that has assumed the other characteristics of heterochromatin, including allocyclic condensation and late replication (see X-chromosome Inactivation section).

Constitutive heterochromatin is composed largely of a type of DNA, satellite DNA, which differs in base composition and physical characteristics from the remainder of the DNA. When DNA is fragmented and ultracentrifuged, the lightest and heaviest fragments settle at a different rate than the remainder of the DNA, appearing as separate satellite bands. Satellite DNA is composed of multiple tandem repeats of simple-sequence DNA, 2 to 12 bp in length, resulting from amplification of these simple sequences. Divergence owing to mutation produces related but distinct satellites within an organism. In addition to the satellite DNA, other repeated sequences are found in the human genome. These include short interspersed repeated sequences, which are approximately 300 bp in length, Alu elements (which are repeated DNA sequences cleaved by the restriction endonuclease AluI), and long interspersed repeated sequences. Eight different

satellites identified by gradient centrifugation have been defined in human DNA and have been localized in the centromeric and telomeric regions of the chromosomes by *in situ* hybridization. Analysis of human genomic DNA using restriction endonucleases (enzymes that cleave DNA molecules at specific recognition sites) has revealed additional satellite DNA composed of tandem repeats that also hybridize to centromeric regions. One of these, alpha-satellite DNA (see above), is composed of a number of subfamilies that differ with respect to the sequence and location of sites of cleaving by restriction endonucleases.

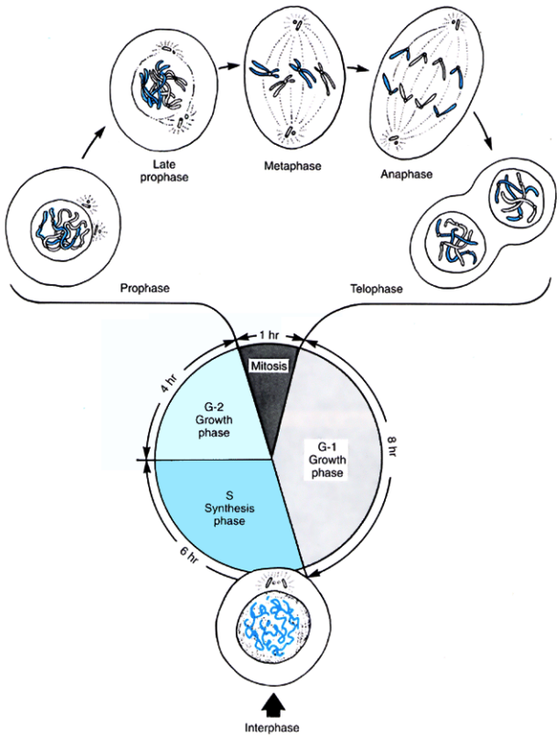

FIGURE 29.11. The mitotic cycle. The mitotic division comprises only a small segment (0.75 to 1.0 hour) of the cycle, which is characterized by an S or synthesis phase and two growth phases, all occurring during interphase.

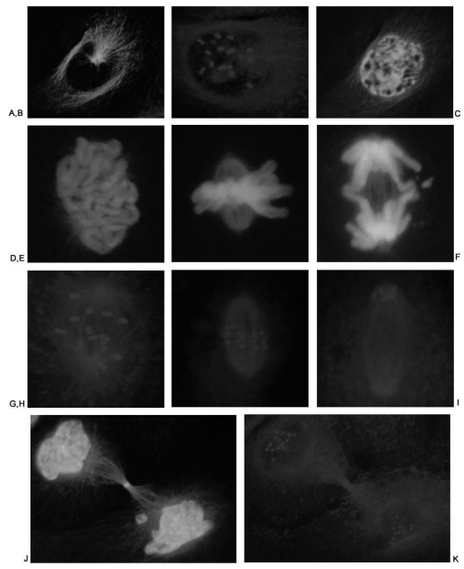

FIGURE 29.12. Components of the mitotic apparatus after staining with specific antibodies and fluorescent stains. Cells are from a mammalian cell line (PtK). **A:** The microtubules are stained green with antitubulin antibodies and fluorescein-labeled secondary antibodies. **B:** The kinetochores are stained red with anticentromere antibodies from a patient with scleroderma plus rhodamine-labeled secondary antibodies. **C:** The chromatin of an early prophase cell. The chromosomes are stained blue with DAPI stain. Centrosome activity is revealed in the two asters of the cytoplasmic microtubules (green), but the nuclear envelope blocks interaction with kinetochores. **D–F:** Prometaphase through anaphase. The chromosomes are stained blue with DAPI and the spindle green with antitubulin antibodies and fluorescein-labeled secondary antibodies. **G–I:** Prometaphase through anaphase stained to show kinetochores (with anticentromere antibodies and rhodamine-labeled secondary antibodies). **J, K:** A pair of cells in late telophase-interphase, when nuclei are essentially reestablished, but the two cells are connected by a cytoplasmic bridge. **J:** Same cells stained to show chromatin and spindle as above. **K:** Same cell stained to show kinetochores. (From McIntosh J, Koonce MP. Mitosis. *Science* 1989;246:622–628, with permission.)

Alpha-satellite sequences are located at the centromeres of human chromosomes. The alpha-satellite regions of most human chromosomes differ from each other (20).

Mitosis

DNA packaging changes during the cell cycle. From great extension during transcription, there is an increasing formation of loops as metaphase approaches, concurrent changes in the methylation of chromatin, and the presence of a variety of associated histone and nonhistone proteins as the chromosome is again compacted.

The culmination of contraction of the interphase chromosome is the mitotic division. Mitosis, which is necessary to distribute the chromosomes equally at cell division, is only a transient phase occupying approximately 1 hour of a cell cycle, which comprises some 18 to 24 hours (Fig. 29.11). At the initiation of the cell cycle, cells may be activated from a resting state, G-0, and enter the cell cycle. During the G-1 stage of the cell cycle, events occur that are necessary for the subsequent S (synthesis) phase in which the chromosomes are replicated. DNA replication is followed by G-2, a period in which further changes occur in preparation for formation of the spindle, in nuclear membrane breakdown, and in further shortening of the chromosomes composed now of two chromatids. At the beginning of metaphase, the chromosomes align themselves on the metaphase plate so that each short thick chromatid is oriented toward one pole of the mitotic spindle. As anaphase occurs, the two chromatids of each chromosome separate beginning at the kinetochores and move to opposite poles of the spindle. By telophase, the chromosomes are grouped at the poles. A nuclear membrane is reformed and the chromosomes uncoil, forming the interphase nuclei of the daughter cells (Fig. 29.12) (21).

Meiosis

Whereas mitotic divisions result in two identical daughter cells, the essence of meiosis is pairing, recombination, and a reduction in chromosome number to the haploid 1N number. DNA replication during premeiotic S is three to six times longer than the S phase of mitotic cells. The DNA is almost completely replicated, with a small portion remaining unreplicated until replication is finally completed at zygotene. Meiosis results in a reduction to the haploid chromosome number because two cell divisions occur with only one replication of DNA. The synaptonemal complex (SC), a unique structure not found in mitotic divisions, holds the paired homologous chromosomes together during meiosis I and facilitates the exchange of chromatin that results in crossing over.

Meiosis is characterized by a series of stages that are microscopically distinct, with significant changes in chromosome behavior seen as well at the electron microscope level (Fig. 29.13). The chromosomes are at their greatest length at leptotene. They are still unpaired, but because DNA replication has occurred, two chromatids may be observed. At this stage, the telomeres are attached to the nuclear membrane and synapsis of the chromosomes begins from these ends. The homologous chromosomes are brought together by the protein chromosome cores to which the loops of chromatin are attached. Synapsis is complete at zygotene, the core proteins from the homologous chromosomes forming the SC. This structure, specific to meiosis, is essential for maintaining the alignment of the homologous chromosomes, which are now closely paired (Fig. 29.14).

At the pachytene stage of meiosis, the paired homologous chromosomes (or bivalents), each composed of four chromatids (tetrads), are held in register by the SC as crossing over occurs. The SC, a ladderlike structure composed of two lateral elements on either side of the chromosomes and a central fibrillar region, is complete. Recombination nodules, units that mediate the molecular process of exchange, appear on the SC and chiasmata are visible. The latter are evidence that crossing over has occurred.

The recombination nodules correspond in number and position with chiasmata. At diplotene, the SC begins to disappear, but the chromosomes are held together by chiasmata. If no chiasmata are present, the bivalent falls apart and the homologous chromosomes will segregate independently. Thus, the chiasmata have an additional important function in holding the paired homologous chromosomes together.

At diakinesis, the chromosomes shorten, and as they shorten, the chiasmata appear to move to the ends of the chromosomes (terminalize), and there is a reduction in the total number of chiasmata. The bivalents move to the periphery of the nucleus. The nuclear membrane disappears and chromosomes align on the spindle. At metaphase as the paired homologs align, the kinetochores are widely separated facing opposite poles of the spindle. Orientation of centromeres of nonhomologous chromosomes in the metaphase spindle is random, resulting in independent assortment of the several pairs of chromosomes.

When the homologs separate, the telophase groups of chromosomes at the poles contain half the number of chromosomes of the original cell. However, each chromosome still has two chromatids, and each is referred to as a dyad.

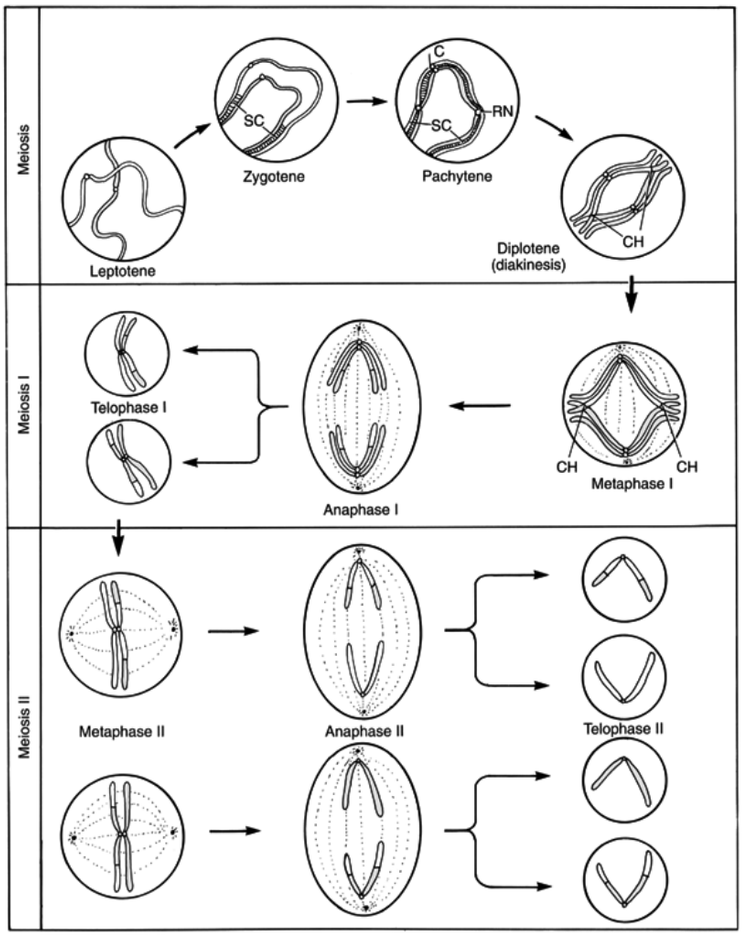

FIGURE 29.13. The meiotic division. Note the extended chromatin of leptotene, the beginning of the formation of the synaptonemal complex (SC) at zygotene, the completed synaptonemal complex showing recombination nodules (RN) at pachytene, the four strands showing crossing over at diplotene to diakinesis with the centromeres (C) widely separated and the chromosomes held together by chiasmata (CH), and the alignment of homologs at metaphase I and separation at anaphase I (only one daughter cell shown). Prophase II is short and is not shown. At metaphase II the sister chromatids separate, and at telophase II the haploid number results.

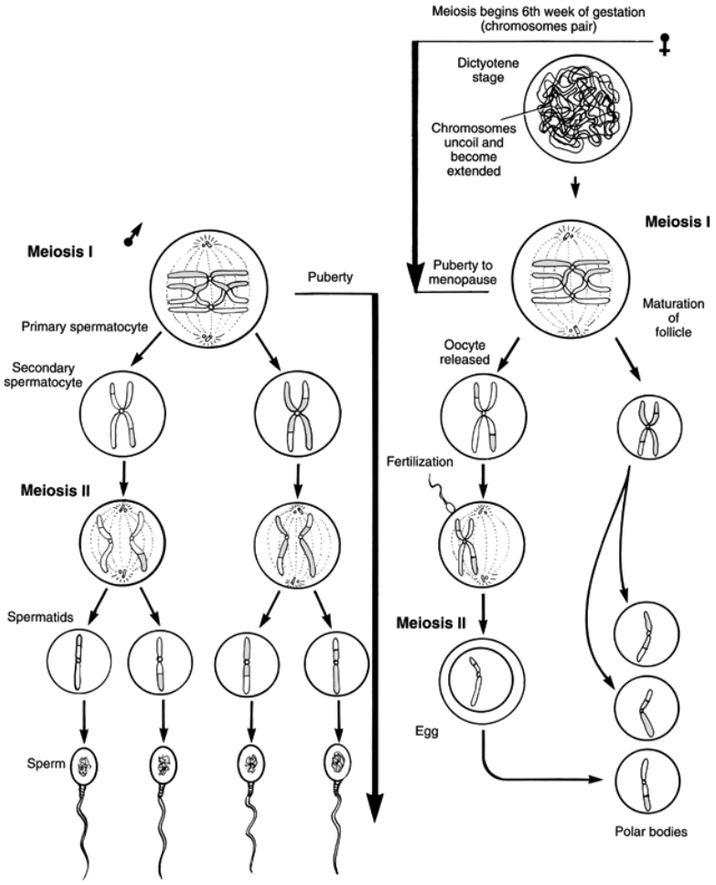

FIGURE 29.14. Comparison of meiosis in male and female gametogenesis.

The subsequent interphase is short and without a period of DNA replication, and the dyads separate at the second meiotic division. Each of the products of meiosis now has half the number of chromosomes and half the amount of DNA of the original germinal cells.

In males, meiosis occurs in germ cells, which begin to divide meiotically at puberty. Meiotic divisions are of much longer duration than mitosis, requiring 15 to 32 hours to complete the division. The spermatogonia initially turn into primary spermatocytes. These spermatocytes enter meiosis I and emerge as haploid

secondary spermatocytes. Secondary spermatocytes enter meiosis II, emerging as spermatids. Approximately 100 to 200 million spermatids are in each ejaculate. The transition from spermatogonia to mature sperm is a relatively rapid process, requiring 60 to 65 days.

In females, the first meiotic division is initiated prenatally at approximately 3 to 6 weeks of gestation. The initial process of transition from primordial germ cell to oogonia involves 20 to 30 mitotic divisions. The progression from oogonia to mature ova involves a complex series of intermediate events and is completed as each egg matures and is released from the follicle. This may occur at any time from puberty to menopause. The second

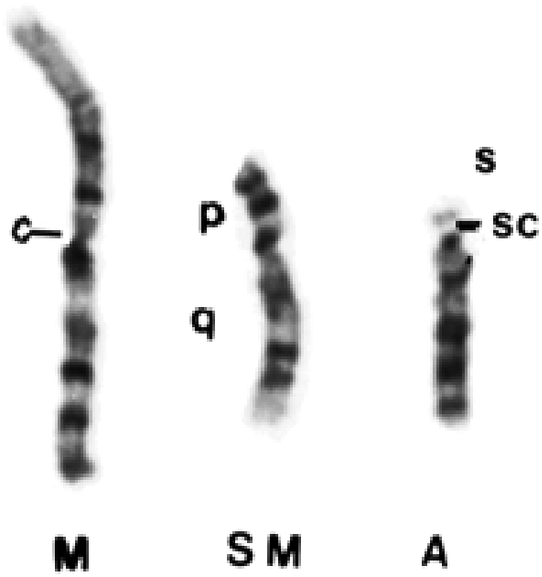

FIGURE 29.15. Morphologic characteristics used to group human chromosomes. M, metacentric; SM, submetacentric; A, acrocentric; c, centromere; p, short arm; q, long arm; s, satellites; sc, secondary constriction.

meiotic division occurs in the fallopian tube after fertilization. There is a very lengthy interval between the onset of meiosis and its eventual completion. Each of the meiotic divisions produces a polar body so that at maturation, the egg and two polar bodies result (Fig. 29.14).

There are several distinct differences between mitosis and meiosis. Mitosis occurs in all tissues, meiosis only in the testis and ovary. Diploid somatic cells are produced through mitosis, whereas meiosis produces haploid sperm and egg cells. There is normally one round of DNA replication per cell division in mitosis and one round of replication in meiosis; however in the latter, there are two cell divisions during this interval. Prophase is very short in mitosis (approximately 30 minutes in human cells), but is long and complex in meiosis I and can take years to complete. Recombination is rare and abnormal in mitosis but is normally seen at least once for each pair of homologs in meiosis. All the daughter cells in mitosis are genetically identical, but they are different in meiosis because of recombination and independent assortment of homologs.

CHROMOSOME IDENTIFICATION

Part of "29 - Basic Cytogenetics"

Human chromosome morphology is usually based on the appearance of mitotic metaphase chromosomes. Metaphase chromosomes are composed of two identical chromatids resulting from the prior replication of DNA during the S phase. Chromosomes may differ in length and in position of the centromeres. The chromosomes appear constricted at the centromere or primary constriction, and this constriction usually divides each chromosome into two arms. The arms are designated p (the short arm) and q (the long arm) (Fig. 29.15). These arms may be equal, in which case the chromosome is referred to as metacentric; if the arms are unequal, the chromosome is called submetacentric. The centromere may be near one end of the chromosome (acrocentric chromosome) or terminal (telocentric chromosome).

The morphology of the human chromosome was initially defined by the relative length of the chromosome compared with the total length of a normal X-containing haploid set and by two parameters relative to the position of the centromere: the arm ratio and the centromeric index (Fig. 29.2).

Another defining feature of the chromosome is the occurrence of secondary constrictions, a thinning or indentation of the chromosomes, which may be visible in only a portion of the cells. These constrictions occur in areas of heterochromatin and at the tip of the acrocentrics, where they separate a small segment, the satellite, from the chromosome. The secondary constrictions vary in size; in human acrocentric chromosomes, the region of the constriction between the main part of the chromosome and the satellite contains the nucleolar-organizing region.

Chromosome Staining Patterns

Chromosome bands in human chromosomes were first demonstrated by Caspersson in 1970. A band is defined as an area of the chromosome that is darker or lighter than its adjacent segments. The chromosome consists of a continuous series of dark and light bands. Several staining procedures have been developed, and bands that appear dark with one procedure may be light with another. Chromosome banding patterns are a means of identifying individual chromosomes (22,23 and 24).

Q and G Bands

Caspersson used quinacrine mustard, a fluorescent dye, to demonstrate areas of bright and dull fluorescence on the arms of the chromosomes. The bands produced are referred to as Q-bands. Q-banding permits identification of each chromosome in the human karyotype. In particular, the Y chromosome is readily differentiated from the remaining acrocentric chromosomes by the brilliant fluorescence of the distal half of Yq, which is also visible in the interphase nucleus as a brilliant Y body. With Q-banding, centromeric regions and satellites demonstrate variations in staining intensity and size that are inherited (Fig. 29.16). The staining reaction of Q-banding is based on interaction with specific bases, adenine and thymidine. Other adenine-thymidine (AT)-specific fluorochromes such as Hoechst 33258 and DAPI produce a similar banding pattern.

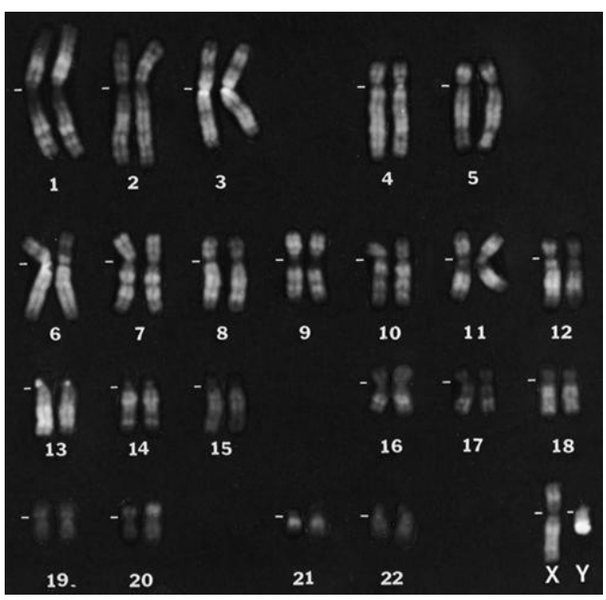

FIGURE 29.16. Q-band karyotype. (Reproduced from Lin CC, Vehida IA. Fluorescent banding of chromosomes. In: Kruse PF, Patterson MK, eds. Tissue culture methods and applications. New York: Academic Press, 1973:778–781, with permission.)

G-bands are produced by pretreatment with mild salt or proteolytic enzymes, followed by staining with one of the Romanowsky dyes (Giemsa, Wright's, or Leishman's stain) (Fig. 29.17). The patterns of G- and Q-bands are similar and correspond to the pattern of chromomeres seen in the chromosomes of meiotic pachytene. The G/Q-bands condense early in mitosis and meiosis, and replication studies with tritiated thymidine (^{3}HT) or bromodeoxyuridine (BrdU) show that these regions replicate late in the cell cycle.

Although darkly staining G-bands generally correspond to bright Q-bands, there are some differences in staining, particularly in some paracentromeric regions that stain negatively by Q-banding but stain darkly with G-banding. Similarly, the segment of the Y chromosome that stains brilliantly with Q-banding stains with G-banding uniformly with the remainder of the chromosome. Thus, although there are similarities in banding patterns, the two banding methods have different uses in cytogenetic

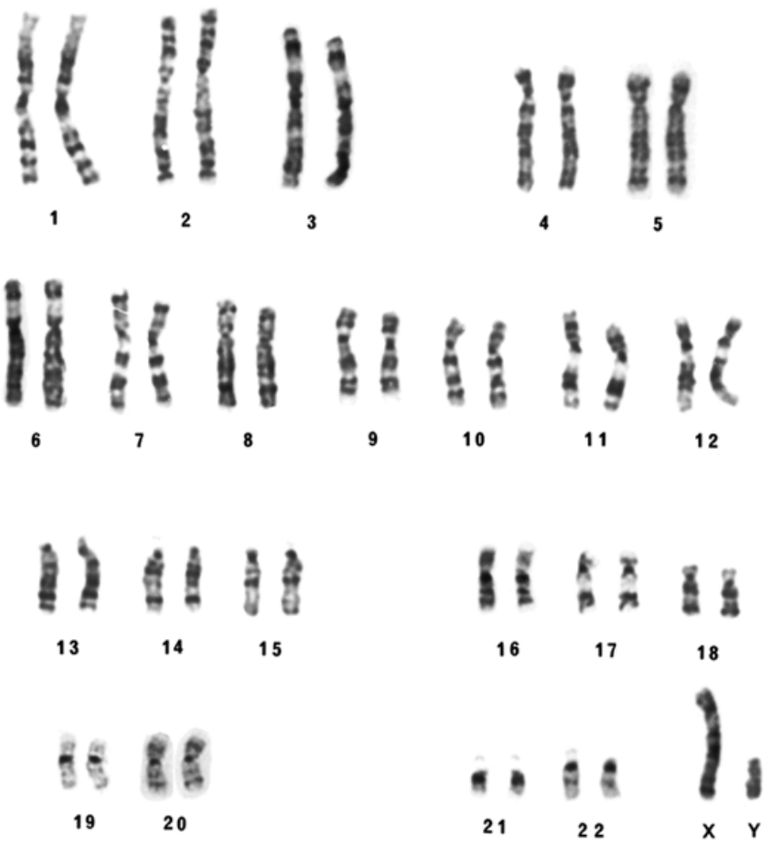

FIGURE 29.17. G-band karyotype of a normal male.

studies, G-banding being used more routinely for cytogenetic studies and Q-banding reserved for special purposes requiring visualization of polymorphisms on the Y chromosome.

Method for G-Banding with Trypsin

To obtain sharply defined bands with trypsin banding, slides must be aged. Freshly prepared slides are placed in a drying oven at 65°C overnight or longer, depending on humidity, and then trypsinized. The materials needed are 0.1 g Difco powdered trypsin (1:250) in 100 mL isotonic buffered saline (Isoton), isotonic buffered saline, phosphate buffer (pH 6.8), and Giemsa working solution (1 mL Giemsa and 49 mL phosphate buffer at pH 6.8).

Slides are treated in trypsin solution for 3 to 7 seconds, rinsed in Isoton and fetal calf serum and then in Isoton alone. The slides are then stained for approximately 2 to 4 minutes in Giemsa solution, rinsed in phosphate buffer (pH 6.8), then in distilled water, and allowed to dry.

Method for QM Staining

The materials needed are 5 mg quinacrine mustard dihydrochloride in 80 mL KH_2 PO_4 buffer (store in light-tight container) and buffer (18.16 g KH_2 PO_4 in 2 L of distilled H_2O).

Slides do not need to be aged. Stain slides 1 to 2 minutes and rinse in distilled water. Place slides in KH_2 PO_4 buffer for 1 to 2 minutes. Place two or three drops of KH_2 PO_4 buffer on slide, add coverslip, blot excess buffer, and seal edges of coverslip. Store in the dark. Observe with fluorescent microscope using a wavelength of 450 to 500 nm.

R-Bands

R-banding is produced by treatments that selectively denature AT-rich DNA; for example, heat denaturation of chromosomes at 85°C followed by staining with Giemsa or with acridine orange. Fluorochromes with an affinity to guanine-cytosine (GC) bp such as chromomycin A3 or olivomycin will also produce

a fluorescence pattern similar to that of R-bands. R-banding may also be produced by BrdU incorporation, a replication banding technique (RBG) that takes advantage of the late replication of R-bands (discussed Replication Banding section).

R-banding is the reverse of G/Q-banding. Regions that appear light with G-banding are darkly stained with R-banding (Fig. 29.18). After R-banding, the ends of the chromosomes appear darkly stained. Thus, it is useful to utilize R-banding when an abnormality involving the chromosome ends, such as a terminal deletion, is suspected. The extent of deletions may be more precisely determined from the darkly staining R-bands than with G-banding, in which the same band is lightly staining.

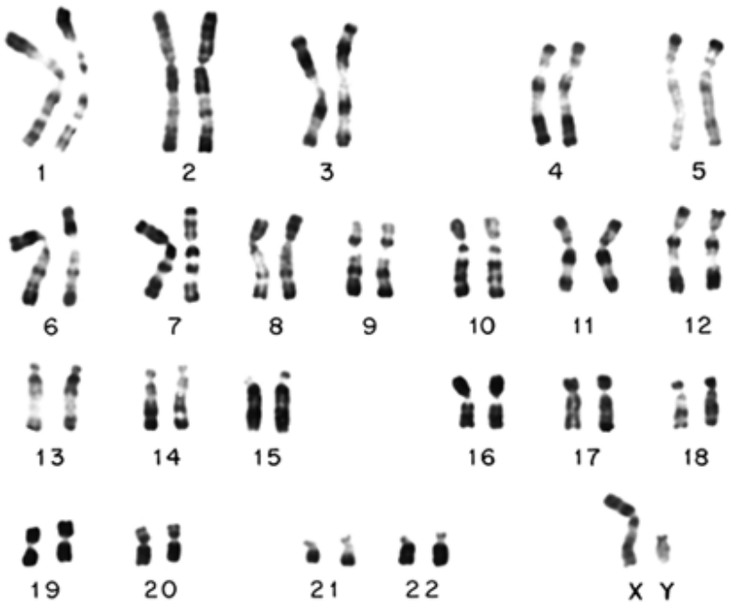

FIGURE 29.18. R-band karyotype of a normal male. (From Drouin R, Richer CL. High-resolution R-banding at the 1250-band level. II. Schematic representation and nomenclature of human RBG-banded chromosomes. *Genome* 1989;32:428, 429, with permission.)

R-bands are relatively GC rich, replicate in the first half of the S phase, and condense late in prophase. *In situ* hybridization of DNA complementary to mRNA sequences indicates that the coding DNA is localized in R-bands. Among genes and genetic diseases localized to specific bands on the chromosome, the greatest proportion (74%) is located in G-negative bands.

R-Banding Method

Aged slides are incubated in Sorensen's buffer pH 6.5 at 85°C for approximately 8 minutes, rinsed in the same buffer at room temperature, stained in Giemsa for 5 to 10 minutes, rinsed in distilled water, and allowed to dry.

C-Bands

C-banding is derived from the methodology used by Pardue and Gall for *in situ* hybridization of mouse satellite DNA to mouse centromeric heterochromatin. Arrighi and Hsu found that this method produced darkly staining centromeric heterochromatin

without the hybridization step by staining with Giemsa after denaturation with sodium hydroxide (barium hydroxide may be substituted) and subsequent incubation in a salt solution. The bands at the centromeres are readily observed (Fig. 29.19). These heritable regions vary in size, may differ in homologs, and may vary in position in the long or short arm pericentromeric region. C-banding may also be obtained after treating fixed cells on slides with the restriction endonucleases AluI, DdeI, HaeIII, MboI, RoaI, or HinfI.

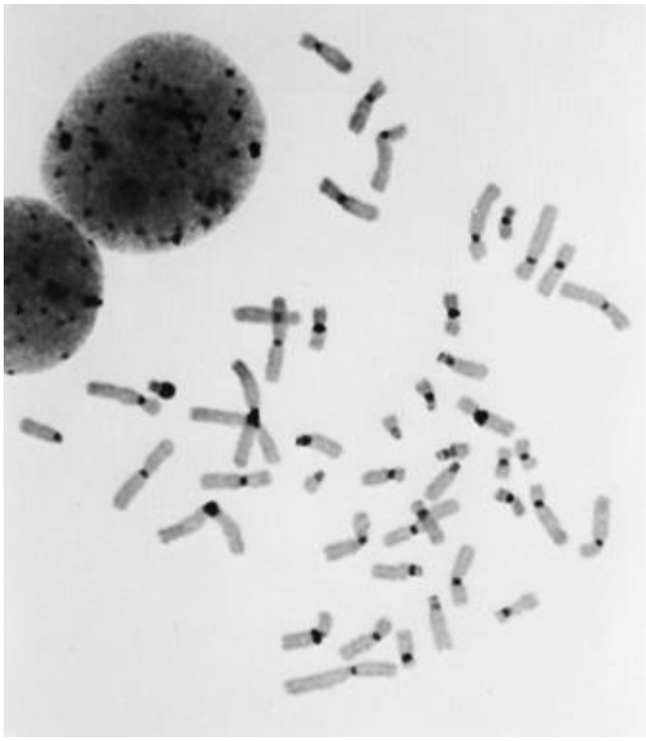

FIGURE 29.19. C-banded metaphase: centromeric and paracentromeric regions of chromosomes 1, 9, 16, and Yq stain. (Courtesy of J. Zunich.)

C-banding is used to identify the heterochromatic segments (for example, in suspected dicentric chromosomes) and to identify chromosome variants when there is a question of whether an unusual finding is a variant or an abnormality. Familial variants may also be used to trace the origin of specific abnormalities (e.g., Down syndrome).

C-Banding Method

Slides that have been aged at least 1 week are incubated for 1 hour in 0.2N HCl, rinsed in distilled water, and incubated for approximately 3 minutes in a saturated solution of $Ba(OH)_2$ diluted with distilled water [15 mL $Ba(OH)_2$ and 35 mL H_2O]. Slides are rinsed in distilled water until the $Ba(OH)_2$ film disappears and are then incubated in 2×SSC at 60°C for 1 hour. They are rinsed and stained in Giemsa for 10 minutes, rinsed again, and dried.

Chromosome Heteromorphisms

Constitutive heterochromatin in human chromosomes may vary in size or position in the chromosome. This variation in amount of highly repetitive DNA results in chromosome variants or heteromorphism. Homologous chromosomes may vary in the amount or position of C-bands and in the intensity of fluorescence or size of Q-bands. Individual variation in C heterochromatin is inherited and the heteromorphisms segregate in a mendelian fashion.

C-band heteromorphisms include variation in the size and position of the centromeric heterochromatin of all chromosomes

and of the paracentromeric heterochromatin of chromosomes 1, 9, and 16 and the distal long arm of Y. Variation in the size of short arms or satellites may also be documented by C-banding. The variation in size is continuous and may be classified by length into very small, small, intermediate, large, and very large. In some cases, large C-bands may appear to be composed of two segments. The position of C-bands may be in the long or short arm or part may be in the long arm and part in the short arm. Although Q- and C-band variants have been studied in normal and abnormal populations, no clinical significance has been found.

THE SIGNIFICANCE OF BANDING AND CHROMOSOME STRUCTURE

Part of "29 - Basic Cytogenetics"

Several lines of evidence have suggested that G-bands are more AT rich than R-bands. Evidence from base-specific fluorochromes such as Hoechst 33258 supports this observation. Autoradiographic studies using tritiated thymidine or tritiated guanidine and buoyant density data suggest that G- and R-band DNA differ in base ratio. The differences in R- and G-bands may be related to the distribution of families of interspersed repeated sequences. The short interspersed repeated sequences, of which the Alu DNA sequence family is predominant, occur mainly in R-bands. Alu is 56% guanine plus cytosine. In G-bands, the long interspersed repeated sequences, or L_1 family, occur more frequently. L_1 is composed of 58% adenine plus thymidine. Thus, the difference in distribution of these repeated sequences may account for the banding with fluorescent dyes and the reaction with base-specific antibodies. The basis for banding with proteolytic enzymes and Giemsa staining may be related to differences in the distribution of interacting proteins.

C-bands are areas of the chromosome that are composed of condensed and highly repetitive, nontranscribed satellite DNA, which is highly methylated (see Heterochromatin section). C-banding procedures result from the differential extraction of DNA in which more DNA remains in the C-band region. This may be related to a difference in protein-DNA interaction interfering with DNA extraction. Alpha-satellite DNA has been found by restriction analysis and *in situ* hybridization to be located in the C heterochromatin of all human chromosomes. Subsets of alpha-satellite sequences have been localized to specific centromeric regions (although some are present in more than one chromosome).

The alphoid sequences are hypermethylated and may be related to the inactivity of C heterochromatin. Thus, the studies of the basis for staining procedures used for the identification of human chromosomes have led to a further understanding of the structure of chromosomes. Some of the functional and biochemical characteristics of chromosomes are summarized in Table 29.1 (25,26,27,28 and 29).

TABLE 29.1. FUNCTIONAL AND BIOCHEMICAL ATTRIBUTES OF CHROMOSOME BANDS

	Bands		
Attribute	**G/Q**	**R**	**C**
Base composition of DNA	AT rich	GC rich	Mainly AT rich
Timing of DNA replication	Last half of S phase	First half of S phase	Late S phase
Time of condensation	Early mitosis	Late mitosis	Remains condensed in interphase
Concentration of expressed genes	Low	High	None
Enriched repeated DNA sequences	Lines (L_1)	Sines (Alu)	Satellite

AT, adenine thymidine; GC, guanine Cytosine.

DA/DAPI Staining Method

4′6-Diamidino-2-phenylindole (DAPI) is a fluorochrome that, when combined with a nonfluorescent counterstain, distamycin A (DA), shows bright fluorescence at secondary constrictions of chromosomes 1, 9, 16, the proximal 15 (15p11), and distal Yq (Fig. 29.20). It is particularly useful in identifying marker chromosomes that have originated from 15p, which fluoresce brightly after DA/DAPI staining. Both DAPI and DA bind preferentially to AT-rich DNA.

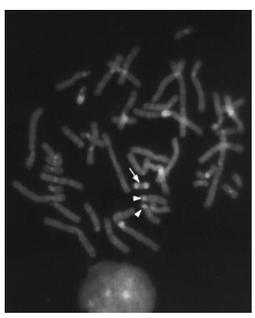

FIGURE 29.20. Cell with an i(15p) marker after DA/DAPI staining. The paracentric heterochromatin of chromosomes 1, 9, 16, Yq, and 15p (*arrowheads*) stain brightly. An extra marker chromosome (*arrow*) derived from 15p is also shown to fluoresce after DA/DAPI staining.

Slides are flooded with DA (DA) 0.2 mg/mL of McIlvaine's citric acid, Na_2 HPO_4 buffer at pH 7.0), covered with a coverslip, and incubated at room temperature for 15 minutes. The coverslip is removed and the slide rinsed with buffer at pH 7.0.

The DAPI solution (0.2 to 0.4 μg/mL) is added to the slide, and the slide is coverslipped and incubated in the dark at room temperature for 15 minutes, rinsed, mounted in buffer, and sealed. The slides are observed with a fluorescence microscope using a 360-nm excitation filter and a 460-nm emission filter.

Nucleolar Organizing Region Bands

The specific chromosome region in the satellite stalk that organizes the nucleolus, the nucleolar organizing region (NOR) may be observed in metaphase chromosomes by a silver impregnation method (Ag-NOR banding) (Fig. 29.21). This technique stains nonhistone residual proteins that appear to be located specifically at functional NORs and localizes the areas coding for the 18s and 28s ribosomal RNA. Each of the acrocentric chromosomes may bear an active NOR. Usually not all 10 of the acrocentric NORs are active in any one cell. NORs may vary in size and in some cases, double NORs may be present in a chromosome. These variations are consistent and heritable from parent to child.

FIGURE 29.21. The active nucleolar organizing regions (NOR) [Ag-NOR staining (silver impregnation method)] are seen as darkly staining areas at the ends of each of the 10 acrocentric chromosomes. *Arrow* indicates three acrocentric chromosomes in association and the NOR regions of the three fused.

Replication Banding

Early cytogenetic studies using ^{3}H-thymidine and autoradiography demonstrated that different chromosomes and regions of chromosomes completed their replication at different times during the S phase. More recently, it has been possible to demonstrate these replication differences and the differences in replication time of G (late) and R (early) bands using BrdU, an analog of thymidine. When BrdU is added to the culture, it is incorporated into DNA during the cell cycle. If the cells are treated with Hoechst 33258 and subjected to photolysis and differential staining with acridine orange (RFA technique) or with Giemsa (FPG technique), R-bands are produced. BrdU also interferes with chromosome condensation. This banding technique is often used to produce R-bands in previously synchronized cultures. Because R-bands have completed their replication early in S phase, the regions incorporating BrdU during the last half of S will be G-bands. Thus, the R-bands will be dark and the G-bands light after FPG staining. Alternatively, the same staining procedure may be used to show G-bands if the cells are grown initially in BrdU and thymidine is added late in replication (Fig. 29.22).

FIGURE 29.22. Replication banding (RBG). Banding after treatment of the cell for the last 5 hours with bromodeoxyuridine. This technique is frequently used to demonstrate the late-replicating X (*arrow*). The chromosomes show an R-banding pattern.

The BrdU/FPG method is most useful in demonstrating the differences in the two X chromosomes because the late-replicating X chromosome stains light and the early-replicating one dark with this method. However, much of this work has been supplanted by molecular studies of X-inactivation (see below).

FPG Method

Lymphocytes are grown for 48 to 54 hours in RPMI 1640 and are synchronized with excess thymidine (concentration 1.24×10^{-3} M) for 17 hours. The block is released after rinsing by resuspending in TC199 plus BrdU (10^{-3} mol/L) for 4.5 hours, and cells are harvested without colcemide exposure.

Slides are stained with Hoechst 33258 (2.5 g/mL) for 15 minutes. The slides are exposed to ultraviolet light for 120 to 150 minutes and stained with Giemsa (1%) for 5 minutes.

High-Resolution Banding

Although most laboratories use metaphase chromosomes for routine chromosome analysis, the need for procedures that demonstrate subtle gains or losses of single bands has led to the development of methodology for high-resolution imaging of chromosomes. Identification of small deletions involved in Prader-Willi (PWS), Miller-Dieker, and other deletion syndromes requires the use of methods that will provide chromosomes with identifiable bands on the order of 800 to 1,000 bands. High-resolution chromosomes may be obtained by using compounds such as ethidium bromide or actinomycin D, which interfere with the condensation of the chromosomes and produce longer chromosomes with subdivided bands. Alternatively, Yunis' method of synchronization of cells (which uses antimetabolites to arrest cells in S phase) may be used, followed by release with thymidine for specific periods to accumulate cells in particular stages of prophase or prometaphase. Although standard metaphase chromosomes demonstrate 400 to 500 bands, high-resolution methods may resolve 800 to 1,200 bands in prometaphase or prophase chromosomes. (The latter technique may also be used in conjunction with replication banding with BrdU to give high-resolution R banding.) The chromosome procedures may also be altered by increasing hypotonic treatment and reducing colcemide time to permit maximum length and greatest spreading of the more extended chromosomes.

High-resolution chromosomes are not only extended compared with metaphase chromosomes but also have a greater number of bands. Both light and dark bands seen at the 400-band level may be resolved at the earlier stages of division into multiple light and dark bands (Fig. 29.23).

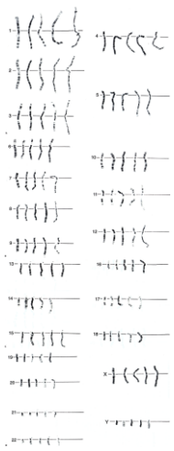

FIGURE 29.23. A-D: High-resolution banding of human chromosomes. The first chromosome of each series is shown at approximately the 475-band level, with increasing length and band resolution as the chromosomes become more extended in prometaphase.

Method of Synchronization for High-Resolution Chromosomes

After incubation of leukocyte cultures grown in RPMI 1640 for 72 hours, methotrexate (final concentration 10^{-7} mol/L) is added to the cultures. Seventeen hours later, the incubated cells are released from the block by rinsing in RPMI 1640 and are grown for an additional 5 to 5.5 hours, treated with colcemide (0.05 µg/mL at room temperature) for 10 minutes, and harvested. Alternatively, the block may be released with 0.1 ml thymidine (1×10^{-3} mol/L) added to each 10-mL culture.

Ethidium Bromide Method for Prometaphase Chromosomes

Leukocyte cultures grown for 72 hours are harvested by addition of 0.05 mL of 6 mg/mL of colcemide and 0.1 mL of a 1 mg/mL solution of ethidium bromide for 2 hours. The cells are fixed and processed in a standard manner.

MOLECULAR CYTOGENETICS

Part of "29 - Basic Cytogenetics"

In the past 10 years, the burgeoning field of molecular cytogenetic has had a monumental effect on the study of chromosomes. Before the introduction of this methodology, chromosomes could only be analyzed using conventional methods already detailed (i.e., G-banding). This limited both our innate understanding of the structure of chromosomes and the resolution allowing detection of cytologic changes. These molecular cytogenetic methods include both FISH as well as the utilization of microsatellite markers to define chromosome structure (29).

Overall, the objective of *in situ* hybridization is the hybridization of a labeled, denatured, single-stranded DNA probe to a target DNA segment that has been denatured in place on a microscope slide. Initial studies on metaphase chromosomes (30) were done using radioactive DNA probes. This had limited application (and almost no clinical application) because of the difficulty involved with the technology. Many of the studies involved repetitive DNA sequences, although there were limited studies for gene localization. However, the technology became much more accessible and widespread after the initial work of Pinkel et al. (31) with nonradioactive *in situ* hybridization. Most probes (and almost all commercially obtained probes) now are directly labeled with a fluorochrome and can easily be detected after hybridization. Probes generated for research studies may be labeled with biotin or digoxigenin and detected indirectly with fluorochrome-labeled antibodies. The utilization of fluorescent probes is combined with fluorescent microscopy, in which one or more probes, each labeled with a different color, can be detected. New methodology (see below) can now be utilized to have the chromosomes fluoresce with 24 different colors, one for each chromosome pair. Less frequently, hybridization and detection of probes are performed using enzymatic methods.

The technology has advanced so that there are many different types of DNA probes that can be used for FISH analysis. These include (a) repetitive DNA segments, the most common which is alpha-satellite DNA found at the centromere regions of all chromosomes; (b) whole chromosome libraries, which uses DNA specific to one chromosome and the entire DNA from that chromosome is used as a probe for hybridization; and (c) and unique (single-copy) sequences of DNA that can be used as a probe for hybridization. Many applications of these probes have been developed, making the possibilities of this field endless. For example, the use of chromosome paints and libraries has been extended to include spectral karyotyping and multicolor FISH, which uses 24 colors to study metaphase chromosome. This technology has become increasingly useful in analyzing preparations from cancer specimens and markers and *de novo* unbalanced rearrangements in constitutional abnormalities. Single copy probes can vary from commercial probes (e.g., those commonly used to detect microdeletion syndromes) to home-brew probes, which can range in size from <1 kb to >1 MB [e.g., yeast artificial chromosomes (YACs)]. The utilization of these home-brew probes has become greater over the past several years especially with the advent of a project to create a map in which bacteria artificial chromosomes (BACs) are localized to every 1 MB in the genome. One unique

type of probe that has been developed is the subtelomeric probe, which is a chromosome-specific probe localized to subtelomeric regions in the chromosomes. This type of probe has been shown to be very useful in the detection of subtle rearrangements involving the ends of chromosomes. The utilization and specific applications of the above mentioned probes are discussed in more detail in the next several chapters (32,33).

Listed below are basic protocols for labeling probes as well as for hybridizing them to the target of interest. Only general protocols are listed:

Bionicking cosmids, BACs, plasmids, phage, and YACs:

In a 500-µL Eppendorf tube, add:

1 µg cosmid, BAC, plasmid or phage DNA

× µL distilled H_2O

10 µL dNTP deoxy-Nucleotide Triphosphate

10 µL enzyme

100 µL total

(If YACS are used, 20 µL YAC DNA is utilized in a total of 250 µL.)

After vortexing and spinning each tube, place each tube into in a 15°C water bath for 1 to 2 hours.

Add 10 µL stop buffer, vortex and spin and store at -20°C until use.

Hybridizing cosmid, BAC, plasmid, and phage probes:

Concentrate the probe overnight at -20°C:

50 ng labeled probe

15 µL Cot-1 DNA

1/10 volume 3M sodium acetate, pH 5.2

2.5 × volume cold 100% ethanol

The concentrated probe is spun at 15,000*g*, aspirated, and dried on a 37°C hot plate.

The pellet is resuspended in 10 to15 µL of 50% hybridization buffer, vortex, spun and placed in a 37°C water bath for 30 minutes. It is then allowed to reanneal in a 37°C water bath for 3 hours.

The denatured probe is then hybridized to the denatured slide at 70°C for 2 minutes and then placed at 37°C overnight. The price of treatments will vary depending on the target DNA to be hybridized.

The slides are then washed in 50% fomamide at 43°C for 15 minutes, then in 2XSSC at 37°C for 8 minutes.

The biotin is detected using a fluorescein-labeled avidin.

(This protocol will change depending on the type of probe, the target DNA, and the source of the probe. Most commercial probes are direct labeled and this last step is not necessary.)

All the discussed probes can be hybridized to a variety of target DNA. The most common and familiar target is the metaphase chromosome. Interpretation of the FISH studies on these specimens is very straightforward and metaphase chromosomes are the most commonly utilized specimen. FISH can also be used on interphase cells. The interphase cells can be either from direct preparations (e.g., amniotic fluid cells used to detect aneuploidy) or from cultured cells. Additionally, preparations from tissue specimens can be utilized, where interphase cells can be studied either as dispersed cells or in paraffin sections, where the original tissue architecture is intact. This latter methodology is extremely useful for Her2-neu analysis in breast cancer.

Another molecular methodology that can be utilized for the analysis of chromosomes is the use of the polymerase chain reaction (PCR) of highly polymorphic di-, tri-, and tetranucleotide microsatellite markers. As these can be used to detect the presence or absence of specific DNA sequences, they are an effective way to study chromosome structure when parental and proband DNA is available. In combination with FISH, microsatellite markers can delineate both deletions and duplications. In cases of nondisjunction, they are the most efficient means for determining the origin of nondisjunction.

The advances in molecular cytogenetics in the past several years have greatly recast the way clinical and research cytogenetic studies proceed. As is demonstrated in the following chapters, its use has influenced the evaluation of somatic abnormalities seen in neoplasia as well as the study of constitutional abnormalities (e.g., detected postnatally in peripheral blood specimens or prenatally in amniotic fluid and chorionic villus samples).

THE SEX CHROMOSOMES

Part of "29 - Basic Cytogenetics"

In humans, females have two X chromosomes and males an X and a Y chromosome. The fact that this difference in the number of X chromosomes did not result in differences in expression of X-linked genes between males and females led H. J. Muller in 1931 to propose the concept of dosage compensation. In humans and most mammals, dosage compensation is achieved by inactivation of excess copies of the X chromosome, and equal amounts of gene product result from transcription of the single active X in both males and females (34,35).

The X Chromatin Body

In 1948, Murray Barr and his graduate student E. C. Bertram identified a nucleolar satellite that was present in histologic preparations of neurons of female cats but not of male cats. After further verification on human preparations, they called the sex-specific chromatin mass “sex chromatin.” (Sex chromatins are now also called Barr bodies.) Subsequently, Barr observed that individuals with ovarian dysgenesis (Turner syndrome) had male-type nuclei—lacking a sex-chromatin body—and that biopsies from males with Klinefelter syndrome were similar to those of normal females in that a sex-chromatin body was present. When the chromosome defects in these syndromes were observed, the correspondence of the number of Barr bodies to the number of inactive X chromosomes became evident.

Further contribution to an understanding of X chromatin came with the demonstration of asynchronous replication of the sex chromosomes, one of the two X chromosomes replicating later in the S phase, and of the mosaicism in the expression of X-linked genes.

In humans, females heterozygous for glucose-6-phosphate dehydrogenase (G6PD) deficiency demonstrated two types of erythrocytes, and in the mouse, coat color variegation resulting

from X-linked coat color mutants or autosomal genes translocated to the X chromosomes occurred in female mice but not in male mice.

These observations led Lyon in 1961 to propose the single active X hypothesis that one of the two X chromosomes in each cell of a female is transcriptionally inactive, that inactivation occurs early in embryogenesis at which time random inactivation of maternally and paternally derived X chromosomes occurs, and that inactivation in the lineage of an X is stable and is transmitted to all descendants (clonal).

This hypothesis received confirmation from a variety of experiments demonstrating mosaicism in the expression of X-linked genes in mice, humans, and other mammals. Single cells cloned from tissue cultures derived from females heterozygous for G6PD demonstrated either A or B electrophoretic variants of G6PD, but never both. Similar behavior of other X-linked enzymes and the presence of two cell populations in heterozygous females who carry the gene for disorders such as ocular albinism and hypohidrotic ectodermal dysplasia provided additional confirmation and acceptance of the Lyon hypothesis. X-inactivation occurs in all mammals, including marsupials but not in other groups (36,37).

The Timing of Inactivation

The onset of inactivation may be demonstrated by the appearance of the sex-chromatin body, the change to asynchronous and late replication of one of the X chromosomes, hypoacetylation of histone proteins, or the appearance of differences in X-linked enzyme activity. These events indicate that the typical euchromatin on the X chromosome converts to heterochromatin. These changes may be shown directly at different stages of embryogenesis or indirectly by the use of chimeric mice. By transplanting single cells from an embryo heterozygous for pigment mutants at different stages of embryogenesis into blastocysts carrying a different mutant, it has been possible to demonstrate (a) lack of inactivation by the appearance of three different colors in patches or (b) if inactivation has occurred, by the occurrence of only two of the pigment mutants.

Using the tools described, it has been shown that inactivation does not occur in all tissues simultaneously but occurs at different times in cell lineages as differentiation occurs. Thus, in the blastocyst that occurs at 3 days in the mouse, X-inactivation is limited to the trophectoderm. Inactivation occurs between 6 and 13 days in the inner cell mass and at the differentiation of the primitive ectoderm. Inactivation in the germ-cell progenitors appears to occur by day 12, but, because both Xs are active in the mature oocyte, reactivation of the X chromosomes must occur before meiotic prophase.

Exceptions to the Lyon Hypothesis

Nonrandom Inactivation

Although the tenets of the Lyon hypothesis as previously explained still hold today, there are some notable exceptions to these rules. Although inactivation is random with respect to the parental origin of the X, there are cases that demonstrate nonrandom X-inactivation. Exceptions to random inactivation of maternally and paternally derived X chromosomes occur in apparent nonrandom inactivation of X chromosome abnormalities, in nonrandom inactivation of paternal X chromosomes in trophoblastic tissues, and in nonrandom inactivation of X chromosomes bearing particular X-linked genes.

Apparent preferential inactivation of X-chromosome abnormalities such as isochromosome X, ring X, and deleted X occur regularly in humans. In each case, random inactivation of the normal X would result in cells nullisomic for a portion of the X chromosome and inviability or lessened viability. In balanced X-autosomal translocations, random inactivation appears to be followed by selection, presumably as a result of the spreading of inactivation into autosomal segments. Cells with such autosomal segments inactivated will have reduced viability, and, as a result, cells with the translocation active and the normal X inactivated usually predominate.

Conversely, in unbalanced X-autosome translocations, the abnormal X appears to be preferentially inactivated as a result of selection of cells with a balanced karyotype. In these instances, spreading of inactivation to the autosomal segment may be incomplete, and phenotypic expression of the extra segment may occur.

Additionally there are some cases in which individuals have two normal X chromosomes but still show preferential inactivation of one particular X chromosome. Some of these cases have been shown to be owing to a mutation in the *Xist* (X inactive specific transcripts) gene, whereas the cause for other cases is still unknown. Many of these cases can be traced within families.

Preferential expression of the maternally derived X chromosome has been shown to occur in tissues of marsupials and in the extraembryonic membranes of rodents and humans. Unlike X rearrangements, the preferential inactivation of paternal alleles does not result from selection but appears to be initial nonrandom inactivation owing to differences in parental origin—“imprinting” (38,39).

Active Genes

Implied in the Lyon hypothesis is that all the genes on the inactive X chromosome are inactive; however, this is not always the case. Early studies indicated that the inactivated X chromosome is not completely inactive. The pseudoautosomal region, the distal portion of the Xp (a segment of the X that undergoes recombination with the Y chromosome) escapes inactivation in humans and mice. In this region is MIC2, a cell surface antigen that is located at the proximal end of the pseudoautosomal region in humans. Several DNA probes have been localized to the human pseudoautosomal region with DXYS14 at the telomeric end. Steroid sulfatase (STS), a gene resulting in X-linked ichthyosis, and the Xga blood group map close to the pseudoautosomal region and escape inactivation in humans. More recently, it was shown that this phenomenon is much more widespread (40).

In a study of X-linked genes, Brown et al. (41) used a rodent/human somatic-cell hybrid to study the expression of 33 X-linked genes. They were able to isolate both active and inactive X chromosomes individually in the rodent/human somatic-cell hybrids. Their studies indicated that six of the 33 genes showed that they escaped X-inactivation, and each demonstrated expression

from both the inactive as well as the active X chromosome. Although many of the genes in this initial study were chosen because of some prior knowledge concerning their inactivation pattern, four of the 17 genes selected, without prior knowledge, were found to escape inactivation. This suggests that a higher proportion of genes may escape inactivation than was originally anticipated. More recent evidence showed that greater than 16 genes are known to escape activity (42). It has been estimated that as many as one third of all the X-linked genes may escape inactivity.

Permanence

One last exception to the Lyon hypothesis concerns the fact that inactivation is permanent. Although one X chromosome is always inactive in somatic cells, this inactivation is reversible in the development of the germ cells. In female germ cells, both X chromosomes are active. In contrast, the single X chromosome in male germ cells is inactive.

DETECTION OF X-INACTIVATION

As explained above, initial studies utilized BrdU incorporation for the cytologic identification of the inactive X chromosome. More recent work provided molecular methodology to quantitate more precisely X-chromosome inactivation. The easiest and most common method of X-chromosome inactivation involves the use of differential methylation of the androgen receptor gene (43). A polymorphic CAG repeat in the first exon is amplified by PCR and selective digestion of the DNA with a methyl-sensitive enzyme can distinguish the active and inactive X chromosome. Other methods that parallel this procedure include the use of a transcribed polymorphism of the *Xist* gene (44), a transcriptional polymorphism of gene *p55* (45) and differential methylation at the FMR-1 locus (46).

Inactivation Center

Studies of X-autosome translocations in mice and humans suggest that inactivation proceeds from a region controlling inactivation, the inactivation center, and spreads to the rest of the chromosome. Thus, in reciprocal translocations between an X and an autosome, only one of the two segments will show inactivation. The X controlling element, the X_{ce} locus, is considered to be the major controlling center for X-inactivation in mice. Evidence from allelic variants of X_{ce} suggests that this locus controls the probability of inactivation of the X chromosome and can also control the preferential inactivation of paternal X chromosomes in extraembryonal membranes.

In humans, Therman proposed the presence of an inactivating center between Xq11.2 and Xq21.1 on the basis of failure of inactivation in the absence of this segment in various deletions and rearrangements and on the evidence of the occurrence of bipartite sex chromatin when this region of the X is duplicated (Fig. 29.24).

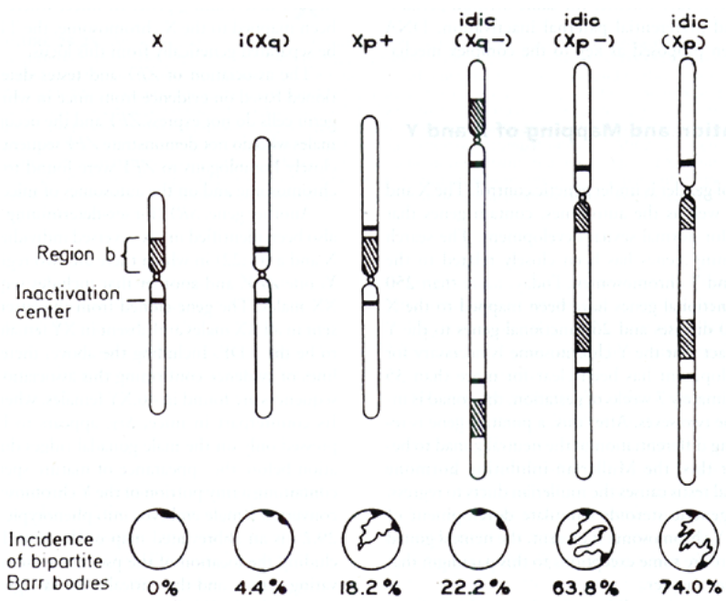

FIGURE 29.24. The location of the X-inactivation center of Xq and the presumably active (b) region on Xp in six structurally different X chromosomes, plus the incidence and hypothetical structure of bipartite Barr bodies formed by them. (From Therman E, Sarto GE. Inactivation center on the human X chromosome. In: Sandberg AA, ed. *Cytogenetics of the mammalian X chromosome, part A*. New York: Alan R. Liss, 1983:315–325, with permission.)

The inactivating center, identified by Hunt Willard, appears to be at Xq13 in humans. The *Xist* gene is transcribed from the X_{ce} on the inactive X chromosome. The *Xist* gene transcribes a large mRNA, approximately 15 to 17 kb, which is retained in the nucleus. This mRNA seems to coat the inactive X. Before inactivation, there appears to be only a dot of RNA on each chromosome. However, after inactivation, the level of *Xist* RNA is increased and the inactive chromosome appears to be coated. This increased level of *Xist* RNA appears not to be owing to increased transcription but rather to a stabilization of transcription.

As described previously, once inactivation has been initiated, it spreads outward on the inactive X. Early cytologic evidence from X-autosome translocations in humans and mice suggests that autosomal regions close to the point of translocation are more likely to be inactivated. Studies of similar translocation in human chromosomes suggest that inactivation may skip some regions and inactivate others farther from the translocation point. More recent quantitative work, (47) confirmed these cytologic observations. This group studied 20 transcribed sequences in 4q24-qter, using reverse transcription PCR analysis. The der(X)t(X;4)(q22;q24) had been isolated in a somatic cell hybrid, and these studies indicated three known genes and 11 expressed sequence tags (ESTs) were not expressed (inactive), three genes and three ESTs escaped inactivation. This study molecularly confirmed the cytologic conclusion that the spreading of inactivation occurred, but is incomplete and noncontiguous (48).

To attribute X- inactivation to any mechanism, it is necessary to explain the initiation, promulgation, and maintenance of X-inactivation and to consider whether the same method pertains to both random and preferential paternal inactivation. DNA methylation has been proposed as key to the complex mechanism involved.

Sex Determination and Mapping of X and Y Chromosomes

The determination of gender is under genetic control. The X and Y chromosomes, as well as the autosomes, contain genes that must be functional for normal sexual development. The search for the sex-determining genes has been closely related to the mapping of the X and Y chromosomes. Today, more than 250 diseases and 300 functional genes have been mapped to the X chromosome and 20 diseases and 26 functional genes to the Y chromosome. The fact that the Y chromosome is necessary for normal sexual development has been clear for more than 35 years. Before approximately 7 weeks of gestation, the gonad is indistinguishable in the two sexes. After this, a putative gene is responsible for inducing differentiation of the neutral gonad to become a testis. After this, the Mullerian-inhibiting hormone secreted from the fetal testis causes the mullerian ducts to regress, and released androgenetic steroids stimulate development of male genitalia. If no Y chromosome is present, the neutral gonad forms an ovary. There are some exceptions to this paradigm that are covered in another chapter.

There have been several candidates for the sex-determining gene or genes, described previously. Initially, the H-Y antigen, a male-specific antigen, was for many years considered to be the testis-determining factor (TDF) subsequent to this, *ZFY*, a zinc finger gene on the Y chromosome, was enthusiastically received as the possible TDF. Both are now considered to be related to sperm maturation rather than to the initial differentiation of the testes.

The H-Y antigen was initially demonstrated when skin transplanted from male isogenic mice was rejected by females of the same strain. The antigen has also been demonstrated by serologic tests using antisera produced after inoculation of females with male cells or by cytotoxicity assays with T cells. When interspecific comparisons demonstrated conservation of the soluble antigen in evolution, it was hypothesized that the H-Y antigen and TDF were the same. More recent evidence indicates that the serologic and transplantation antigens are coded by two different genes and further evidence indicates that neither is the TDF. A gene with properties similar to the serologically detected antigen has been localized to chromosome 6, and its presence in females as well as X-chromosome abnormalities removes it from contention as TDF. The T-cell toxicity antigen has been localized to the long arm of the Y, whereas evidence from XX males indicates that TDF is on the short arm of the Y chromosome.

The identification of XX males in whom the distal portion of the Yp chromosome has been transferred to the X and t(Y;15) females with a corresponding deletion of the Y chromosome led to the cloning of a 140-kb segment of the Y chromosome that coded for a regulatory protein, a zinc finger protein (the human gene is designated *ZFY*). Although it was suggested that the H-Y antigen may be the biochemical expression of the TDF (because both have at least one locus in or close to the pseudoautosomal region), evidence accumulated to indicate that *ZFY* is not the sex-determining gene. In mice, where the H-Y antigen has been mapped to the X chromosome, the TDF (Tfy in mice) can be separated genetically from this locus.

The association of *ZFY* and testes determination was questioned based on evidence from mice in which fetal testes lacking germ cells do not express *ZFY* and the occurrence in humans XX males who do not demonstrate *ZFY* sequences. In addition, genes closely homologous to *ZFY* were found to be present on the X chromosome and on the autosomes of mice and marsupials.

Another gene, *SRY* (for *s*ex-determining *r*egion on the *Y*), had also been identified in sex-reversed individuals, i.e., a female with X and a t(Y;22) in which there are two regions deleted from the Y, one *ZFY*, and another that includes sequences present in all XX males. The gene cloned from the latter region, *SRY*, is present in all XX males and absent in XY females, and now is known to be the TDF. Including the above, there are several different lines of evidence confirming this association. Mutations in *SRY* sequences are found in 46,XY females, where *SRY* is not deleted. Its counterpart in mice, *Sry*, appears to be testis specific, expressed only on the male gonadal ridges during testis differentiation before the appearance of mature sperm. Transgenic mice containing a tiny portion of the Y chromosome, containing *SRY*, converted female embryos into phenotypic normal mice. Figure 29.25 is an abbreviated map of the X and Y chromosomes including the location of the pseudoautosomal region, the inactivating center, and the critical area—a segment that must be intact in both X chromosomes to permit normal ovarian development in females. The *SRY* gene was one of the first major genes to be cloned by *positional cloning* as a result of the Human Genome Project (49,50).

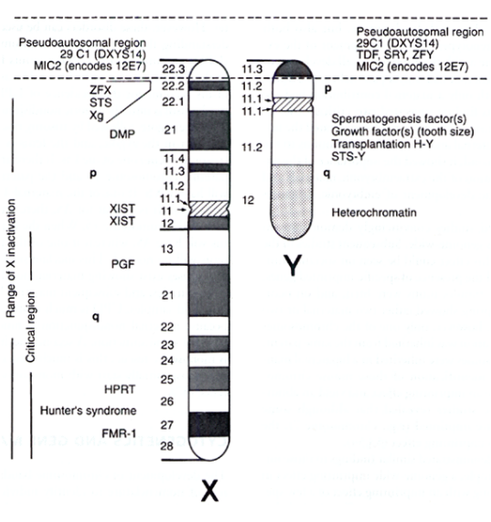

FIGURE 29.25. An abbreviated map of the X and Y chromosomes shows loci and areas related to sexual differentiation. ZFX and ZFY, loci for zinc finger protein on X and Y chromosomes; DXYS14, pseudoautosomal locus defined by probe 29C1, the most distal of a group of probes localized to this region; MIC2, pDP1002 encoding cell surface antigen 12E7; pseudoautosomal region, region of pairing of X and Y chromosomes (this region is not inactivated); STS and Xg, steroid sulfatase and Xga blood group (both are located close to the pseudoautosomal region and both escape inactivation); SRY, sex-determining region of the Y chromosome; HY, locus-encoding transplantation histocompatibility HY; MIC2, locus-encoding histocompatibility cell surface antigen 12E7; gonadal development, regions of Xp and Xq that, when deleted, result in gonadal dysgenesis; critical region, region whose integrity is important in gonadal development of balanced X/autosomal translocation carriers; inactivation center, region controlling X inactivation.

The usefulness of chromosome abnormalities of X and Y and of cytogenetic analyses of unusual XX males and XY females in resolving the question of the location of the sex-determining gene cannot be discounted. The usefulness of chromosome abnormalities to mapping of the human genome is discussed further in the following section.

Imprinting

Although an equal number of autosomal chromosomes are inherited from both the mother and the father of an individual, the genetic contribution from both parents may be different. Genomic imprinting, which refers to the differential modification of both the paternal and maternal contributions to the zygote, results in the differential expression of paternal genes. For example, in some genes the paternal and maternal alleles function differently. The best example of this is in the proximal region of the long arm of chromosome 15, where the *SNRPN* gene is functioning in the paternal genome only, whereas the *UBE3A* gene is functional in the maternal genes only. Loss of the paternal genes in 15q results in PWS, and loss of the maternal genes results in Angelman syndrome (AS). These syndromes are discussed in detail in a later chapter.

Most of the imprinting studies were first described in mouse models and can best be described using these models. Zygotes containing either two maternal haploid complements, two paternal haploid complements, or one complement from each parent have been studied. To create these complements, either the male or female pronucleus complement has been microsurgically removed from the fertilized oocyte and the desired complement constructed. Logically, it would follow that if the paternal complement had no effect on development, then all three scenarios would yield equivalently normal zygotes. However, these studies indicated that only the complement with both a maternal and paternal chromosome complement developed normally. In zygotes with maternal or paternal complements only, not only did

the fetus demonstrate abnormal development, but also both classes had different phenotypes. Good development of the extraembryonic membrane and lack of the inner cell development were noted in the zygotes that had only a paternal contribution, whereas the zygotes with only a maternal contribution had the reverse phenotype. This finding suggested two critical observations regarding imprinting. First, it clearly demonstrated the importance of both the paternal and maternal contributions to the developing embryo. Second, it showed the importance of the paternal loci in the formation of the extraembryonic materials and the maternal loci in the development of embryonic structures (39,51,52).

The aforementioned studies convincingly demonstrate an imprinting effect that is genome-wide. Subsequent studies in the mouse indicated that this effect could be seen on specific chromosomes and indicated the presence of specific imprinted genes. Mice heterozygous for translocations were bred, and on occasion, the resultant offspring showed either two maternal or two paternal chromosomes; however, only one of the chromosomes involved in the translocation was inherited from the same parent. The rest of the chromosomes were inherited in a biparental manner. This allowed the identification of those mouse chromosomes that demonstrate an imprinting effect and yield an abnormal phenotype. These studies revealed that although some mouse chromosomes are imprinted (e.g., chromosome 7), the vast majority shows no imprinting effect (53,54).

Studies in humans demonstrated similar findings to those initiated in mice. For example, a genome-wide imprinting effect in humans can be seen along with an imprinting effect of a few specific chromosomes. Genome-wide imprinting effects include hydatidiform moles and ovarian teratomas. Moles are an abnormal product of conception in which the chorionic villi are hydropic and hypoplastic and have a predilection to become malignant. There are two types of moles, complete and partial. Complete moles have no fetal development or normal villi, whereas in partial moles, there is fetal development, but the villi are abnormal. The chromosome complement in complete moles is 46,XX with the entire complement of androgenic origin. Partial moles are triploid (69 chromosomes) with two of the three complements paternal in origin. In contrast to these, ovarian teratomas are benign cysts with two maternal and no paternal chromosome complement. They are thought to represent the parthenogenetic outcome of an unfertilized oocyte. The ovarian teratomas are not malignant but are very well differentiated (55).

In addition to the genome-wide imprinting abnormalities, there are also chromosome-specific imprinting effects in humans. In some cases, disorders have been associated with imprinting of specific chromosomes, such as for chromosome 15 (PWS and AS), chromosome 11 (Beckwith-Wiedemann syndrome), and chromosome 6 (neonatal diabetes). For other chromosomes, nonspecific findings have been associated with imprinting (e.g., chromosomes 7 and 14). Many of the imprinted genes in humans appear to be clustered, such as in proximal 15q (15q11-q13), and they can also be found in the orthologous region in mice (chromosome 7) (56).

The phenotypic description of the two most widely studied imprinting syndromes, PWS and AS, is discussed in a later chapter. However, these disorders can be used as a paradigm for understanding the mechanism of autosomal uniparental disomy (UPD) and imprinting. UPD accounts for approximately 25% of the PWS cases, yet only 3% of AS cases. Two major mechanisms account for the incidence of UPD. The most common mechanism is initially meiotic nondisjunction leading to trisomy 15 in the zygote, followed by trisomy rescue. Three chromosome 15s start in the zygote, and the fetus is rescued by eliminating (trisomy rescue) one of the 15s. If there are two maternal and one paternal chromosome 15 and the paternal 15 is lost, the fetus will have PWS. If one of the maternal 15s is lost, the fetus will be normal. It is similar for AS; there are two paternal and one maternal chromosome 15. When the maternal 15 is lost, the fetus will have AS, whereas if one of the paternal 15s is lost, the fetus will be normal. This mechanism has been confirmed because cases exist showing maternal nondisjunction in chorionic villus samples, and subsequent maternal UPD detected in amniotic fluid samples. UPD is much more commonly seen in PWS because maternal nondisjunction is much more frequent than paternal nondisjunction. A second mechanism leading to UPD is monosomy rescue; this is much less common because the zygote must initially start with monosomy 15, an unlikely occurrence (57).

CYTOGENETICS AND GENE MAPPING

Part of "29 - Basic Cytogenetics"

The development of chromosome banding methods and a system of nomenclature to identify individual chromosome arms and bands was an important step needed to allow the assignment of human genes and DNA probes to individual chromosomes, regions, and bands (gene mapping). As banding procedures and identification of chromosome variants and chromosome abnormalities became available, techniques of gene mapping were simultaneously developed.

Cytogenetics has made important contributions to gene mapping by a number of different approaches, including the use of classic mapping techniques with chromosome variants and abnormalities used as markers, deletion mapping with and without concurrent dosage studies, somatic cell hybridization, and *in situ* hybridization, especially FISH.

Although assignment of genes to the X chromosome based on sex linkage was possible before cytogenetic studies, the assignment of genes to specific autosomes was possible only after chromosome variants were observed. The first gene assignment, the Duffy blood group, used the segregation of a familial chromosome 1 variant, an extended paracentric heterochromatic band of chromosome referred to then as “uncoiler,” and the concurrent segregation of the Duffy blood group.

The presence of chromosome variants in a family made it possible to establish how often the variant was inherited with specific markers. The degree of linkage of genes on a chromosome is related to their closeness in position on a particular chromosome. Those farther apart are more likely to undergo crossing over and separation at meiosis. Recombination, when genes are close together, may be close to zero; if far apart or on different chromosomes, it will approach 50%. This is the recombination

frequency. Gene mapping is based on the degree of recombination, the frequency serving as a measure of genetic distance, and the relative distance apart of the variant and gene on a genetic map.

Thus, investigators used C-band variants to localize and order a number of genes on chromosome 1. Similarly, segregation in families of translocations or other cytogenetically marked chromosomes have been used to localize genes to chromosomes. For example, it was possible to use a fragile site on chromosome 16 (at 16q21-22), segregating as an autosomal dominant trait, to demonstrate linkage with alpha-haptoglobin by following segregation and recombination of the two in a large family and thus to localize the alpha-haptoglobin gene close to this fragile site.

A second approach to gene mapping, somatic cell hybridization, involves the fusion of human cells, fibroblasts, or lymphoblastoid cell lines with rodent cells. If both parental lines are drug sensitive, the use of selective media will allow growth of the cell hybrids but not the parental cell lines. Fusion is facilitated by use of Sendai virus or polyethylene glycol. Although the hybrid cells initially contain chromosomes of both parent lines, human chromosomes are gradually lost from unstable hybrid cells. Eventually only one or a few human chromosomes are retained in a stable cell line. Cytogenetic recognition of the individual human chromosomes or, alternatively, recognition of a protein associated with a specific chromosome permits identification of a number of unique cell lines. A collection of such cell lines, each with a different chromosome or chromosomes (a cell panel) allows the presence of a particular chromosome to be correlated with a unique gene product. Thus, a specific gene is localized to a chromosome.

More recently, linkage studies using cell hybridization have employed lymphoblastoid cell lines derived from individuals with different chromosome abnormalities to develop panels with multiple overlapping rearrangements of the same chromosome. These facilitate localization of a particular gene to a specific region or band.

The first use of deletions to map chromosomes was in *Drosophila*. A series of chromosome deletions seen in the salivary gland chromosomes were compared with the expression of specific genes, and the position of the gene on the *Drosophila* chromosomes was established. In human chromosomes, deletion mapping has taken several forms. One relates reduced enzyme levels, loss of an allele, and occurrence of a deletion to localize a gene. For example, Ferguson-Smith used a series of abnormalities of chromosome 2 to localize red cell phosphatase (ACP_1) to the region 2p23. Trisomies and duplications have also been used to localize genes by gene dosage studies or by the presence of three different alleles. For example, individuals trisomic for 6p21-6pter with three different histocompatibility haplotypes facilitated the localization of the histocompatibility locus to 6p21 to 6pter.

A panel of abnormalities of chromosome 9, including duplications and deletions, has been used in dosage studies of human red cell adenylate kinase (AK-1). Demonstration of an increase of AK-1 activity by 43% in one duplication permitted the assignment of AK_1 to 9q33-qter. In this case, the chromosome involved had been previously identified by cell hybridization, and dosage studies with the panel of cell lines permitted further localization to a region. A classic demonstration of mapping a disease gene involves the localization of Duchenne's muscular dystrophy (DMD). An Xp deletion in a male with DMD localized this disorder to Xp21, which was later confirmed by a series of females having DMD, with X/autosomal translocations containing an Xp21 breakpoint.

The most direct cytogenetic method of gene localization has been *in situ* hybridization, which permits direct visualization of the location of a probe on a chromosome. This method originated in attempts to localize satellite DNA by hybridizing DNA labeled with tritiated nucleotides to chromosomes that had been previously denatured. After a period of incubation, slides that had been dipped in photographic emulsion subsequent to hybridization were observed. The appearance of silver grains on the slides showed the location of the decaying isotope and hence of the hybridizing DNA.

Although this method was initially used for localizing satellite DNAs and other repetitive DNAs and RNA to chromosomes, Harper and Saunders subsequently adapted the methodology to permit its use with single-copy probes. Their adaptations included the use of dextran sulfate in the hybridization reaction and probes contained in a vector that had been nick-translated to label the DNA with tritiated nucleotides. These adaptations resulted in networking of vectors and accumulation of the label at specific sites on the chromosome. The labeled chromosomes may be photographed for grain location and then banded and rephotographed or the grain developed and the chromosomes banded, usually with a fluorescent dye, and observed simultaneously. A further development of *in situ* hybridization was the use of chromosomally abnormal cells, such as those bearing a translocation, for regional mapping. In such cases, the mapping of the probe to the translocated segment can identify the specific region or band to which the grain is confined (58).

Most recently, hybridization with radioactive probes has been replaced by the use of FISH. With this method, the nick-translated probe is commonly a biotin-labeled probe; random primer, also conjugated with avidin, can be used to label and can be subsequently visualized by use of antiavidin antibodies and immunofluorescence with fluorescein on counterstained chromosomes (this technology was explained in more detail earlier). This method has the advantage that, by use of two separate fluorescent dyes, it is possible to visualize the chromosomes at two different wavelengths, one producing banding and the other demonstrating the localization of the probe. The process is faster and the hybridized probe is more specifically localized (Fig. 29.26). One of the problems with the use of radioactive probes was the occurrence of grain on other chromosomes of the cell as a result of scatter of radioactive emissions, which necessitated grain counting and statistical evaluation of the results. The fluorescence approach is more specific and is useful for both repetitive and single-copy probes. What has become especially efficacious about this technique is the ability to use almost any size probe (1 kb to >1 MB), for mapping. These probes can be labeled and easily mapped to the appropriate chromosome. If a probe is too small to detect a signal, it can be labeled and hybridized

to either cosmid, BAC, or PAC libraries to obtain a larger probe that can be used with FISH (59,60 and 61).

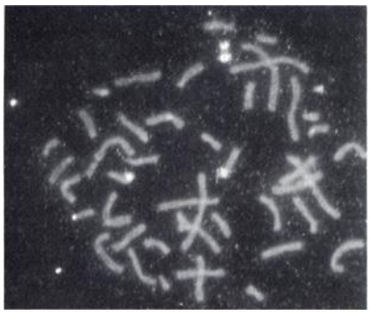

FIGURE 29.26. Localization of alpha-satellite probe from chromosome 15 to both chromosome 15s and to a marker chromosome derived from chromosome 15, i(15p).

The overall usefulness of the fluorescence techniques has not only been demonstrated in metaphase chromosome spreads, but also by its ability to delimit the position of linked genes on a chromosome by using interphase cytogenetics and labeling with several fluorescent dyes emitting in different wavelengths. This provides much greater resolution when trying to map a gene. Fiber-FISH provides even greater mapping resolution. This is a technique in which chromosomes are mechanically stretched and then the probe applied. This provides much greater spatial resolution allowing the precise ordering of closely mapped genes and DNA segments (62).

Gene mapping studies have included combinations of the above techniques with molecular methods. Although chromosome variants were initially useful, the variation in DNA by the use of restriction endonuclease digestion has been so much greater that chromosome variants are now rarely used for conventional linkage studies. In turn, microsatellite markers (STSs, as described previously) are now routinely utilized for these studies, and soon single nucleotide polymorphisms will be routinely used. The cosegregation of these molecular polymorphisms and recombination frequency of these markers in families can be used for genetic linkage studies. It is this approach that has led to the identification of probes diagnostic for genetic disorders and ultimately to their chromosome localization, either by linkage to previously located genes or by *in situ* hybridization.

Since 1973, International Human Gene Mapping Workshops have met regularly to summarize the assignment of genes to chromosomes. From 25 genes mapped in humans in 1973, the conference of 1991, the Eleventh International Workshop, reported 2,325 genes identified and localized (63,64). The data generated at these conferences have been summarized in published reports and include information on the genetic constitution of each of the chromosomes, assignment of mendelian disorders and clinical disorders, and catalogs of cloned genes and DNA fragments. An example of the extent of mapping is shown in Fig. 29.27, where selected anchor loci are indicated for chromosome 1 and a human disease phenotype for that chromosome is also shown. The progress of mapping the human genome is rapidly increasing, with international cooperation in this effort and with molecular biology, computer science, and technology making contributions to progress in this field. It should be noted that the mapping effort has become so extensive that each individual chromosome has individual meeting and workshop reports.

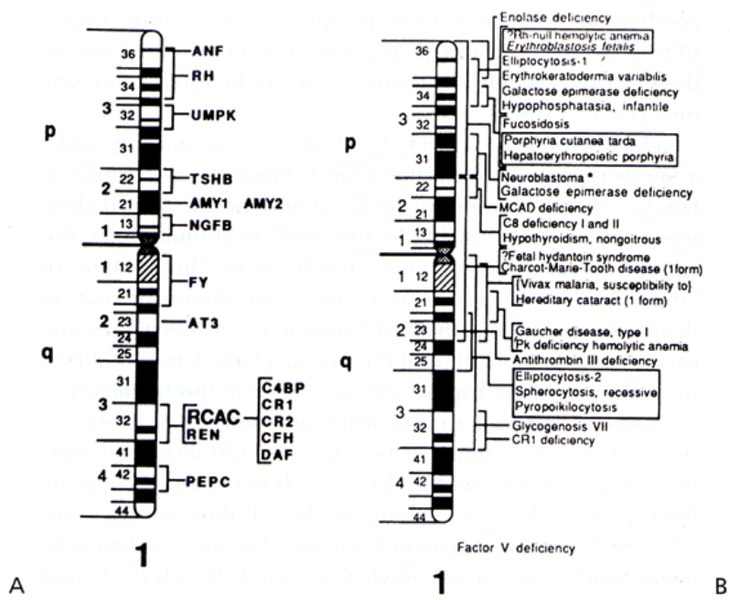

FIGURE 29.27. Gene localization on chromosome 1. **A:** Selected anchor loci. ANF, natriuretic factor; RH, rhesus blood group; UMPK, uridine monophosphate kinase; TSHB, thyroid-stimulating hormone, ß subunit; AMY1, amylase (salivary); AMY2, amylase (pancreatic); NGFB, nerve growth factor ß; FY, Duffy blood group; AT3, antithrombin III; RCAC, regulator of complement activation center; C4BP, complement component 4 binding protein; CR1, complement component 3b; CR2, complement component 3d; CFH, complement factor H; DAF, decay accelerating factor of complement; REN, renin; PEPC, peptidase C. **B:** Disorders for which the mutation has been mapped to chromosome 1. 30
Clinical Cytogenetics

Daniel L. Van Dyke

Anne Wiktor

In Chapter 29, normal chromosome structure and the normal karyotype were described. This chapter addresses cytogenetic pathology associated with birth defects, mental retardation, infertility, and pregnancy loss. Approximately 0.6% of newborns have a chromosome abnormality, constituting a major cause of lethal or debilitating birth defects and mental retardation. Among couples who experience two or more miscarriages, 5% have a balanced chromosome rearrangement. Most of these are familial, and some also confer an increased risk of having a liveborn child with an abnormal karyotype. Approximately 50% of first-trimester miscarriages have a chromosome abnormality, making this by far the most common cause of pregnancy loss, and perhaps 100% of leukemia and cancer acquire an abnormal karyotype. We begin with a discussion of the variety of numerical and structural chromosome abnormalities and continue with examples and descriptions of cytogenetic changes associated with birth defects, mental retardation, and male and female infertility. The main indications for chromosomal study are summarized, followed by techniques for chromosome preparation and guidelines for analysis. The recommendations of the International System for Human Cytogenetic Nomenclature (1) are used to describe karyotypes throughout this section (Table 30.1).

CHANGES IN CHROMOSOME NUMBER AND STRUCTURE

Part of "30 - Clinical Cytogenetics"

Changes in Chromosome Sets (Ploidy)

The normal karyotype contains two copies of every autosome plus two sex chromosomes. This is diploid, or 2n. A sperm or ovum is haploid, or 1n, and normally contains one copy of each autosome plus an X or a Y chromosome.

Triploidy (three haploid sets, or 3n) results when two sperm fertilize one ovum (Fig. 30.1A). Approximately 7% of first-trimester miscarriages are triploid. Rare triploid stillbirths and liveborn infants have occurred. The karyotypes 69,XXY and 69,XXX are most common, whereas 69,XYY is far less common and 69,YYY is never seen. Triploidy can also occur from fertilization of a diploid ovum, but most of these conceptions are unable to survive long enough to be observed among miscarriage specimens. This implies that two maternal contributions are more detrimental than are two paternal contributions, probably because of imprinting difference between the maternal and paternal haploid sets, as described in chapter 29. Triploidy appears to occur sporadically among miscarriages, and the risk of recurrence in subsequent pregnancies is not increased. In the *in vitro* fertilization laboratory, a higher concentration of sperm in the fertilization culture can increase the rate of formation of triploid embryos.

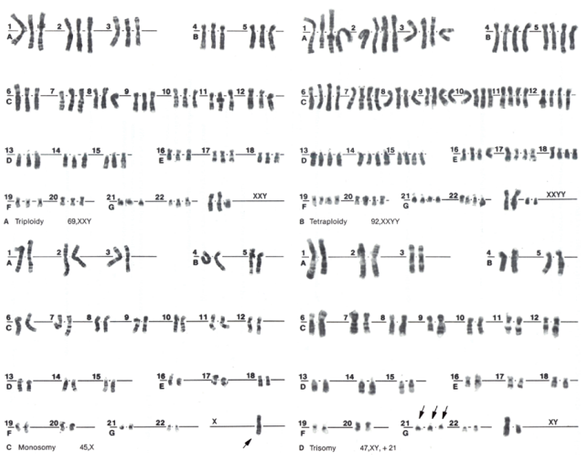

FIGURE 30.1. Numerical changes. An abnormal number of haploid sets (n) is found in triploidy (3n) **(a)** and tetraploidy (4n) **(B)**. Monosomy X **(C)** (*arrow*) is the most common monosomy (loss of a single chromosome, 2n-1), and trisomy 21 **(D)** (*arrows*) is the most common trisomy among liveborn infants (gain of a single chromosome, 2n+1).

Tetraploidy (4n) usually results from failure of cell division after a round of mitosis, and the karyotype is typically 92,XXXX or 92,XXYY (Fig. 30.1B). There is evidence from tumor studies that tetraploidy can also arise from fusion of two diploid cells. Approximately 2.5% of first-trimester miscarriages are tetraploid. A few patients with birth defects have been reported as having a mixture of diploid and tetraploid cells. However, because tetraploidy can also arise in cell culture, this is a difficult diagnosis to confirm, and the significance of such cells must be questioned. Tetraploidy appears to arise sporadically, and there is no increased risk of recurrence in subsequent pregnancies.

Changes in Chromosome Number in a Diploid Background

In the haploid, diploid, triploid, and tetraploid karyotypes, there are one, two, three, and four copies of each chromosome, respectively. The normal karyotype is euploid (Latin, *true number*). When an individual chromosome is lost or gained, the karyotype is aneuploid (Latin, *not true number*). The loss or gain of a single chromosome from a diploid background is monosomy or trisomy, respectively.

Down's syndrome (trisomy 21), identified by Lejeune in 1959, was the first clinical condition in which a gain of a single chromosome was reported (Fig. 30.1D). Trisomy 18 and 13 (Edward's and Patau's syndromes, respectively, after the men who described their chromosomal etiologies in 1960) are also classic trisomy syndromes associated with major birth defects, mental retardation, and a high risk of perinatal death. Trisomy X is mild by comparison. Most of the other autosomal trisomies are associated with fetal demise and are not commonly found among liveborn infants (Table 30.2). Trisomy 8 is a common abnormality in leukemia and trisomy 7 is common in many solid cancers.

TABLE 30.2. AUTOSOMAL TRISOMY AND ISOCHROMOSOME CONDITIONS THAT HAVE BEEN OBSERVED IN MISCARRIAGE SPECIMENS AND AMONG LIVEBORNS

Chromosome	% of Trisomic Miscarriages[a]	Liveborns[b]

[a] Autosomal trisomy is identified in 25% to 30% of miscarriage specimens. The percentage of each chromosome among autosomal trisomies is shown. Data from ref. 2.

[b] More than 50 reported cases but less than 1 per 10,000 livebirths is considered uncommon, 10 to 50 reported cases is considered rare, and fewer than 10 reported cases is considered very rare. The designation “none?” means that this has been reported but the finding is controversial. A blank space indicates that the condition has not been observed.

[c] Syndrome is described in the text.

During meiosis I (see Chapter 29), the chromosome homologs segregate to opposite sides

of the meiotic cell. During meiosis II or mitosis, sister chromatids segregate to opposite sides of the cell. This is normal disjunction. If sister chromatids fail to segregate normally (primary nondisjunction), the daughter cells become aneuploid (Fig. 30.2). Most pentaX (49,XXXXX) or 49,XXXXY cases probably arise as a result of maternal nondisjunctional events during both meiosis I and II, with a normal paternal contribution of an X- or Y-bearing sperm.

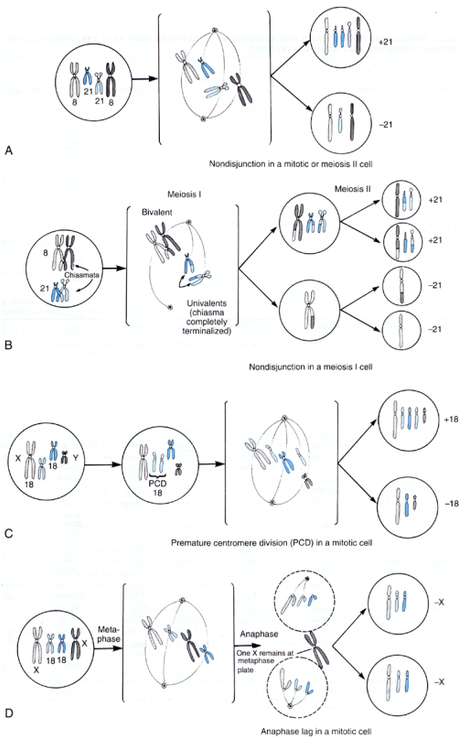

FIGURE 30.2. Origins of aneuploidy. Nondisjunction **(a)**, an important source of trisomy and monosomy, occurs during mitosis or meiosis II when sister chromatids (or when homologs in meiosis I, as shown in **B**) move together to the same daughter nucleus. A second source of aneuploidy **(C)** is premature division of the centromere, which permits the site chromatids to drift apart and segregate independently during anaphase to daughter nuclei. Monosomy can also arise through anaphase lag **(d)**, in which one chromatid is excluded from either daughter nucleus.

Because trisomy 21 (Down's syndrome) is the most common single identified cause of mental retardation, the biological basis of nondisjunction is of great interest. The parental origin and meiotic stage of the nondisjunctional error can often be identified from studies of chromosome 21 short arm variants and restriction fragment length polymorphism using DNA probes from 21q in Down's syndrome patients and their parents. From such studies, it has been established that more than 90% of the nondisjunctional events occur during maternal meiosis and the rest during paternal meiosis or an early embryonic mitosis. Most of these errors occur during meiosis I. The average maternal age for trisomy 21 children is approximately 30 years compared with the population average maternal age of approximately 25 years. Maternal age is also advanced for 47,XXX and 47,XXY and the other autosomal trisomies (Table 30.3). The biological basis for the maternal age effect is not completely understood, but the frequency of recombination (crossing over) appears to be lower in most cases, with zero or only one recombination event, and the recombinations appear to be mostly near the end of the chromosome. This results in a much weaker physical connection between the two chromosome 21 early in meiosis I and allows them to drift apart (Fig. 30.2B). In other cases of maternal age-associated nondisjunction, an opposite effect may be occurring: a greater number of recombination events than normal or a recombination event close to the centromere may lead to a stronger physical connection between the chromosomes (an entanglement perhaps) such that they cannot separate normally at the first meiotic division, and both chromosomes travel together to the same daughter cell (4).

TABLE 30.3. CHROMOSOME ABNORMALITY RATES PER THOUSAND IN LIVEBIRTHS BY 5-YEAR MATERNAL AGE INTERVALS*a*

Maternal Age	Down's Syndrome[b]	Edwards' Syndrome	Patau's Syndrome	47,XXY	47,XXX
15–19	0.6	0.06	0.03	0.4	0.4
20–24	0.7	0.07	0.04	0.4	0.4
25–29	0.9	0.09	0.05	0.4	0.4
30–34	1.4	0.14	0.07	0.6	0.4
35–39	4.2	0.42	0.21	1.1	0.7
40–44	14.2	1.42	˜0.60	2.6	1.9
45–49	˜50	?1.42	?0.6	6.6	3.5

[a] The statistics are from ref. 3.

[b] Average of studies of rates in New York and Sweden.

Many other risk factors for nondisjunction have been postulated, but none has been clearly demonstrated as important, including paternal age, decreasing sexual activity with advancing

age, ionizing radiation, maternal thyroid dysfunction, inbred population groups, chromosome 21 short arm variants, and rearrangements involving other chromosomes.

An individual who is trisomic, such as a female with trisomy X or 21, has an increased risk of having offspring with the same trisomy. The formation of a 24,X,+21 or 24,XX ovum in a trisomy 21 or trisomy X female, respectively, is called secondary nondisjunction. One would expect 50% of the conceptions of a 47,XXX mother to be either 47,XXX or 47,XXY and 50% of the conceptions of a 47,XX,+21 mother to have trisomy 21, as products of secondary nondisjunction.

The only monosomy observed in liveborn infants or miscarriages is 45,X. This is important in Ullrich-Turner syndrome (Fig. 30.1C) and is observed in approximately 9% of miscarriages. Monosomy 21 and 22 are rarely identified in miscarriages. Conceptions with autosomal monosomy appear unable to survive long enough to be recognized and are probably lost before the time of implantation. Conversely, monosomy 7 is a common change in acute myeloid leukemia and myelodysplasia, and monosomy 22 is an important abnormality in meningioma (see also Chapter 32 and Chapter 33). Although maternal age is a major risk factor in trisomy, it is not advanced in monosomy X.

Mosaicism

Nondisjunction or anaphase lag in mitotic cell division creates mosaicism, a mixture of cells with different karyotypes. Mosaics for trisomies 13, 18, and 21 and monosomy X are all well known and in general have a similar or less severe phenotype than the nonmosaics. Several other mosaic trisomies have been observed in liveborn infants (Table 30.2). Patients with trisomy 8 are probably all mosaic with both normal and trisomic cell lines. It has been suggested that cultured fibroblast cells from trisomy 8 mosaics typically have a higher proportion of +8 cells than do lymphocytes. Different cell types probably tolerate some chromosome abnormalities differently. Several tissue-limited or tissue-dependent mosaic chromosome abnormalities have been identified in patients who have mental retardation, asymmetric skeletal or other malformations, and a variegated, swirled, or linear streak pattern of skin pigmentation, similar to hypomelanosis of Ito (Table 30.4). Many of these subjects have a normal blood karyotype with mosaicism found only in cultured fibroblast cells. Although the true frequency of clinically important mosaicism is uncertain, trisomy 8 and diploid/triploid mosaicism are among the most important distinct mosaicism syndromes.

TABLE 30.4. TISSUE-LIMITED MOSAICISM*a*

Characteristics common to tissue-limited mosaicism
Mental retardation and minor malformations and
Joint contractures (arthrogryposis)
Diaphragmatic hernia (in Killian syndrome)
Pigmentary dysplasia (e.g., hypomelanosis of Ito)
Chromosome abnormalities frequently showing tissue-limited mosaicism
Diploid/triploid mosaicism
Warkany's syndrome
Pallister-Killian syndrome
Supernumerary marker
Incontinentia pigmenti, mental retardation
Turner's syndrome with mental retardation
46/69 mosaicism
Trisomy 8
Secondary trisomy 12p
Various 46/47,+mar or +ring chromosome
X; autosome translocation with Xp11 breakpoint
46, X/46,X,r(X) with loss of XIST function

[a] If tissue-limited mosaicism is identified, uniparental disomy may also be present and may further complicate the phenotype.

Mosaic autosomal monosomy is very rare (other than in cancer cells), and we are aware of only a very few cases of -21 or -22 mosaicism in liveborn infants, prenatal diagnostic specimens, or miscarriages. We have seen one amniotic fluid specimen with -21/diploid mosaicism. The parents elected to interrupt the pregnancy, so it is uncertain whether the fetus would have been viable. The source of mosaic monosomy/diploidy could be mitotic nondisjunction, premature centromere division, or anaphase lag (Fig. 30.2). Because lymphocyte chromosome preparations in most laboratories have approximately 5% of cells with 45 chromosomes, it is difficult to detect a low-frequency mosaic monosomy against this background level of aneuploidy. Cell cultures from some subjects with autosomal rings or dicentrics (see below) have a low frequency of monosomy owing to loss of the mitotically unstable chromosome, but the *in vivo* viability of such cells is unclear. Mosaic monosomy X, with either 46,XX or 46,XY or altered sex chromosome structure, is common among patients with Ullrich-Turner syndrome, gonadal dysgenesis, and ambiguous genitalia. Approximately one in 2,500 prenatal studies is 45,X/46,XY, usually resulting in a phenotypically normal male infant. The frequency of cells 45,X,-Y in males and 45,X,-X and 47,XXX in females increases with advancing age. In females, this age effect becomes evident by age 30, and in males by age 55.

Changes in Chromosome Structure

Changes in chromosome structure fall into three broad categories: deletion, duplication, and rearrangement. A structural change can involve a single base pair (bp) or millions of bases of DNA. The lower limit of resolution through the microscope, and therefore the limit for classic cytogenetic techniques, is approximately 2,500,000 bp [2,500 kilobase (kb)]. The average chromosome contains approximately 100,000 kb, much of it nontranscribed, and the average gene is approximately 40 kb in length. The average 2,500-kb segment is thought to contain approximately 60 genes.

Deletion

A deleted chromosome has lost part or all of one of its arms (Fig. 30.3A, Fig. 30.3B). A chromosome with a deletion of its centromere region (acentric) is usually lost within a few cell divisions. Most chromosome deletions appear through the microscope to be terminal; that is, the telomere (chromosome end) appears to have been lost. However, it is doubtful whether a chromosome with a terminal deletion is stable because the telomere appears to be an essential structure (discussed in more detail in Chapter 29). For example, deletions induced by ionizing radiation have “sticky ends” and frequently form unstable chromosome rearrangements, whereas deletions associated with birth defects are highly stable. Some R-banding studies have suggested that the terminal R band is not lost from deletions that appear by G banding to be terminal. Nevertheless, the ISCN (1) provides for interpretation of a deletion as terminal if it appears to be so through the microscope.

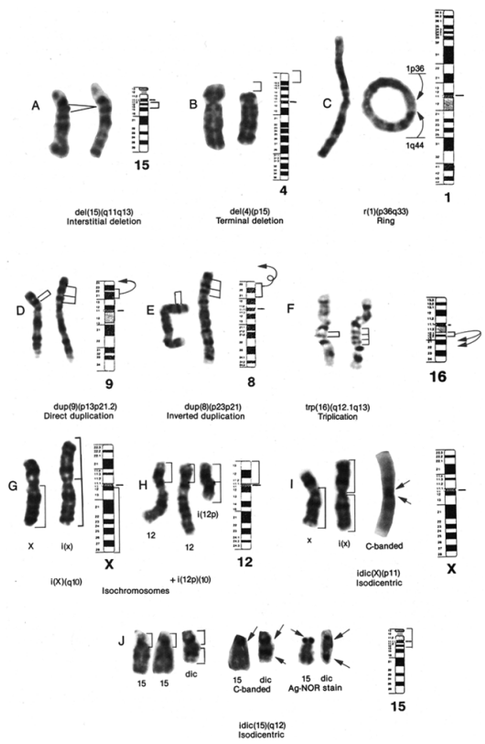

FIGURE 30.3. Structural changes. A chromosome deletion can be interstitial **(a)**, terminal **(B)**, or involving both chromosome ends to form a ring **(C)**. A tandem duplication can be direct **(d)** or inverted **(E)** with respect to the centromere. A tandem triplication is shown in **F**. (Courtesy of The Children's Hospital, Denver, CO.) A monocentric or dicentric isochromosome can replace a normal homolog **(G, I)** or represent an extra element in the karyotype **(H, J)**.

Deletions have been observed for many but not all regions of the karyotype. Several deletion syndromes (a syndrome is a constellation of features typical of patients with the defect) were characterized before the advent of chromosome banding because the structural change was obvious even on uniformly stained chromosome preparations. These include 4p- and 5p- (Wolf-Hirschhorn and cri-du-chat syndromes, respectively), 18p- and 18q- syndromes, and X chromosome deletions associated with gonadal dysgenesis. Some patients with the classic deletion syndromes have been identified only by using high-resolution cytogenetics, because the deletion can be quite small (the 4p- in Fig. 30.3B was not seen in metaphase spreads with shorter chromosomes). For genetic counseling, the parents of patients with deletions need to be karyotyped because 10% to 15% are derived from familial, balanced chromosome rearrangements. If the parents' karyotypes are normal, the risk of recurrence is very low. Deletions are also important in carcinogenesis, permitting the loss of expression of tumor suppressor genes (see Chapter 34).

Ring

Breakage in both arms of a chromosome and repair by fusion at the two breakpoints results in a circular chromosome, or ring (Fig. 30.3C). A ring can arise in any cell, and many patients with rings are mosaic with a normal cell line. Complicated structures that arise during replication can produce daughter cells with multiple rings and rings that have zero, two, or even more centromeres. This instability often generates cell lines with rings of different sizes and with monosomy for the chromosome involved. Rings of every chromosome have been observed, and a few have been sufficiently common to delineate syndromes. However, differences among patients in breakpoints of the rings and the frequent mitotic rearrangement of rings lead to wide variation in the phenotypes of patients who appear to have the same ring.

Although the risk of recurrence in future pregnancies is considered very low, chromosome studies of parents are necessary because some familial rings have been found. If the deletion at both ends of the chromosome is very small, the phenotypic effects can be minimal. Some individuals with rings have had a normal or nearly normal phenotype and have reproduced, but their offspring are at an increased risk for birth defects. For example, we identified a four-generation family with a ring chromosome 21 (5). One mildly mentally retarded child had a ring 21 with more material lost than the ring in her mother's cells. If an individual is mosaic with normal diploid cells, an error early in embryogenesis is likely, and the parents would be expected to have normal chromosomes, although reversion from a ring to a stable rod chromosome has been reported.

Duplication

A cytogenetically visible duplication almost invariably results in a miscarriage or a livebirth with birth defects and mental retardation. The exceptions primarily involve duplications of heterochromatic (C band–positive) segments and acrocentric short arm variants. Gene duplication has been important in evolution, allowing species to experiment with nonessential, duplicate genes. The hemoglobin and immunoglobulin gene families are classic examples of evolution after gene duplication.

A segment can be duplicated on the same chromosome or on a nonhomologous chromosome (intrachromosomal or interchromosomal duplication, respectively). An intrachromosomal duplication can be immediately adjacent to the normal segment

(tandem or contiguous, ABCDEEFG) or, less frequently, separated by nonduplicated material (noncontiguous, ABCD*EF*G). When the duplicated segment has a normal orientation with respect to the centromere, it is a direct duplication (ABCcenD *EFEF*G), otherwise it is an inverted duplication (ABCcenD *EFFE*G) (Fig. 30.3D, Fig. 30.3E). In practice, it is not always possible to determine the orientation of a duplicated segment or whether the duplication is contiguous. The source of a small duplicated segment is often somewhat speculative, and biochemical, molecular, or molecular cytogenetic studies are often useful to confirm a cytogenetic impression.

A direct duplication is the most common intrachromosomal duplication, probably because it can arise from a simple unequal exchange between sister chromatids in a mitotic or meiotic cell, whereas an inverted tandem duplication requires three chromosome breaks (Fig. 30.4A, Fig. 30.4B). A similar unequal exchange mechanism probably accounts for many deletions as well. The mean parental age is significantly advanced in patients with inverted duplications, suggesting a meiotic origin, but it is normal in patients with direct duplications. Most tandem duplications are new mutations with a low risk of recurrence. Chromosome studies of the parents are necessary in all duplication cases to look for a familial chromosome rearrangement and to provide accurate genetic counseling. For an interchromosomal duplication, where the extra material is derived from a different chromosome, the odds that a parent carries a balanced translocation are significantly greater than the 10% to 15% for a deletion. Duplications and deletions associated with familial chromosome rearrangements are discussed further below.

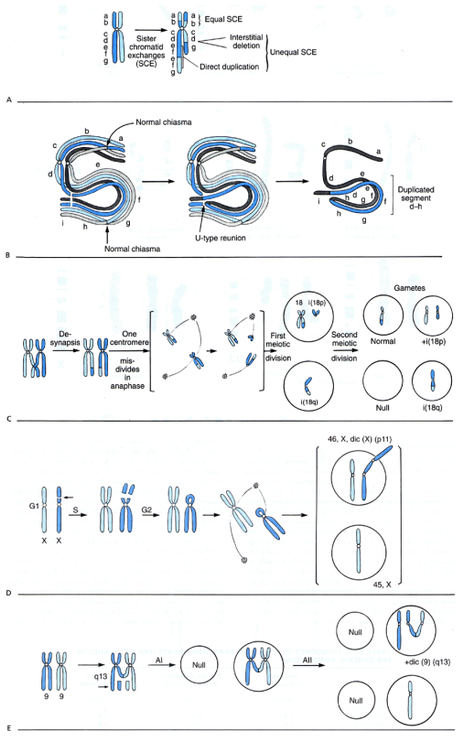

FIGURE 30.4. Origins of duplications and isochromosomes. A direct duplication **(a)** can arise in a mitotic or meiotic cell by unequal sister chromatid exchange or recombination. The reciprocal product is a deletion. An inverted duplication **(B)** probably results from a three-break rearrangement between homologous or sister chromatids during meiosis I. The repair of the three breaks would include a U-type reunion. It is shown here arising in meiosis I, with one break in the proximal long arm and two breaks in the distal long arm. The repair process results in duplication of the intervening segment. Several mechanisms of isochromosome formation have been proposed. In meiosis I, desynapsis of the two chromosome 18s can lead to misdivision of a centromere in anaphase I to form monocentric isochromosomes of each chromosome arm **(C)**, and gametes could have either an i(18q) replacing a normal 18, or a supernumerary i(18p). As shown in this example, both 46,i(18q) and 47,+i(18p) have been observed. Formation of a dicentric isochromosome X can result from repair of a chromosome break with a U-type reunion. In a mitotic cell (as shown in **D**), this would produce an individual with 45,X/46,X,idic(X) mosaicism and in some cases a 46,XX line as well. The acentric short arm remnants would be lost. In contrast to the mitotic origin of the dicentric that replaces a normal homolog (as in **D**), during meiosis, a supernumerary dicentric isochromosome is more likely to arise. In **E**, a chromatid break in both chromosome 9s and U-type reunion are shown. In anaphase I, the homologous chromosomes are attached by the rearrangement and travel together to the same daughter cell. One might expect an anaphase bridge to occur because the two centromeres typically are drawn to opposite poles, but “centromere cooperation” appears to occur in dicentric chromosomes in which the centromeres are close together. The final result is one gamete with a normal chromosome 9 plus the dicentric, one normal gamete, and two null gametes. The acentric fragments are lost.

Isochromosome

In an isochromosome, the arms are mirror images (Fig. 30.3G,Fig. 30.3H,Fig. 30.3I and Fig. 30.3J and Fig. 30.4C,Fig. 30.4D and Fig. 30.4E). The isochromosome can replace a normal chromosome (monoisodisomy) or be an extra chromosome

in an otherwise normal karyotype (secondary trisomy). It can be monocentric with two long or two short arms of the chromosome, or dicentric with the material between the centromeres continuing the mirror image: ABCDcenDCBA or ABCDcenEF::FEcenDCBA, respectively. Isochromosome Xq is associated with gonadal dysgenesis and features of Ullrich-Turner syndrome. Isochromosome Yp and Yq are associated with male infertility and with abnormal sex differentiation, and several autosomal isochromosome syndromes have been identified (Table 30.2). Even though the origin of secondary trisomies is often a meiotic error, mosaicism is frequent because dicentric chromosomes are mitotically unstable, and the karyotype reverts to normal in cells that lose the isochromosome (compensating nondisjunction). Parental karyotypes are usually normal but should be studied because some rearrangements, mainly paracentric inversions (see below), can give rise to an apparent isochromosome. Parental mosaics have also been described. Isochromosomes are also important in the cytogenetic evolution of leukemia and solid cancer.

Rearrangement

The three main categories of balanced chromosome rearrangements are robertsonian translocations, reciprocal translocations, and inversions. One in 175 to 250 phenotypically normal subjects carries a balanced rearrangement (Table 30.5). The identification of balanced rearrangements is important because carriers have increased risks for having miscarriages and malformed liveborn infants, and some male carriers have reduced fertility. A rearrangement can be carried by many family members, conferring risk to many relatives. Furthermore, new mutation carriers of apparently balanced reciprocal translocations and inversions (but not centric fusions) are overrepresented among the mentally retarded. There are several possible explanations for this, including loss of gene function because of breakpoints within genes, undetected deletion at one or both chromosomal breakpoints, or position effects (changes in gene expression because of different location in the genome, such as movement away from or adjacent to controlling elements or heterochromatin).

TABLE 30.5. FREQUENCY OF BALANCED REARRANGEMENTS (PER THOUSAND) IN THE GENERAL POPULATION*a*

	Newborn (Unbanded)[a]	Prenatal + Newborn (Banded, to 1982)	Prenatal (1982–1990)
Sample size	56,952	12,923	11,500
Translocations			
Robertsonian	0.9	0.9	1.4
Reciprocal	0.9	1.5	1.8
Inversions			
Pericentric	0.1	0.7	1.7
Paracentric	0	0.3	0.9
Total	1.9	3.4	5.8

[a] Estimates from newborn surveys using routine stained (unbanded) chromosome preparations were accurate for robertsonian translocations because the chromosome count is 45. Reciprocal translocations and pericentric inversions were identified only if centro mere positions changed. No paracentric inversions were found. Estimates based on prenatal genetic studies using banded chromosomes vary somewhat, the differences at least partly owing to improvements in the quality of banding over time. The statistics are from various sources summarized in refs. 6,7 and 8 and Van Dyke et al., unpublished data.

Robertsonsian Translocation

A centric fusion or robertsonian translocation arises from the fusion of two acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22) (Fig. 30.5). During the resting phase of the cell cycle multiple nucleoli form, each involving the nucleolar organizing region (NOR) of one acrocentric chromosome. With time, the number of nucleoli becomes fewer and their size larger as they coalesce. In a metaphase chromosome preparation, remnants of nucleolar activity are evidenced by acrocentric associations (Fig 30.5B). Acrocentric association no doubt plays a role in the formation of centric fusions. For reasons that are not understood, the frequency of different robertsonian translocations is nonrandom (Table 30.6).

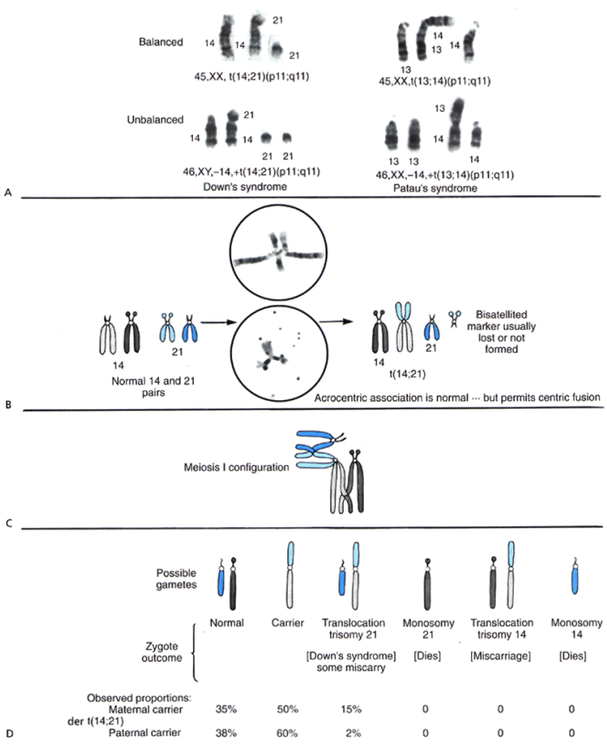

FIGURE 30.5. Robertsonian translocation (centric fusion). The most important robertsonian translocations are der(14;21) and der(13;14). Partial karyotypes of a balanced and an unbalanced set are shown in **A**. Acrocentric association **(B)** is normal chromosome behavior. It is a remnant of nucleolar activity, as shown by the common stream of silver staining (AgNOR staining). This close association probably accounts for the relatively high frequency of centric fusions compared with other balanced rearrangements. The reciprocal product of a centric fusion, a bisatellited marker chromosome, is usually not found. A meiosis I configuration **(C)** formed in a carrier of a der(14;21) is shown, along with the six possible gametic products **(d)**, of which only three are ever observed. Frequency statistics are based on prenatal diagnosis results in carriers (9).

TABLE 30.6. DISTRIBUTION OF EACH TYPE OF ROBERTSONIAN TRANSLOCATION IN THREE POPULATION SAMPLES*a*

Translocation	Unbiased Surveys (%)	Multiple Miscarriages (%)	Unbalanced Translocations (%)
13;13	2.3	3.6	3.3
13;14	71.0	59.6	12.8
13;21	0.9	0.4	2.6
14;21	9.3	8.0	40.7
15;21	0.9	1.2	3.8
21;21	2.3	0.4	28.4
21;22	0.5	0.8	2.8
All others[b]	12.6	26.0	5.5

[a] The statistics summarize the distribution of robertsonian translocations among subjects karyotyped in newborn surveys and routine screening programs such as prenatal diagnostic studies, couples who experienced multiple miscarriages or reduced fertility, and probands with malformations and an unbalanced robertsonian translocation (approximately two thirds of whom had Down's syndrome). The unbiased surveys show that der(13;14) is by far the most common robertsonian translocation. The pattern for the multiple miscarriage and infertility group is similar to that of the unbiased surveys. The der(14;21) and der(21;21) are relatively more important clinically than their frequencies in the general population would suggest. Together they comprise only 12% of robertsonian translocations, but because of their association with Down's syndrome, they account for two thirds of those with unbalanced translocations. Statistics are adapted from ref. 41, pooled with data from our laboratory.

[b] All other robertsonian translocations include der(14;14), der(15;15), der(22;22), der(13;15), der(13;22), der(14;15), der(14;22), and der(15;22).

Individuals who carry a *de novo* balanced robertsonian translocation have no increased risk for having malformations or mental retardation; these are not seen in increased frequency among patients with mental retardation or birth defects. However, rare patients with a *de novo* centric fusion involving chromosome 15 have been described as having Prader-Willi syndrome (PWS) or Angelman syndrome (AS) (described later).

Some patients with trisomy 21 (Down's syndrome) and trisomy 13 (Patau's syndrome) have unbalanced forms of robertsonian translocations (Fig. 30.5). This is the primary reason for studying the karyotype of a Down's syndrome patient because the diagnosis can usually be made clinically. The risk that a carrier of a balanced translocation will have chromosomally unbalanced offspring depends on the translocation involved, the gender of the parent, and the likelihood of survival of the abnormal conceptus (see the sections on trisomies 13 and 21, below). The expected 1:1 ratio of normal to balanced karyotypes among offspring is not found, as more than half of the normal offspring are translocation carriers. This observation is not yet understood.

The frequency of robertsonian translocations in the general population is approximately one in 900, and they are more common among couples with multiple miscarriages and males with infertility. In studies of consecutive newborns or prenatal diagnosis specimens, the sex ratio of centric fusion carriers is approximately equal, whereas among the parents of carriers or unbalanced progeny, many more mothers are carriers. The difference

is probably related to the observed reduced fertility in some male carriers of centric fusions.

Reciprocal Translocation

A reciprocal translocation involves the exchange of chromosome segments, usually involving breakpoints on each of two nonhomologous chromosomes. One in 500 to 650 liveborn infants carries a balanced reciprocal translocation. Unbalanced translocations and complex rearrangements involving more than two breakpoints are less common. One translocation, t(11;22) (q23;q11.2), is seen in approximately 1 in 5,000 normal subjects. Other than recurring translocations in cancer and leukemia, this is the only important exception to the practically random distribution of chromosomal breakpoints among reciprocal translocations. The 22q "hot spot" for chromosome breakage includes repetitive DNA sequences, a low copy repeat cluster, LCR22, that may be a predisposing factor for the t(11;22) and for the 22q11 deletion syndrome (described later).

A major factor in the reproductive risks to a translocation carrier is the viability of the possible unbalanced meiotic products (Fig. 30.6). [Several chapters in Daniel's book (10) are devoted to this issue.] In general, risks of having a child with an unbalanced form of a reciprocal translocation range from nearly zero to 25% to 30%; the risk of miscarriage averages approximately 25%; and some males have reduced fertility. Unbalanced products with small duplications or deletions are more likely to be viable, and a gain of 1% or loss of 0.5% of the haploid complement is usually viable, whereas a gain of 4% or loss of 2.5% is likely to be lethal. The short arms of chromosomes 17 and 20 each constitute approximately 1% of the haploid complement, so either arm is a handy point of reference for predicting the viability of a rearrangement. However, viability is determined more by the genes that reside on a chromosomal segment than by its length, so there is wide variation, with some larger chromosomal segments viable as duplication or deletion and a few smaller segments never observed in a chromosomal imbalance.

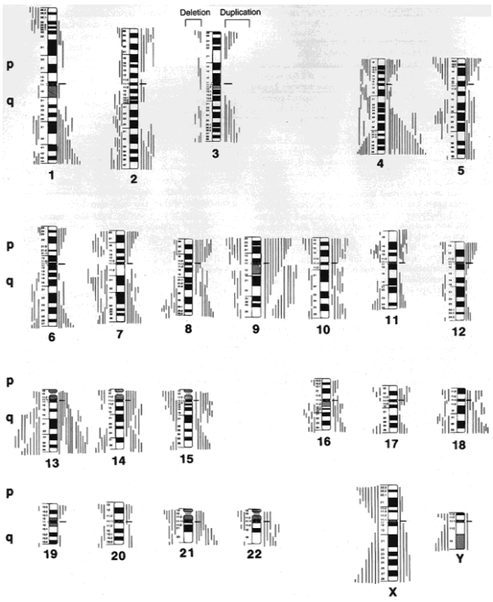

FIGURE 30.6. Chromosome deletions and duplications. The idiogram depicts the deletions (at left of each chromosome) and duplications (at right) that have been observed among liveborn infants. Mosaic cases with a normal cell line are excluded. The length of each line represents the chromosome segment that was lost or duplicated. The relative frequency of each chromosomal imbalance is not represented here. In general, smaller amounts of imbalance are more common, but there are many exceptions. For example, gain and loss of chromosome 13 and chromosome 18 segments are among the most common, whereas even the smallest changes to chromosome 19 are very rare.

Of the unbalanced meiotic products, adjacent I segregants are the most commonly observed (Fig. 30.7). Adjacent II segregants usually have greater imbalances and are rarely seen. If one of the translocation chromosomes is small, then a 3:1 segregation product may result in tertiary trisomy. For the t(11;22) mentioned previously, the risk is approximately 5% for the viable tertiary trisomy, and a maternal age effect may be superimposed on this risk, analogous to the maternal age effect in primary trisomy.

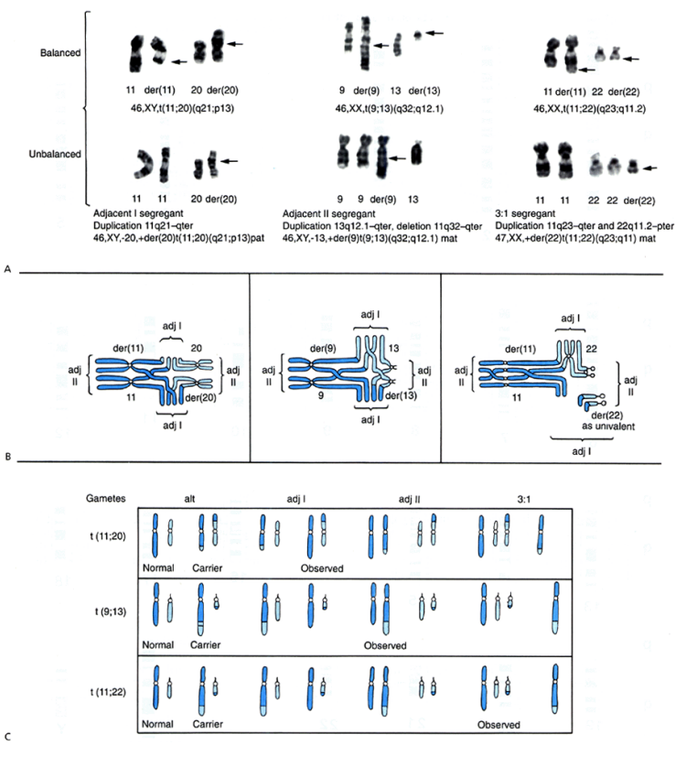

FIGURE 30.7. Segregation in reciprocal translocations. In **A**, three different translocations are shown in their balanced form and in an unbalanced form. In **B**, a meiosis I prophase quadrivalent is depicted for each translocation. The theoretically possible meiosis I segregants include alternate (alternate chromosomes segregate together), adjacent I (nonhomologous centromeres segregate together), adjacent II (homologous centromeres segregate together), and 3:1 segregation (more common when one element is small). Only alternate segregation leads to chromosomally balanced gametes. The meiotic products are shown in **C**, and for the specific translocation used as an example in **A** and **B**, the viable gametes that have been observed are noted.

Insertion and Shift

An insertion is a three-break translocation resulting from removal of a chromosomal segment (two breakpoints) to another site in the karyotype (third breakpoint). A shift is an insertion within the same chromosome (Fig. 30.8). Although insertions are uncommon, they are clinically important because the risk of a chromosomally unbalanced conception in a carrier can be

50%. As with a reciprocal translocation, the risk to have a viable livebirth with a deletion or duplication depends greatly on the size of the inserted segment.

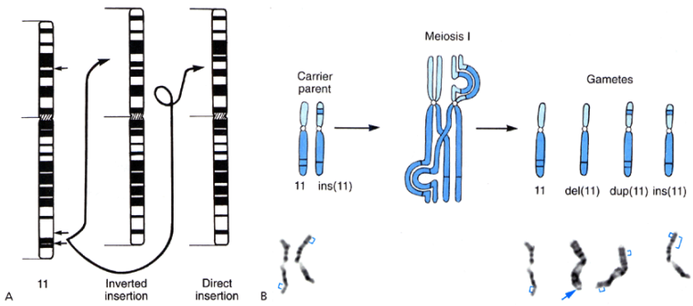

FIGURE 30.8. Recombination in insertion (shift). An intrachromosomal shift requires three breakpoints, as shown in **A** for a chromosome 11 shift. The insertion can be inverted with respect to the original centromeric orientation, or direct. In **B**, the chromosome 11s of the carrier parent are shown diagrammatically and as a partial karyotype. Because the inserted segment is small, it is appropriate to show the meiosis I prophase configuration without synapsis of the insertion segment. Nonrecombinant gametes perpetuate the parental karyotypes, whereas recombination will produce deletion and duplication gametes. Both were observed in siblings with mental retardation and mild malformations. (From Forsythe MG, Walker H, Weiss L, et al. Duplication and deletion 11q23–q24 recombinants in two offspring of an intrachromosomal insertion ("shift") carrier. *Henry Ford Hosp Med J* 1988;36:183–186, with permission.)

Inversion

An inversion is a two-break rearrangement in which a chromosome segment is turned 180° (12) (Fig. 30.9). A paracentric inversion involves only one arm. A pericentric inversion includes the centromere and material from both arms. Balanced pericentric and paracentric inversions are more difficult to identify than translocations, so estimates of their frequency in the general population have increased as the quality of chromosome preparations has improved (Table 30.5). Inversions have been called crossover suppressors because the meiosis crossover products are often nonviable recombinants. Meiotic pairing is expected to create an inversion loop, but an inverted or noninverted segment that is small may remain unpaired during meiosis. Recombination within the inversion loop creates unbalanced products with duplication of material from one end of the chromosome and loss of material from the other end; the inverted segment is neither duplicated nor deleted (15). For a paracentric inversion one recombinant product is dicentric and one acentric.

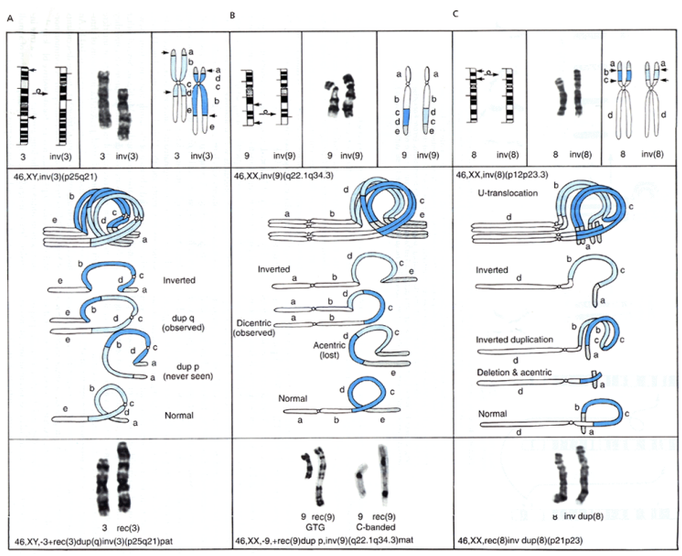

FIGURE 30.9. Recombination in inversion. Three examples are provided to show the results of recombination in pericentric and paracentric inversions. A partial karyotype of the carrier parent and affected offspring is provided at top and bottom, respectively, with an illustration of the meiosis I prophase configuration and recombinant and nonrecombinant products. A pericentric inversion 3 **(a)** and a paracentric inversion 9 **(B)** are shown. A two-break exchange within the paracentric inversion loop **(C)** during meiosis I in a paracentric inversion 8 carrier mother resulted in a child with an inverted duplication of 8p. The inv(9) family was reported by Worsham et al. (13) and the inv(8) family by Feldman et al. (14).

Among pericentric inversions, the risk for producing a malformed livebirth or a recognized miscarriage with a recombinant chromosome varies greatly. In general, a small inversion has a lower likelihood of meiotic exchange between the inverted region and the normal homolog, and therefore a smaller proportion of gametes carry an unbalanced recombinant. Moreover, such recombinants have a greater imbalance and the consequence is lower viability. Conversely, a larger inversion has a greater chance of recombination within the inversion loop, and the recombinants have a smaller imbalance, increasing the chance of producing a miscarriage or malformed livebirth. One can apply some of the same empirical risk data from translocations to pericentric inversions: that viability is dramatically reduced if the imbalance is greater than 0.5% deletion or 1% duplication.

The frequency of balanced pericentric inversions in the general population is approximately one in 600. Pericentric inversions are found more frequently among couples with multiple miscarriages, and probands with unbalanced recombinants are found among patients with birth defects and occasionally in miscarriage specimens. A pericentric inv(3)(p25q21) is responsible for at least 30 patients with a recombinant chromosome having duplication of 3q21–qter and deficiency 3p25–pter (Fig. 30.9A). This inv(3) may have originated in France and been carried by descendants to Canada and the United States, including Detroit, where we identified a branch of the family that came from Newfoundland to Ontario and southeast Michigan. Several other pericentric inversions are considered normal variants because they are not known to create unbalanced recombinants or interfere with fertility. These include small pericentric inversions of chromosome 2 and a metacentric Y chromosome inv(Y)(p11q11). An inv(2)(p12q14) appears to be more frequent among descendants of Sephardic Jews from North Africa and Spain. A common normal variant, inv(9)(p11q12), has a C band–positive block in the short arm in addition to the long arm but may not be a true inversion. It may instead have originated by amplification of a small segment of repetitive DNA in the proximal short arm.

The frequency of balanced paracentric inversions in the general population is approximately one in 1,000, based on our experience from prenatal genetic studies. Many paracentric inversions are not detected in routine studies because the altered pattern of chromosome banding can be quite subtle. Most have been identified by chance (mainly prenatal genetic studies) and only a very few from unbalanced recombinant offspring or *de novo* mutations in patients with birth defects or mental retardation. For a paracentric inversion carrier, the risk of producing a viable conception carrying a recombinant is low because, in general, the acentric and dicentric recombinant products are lost. Nevertheless, our laboratory has identified a girl with a stable dicentric recombinant chromosome whose mother carries a paracentric inv(9)(q22.1q34.3), and a girl with an unusual monocentric recombinant whose mother carries an inv(8)(p21p23) (Fig. 30.9B, Fig. 30.9C). Because only one other dicentric and five other monocentric recombinants from paracentric inversions have been reported in the literature, it is clear that viable recombinants of paracentric inversions are rare. Conversely, there may be significant underreporting in the genetics literature because we identified two of the reported cases. Although the risks for having offspring with unbalanced recombinant chromosomes are probably extremely low for most carriers of paracentric inversions, one must recognize that stable dicentric and monocentric chromosome imbalances can occur.

Uniparental Disomy

Genetic imprinting and uniparental disomy (UPD) were briefly described in Chapter 29. The normal expectation of human reproduction is that one inherits one of each chromosome from each parent. This is termed biparental disomy. However, some individuals have both copies of one chromosome from the same parent, and no contribution from the other parent (uniparental disomy). UPD can result in an abnormal phenotype in one of two principle ways.

First, if the individual inherits both copies of the same chromosome (isodisomy) from a parent and that chromosome carries a recessive mutation, then the mutation will be expressed. The first evidence of uniparental disomy in humans was found in a girl with cystic fibrosis (CF) who was homozygous for a mutation that her mother carried; her father was not a CF carrier. Additional molecular genetic studies proved that the girl had maternal isodisomy 7. Similar cases have since been found for other recessive disorders, and it has been postulated that 1% to 2% of recessive disease is owing to UPD (16).

Genetic imprinting (see Chapter 29) underlies the second class of an abnormal phenotype associated with UPD. For chromosomes that contain imprinted genes, biparental inheritance is essential to normal development. The two microdeletion syndromes, PWS and AS (see below), result from deletion of the

same segment of chromosome 15: deletion of the maternally inherited segment results in AS and deletion of the paternally inherited segment results in PWS. Likewise, paternal UPD results in PWS because the maternally imprinted chromosome 15 is absent, and conversely, maternal UPD results in AS. The girl with CF, mentioned earlier, also had small stature. Other children with UPD7, but without CF, also have short stature. This imprinting effect UPD7 is described in more detail later (see section on Russell-Silver syndrome). The origin and phenotypic effects of UPD have been the subjects of active study (cf. 17,18).

As with primary trisomy, there is also a maternal age effect in UPD, particularly maternal UPD (Fig. 30.10). A trisomic embryo can become mosaic by mitotic loss of one of the three chromosomes, thus reverting to the normal disomic state (compensating nondisjunction or trisomy rescue). If the disomic cell population has a proliferate advantage over the trisomic population, it can come to predominate in both the placenta and, more important, in the embryo proper. There is one chance in three that trisomy rescue will result in UPD. Because trisomy rescue also implies chromosomal mosaicism, an abnormal phenotype cannot be ascribed solely to UPD. Abnormalities can result even if the trisomy is limited to the placenta. For example, mosaic trisomy 16 confined to the placenta, with or without UPD, has been associated with intrauterine growth retardation (19).

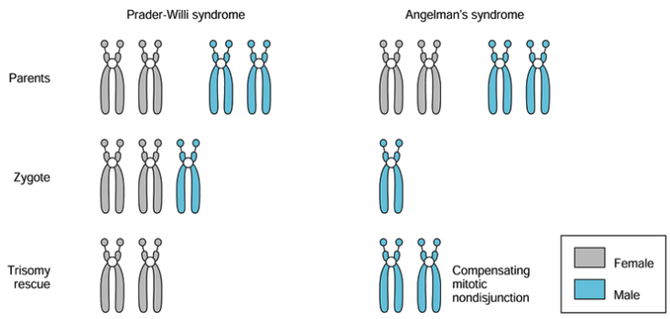

FIGURE 30.10. Illustration of common pathways to uniparental disomy. Chromosomes shaded light grey are maternally derived and dark grey are paternally derived. Paternal uniparental disomy, on the left, can be derived from a maternal meiotic nondisjunction leading to monosomy in the zygote. This is followed early in embryogenesis by a compensating mitotic nondisjunction of the paternally derived chromosome. Maternal uniparental disomy, on the right, can be derived from a maternal meiotic nondisjunction leading to trisomy in the zygote. This is followed early in embryogenesis by a compensating mitotic nondisjunction. The type of disomy that results depends on which chromosome is lost. If one of the maternal chromosomes is lost, the diploid cell population would exhibit normal biparental disomy, but if the paternal chromosome is lost as shown, the diploid cell population exhibits uniparental maternal disomy. (From Ledbetter and Greenberg, personal communication.)

AUTOSOMAL CHROMOSOME SYNDROMES

Part of "30 - Clinical Cytogenetics"

The diversity of autosomal chromosome imbalance is immense, so it follows that the variety of phenotypes associated with autosomal imbalance is great. Only a minority of chromosome syndromes can be identified by physical examination alone. Rather than compare and contrast all chromosome syndromes in detail, it is appropriate to examine the features common to many conditions. The two features found in almost all chromosome imbalances are growth retardation and mental retardation. Congenital heart disease, microcephaly, dysmorphic facial features (including hypo- or hypertelorism, broad nasal bridge, micrognathia, and low-set ears, and, in males, cryptorchidism) are also common and reflect the complexity of embryogenesis of the brain, face, urogenital tract, and heart and the sensitivity of these processes to perturbations of genetic balance. In general, any individual with mental retardation and more than two minor or major congenital anomalies is a candidate for chromosome studies unless a clearly defined nonchromosomal cause is evident.

As stated earlier, gain of a chromosome segment is tolerated better by the developing organism than is the loss of the same segment. In addition to trisomy 13, 18, and 21, several other autosomal trisomies have been reported in liveborn infants (Table 30.2). Likewise, duplication of whole arms in isochromosomes has been observed, as well as triplication through secondary trisomy. The map of reported duplications and deletions in liveborn infants (Fig. 30.6) shows visually that the amount of autosomal duplication tolerated is usually greater than that of deletion. It also shows the variety of potential chromosomal imbalance; virtually any segment can be duplicated or deleted.

Many chromosomal syndromes have been described in the *Clinical Atlas of Human Chromosomes* (20), *Smith's Recognizable Patterns of Human Malformation* (21) and the Online Mendelian Inheritance in Man (OMIM) (http://www3.ncbi.nlm.nih.gov/Omim/). In this section, we present brief descriptions of some well-known chromosomal syndromes and three categories of new syndromes: those associated with a deletion or duplication involving loss or gain of a small number of genes, those with tissue-limited mosaicism, and those related to genetic imprinting. Although each syndrome is defined by a pattern of defects, not all patients exhibit the entire constellation; rather, each defect is more common in that condition, and most of the patients will have some of the features.

The contiguous gene syndromes (Table 30.7) have several features in common (22). They result from duplications or deletions of small segments of chromosome material, containing only a few genes that are functionally unrelated, but by chance are closely linked on the chromosome. The phenotype tends to be variable because of different chromosomal breakpoints, making delineation of a clear syndrome sometimes more challenging. The occurrence of a contiguous gene syndrome is usually sporadic, but clusters within families are known. The familial clusters are owing to balanced chromosome rearrangements that carry a risk for producing unbalanced offspring with the syndrome. Before their chromosomal basis was identified, many of these syndromes were thought to represent autosomal recessive conditions or new dominant mutations. The phenotypes of some microdeletion or microduplication syndromes may involve loss or duplication of just one major gene, such as elastin in Williams syndrome (23), and there are many individual malformations that are significantly associated with loss of specific chromosomal segments (e.g., anal atresia and loss of 13q22 to 13q34 and aortic stenosis and loss of 11q23 to 11q24) (24).

For the study of contiguous gene syndromes, high-resolution cytogenetic methods or molecular cytogenetic techniques using specific DNA probes are essential. The mid to early metaphase analysis that is the accepted standard in most cytogenetics laboratories is not sufficient for reliable identification of these syndromes. This underscores the importance of good communication between the laboratory and the referring physicians. The smallest karyotype changes can appear normal, even when using high-resolution banding methods, because the imbalance is below the resolution of the light microscope. With advances in molecular cytogenetic technology, DNA probes for several contiguous gene syndromes are commercially available. For some syndromes, DNA probe technology (discussed later) has become the standard of care as an adjunct to karyotype analysis because it provides sensitive and specific assays for the detection of the smallest chromosomal deletions and duplications.

Wolf-Hirschhorn Syndrome (Wolf's Syndrome) (Deletion 4p)

Deletion of a segment of the short arm of chromosome 4 was detected by Wolf and Hirschhorn and their co-workers in 1965, before the advent of chromosome banding methods. Some cases have been difficult to identify even with routine G banding, however, and the deletion can sometimes be detected only using high-resolution banding or fluorescence *in situ* hybridization (FISH), described in Chapter 29). The specific genes deleted have not been identified yet, but the critical region for the syndrome has been narrowed to a small gene-dense segment of band

4p16.3 (25). In 10% of cases, one parent carries a balanced chromosome 4 rearrangement. The sex ratio is 2:1 female:male. This syndrome is less common than deletion 5p, which has a milder phenotype.

Phenotype

There are prenatal and postnatal growth retardation and severe hypotonia. The common major birth defects include microcephaly, cleft lip and palate, and severe heart malformation. Facial features include cranial asymmetry, prominent forehead, hemangioma, preauricular pits or tags, coloboma of the iris or other eye malformations, cleft lip with or without cleft palate, hypertelorism with a broad and prominent nasal root, micrognathia, and a long neck (Fig. 30.11). Many other birth defects have been seen, including brain and kidney malformations, hernias, abnormal external and internal genitalia, simian creases, and cutis aplasia of the scalp. Because of the severe malformations, many are stillborn or die in the first year, although survival beyond age 20 has been reported. Mental retardation is uniformly profound, and survivors have seizures and severe hypotonia. A microdeletion involving band 4p16.3 has been associated with both Wolf-Hirschhorn syndrome and Pitt-Rogers-Danks syndrome.

Cri-du-Chat Syndrome (Deletion 5p)

In 1963, Jerome Lejeune described loss of material from chromosome 5 as the cause of cri-du-chat syndrome. As with deletion 4p, this deletion was known before chromosome banding was introduced, but some cases with very small deletions have been reported using routine G-banding and high-resolution banding methods. The smallest deletions, involving band 5p15.1, can be easily missed by a routine G-banding study. Before the introduction of chromosome banding, chromosomes 4 and 5 were not distinguishable, but autoradiographic methods revealed differences in the pattern of DNA replication. Thus, it was soon clear that Wolf's and cri-du-chat syndromes were associated with deletions on different chromosomes. The incidence of cri-du-chat syndrome is approximately one in 45,000 newborns, and 12% result from familial rearrangements involving chromosome 5. The mean parental age is normal. Among *de novo* deletions, approximately 80% represent a mutation in the chromosome 5 inherited from the father. Slightly more females than males are affected (26).

Phenotype

Cri-du-chat syndrome can be suspected in infants with a plaintive, meowing cry, low birth weight, and failure to thrive. Some

mothers have described weak fetal movements. Life-threatening birth defects are uncommon, but because of neonatal complications, approximately 10% do not survive beyond the first few months. The newborn frequently has low birth weight and small head circumference. The weak kittenlike cry that gives the syndrome its name is at least partly owing to an anatomic abnormality of the larynx. Although the cry changes with age, it does not become normal. Facial features include microcephaly, a round face, low-set ears, strabismus, broad nasal bridge, and epicanthus, which give the impression of hypertelorism, micrognathia, and occasionally facial asymmetry (Fig. 30.12). The hands and feet are small, and hands often have a simian crease, fifth digit clinodactyly, and single flexion crease. With age, premature gray hair, dental malocclusion, inguinal hernia, diastasis recti, and scoliosis are common. Infants have hypotonia, but older individuals can have normal tone or hypertonia. The IQ varies mostly between 20 and 50 but can range up to mildly retarded, with skills approaching those of 5 or 6 year olds.

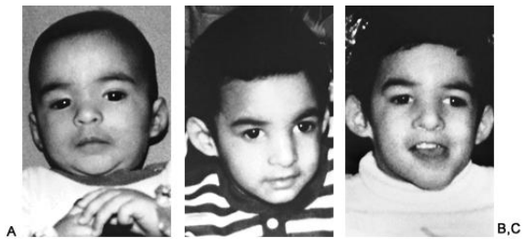

FIGURE 30.12. Three photographs of a patient with cri-du-chat syndrome depict the characteristic facial appearance at ages 5 **(a)**, 24 **(B)**, and 36 **(C)** months.

Russell-Silver Syndrome

Individuals with this syndrome have pre- and postnatal growth retardation, skeletal asymmetry, which can be mild, a normal head circumference with a small triangular-shaped face, clinodactyly, and usually normal intelligence. This is a genetically heterogeneous condition, but approximately 10% of subjects have maternal UPD7. The association with maternal UPD7 was first identified in two unrelated patients with Russell-Silver syndrome and CF who were homozygous for CF mutations that were carried only by their mothers. UPD7 has also been described in several individuals with isolated small stature (primordial dwarfism). The *GRB10* gene on chromosome 7 codes for a protein that binds to the insulin receptor, is probably imprinted (transcribed from the paternal chromosome 7 only), and is likely to be partly responsible for the growth retardation in this syndrome.

Williams' Syndrome (Deletion 7q11.23)

This microdeletion syndrome (23) can be diagnosed clinically, and the diagnosis can almost always be confirmed by FISH analysis showing deletion of the 7q11.23 subband that includes the elastin (*ELN*) gene locus and perhaps other adjacent genes. *ELN* gene mutations have been found in familial forms of supravalvular aortic stenosis, without other features of Williams' syndrome. LIM kinase gene loss may be causally associated with the spatial-cognitive defect, as Williams' syndrome patients with the smallest deletions exhibit loss of both *ELN* and *LIMK1*. The incidence of Williams syndrome is one in 20,000 to one in 50,000 livebirths.

Phenotype

The physical characteristics are somewhat variable, but the key features are supravalvular aortic stenosis (occasionally other heart defects), small stature, prominent lips, medial eyebrow flare, stellate iris pattern, anteverted nares, long philtrum, and a hoarse voice (Fig. 30.13). Hypercalcemia, if present, helps to establish the diagnosis. Mild to moderate mental retardation is typical. The behavioral phenotype is somewhat distinctive and includes an outgoing and loquacious (“cocktail party”) personality.

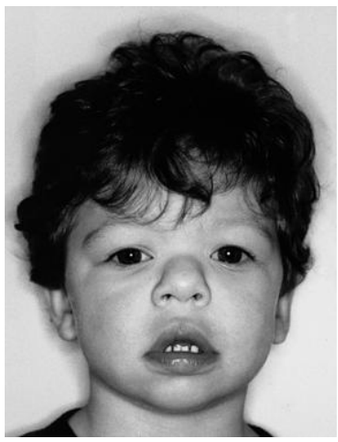

FIGURE 30.13. Patient with Williams syndrome at age 30 months. (Photograph courtesy of E. V. Bawle.)

Trisomy 8 Mosaicism (Warkany's Syndrome)

Most, perhaps all, cases are mosaic with a normal cell line. One commonly finds dramatic differences in the proportion of abnormal cells between tissues. The proportion of trisomy 8 cells appears to decrease with age, especially in the lymphocyte population. The incidence of this condition is estimated to be one in 10,000 newborns, but it is certainly underdiagnosed. The sex ratio is 3:1 male to female. The mean parental age is advanced, suggesting a meiotic nondisjunction leading to trisomy, and a mitotic compensating nondisjunction leading to the karyotypically normal cell population, but the available evidence suggests that trisomy 8 miscarriage usually results from maternal meiotic nondisjunction and that trisomy 8 in liveborn mosaics results from postzygotic error.

Phenotype

A normal birth weight with postnatal growth retardation is typical. The face is only mildly dysmorphic with a prominent forehead, malformed ears, bulbous nose with upturned nares, everted lower lip, protruding lower helix of ear, down-slanting palpebral fissures, and mild micrognathia (Fig. 30.14). Multiple skeletal abnormalities are common, including additional vertebrae or hemivertebrae, spina bifida occulta, broad dorsal ribs, hypoplastic iliac wings, and hypoplastic patellae. Other features include a long and slender body habitus, simian creases, deep plantar and palmar furrows (which may disappear in late childhood) and a similar deep furrow on the lower lip, mild joint contractures, mild congenital heart defects, and absent corpus callosum. Males often have hypospadias, cryptorchidism, or inguinal hernia. Life-threatening birth defects are unusual. Mental retardation is usually moderate but widely variable.

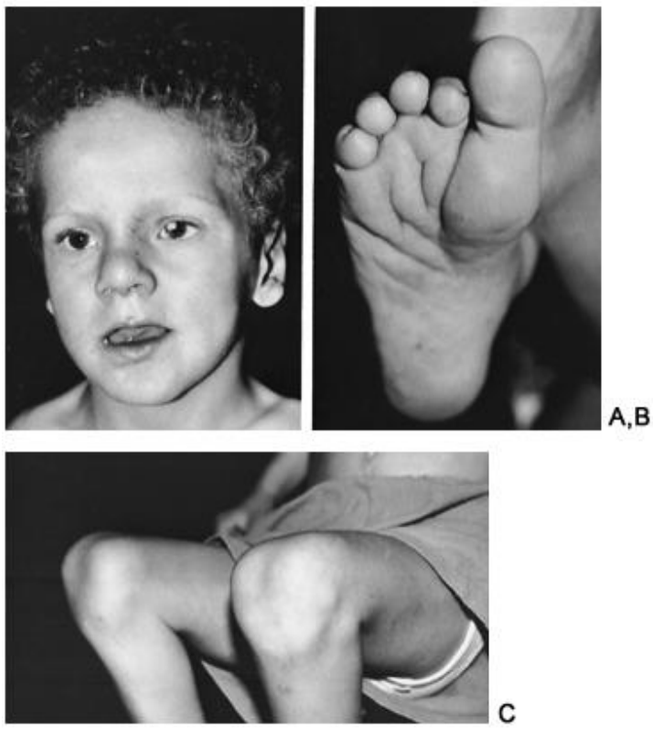

FIGURE 30.14. Trisomy 8 mosaic syndrome includes malformed ears with protruding lower helix, bulbous nose, and downward slanting palpebral fissures **(a)**. Deep creases are common in the palms and soles **(B)**, and absent or hypoplastic patellae **(C)** are characteristic. (Photographs courtesy of C. A. Williams.)

Secondary Trisomy 9p [47,+dic(9p) or 47,+i(9p)]

An extra isochromosome 9p has been identified in 13 patients, and we identified it once in a prenatal genetic study. The karyotypic interpretation can be confirmed by the observation of elevated galactose-1-phosphate uridylyl transferase (GALT) enzyme activity. The GALT gene, resides within band 9p13. The isochromosome is often dicentric. There is tissue-limited mosaicism in which most lymphocyte metaphases carry the isochromosome, whereas cultured fibroblast cells exhibit mosaicism. This reduced expression in fibroblasts may carry over to amniocytes and chorionic villus cells and make prenatal diagnosis more difficult. The average maternal age (31 years) is advanced.

Phenotype

Birth defects have included congenital heart disease, cleft lip and palate, joint dislocations, hemivertebrae, scoliosis and kyphosis, hypoplastic clavicles, kidney malformations, cryptorchidism in males, and simian creases. Facial features include hypertelorism and micrognathia. Approximately one half have died within a year. The severity of mental retardation has been variable, and one affected man has been described as semiindependent with an IQ of 63.

Beckwith-Weidemann Syndrome (Duplication of Band 11p15.5)

The overall incidence of Beckwith-Wiedemann syndrome (BWS) (or EMG syndrome: *e*xomphalos, *m*acroglossia, and *g*igantism) has been estimated as one in 14,000 livebirths. There is considerable genetic heterogeneity (27). Approximately 65% of patients have a normal karyotype and have no family history. These subjects apparently represent new mutations, perhaps some of which involve an imprinting control region on chromosome 11. Autosomal dominantly inherited Beckwith-Wiedemann syndrome (15% of cases) has been localized to 11p15.5, and all affected individuals inherit the mutation from their mother. The gene encoding insulinlike growth factor 2 (IGF2) is imprinted and expressed only on the paternally derived chromosome 11, and another gene in the BWS critical region, H19, is imprinted and expressed only on the maternally derived chromosome 11. It is likely that these two genes play a role in the disease. A visible chromosomal duplication involving band 11p15 is present in approximately 3% of cases, and a paternal origin of the duplication was identified in all the patients evaluated so far. The remaining 20% of cases appear to arise sporadically as a result of paternal UPD 11. In contrast to other disorders associated with UPD, here the UPD appears to be segmental (confined to part of chromosome 11) and appears to arise postzygotically, resulting in mosaicism for UPD and normal biparental disomy (28).

Phenotype

Patients with the visible chromosome change have mental retardation and usually congenital heart disease; some have been stillborn. Other features of the syndrome include gigantism and generalized organomegaly, a large tongue, and omphalocele (Fig. 30.15). Neonatal hypoglycemia is identified in 35% to 50% of subjects. Craniofacial features include microcephaly, linear creases on ear lobes, indentations on the posterior edge of the helix, and nevus flammeus. Cleft lip is an occasional finding. Among the dominantly inherited cases, there is approximately an 8% risk of cancer: Wilms' tumor (60% of tumors), adrenocortical carcinoma (15%), and other tumors, including gonadoblastoma, hepatoblastoma, and rhabdomyosarcoma. Presumably, the cases with a visible duplication have a similar risk. Genes that reside in this region include insulin and IGF. If they are duplicated, they may account for some of the phenotypic features, such as macrosomia and neonatal hypoglycemia. Hemihypertrophy and Wilms' tumors appear to be more common in the UPD group, and omphalocele more frequent in the patients with biparental inheritance of chromosome 11. In tumor cells, loss of heterozygosity is observed for 11p genes, including the HRAS1 locus (see Chapter 34). Mental retardation can be secondary to the associated hypoglycemia or the chromosome abnormality but is not a constant feature of the autosomal dominantly inherited syndrome.

FIGURE 30.15. Patient with Beckwith-Wiedemann syndrome. (Photograph courtesy of C. A. Williams.)

WAGR Syndrome (Deletion of Band 11p13)

This contiguous gene syndrome is associated with the loss of band 11p13 and occasionally with a familial chromosome rearrangement. The incidence of WAGR (*W*ilms' tumor, *a*niridia, *g*enitourinary malformations, and mental *r*etardation) syndrome is approximately one in 50,000 live births, and the association between aniridia and Wilms' tumor was known many years before the chromosomal basis was identified. Either aniridia or Wilms' tumor alone can be inherited as a discrete autosomal dominant trait with normal intelligence and no visible deletion. Expression of the WAGR syndrome requires deletion of both the *PAX6* gene, associated with familial aniridia, and the *WT1* gene, associated with the genitourinary malformations and the increased risk of Wilms' tumor. Approximately one in 70 Wilms' tumor patients has aniridia. The sex ratio is approximately two males to one female.

Phenotype

Wilms' tumor (nephroblastoma) is identified in 35% to 50% of patients with the deletion, and males have an increased risk of gonadoblastoma. Genitourinary malformations are present in 90%, including ambiguous genitalia in most males. Aniridia is present in 97% of patients who have the other three major features. Craniofacial features include microcephaly (in 50%), prominent lips, micrognathia, and malformed ears. Moderate to severe mental retardation is present in 90% of cases.

Secondary Trisomy 12p, Killian's or Pallister-Killian Syndrome, Mosaic Tetrasomy 12p, 47,+i(12p)

This syndrome results from an extra isochromosome 12p, and all cases are mosaic. The isochromosome looks very much like an i(21q), and many cases have been misidentified as such and called tetrasomy 21. The phenotype is not similar to Down's syndrome. Increased expression of the LDHB enzyme (lactate dehydrogenase B, located within band 12p12) has confirmed the abnormality to be a +i(12p), and today FISH would be the quickest way to confirm the chromosome 12 origin. More than 60 cases have been reported (29), and we have seen at least four cases in our laboratory. Tissue-limited chromosomal mosaicism and early perinatal death have probably resulted in most diagnoses being missed, so the incidence of this syndrome is uncertain. More than 99% of lymphocytes have a normal karyotype, whereas at least 10% of fibroblasts typically have the extra i(12p). Cells with the isochromosome are probably present in the blood prenatally but disappear very soon after birth. Alternatively, patients who are identified in the newborn period may be more severely affected because of the involvement of other tissues, including peripheral blood. A high proportion of abnormal cells has been reported in bone marrow preparations from subjects who had very few cells in phytohemagglutinin (PHA)-stimulated blood cultures, suggesting poor PHA response by, or *in vitro* selection against, lymphocytes that carry the isochromosome. Parental age is more advanced than in trisomy 21, with a mean maternal age of 31 years and a mean paternal age of 34 years.

Phenotype

The birth weight is usually normal or elevated. Diaphragmatic hernia is a key feature and a common cause of perinatal death. Associated features include severe hypotonia, short limbs, imperforate anus, and talipes. Craniofacial features include a high forehead, sparse hair, small dysplastic ears, hypertelorism, irregularly shaped bushy eyebrows, flat nasal bridge with short nose and anteverted nares, and thin upper lip. Other findings include supernumerary nipples, sacral dimple, short fingers, broad hands and feet, vertebral and joint deformities, and disordered or dysplastic skin pigmentation, dental eruption, and hair distribution. The pigmentary dysplasia can suggest hypomelanosis of Ito or incontinentia pigmenti with swirls of hypopigmentation or can be expressed as sparse hypopigmented macules that are clearly seen only with a Wood's lamp. Those who live beyond the neonatal period usually have seizures and severe mental retardation. The first described cases were bedridden patients who had mental retardation, seizures, and joint contractures. It is important to distinguish this sporadic condition from autosomal recessively inherited Fryn's syndrome.

Trisomy 13 (Patau's Syndrome)

Trisomy 13 is present in one in 5,000 newborns. As with other autosomal trisomies, the average maternal age is advanced. Primary trisomy 13 is present in 75% of cases, 4% are mosaics, 10% have an unbalanced der(13;13), and 10% have an unbalanced der(13;14). Other robertsonian translocations associated with trisomy 13 are rare. At least one half of the der(13;14) but fewer than 10% of the der(13;13) cases are familial. The der(13;14) is the most common balanced rearrangement in humans, with a frequency of approximately one in 5,000 in the general population. The reproductive risk to a der(13;13) carrier parent is 100%, and for a der(13;14) carrier parent the reproductive risk is estimated to be 1% for a carrier female and less than 1% for a carrier male. The majority of der(13;14) carrier parents of unbalanced progeny are female, and as far as we know, all the der(13;13) carrier parents of unbalanced progeny have been female.

Phenotype

Many trisomy 13 conceptions result in miscarriage or stillbirth. In liveborn infants, the common and key physical features are microcephaly, localized areas of cutis aplasia on the scalp, microphthalmia, bilateral cleft lip, and polydactyly with hyperconvex and narrow fingernails (Fig. 30.16). Midline facial defects are commonly associated with holoprosencephaly and can be as severe as cyclopia. Multiple ocular malformations have been reported, with microphthalmia or anophthalmia most common. Other features include malformed low-set ears, micrognathia, short neck with extra skin folds at the nape of the neck, broad flat nose, and hemangiomata. Other malformations include heart defects (ventricular or atrial septal defect or patent ductus arteriosus), kidney malformations, single umbilical artery, cryptorchidism

in males, and a single palmar crease. Polymorphonuclear cells have characteristic nuclear projections, and persistent embryonic hemoglobin has been reported. Mental retardation is profound and seizures are common. Half of trisomy 13 liveborn infants die within the first month and 90% die within the first year. Survival longer than 5 years is unusual.

FIGURE 30.16. Fetus with trisomy 13, with bilateral clefts and postaxial polydactyly. (Photograph courtesy of J. R. Roberson and L. Weiss.)

Retinoblastoma (Deletion of Band 13q14)

A contiguous gene syndrome of retinoblastoma and birth defects is associated with an interstitial deletion of a small segment of chromosome 13 including band 13q14 that can usually be detected by G banding or FISH. The deletion usually arises as a new mutation of paternal origin. The dominantly inherited retinoblastoma gene (RB1) resides within band 13q14. The incidence of retinoblastoma is approximately one in 23,000 liveborn infants. Among patients with retinoblastoma, the tumors are bilateral in approximately 20%, and 5% of the bilateral cases have a visible chromosome 13 deletion. Retinoblastoma patients without birth defects (sporadic or dominantly inherited type) have normal 13s, although some of their tumors have a visible del(13) or loss of heterozygosity at 13q14. This is discussed in greater detail, along with the two-mutation model for carcinogenesis, in Chapter 34. The esterase D gene is closely linked to the RB1 locus and is deleted in approximately 95% of deletion cases.

Phenotype

The craniofacial features are variable but include macrocephaly (or, with larger deletions, microcephaly), prominent eyebrows, nasal bridge with a bulbous nasal tip, and a wide mouth with a thin vermilion border. There is a high risk of retinoblastoma and osteosarcoma, and most patients have been ascertained because of the association of retinoblastoma and birth defects. In approximately half of the cases with retinoblastoma, the tumor is unilateral. A few patients who have a 13q deletion that includes loss of the esterase D gene do not have retinoblastoma. Even so, these patients may remain at risk for other neoplasias. Molecular genetic studies to detect submicroscopic mutations within the retinoblastoma gene may be useful in such patients. Mental deficiency can be severe, but some patients who have a visible deletion reportedly have normal intelligence. Familial deletions and balanced chromosome 13 rearrangements have been reported, as well as duplication of band 13q14 associated with a normal phenotype in a few relatives.

Prader-Willi Syndrome (Prader-Labhart-Willi Syndrome) [del(15)(q11.2q12) or UPD15mat]

The incidence is at least one in 20,000 livebirths, and the recurrence risk is less than 1%, with very few familial cases reported. Most patients (70%) have an interstitial deletion of 15q11.2–q12 or q13 that always includes the loss of subband 15q11.2 and always involves the chromosome 15 inherited from the father. Approximately 20% of cases result from maternal UPD15; the genetic error in most UPD15 cases is maternal meiotic nondisjunction followed by a compensating mitotic nondisjunction (Fig. 30.10), and there is an increased mean maternal age in this group. A few patients (less than 5%) have some other chromosome 15 abnormality, such as a robertsonian translocation or an extra bisatellited dicentric, dic(15)(q11), associated with UPD of the structurally normal chromosome 15 pair. The cytogenetics of PWS is of more than academic interest when it bears on the clinical interpretation of chromosome 15 abnormalities in prenatal diagnostic cases (Chapter 31). Within the region 15q11.2q12 is a series of genes that are known to be imprinted and expressed only from the paternally inherited chromosome 15 (Chapter 29). The most appealing candidate gene is *SNRPN*, which is imprinted and expressed only from the paternal copy of chromosome 15 (30). A very small number of PWS patients appears to have a deletion, translocation, or point mutation affecting the function of a hypothesized “imprint control element” that controls the imprinting pattern of *SNRPN* and other genes in the 15q11.2q12 region.

The most efficient laboratory diagnosis for PWS employs a DNA methylation study as the first step because that assay will detect either a deletion or UPD (31). If the DNA results are abnormal, FISH analysis is appropriate to distinguish deletion from UPD. Karyotype analysis is appropriate in all cases and should be considered concurrently with the DNA analysis or at least if the DNA results are normal to look for other chromosome abnormalities including a distal 1p or 2q deletion (Table 30.7).

Phenotype

Birth weight and head circumference are generally normal. Prematurity, decreased prenatal movement, and breech presentation are common. As infants, these patients have hypogonadism (cryptorchidism and micropenis in males and hypoplastic labia in females), mild ocular and cutaneous hypopigmentation, strabismus, significant hypotonia, and failure to thrive; many need to have special help with feeding because of a weak suck (32). Some parents have commented about the child having cold hands and feet and skin mottling. Craniofacial features include narrow bitemporal diameter, high forehead, almond-shaped eyes, epicanthus, malar hypoplasia, and small mouth with down-turned corners. By 3 years of age, hyperphagia leading to marked obesity and small hands and feet are characteristic features (Fig. 30.17). The patients with UPD usually have a milder phenotype and tend to be identified at an older age than do the deletion cases (33). Mental retardation is usually moderate (average IQ is 65), significant behavioral problems are common, and approximately 10% have seizures.

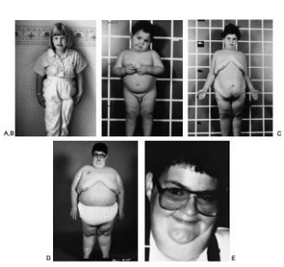

FIGURE 30.17. Although children with Prader-Willi syndrome characteristically have significant obesity, in some cases weight can be controlled through the efforts of committed parents working with dedicated health care professionals and support groups, as shown by the Prader-Willi syndrome patient depicted in **A** at age 5. Another patient shown in **B–E** at ages 4, 11, and 21 years has the more typical phenotype. (Photographs courtesy of L. Weiss and the parents of the patients.)

Angelman Syndrome [del(15)(q11.2q12) or UPD15pat]

The incidence is approximately one in 15,000 births, with most cases diagnosed after 2 years of age. This is a contiguous gene syndrome in which approximately 50% of patients have a *de novo* 15q11.2-12 microdeletion or other rearrangement visible with high-resolution G banding, and another 35% have a deletion detectable by FISH. The deletion in AS is indistinguishable from that seen in PWS, with the critical distinction that it always involves the chromosome 15 inherited from the mother. Approximately

5% of subjects have paternal UPD15, again in contradistinction to the maternal UPD15 in PWS. The AS recurrence risk is very low but is apparently higher than for PWS because several families have two or more affected members, and some families appear to transmit a defective gene at this locus or at the hypothesized imprint control element, with the syndrome only expressed when the mutation is inherited from the mother. A few families have a chromosome 15 rearrangement that is unbalanced in the affected family members. The gene responsible for most if not all the AS phenotype is UBE3A, which is expressed only from the maternal copy of chromosome 15 in the developing brain but appears to be expressed equally from both 15s in other tissues (34). Several cases have been found with point mutations within the UBE3A gene (35,36). The risk of recurrence is estimated to be <1% for the *de novo* deletion and UPD cases but as high as 50% for others. Molecular and cytogenetic laboratory diagnosis for AS employs the same steps as discussed for PWS.

Phenotype

In AS, there is microcephaly of postnatal onset, developmental delay, hypotonia with brisk reflexes, blue eyes and fair skin compared with other family members, and choroid and iris pigment hypoplasia (25% have oculocutaneous albinism). Seizures and an abnormal electroencephalogram (EEG) are typical with onset by age 10 months. The diagnosis is usually not suspected until at least age 2, after the appearance of the characteristic hyperkinetic behavior with a stiff, ataxic gait. The facial expression is alert with frequent and inappropriate smiling and laughter (Fig. 30.18). Mental retardation is severe.

FIGURE 30.18. Patient with Angelman syndrome. (Photograph courtesy of L. Weiss.)

Secondary Trisomy 15q1pter [47,+dic(15)(q1)]

A dic(15)(q1) present as a 47th chromosome has been described in numerous subjects, and it is present in approximately one in

5,000 liveborn infants. The phenotype depends largely but not entirely on the amount of material duplicated (actually triplicated) (37). In the smaller dicentrics, with a karyotype of 47,+dic(15)(q11.1), the two centromeres are very close together with little 15q material duplicated. Such bisatellited markers are often familial and consistent with an entirely normal phenotype. However, these can be associated with PWS or AS owing to UPD of the two structurally normal 15s or a 15q deletion. Larger dic(15) chromosomes that have an acrocentric appearance on G-banding are usually new mutations and are associated with mental retardation and mild dysmorphic features. The breakpoint is between 15q11.2 and 15q15, so the PWS/AS critical region is included in the dicentric. The secondary trisomy typically arises *de novo*, usually is maternal in origin, and the average maternal age is advanced (mean, 35 years).

Smith-Magenis Syndrome (Deletion of Band 17p11)

This rare contiguous gene syndrome is associated with an interstitial deletion involving band 17p11 only. In all but one case, the deletion has represented a new mutation (the mother in one case appears to be mosaic), and the deletion apparently involves the paternal chromosome 17 in most cases. One relatively mildly affected patient has a *de novo* translocation with a breakpoint within band 17p11. The deletion is usually detectable by karyotype analysis, but if the diagnosis is suspected and the karyotype appears to be normal, FISH analysis is indicated. There may be as few as two genes deleted to create this syndrome.

Phenotype

The phenotype (Fig. 30.19) is variable but includes failure to thrive, brachycephaly, prominent forehead, microcephaly, flat and broad midface, broad nasal bridge, strabismus, myopia, malformed ears, high or cleft palate, prognathism, short and broad hands and feet, scoliosis, and cryptorchidism (38). The voice is hoarse and sensorineural or conductive hearing loss is common. Heart and kidney abnormalities are present in approximately one third of subjects. Mental retardation is variable but usually severe with seizures and hyperactivity. Unusual features of the syndrome include decreased reflexes, decreased sensation, and other features of peripheral neuropathy, specific self-destructive behavior, including insertion of foreign objects into bodily orifices and pulling out finger and toe nails, and sleep abnormalities (especially disturbed rapid eye movement sleep).

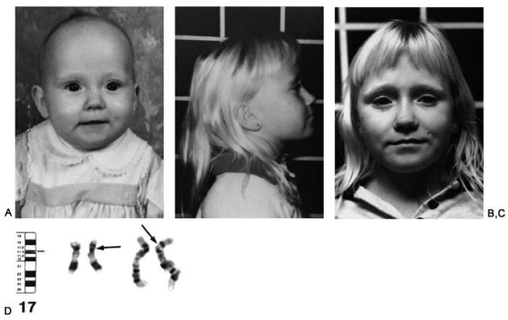

FIGURE 30.19. Patient with Smith-Magenis syndrome at age 9 months **(a)** and 8 years **(B and C)**. She has an IQ of approximately 70 and has a significant sleep disturbance. She has a *de novo* interstitial deletion involving band 17p11 only **(d)**. Two chromosome 17 pairs are shown, with arrows pointing to band 17p11 in the normal homolog. The deletion homolog is at the left in each pair. (**A–C**, photographs courtesy of J. R. Roberson and L. Weiss.)

Miller-Dieker Syndrome (Deletion of Subband 17p13.3)

This rare contiguous gene syndrome has been associated with the loss of subband 17p13.3, owing to either a simple deletion or an unbalanced chromosome rearrangement. Parental karyotypes need to be studied carefully to look for a familial translocation, which, if present, would indicate a significant risk of recurrence. Nearly one half of the patients with a 17p deletion have normal-appearing chromosomes even under high-resolution analysis, so FISH is an appropriate adjunct to high-resolution karyotype analysis if the diagnosis is suspected. In some patients with isolated lissencephaly, a submicroscopic deletion of the proximal segment of band 17p13.3 has been identified. Mutations in the *LIS1* gene are responsible for the lissencephaly in many cases of isolated lissencephaly, and in Miller-Dieker syndrome, loss of perhaps one other gene is responsible for the heart and kidney defects.

Phenotype

A key feature is microcephaly and a prominent forehead with vertical skin furrowing and bitemporal narrowing (Fig. 30.20). The phenotype includes type I lissencephaly (cerebral agyria or smooth brain with a four-layered cortex), profound EEG abnormality, seizures, profound hypotonia, severe to profound mental retardation, and pre- and postnatal growth retardation. Other facial features are ptosis, upturned nares, long philtrum with thin upper lip, mild micrognathia, and malformed ears. Heart and kidney defects are common. Most die in infancy.

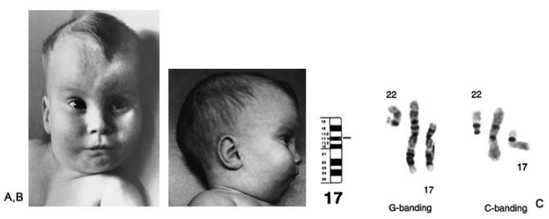

FIGURE 30.20. This Miller-Dieker syndrome patient had a *de novo* dicentric translocation between chromosomes 17 and 22. At age 12 months, she was beginning to smile socially but still had very poor head control **(A, B)**. Karyotype studies showed this patient had one normal copy of chromosomes 17 and 22. The other 17 and 22 were represented by a dicentric chromosome that contained most of 22p and appeared to have lost at least part of band 17p13. Two partial karyotypes are shown **(C)**. Molecular genetic studies confirmed the deletion of this region and demonstrated the paternal origin of the chromosome rearrangement (Unpublished results from D. Ledbetter). (**A, B**, photographs courtesy of L. Weiss.)

Trisomy 18 (Edwards' Syndrome)

Primary trisomy 18 is identified in one in 6,000 to 8,000 liveborn infants but is much more common among stillborns and represents approximately 6% of second-trimester miscarriages with an autosomal trisomy. Translocations are very uncommon. There is a maternal age effect, and the nondisjunctional event occurs

during maternal meiosis in approximately 95% of cases. The sex ratio is approximately 4:1 female to male.

Phenotype

Prenatal movement is weak, and polyhydramnios and a single umbilical artery are common. There is significant pre- and postnatal growth retardation (Fig. 30.21). Newborns are hypotonic but later become hypertonic. The head is microcephalic with a prominent occiput, narrow midface, and micrognathia. Ears have a simple helix, the nose is small with upturned nares, and the mouth is small with a high-arched palate. Heart, kidney, and genitourinary tract malformations are common. The hands are typically clenched with the second finger overlapping the third finger, and fifth overlapping the fourth. Among the many other features of trisomy 18 syndrome are single palmar crease, a simple

arch dermatoglyphic pattern on multiple fingertips, loose skin at the nape of the neck, hypoplastic nipples, dislocated hips, rockerbottom feet, and diaphragmatic hernia. Mental retardation is profound. Half of liveborn infants die within 2 months and fewer than 10% survive 1 year. Survival beyond age 5 is exceptional. Chromosomal mosaics with a normal cell line constitute approximately 10% of liveborn infants, and the phenotype can be somewhat moderated in these patients.

FIGURE 30.21. Infant (**A** and **B**) with trisomy 18. **C**, This 25 year-old female with nonmosaic trisomy 18 is one of the longest surviving patients with this syndrome. (Photographs **A** and **B** are courtesy of C. A. Williams; **C**, photograph courtesy of L. Weiss.)

Deletion 18p

Deletion of part of this small arm was identified before the use of banding techniques and in fact was the first published deletion syndrome. Some ring chromosome 18 patients have a deletion 18p phenotype. Most 18p deletions are new mutations, but the parents should be karyotyped to look for a balanced rearrangement. The average parental age is advanced, which is atypical for chromosome deletions and is unexplained. Slightly more females than males are affected.

Phenotype

Approximately 10% to 15% of patients have gross craniofacial malformations including holoprosencephaly, but in the patients without major brain malformations, there are usually no life-threatening birth defects. The physical features include growth retardation and facial features of mild microcephaly, low-set, soft, and malformed ears, strabismus, ptosis, epicanthus, flat nasal bridge, upturned nares, Cupid's bow of upper lip, and micrognathia. Dentition is poor and severe caries are very common. A short neck, broad chest, and mild edema of hands and feet can be reminiscent of Ullrich-Turner or Noonan's syndrome. Other features include hernias and IgA deficiency. Mental retardation is typical but severity varies.

Trisomy 20

This unusual trisomy is found in miscarriage specimens, and mosaic trisomy 20 is found in approximately one in 2,500 amniotic fluid chromosome studies (39). There is no syndrome of birth defects associated with trisomy 20 mosaicism, and most newborns have been phenotypically normal. The mosaicism has been confirmed in foreskin fibroblasts and other tissues but never in peripheral blood cells. The risk of malformation or mental retardation seems low for cases identified prenatally, but this tissue-limited mosaicism is still poorly understood.

Trisomy 21 (Down's Syndrome)

One infant in 800 to 1,000 has Down's syndrome (40). Primary trisomy 21 accounts for approximately 93% of all cases. Another 2% to 3% are mosaics, 3.5% to 5% have a robertsonian translocation, and fewer than 1% have other rearrangements. The sex ratio among Down's syndrome liveborn infants is approximately three males to two females. In 1960, 11% of births were to women over age 35, whereas this frequency is only approximately 5% today, and in the United States, nearly one half of pregnant women over age 35 obtain prenatal diagnosis. This has resulted in a small decrease in Down's syndrome births overall but a relative increase of Down's syndrome babies born to younger women. The availability of serum screening the pregnant population (Chapter 31) is decreasing the incidence of Down's syndrome further. Rare patients with duplication of small segments of chromosome 21 have been instructive in the development of a phenotype map of chromosome 21 in which duplication of band 21q22.3 is essential for the expression of the Down's syndrome phenotype (Fig. 30.22A).

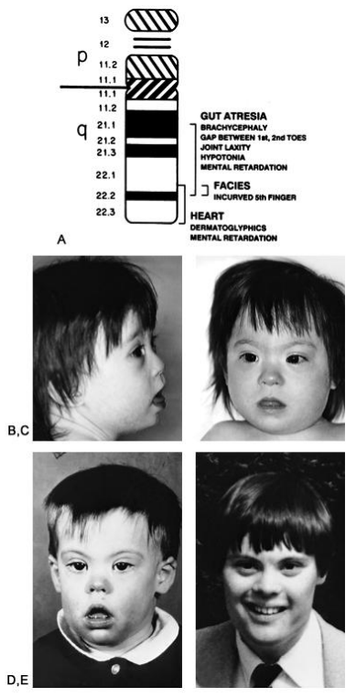

FIGURE 30.22. The phenotype of Down's syndrome. Individual stigmata of the Down's syndrome phenotype have been mapped by molecular analysis of small duplications involving chromosome 21 **(a)**. **B–D:** the childhood phenotype is illustrated, showing many of the features detailed in the text. The male shown in **D** is shown in **E** at age 18 years. (**B, C**, photographs courtesy of D. D. Weaver and C. A. Moore; **D, E**, photographs courtesy of L. Weiss and J. R. Roberson.)

The maternal age effect in trisomy 21 is illustrated in Fig. 30.23, and rates of Down's syndrome and other trisomies are

provided in Table 30.3. There is also a maternal age effect in mosaic trisomy 21; this finding and other studies suggest that most mosaics begin as trisomic conceptions, and anaphase lag gives rise to the diploid cell line. The normal cell line may have a selective growth advantage that results in an increase in the proportion of normal cells with age, especially in lymphocytes.

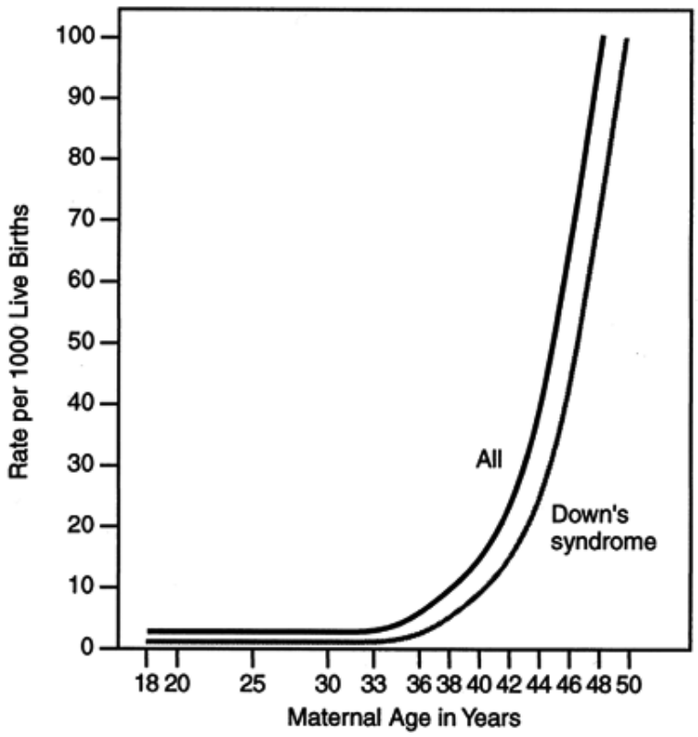

FIGURE 30.23. Frequency of Down's syndrome, and of all trisomies, among liveborn infants, by maternal age. [Statistics from Hook (3).]

In a few trisomy cases (3% in one study, 0.3% in another study), one parent appears to be a trisomy 21 mosaic, and presumably the trisomy 21 offspring resulted from secondary nondisjunction. The incidence of parental mosaicism is probably greater among parents with more than one child with the same trisomy and may be lower in older parents. The mosaic parents in general have normal intelligence and no obvious Down's syndrome stigmata. It has not become standard practice to study the chromosomes of parents of trisomy 21 patients, partly because it is impossible to disprove that a parent is a low-level mosaic and partly because even if one or two +21 cells are observed among 100 cells, the chance remains that this is a technical artifact rather than a clear demonstration of +21 mosaicism. Instead, it seems reasonable based on the available data to advise the parents of a risk of recurrence of at most 1% more than the maternal age-associated risk. Experience shows approximately a 0.5% recurrence risk for trisomy 21 plus 0.5% for other chromosome abnormalities (the latter risk does not appear to be significantly greater than the general population risk). It has also been proposed that a woman who has a trisomy 21 miscarriage has an increased risk of having a trisomy 21 liveborn infant, but the evidence for this, independent of maternal age effects, is weak. In general, other relatives of a trisomy 21 individual (e.g., siblings) do not have an increased risk beyond their maternal age-associated risk of having a trisomy 21 child.

The majority of translocations associated with Down's syndrome are der(14;21) or der(21;21). Approximately one half of der(14;21) cases are inherited, but only 5% of der(21;21) cases are inherited (Table 30.8). This low frequency of inherited der(21;21) cases, together with recently presented molecular genetic studies, is consistent with the hypothesis that these are often isochromosomes rather than robertsonian translocations, but another factor in their high mutation rate is that a der(21;21) cannot be passed through multiple generations. In most inherited

cases, the mother is the carrier; there appears to be reduced fertility in some carrier males and lower empirical risk of Down's syndrome in the offspring of carrier males. Recurrence has been reported in several instances of apparently *de novo* der(21;21) or other robertsonian translocation Down's syndrome cases, suggesting germ line mosaicism in a parent, and as with trisomy 21, it is reasonable to advise parents of *de novo* translocation cases that the risk of recurrence is approximately 1% more than the maternal age-associated risk.

TABLE 30.8. ROBERTSONIAN TRANSLOCATIONS IN DOWN'S SYNDROME*a*

			Risk to Carrier[c] (%)	
	% of Cases[a]	% Inherited[b]	Female	Male
der (14;21)	51.7	50	14	4
der (13;21)	2.9	-[d]	-	-
der (15;21)	4.6	-	-	-
der (21;21)	37.2	5	100	100
der (21;22)	3.5	-	7	≤3

[a] Based on data from Therman et al. (41) and cases from our laboratory.

[b] Based on a sample of 4,760 cases of Down's syndrome from Giraud and Mattei (42).

[c] Risk of bearing an offspring with Down's syndrome owing to an unbalanced form of the translocation. Statistics for der (14;21) are from Daniel et al. (43). Statistics for der (21;22) are from Chapman et al. (44).

[d] A – indicates that the data are insufficient to make an estimate. The proportion of inherited der (13;21), der (15;21), and der (21;22) may be similar to that of der (14;21). The estimate for der (21;21) also includes our experience of 10 *de novo* and zero inherited cases. However, the 5% seems to be an overestimate.

The increase in trisomy with advancing maternal age is reflected in a relative decrease in translocation cases with advancing maternal age. This is helpful in genetic counseling situations when the karyotype of the affected person and the parents is unknown and they are unavailable for evaluation. If the mother's age was under 30 when the affected person was born, the chance of a familial translocation is approximately 1.5%, whereas that chance is 0.4% if maternal age was 35 years, and 0.04% if maternal age was 40 years.

Phenotype

As many as 75% of trisomy 21 conceptions result in miscarriage (Table 30.2), and 1% of stillborns have trisomy 21. Among trisomy 21 pregnancies identified by midtrimester amniocentesis and not electively interrupted, approximately one fourth abort spontaneously or are stillborn. There is significant pre- and postnatal growth retardation with reduced birth weight. Heart defects, mainly endocardial cushion defects (atrioventricular septal defect, ventricular septal defect, patent ductus arteriosus, or tetralogy of Fallot) are present in 40% of subjects. The facial features in Down's syndrome commonly include a round and flat face, ear malformations such as a folded upper helix, epicanthus, upward-slanting palpebral fissures, Brushfield spots, flat nasal bridge, and open mouth with a protruding tongue (Fig. 30.22B,Fig. 30.22C and Fig. 30.22D). The hands frequently have a transverse palmar crease, short fifth finger with a single flexion crease, and clinodactyly. There is often a gap between toes 1 and 2. Many have an umbilical hernia. Radiologically, there is a small pelvis with hypoplastic iliac wings and small acetabular angle. A multitude of less common birth defects in Down's syndrome include strabismus, cataracts, duodenal atresia, imperforate anus, and an increased risk of leukemia. Hundreds of genes are duplicated in trisomy 21, and those that play the greatest role in Down's syndrome are beginning to be understood (45).

Newborns are hypotonic, especially if a heart defect is present, and have poor reflexes. Many have loose skin on the back of the neck that is a remnant of prenatal lymphatic edema. They do not have a significant adolescent growth spurt. Adolescents and adults have short stature [standard growth charts for Down's syndrome are available in Cronk et al. (46)]. A tendency to be overweight is typical. Hypothyroidism is common (and treatable) among infants and children with Down's syndrome. There is also an increased risk of atlantoaxial instability, diabetes mellitus, depression, premature aging of the skin, and dementia. There are numerous other health issues that arise more commonly throughout life (47).

Only one male is known to have reproduced (one chromosomally normal offspring). Females have reproduced, and approximately 40% of their offspring have had Down's syndrome owing to secondary nondisjunction. (The expected 50% risk is not met, perhaps because of reduced viability of the +21 embryos.) Congenital heart disease and heart failure, respiratory tract infection, intestinal obstruction, and leukemia are major factors in mortality. Of patients without heart defects, 90% survive 1 year and 80% survive to age 30. Those who have heart disease are smaller on average, with 75% surviving 1 year and 50% to age 30. Only 45% of Down's syndrome patients are expected to survive to age 60, compared with 86% of the general population.

Developmental delay is not always evident until after 1 year of age because the infants tend to be content and only modestly delayed in milestones that are normally attained by 12 to 18 months. Mental retardation is usually mild to moderate, and children are often placed in education programs for the trainably or educably mentally impaired. In institutionalized populations, there is an excess of males among the Down's syndrome patients, probably because affected males present more severe behavior problems. Whereas most were institutionalized years ago, today most adults with Down's syndrome live with family or in group homes, and many work in sheltered situations. As marketplace demands have increased for unskilled labor, an increasing number of adults with Down's syndrome find employment.

There have been no prospective studies of the phenotype and development in trisomy 21 mosaics, so the likelihood that a mosaic will have a moderated phenotype is unknown. Nevertheless, as is true of other mosaics, individuals with a milder or atypical

Down's syndrome phenotype appear more likely to have mosaicism with some karyotypically normal cells (48). As stated earlier, a few individuals with low-level +21 mosaicism have been identified after having a Down's syndrome child.

Cat Eye Syndrome (Secondary Trisomy 22q11pter)

Patients with this phenotype often have a *de novo* extra bisatellited chromosome derived from chromosome 22 (an example of a bisatellited chromosome 15 is provided in Fig. 30.3J). *In situ* hybridization using a chromosome 22q11 DNA probe has shown that this band is consistently duplicated. Although the defect usually arises *de novo*, in two cases, the parent carried the extra isochromosome but had normal intelligence and a diagnosis of Duane's syndrome (radial ray abnormalities and deafness). Maternal origin of the *de novo* extra chromosome was shown in at least two cases. Tissue-dependent mosaicism is common: one patient had 3% normal cells in lymphocytes, but 70% of cultured fibroblasts had normal chromosomes.

Phenotype

The common facial features are coloboma of the iris, down-slanting palpebral fissures, preauricular tag or pit, and imperforate anus. All these features are not seen in every instance, however. Mental retardation is usually mild to moderate, but congenital heart disease or severe kidney defects can cause death in infancy.

22q11 Deletion Syndrome, DiGeorge Syndrome, and Velocardiofacial Syndrome

Patients with this common deletion (one in 4,000 liveborn infants) involving band 22q11.2 exhibit a wide phenotypic spectrum. A 22q11 deletion accounts for approximately 8% of patients with cleft palate (without cleft lip), 5% of newborns with heart defects, and 20% of familial heart defects. The phenotypic heterogeneity among 22q11 deletion patients cannot be explained by genetic heterogeneity because family members can be affected very differently. Individuals whose phenotype is consistent with the 22q11 deletion phenotypic spectrum should have a routine G-banded karyotype study and FISH analysis for the 22q11 deletion. A karyotype is important because similar phenotypes are exhibited by several less common chromosome abnormalities, such as a 4q, 8p, 10p, or 18q deletion. If an abnormality is identified, the parents should be studied because 10% to 15% of cases are familial (49). The risk of recurrence is very low if neither parent carries the deletion. The deletion maps within a 250-kb region of proximal 22q, and probably numerous genes are lost (50).

Phenotype

The phenotypic spectrum of the 22q11 deletion syndrome includes patients with features of DiGeorge syndrome, velocardiofacial syndrome (also known as Schprintzen syndrome, CHARGE association, Opitz GBBB syndrome, Robin sequence, isolated cleft palate, and isolated conotruncal heart defect) (51). The abnormalities may include conotruncal heart defects, and thymic and parathyroid hypoplasia with associated hypocalcemia, seizures, and cellular immune deficiency. Approximately 8% patients die in infancy because of heart defects or immune deficiency. Giant platelets appear to be a very common finding (52). Affected individuals often have a “pixie” face with low-set ears, a prominent nose, and hypertelorism (Fig. 30.24). Approximately 10% have renal abnormalities, and 10% to 30% have conductive hearing loss. Many of the malformations result from flawed embryonic development involving the

third and fourth branchial arches. Intelligence ranges from normal (sometimes with delayed speech development) to moderate-severe mental retardation. Behavioral problems are identified in approximately 9% of children and 15% of adults and include psychotic episodes in 1% of children and 8% of adults.

FIGURE 30.24. Three family members with 22q11 deletion syndrome (velocardiofacial syndrome). **A:** Mother; **B:** daughter at age 8 and son at age 4. Fluorescent *in situ* hybridization studies confirmed a deletion of the 22q11 critical region in all three family members. (Photographs courtesy of E. Bawle.)

Tertiary Trisomy from t(11;22)(q23;q11.2)

A European collaborative study (53) identified more than 100 families with this particular translocation. Our laboratory has identified five unrelated families, three through prenatal genetic studies and two through studies of couples with multiple miscarriages. Many families have been identified through an abnormal proband who carries an extra small chromosome (Fig. 30.7), and the risk of 3:1 meiotic segregation is 5%, with the majority of the affected individuals having 47 chromosomes with two normal 11s and 22s plus the small derived 22 from the translocation. The net result is duplication of proximal 22q and distal 11q. Many patients are mosaic, and extra care must be exercised in prenatal studies of these families to identify affected mosaics. The carrier parent is the mother in approximately 90% of cases, and many carrier males have reduced fertility. A peculiar pattern of segregation has also been observed in female carriers: nearly 70% of the normal offspring of carriers are themselves carriers, and more than half of the carrier progeny are females. This deviation from randomness is not yet understood. The pattern of segregation to offspring of male carriers appears to be normal.

Phenotype

The phenotype includes hypotonia, microcephaly, malformed ears with preauricular pits and tags, cleft or high-arched palate, micrognathia, dislocated hips, anal atresia or anal stenosis, and cryptorchidism. Two thirds have congenital heart defects (atrial or ventricular septal defect or patent ductus arteriosus). Mental retardation is moderate to severe.

Triploidy and Diploid/Triploid Mosaicism

Triploidy is identified in 7% of miscarriages and is found rarely in stillborns, with 60% being 69,XXY, 35% being 69,XXX, and only 5% being 69,XYY. Triploids with 69,XYY are less common and tend to be found in earlier miscarriages, suggesting less viability compared with XXY or XXX triploids. The liveborn incidence may be as great as one in 2,500 births, but most escape detection because of neonatal death. The mean parental age is not advanced. Probably all liveborn infants with triploidy have a mixture of diploid and triploid cells. The diagnosis of diploid/triploid mosaicism is typically made by karyotyping cultured skin fibroblast cells. This syndrome is surely underdiagnosed because the lymphocyte population is primarily diploid. It is possible that triploid lymphocytes are nonviable or do not respond to the mitogen.

Several plausible origins have been proposed for diploid/triploid mosaicism. A relatively common origin of this mosaicism may be fertilization of both the egg and a first or second polar body, one with a single sperm and the other with two sperm. Subsequently, the two zygotes develop as a single organism. This sequence of events actually results in chimerism, not mosaicism. (A chimera is an organism that results from fusion of more than one zygote.) An alternative origin is fertilization of separate ova, with postzygotic fusion during the earliest stages of embryogenesis.

Phenotype

Triploid miscarriages are often associated with cystic villi or a hydatidiform mole. The embryos often have retarded limb development and generalized growth retardation, facial malformations, open spine defects, syndactyly, and subectodermal hemorrhage. We identified several triploids in amniotic fluid cell cultures studied because of an elevated maternal serum α-fetoprotein level or anatomic malformations observed on ultrasonography. Key physical features of triploid stillborns and liveborn infants include significant intrauterine growth retardation, disproportionately small body compared with the head size, syndactyly, and ambiguous genitalia. A history of polyhydramnios or oligohydramnios and a large placenta with hydatidiform changes are common. Open spine defects are present in 25% and a few have omphalocele. Most affected males have abnormal external genitalia. Liveborn infants usually die in the neonatal period, although one patient was 21 years old at diagnosis. Liveborn infants, as might be expected, frequently also have a diploid cell line and can present with bodily and facial asymmetry. Mental retardation is variable but usually severe.

SEX CHROMOSOME SYNDROMES

Part of "30 - Clinical Cytogenetics"

As reviewed in Chapter 29, our understanding of the sex chromosomes has improved greatly over the past few years. Males have an X and a Y chromosome and females have two X chromosomes, one of which is inactivated to compensate for the single X dosage in males. Most of the genes on the X and the Y chromosomes are unique to each, but some are shared. Many of the genes that are shared by the X and the Y chromosomes are confined to the pseudoautosomal region on distal Xp and Yp and are not inactivated on the inactive X in females. Some of the genes that reside in proximal Xp and Xq also appear to have counterparts on the Y and are expressed on both the active and the inactive X, thus maintaining the equivalence of gene expression between the sexes. A small number of expressed genes on the Y chromosome, including SRY (sex-determining region of Y), appear to be responsible for male sexual differentiation. As our understanding of these various groups of X- and Y-linked genes improves, so will our understanding of their effects in the sex chromosome syndromes (54).

Monosomy X and Structural Abnormalities of the X Chromosome

The incidence of monosomy X is approximately one in 3,000 newborns. A mosaic chromosomal constitution is identified in 50% of girls with Ullrich-Turner syndrome: 15% have some 46,XX cells (45,X/46,XX mosaicism), 20% have an isochromosome Xq, 10% have mosaicism with a Y chromosome

(45,X/46,XY), and most of the remainder have X or Y rearrangements (e.g., deletions, rings, isochromosomes). Among nonmosaic 45,X cases, the nondisjunctional event results from loss of the paternal X in the majority (70% to 80%). This is a striking difference from the maternal meiotic error associated with autosomal trisomy.

Phenotype

The phenotype of Ullrich-Turner syndrome patients is variable and depends in large measure on the karyotype (Fig. 30.25). The nearly universal features are decreased birth weight and short stature (in the range of the fifth percentile on a growth curve), and gonadal dysgenesis. Common features (25% to 75% of cases) include high-arched palate, visual defects (usually strabismus), webbed or short, broad neck, low posterior hairline, shield chest, pigmented nevi, cubitus valgus, short fourth metacarpal, and thyroid disease. Lymphedema is common and is severe in abortuses and stillborns. One third of patients have bicuspid aortic valves, and 12% have other severe heart defects such as a ventricular septal defect or coarctation of the aorta. More than one half have kidney malformations (including double collecting system, malrotation, or malformation), making recurrent urinary tract infections common, although life-threatening renal malfunction is uncommon.

FIGURE 30.25. A: Ullrich-Turner syndrome in infancy is sometimes suspected on the basis of lymphedema involving the hands and feet and loose skin at the back of the neck. **B:** Neck webbing is shown in an older patient. The girl depicted in **C** and **D** at ages 16 months and 11 years, respectively, is now a well-adapted young adult. (Photographs are courtesy of L. Weiss and J. R. Roberson.)

In a population survey of consecutive newborns, 13 subjects with a 45,X chromosomal constitution were identified. Three of the 13 died neonatally and one died at age 11. All four of these had serious congenital heart disease. Of the nine survivors, five had multiple stigmata of Ullrich-Turner syndrome, two had pedal edema only, and two had high-arched palate only.

Most Ullrich-Turner syndrome patients have streak gonads at birth; their ovaries appear normal at 12 weeks of gestation, but the ovarian follicles degenerate after that time. One fifth of Ullrich-Turner syndrome patients have spontaneous menstruation, and most of these are 45,X/46,XX mosaics. The available data on their pregnancy outcomes suggest a high risk for miscarriage and 45,X liveborn infants, and possibly an increased risk of trisomy 21.

Mosaic individuals have a better prognosis, including lower risk of Ullrich-Turner syndrome stigmata and lower risk for gonadal dysgenesis, whereas 45,X without obvious mosaicism is more often associated with Ullrich-Turner syndrome. Ring X and isochromosome X patients usually have features of Ullrich-Turner syndrome, but these patients typically have a 45,X cell line as well. Many females with Xq deletions are less severely affected. A few patients with Xq deletion have been fertile, and the chance of fertility may depend on the breakpoint or perhaps to a greater extent on whether a 45,X or 46,XX cell line mosaicism is present. Those with Xp deletions often have features of Ullrich-Turner syndrome, including short stature and primary or secondary amenorrhea, although a few have been fertile.

The incidence of mental retardation among patients with Ullrich-Turner syndrome is not dramatically increased, and the majority have normal intelligence. They are more likely to have problems with spatial relations and numerical identification. There is often a deficiency in perceptual motor organization or in fine motor execution. Therefore, the nonverbal IQ is lower than the verbal IQ. Personality traits commonly include inertia to emotional arousal, a high capacity to deal with stress, and strong traditional femininity. Mosaicism with a very small ring X chromosome has a high risk of mental retardation, and this is usually owing to lack of normal inactivation of the ring chromosome (55). Some females with X;autosome translocations have mental retardation or express an X-linked mendelian disorder owing to interruption of gene function at the translocation breakpoint.

45,X/46,XY Mosaicism

The phenotype of 45,X/46,XY mosaics is extremely varied, ranging from typical Ullrich-Turner syndrome to ambiguous genitalia

to normal male. Females with a 45,X/46,XY karyotype or who have a structurally abnormal Y-derived chromosome have a 15% to 25% risk of gonadoblastoma. Their gonads should be removed before school age because of this risk.

Many phenotypically normal males with 45,X/46,XY mosaicism have been identified in prenatal studies, but their fertility has not been evaluated because they have not yet reached reproductive age. However, this karyotype does not appear to be over-represented in studies of male infertility nor is there an increased risk of gonadoblastoma in phenotypically normal males who have 45,X/46,XY mosaicism.

46,XY Females

Females with nonmosaic 46,XY typically have gonadal dysgenesis and little secondary sexual development but few other features of Ullrich-Turner syndrome. There is a high risk of gonadoblastoma. Most 46,XY females have a structurally normal X and Y chromosomes and have a mendelian inherited disorder of sexual differentiation, such as testicular feminization syndrome (X-linked recessive) or 5α-reductase deficiency (autosomal recessive). As mendelian traits, such disorders carry a significant risk of recurrence (56).

A few 46,XY females were identified as having del(Y)(p11) who are probably affected because their Y chromosome has lost the SRY. Females with a Y chromosome deletion are more likely to exhibit some of the features of Ullrich-Turner syndrome, although most appear to have normal stature. As with the nondeletion cases, there is a high risk of gonadoblastoma. In distinction to the nondeletion cases, the Y deletions are not known to have an increased risk of recurrence in a family. Molecular genetic studies showed that Yp-specific DNA probes did not hybridize with the deleted Y chromosome. The deletion breakpoints differed slightly, but the deletions overlapped in the sex-determining region. One patient had a more complex deletion involving two noncontiguous DNA segments. The normal stature and the gonadoblastoma support the hypothesis that proximal Yp or the long arm of the Y contains some of the genes for stature and spermatogenesis.

Triple X Syndrome 47,XXX

The incidence of 47,XXX is approximately one in 1,000 liveborn females. There is a maternal age effect, with maternal meiosis I errors in 50% of cases; paternal errors account for fewer than 10% of cases. Triple X women do not appear to have an increased risk for having XXX or XXY offspring. The phenotype typically is within normal limits, with development of secondary sexual characteristics and normal fertility. Many but not all triple X females are developmentally normal, although the exact risk of mild or more severe mental retardation is uncertain. Among females with mild mental retardation, the frequency of triple X is increased to approximately one in 200. Ten 47,XXX females who were identified in unselected newborn surveys have been followed to age 20 to 22 (57). As children, they had less motor coordination and more speech and language problems than their peers, but standard speech therapy seems to have been sufficient for most of them. One was in a school program for the educationally mentally impaired, three were mainstreamed with some remedial education, and six were in regular classes. Four of the 10 have an IQ of 60 to 80, so in this small, unselected sample 40% had mild mental retardation. At age 20 to 22 years, nine of the 10 appear to cope well in society and hold a job or have a family.

Klinefelter's Syndrome 47,XXY

The incidence of 47,XXY is approximately one in 700 male newborns. Because of the maternal age effect in 47,XXX and 47,XXY, these karyotypes are seen more frequently in prenatal genetic studies. For 47,XXY, maternal and paternal meiotic errors are responsible in approximately equal proportions.

Phenotype

The phenotype of Klinefelter's syndrome includes tall stature, small testicles and prostate, and infertility. Half have a eunuchoid habitus and half have gynecomastia. A few have a varicocele, undescended testes, or a small penis.

Because of the relatively mild phenotype, most subjects with Klinefelter's syndrome are never identified. The diagnosis is usually made during adolescence or adulthood because of small testicles, gynecomastia, or infertility. Mosaics, mostly 47,XXY/46,XY, constitute approximately 10% of Klinefelter patients, and as a group have milder symptoms. Most have azoospermia and most of those who have oligospermia are chromosomal mosaics. As children, many have mild speech and language deficits, which respond to standard speech therapy. They also tend to have a poor attention span and memory and low self-esteem. Early educational intervention appears to be effective in overcoming these potential liabilities. Twelve men with Klinefelter's syndrome who were identified in unselected newborn surveys have been followed to age 20 to 22 (57). Eight had a normal IQ and have coped well in society. Four had IQs of 80 to 90 and had learning problems in school. Two of these men were said to cope well as adults and have found employment. The other two had psychiatric problems as well as learning difficulties and were said not to cope well. Nevertheless, the XXY men as a group were said to be not as severely affected as the XXX women.

More severely affected variants of XXY include 48,XXYY; 49,XXXYY; 49,XXXXY, and other karyotypes. Their cumulative incidence is probably approximately one in 2,500 males. Hypogonadism is present, and cryptorchidism is more common. Adult height is more than 6 feet (180 cm) in 80% of variants, and skeletal abnormalities are not uncommon. Mental retardation is more likely than in 47,XXY.

46,XX Males

The incidence of 46,XX males is approximately one in 20,000 liveborn males. These are phenotypic males who have normal or slightly shorter stature and normal external genitalia but who have reduced testosterone levels, reduced facial and body hair, dysgenetic testes, and azoospermia, and may have gynecomastia. There is strong cytogenetic and molecular genetic evidence favoring an aberrant paternal meiotic exchange between the X and

Y chromosomes, such as unequal meiotic exchange, resulting in an X;Y rearrangement. Some of these are cytogenetically visible. Many other XX males have molecular evidence of a rearrangement between the X and Y that results in the SRY being moved to one X chromosome, i.e., Yp-specific DNA is present. A minority of XX males (10%) do not have evidence of Yp-specific DNA, and their phenotype includes gynecomastia and hypospadias or a small penis.

47,XYY Males

The frequency of XYY is approximately one in 800 males, with no maternal age effect because the nondisjunction occurs during male meiosis or as a postzygotic error. As is true for XXX and XXY, most individuals with an XYY constitution are never identified. Stature is taller than average; one in 200 males taller than 6 feet (180 cm) have an XYY constitution. Fertility appears to be normal in most but not all cases because approximately 1% of men with oligospermia have XYY. The personality is described as impulsive in nature but variable in how that is expressed. Some XYY males are overtly aggressive and others are timid and have autistic features. For reasons that are not entirely clear, approximately one in 200 prisoners have 47,XYY. As children, XYY boys tend to have a high activity level, poor emotional control, and a weak self-concept and tend to be clumsy and easily frustrated. There may be a higher frequency of XYY boys with severe behavior disorders, and on average, the IQ appears to be slightly lower. However, most XYY males have intelligence and personality traits within normal limits. The frequency of tall stature, lower IQ, and criminal records is similar in XYY and XXY males, so the phenotype cannot be attributed directly to the extra Y chromosome. Early-intervention education programs may be useful in 47,XYY as well as in 47,XXX and 47,XXY.

INDICATIONS FOR CHROMOSOME STUDIES (SUBPOPULATIONS)

Part of "30 - Clinical Cytogenetics"

Miscarriages, Stillbirths, and Liveborn Infants

Miscarriage occurs in approximately 15% of all recognized pregnancies, with stillbirth representing another 1%. A chromosome abnormality is observed in 11% of stillbirths and 5% of perinatal deaths, compared with less than 1% of liveborn infants. Although the frequency of chromosome abnormalities is highest in macerated or malformed fetuses, many anatomic defects are not obvious, particularly those associated with trisomy 18, which constitutes approximately 30% of chromosome defects among stillborns. Therefore, it is appropriate to karyotype all stillbirths as part of a formal protocol that should also include family and obstetrical history, photographs of the face and any malformations, a whole-body radiograph, bacterial cultures, and autopsy. When malformation or a chromosome abnormality is identified, genetic counseling is warranted. The resources are unavailable to karyotype all miscarriage specimens, but for couples with two or more pregnancy losses, it is appropriate to carry out chromosome studies of the abortus as well as peripheral blood karyotype studies of the couple.

Approximately 50% of first-trimester, 25% of second-trimester, and 11% of third-trimester miscarriages have a chromosome abnormality (Table 30.9). For the earliest recognized miscarriages (less than 8 weeks from last menstrual period), however, there is some evidence that the frequency of chromosome abnormalities may be as low as 10%, although this may be an underestimate because 20% of normal-appearing *in vitro* fertilization embryos have a chromosome abnormality. Ectopic pregnancies do not have a substantially increased frequency of chromosome abnormalities.

TABLE 30.9. INCIDENCE OF CHROMOSOME ABNORMALITIES IN MISCARRIAGES AND STILLBORNS COMPARED TO NEWBORNS*a*

	Miscarriages[b] (%)	Stillborns (%)	Newborns (%)
Normal karyotype	50	95	99.3
Abnormal karyotype	50	5	0.7
Tetraploid	2.5	<<1%	-
Triploid	7	0.2	-
Trisomy (autosomal)	30	3.0	0.14
+13	1.5	0.5	0.01
+15	2.3	-	-
+16	9.9	-	-
+18	1.8	1.4	0.01
+21	2.6	0.8	0.11
+22	2.8	-	-
All other	9.1	0.3	0.01
Monosomy X	8.6	0.05	0.01
XXX, XXY, XYY, variants	0.6	0.5	0.2
Other	3	1.4	0.4

[a] Statistics compiled from Angell et al., (58), Simpson and Bombard (59), and Hook and Hamerton (6).

[b] Mostly first-trimester miscarriages.

Polyploidy is observed in 10% of abortus specimens, with 3% being tetraploid and 7% being triploid. These are often associated with an empty sac or a severely disorganized embryo, but mosaics are often less severely affected and some liveborn infants are known with polyploidy mosaicism.

Hydatidiform degeneration of the placenta is frequent in triploid conceptions, and although some hydatidiform moles are triploid, the majority of complete moles (which carry a risk of malignant degeneration) are diploid with two paternal and no maternal contribution to the zygote. Diploid moles appear to arise from fertilization of an empty (degenerating) egg by a haploid sperm with subsequent duplication of the paternal chromosomes or by dispermy (fertilization by two sperm). The absence of embryonic development in diploid moles is consistent with the hypothesis that a paternal chromosome set is required to form the placenta and a maternal set required to form the embryo.

Trisomy for the autosomes (chromosomes 1 to 22) as a group comprises approximately 30% of all miscarriages (Table 30.2). By far the most common is trisomy 16, which accounts for approximately one third of cases. Trisomy 16 is frequently associated with an empty sac and hydatidiform degeneration of the placenta. Trisomy 1 has not yet been seen in a miscarriage specimen. As with liveborn trisomy, there is a maternal age effect, and most trisomic miscarriages result from nondisjunction during maternal meiosis I.

In general, women who have one or more miscarriages have an increased risk of miscarriage in future pregnancies compared with women who have no history of miscarriage (25% versus 12%). However, this information is based on unkaryotyped miscarriages, so it is unclear whether there is a maternal age-independent increased risk of pregnancy loss subsequent to a trisomic miscarriage.

After a couple experiences a trisomic miscarriage, there is an increased likelihood that any subsequent miscarriage will also be trisomic, although not necessarily for the same chromosome (Table 30.10). Some centers recommend prenatal diagnosis in future pregnancies for women who have had a trisomic miscarriage, but there is only weak evidence that such women have a maternal age-independent increased risk for having a liveborn trisomic.

Monosomy for an autosome is extremely rare, and most monosomies have never been observed. One plausible reason is that loss of a chromosome or chromosome segment has a much more severe effect on phenotype than does gain of the same chromosome or chromosome segment. In contrast, monosomy X accounts for approximately 9% of miscarriages.

Although 45,X is compatible with full-term development, the

TABLE 30.10. FREQUENCY OF RECURRENT TRISOMIC AND CHROMOSOMALLY NORMAL MISCARRIAGES AMONG 125 PAIRS OF ABORTUSES*a*

	Karyotype of Second Loss		
Karyotype of First Loss	**Normal**	**Trisomic**	**Other**
Normal	55	6	7
Trisomic	8	24	2
Other	9	8	6

[a] Adapted from Hassold TJ. A cytogenetic study of repeated spontaneous abortion. *Am J Hum Genet* 1980; 32:723–730.

great majority do not survive to term. In one study, only 1% to 6% of 45,X miscarriages had cytogenetic or molecular evidence of mosaicism, whereas at least 50% of liveborn infants are mosaics.

Other chromosome abnormalities seen in miscarriages and stillborns include unbalanced rearrangements, and the balanced translocation or inversion is sometimes identified in a parent.

The reasons for miscarriage or stillbirth in chromosomally normal conceptions are legion, but there are major categories that can be explored in women who have more than one chromosomally normal miscarriage. Smoking, alcohol, cocaine, and infections are major environmental factors in chromosomally normal miscarriages. Conversely, the identification of a chromosome abnormality in an abortus is generally sufficient to exclude a teratogenic or other nonchromosomal cause. This can be useful to some couples who are concerned about environmental exposures or other factors as a cause for their miscarriage. If one of two miscarriages is aneuploid and the other euploid, it is also safe to conclude that the multiple miscarriages are not causally related.

Multiple Miscarriages

Because 15% of recognized pregnancies end in miscarriage or stillbirth, simple probability dictates that 2% of couples with two pregnancies will have two miscarriages, and 6% of couples with three pregnancies will have two miscarriages. Nonetheless, in 4% of couples (2% of subjects) who experience multiple pregnancy losses (more than one miscarriage or stillbirth), one member of the couple carries a balanced chromosome rearrangement. By comparison, the incidence of balanced chromosome rearrangements in the general population is only 0.6% (Table 30.5). This increased frequency of rearrangements justifies a chromosome study in all couples who experience more than one pregnancy loss.

The rearrangements found in couples with multiple miscarriages include reciprocal translocations (50%), robertsonian translocations [35%, mostly der(13;14)], inversions (13%, mostly pericentric), and 2% others (e.g., X deletion or normal/ring mosaic). The majority (75%) of the identified carriers are female. The nature of the chromosome rearrangement in a specific family influences the risk of miscarriage or malformed liveborn, but it is reasonable to suggest family studies and offer prenatal diagnosis to the carriers. Couples with three or more consecutive miscarriages may have a lower frequency of rearrangements as obstetric, immunologic, and endocrinologic risk factors become more likely.

Many women who have multiple miscarriages have a small proportion of 45,X or 47,XXX cells in their peripheral blood chromosome preparations. This finding is age related and does not indicate an increased risk for subsequent miscarriages or conceptions with an abnormal karyotype beyond the patient's age-related

risk. The frequencies of 47,XXX and 47,XYY constitutions are probably no greater in multiple miscarriage subjects than in the general population. There have been suggestions of an association between miscarriages and chromosome variants, especially 9qh and Yqh, but the evidence favoring this association is weak.

Male Infertility

A chromosome abnormality is detected in 15% of men with azoospermia and in 6% with low sperm counts (less than 10 million/mL) (Table 30.11). Among men with sperm counts ranging from 10 to 20 million, approximately 2% have a chromosome abnormality. Men with a 47,XXY karyotype are in the majority in the azoospermic group, but balanced rearrangements are more important among the oligospermic men. 47,XYY is not overrepresented among azoospermic men but is more frequent in oligospermia.

TABLE 30.11. CHROMOSOMES IN AZOOSPERMIA AND OLIGOSPERMIA*a*

Azoospermia: 15% abnormal (73 of 489 men)
56 47,XXY
5 47,XYY mosaics
1 47,XYY mosaic
5 46,XX males
1 45, X/46,XY mosaic (30:70 ratio)
5 Balanced rearrangements
Oligospermia (less than 10 million/mL sperm count): 6% abnormal (58 of 959 men)
7 47,XXY
4 47,XXY mosaics
7 47,XYY
1 47,XYY mosaic
32 Balanced rearrangements
1 46,X, del (Y)(q12) new mutation
6 46,XY/47,XY, +marker

[a] Data from Retief et al. (61) and Bourrouillou et al. (62).

A 45,X/46,XY mosaicism does not appear to be a significant risk factor for infertility. Most prenatally diagnosed cases have normal-appearing male external genitalia at birth. Males with obstructive infertility (e.g., congenital absence of the vas deferens) should be tested for mutations at the CF gene locus. Many males with nonobstructive infertility have a submicroscopic deletion that spans the *DAZ* gene locus on Yq. These possibilities need to be considered before intracytoplasmic sperm injection (63).

Female Infertility

A chromosome abnormality is detected in 25% of primary amenorrhea and gonadal dysgenesis patients, with approximately 10% numerical and 10% structural changes of the X, and 5% 46,XY or structural changes involving the Y chromosome. In one study, 33% of patients with secondary amenorrhea had an X abnormality, and in our experience, 10% of women karyotyped because of premature menopause have an isochromosome Xq or other structural abnormality of the X chromosome. Some women with premature ovarian failure are fragile X carriers (64). There are many genetic but nonchromosomal causes of female infertility (56).

Ambiguous Genitalia

Ambiguous genitalia in a newborn becomes a social emergency for the family, whether it appears as an isolated birth defect or as part of a syndrome. Abnormalities of the external genitalia can be associated findings in several sex chromosome abnormalities. For an infant with hypotonia as well as hypogonadism, Down's syndrome and PWS should be considered, and high-resolution cytogenetic studies should be done. The biochemistry of abnormal sexual differentiation in chromosomally normal 46,XX and 46,XY newborns and the many nonchromosomal causes of ambiguous genitalia are beyond the scope of this chapter (65,66,67 and 68).

The karyotype is essential and should be done as a stat specimen. It is standard practice to order serum 17-hydroxyprogesterone and testosterone measurements, either at the same time or depending on the cytogenetic result. Because many hospitals send these tests to reference laboratories, the urgency of the karyotype result is accentuated. Until the question of gender is answered, anxiety is tremendous. The physicians and other medical staff generally prefer to avoid mention of gender, and use the ambiguous term gonads rather than testes or ovaries.

Mental Retardation and Multiple Congenital Anomalies

Estimates of the frequency of chromosome abnormalities among the mentally retarded vary widely, but we find that the following estimates have been workable. Among the moderately to severely retarded, Down's syndrome is present in 10% to 15%, and 3% to 5% have other chromosome abnormalities, including other trisomies, and balanced and unbalanced structural changes. The fragile X syndrome can be identified in 3% to 6% of males and in 3% to 4% of females whose IQ is between 55 and 75 (69,70). The frequencies of *de novo* balanced reciprocal translocations and inversions are increased, but inherited balanced rearrangements and *de novo* robertsonian translocations are not more frequent among the mentally retarded. The likelihood of finding a chromosome abnormality is greater if multiple minor or major malformations are present. Of patients with congenital heart disease, 13% have a chromosome defect, mainly Down's syndrome, and to a lesser extent trisomy 8, 13, 18, monosomy X, and unbalanced chromosome rearrangements.

Tissue-limited mosaicism is present in 3% to 10% of subjects with multiple malformations, mental retardation, a normal blood karyotype, and no clear nonchromosomal syndrome.

Pigmentary Dysplasia

Several recent studies have drawn attention to an association between swirls and lines of hyperpigmentation or hypopigmentation of the skin and chromosomal mosaicism (71). In some patients, the pigmentary changes can be seen better using an ultraviolet lamp. The terms *hypomelanosis of Ito* and *incontinentia pigmenti chromiens* have been used to describe these pigmentary abnormalities, which traverse the trunk in a generally horizontal

pattern and linearly along the arms and legs. The lines may reflect migration of melanocytes from the neural crest region during early embryogenesis. The associated chromosome abnormalities include XX/XY chimerism, diploid/triploid mosaicism, secondary trisomy 12p, and a variety of rings with normal/ring mosaicism, including patients who have some features of Ullrich-Turner syndrome, seizures, mental retardation, and a small ring X. Several X;autosome translocation cases are represented in this group, and the X breakpoint is often near the locus of a hypothesized gene for incontinentia pigmenti, although the patients do not have classic incontinentia pigmenti.

In patients with pigmentary dysplasia and mental retardation, seizures, or other birth defects, chromosome studies should be extended to cultured fibroblasts if the blood karyotype is normal, and biopsies should be taken from skin with each pigmentary expression or from the borders between areas of different pigment.

Arthrogryposis (Congenital Contractures)

Of patients with arthrogryposis and delayed development or mental retardation, approximately 15% have a karyotype abnormality, and half of these are mosaics (72). Trisomy 8 mosaicism is perhaps most common, but contractures have been associated with a variety of other chromosome abnormalities. A blood karyotype should be studied if multiple joint contractures are associated with developmental delay, and especially if other birth defects are present. If the blood karyotype is normal, a cultured skin fibroblast chromosome study should be studied.

METHODS

Part of "30 - Clinical Cytogenetics"

Chromosome preparations for cytogenetic analysis can be obtained from many tissue sources. Peripheral blood is the most frequently used specimen for routine chromosome analysis, as it is the easiest tissue to obtain. Blood karyotypes are usually ordered because of the presence of birth defects, mental retardation, infertility, or multiple miscarriages. Lymphocytes are incubated under appropriate conditions, during which blast transformation is induced by one of several lectins, such as PHA. Cell harvest begins with the addition of an agent (e.g., Colcemid or vinblastine) to arrest cell division at the metaphase stage. Other treatments may be employed to inhibit chromosome condensation or prepare the cells for specialized banding patterns such as red-blue-green (RBG) staining (Chapter 29). The cultures are then treated with a hypotonic solution to swell the cells and allow dispersion of the chromosomes within the cell membrane. Fixative is used as a wash solution to lyse the remaining red cells and remove some chromosomal proteins. Microscope slides are prepared and treated with one of several staining or banding methods. Chromosome preparations are then analyzed through the microscope for numerical and structural aberrations, and findings are documented with photographs or computer-generated images.

Chromosome analysis in newborns requires special consideration because a smaller volume of specimen is usually received and decisions regarding life-support systems or surgical intervention require rapid or stat analysis and interpretation. Direct preparations can be obtained from bone marrow cells harvested from specimens immediately after being received in the laboratory, although the quality is inconsistent. Whole blood specimens or bone marrow aspirates can be cultured as briefly as overnight. Thus, analysis of numerical and major structural changes can be performed within 6 hours, but normal results from marginal preparations must be confirmed with better material. This technique or a 48-hour method can be employed for prenatal percutaneous umbilical blood samples.

Fibroblast monolayer cultures can be established from miscarriage material to help identify the cause of the loss and from skin biopsies to look for sex-chromosome mosaicism or tissue-limited mosaicism. Cultures are established using small tissue pieces (explants) or dissociated cell suspensions obtained by treatment of tissue pieces with enzymes that break collagen fibers in tissues. Harvest techniques follow the basic principles used in harvesting lymphocytes.

The use of other tissues for chromosome analysis has been described in the literature but is not routinely done. Culture of urine sediment cells from newborns has been employed to confirm a prenatally detected trisomy mosaicism. Sperm chromosome analysis is being used by a few laboratories to detect germ cell mosaicism.

Many methods for cell culture, banding techniques, and differing protocols for cell analysis have been published. Each institution must modify procedures to suit their laboratory conditions and needs. The methods described here are those currently used in our laboratory and meet the requirements of accrediting agencies.

Cytogenetic Procedure for Peripheral Blood

Reagents

Blood culture media: 500 mL RPMI 1640 (GIBCO, Rockville, MD) with 100 mL fetal bovine serum, 6.5 mL penicillin-streptomycin, 7 mL L-glutamine. Dispense 10 mL aliquots into sterile T-25 flasks and add 0.33 mL PHA to each flask. Store at 4°C for as long as 2 weeks.

Fetal bovine serum (Hyclone, Logan, UT).

Penn-Strep (GIBCO): 10,000 IU/mL penicillin and 10,000 µg/mL streptomycin.

L-Glutamine (GIBCO): 200 mmol/L.

PHA (GIBCO).

Ethidium bromide (BioRad, Hercules, CA): 1 mg/mL. Warning: Mutagenic.

Colcemid (GIBCO): 10 µg/mL.

Acetic-methanol fixative: 3 parts anhydrous methanol: 1 part glacial acetic acid. Prepare fresh for each use.

Hypotonic: 0.075 mol/L KCl (5.59 g/L).

Microscope slides can be washed in a sonicator using methanol. Sonicate for 10 to 15 minutes, rinse in distilled water, and store at 4°C in distilled water.

Except where noted, all centrifugation steps are performed under the same conditions: 10 minutes at approximately 165*g* (e.g., 900 rpm using a 175-mm radius head).

Culture

This method is used to obtain routine mid to early metaphase preparations. To obtain prometaphase chromosomes for high-resolution analysis, a modification of the method is provided in Chapter 29.

1. Obtain 10 mL heparinized blood (usually drawn in a Vacutainer) and allow the blood to settle at room temperature. For small volumes of blood, cultures can be established using whole blood.
2. With a sterile pipette, collect the buffy coat layer between the plasma and red blood cells and transfer to a sterile tube. Obtain 1.5 mL plasma and white cells and mix well in the tube.
3. Using sterile technique, establish two cultures per patient by inoculating blood culture medium with 0.75 mL buffy coat suspension or 0.5 mL whole blood.
4. Incubate in 5% CO_2 at 37°C.

Harvest

5. On the third day, after 66 to 71 hours of incubation, add 0.1 mL ethidium bromide and 0.1 mL Colcemid to each flask. Return flasks to the incubator for 2 hours. *Variation*: Rush or stat cultures can be harvested after 48 hours of incubation.
6. Gently swirl the culture to loosen cells that have adhered to the flask and transfer culture to a conical centrifuge tube.
7. Centrifuge for 5 minutes at 1,400 rpm and aspirate the supernatant.
8. Add 10 mL of prewarmed (37°C) hypotonic solution and mix gently with a pipette to a smooth suspension. Incubate in 37°C water bath for 20 minutes, resuspend cells at 5-minute intervals.
9. Add 2 mL of freshly prepared cold (4°C) fixative and mix well with pipette.
10. Centrifuge and aspirate the supernatant.
11. Resuspend cell pellet in residual supernatant (approximately 0.5 mL) using a pipette. Add 10 mL fresh cold fixative, mix well, and allow to stand for 20 minutes at room temperature.
12. Centrifuge and aspirate the supernatant.
13. Continue the wash procedure with fresh fixative until the cell pellet is clean and white. After the final wash, resuspend the cells in fresh fixative to form a cloudy suspension. The cells are now ready to be dropped onto slides. If the cells are to be stored, add fresh fixative but do not resuspend the pellet. Store in a tightly capped tube at 4°C.

Slide Preparation

14. If the pellet was stored, rewash cell pellet with fixative and resuspend cells with fixative to produce a slightly cloudy suspension.
15. Using a glass pipette, place two to four drops of the cell suspension on a cold, precleaned, wet slide. Blow, drain, or shake the excess fluid from the slide and dry on 65°C warming plate.
16. Examine slides with phase optics and adjust dropping technique for future slides. Ideally, metaphases should be black and chromosomes well spread and nonrefractory. Changes in room humidity, height at which the suspension is dropped, and steaming of slides over boiling water will affect the spreading. Generally, four to six slides per patient are adequate to complete the analysis.
17. Place slides in 90°C drying oven for 60 minutes.
18. Allow slides to come to room temperature before banding and staining. (See Chapter 29 for chromosome banding methods.)

Cytogenetic Procedure for Tissue Specimens and Skin Biopsies

Reagents

Ham's F-10 Complete medium: 100 mL bottle (GIBCO) with 25 mL fetal bovine serum, 0.25 mL gentamicin, and 1.5 mL L-glutamine. Store at 4°C for as long as 2 weeks. Complete F-10 can also be used as a transport medium.

Minimum Essential Medium-Alpha Complete Medium (MEM-alpha): 100 mL bottle (GIBCO) with 25 mL fetal bovine serum, 0.25 mL gentamicin, and 2.0 mL L-glutamine. Store at 4°C for as long as 2 weeks.

Chang's Complete Medium: 100 mL bottle (Irvine, Santa Ana, CA) with 14 mL Supplement C, 0.25 mL gentamicin, and 2.0 mL L-glutamine. Store at 4°C for 3 days.

Gentamicin (GIBCO): 10 mg/mL.

L-Glutamine (GIBCO): 200 mmol/L.

Nystatin (GIBCO): 10,000 IU/mL.

Penn-Strep (GIBCO): 10,000 IU/mL penicillin; 10,000 µg/mL streptomycin.

Fetal bovine serum (Hyclone, Logan, UT).

Hanks' buffered saline solution (HBSS) (GIBCO).

1×: 100 mL bottle with 0.25 mL gentamicin.

10×: 100 mL bottle with 2.5 mL gentamicin.

Colcemid (GIBCO): 10 µg/mL.

Hypotonic: 0.4% KCl (0.054 mol/L KCl).

Acetic-methanol fixative: 3 parts anhydrous methanol: 1 part glacial acetic acid. Prepare fresh for each use.

Trypsin solution (GIBCO): 0.25% 1× with ethylenediaminetetraacetic acid (EDTA)

Collagenase 10× stock solution: 100 mg collagenase V (Sigma, St. Louis, MO) in 10 mL HBSS. Filter sterilize and dilute with F-10 medium to make up working solutions of 1×, 2×, and 5×. Store at 4°C.

Culture

Cell cultures are initiated in a laminar flow hood using sterile technique, and cultures are incubated at 37°C in a 5% CO_2 atmosphere. Methods vary somewhat for fetal tissues, placental villi, and skin biopsies.

Fetal Tissues

1. Tissue samples are delivered to the laboratory in a sterile container with normal saline, Ringer's solution, or transport medium. Various sources of tissues from miscarriage material can be used to establish cultures. Fetal villi, membrane, cord, or skin are the most likely to produce fibroblast cultures. Frozen tissue samples or those exposed to formalin or formaldehyde will not be viable.
2. Using sterile forceps, place each piece of tissue in a large Petri dish containing 10× HBSS. Transfer pieces to another Petri dish containing 1× HBSS and gently swirl to rinse.
3. Sort each different tissue type into a separate dry dish and keep moist with a small volume of HBSS.
4. Trim away any necrotic areas, cartilage, decidua, or blood clots. Limit the total size of each sample to 5 mm^3 or smaller to ensure adequate enzyme dissociation. Because some tissue types dissociate poorly, such as umbilical cord, they should be cut into smaller pieces.
5. By “scissoring” two scalpels blade to blade, mince each tissue piece into cuttings of 1 mm^3.
6. Using fine sterile forceps, transfer cuttings to a sterile tube containing 5 mL of prewarmed working enzyme solution and incubate the tissue in the appropriate enzyme solution at 37°C in a dry bath as follows: for early gestation products of conception or macerated fetal parts use 1× collagenase for 1 to 3 hours; for foreskin, late-gestation cord, skin, tendon, artery, and other fibrous tissues, use 2× or 3× collagenase for 2 to 4 hours.
7. After enzyme treatment, pipette the suspension vigorously using a 5-mL pipette to triturate.
8. Centrifuge and aspirate the supernatant.
9. Resuspend the pellet in 5 mL of prewarmed complete F-10 medium or MEM-alpha.
10. Centrifuge and aspirate the supernatant.
11. Resuspend the cell pellet in an appropriate volume of fresh complete MEM-alpha. Usually 5 mL is used to establish three T-25 flask cultures.
12. Set the tube upright for 10 to 30 seconds to allow the larger tissue fragments to settle to the bottom. Establish *in situ* cultures by aliquotting 0.5 mL of the cell suspension of mostly single cells and small cell aggregates onto four to six sterile 22-mm coverslips in 35-mm culture dishes. Establish one culture with 1–2 mL each of the bottom suspension including the larger tissue fragments. Incubate cultures at 37°C.

The cultures established from the small cell aggregates can be fed after 1 day, but the explant cultures should not be disturbed until the explants are firmly attached to the flask, usually 2 to 3 days. If little dissociation is observed after short-term enzyme treatment, establish the single-cell suspension in one flask and transfer the larger fragments to fresh 1× collagenase solution and incubate overnight. Rinse and establish another culture the next day.

Placental Villi

This is a variation of the chorionic villus sample method for prenatal diagnosis, detailed in Chapter 31.

1. After the villi have been rinsed in 10× and 1× HBSS as with other tissues, examine carefully through a dissecting microscope and discard fragments of maternal decidua.
2. Carefully remove 10 to 20 mg of the most viable-appearing villi and place in a 60-mm sterile culture dish.
3. Add 5 mL of 1× trypsin-EDTA solution and incubate at 37°C for approximately 90 minutes. Macerated villi often digest more quickly and should be monitored.
4. After trypsin incubation, gently swirl the softened villi using a pair of sterile forceps and transfer the entire suspension to a sterile tube containing 5 mL 1× collagenase working solution.
5. Incubate at 37°C for 1.5 hours and establish cultures as previously described.

Skin Biopsies

Because most skin biopsies are obtained under aseptic conditions, it is not necessary to rinse in HBSS.

1. Suspend the biopsy in the transport medium with gentle agitation and carefully pour it into a 100-mm sterile culture dish.
2. Transfer the tissue and a few drops of fluid to a dry dish.
3. Obtain four to six 1-mm^3 pieces by scissoring two scalpels blade to blade through the specimen.
4. Transfer one or two fragments into each of three or four flasks. Gently create a puddle with 0.5 mL of fresh MEM-alpha over each explant and incubate undisturbed for 2 to 3 days or until growth is observed. Usually epithelial growth is first noted, followed by fibroblast growth.

Feeding

The cells in the suspension cultures usually attach after 1 day and can be fed at that time. *In situ* cultures are fed with 1.5 mL of prewarmed MEM-alpha every 4 days until harvest. To feed cultures, aspirate media carefully (do not dislodge cells) and add 3 mL of prewarmed MEM-alpha. Explant flasks need to be handled with care until fibroblast growth is well established. When initial epithelial growth is noted (3 to 5 days), add approximately 1 mL of fresh Ham's F-10 media and leave undisturbed for another 5 to 7 days.

If the cultures become contaminated with yeast or fungus, aspirate the medium and rinse the cultures with 1× HBSS. Add to the flask 3 mL of fresh media and 0.01 mL Nystatin. Return the cultures to the incubator and monitor carefully.

Subculture of Tissue Specimens

Subculture of a flask or coverslip may be necessary if additional cells are required or if the culture becomes confluent.

For coverslip subculture, follow the protocol described in Chapter 31 for subculture of amniotic fluid cell cultures. Use the following protocol for T-25 flask subculture:

1. Rinse each flask with 3 mL 1× HBSS.
2. Add 2 mL trypsin-EDTA solution to each flask and incubate at 37°C for approximately 5 minutes. Monitor cell release using an inverted microscope.

3. Gently tap the base of the flask against a large rubber stopper to dislodge the cells and obtain a single-cell suspension.
4. Add 2 to 4 mL of complete medium to inactivate the trypsin.
5. Establish four to six coverslips and retain the rest of the cell suspension in the original flask.
6. Incubate cultures at 37°C and maintain subcultured flasks until harvest.

Harvest

For harvest of *in situ* cultures, follow the protocol described in Chapter 31 for amniotic fluid cell *in situ* cultures. For flask cultures, use the following protocol. Sterile technique is not required unless the culture is to be carried for additional harvests. Cultures are examined using an inverted microscope. Cultures are ready for harvest when they are approximately 60% confluent. Slower growing cultures may give a better yield of mitotic cells if harvested at 80% confluency.

1. Add Colcemid, 0.01 mL per milliliter of medium in flask.
2. Return the culture to the incubator for 2.5 hours or until rounded up (mitotic) cells are evident.
3. Pour medium from the flask into a 15-mL centrifuge tube.
4. Add 2 mL 1× HBSS to the flask, swirl gently, and decant into tube containing the medium.
5. Add 2 mL 1× trypsin-EDTA solution to the flask. Incubate at 37°C for 5 minutes.
6. When most of the cells are free floating, gently tap the base of the flask against a large rubber stopper to loosen any cells still adhered to the flask.
7. Add 2 mL of F-10 medium to each flask to inactivate the trypsin.
8. Gently swirl and immediately decant into the tube. If the culture is to be maintained, add 3 mL of fresh media and return the flask to the incubator.
9. Centrifuge and aspirate the supernatant.
10. Add approximately 8 mL of prewarmed 0.04% KCl hypotonic solution and mix well. Incubate in 37°C water bath for 15 minutes.
11. Add 4 mL of freshly prepared cold (4°C) fixative and mix well with a pipette.
12. Centrifuge and aspirate the supernatant.
13. Resuspend the cell button by flicking the bottom of the tube with a finger. Add 4 mL of fresh cold fixative and mix well with a pipette.
14. Centrifuge and aspirate the supernatant.
15. After the final wash, the cells are ready to be dropped onto slides, or the pellets can be stored as a cell-fixative suspension in a tightly capped tube at 4°C.

Slide Preparation

Slides are prepared in much the same way as lymphocyte metaphase slides, but because of the small pellet, extra care is taken to conserve material.

Technical Variations

Fluorescence In Situ Hybridization

The mapping of the human genome has made it possible to extend the applications of molecular biology to cytogenetics. FISH techniques allow the highly sensitive detection of specific nucleic acid sequences in specimens on fixed microscope slides.

Several types of DNA probes have been developed and each has unique applications. A repetitive sequence probe (usually centromere-specific alphoid sequence probes) has unique DNA sequence repeats in multiple copies and is useful in determining ploidy and in identifying small marker chromosomes. Chromosome paints consist of a cocktail of different repeat and unique sequence probes, all located on the same chromosome. The unique sequences are homologous to DNA sequences along the entire length of the chromosome (Fig. 30.26A). Chromosome painting is useful in identifying translocation segments and in studies using somatic cell hybrids. Locus-specific probes are isolated for the identification of a specific gene or unique DNA sequence. For example, a locus-specific probe from the long arm of chromosome 7 can be used to look for a microdeletion associated with Williams syndrome (Fig. 30.26B).

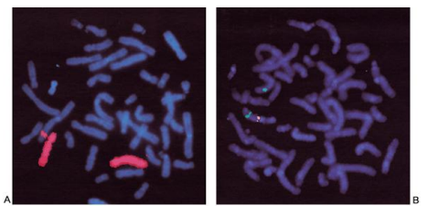

FIGURE 30.26. Fluorescence *in situ* hybridization in **A** employed a chromosome 5 painting probe on a cell from a patient with severe mental retardation and self-abusive behavior. On G-banded analysis, an abnormal dark staining band was seen in the p arm of chromosome 1. Using a 24-chromosome painting probe device (Cytocell, Ltd., Oxfordshire, UK), the abnormal segment was identified to be derived from chromosome 5 and confirmed using another chromosome 5 painting probe (Vysis, Inc, Downer's Grove, IL.). A hybridization signal is seen on both normal 5 homologs as well as an inserted segment in the p arm of chromosome 1. His karyotype is 46,XY,ins(1;5). In **B**, a locus-specific probe cocktail (Vysis, Inc., Downer's Grove, IL) used in the identification of patients with Williams syndrome was applied to a cells from a patient with clinical features of the syndrome. The orange-pink signal identifies the hybridization of a probe containing DNA sequences (including the elastin gene) known to be deleted in Williams syndrome (7q11.23). The green hybridization signal identifies control probes for 7q31. The absence of a signal with the critical region probe on one chromosome 7 identifies a deletion of the elastin gene.

For most FISH protocols, slides are prepared using standard protocols. If the slides are not aged, they are often pretreated in 2×SSC, which artificially ages the preparations. The chromosomal DNA and labeled probes are denatured, the probe is applied to the slide and incubated to allow hybridization of probe and target DNA sequences. After hybridization, excess probe is removed by stringent washing. The slides are counterstained, and the hybridization signal is analyzed using a fluorescence-equipped microscope.

With the increasing availability of commercially produced probes, FISH has become a valuable tool for cytogenetic analysis. In recent years, probes have been developed for several microdeletion syndromes including velocardiofacial syndrome and Williams syndrome, and their use has become standard in most cytogenetics laboratories. Telomere-specific probes for each arm of all chromosomes have been developed and are used to identify subtelomeric rearrangements that are estimated to be present in perhaps 6% of patients with mental retardation. Probes to identify rearrangements characteristic of specific leukemias [e.g., t(9;22) in CML and t(15;17) in AML-M3] as well as other cancer probes [e.g. her2-neu for breast cancer testing] are available and are most helpful in identifying abnormalities where sample volume is limited or where cell culture is impractical. New technologies using 24 different colored probes (one for each chromosome) are being developed and will prove most beneficial in the analysis of complex chromosome rearrangements in cancers.

Analysis of Chromosome Preparations

Cells in mid or early metaphase are usually suitable for analysis. Shorter chromosomes with fewer bands are easier to analyze but may mask subtle deletions or inversions. Selection of cells should be appropriate for each specimen type, and each laboratory should establish criteria for its own standards. A chromosome band resolution similar to that depicted in Fig. 30.6 is reasonable for most applications other than high-resolution analysis for the

contiguous gene syndromes. We specifically look for bands 17p13, 17p11.2, and 17q23 as markers of adequate resolution for routine analysis.

Preparations are analyzed using a light microscope. There are several fine manufacturers; we use a Zeiss Axioscope equipped with a 12-V, 100-W halogen lamp, mechanical, stage with verniers, 10×, 20× phase 2, and 100×/1.30 oil plan neofluar objectives, and a basic top-mounted 35-mm camera. A complete system cost approximately $18,000 in 1999.

Suitable metaphase cells have a sharp banding pattern and a small number of overlapping chromosomes, with the chromosome spread having a roughly circular shape. Excessively spread, teardrop-shaped metaphase cells are frequently broken, with one or more chromosomes lost. The location of each analyzed cell is recorded. The number of chromosomes in each spread is counted. The counts are pooled to determine the modal number (the count representative of most cells).

After the chromosomes are counted, the banding pattern of each chromosome is carefully inspected. In a sufficient number of cells, band-to-band comparison studies are done on each pair, and any structural differences are noted. Any abnormality should be confirmed in other cells because morphologic changes can occur within any cell as an artifact. Because banding intensity and condensation of chromosomal material varies between cells, thorough analysis of an adequate number of cells is essential for the proper interpretation of results. A structural or numerical abnormality found in one cell should be sought when scoring other cells. It is reasonable to assume the presence of a second clone if, among 30 cells scored, at least two cells have the same extra chromosome or the same chromosome rearrangement, or at least three cells have lost the same chromosome. In an abnormal karyotypic background, the presence of one normal cell usually indicates that a normal cell line is present.

The number of cells to be studied depends on the specimen type and the indication for the study (Table 30.12). If there is any question of chromosomal mosaicism, we analyze at least 30 cells (e.g., abnormal sex differentiation, suspected sex chromosome syndrome, or infertility). For situations in which mosaicism is occasional but is not a strong consideration, we analyze at least 20 cells (e.g., multiple congenital anomalies, mental retardation, possible Down's syndrome, or stillborns).

TABLE 30.12. BLOOD AND TISSUE ANALYSIS

Blood karyotype analysis, number of cells to study		
20 metaphase cells in most cases		
30 cells if mosaicism is possible; rule out (r/o) sex chromosome abnormality, ambiguous genitalia, male or female infertility, trisomy 8 mosaicism, or parent of a chromosomally abnormal offspring		
r/o Prader-Willi syndrome: also focus high-resolution at 15q1, 1p36, and 2q37; molecular studies are usually also ordered.		
r/o Turner syndrome: also focus high-resolution at 2q37		
Heart defect or r/o DiGeorge or VCFS; also focus high resolution at 22q11, 4q, 10p, 17p, and 18q. FISH studies are often ordered if DiGeorge or VCFS is suspected		
Tissue karyotype analysis		
20 metaphase cells in most cases		
30 cells from multiple cultures if tissue-limited mosaicism is suspected		
10 cells if karyotype is nonmosaic abnormal		
5 cells to confirm an abnormal prenatal karyotype		
Looking for mosaicism:		
When the 20- or 30-cell study is completed		
if one cell is found with	then analyze an additional	and if normal, interpretation is
Monosomy	0 cells	Random loss
A missing sex chromosome (if sex mosaic is possible)	20 cells	Random loss
+8, 9, 12–15, 18, 20–22, X, Y	20	Artifact
Other trisomic cell	0	Artifact
Balanced rearrangement	0	Artifact
if multiple miscarriages	20	Artifact
Unbalanced structural change	20	Artifact
≥50 chromosomes	0	Artifact
Normal cell in otherwise abnormal karyotype	20	Mosaic possible
+Marker	20	Artifact
if two cells are found with		
The same missing chromosome, look for mosaic or a ring	20	Random loss
–Y in male over age 50	0	Not clinically significant
-X or +X in female over age 23	0	Not clinically significant
If true mosaicism is found, consider UPD studies		

UPD, uniparental disomy.

These guidelines are used in our laboratory and are provided as an example of protocol development to make the most efficient use of personnel working at the microscope and to assist the staff in the preliminary interpretation of findings that are usually not clinically significant. All abnormal cells are also brought to the attention of the person responsible for clinical interpretation of the karyotype findings.

After the analysis, photographs are taken of metaphase cells representative of the analyzed cells (73,74). Photographs serve as a permanent record of what was observed, and we do not recommend their use as an alternative to routine analysis through the microscope. Black and white enlargements are made, and individual chromosomes are cut to arrange a karyotype. The final report includes at least two full karyotypes.

Guidelines and recommendations for culture and analysis for all specimen types have been established by the American College Medical Genetics (75) and the Association of Genetic Technologists (76) and are pending from the American College of Medical Genetics. Chromosome nomenclature should conform to standards established by the Standing Committee of Human Cytogenetic Nomenclature (1).

As an alternative to photographic documentation, computerized

systems for cytogenetic analysis have been developed by several companies. Basic systems allow the technologist to image digitally metaphase cells and prepare a karyotype. The karyotype can be printed in hard copy format and can be archived on a disk or other memory system. Sophisticated systems are able to locate automatically metaphase cells on slides, count the number of chromosomes, and produce a karyotype of the cells, using the technologists to isolate and identify some or all of the individual chromosomes in an interactive process.

Sex Chromatin Studies (Barr Bodies)

The Barr body, formed during interphase from the inactivated X chromosome, can be observed in cells from normal females and males with Klinefelter's syndrome, but not in normal males or females with 45,X or 46,XY constitutions. Females with more than two X chromosomes have some cells with multiple Barr bodies, and some structurally abnormal X chromosomes show smaller or larger Barr bodies. Scoring Barr bodies in buccal mucosal cells is less costly than karyotype analysis, but the technical limitations of the test are considerable, and the presence of the Y chromosome is not addressed without application of a second stain for the Y body (the quinacrine-brilliant segment of Yq). Because of the obvious benefit of a full cytogenetic study, sex chromatin studies have fallen out of favor.

Prenatal Cytogenetic Diagnosis

Daniel L. Van Dyke

Jacquelyn R. Roberson

Anne Wiktor

With advancing maternal age, there is an increased risk of having a child with Down's syndrome. This fact has led to the development and wide acceptance of prenatal diagnosis of chromosomal and nonchromosomal birth defects and inherited conditions. The methods used to obtain fetal cells for prenatal diagnosis include amniocentesis, chorionic villus sampling (CVS), and umbilical blood sampling (1). Methods to obtain fetal cells from the maternal blood circulation may not be perfected for years, but several biochemical measures of maternal serum are used to screen pregnancies at increased risk. Including all accepted reasons (Table 31.1), prenatal diagnosis is indicated in 5% to 8% of all pregnancies. Other than screening for neural tube and abdominal wall defects, nonchromosomal prenatal diagnostic studies are beyond the scope of this chapter. For a detailed discussion of these topics, the reader is referred to Milunsky (2).

TABLE 31.1. INDICATIONS FOR PRENATAL CYTOGENETIC OR AFP DIAGNOSIS

Advanced maternal age
One parent carries a chromosome rearrangement
Previous offspring with a chromosome abnormality
Previous offspring with a neural tube defect or hydrocephalus
High maternal serum AFP
Low maternal serum AFP (or similar screening result)
Fetal abnormality detected by ultrasound examination
Fetus at risk for X-linked or prenatally diagnosable inherited disease

AFP, α-fetoprotein.

Amniocentesis for prenatal genetic diagnosis is typically performed at 16 to 20 weeks. The procedure has been performed as early as 9 weeks, although its safety seems questionable before 15 weeks of gestation. Genetic amniocentesis has become widely available since it was introduced in the late 1960s, it is regarded as safe to the mother and fetus, and the culture success rate is 99.5% or better. Methods are also available to screen amniotic fluid interphase cells for the common trisomies and sex chromosome abnormalities, using fluorescence *in situ* hybridization (FISH) of probes for chromosomes 13, 18, 21, X, and Y.

Although CVS for prenatal diagnosis got off to a rocky start, its acceptance is increasing again. The reason for concerns in the early 1990s was an association between CVS and limb reduction defects, but this was primarily limited to procedures done before 10 weeks of gestation. The risks of the procedure to the mother and the embryo are now considered acceptable if performed after 10 weeks of gestation, with more than 96% of procedures providing a satisfactory cytogenetic result (3,4,5 and 6). CVS for first-trimester prenatal diagnosis is routinely done between gestational age of 10 and 12 weeks using an ultrasound-guided biopsy catheter passed through the cervix (transcervical CVS) or abdominal wall (transabdominal CVS). Transabdominal CVS (placental biopsy) can also be performed during the second and third trimesters and is sometimes useful to evaluate the karyotype when oligohydramnios or fetal defects are found on ultrasound examination.

For CVS, two general chromosome preparation methods have been developed: direct preparation and short-term cell culture. Short-term culture of cells, mainly originating from the mesenchymal core of the chorionic villus, has the disadvantage of a longer reporting time. However, this is offset by the advantages of better quality preparations, the opportunity to analyze independent colonies of cells harvested *in situ*, no greater frequency of false-positive results (0.5% to 1% of specimens), and a lower frequency of false-negative results. (A false-positive result would mean the karyotype interpretation is abnormal but the fetal karyotype is actually normal. A false-negative result would mean that the karyotype interpretation is normal, but the fetal karyotype is actually abnormal.)

The alternative CVS method is a direct preparation of uncultured, rapidly dividing cytotrophoblast cells that comprise the outer sheath of the villus, after 24 to 48 hours of incubation of these cells. This has the advantage of more rapid reporting time but the disadvantages of a higher false-negative rate and poorer quality preparations. The false-negative rate of 0.03% to 0.1%, missing approximately 1% of the true fetal chromosome abnormalities, has been a major factor leading to broader acceptance of CVS culture techniques. For second- and third-trimester CVS, the direct method, or percutaneous umbilical blood sampling (PUBS), may be preferable to culture of amniocytes or CVS cells if a very rapid result is the first consideration, although false-negative CVS direct preparation results have been reported for all three trimesters. Thus, cultures should be employed for any CVS chromosome studies. The false-negative rate is unknown for second- and third-trimester CVS studies.

PUBS has also been used to obtain fetal cells for chromosome analysis, although it is not widely used for this purpose, being more applicable to studies of fetomaternal infections and Rh incompatibility.

INDICATIONS FOR PRENATAL CHROMOSOME ANALYSIS

Part of "31 - Prenatal Cytogenetic Diagnosis"

Maternal Age

In our center, approximately 55% of prenatal diagnostic procedures are done primarily because the mother will be age 35 years or older at birth. The risks of trisomy 13, 18, 21, X, and 47,XXY all increase with maternal age (7) (Table 31.2). There is an increased risk of some other chromosome defects with maternal age as well, including deletion 18p, extra isochromosomes, and other small accessory marker chromosomes. In our experience, such nontrisomic chromosome imbalances that are associated with maternal age constitute 10% of prenatally diagnosed chromosome abnormalities. In the United States, a maternal age of 35 years at the expected date of confinement (EDC) is the accepted age at which physicians routinely offer prenatal diagnosis Some centers have suggested lowering the age criterion to age 32 at EDC. In fact, any criterion is to some extent arbitrary. Some women would like to have prenatal diagnosis no matter what their risk; others think it wholly unnecessary. Increasingly, women over age 35 are basing their decision to undergo amniocentesis on the estimated risk provided by maternal serum screening programs.

TABLE 31.2. RATE PER THOUSAND OF CHROMOSOME ABNORMALITIES AT CVS AND AMNIOCENTESIS, AND IN LIVEBIRTHS, BY MATERNAL AGE

	Trisomy 21			All Abnormalities		
Maternal Age	CVS	Amnio	Livebirth	CVS	Amnio	Livebirth
35	4.2	4.0	2.6	8.8	8.0	5.2
36	5.7	5.2	3.4	11.5	9.9	6.4
37	7.5	6.7	4.4	15.1	12.2	7.9
38	10.0	8.7	5.7	19.8	15.2	9.8
39	13.4	11.2	7.3	26.0	19.0	12.1
40	17.9	14.5	9.4	34.1	23.8	15.2
41	23.8	18.7	12.2	44.7	29.9	19.0
42	31.7	24.1	15.7	58.6	37.6	23.9
43	42.3	31.1	20.2	76.8	47.2	30.2
44	56.4	40.1	26.1	100.8	57.8	37.3

47	˜130	86.2	56.0	˜230	110.9	73.6
48	˜180	111.2	72.3	˜300	139.9	90.4

CVS, chorionic villus sampling; amnio, amniocentesis. Statistics from Hook (7).

A chromosome abnormality is identified in 5% to 8% of CVS from women age 35 or older, compared with 1.5% to 3% of amniotic fluid samples from the same age group. The abnormality rate is higher in earlier gestational weeks. However, if detailed ultrasound examination is employed to exclude deceased embryos, the rate of chromosome abnormalities at CVS is approximately the same as for amniocentesis. Most centers do not attempt CVS if the embryo is dead, but perhaps it is worth considering because nearly all this subset have an abnormal karyotype and the cell culture success rate is much better for CVS than for evacuated products of conception.

Positive Family History

Between 1% and 3% of prenatal chromosome studies are performed because one parent carries a balanced chromosome rearrangement or the couple has had a child or stillborn with a chromosome abnormality. The risk of a liveborn infant with an unbalanced chromosome rearrangement varies with the specific rearrangement. In general, the risk is higher if the carrier is female. The risk of recurrence for a structural chromosome abnormality is probably much less than 1% if the parental karyotypes are normal.

For recurrence of a numerical chromosome abnormality such as trisomy 21, the empirical risk is almost never more than 1% greater than the maternal age-adjusted risk.

Prenatal Screening

Prenatal screening of maternal serum α-fetoprotein (MSAFP) and related tests (described below) has become part of routine obstetric care. Abnormal serum screen results account for approximately 30% of amniocentesis procedures at our institution. The proportion of women tested and the proportion of tests for these indications vary somewhat among centers. Most centers study the karyotype for screen-positive maternal serum multiple markers whether it is screen positive for neural tube defects or chromosome abnormalities as an indication, even though a high MSAFP is not generally considered a risk factor for a chromosome abnormality.

In our experience, a clinically significant karyotype abnormality is identified in 0.6% to 1% of amniotic fluid chromosome studies done because of abnormal maternal serum screening.

Ultrasound-Identified Abnormalities

Approximately 10% of prenatal cytogenetic studies are done because an ultrasound examination identified anatomic defects, obstructive uropathy, intrauterine growth retardation (IUGR), nonimmune hydrops, oligohydramnios, or polyhydramnios (Table 31.3). Of these, 10% to 20% (in our laboratory) have a chromosome abnormality: 20% of these were 45,X, 27% trisomy 21, 18% trisomy 18, 8% trisomy 13, 5% triploid, and 22% involved structural or other abnormalities. Fetal nuchal skin thickening observed between 15 and 20 weeks of gestation is used in some centers as a risk factor for trisomy 21 (11). Cystic hygroma is associated with 45,X in 50% to 75% of cases. There is usually more generalized fetal edema or fetal hydrops, and if so, spontaneous fetal death is very likely. Cystic hygroma is less commonly associated with trisomy 21 and other chromosome abnormalities, although nonimmune hydrops without cystic hygroma has approximately a 25% rate of chromosome abnormalities with approximately half of these being trisomy 21, one fourth 45,X, and one fourth other abnormalities. If amniotic fluid is inaccessible, it is possible to obtain cells for both phytohemagglutinin-stimulated culture and for standard monolayer culture from a sample of any bodily fluid or chorionic villi.

TABLE 31.3. KARYOTYPE AND FETAL ABNORMALITIES DETECTED ON ULTRASOUND EXAMINATION

Structural Abnormality	Most Common Chromosome Abnormality
Intrauterine growth retardation	Triploid, +18, +13, +21, 45,X
Brain	
Ventriculomegaly	+18, +21, triploid, +13
Holoprosencephaly	+13, +18, triploid
Microcephaly	+13
Choroid plexus cysts	+18
Dandy-Walker cyst	+18, +13
Agenesis of corpus callosum	+18, +13, triploid
Strawberry-shaped head	+18
Neck and face	
Cleft lip	+13, +18
Micrognathia	+18, triploid, +13
Nuchal cystic hygroma	45,X, +21
Nuchal thickening	+21, +13, +18
Thorax and abdomen	
Heart defect, structural	22q11 deletion, +21, +13, +18, triploid, 45,X
Nonimmune hydrops	45,X, +21
Diaphragmatic hernia	+18, +i(12p)
Omphalocele	+18, +13
Duodenal atresia	+21
Echogenic bowel	+21 (also cystic fibrosis)
Bladder outlet obstruction	+18, +13
Multicystic/dysplastic kidney	+13
Limbs	
Short femur	+21, +13, +18, triploid, and 45,X
Polydactyly	+13
Syndactyly	+18, triploid
Placenta, amniotic fluid	
Partial mole	Triploid
Complete mole	Androgenic 46,XX
Polyhydramnios	+21, +18M

Frequency estimates are from our laboratory experience. The risk of a karyotype abnormality associated with an isolated defect is usually low and sometimes confers no increased risk. The observation of one defect is an indication for a detailed ultrasound examination. Sources include Eydoux et al. (8), Snijders and Nicolaides (9), Stoll et al. (10), Van Dyke and Wiktor, unpublished data.

Fetal cardiac defects merit special mention because of their association with the velocardiofacial (22q11 deletion) syndrome. The classic phenotype (Chapter 30) includes a conotruncal heart malformation. However, the phenotypic spectrum associated with 22q11 deletion is very wide, and almost all structural heart defects have been reported in affected patients (12). We therefore use a FISH probe for the critical region associated with 22q11 deletion syndrome in addition to routine karyotype analysis in all prenatally diagnosed structural heart defects (excluded are hypoplastic left heart, echogenic focus in the heart, and fetal arrhythmia). Using this protocol, we identify a 22q11 deletion in 9% of such pregnancies.

Chromosome Instability Syndromes

Prenatal diagnosis of the mendelian chromosome instability syndromes are described in Chapter 29.

X-Linked Mendelian Disorders

A large number of X-linked conditions such as fragile X syndrome, Duchenne's and Becker's muscular dystrophy, hemophilia A and B, and Hunter's syndrome can be prenatally diagnosed with confidence (http://www.genetests.org/). Fetal sex can be determined by chromosome analysis or FISH analysis of X and Y chromosome-specific DNA sequences.

GENETIC COUNSELING

Part of "31 - Prenatal Cytogenetic Diagnosis"

Before any prenatal diagnostic procedure, it is important to obtain a family history. This would include, at a minimum, all first-degree relatives of both parents for birth defects, mental retardation, heritable diseases. It is also important to look for other risk factors that can be addressed in a constructive way (e.g., maternal diabetes or seizures, exposure to alcohol, cocaine, or other teratogenic agents). If the indication is a family history of a specific birth defect, a known syndrome, or an inborn error of metabolism, it is imperative that the specific diagnosis be confirmed. Failure to do so can cause a prenatal diagnostic error. For routine obstetric use, several brief questionnaires have been devised to assist in identifying genetic and teratogenic risk factors.

Informed consent for a prenatal diagnostic procedure should include discussion of the risks to the mother and the fetus and accuracy of the tests being done on the sample. If the patient is trying to choose between CVS and amniocentesis, a discussion of the advantages and limitations of each technique should be provided (Table 31.4). For amniocentesis, there is approximately a one in 500 risk of miscarriage or infection. Infection is a potentially serious risk to the mother and her future fertility. For CVS, the risk of miscarriage is estimated at 1/125 to one in 300. Although the risk of severe maternal infection after transcervical CVS has been estimated at approximately one in 500, as experience with the procedure has increased, this risk seems to have decreased dramatically. Because of the potential of a vascular disruption sequence (e.g., limb reduction or hypoglossia-hypodactyly

sequence), CVS is no longer recommended before 10 weeks of gestation. It is uncertain whether the relatively small increased risks of miscarriage owing to CVS or amniocentesis procedures are statistically different from each other. It is important that patients understand that prenatal diagnosis employs a specific set of tests and does not identify all causes of birth defects or mental retardation and that some diagnostic results are difficult to interpret or need further studies before interpretation is possible.

TABLE 31.4. COMPARATIVE ADVANTAGES OF PRENATAL CYTOGENETIC DIAGNOSIS USING THE CHORIONIC VILLUS SAMPLING AND AMNIOCENTESIS TECHNIQUES

Chorionic villus sampling
Earlier gestational age provides more personal privacy
Pregnancy termination at an earlier gestational age is quicker and safer
Preferred by many women, assuming similar risks to fetus and mother
Anxieties relieved sooner, although amniocentesis follow-up, necessary in 1% to 3%, is a source of new anxiety
Amniocentesis
Usually less expensive
Risks to fetus and mother are slightly lower
Wide availability
Available after maternal serum screening
Ability to assay amniotic fluid α-fetoprotein and acetylcholinesterase
Fewer confusing results (e.g., mosaicism 0.3% vs. 2% in chorionic villus sampling)

A follow-up study, usually including amniocentesis, is necessary in 1% to 2% of CVS cases because of an inadequate sample or an indeterminate cytogenetic result (usually mosaicism). In addition, approximately 1% of women who have CVS also need amniocentesis because of an elevated MSAFP result.

An abnormal or unexpected cytogenetic result is obtained in approximately 3% of all prenatal studies (Table 31.5). Half of these are autosomal or sex chromosomal trisomies. Many of the rest require follow-up studies and can be difficult to interpret.

TABLE 31.5. CHROMOSOME ABNORMALITY IN PRENATAL STUDIES AND PARENTAL DECISIONS REGARDING CONTINUATION OF THE PREGNANCY IN OUR PROGRAM

Abnormality	% of All Results[a]	% of All Abnormals	% Who Continued
47,+21	0.7	31	8
47,+13	0.1	5	0
47,+18	0.1	5	0
46/47,+20	0.05	2	75
45,X[b]	0.1	4	(None has survived)
47,XXX	0.1	4	25
47,XXY	0.1	5	66
47,XYY	0.07	3	0
45,X/46,XX or XY[b]	0.1	4	100
Inherited balanced rea	0.6[c]	26	100
De novo balanced rea	0.1	5	100
Inherited extra marker	0.07	3	100
De novo extra marker	0.05	2	50
Other	0.02	1	—

[a] Approximately 2% to 3% of prenatal studies have an abnormal cytogenetic result, and 0.3% are true mosaics (or roughly 10% of the abnormal results).
[b] The nonmosaic 45,X cases were associated with ultrasound-diagnosed abnormalities. The 45,X mosaics all appeared normal on ultrasound and had a normal outcome at birth.
[c] Between 75% and 85% are inherited from the mother.

At the time of CVS, approximately 10% to 13% fetal nonviability or an abnormal gestational sac is discovered (this is the frequency in the CVS population, not the entire pregnant population). Approximately 6% of women of ages 35 to 39, and approximately 20% of women age 40 or over miscarry between weeks 7 and 12. Among women age 35 or over who schedule amniocentesis, approximately 4% miscarry before their appointment date. When fetal demise is discovered at ultrasound, the prenatal clinic staff must be prepared to help the family deal with their grief.

Parents do not need to commit themselves to discontinue a pregnancy should a chromosome abnormality be identified. One cannot be expected to make such decisions in the abstract. These are complicated, personal decisions in which the genetics counseling team can and should play a supporting and nondirective role. The burdens of a developmentally disabled child can be tremendous on a family and may lead to high divorce rates and other less obvious outcomes, including annual costs of care of

more than $100,000. The decision whether to continue the pregnancy depends to some extent on the perceived burden of the defect (Table 31.5), but some parents will continue the pregnancy regardless of the diagnosis, and others will elect to terminate the pregnancy in relatively low-risk situations.

When a trisomic pregnancy is continued, the remaining chance of spontaneous fetal demise is approximately 30% for trisomy 21, 40% for trisomy 13, and 70% for trisomy 18. For monosomy X, the chance of a demise approaches 100%.

For laboratory and clinic quality assurance, our clinic employs postcard or telephone follow-up of every continued pregnancy with a normal karyotype result. One cannot assume that a discrepant result will be automatically reported. Long-term follow-up of continued pregnancy after an abnormal or unclear cytogenetic result is recommended.

SCREENING FOR NEURAL TUBE DEFECTS

Part of "31 - Prenatal Cytogenetic Diagnosis"

Prenatal diagnosis for spina bifida defects is the second most common reason for amniocentesis. Open neural tube defects, including anencephaly, meningocele, and meningomyelocele, occur in approximately one to two newborns per thousand in the United States.

Anencephaly is a lethal condition, and most affected fetuses are stillborn. The prognosis for meningocele and meningomyelocele can be quite variable, depending on the anatomic site of the defect, the extent of spinal cord damage, and the presence or absence of associated hydrocephalus.

The familial nature of spina bifida has been well documented, although many genes influence the risk (multifactorial inheritance). For couples who have one child with spina bifida, the empirical risk for recurrence is in the range of 2% to 5%. However, 95% of infants with spina bifida are born to couples with no family history.

Some cases of spina bifida are associated with other anomalies as part of a genetic syndrome such as Meckel or Roberts syndrome, both autosomal recessive conditions with a 25% risk of recurrence. Some can be associated with other risk factors such as maternal diabetes or prenatal medication exposure (i.e., isotretinoin or valproic acid).

Prior to availability of MSAFP screening, only patients with a positive family history of spina bifida were offered prenatal diagnosis. Although ultrasound examination can identify between 50% and 75% of spina bifida defects in the second trimester of pregnancy (13), its high cost has prevented its adoption as a screening test.

α-Fetoprotein (AFP) is the major protein in fetal plasma in early pregnancy. Peak levels of AFP are attained in fetal plasma at 12 to 14 weeks of gestation. The concentration falls rapidly thereafter. AFP levels in amniotic fluid parallel fetal serum levels at 1/100th concentration. In maternal serum, however, AFP levels rise throughout the first and second trimesters and peak at 28 to 30 weeks of gestation (Fig. 31.1). In 1972, Brock and Sutcliffe (14) were the first to diagnose spina bifida defects prenatally by elevated amniotic fluid AFP levels.

In 1973, Brock and co-workers first reported the use of MSAFP assays to identify pregnancies at increased risk for spina bifida, introducing the concept of mass screening for open neural tube defects. Patients with elevated MSAFP values could then be offered diagnostic testing such as amniocentesis and ultrasound evaluation.

Antenatal Screening for Spina Bifida

Although neonatal screening for some genetic disorders such as phenylketonuria was commonplace by the early 1960s, the idea of prenatal screening evoked considerable anxiety. The anxiety was partly related to the fact that an elevated MSAFP level was not always associated with a birth defect in the fetus. Furthermore, an elevated MSAFP did not identify all the fetuses that had a neural tube defect. However, the element of false-positive and false-negative test results is inherent in the concept of screening tests. A valid screening test identifies a subgroup of patients that has a sufficient likelihood of an abnormality to warrant further diagnostic investigation. Over time, MSAFP screening gained broad acceptance, and during 1990, approximately one half of all pregnancies in the United States were screened.

The United Kingdom was the first to apply population-based screening for spina bifida defects (Table 31.6). Maternal serum samples obtained between 15 and 20 weeks of gestation were found to have the best predictive value. Approximately 85% of affected fetuses were identified with MSAFP cutoffs of 2.5 multiples of the median (MoM). Approximately 5% of all pregnant women would have values above this level, but only one woman in 50 in this high-risk group would actually carry a fetus with anencephaly or spina bifida. One half of the women with initially elevated MSAFP values had an inaccurate estimate of gestational age, fetal demise, or twin gestation as the cause of the elevation. Because an elevated MSAFP result is not diagnostic of a fetal abnormality, MSAFP screening can be effective only within a well-integrated program offering genetic counseling, ultrasound evaluation, and amniocentesis (15). The United Kingdom's nationalized health care system offered an ideal setting for such a coordinated program. After encouraging data were presented concerning MSAFP screening programs in the United Kingdom and after extensive confirmatory studies, MSAFP test kits were released in the United States in 1983.

MSAFP Methods

MSAFP determinations are usually made by radioimmunoassay or immunometric assay techniques. Values may be expressed in either nanograms or International Units per milliliter. Commercial MSAFP kits have been tested in clinical trials and “kit” normal ranges are published for each week of gestation, but there is considerable variability among laboratories. Therefore, “kit normal values” are not recommended in establishing upper (or

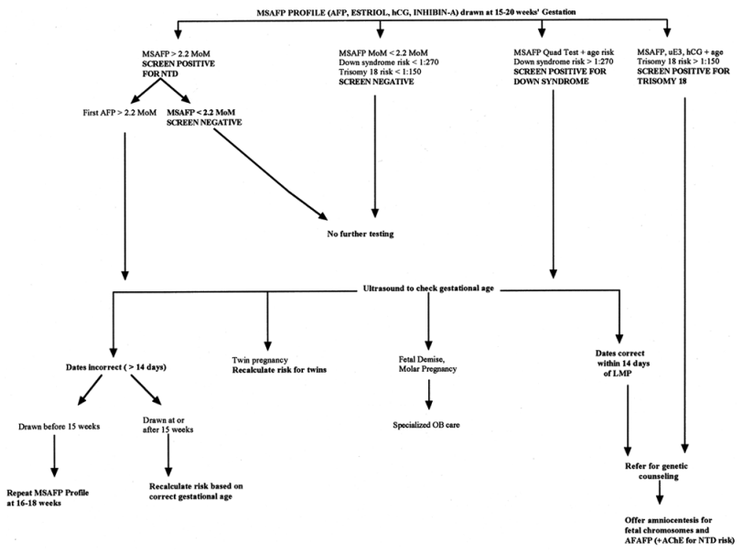

FIGURE 31.1. Protocol used at Henry Ford Hospital for the management of patients with abnormal maternal serum screening results.

TABLE 31.6. REQUIREMENTS FOR A WORTHWHILE SCREENING PROGRAM

Aspect	Requirement
Disorder	Well defined
Prevalence	Known
Natural history	Medically important disorder for which an effective remedy is available
Finance	Cost-effective
Facilities	Available or easily installed
Ethics	Procedures following a positive result are generally agreed on and acceptable to screening authorities and patients
Assay	Simple and safe
Test performance	Distributions of test values in affected and unaffected individuals are known. The extent of overlap is small. A suitable cutoff level is defined.

From Cuckle HS; Wald NJ. Principles of screening. In: Wald NJ, ed. *Antenatal and neonatal screening*. London: Oxford University Press, 1984;1–22, with permission.

lower) limits of normal. Each laboratory must establish its own median for each gestational week between 15 and 20 weeks of gestation. To facilitate interlaboratory communication, AFP values are expressed as MoM. For example, if laboratory A has a median value of 30 IU/mL at 16 weeks and laboratory B's median is 39 IU/mL, both values would be called 1.0 MoM at 16 weeks of gestation.

Determination of the appropriate cutoff for AFP depends on several criteria (Table 31.7). Most laboratories set a cutoff in the range of 2.0 to 2.5 MoM. MSAFP cutoffs in this range usually result in an 85% to 90% detection rate for open spina bifida, with a false-positive rate of 3% to 5%.

TABLE 31.7. PREVALENCE, DETECTION RATE, AND SPECIFICITY IN SCREENING FOR SPINA BIFIDA

The *birth prevalence* of spina bifida varies in a specific geographic region. In the United States, the prevalence is greater in the Northeast than in the Southwest. The prevalence in the United States also varies by ethnic group: approximately 1/700 in whites compared with 1/1,500 in blacks. The overall incidence in the United States is 1/1,000 livebirths.

The *detection rate* (sensitivity): The proportion of affected individuals with a positive test result.

The *false-positive rate*: The proportion of unaffected individuals with a positive test result.

Steps in determining an AFP screening policy:

1. What is the local birth prevalence of open spina bifida?
2. What risk of open spina bifida is acceptable after screening?
3. The likelihood ratio (LR) is determined by considering the factors in 1 and 2.
4. 
5. There is only one AFP cutoff that corresponds to a given LR.

AFP, α-Fetoprotein. From Wald NJ: Principles of screening. *Antenatal and neonatal screening*. London; Oxford University Press, 1984; 1–22, with permission.

Issues in the Interpretation of MSAFP Screening Results

By midtrimester, the primary source of AFP in amniotic fluid is fetal urine. If a fetus has an open body wall defect, additional AFP leaks into the amniotic fluid as a transudate from the fetal serum.

Gestational Age

MSAFP normally increases by approximately 15% per week from 14 to 21 weeks of gestation. Before 15 weeks of gestation, fetal urine is not the primary source of amniotic fluid. After 22 weeks of gestation, the fetal liver gradually switches from production of AFP to production of other serum proteins such as albumin. Therefore, outside this gestational range, AFP is an unpredictable marker for spina bifida. In addition, discrepancies in gestational dating can have a significant impact on AFP interpretation. The first step in interpretation of abnormal AFP results is usually an ultrasound examination to check gestational dates (Fig. 31.1). Ultrasound gestational dating in the second trimester by biparietal diameter (BPD) is usually considered accurate to within 7 to 10 days. Weeks of gestation are calculated through the last completed week (e.g., 16.1 to 16.9 weeks of gestation are within the 16th week). MSAFP interpretations are usually revised if the ultrasound examination findings change the gestational dating by at least 10 to 14 days.

Race

MSAFP values tend to be 12% to 15% higher in black women compared with white, and blacks have a lower prevalence of spina bifida defects. Because of these differences, application of a uniform cutoff without regard to race would label a larger proportion of black patients as elevated, leading to a higher amniocentesis rate in blacks. For screening programs with a significant black patient population, racially pooled samples would also raise the medians for the entire population, and this in turn could lead to a lower detection rate in nonblacks. This problem can be addressed in one of two ways. Some laboratories establish separate medians for black and nonblack patients. Others calculate medians for nonblacks and use a correction factor to provide race-adjusted medians for black patients.

Diabetes

Pregnant women with insulin-dependent diabetes mellitus have an increased risk for birth defects, including open and closed central nervous system defects and congenital heart defects. Some studies suggest a 15% to 20% rate of birth defects compared with the general population incidence of 3% to 5%. For this reason, some programs use a lower cutoff MoM for open neural tube defects in diabetic patients. Many geneticists recommend more thorough diagnostic evaluation in pregnancies of insulin-dependent diabetic women, including amniotic fluid AFP, acetylcholinesterase (AChE), and detailed fetal ultrasound examination. In addition, diabetic mothers have 70% to 80% lower MSAFP levels at each week of gestation. To compensate for this, many laboratories use a correction factor to adjust the MoM.

Twins

MSAFP cutoffs for singleton pregnancies (2.0 to 2.5 MoM) label 56% of twin gestations as elevated (Fig. 31.2). This is not

surprising because each normal fetus contributes approximately 1.0 MoM of AFP to the maternal circulation. Therefore, many laboratories set the upper limit of normal for twin gestations at double the singleton cutoff (4.0 to 5.0 MoM). However, because twins are not usually concordant for spina bifida, a more important screening concern is the expected MSAFP results for discordant twins, i.e., when one twin is affected and one is not. In singleton pregnancies, the median MSAFP value for a fetus with open spina bifida is 3.7 MoM, so screening programs that set their twin cutoff below 4.7 MoM (1.0 MoM + 3.7 MoM) can expect at least a 50% detection rate for discordant twins.

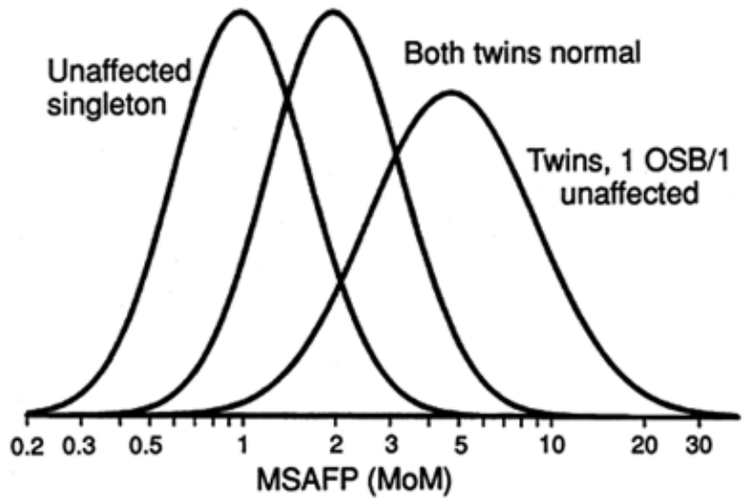

FIGURE 31.2. Distribution of maternal serum α-fetoprotein values for singleton and twin pregnancies. Median multiple of median (MoM) for normal singletons is 1.0 MoM. Median MoM for normal twins is 2.0 MoM. Median MoM for twins—one twin normal and one with open spina bifida (OSB) is 4.8 MoM. (From Palomaki G, Foundation of Blood Research, Scarborough, ME, with permission.)

Procedure-Related Elevations of MSAFP

Both amniocentesis and CVS are associated with fetomaternal bleeding, which causes a transient elevation in MSAFP of 2 to 4 weeks' duration. Genetics programs that obtain blood samples for MSAFP on amniocentesis patients must obtain samples before performing the procedure.

First-trimester CVS or early amniocentesis (11 to 14 weeks of gestation) offers the advantage of earlier fetal chromosomal or biochemical diagnosis, but spina bifida prenatal diagnosis by assay of amniotic fluid AFP is not yet available at that gestational age. Therefore, all such patients should be offered the option of MSAFP screening at 16 weeks of gestation. Approximately 1% of CVS patients have an elevated MSAFP at 16 weeks and require amniocentesis and detailed ultrasound evaluation.

AFP elevations are not specific for neural tube defects. Other open body wall defects, such as gastroschisis and omphalocele, also allow excess AFP transudation. Many other fetal anomalies may also be associated with elevated MSAFP (Table 31.8). Because many of these can be identified prenatally, complete diagnostic evaluation is recommended, including amniocentesis for amniotic fluid AFP, acetylcholinesterase, fetal karyotype, and ultrasound examination.

Multiple Marker Screening for Trisomies

An association between low MSAFP values and chromosome abnormalities was first reported in 1984 (17). The MSAFP median for Down's syndrome fetuses is approximately 0.7 MoM for normal singleton pregnancies. Some reports suggested that trisomy 18, triploidy, and sex chromosome abnormalities also have lower median MSAFP values. The etiology of low MSAFP in chromosomal syndromes is unclear, although placental immaturity has been suggested (18).

Before MSAFP screening, maternal age was shown to be the strongest indicator of risk for Down's syndrome and other trisomies. However, only 20% of Down's syndrome fetuses were born to women age 35 or older. Screening for low MSAFP provides an independent indicator of increased risk for Down's syndrome. Studies showed that approximately 20% of Down's syndrome fetuses had MSAFP values less than 0.4 MoM, whereas only 5% of all MSAFP values fall below this level (19).

Most laboratories have adopted multiple marker screening for Down's syndrome (Table 31.9). The most common combination of markers used is triple screening with MSAFP, estriol (uE3), and human chorionic gonadotropin (hCG). Researchers documented that Down's syndrome fetuses tended to have low MSAFP and uE3 with elevated levels of hCG. The median MoM for a Down's syndrome fetus was 0.7 MoM for MSAFP, 0.7 MoM for uE3, and 2.05 MoM for hCG (21). Using a published algorithm that assigns a likelihood for Down's syndrome based on the multiple markers and the woman's age at EDC, triple screening detects approximately 68% of all Down's syndrome cases when a 1 in 270 cutoff for Down's syndrome is used. In our program, women whose risk for Down's syndrome is at least one in 270 (the mid trimester risk for Down's syndrome in a 35-year-old woman) are offered further diagnostic evaluation including an ultrasound examination to confirm gestational dates and amniocentesis. It remains the standard of obstetric care to offer amniocentesis to all women over age 35 at the EDC. However, many women over age 35 choose to have maternal serum multiple marker screening to reassess their risk for Down's syndrome before deciding whether to have invasive prenatal testing.

Since 1987, investigators have identified several fetoplacental chemicals in maternal serum, which have a predictive association with Down's syndrome. Bogart and co-workers (22) reported a 56% detection rate for chromosomally abnormal fetuses using a simple cutoff of 2.5 MoM for maternal serum hCG. Canick and

co-workers (18,23) found that the median value of maternal serum estriol in 22 Down's syndrome fetuses was approximately 0.79 MoM. Cuckle and co-workers found that the median MoM for dimeric inhibin-A was 1.59 in 19 Down's syndrome fetuses (24).

Most maternal serum screening programs that use multiple markers also screen for trisomy 18. Studies have demonstrated that MSAFP, uE3, and hCG tend to be low when the fetus is affected with trisomy 18. Trisomy 18 occurs in approximately one in 2,400 pregnancies at mid trimester and one in 8,000 pregnancies at birth. The risk for trisomy 18 increases with maternal age and is approximately one fourth of the second-trimester risk for Down's syndrome at mid trimester. By 1990, a screening protocol that used fixed cutoffs of 0.75 MoM for MSAFP, 0.60 MoM for uE3, and 0.55 MoM for hCG had an estimated 60% detection rate for trisomy 18. Subsequently, a risk-based algorithm that included maternal age in the calculation was shown to have a 70% detection rate for trisomy 18. Less than 0.5% of screened pregnancies have values in this range. Our program employs a one in 150 second-trimester risk cutoff for trisomy 18 screening using MSAFP, uE3, and hCG.

Many multiple marker screening programs are adding a fourth maternal serum marker to their screening panel. The addition of maternal serum inhibin-A to the triple screen has been shown to decrease the false-positive rate from 6.6% to 5.0% and increases the detection rate for Down's syndrome from 70% to 75% (20). Inhibin-A is a placental marker that tends to be elevated in Down's syndrome pregnancies. The median MoM for dimeric inhibin-A in a Down's syndrome fetus is 1.95 MoM (25). Our program recently added inhibin-A to the screening panel for Down's syndrome.

Maternal Weight

Shortly after the introduction of low MSAFP screening, genetics centers noted a disproportionately high number of obese patients in the low MSAFP group. This association was owing to dilution of fetal AFP in the greater serum volume in heavier women. Most laboratories now use a weight correction factor for each marker to lessen this bias.

Multiple marker screening for Down's syndrome is also dependent on accurate gestational dating. Very low values are often associated with a gestational age less than 14 weeks, molar pregnancy, or missed abortion. MSAFP values are reinterpreted if an ultrasound examination demonstrates a change in dates of at least 10 to 14 days (Fig. 31.1). Recalculation of screening positive for trisomy 18 results is not recommended based on ultrasound gestational dating because trisomy 18 fetuses often have severe growth retardation.

Amniotic Fluid AFP

Prenatal diagnosis of open spine defects by amniotic fluid AFP analysis has been routinely available since the early 1970s. More than 98% of cases of anencephaly and open spine defects have amniotic fluid AFP levels higher than 2.5 MoM compared with less than 1% of normal fetuses that have values higher than 2.5 MoM.

Other anomalies associated with defects in the fetal skin, such as omphalocele and gastroschisis, also result in elevated amniotic fluid AFP.

False-positive amniotic fluid AFP values may be associated with fetal blood admixture in the amniotic fluid sample. A Kleihauer-Betke test on the sample can confirm the presence of fetal red cells.

Amniotic fluid AChE is a second biochemical marker that is positive in 95% of fetuses with an open neural tube defect (26). The likelihood of an open spine defect is greater than 99.5% when amniotic fluid AFP and AChE are both positive. Some fetuses with ventral wall defects may also have positive AChE results. Wald and co-workers (27) found that the ratio of pseudocholinesterase to AChE was a useful tool to differentiate open spina bifida from ventral wall defects.

Some patients may present with the diagnostic dilemma of elevated amniotic fluid AFP and negative AChE assay. This biochemical pattern may be seen in one third of fetuses with ventral wall defects, which can usually be identified by an ultrasound examination. The most common reason for positive amniotic fluid AFP and negative AChE is fetal hemorrhage into the amniotic fluid, and this pattern is observed in 90% of fetal blood contamination cases because the concentration of AChE is lower in fetal blood than in fetal cerebrospinal fluid. In the remaining 10%, the hemorrhage is so extensive that AChE is also elevated. Positive amniotic fluid AFP associated with negative AChE has also

been reported in congenital nephrosis. Most pregnancies with a positive AFP and negative AChE pattern end in the delivery of a normal full-term infant.

Detailed ultrasound evaluation in midtrimester is useful to identify the level of the spinal defect and to detect early changes of fetal hydrocephalus in most cases (Fig. 31.3).

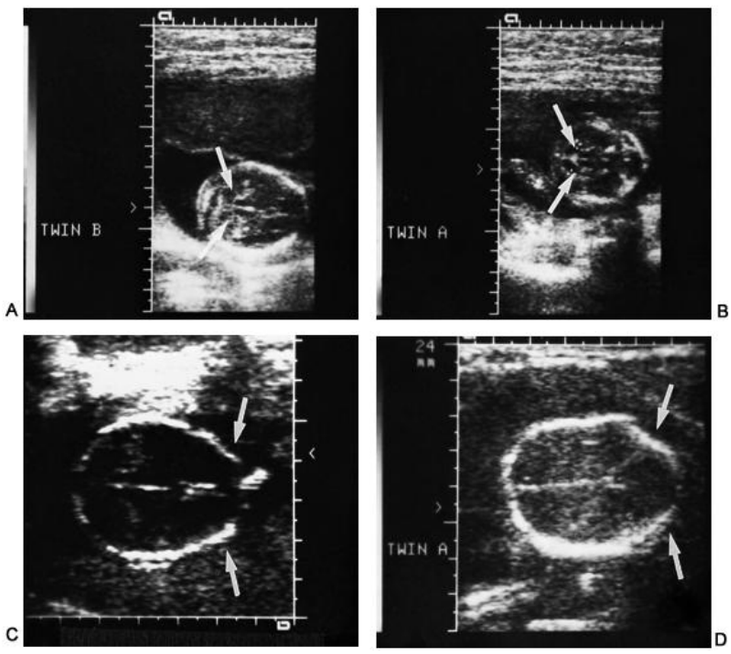

FIGURE 31.3. Comparison of mid-trimester cranial ultrasound findings in fetuses with and without open spina bifida. **A:** Normal transverse scan of cranium at the level of the cerebellum (*arrows*). **B:** Scan at the same level of a fetus with open spina bifida, demonstrating a positive "banana sign," compression of the cerebellum owing to Arnold-Chiari malformation. **C:** Transverse scan of a normal fetus at the level of the lateral ventricles. **D:** Scan at the same level of a fetus with open spina bifida, demonstrating the positive "lemon sign," reflecting a narrowing of the frontal calvarium.

SPECIMEN COLLECTION, CELL CULTURE, AND SLIDE PREPARATION

Part of "31 - Prenatal Cytogenetic Diagnosis"

Amniocentesis is the most commonly used procedure to obtain fetal cells at 14 to 20 weeks of gestation. Most laboratories culture amniocyte cells on coverslips in small Petri dishes and harvest the mitotic cells *in situ* for analysis of chromosomes from cells of distinctly different colonies. Harvesting of amniocyte cultures follows the same principles used in harvesting lymphocytes and other cell types or tissues. Colcemid is added to arrest cell division at metaphase, and treatment with a hypotonic solution disperses chromosomes within the cell membrane. The cells are then fixed *in situ*, chromosome preparations are stained usually using GT banding, and metaphase spread are analyzed microscopically.

CVS is generally performed during the first trimester. The villi can be used to obtain chromosome preparations by direct harvest or monolayer culture methods. By using a direct harvest method, metaphase spreads can be prepared within a few hours after sampling. For monolayer cultures, cells in the chorionic villi are enzymatically and mechanically dissociated, and the cell suspension is used to establish *in situ* cultures. *In situ* harvest methods are similar to those for amniotic fluid cultures and permit analysis of independent colonies of cells.

PUBS provide a fetal tissue source from pregnancies at 20 weeks of gestation or beyond, and up to term depending on the indication for the study. Fetal blood samples drawn directly from the umbilical cord can provide chromosome preparations within 48 hours. Specimens are cultured and harvested using standard lymphocyte culture methods.

Methods to Obtain Chromosome Preparations for Prenatal Testing

Reagents

Chang complete media: 90 mL (Irvine Scientific, Santa Ana, CA) with 14 mL frozen supplement C, 0.25 mL penicillin-streptomycin and 2.0 mL L-glutamine. Store at 4°C for as long as 3 days.

Amnio-Max: 90 mL (GIBCO, Rockville, MD) basal media with vial of 14 mL frozen supplement. Store at 4°C for as long as 3 days and protected from light.

RPMI complete media: 100 mL RPMI 1640 (GIBCO) with 18 mL fetal bovine serum, 1.5 mL L-glutamine, 0.25 mL penicillin-streptomycin. Store at 4°C for as long as 7 days.

CVS media (Chang 60/RPMI 40): 60:40 mix of Chang complete and RPMI complete media. Store at 4°C for as long as 7 days.

CVS transport media: 100 mL RPMI 1640 (GIBCO) with 1.5 mL L-glutamine, 1.0 mL heparin, 5.25 mL fetal bovine serum, and 0.25 mL gentamicin. Store at 4°C for as long as 14 days.

Gentamicin (GIBCO): 10 mg/mL.

L-Glutamine (GIBCO): 200 mmol/L.

Penicillin-streptomycin (GIBCO): 10,000 IU/mL penicillin and 10,000 IU/mL streptomycin.

Sodium heparin: 1,000 USP/mL

Colcemid (GIBCO): 10 µg/mL.

Fetal bovine serum (Hyclone, Logan UT).

Hanks' buffered salt solution (HBSS) (GIBCO) 1×: 100-mL bottle with 0.25 mL gentamicin.

Collagenase V (Sigma, St. Louis, MO): 100 mg in 10 mL HBSS. Filter sterilize. Store at 4°C for as long as 7 days.

Hypotonic: 0.8% sodium citrate or 1.0% sodium citrate.

Fixative: 3:1 anhydrous methanol:glacial acetic acid. Prepare fresh before each use.

Trypsin solution (GIBCO): 0.05% 1× with ethylenediaminetetraacetic acid (EDTA).

Ethidium bromide (SIGMA): 0.3 mg/mL. Warning: mutagenic.

Sterilized 22-mm^2 coverslips are prearranged in sterile 35-mm culture dishes.

All centrifugation steps are performed under the same conditions: 10 minutes at 140*g* (e.g., 800 rpm using a 185-mm radius centrifuge head.)

All tissue culture work is performed in a laminar flow hood using sterile technique. All cultures are incubated in 5% O_2/5% CO_2/90% N_2 incubators. The cultures grow more quickly in a low-oxygen atmosphere, but traditional incubators with 5% CO_2 can be used.

Culture of Amniotic Fluid Cells

1. Two tubes of amniotic fluid (Fig. 31.4), with 20 mL total, are generally sent to the laboratory. If AFP and/or AChE assays are requested, aliquot 1 to 2 mL per test into a sterile tube. Centrifuge both tubes.

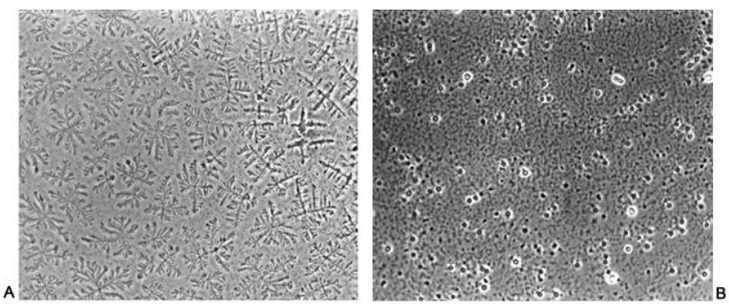

FIGURE 31.4. Urine and amniotic fluid can be distinguished by microscopic examination of a droplet of the fluid spread and dried on a microscope slide. The proteins in amniotic fluid give the appearance of ferning **(a)** that is not observed with urine **(B)**.

2. Remove all but 0.5 mL of supernatant from each tube. Add 2 to 3 mL media to each of the original tubes and resuspend the cells. Note: Cultures are initiated using both Chang complete and Amnio-Max media. Generally, each tube of amniotic fluid received is set up with different media.
3. Distribute the cell suspension from each tube among a total of eight coverslip cultures. When specimens are grossly bloody or when a large number of cells is required for special testing protocols, establish cultures in T-25 flasks. Add another 3 mL media to each flask culture. *Note*: Extreme care must be taken in labeling specimens for prenatal testing. A name and/or identification number should appear on each culture as well as identifying which amniotic fluid tube was used to establish the culture. Analysis should be performed on cells cultured from each tube.
4. Incubate cultures at 37°C.

5. After 12 to 24 hours of incubation, gently add 1 to 1.5 mL prewarmed media to each coverslip, taking care not to dislodge cells that have adhered to the coverslip.
6. On days 3 to 5 of culture, aspirate the media from the culture dish and flask and replenish with 1.5 mL prewarmed media (4 mL media for flask cultures). Maintain flask cultures by replenishing the media every third day with 4 mL prewarmed media. Coverslip cultures should be fed every third day until they are ready to harvest.
7. Cultures are examined on days 4 to 6 of culture and every day thereafter until all cultures are harvested. An inverted microscope is used to evaluate cell growth. A coverslip is ready to harvest when there are three or more feathery colonies with 40 to 65 cells per colony.

Culture of Chorionic Villus Cells

1. A 5- to 15-mg sample of chorionic villi (Fig. 31.5), or more, is transported to the laboratory in transport media. A sample of less than 5 mg of villi is only marginally satisfactory.
2. Transfer the specimen to a large culture dish, and using two tuberculin syringes, dissect away any blood clots and tissue that do not appear to be villus in origin.

Direct Preparation

1. Select six pieces of the most active-looking (thicker, bushlike in appearance) and place the pieces in a 35-mm culture dish with 2 mL of Chang media and incubate overnight.
2. Add 30 µL Colcemid and incubate for 3 hours.
3. Carefully remove the media from the culture dish. Add 2 to 3 mL of 1.0% sodium citrate and incubate at room temperature for 5 minutes.
4. Carefully aspirate the hypotonic solution and add 2 mL of fixative. Incubate at room temperature for 10 minutes.
5. Aspirate the fixative and add 2 mL of fixative. Place the culture dish in a -20°C freezer for 20 minutes. Aspirate the fixative and replace with 2 mL of fixative.
6. Transfer a piece of the villus to the lid of the culture dish and allow to dry briefly. Using a Pasteur pipette, add two to three drops of 30% glacial acetic acid to the villi and allow small bubble to appear on the sample (approximately 20 seconds). The longer the villus is in the 30% acid solution, the worse the morphology but the higher the mitotic index.
7. Pipet the sample and acid mixture to a dry microscope slide on a 42°C hot plate.
8. Place the slide in a 90°C drying oven for 1 hour.
9. Chromosomes are G-banded using trypsin as described in Chapter 29.

Collagenase Culture Initiation

1. Select villi with buds and visible capillaries and rinse several times in HBSS.
2. Transfer villus pieces into a 60-mm culture dish containing 5 mL trypsin-EDTA solution. Swirl the dish gently and incubate at 37°C for at least 2 hours.
3. With sterile forceps, pick each piece and shake vigorously in the trypsin solution. Place the pieces in a 60-mm culture dish containing 0.5 mL Chang media. Using two sterile tuberculin syringes or two scalpels, mince the tissue into small pieces, approximately 1 to 2 mm in diameter. Add 4 mL Chang media and 0.5 to 0.7 mL collagenase. Incubate the collagenase-cell suspension for 2 hours.
4. Resuspend the villus/collagenase mixture vigorously and transfer the mixture to a sterile 15-mL tube.
5. Centrifuge and aspirate the supernatant.
6. Add 5 mL Chang media and mix well.
7. Centrifuge and aspirate the supernatant.
8. Resuspend the cell pellet in 2 mL of fresh CVS media.
9. Establish *in situ* cultures as for amniocytes and maintain the cultures using CVS media. Harvest cultures following protocol for amniotic fluid.

Subculture of Flasks and Coverslips

Subculture of a flask or coverslip culture may be necessary if a culture is needed for noncytogenetic studies or the culture becomes confluent. Harvests from subcultures are usually better quality if carried out either 1 day after feeding or 2 days after subculture. For flask cultures, follow the protocol for subculture of fibroblast cultures (Chapter 30). For coverslip cultures:

1. Remove media and replace with HBSS (3.0 mL for flask, 1.5 mL for coverslip culture). Swirl the culture to rinse and remove the HBSS.
2. Add trypsin EDTA (2 mL for flask, 1 mL for coverslip culture).
3. Incubate at 37°C for 5 minutes.
4. Lightly tap the culture vessel to dislodge some of the cells.
5. Add complete media to inactivate the trypsin and split the culture into one or more vessels.
6. Feed with media on the following day.

Harvest

Sterile technique is not required. For harvest of tissue culture flasks, follow the protocol described in Chapter 30 for fibroblast cultures. For coverslip cultures:

1. Add 50 µL ethidium bromide to each coverslip culture and return it to the incubator for 50 minutes. Add 10 µL Colcemid and return the culture to the incubator for an additional 30 minutes.
2. Using a Pasteur pipette held against the side of the dish, aspirate all of the media, taking care not to touch the coverslip.
3. Gently add 2 mL of hypotonic solution and incubate at room temperature for 23 minutes.
4. Gently add 3 mL of fixative to the dish and incubate at room temperature for 3 minutes.
5. Aspirate most of the liquid from the dish but do not allow the coverslip to dry out.
6. Add 3 mL of fresh fixative and let stand for 20 minutes.
7. Aspirate fixative and repeat fixative washes twice with incubation times of 20 and 10 minutes.
8. After final wash, aspirate the fixative until a thin layer remains

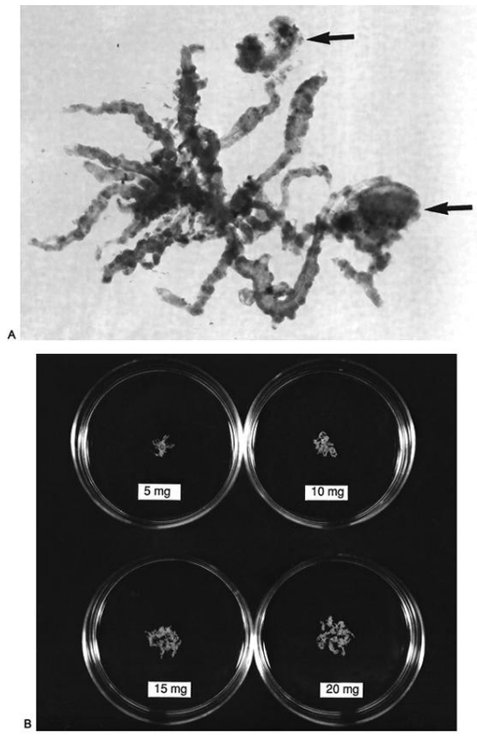

FIGURE 31.5. Chorionic villi **(a)** have a characteristic appearance of fronds of coral, whereas decidua (*arrows*) appear spongiform. **B:** The appearance of 5, 10, 15, and 20 mg of villi in 60-mm Petri dishes.

on the coverslip and the edges around the coverslip begin to dry.

9. Immediately invert the culture dish over an alcohol lamp flame until the cell side of the coverslip is nearly dry. The intensity of heat required for good spreading varies with room humidity.
10. Write the coverslip identification number on the back of the coverslip and place in drying oven at 65°C overnight or at 90°C for 1 hour.
11. Chromosomes are G-banded using trypsin as described in Chapter 29.

Robotic Harvesting of Cultures

In situ cultures can be processed using a robotic harvesting system. This is a time-saving, consistent tool for harvesting and can improve the quality and quantity of metaphases. After incubation in Colcemid, cultures that are ready to harvest are placed on the base of the instrument. The aspiration and dispensing of media, hypotonic, and fixative are all done automatically through a computer-programmed process. The rate of aspiration, amount of solution dispensed, and incubation time between each step can be individually programmed to adapt to each laboratory's individual procedure. After the harvesting procedure is completed, cultures can be placed under an airflow hood to control evaporation of fixative and spreading of the chromosomes.

Culture of PUBS

Lymphocyte cultures are established following the protocol for peripheral blood (Chapter 30). The amount of blood sent is usually 1 mL or less, and whole blood (rather than a buffy coat suspension) is used to inoculate the cultures. Two cultures are established, one to be harvested after 48 hours of incubation and one generally incubated for a standard 66- to 72-hour harvest.

Fluorescent In Situ Hybridization (FISH)

Depending on clinical indication, trisomies 13, 18, 21, and the sex chromosome aneuploidies account for between 85% and 95% of cytogenetic abnormalities associated with mental retardation and birth defects. On this basis, a screening assay to detect aneuploidy of these chromosomes on uncultured amniocyte interphase cells is offered by many cytogenetics laboratories. FISH using DNA probes, either singly or in a cocktail with each probe labeled with a different fluorochrome, is used to screen for aneuploidy by scoring the hybridization signals in interphase cells (Fig. 31.6). An 85% to 95% detection rate is not adequate to employ interphase trisomy screening as a stand-alone test, therefore routine chromosome studies must be done concurrently with interphase trisomy screening.

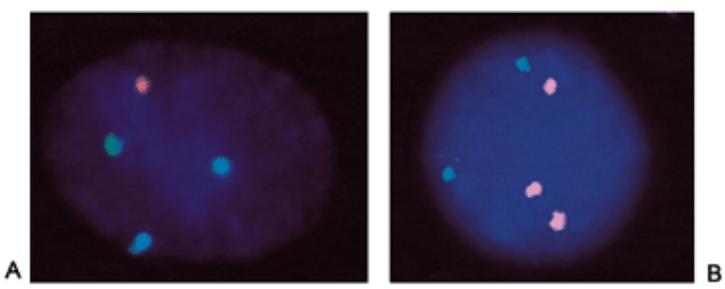

FIGURE 31.6. Fluorescent *in situ* hybridization on uncultured amniocytes. In **A**, using centromere probes for chromosomes X (green), Y (orange) and 18 (aqua), one green and orange signal indicate XY with two aqua signals indicating two copies of chromosome 18. In **B**, region-specific probes for chromosomes 13q (green) and 21q (orange) are used. Three orange signals indicate three copies of chromosome 21 (trisomy 21) and two green signals indicate two copies of chromosome 13.

Including balanced and unbalanced structural rearrangements and chromosomal mosaicism, many of which have clinical implications for other family members as well as for the tested pregnancy, only approximately 65% of chromosome abnormalities are detectable by interphase aneuploidy screening. This weakness, the added cost of the assay, and other technical limitations in aneuploidy screening (28,29) probably account for its narrow acceptance. Although aneuploidy screening is widely available, only approximately 20 laboratories in the United States process more than 50 interphase FISH studies per year. In an era of severe cost constraints in medicine, we discourage most aneuploidy screening by FISH. Nevertheless, situations arise in which the test has added value, such as a late gestational age pregnancy with defects identified on ultrasound examination that are consistent with a known aneuploidy syndrome and in which intervention may be a medical necessity before the results of routine cytogenetic studies become available.

FISH testing using a probe for the critical region associated with velocardiofacial syndrome (deletion 22q11 syndrome) is appropriate for any fetus with a structural heart defect detected on ultrasound. This test can be done after a routine G-banded karyotype analysis if the karyotype is otherwise normal. FISH testing using other individual probes or probe kits can also be useful to characterize rearrangements and marker chromosomes when parental chromosome studies are not informative.

CHROMOSOME ANALYSIS FOR PRENATAL DIAGNOSIS

Part of "31 - Prenatal Cytogenetic Diagnosis"

The analysis of prenatal specimens is done in much the same way as for blood or tissue samples, as described in Chapter 30. The major difference with this specimen type is that cells for analysis can be selected from multiple distinct colonies. Each colony represents an independent sample of a cell or cells taken from the amniotic fluid or chorion. A laboratory ideally should be able to provide a reporting time of 3 to 6 days for PUBS, 6 to 12 days for CVS cultures, and 7 to 14 days for amniotic fluid cell cultures.

For *in situ* harvests, the College of American Pathologists and the American College of Medical Genetics (30) recommend analysis of at least 15 metaphase cells taken from 15 different colonies and representing at least two independent cultures. In general, one cell per colony is analyzed, but other cells in the colony should be analyzed if an abnormality is found. We try to sample the greatest variety of cells to increase the likelihood of finding mosaicism and to reduce the risk of maternal cell contamination. Our decision tree for the number of metaphase cells to study is similar to the revised recommendations of Hsu and

Benn (31) for a standard, moderate, or extensive workup (Table 31.10).

TABLE 31.10. PRENATAL KARYOTYPE ANALYSIS

Number of cells to study		
Routine colony analysis: 15/15/2 (15 cells from 15 colonies from at least two cultures)		
CVS direct preparation: can serve for no more than four of the 15 cells		
Heart defect by ultrasound: 15/15/2 and FISH for 22q11 deletion		
FISH is not needed for echogenic focus or hypoplastic left heart[a]		
Amniotic fluid study after CVS mosaic diagnosis: 30/30/3		
Nonclonal analysis (suspension harvest or subcultures):		
20 cells with at least two cells from a second culture		
Mixed-colony and nonclonal analysis:		
20 cells including as many different colonies as possible		
Looking for mosaicism:		
If additional analysis is required, study colonies from other cultures		
one colony with one or more cells:	then analyze a total of:	and if normal, interpretation is:
Monosomy	20/20/2	Pseudomosaic
Trisomy	30/30/3	Pseudomosaic
45,X,–Y or 45,X,–X	30/30/3	Pseudomosaic
Balanced rearrangement	20/20/2	Pseudomosaic
Unbalanced structural change	20/20/2	Pseudomosaic
+ marker	20/20/2	Pseudomosaic
Tetraploidy	15/15/2	Artifact
One mixed colony		
46/45 any missing chromosome	15/15/2	Random loss
46/47,+13, +18, +21, ±X, ±Y	20/20/2	Artifact
46/other abnormality	15/15/2	Artifact
46/92	15/15/2	Artifact
multiple colonies in only one culture		
Unbalanced structural change	30/30/3	Pseudomosaic
+ marker	30/30/3	Pseudomosaic
Mixed colonies with 46/92	15/15/2	Artifact
Tetraploidy, pure	30/30/3	May require follow-up
multiple colonies from more than one culture		
46,XY/46,XX	15/15/2 46,XY	Maternal cell admixture, chimerism is very rare
Any other result	30/30/3	True mosaic, may consider UPD studies

These guidelines are used in our laboratory and are provided as an example of protocol development to make the most efficient use of personnel working at the microscope and to assist the staff in the preliminary interpretation of findings that are usually not clinically significant. All abnormal cells are also brought to the attention of the person responsible for clinical interpretation of the karyotype findings.
CVS, chorionic villus sampling; FISH, fluorescent *in situ* hybridization; UPD, uniparental disomy.

[a] Thomas, JA, Graham JM Jr. Chromosome 22qll deletion syndrome: an update and review for the primary pediatrician. *Clin Pediatr* 1997;36:253–266.

For CVS, reliance on direct chromosome preparations alone is not recommended. Cultured cells or pooled analysis from direct preparations and cultures is preferable. If both methods are employed, at least 15 cells should be analyzed, with at least 10 cells coming from the culture harvests.

It is important to confirm abnormal prenatal diagnosis results after birth or pregnancy interruption. The parents very often benefit from certain knowledge of a correct result, and the practice serves as a powerful quality-control device for the cytogenetics laboratory. For a urea termination, fetal tissues are usually nonviable in tissue culture, but an amniotic fluid sample can be obtained before instillation of the urea, and chorionic villi obtained after delivery are also usually viable.

CYTOGENETIC RESULTS

Part of "31 - Prenatal Cytogenetic Diagnosis"

Growth Failure

For amniotic fluid samples, growth failure is rare in an experienced laboratory. Aside from technical catastrophe, sources of growth failure include maternal urine or hygroma fluid submitted as amniotic fluid or heat or cold damage during transport of the specimen to the laboratory. A bloody amniotic fluid sample may grow more slowly, but a result can usually be expected. First-trimester CVS growth failure should be well under 1% for specimens that contain 5 mg or more of chorionic villi and have visible blood vessels (32,33). The amniotic fluid cell culture failure rate should be 0.1% or less.

Maternal Cell Contamination

A few mitotic cells of maternal origin are observed in approximately 0.2% to 0.5% of amniotic fluid cultures. We request at least two aliquots of fluid and find that maternal cell contamination (MCC) is usually confined to cultures established from the first tube collected during amniocentesis. Some laboratories prefer to discard the first 2 mL of amniotic fluid. MCC is usually not an interpretive problem because in almost every recognized case, the majority of colonies in the culture are not maternal, and diagnostic errors (wrong sex or missed chromosome abnormality) are rare. Clusters of MCC can be caused by an inexperienced person performing the amniocentesis procedure.

In CVS direct preparations, the very low rate (less than 0.1%) of MCC is owing to the relative absence of mitotic activity in the decidual fragments. The experience varies among laboratories, but MCC is identified as a 46,XX/46,XY admixture in 0.5% to 2% of CVS cultures. Undoubtedly, there is an equal frequency of unrecognized admixtures of maternal and 46,XX fetal cells. The maternal cells are usually in the minority and have caused few cytogenetic errors in experienced laboratories, although their presence can be problematic for biochemical or DNA assays.

The theoretical concern is that a mixture of 46,XX and 46,XY may represent a true chimera. The incidence of chimeras has been estimated to be one in 60,000 newborns. Weighing this incidence against the rate of 46,XX/46,XY cell admixture in prenatal genetic cell cultures, the likelihood of MCC in any individual case seems very high, even if 46,XX cells are seen in multiple culture vessels. When the 46,XX cells are confined to one or a minority of the cultures, they almost certainly represent MCC. When an XX/XY admixture is identified, some laboratories raise the question of chimerism and some do not. Exceedingly few true chimeras identified in prenatal genetic studies have been described in the literature, and it is likely that a chimera presenting at prenatal diagnosis will not be identified as such. Often, the XX/XY admixture is identified in cultures established from the same tube of amniotic fluid, making MCC the most likely interpretation. Other possible sources of XX/XY admixture include cross-contamination of samples, twins, or a resorbed twin. An ultrasound examination for fetal gender may be of value in selected cases.

Chromosome Rearrangement

If a chromosome rearrangement is identified, parental karyotype studies are indicated because the risk to the fetus depends on whether the rearrangement is balanced and whether it is familial (34,35) (Table 31.5 and Table 31.11). A balanced familial translocation or inversion does not confer a significantly increased risk for birth defects or mental retardation nor does a familial extra marker chromosome. A duplication or deletion involving euchromatin generally results in mental retardation with or without birth defects. A familial robertsonian translocation involving chromosome 14 or 15 appears to carry a small increased risk of uniparental disomy (UPD) (40; LG Shaffer, personal communication, 1999).

TABLE 31.11. ESTIMATE OF THE INCREASED RISK OF MENTAL RETARDATION (WITH OR WITHOUT BIRTH DEFECTS) ASSOCIATED WITH CHROMOSOME REARRANGEMENTS

Type of Rearrangement	Risk Estimate (%)
Unbalanced rearrangement	Nearly 100
Balanced rearrangement	
Familial	0
Robertsonian involving 14 or 15	˜0.5, test for UPD
De novo	
Robertsonian translocation	0–1
Reciprocal translocation	3–15
Inversion	6–20
Extra marker, familial	Near 0
Extra marker, *de novo*	
Not satellited	15–28
Monosatellited	7–20
+i(12p) or +i(18p)	100
Bisatellited	
Monocentric	Probably <5
Dicentric, 1 G-light band	Probably <10
Dicentric, >1 G-light band	High risk

The background risk is estimated to be 3%, so total risk is the sum of the two risk estimates. The total frequencies of each class of abnormality are summarized in Table 31.4. Statistics are from many sources, including Crolla et al. (36), Hsu (37), Hsu and Perlis (38), Warburton (34), Steinbach et al. (39), and Van Dyke, unpublished data.

UPD, uniparental disomy.

Extra Marker Chromosomes

For an extra marker chromosome (also termed extra small accessory chromosome), whether mosaic or not, the karyotype of each parent needs to be studied with specific attention to the presence of a similar marker in a small proportion of their blood cells (35,39). Approximately 60% of such markers identified in our program are familial. If the marker is a small acrocentric, consider the possibility that one parent carries the relatively common t(11;22) translocation associated with cat's-eye syndrome (Table 31.5 and Table 31.11 and Fig. 30.7).

If the marker is not familial, its chromosomal origin should be determined to the extent possible. Approximately 85% of extra markers are satellited, and most of these are derived from chromosome 15 or 22. If the marker is satellited, FISH testing using a beta-satellite probe (for the heterochromatic region of the acrocentric chromosomes) and alpha-satellite probes for each of the acrocentric chromosomes can be performed to determine whether it is mono- or bisatellited. If the marker is bisatellited and either monocentric or dicentric with only a tiny amount of G-band light-staining material between the centromeres, the empirical risk to the fetus is small (Table 31.11). If the marker is

derived from chromosome 15, additional FISH and UPD studies may be required to estimate the risks to the fetus (40,41,42 and 43). If the marker is small and derived from chromosome 14 or 22, it may be important to consider testing for UPD of chromosome 14 and for duplication of proximal 22q (cat eye syndrome, see Chapter 30).

If the marker is not familial and is nonsatellited (approximately 15% of extra markers), FISH techniques such as M-FISH or 23-chromosome centromere kits may be used experimentally to identify its chromosomal origin. At least an X and Y centromere region probe should be considered, as approximately 25% are X or Y derived. A small ring chromosome can easily be distinguished from a rod chromosome using a routinely stained (nonbanded) preparation. A ring chromosome will have ring shape; even a tiny ring chromosome will look like a ring in at least some cells. Many cytogeneticists are using FISH techniques to characterize these small marker chromosomes to improve genetic counseling and to improve our understanding of the associated risks (44,45). Several extra markers have been associated with UPD of the normal homologs, so UPD testing is probably indicated if the chromosomal origin of the marker can be established.

Polyploidy

A diagnosis of tetraploidy or mosaic tetraploidy should be confirmed by an independent specimen and follow-up detailed ultrasound examination, unless defects were observed by ultrasound. Tetraploidy is a common artifact of harvest procedures in monolayer cultures. Triploidy is an occasional finding in prenatal studies, and, when seen in an amniocentesis culture, unambiguous abnormalities are usually evident on ultrasound examination.

Autosomal Monosomy Mosaicism

Rare cases of true mosaicism for monosomy 21 and monosomy 22 have been reported. A diagnosis of monosomy mosaicism should be considered if multiple cultures have colonies with the same monosomy. The diagnosis is sufficiently uncommon that detailed ultrasound and a confirmatory study (amniocentesis or PUBS) can be considered.

Trisomy 20 Mosaicism

Approximately one in 2,500 amniotic fluid cell cultures reveals true trisomy 20 mosaicism. Many cases have been confirmed in fibroblast cultures from various tissue sources from the fetus or newborn, including urine sediment cells (originating from the bladder and kidney) and extrafetal membranes, although almost never from peripheral blood cultures. The clinical significance of this finding is still poorly understood; however, a trisomy 20 syndrome has not been described, but approximately 6% of cases have an abnormal outcome, and among cases with more than 50% of cells with trisomy 20, the risk appears to be closer to 20% (46). Most newborns with this prenatal diagnosis have had a normal phenotype at birth and during early childhood. More long-term follow-up studies are needed to provide better information to parents.

Sex Chromosome Aneuploidy

The phenotypes of the nonmosaic sex chromosome abnormalities 45,X; 47,XXX; 47,XXY; and 47,XYY are described in Chapter 30 and were reviewed by Robinson et al. (47). The incidences

TABLE 31.12. PRENATAL EFFECTS OF CONFINED PLACENTAL MOSAICISM

Chromosome	Risk
2	Moderate for IUGR
3	Moderate for IUGR
7	Low
8	Low
9	Moderate for IUGR
13	Moderate to high for IUGR
15	Moderate for IUGR
16	High for IUGR or IUFD

20	Low
22	Moderate to high for IUGR or IUFD
X	Low
Tetraploid	Low

IUGR, intrauterine growth retardation; IUFD, intrauterine fetal demise.
From Leschot NJ, Schuring-Blom GH, Van Prooijen-Knegt AC, et al. The outcome of pregnancies with confined placental chromosome mosaicism in cytotrophoblast cells. *Prehat Diagn* 1996;16:705–712.

of 47,XXY and 47,XXX increase with advancing maternal age, and together they constitute nearly 10% of the chromosome abnormalities we have detected prenatally.

45,X/46,XY Mosaicism

Determine whether the 45,X cell population is secondary to the presence of a cell population with an unstable Y-chromosome rearrangement such as a ring or dicentric. Such karyotypes represent a distinct and clinically important diagnostic group.

In our experience, simple 45,X/46,XY mosaicism constitutes approximately 2% of all abnormalities found prenatally. In many of the first X/XY cases, the pregnancies were terminated because of the known association with Ullrich-Turner syndrome, mixed gonadal dysgenesis, and ambiguous genitalia. However, because most of the fetuses had normal-appearing male external genitalia, the parents of most of the more recent cases have continued the pregnancies. Although further research is required, the risk of abnormal sexual differentiation in prenatally diagnosed 45,X/46,XY is 5%. Detailed ultrasound examination of the external genitalia can be useful. The mosaicism is occasionally confirmed in fetal or extrafetal tissues. Confirmatory cytogenetic studies and long-term clinical follow-up are encouraged (48).

45,X/46,XX Mosaicism

This prenatal diagnosis requires further study, but in the absence of ultrasound evidence of a cystic hygroma or nonimmune hydrops, there may be little risk of fetal death or an Ullrich-Turner syndrome phenotype. As with 45,X/46,XY, this result appears to be consistent with a normal phenotype in most instances. The risk of isolated gonadal dysgenesis without an Ullrich-Turner phenotype is uncertain in this group. Many have normal puberty and fertility, although there is a suggestion of an increased risk of miscarriage or early menopause, so the 45,X/46,XX mosaic would want to take this into consideration in her own family planning. As with other prenatally diagnosed mosaics, cytogenetic confirmation and long-term follow-up are encouraged.

Prenatal Diagnosis of Mosaicism

Chromosomal mosaicism is one of the most academically interesting areas in clinical cytogenetics. Because of its clinical significance, the diagnosis of mosaicism has been particularly challenging in prenatal cytogenetic studies (38,49,50 and 51). When an abnormality is found in some but not all cells, the clinical significance is not always clear, and several possibilities need to be considered, including MCC, true fetal mosaicism, confined placental mosaicism (CPM), and cell culture artifact.

No cytogenetic techniques can identify all mosaics. Amniotic fluid cell karyotypes exhibit mosaicism in approximately 0.3% of studies, and the majority of these can be confirmed by analysis of other tissues. In practical terms, true mosaicism is considered to be confirmed only if the abnormality is identified in more than one culture vessel or preparation. Mosaicism limited to a single culture vessel is termed *pseudomosaicism* (52). Based on the high frequency of pseudomosaicism (approximately 4% of all amniotic fluid karyotype studies), and the very small number of reported false-negative results, pseudomosaicism probably reflects true fetal mosaicism in fewer than 1% of cases (53,54 and 55). Although it is possible to garner additional data using FISH (56), the additional data are not always easy to interpret, and we are not aware of any laboratories that routinely employ FISH when pseudomosaicism is detected.

Many laboratories use different protocols depending on whether the possible mosaicism is consistent with viability. However, because most rare autosomal aneuploidies have been reported as mosaics in liveborn infants (Table 30.2) (57), we treat almost all cases of possible mosaicism in much the same way (Table 31.10).

Chorionic villus cell karyotype studies exhibit true mosaicism in approximately 2% of studies, but only approximately 10% of these represent true mosaicism in the fetus (58). Most of the remainder reflect mosaicism that is confined to the placental tissues (59). CPM is observed more often in direct preparations of cytotrophoblast cells than in preparations from cultured cells from the villus mesenchyme (50). The rate of true mosaicism interpreted only as pseudomosaicism is probably much lower than for amniotic fluid cell cultures.

CPM can be clinically significant in two principal ways. First, many CPM mosaics identified with CVS probably arise as trisomic conceptions. Fetal viability is salvaged by a compensating mitotic nondisjunction (trisomy rescue) that produces a karyotypically normal cell population, and, as discussed in the previous chapter, trisomy rescue can result in clinically significant UPD.

Second, CPM for some chromosomes is associated with an increased risk of IUGR or intrauterine fetal demise (IUFD) (60). The specific risks are not well understood, but CPM can be confirmed in at least 35% of CVS-identified mosaics that are later associated with IUGR (61). Likewise, detailed cytogenetic studies of term placentas from IUGR pregnancies indicate that at least 5% of isolated IUGR is associated with CPM (62,63). The risks differ depending on the chromosome involved, with CPM trisomy 9, 16, and 22 apparently having the greatest risks of severe IUGR and IUFD. A meiotic origin of the trisomy appears to confer a greater risk than a mitotic origin (64). When CVS-identified CPM is associated with fetal malformations, it seems likely that UPD or true fetal mosaicism is also present. More studies are needed to understand fully the effects of CPM, UPD, and tissue-limited fetal mosaicism on placental insufficiency and fetal demise (Table 31.12).

Among nonmosaic trisomy 13 and 18 liveborn infants, placental karyotype studies indicate that CPM with chromosomally normal placental cells contributes to the viability of these two nearly lethal trisomies (65).

Protocol for Mosaicism

Several protocols have been proposed to distinguish true mosaicism from pseudomosaicism. Because we employ an *in situ* harvest method for both amniotic fluid and chorionic villus cell cultures, our protocol for dealing with possible mosaicism is similar for both cell types (Table 31.10). Stated briefly, true mosaicism is likely only when abnormal colonies are detected in independent preparations.

Mixed Colony

If one colony has a mixture of abnormal and normal cells, and no other colony shows that abnormality, the abnormal cells are usually considered an *in vitro* artifact.

Most amniotic fluid cell colonies represent single clones, but most CVS colonies do not. A colony can arise from several cells attached together in the original inoculum; cells can be dislodged during handling and feeding of cultures; and the cells do have limited mobility, so they can infiltrate nearby colonies or establish new, apparently independent colonies. Furthermore, independent clones can form a single colony as they expand. We have observed mosaicism limited to one side of a large colony, with normal cells on the other side. This might be interpreted as a mixed colony, but examination of the clonal growth patterns under lower magnification can sometimes reveal that there were originally two separate colonies.

Pure Colony

If one colony is abnormal, we usually attempt to score five to 15 additional colonies for that abnormality, particularly colonies in other cultures. In most cases, the additional cells scored do not have the same abnormality, and the abnormal colony is interpreted as a probable artifact of no clinical significance (pseudomosaic).

Single Abnormal Cell

If a colony has only one metaphase, its karyotype is abnormal and the abnormality is not consistent with a viable mosaicism (Table 30.2), it is reasonable to interpret it as an artifact (pseudomosaic) (67). A single hypodiploid cell (even 45,X) almost always represents an artifact of culture or slide preparation. However, if the defect is consistent with a viable numerical or structural mosaicism, we follow the same protocol as for a pure abnormal colony, and score five to 15 additional colonies for that abnormality (Table 31.10).

Multiple Pure Colonies in One Culture

If multiple colonies have the same chromosome abnormality, all from the same culture vessel, we attempt to score 15 or more additional colonies from other culture vessels. In actual practice, the technologists often score all colonies from all available cultures. It seems highly unlikely that a mutation in cell culture could produce more than two or three abnormal colonies. In an amniotic fluid cell culture, as well as in a CVS culture, multiple abnormal colonies may reflect CPM with fragments of cytogenetically abnormal chorionic villi having been introduced into just one culture vessel. If the mosaicism is not confirmed in any other cultures, the finding is usually interpreted as an artifact (pseudomosaic) or confined placental mosaicism.

Although follow-up at birth is encouraged, aggressive prenatal follow-up studies, such as repeat amniocentesis, or amniocentesis after CVS for analysis of another tissue, are generally not done if the mosaicism is limited to a single culture vessel. Such aggressive follow-up would increase the risks to the fetus without ensuring an accurate cytogenetic diagnosis. If all the colonies in one culture have the same abnormal karyotype, but no colonies from other cultures have it, one must consider the possibility of mixed-up samples.

Multiple Mixed Colonies in Multiple Cultures

This situation is very unusual but may raise questions of an unstable chromosome, such as a ring or dicentric, or of a chromosomal instability syndrome, which would need further investigation. Tetraploid and diploid cells appearing together within multiple colonies probably reflect a tissue culture artifact.

Chromosomal fragile sites, other than the fragile site at Xq27.3, are generally considered to be of no clinical significance but can present themselves in this way (Fig. 31.7). Region 1q11–q12 is a C-band positive variable region, also known as 1qh or, in the older literature, the “uncoiler locus.” In CVS preparations, 1qh is true to its original moniker because in some individuals, it uncoils dramatically (Fig. 31.7). This behavior is not observed to the same extent in routine preparations of other cell types and is of no known clinical significance when observed in a CVS preparation.

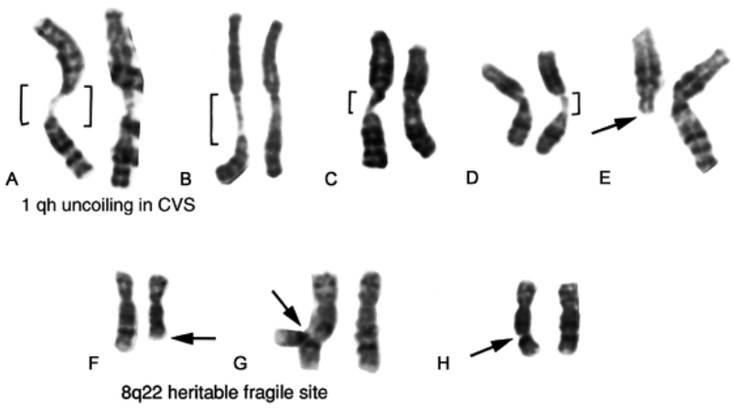

FIGURE 31.7. The uncoiler locus and the fragile site at 8q22. Chromosome 1 uncoiling **(A–D)**, usually not seen in chromosome preparations from other cell types, is a common artifact in CVS preparations. Both homologs (as in **A**) are frequently involved, and in occasional cells **(E)**, an entire arm is lost. A chromosomal fragile site can give the appearance of chromosomal mosaicism by producing multiple colonies with the same abnormality, yet have no clinical significance. The case depicted here had three colonies with one or two cells **(F)** having a del(8)(q22); the remaining cells in each colony had a normal karyotype. One cell **(G)** had a triradial configuration at 8q22. Many other cells had a chromatid break or chromosome break **(H)** at the same site. This finding was interpreted as a heritable fragile site with a high rate of chromosome breakage located at the common fragile site 8q22.

Multiple Culture Vessels

If an abnormality is observed in multiple colonies grown in more than one culture vessel, the interpretation is true mosaicism. Genetic counseling is indicated, and follow-up depends on the cytogenetic abnormality and on whether the mosaicism is identified in CVS or amniotic fluid cell cultures.

Follow-up Studies for Amniotic Fluid Cell Mosaicism

For true mosaicism in an amniotic fluid study, a confirmatory prenatal study is usually not undertaken. A follow-up study and a detailed ultrasound examination of the fetus may be appropriate when (a) the physicians and family agree to confirm mosaicism (or other abnormal result) when the family's decision would be to consider interrupting the pregnancy only if the abnormality

is confirmed, (b) only a single culture is available or an uncertain result is obtained from a very small sample of amniotic fluid or villi, (c) the quality of the cytogenetic preparation is below usual standards and has led to an uncertain result, and (d) a 46,XX and 46,XY admixture in multiple cultures is observed (raising the possibility of chimerism).

A normal result on confirmatory studies cannot rule out mosaicism nor ensure a normal outcome of the pregnancy. Even if mosaicism is confirmed by amniocentesis or CVS, the clinical interpretation is subject to uncertainties about the risk to the fetus and the likelihood of the mosaicism in the fetus. In some circumstances, tissue-limited mosaicism is possible (e.g., trisomy 20 or extra marker chromosome), so a PUBS is not always an appropriate sample for confirming mosaicism.

There are many unknowns in the clinical interpretation of mosaicism, *de novo* balanced rearrangements, and extra marker chromosomes. For this reason, we urge all groups involved in prenatal diagnosis to participate in cytogenetic and clinical follow-up studies, including long-term clinical follow-up, and cytogenetic studies of placenta, amnion, circumcision skin, and other tissues when possible.

In low-level true mosaicism, the clinical risks are not always clear, and follow-up using PUBS and detailed ultrasound examination may be informative (46). UPD studies may be indicated to clarify clinical risks for low-level mosaicism for some abnormalities, such as trisomy 15 (Table 31.13).

TABLE 31.13. UNIPARENTAL DISOMY AND PHENOTYPE

Chromosome	Effect of Maternal UPD	Effect of Paternal UPD
1	None	None
2	IUGR?	No cases
3		No cases
4	None	No cases
5	No cases	None

15	Prader-Willi syndrome	Angelman syndrome
16	IUGR, birth defects in some?	None
17	No cases	No cases
18	No cases	No cases
19	No cases	No cases
20	None	None
21	None	None
22	None	None
XX	None	Short stature?

The clinical importance of uniparental disomy (UPD) is discussed in greater detail in Chapter 30. Also discussed in Chapter 30 are Russell-Silver, Beckwith-Wiedemann, Prader-Willi, and Angelman syndromes. Listed here are the reported effects of UPD for individual chromosomes (57,62,64,67,68 and 69). The conclusions are often based on very small sample size (sometimes only one case), and in some instances autosomal recessive disease or tissue-limited mosaicism in the fetus cannot be excluded. For most chromosomes, information is based on individual case reports, so the magnitude of the risk of UPD is not known. No studies have been conducted to determine the frequency and clinical effects of UPD in unselected populations, so the risks are uncertain but not negligible (70). Several cases of UPD15 have been diagnosed prenatally after detecting trisomy 15 mosaicism in amniotic fluid or chorionic villus sampling cell cultures (40,71).
None, no clinical effect suspected; no cases, none has been identified as yet; MR, mental retardation.

Follow-up Studies for CVS Mosaicism

Mosaicism found in a CVS requires follow-up. This usually includes amniotic fluid cell karyotype studies. If mosaicism is detected in a direct preparation but not in the cultures, there is approximately a 7% chance that it will be confirmed (58). If the mosaicism is detected in CVS cell cultures, approximately 11% are confirmed, and if both a direct preparation and cultures are mosaic, approximately 21% are confirmed by amniocentesis. Mosaicism for trisomy 13, 18, or 21 is confirmed in approximately 19% of cases, sex chromosome aneuploidy in approximately 15%, extra marker chromosomes in approximately 25%, and all others in fewer than 10% of cases. A normal amniocentesis result indicates that the fetus is most likely not mosaic, although CPM is likely and in some cases this confers a risk of IUGR or IUFD (Table 31.12). If the mosaicism involves a chromosome that is imprinted, UPD studies may be indicated (Table 31.13).

Cytogenetic Studies in Neoplastic Hematologic Disorders

Gordon W. Dewald

Rhett P. Ketterling

William A. Wyatt

Peggy J. Stupca

Conventional cytogenetic studies help classify malignant hematologic disorders that are associated with specific chromosome abnormalities. The observation of cytogenetic subclones provides clues to disease progression. Cytogenetic studies are useful to assess the effectiveness of treatment and to monitor remission. Moreover, fluorescence *in situ* hybridization (FISH) with chromosome-specific DNA probes enhances testing for patients with malignant hematologic disorders. FISH readily permits analysis of large numbers of proliferating (metaphase) and nonproliferating (interphase nuclei) cells and is useful in establishing the percentage of neoplastic cells before and after therapy. Consequently, cytogenetic studies are widely used by hematologists in the diagnosis and management of their patients. In 1995, the 190 United States' cytogenetics laboratories collectively reported doing 82,855 chromosome studies on patients with neoplastic hematologic disorders (1).

This chapter presents a model for the role of chromosome abnormalities in the origin and progression of malignant hematologic disorders. Information is provided about the types of specimens to collect, procedures for transporting specimens, common laboratory procedures, and the interpretation of results for conventional cytogenetic studies. The application of FISH in the workup and management of patients with hematologic disorders is emphasized. An overview of genetic testing to assess the effectiveness of treatment and discriminate between congenital and acquired neoplastic cytogenetic abnormalities is presented. Finally, the kinds of chromosome abnormalities that occur and their association with current classification schemes for hematologic disorders are presented.

CHROMOSOMAL BASIS OF MALIGNANCY

Part of "32 - Cytogenetic Studies in Neoplastic Hematologic Disorders"

Types of Chromosome Abnormalities

Chromosome abnormalities generally are classified as either numerical or structural (Fig. 32.1). The numerical abnormalities are subclassified into polyploid or aneuploid. The term polyploid refers to chromosome complements that are multiples of 23, which is the haploid number of chromosomes; for example, diploidy refers to 46 chromosomes, triploidy to 69 chromosomes, and tetraploidy to 92 chromosomes. In neoplastic disorders, most polyploid clones associated with advanced stages of disease are derived either from the fusion of neoplastic cells or from endoreduplication.

Aneuploid refers to chromosome complements that involve irregular multiples of the haploid number. For example, a cell that has trisomy 8 is characterized by 47 chromosomes, including three number 8 chromosomes. A cell that is monosomy 7 contains 45 chromosomes and is lacking a chromosome 7. Aneuploid abnormalities usually occur as a consequence of mitotic malfunction, such as chromosome nondisjunction.

Structural abnormalities are classified as translocations, deletions, inversions, duplications, or isochromosomes. Reciprocal translocations involve the interchange of parts of different chromosomes and are the most common type of translocation in hematologic disorders. Deletions involve the loss of part of a chromosome and are either terminal or interstitial. Inversions produce a reversal in the direction of an interstitial part of a chromosome and are either pericentric or paracentric. Pericentric inversions involve both arms while paracentric inversions occur on one arm. Duplications produce two or more copies of a particular DNA segment on the same chromosome. Isochromosomes produce a mirror-image band pattern with respect to the center of the chromosome and arise from a break and fusion of sister chromatids or a translocation between homologous chromosomes.

Origin of Abnormalities

Most structural abnormalities of chromosomes originate during replication or repair of DNA, when the DNA is particularly vulnerable to breakage and fusion. Structural abnormalities of chromosomes occur in interphase when chromosomes are uncoiled and DNA of different chromosomes is overlapped or in close association. DNA breakage and refusion can involve multiple loci and occasionally DNA from several chromosomes. These events may be from recombination involving repetitive or homologous DNA sequences. The subsequent refusion or repair of broken DNA can result in the formation of variant translocations with

or without DNA loss. This observation explains why certain variants of classical structural abnormalities are associated with specific hematologic disorders.

The Ph-chromosome is an example of variation in DNA breakage and fusion in the origin of a specific translocation. Conventional cytogenetic studies indicate several forms of Ph-chromosomes, including classical t(9;22)(q34;q11.2), complex (three or more chromosomes) or masked (submicroscopic insertion). Molecular genetic studies provide evidence of further genetic variation among Ph-chromosomes. In some patients, small deletions and duplications of DNA sequences have been detected within the BCR and ABL gene. Moreover, the DNA break and fusion point with the BCR may occur within the major or minor BCR region and sometimes elsewhere within the BCR region.

FISH studies suggest even further genetic variation among Ph-chromosomes (2). The typical Ph-chromosome involves a break in the BCR region on chromosome 22 and ABL region on chromosome 9. Usually, a reciprocal translocation forms so that a BCR/ABL fusion occurs on both the abnormal chromosomes 9 and 22. Approximately 20% of these patients have an atypical FISH pattern at the fusion site on the abnormal chromosome 9, which indicates loss of portions of the BCR and/or ABL hybridization sites and some adjacent DNA sequences. This loss of DNA sequences most likely occurs during the formation of translocations and does not appear to affect the oncogenic process of chronic myeloid leukemia.

Chromosome abnormalities occur sporadically in cells of every person on a regular basis. In the authors' cytogenetic practice, structural chromosome abnormalities are observed in normal bone marrow specimens at a frequency of 0.6%. These sporadic cells occur in all tissues and represent new mutations rather than clinically significant clones. If more than one metaphase in 30 has nonclonal structural abnormalities, most cytogeneticists become concerned that the patient has a breakage syndrome or was exposed to toxic substances such as chemotherapy or an environmental carcinogen. Several genetic mechanisms to repair DNA damage exist. Most damaged DNA is repaired without producing chromosome abnormalities.

Any mutation affecting the genes that control repair processes can significantly affect the proportion of cells with chromosome abnormalities. This explains the considerable incidence of cells with structurally abnormal chromosomes in patients with chromosome breakage syndromes. The incidence of malignant disorders is higher among people with these genetic disorders than among people with normal DNA repair mechanisms.

Patients with Fanconi's anemia have chromosomes that are particularly subject to breakage by bifunctional alkylating agents such as mitomycin C. Culturing cells of Fanconi anemia patients in the presence of alkylating agents like mitomycin C or

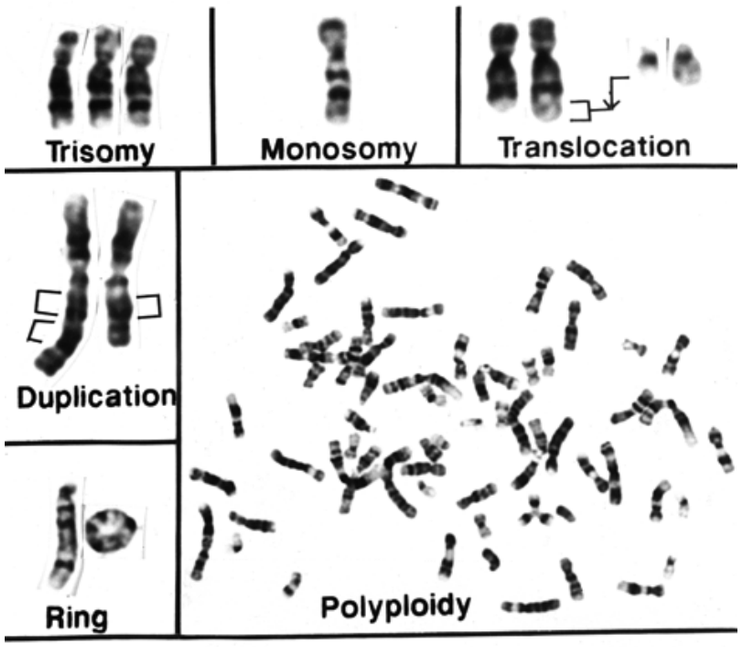

FIGURE 32.1. Examples of common chromosome abnormalities. Trisomy is the presence of three copies of any chromosome. Monosomy denotes the presence of a single copy of any chromosome. Translocations involve the exchange of chromatin between any two or more nonhomologous chromosomes. Duplications produce structural abnormalities with multiple copies of genes. Deletions result in the loss of a portion of a chromosome; a ring chromosome is an example of a deletion. Polyploid cells involve 69 or 92 chromosomes or some exact multiple of the haploid chromosome number.

diepoxybutane, produce many metaphases with radial formations (3). This test is particularly important in the workup of children with aplastic anemia, which may be undiagnosed Fanconi anemia. A chromosome study on peripheral blood must be performed in these patients because they are hypersensitive to alkylating agent chemotherapy, which is used to ablate the bone marrow prior to transplantation. If the patient's chromosomes are hypersensitive, a lower dose of ablative chemicals is needed to avoid causing excess genetic damage in nonneoplastic cells.

Formation of Clones

The clonal pattern of malignancies has been demonstrated with cytogenetic studies, molecular genetic methods, immunocytochemical techniques, enzyme markers, and many other procedures. Cytogenetic studies suggest that nearly all malignant disorders are associated with chromosomally abnormal clones. Numerous cytogenetic reports have been published in recent years recording the presence of chromosomally abnormal clones in a wide variety of hematologic disorders and solid tumors (4).

The formation of each neoplastic clone probably begins with a chromosome abnormality in a single cell, which then proliferates (Fig. 32.2). Observation of identical chromosome abnormalities in different cells of the same tumor is evidence of clonality. The formation of structural abnormalities of chromosomes may be relatively random with respect to the site of breakpoints. Theoretically, a break could affect any site on any chromosome. Considering that the human diploid genome has approximately 6 billion base pairs distributed among 46 chromosomes, about 36×10^{18} different chromosome rearrangements are possible. Certain chromosome abnormalities may produce biologically significant genetic imbalances that affect critical cellular pathways and may result in cell death prior to proliferating. Other chromosome abnormalities may be balanced, which may not affect the cell phenotype or may produce clones with malignant potential. This effect has been observed in patients with ataxia-telangiectasia.

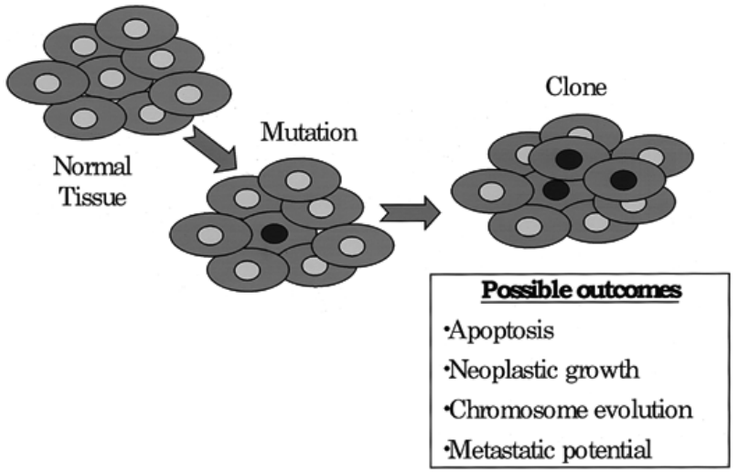

FIGURE 32.2. Formation of a clone. In the early stages, the cells of a chromosomally abnormal clone may die as a consequence of genetic imbalance or may be destroyed by the immune system. If not, the clone may proliferate and form a malignant tumor, and subclones may form as a result of chromosome evolution.

Some chromosome changes are not lethal, but rather enhance the proliferative potential of cells and promote malignancy. These abnormalities may activate oncogenes or disrupt the action of tumor-suppressor genes, which control critical cellular pathways. This explains the correlation of these chromosome changes to specific malignant neoplastic disorders.

Breakage of chromosomes is most likely not random. The likelihood of developing a chromosome abnormality with oncogenic potential is affected by the presence of fragile sites, the association of homologous DNA sequences, carcinogens, and cell survival (Fig. 32.2). In fact, because the number of possible chromosome rearrangements is 36×10^{18}, the probability of developing a common chromosome abnormality by accident seems so remote that chance alone would not explain the relatively high frequency of hematologic disorders.

Chromosome Evolution and Tumor Progression

As neoplastic cells proliferate in most tumors, additional chromosome abnormalities appear in sporadic malignant cells by “chromosome evolution.” These cells divide to produce subclones that contain the initial chromosome abnormality as well as one or more secondary chromosome abnormalities. For example, in chronic myeloid leukemia a t(9;22)(q34;q11.2) is considered the primary chromosome anomaly. The observation of t(9;22)(q34;q11.2) and trisomy 8 in a subset of cells is evidence of a subclone.

Chromosome evolution is responsible for the complex karyotypes observed in many hematologic disorders. The mechanisms of chromosome evolution include nondisjunction, cell fusion, and a wide variety of structural abnormalities. The role of chromosome evolution in tumor progression is not entirely understood. A general correlation does exist between the aggressiveness of hematologic disorders and the appearance of subclones. The number of chromosome abnormalities in an abnormal clone may provide a crude measurement of tumor progression. Indeed, many high-grade lymphomas have very complex karyotypes, while low-grade lymphomas often have only one or two chromosome abnormalities. Chronic myeloid leukemia and the 5q- syndrome are two well-studied disorders where chromosome evolution correlates with more aggressive stages of the disease. Evidence is rapidly accumulating that suggests a similar correlation exists between karyotype complexity and disease progression in other hematologic disorders, especially among the myeloproliferative and myelodysplastic syndromes.

Chromosome evolution may affect tumor response to therapy. Treating a tumor with multiple subclones may be akin to dealing with a patient who has several concurrent neoplastic disorders. For these patients, it may be necessary to develop more than one form of treatment to combat the genotype of each subclone. Evidence suggests that patients with acute myeloid leukemia evolving from a myelodysplastic syndrome with complex karyotypes do not respond well to standard therapies. By comparison, patients with classical chromosome abnormalities associated with overt acute myeloid leukemia such as t(8;21) and t(15;17), experience better response to standard therapies.

Oncogenes

Cell division is initiated and regulated by numerous genes. Under normal circumstances, the genes that govern cell division serve important functions during embryogenesis, growth, and cell repair to ensure the production of new cells. In mature cells in which mitosis is no longer necessary, these genes are inactive. Through mutation, one or more of the genes that control cell division may become reactivated. These genes are inappropriately expressed and, because of lack of regulation, can result in uncontrolled cell proliferation. These aberrantly expressed developmental genes have become known as oncogenes.

The oncogene copy number is increased by trisomy and decreased by monosomy, but the degree of genetic imbalance seldom is more than one gene copy. Recent evidence has emerged to suggest that in some patients, neoplastic cells with trisomy 11 have a submicroscopic duplication of a portion of the MLL oncogene. It is postulated that this duplication is the primary event and trisomy 11 is a result of chromosome evolution. Similar mechanisms may be important for trisomies of other chromosomes.

Structural changes may be more significant than numerical abnormalities in the activation of oncogenes. Evidence indicates that one or more oncogenes are located near sites of chromosome breakage for several of the specific chromosome abnormalities associated with neoplastic disorders (5). These structural changes alter gene expression either by position effect or gene mutation leading to transcription of the oncogene.

Activation of the c-MYC oncogene by the t(8;14)(q24;q32) in Burkitt's lymphoma is an example of a chromosome abnormality, which deregulates cell division. In this translocation, the breakpoints on chromosome 14 are at 14q32, the site of the heavy-chain immunoglobulin gene and on chromosome 8 at 8q24, the site of the c-MYC oncogene. As a consequence of the 8;14 translocation, the c-MYC oncogene is juxtaposed with the heavy-chain immunoglobulin locus on chromosome 14. Transcription of the c-MYC gene then is controlled by the heavy-chain immunoglobulin gene.

Two other translocations associated with Burkitt's lymphoma provide further evidence for the activation of c-MYC in lymphoproliferative disorders. Some patients with Burkitt's lymphoma have a t(8;22)(q24;q11). This translocation brings the lambda immunoglobulin light-chain gene into juxtaposition with the c-MYC oncogene on chromosome 8. Other patients with Burkitt's lymphoma have a t(2;8)(p12;q24), which brings the kappa immunoglobulin light-chain gene into juxtaposition with the c-MYC oncogene. Each of these translocations is known to activate transcription of the c-MYC oncogene.

This mechanism offers an explanation as to why specific chromosome abnormalities are associated with particular neoplastic disorders. B-cells with a t(8;14)(q24;q32) are neoplastic because the heavy-chain immunoglobulin locus induces a hybrid ribonucleic acid (RNA) molecule that is part c-MYC and part heavy-chain immunoglobulin. This translocation has not been observed in other cell types and thus does not appear to have neoplastic potential in cells in which the heavy-chain immunoglobulin locus is not normally transcribed.

Tumor-Suppressor Genes

Tumor-suppressor genes provide another mechanism for tumorigenesis (5). In normal cells, tumor-suppressor genes regulate cellular proliferation. Germline mutations in tumor suppressor genes predispose individuals to developing malignancies. The malignant process is initiated by a mutation or loss of the normal gene, resulting in absence of gene expression. The loss of the normal gene happens by chromosome nondisjunction or by structural rearrangements such as deletions and unbalanced translocations. In a similar fashion, somatic mutations in both copies of a tumor suppressor gene will result in loss of regulation and tumorigenic potential.

Inactivation of tumor-suppressor genes has been implicated in many hematologic disorders. For example, monosomy 7, del(5)(q13q33), del(6)(q14q32), and other losses of chromosomes are candidates for this mechanism although the specific tumor suppressor genes have not be defined.

CONVENTIONAL CYTOGENETIC ANALYSIS

Part of "32 - Cytogenetic Studies in Neoplastic Hematologic Disorders"

Choice of Tissue

Hematologists who use cytogenetic studies need to provide specimens for chromosome analysis that includes malignant cells. Lymph node biopsy specimens are most suitable for lymphomas. Bone marrow specimens are best for patients with myeloproliferative

disorders, myelodysplastic syndromes, chronic lymphocytic leukemias, and acute leukemias. Chromosome studies often can be accomplished on bone marrow biopsy specimens even if the bone marrow aspirate is paucicellular. If the disease has circulating cells, a peripheral blood specimen can be collected, but for myeloid disorders, this should be done only if bone marrow is not available. Only about 60% of blood specimens produce adequate metaphases as compared to more than 95% of bone marrow specimens. Chromosome analysis of peripheral blood is informative mainly in advanced disorders, chronic lymphocytic leukemia, and some cutaneous T-cell lymphomas.

In certain clinical situations, cytogenetics is required on various body fluids for diagnosis or to rule out metastasis or relapse. These fluids include pleural or ascitic effusions, spinal fluid, and rarely other specimens. In pleural fluids, lymphomas are often more readily diagnosed by cytogenetic techniques than by standard cytologic examination (6). Cytogenetics can be successful even on low volume specimens that appear to lack cells.

Most therapeutic agents interfere with attempts to produce metaphases from specimens because these agents are intended to prevent cell division. Successful chromosome studies usually are possible 2 to 3 weeks after treatment. Although the agents used to treat malignancies may induce sporadic abnormalities in chromosomes, they should not interfere with the identification of chromosomally abnormal clones.

Specimen Collection and Transportation

Routine chromosome studies are performed on mitotically active cells. Bone marrow specimens should be <1 mL to reduce the chance of clotting. Successful chromosome studies routinely are accomplished on 0.25 to 0.50 mL of bone marrow. The specimen should be collected with sodium heparin using sterile techniques. If multiple tests are requested for a bone marrow specimen, cytogenetic studies should receive an early tap to improve the likelihood of obtaining dividing cells. This can be done without interfering with the collection of fresh specimens for standard hematologic examination by redirecting the needle during bone marrow collection.

When transporting bone marrow specimens to a cytogenetic laboratory, particular attention should be paid to transportation methods. Bone marrow specimens up to 1.0 mL can be transported in culture medium or in sodium heparin vacutainers. When fresh bone marrow is transported, it is important to send the sample as soon as possible. Alternatively, preprocessing bone marrow specimens with colcemid solution, hypotonic solution, and fresh methanol-glacial acetic acid may be performed (7). Because the cells are transported in fixative, transportation time and environmental conditions do not affect the laboratories' success in obtaining analyzable metaphases. If cells can be processed locally, both a direct technique and short-term culture methods can be used in concert. This method produces successful chromosome studies approximately 96% of the time.

Chromosome analysis of peripheral blood requires 7.0 to 10.0 mL collected in a sterile syringe containing sodium heparin. The specimen should be transferred immediately to a sodium heparin vacutainer to prevent clotting. Sodium heparin is highly recommended as the anticoagulant of choice because other anticoagulants may interfere with cell viability. A cytogenetic laboratory should be consulted if sodium heparin is unavailable to determine a viable second choice.

Chromosome studies can be done on lymph-node biopsy specimens of 1.0 to 3.0 cm^2. The specimen should be transported in a screw-capped, sterile container with sufficient sterile tissue medium with serum, sterile Hank's balanced salt solution, or a sterile isosaline solution to prevent tissue dehydration. The specimen can be refrigerated or sent to the cytogenetic laboratory at ambient temperature.

Processing Specimens for Chromosome Analysis

Various methods exist to process specimens for chromosome analysis. Specimens can be processed immediately after collection using a direct method. Cells are treated with Colcemid for 1 hour, warm hypotonic solution (0.075 M KCl) for 15 minutes and fixed with 3:1 methanol-glacial acetic acid. This method has a success rate of more than 92% and allows a diagnosis within 24 hours.

Short-term cultures of 24 to 48 hours are used by many laboratories. These cultures use a standard medium such as RPMI 1640 with fetal bovine serum, and antibiotics. Cells are incubated in one to three 25-mL T-flasks at 37°C. It is desirable to use a low-oxygen environment (5% oxygen, 5% carbon dioxide, and 90% nitrogen) with these cultures. Cultures can be incubated overnight (14 to 16 hours) with Colcemid (Roche Pharmaceuticals) and FUdR to improve metaphase quality. Cells are harvested for chromosome analysis using the standard procedures with Colcemid, hypotonic solution, and fixative. These methods are successful for more than 90% of bone marrow specimens.

The *in situ* method involves culturing the cells on six to eight chamber slides or coverslips. The cells are cultured in low oxygen using a culture medium such as RPMI 1640 and harvested. This method avoids loss of cells associated with the T-flask technique, is amenable to robotic harvesting (Tecan, Inc.), and allows cultures to be processed easily with different methods (e.g., with or without mitogens) (8). Because few cells are lost during the harvest process, this method is particularly successful on specimens with a low mitotic index.

Most laboratories process hematologic specimens using both a direct preparation and a short-term culture. A comparison of the direct technique versus 24-hour unstimulated cultures in a blind study of 100 unselected bone marrow specimens revealed no significant differences with respect to chromosome morphology, mitotic index, or the detection of an abnormal clone (9). Nevertheless, because one method occasionally fails, it is useful to routinely use at least two methods with each specimen.

Mitogens are used to stimulate division of neoplastic cells in chromosome studies of patients with lymphoproliferative disorders. Mitogens such as phytohemagglutinin, 12-*O*-tetradecanoylphorbol-13-acetate (TPA), Interleukin-2, pokeweed, and inactivated Epstein-Barr virus have been used successfully. Unfortunately, mitogens also may stimulate normal B-cells and T-cells to divide which can interfere with the analysis. Furthermore, not all cells of lymphoproliferative disorders respond to

mitogens. Some laboratories have success by adding hematopoietic growth factors such as PHA-stimulated leukocyte-conditioned medium.

Several techniques have been used to optimize the band resolution of chromosomes. Longer chromosomes are produced by incorporating DNA intercalaters (e.g., actinomycin D or ethidium bromide), methotrexate, or low concentrations of Colcemid into the culture method.

Staining

The most common chromosome staining methods are G-banding and Q-banding. G-bands are easily induced by a brief pretreatment with an enzyme such as trypsin, followed by staining with Leishman's, Giemsa, or Wright's. G-bands produce permanent preparations that easily permit the identification of each chromosome and the detection of subtle structural abnormalities.

Q-banding involves staining the chromosomes with quinacrine mustard and using a fluorescence microscope system. Because this stain usually fades in a few minutes, n-propyl gallate is used to slow the rate of fluorescence loss. This method permits the identification of all chromosomes and detection of subtle structural abnormalities. Q-banding is the staining technique of choice when there are only a few metaphases or when chromosome morphology or metaphase spreading is poor.

Slide Preparation

Several techniques are used to optimize metaphase spreading. These techniques include the use of cold fixative, dropping cell suspensions from increased heights, flame drying the slides, and various methods to modify the rate at which slides dry. These techniques attempt to influence the characteristics of chromosome spreading by modifying the rate at which metaphases dry and chromosomes spread on the coverslip or microscope slide (10). An environmental chamber by Thermatron can be used to control temperature and humidity, which helps to optimize chromosome spreading.

Analysis of Metaphases

At least 20 metaphases are analyzed in order to statistically exclude a clone that accounts for more than 14% of cells with 95% confidence. The analysis of 30 cells excludes a clone that accounts for more than 10% of cells with 95% confidence. In either case, this assumes that metaphases are selected randomly for analysis. Because not all metaphases provide equal information, many technologists do not randomly select metaphases, and usually examine more metaphases than they actually report. During analysis, the number and band pattern of each chromosome is established. Interfering factors for effective analysis include overlapping chromosomes, inconsistent staining, and variable morphology.

Metaphase and Karyotype Documentation

Several metaphases should be documented by photographs or computer images. Many laboratories use computer-assisted karyotype systems to eliminate darkroom procedures, capture FISH images, and integrate data into the laboratory computer system. For each specimen, formal karyotypes are prepared from representative metaphases to objectively compare band patterns between chromosomes. Most laboratory-certifying agencies require preparation of at least two karyotypes from the primary clone and one karyotype from each subclone.

Definition of a Clone

The standard cytogenetic definition of a clone requires at least two metaphases with the same extra chromosome or the same structural abnormality, or the presence of three or more metaphases missing the same chromosome. The stricter definition for chromosome loss helps exclude technical artifacts.

The definition of a clone should include a maximal number of metaphases to be analyzed because nonclonal chromosome abnormalities are relatively common. We prefer to analyze no more than 30 metaphases in each study to avoid false-positive findings and to use laboratory time most efficiently. Nevertheless, the observation of even one cell with a classic chromosome abnormality could be significant. If this abnormality is reported, it should be stated that this discovery does not meet the minimal criteria for a clone.

FLUORESCENCE IN SITU HYBRIDIZATION (FISH)

Part of "32 - Cytogenetic Studies in Neoplastic Hematologic Disorders"

The advent of fluorescent-labeled DNA probes with *in situ* hybridization greatly enhanced the usefulness of cytogenetics to study hematologic disorders. Many fluorescent-labeled DNA probes can be purchased from commercial companies. Other probes are readily made as “home-brew” products using cosmids, plasmid artificial chromosomes, yeast artificial chromosomes, and bacterial artificial chromosomes. Numerous FISH strategies are available to detect abnormalities associated with neoplastic processes. Moreover, FISH can be performed on both proliferating (metaphase) and nonproliferating (interphase) cells. FISH bridges the testing gap between cytogenetic and molecular genetic studies, is less expensive than conventional cytogenetics, can be performed overnight (sometimes in less than 6 hours), and can produce quantitative results with considerable precision.

FISH is used to accurately define the disease-state of many hematologic disorders at diagnosis, during therapy, and remission. It is beyond the scope of this chapter to discuss the entire field of FISH in hematologic disorders. Enough information about FISH is provided to use this technology in clinical practice.

FISH in Clinical Practice

The utility and accuracy of FISH to detect chromosome abnormalities has been established in hematologic disorders. However, the Food and Drug Administration (FDA) has approved only a few commercial FISH probes. Recent data from the College of American Pathologists and American College of Medical Genetics indicate that FISH is widely used by cytogenetic laboratories (11). Nomenclature for both metaphase and interphase FISH

has been created and adopted by cytogeneticists (12). Accrediting agencies have published criteria for FISH in routine practice and at least one accrediting agency provides an on-going proficiency testing program for FISH(11, 13).

Validation of FISH Tests

Validation of new tests is necessary to ensure safe and effective testing for the specific intended clinical purpose. Validation of FISH tests is a multistep process designed to assess probe performance in normal and abnormal specimens, and to establish the ability of laboratory personnel to perform the test consistently.

The procedures to validate FISH tests vary significantly depending upon the specific clinical application and FISH methodology (i.e., whole chromosome-specific paints, centromere-specific probes, locus-specific or telomere-specific probes). Moreover, the extent of validation among laboratories varies depending on probe approval by the FDA and the extent of published work regarding the test. Procedures to validate FISH tests have been reported (13, 14), but because this is a new field, it is anticipated that this subject will be dealt with in more detail by accrediting agencies in the future.

Validation and scoring criteria should consider several factors. Certain biological and technical factors introduce false signal patterns and affect the accuracy of FISH to detect and quantify neoplastic cells. Split signals can result from G_2 separation and asynchronous replication of DNA sequences. In addition, cells in normal individuals occasionally demonstrate aneuploidy. Probe signals sometimes appear to split because of incomplete saturation of the hybridization site, coincidental overlap of signals, and occasional cross-hybridization.

Advantages of FISH

FISH tests can be performed on uncultured interphase nuclei using overnight procedures. Thus, for hematologic disorders where a quick diagnosis is important, FISH is particularly useful. Acute promyelocytic leukemia (AML-M3) is an example of a hematologic disorder where a rapid diagnosis is possible by FISH and these patients can die quickly if left without proper treatment.

Sometimes hematologic specimens are not available for conventional cytogenetic studies. In these cases, FISH studies of interphase nuclei can be performed on a variety of specimens, including fixed cells from peripheral blood or bone marrow, smears made from peripheral blood or bone marrow, touch preparations, and paraffin embedded specimens.

FISH is useful to detect abnormalities when results of conventional cytogenetic studies are inconclusive because of the absence of metaphases, or normal because of cryptic or masked translocations. For example, 5% of patients with chronic myeloid leukemia have a Ph-chromosome from a submicroscopic insertion translocation, which results in BCR/ABL fusion. This translocation is undetectable (masked) in conventional cytogenetic studies, but is readily detected by FISH studies. Similarly, the 12;21 translocation associated with 20% of children with B-cell acute lymphocytic leukemia is undetectable by conventional cytogenetic studies. A FISH test is available to detect the TEL/AML1 fusion, which results from this 12;21 translocation. Thus, when conventional cytogenetics are normal and B-cell acute lymphocytic leukemia is suspected, it is useful to perform FISH studies.

Types of FISH Probes

FISH probes can be classified into four categories: (i) centromere-specific, (ii) telomere-specific, (iii) locus-specific, and (iv) chromosome-specific paints. Probes in these categories can be used alone or in combination and can be labeled with different colored fluorochromes.

Centromere-specific probes are used to detect numeric abnormalities. These probes hybridize to highly repetitive alpha satellite DNA associated with the centromere and are available from commercial sources for most human chromosomes. The gain or loss of specific chromosomes is visualized as an increase or decrease in the number of centromeric FISH signals within a nucleus.

Telomere-specific probes are commercially available and are useful to detect subtle chromosome abnormalities that involve the ends of chromosomes.

Locus-specific probes are used to detect structural abnormalities. The gain of locus-specific probe signals within a nucleus corresponds to duplications or amplification. The loss of locus-specific probe signals indicates a deletion. Locus-specific probes also can be used to detect reciprocal translocations and inversions by using probes that span the breakpoint cluster regions.

Chromosome-specific paints are composed of unique sequence DNA probes that hybridize to loci along the length of each chromosome. The application of these probes is restricted to analysis of metaphases where the morphology of individual chromosomes is discernable. This method is useful to identify marker chromosomes and to detect cryptic translocations. Recent modifications of chromosome-specific paints permit the simultaneous identification of each human chromosome by their color in a single metaphase (Fig. 32.3A). Several different methods have emerged that can be collectively referred to as multicolored FISH.

Probe Strategies and Analytical Sensitivities

Probes used individually or in combination with different colored fluorochromes allow numerous FISH testing strategies. Some FISH strategies employ a probe of one color to detect a genomic target of clinical significance and a different colored probe for a control locus. The addition of a control probe assures that the FISH procedure is working correctly, improves the accuracy of the scoring criteria, and verifies that reportable ranges are maintained. A normal interphase signal pattern is shown in Figure 32.3B.

Strategies that use both a centromere-specific probe and locus-specific probe for the same chromosome permit simultaneous detection of several kinds of chromosome abnormalities with different testing sensitivities. In our experience analyzing 200 cells, the upper boundary of the normal range for detecting a monosomy signal pattern (Fig. 32.3C) is 3% to 5%; for a trisomy signal pattern (Fig. 32.3D), 1% to 3%; for duplications (Fig. 32.3E), 8% to 10%; for deletions (Fig. 32.3F), 8% to 10%; and for gene amplification (Fig. 32.3G), less than 1%.

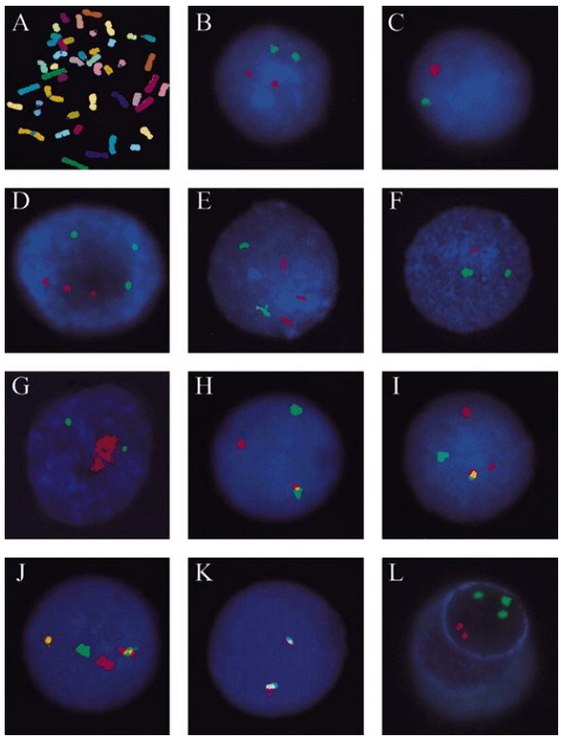

FIGURE 32.3. Example FISH strategies for detection of chromosome abnormalities in hematologic disorders. **(a)** Multicolored FISH chromosome-specific painting system for metaphase analysis. **(B–G)** are examples of interphase FISH patterns using red target and green control loci on the same chromosome: **(B)** normal signal pattern, **(C)** monosomy, **(d)** trisomy, **(E)** duplication, **(F)** deletion, and **(G)** amplification. **(H–K)** are examples of two color interphase FISH fusion strategies: **(H)** S-FISH, **(I)** ES-FISH, **(J)** D-FISH, and **(K)** break-apart. **(L)** Combination immunostain/FISH strategy, using plasma cell cytoplasmic immunoglobulin stain and FISH centromere probes.

FISH strategies to detect translocations and inversions in interphase nuclei have been developed. These strategies have different sensitivities as demonstrated by those employed for chronic myeloid leukemia. The t(9;22)(q34;q11.2) is associated with chronic myeloid leukemia and involves break and fusion points within the BCR region of chromosome 22q11.2 and the ABL oncogene of chromosome 9q34.

One FISH strategy uses a probe for the centromeric side of the BCR region and a different colored probe for the distal side of the ABL oncogene (Fig. 32.3H). As a consequence of the 9;22 translocation, the ABL signal is fused with the BCR signal on chromosome 22, creating a single-fusion signal. This single-fusion strategy is called S-FISH (15). The coincidental overlap of BCR and ABL signals produces false-positive fusion signals in 3% to 5% of normal nuclei, which results in an upper boundary of the normal range of 10%.

Another FISH strategy to detect t(9;22)(q34;q11.2) uses the same BCR probe, but a larger ABL probe to span the entire breakpoint region of ABL. With this method, abnormal nuclei show a BCR/ABL fusion signal on chromosome 22 and a small ABL signal on the abnormal chromosome 9 (Fig. 32.3I). This extra ABL signal strategy is called ES-FISH. This method reduces the problem of scoring cells with false-positive BCR/ABL fusion signals. Nevertheless, false-positive signal patterns result from splitting of ABL signals with coincidental overlap of BCR signals. In our experience, the upper boundary of normal range for this method is 3%.

The most sensitive translocation strategy for t(9;22) (q34;q11.2) involves probes that span both the BCR and ABL breakpoint regions. With this method, abnormal nuclei show two BCR/ABL fusion signals; one on the abnormal chromosome 9 and the other on the abnormal chromosome 22 (Fig. 32.3J). This double-fusion strategy is called D-FISH (16). Nearly all technical and biological artifacts are avoided with D-FISH and this results in an upper boundary of the normal range of <1%.

A break-apart FISH strategy has been developed to detect specific structural rearrangements. This strategy has been used to detect breakpoints within the CBFß gene on chromosome 16q22, the MLL gene on chromosome 11q23, and the ALK gene on chromosome 2p23. This FISH strategy uses different colored probes that hybridize to sequences flanking both sides of the common breakpoint region. In normal nuclei, this signal pattern would appear as two fusion signals (Fig. 32.3K). Any structural abnormality that alters the breakpoint region separates these signals changing both the number and color of the signals in the nucleus (Fig. 32.3H). In our experience, the upper boundary of the normal range for this method is 1% to 3%.

FISH combined with immunostaining methods can be used to establish which hematopoietic cell line is neoplastic. For example, in multiple myeloma, an immunostain for cytoplasmic immunoglobulin to detect plasma cells can be combined with a FISH strategy to detect certain chromosome abnormalities (Fig. 32.3L)(17).

Several FISH strategies can be applied to a single slide to permit “panel FISH testing.” For example, using a set of probes for chromosomes 5, 7, 8, 11, 13 and 20 will allow detection of the most common chromosome abnormalities in myelodysplasia. Probes to detect t(11;14)(q13;q32), +12, del(6)(q13q23), del(11)(q23), del(13)(q12q22), and del(17)(p11) would be a useful FISH panel to study patients with lymphoproliferative disorders.

GENETIC TESTING IN CLINICAL PRACTICE

Part of "32 - Cytogenetic Studies in Neoplastic Hematologic Disorders"

Assessing Effectiveness of Treatment

Numerous treatment protocols for hematologic disorders require quantitative procedures to assess responsiveness to therapy. This can be done by using various genetic tests including quantitative cytogenetic studies, FISH, Southern blot analysis, and reverse transcriptase polymerase chain reaction (RT-PCR). No single genetic testing procedure fulfills all the needs of clinical care for patients with hematologic disorders. Thus, it has become important to use combinations of testing methods that are both accurate and cost-effective for each clinical situation. Testing strategies change over time as methodologies improve or change and new clinical challenges arise. Thus, the review process to develop better genetic testing methods should be an ongoing activity.

The application of genetic testing strategies for chronic myeloid leukemia may be a good model for most hematologic disorders. At diagnosis, it is useful to perform quantitative cytogenetic analysis of 25 or more metaphases from bone marrow. To monitor patients during therapy, quantitative cytogenetic studies on 25 or more metaphases from bone marrow should be done at 3- to 6-month intervals. In lieu of this approach, FISH can be used to study 500 interphase nuclei from blood or bone marrow before and after treatment to track changes in the percentage of cells with BCR/ABL fusion (16). When the results of FISH on interphase nuclei are within the normal range (usually 1% if D-FISH is used), either RT-PCR analysis can be performed or D-FISH analysis of 6,000 or more nuclei could be studied to look for residual disease (2, 16). Remission and relapse can be defined by the test used to detect the abnormal clone. For example, a patient can be in morphological, cytogenetic, FISH, or RT-PCR remission or relapse.

Bone Marrow Transplantation Programs

Chromosome studies are useful before transplantation to establish the karyotype of the neoplastic process. This information helps identify patients who benefit from this procedure and determine the best form of bone marrow transplantation (autologous versus allogenic, purging B-cells, etc.). Genetic testing also is used to establish remission and to determine the best time for bone marrow transplantation.

FISH studies are useful to assess the success of bone marrow transplantation. For opposite sex bone marrow transplantation, DNA probes for the X and Y chromosomes can establish the presence or absence of hematopoietic chimerism. This FISH test can detect donor or recipient cells at a frequency of <1%. FISH with DNA probes specific for a neoplasm is useful to quantify the tumor burden, but the sensitivity of this method varies according to the FISH strategy employed. In some cases, it is useful to use molecular genetic techniques such as RT-PCR to assess the presence of neoplastic cells.

Chromosome studies can determine when relapse is related to the original clone or if a new neoplasm or subclone has emerged. Chromosomal polymorphisms help determine whether the new leukemia involves the donor's cells or the recipient's cells.

Hematopoietic chimerism is common in the posttransplantation period. Molecular genetic methods often detect residual recipient cells as long as 3 years after bone marrow transplantation. Some investigators believe chimerism plays an important role in graft versus host disease.

Constitutional Chromosome Abnormalities

Congenital chromosome abnormalities are part of the constitutional karyotype and, except in cases of mosaicism, occur in all tissues of the patient. Approximately one in 500 adults carries a balanced structural chromosome abnormality and usually is phenotypically normal. However, they have a high risk of having children with birth defects and an elevated rate of miscarriage. The detection of congenital structural chromosome abnormalities is expected to occur during the course of cytogenetic studies for neoplastic disorders. These findings have significant clinical implications for the patients and their blood relatives and they should receive genetic consultation.

In some bone marrow analyses, no clinical or cytogenetic clue is available to clearly distinguish between a constitutional or acquired chromosome abnormality. In these cases, chromosome analysis on peripheral blood cultured in medium containing phytohemagglutinin to stimulate T-cell mitosis is helpful to compare the karyotype of normal T-cells with neoplastic cells.

Certain aneuploid abnormalities are congenital, such as Down, Turner, and Klinefelter syndromes. In these cases, the diagnosis usually is evident by physical examination. Some of these congenital syndromes are associated with a predisposition to develop hematologic disorders. However, these same aneuploid abnormalities are not uncommon in hematologic disorders (18). Fortunately, in hematologic disorders, these aneuploid conditions usually are associated with additional chromosome abnormalities. In these cases, the chromosomally abnormal cells are unbalanced and are associated with neoplastic disease.

CHROMOSOME ABNORMALITIES AND THEIR FREQUENCY OF OCCURRENCE

Part of "32 - Cytogenetic Studies in Neoplastic Hematologic Disorders"

Frequency of Abnormal Clones

All patients with malignancies have one or more clones of neoplastic cells that contain abnormal genes, many of which are detectable by cytogenetic studies. In clinical practice, the frequency with which chromosomally abnormal clones are found in patients with specific hematologic disorders varies considerably. In the authors' cytogenetic and clinical practice, abnormal clones are found in approximately 70% of patients with acute myeloid leukemia, 80% with acute lymphocytic leukemia, 100% with chronic myeloid leukemia, 55% with myelodysplastic syndromes, 39% with polycythemia vera, and 79% with non-Hodgkin's lymphoma. These observations are based on cytogenetic data collected at the time of initial diagnosis. Higher frequencies of chromosomally abnormal clones are observed among patients in more advanced stages of hematologic disorders and lower frequencies are found among patients that undergo successful treatment for their hematologic disorder.

Absence of Abnormal Clones

Several factors contribute to the variations among laboratories with respect to the frequency of detecting chromosomally abnormal clones. The referral patterns of physicians who use cytogenetic studies differ with regard to the type of disease, treatment, and stage of illness. Many cytogenetic studies are done as part of the initial examination of a patient to help establish a diagnosis. This analysis often occurs relatively early in the disease process, when normal cells predominate. The typical cytogenetic study is done on a single bone marrow specimen. Frequently, the most cellular part of the specimen is used for other laboratory tests, such as standard hematologic studies. In such cases, the cytogenetic study is relegated to the “bloody” part of the specimen, often lacking mitotic neoplastic cells. In some hematologic disorders, the neoplastic cells rarely divide, which interferes with the chances of finding a chromosomally abnormal clone. In other disorders, the oncogenic process involves cryptic chromosome abnormalities or submicroscopic mutations which are not detected by standard cytogenetic studies.

In routine practice, usually no more than 4 or 5 hours can be allotted to the analysis of metaphases for each case and investing excessive hours would significantly affect the cost. This work limitation reduces the total number of metaphases that can be analyzed practically in routine practice and increases the chances of missing neoplastic metaphases by sampling error. Moreover, technical experience of the laboratory staff and the processing procedure affects the chances of finding chromosomally abnormal clones. Cytogenetic results often are needed within a few days so that the physician can use the results to manage the patient.

Frequency of Specific Chromosome Abnormalities

Prior to 1985, 43 specific chromosome abnormalities were associated with hematologic disorders. In 1985, the frequency for each of these abnormalities was calculated from 748 predominantly adult patients with an abnormal clone seen at one institution (19). Collectively, these 748 patients had 1,352 chromosome abnormalities. The 43 recognized chromosome abnormalities were seen in 61% of patients. The remaining 39% of patients had other chromosome abnormalities that were not yet associated with any specific hematologic disorder.

Translocations were the most common abnormalities, followed by trisomies, deletions, and monosomies (Table 32.1 and Table 32.2, and Fig. 32.4). The most common specific chromosome abnormality was the Ph-chromosome, followed by +8, -Y, 5q-, -7, 20q-, and +21. The most common trisomy was trisomy 8, followed by trisomy of chromosomes 21, 19, 9, 11, and 7. Loss of the Y chromosome was the most common monosomy, followed by monosomy of chromosomes 7, 5, and X. The most common deletion was 5q-, followed by 20q-, 7q-, 6q-, 13q-, 11q-, 9q-, and 16q-. The most common translocation

was t(9;22), followed by t(8;21), t(1;7), t(8;14), t(9;11), t(4;11), and t(14;18). Isochromosomes, inversions, duplications, haploidy, and polyploidy were infrequent.

[a] The terminology is from the International System for Human Cytogenetic Nomenclature. The following standard notations are used for chromosome anomalies: del, deletion; der, derived; dup, duplication; i, isochromosome; idic, isodicentric; ins, insertion translocation; inv, inversion; p, short arm; q, long arm; t, translocation. The numbers within the first set of parentheses adjacent to the type of anomaly identify the chromosome or chromosomes involved. The numbers within the second set of parentheses identify the breakpoints. Thus, the expression t(9;22)(q34;q11.2) indicates a reciprocal translocation between parts of chromosomes 9 and 22 with breakpoints at 9q34 and 22q11.2.

[b] ALL, acute lymphocytic leukemia (subtype L3 where indicated); AML, acute myeloid leukemia (subtype M1-M7 where indicated); AMM, agnogenic myeloid metaplasia; ALCL, anaplastic large cell lymphoma; ATL, adult T-cell lymphoma; B-CLL, B-cell chronic lymphocytic leukemia; BL, Burkitt's lymphoma; B-NHL, B-cell non-Hodgkin's lymphoma; B-PLL, B-cell prolymphocytic leukemia; CLD, chronic lymphoproliferative disorder; CLL, chronic lymphocytic leukemia; CML Ph+, chronic myeloid leukemia with Philadelphia chromosome; CMML, chronic myelomonocytic leukemia; DLCL, diffuse large cell lymphoma; FL, follicular lymphoma; HSγδTL, hepatosplenic gamma delta T-cell lymphoma; HCL, hairy-cell leukemia; LPL, lymphoplasmacytic lymphoma; MCL, mantle-cell lymphoma; MDS, myelodysplastic syndrome; MM, multiple myeloma; MPD, myeloproliferative disorder; MGUS, monoclonal gammopathy of undetermined significance; MZL, mantle zone lymphoma; NHL, Non-Hodgkin's lymphoma; pre-B-ALL, precursor B-cell acute lymphocytic leukemia; PV, polycythemia vera; RARS, refractory anemia with ringed sideroblasts; SLVL, splenic lymphoma with villous lymphocytes; T-ALL, T-cell acute lymphocytic leukemia; T-CLL, T-cell chronic lymphocytic leukemia; T-CLD, T-cell chronic lymphoproliferative disorder; T-NHL, T-cell non-Hodgkin's lymphoma; T-PLL, T-cell prolymphocytic leukemia; t-AML, therapy-related acute myeloid leukemia; t-MDS, therapy-related myelodysplastic syndrome; 5q- syn, 5q- syndrome.

[c] Frequency of each chromosome abnormality seen in bone marrow specimens among 748 patients with an abnormal clone seen at Mayo Clinic. Because it was not part of our cytogenetic practice to study lymph nodes or patients with most lymphoproliferative disorders during the time period of this study, the data are more representative of acute leukemia, myelodysplastic syndromes, and myeloproliferative disorders. Moreover, physicians at Mayo Clinic primarily see adult patients with hematologic disorders. Data from Dewald GW, Noel P, Dahl RJ, et al., Chromosome abnormalities in malignant hematologic disorders. *Mayo Clin Proc* 1985;60:675–689.

Since 1985, many other chromosome abnormalities associated with hematologic disorders have been reported (4). Many of the newly discovered chromosome abnormalities were either relatively rare or cryptic in nature. Eventually, the clinical disorder(s) associated with each specific chromosome abnormality will be correlated. Currently, physicians and cytogeneticists who interpret chromosome abnormalities need to correlate the cytogenetic results with the clinical scenario of the patient.

Several important international attempts have been made to review the cytogenetic literature in order to correlate chromosome abnormalities with specific hematologic disorders (20, 21 and 22). Most recently, breakpoints for 1,803 structural abnormalities including 215 balanced and 1,588 unbalanced anomalies associated with hematologic disorders and solid tumors were summarized (22).

A list of the most common structural chromosome aberrations in hematologic disorders is shown in Table 32.1 and Table 32.2. Examples of many of these abnormalities are shown in Figure 32.5 and Figure 32.6, and are cross-indexed with the chromosome abnormalities listed in Table 32.1.

SPECIFIC CYTOGENETIC ABNORMALITIES IN HEMATOLOGIC DISORDERS

TABLE 32.2. COMMON AnEUPLOID ABNORMALITIES IN HEMATOLOGIC DISORDERS

Type of Anomaly	No. of Specimens

[a] For explanation of abbrevations, see footnote b in Table 32.1.

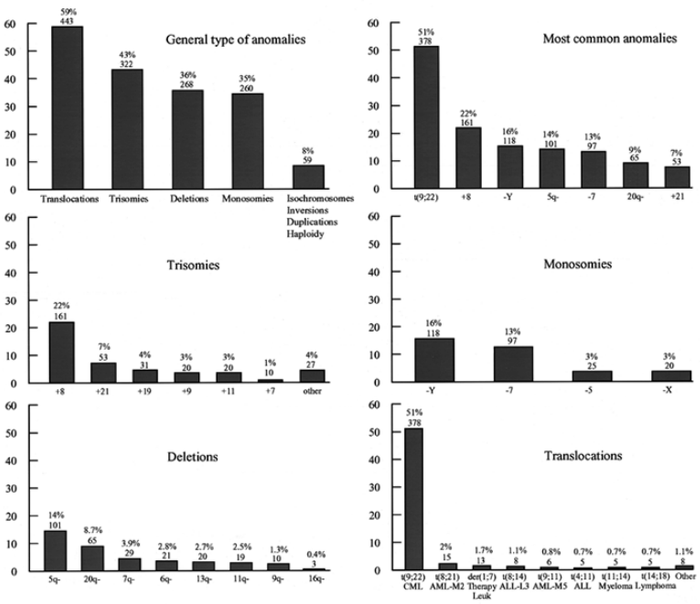

FIGURE 32.4. Frequency of different kinds of chromosome abnormalities in hematologic disorders. ALL, acute lymphocytic leukemia (L3 subtype); AML, acute myeloid leukemia (M2 and M5, subtypes); CML, chronic myeloid leukemia; Therapy Leuk, therapy-related leukemia.

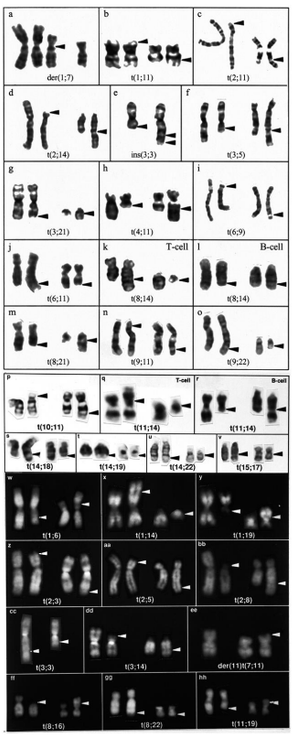

FIGURE 32.5. Examples of common chromosome translocations in hematologic disorders. See Table 32.1 for more information about the breakpoints, associated hematologic disorders, associated genes, and frequency among 748 patients with a chromosomally abnormal clone.

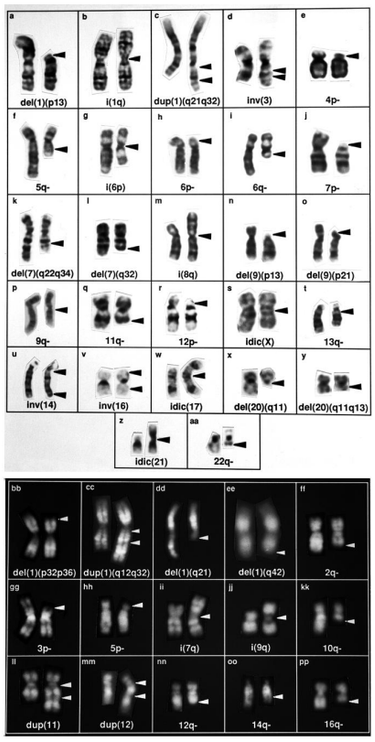

FIGURE 32.6. Examples of common isochromosomes, deletions, inversions, and duplications in hematologic disorders. See Table 32.1 for more information about the breakpoints, associated hematologic disorders, associated genes, and frequency among 748 patients with a chromosomally abnormal clone.

Neoplastic hematologic disorders have been identified in nearly every cell type that comprise the normal bone marrow and lymphoid systems. Not surprisingly, classification of hematologic disorders has evolved according to these primary cell types. Briefly, neoplastic hematologic disorders are grouped into myeloid and lymphoid cell types. Neoplastic myeloid disorders include acute myelogenous leukemias or AML (≥30% myeloblasts in the bone marrow), myelodysplastic syndromes, and chronic myeloproliferative disorders. Each of these general categories is further subdivided into several clinical and/or morphological neoplasms, which are best summarized by the French-American-British (FAB) classification system (Table 32.3, Table 32.4, and Table 32.5)(23, 24).

TABLE 32.3. CLASSIFICATION SYSTEM FOR ACUTE LEUKEMIAS (24)

Acute myeloid leukemia[a]			
FAB Subtype	Frequency in Children	Frequency in Adults	
M0	<5%	2%–3%	Agranular myeloblasts; <3% blasts reactive to myeloid antigens
M1	11%	20%	Lack of maturation beyond the blast stage, ≥3% blasts reactive to myeloid antigens
M2	32%	25%–30%	Maturation to the progranulocyte state or beyond
M3	8%	8%–15%	Abnormal (hypogranular or hypergranular) progranulocytes that display bundles of Auer rods
M4	24%	20%–25%	Blasts with both monocytic and granulocytic characteristics. Monocytes exceed 20% of the nucleated cell population
M5a	11%	5%	Monoblastic cells >50% monocytic differentiation
M5b			Monocytic cells >50% monocytic differentiation
M6	5%	5%	Erythrocytic cells predominately erythroid precursors
M7	9%	1%–2%	Megakaryocytic cells predominately megakaryocytes precursors
Acute lymphocytic leukemia[b]			
FAB Subtype	Frequency in Children	Frequency in Adults	
L1	80%	30%	Small blasts, regular nuclear outline, few or no visible nucleoli, scant cytoplasm
L2	15%–20%	65%–70%	Larger blasts (x2 small lymphocyte), irregular or cleft nucleoli, one or more prominent nucleoli, variable to abundant cytoplasm
L3	3%	3%	“Burkitt's” type, large cells, dense chromatin, round or oval nucleus, moderately abundant cytoplasm, deeply basophilic cytoplasm with prominent vacuoles

[a] Acute myeloid leukemia is classified into eight categories on the basis of cell morphology.
[b] Acute lymphocytic leukemia is classified into three categories on the basis of cell morphology.

Neoplastic lymphoid disorders include acute lymphocytic leukemias (ALL) (≥30% lymphoblasts in the bone marrow), lymphomas, and chronic lymphoproliferative disorders (Table 32.3, Table 32.6). The main division of lymphomas and chronic lymphoproliferative disorders results in two main categories: Hodgkin's disease and non-Hodgkin's lymphoma.

Although non-Hodgkin's lymphoma can be broadly divided into B-cell or T-cell disorders, these subclassifications have had many discrepant and conflicting classification schemes including the Rappaport, Kiel, Lukes-Collins, and Working Formulation (25, 26, 27 and 28). The current classification scheme utilized by the majority of hematologists is the Revised European-American Lymphoma (REAL) classification (Table 32.6)(29). However, a new lymphoma classification scheme by the World Health Organization (WHO) is now available (30).

Because the determination of cell morphology often is difficult, most physicians use supplemental methods such as cytogenetics, cytochemistry, immunologic markers, biochemical markers, and B-cell or T-cell rearrangement studies to help classify hematologic disorders. Much effort has been expended by cytogeneticists, hematologists, and pathologists attempting to correlate the findings of cytogenetic studies with the hematologic classification systems.

Since 1978, six International Workshops on Chromosomes in Leukemia and Lymphoma have been convened for this purpose (31, 32, 33, 34, 35 and 36). These workshops have demonstrated a strong correlation between specific chromosome abnormalities and specific clinical disorders that have helped document the biological validity of the classification schemes. However, these workshops identified many other chromosome abnormalities that do not

TABLE 32.4. FAB CLASSIFICATION SYSTEM FOR MYELODYSPLASTIC SYNDROMES (23, 24)

Subtype	Peripheral Blood	Bone Marrow
Refractory anemia (RA)	<1% blasts	Erythroid hyperplasia
		Dyserythropoiesis
		<5% blasts
		No or few ringed sideroblasts
Refractory anemia with ringed sideroblasts (RARS)	<1% blasts	Erythroid hyperplasia
	Occasional dysplastic neutrophils and platelets	
		>15% ringed sideroblasts
Refractory anemia with excess blasts (RAEB)	Cytopenias	Panmyeloid hyperplasia
		5%–20% blasts
	<5% blasts	
Refractory anemia with excess blast in transition (RAEBIT)	Cytopenias	Panmyeloid hyperplasia
		20%–30% blasts
		Auer rods
	5–29% blasts	
Chronic myelomonocytic leukemia (CMML)	>1 × 10^9/L monocytes	<20% blasts
		Increase in monocytes and precursors
	<5% blasts	
Myelodysplastic syndrome unclassified[a]	Cytopenias	<5% blasts
(MDS-U)	<1% blasts	Multilineage dysplasia

[a] Proposed WHO classification “refractory cytopenia with multilineage dysplasia” or RCMD.

TABLE 32.5. CLASSIFICATION FOR CHRONIC MYELOPROLIFERATIVE DISORDERS

Predominant Abnormal Cell Line	Myeloproliferative Disorder
Erythroid	Polycythemia vera (PV)
Granulocytic	Chronic myeloid leukemia (CML)
	Chronic myelomonocytic leukemia (CMML)
Megakaryocytic	Essential thrombocytemia (ET)
Fibroblast	Agnogenic myeloid metaplasia (AMM)

correlate well with the current classification schemes. In the future, classification schemes are expected to become more based on cytogenetic and/or molecular genetic abnormalities.

Herein, an outline of the current cytogenetics literature is provided for each of the main hematologic disorders including acute leukemia, therapy-related AML and therapy-related myelodysplasia, myelodysplastic syndromes, chronic myeloproliferative disorders, lymphomas and chronic lymphoproliferative disorders, and Hodgkin's disease. For each specific cytogenetic anomaly described, an attempt was made to present a concise summary of main disease associations, unique clinical features, median age at diagnosis, cytogenetic variants, associated cytogenetic anomalies, FISH strategies, gene(s) involved, and molecular testing strategies.

Acute Leukemia (Table 32.3)(37, 38, 39, 40, 41, 42, 43, 44, 45, 46 and 47)

- Among children with acute leukemia, 85% have ALL and 15% have AML
- Among adults with acute leukemia, 20% have ALL and 80% have AML
- Yearly incidence of AML: 1.2/100,000 (children), 3.5/100,000 (age 50), 15/100,000 (age 70), and 35/100,000 (age 90)

TABLE 32.6. REVISED EUROPEAN-AMERICAN LYMPHOMA (REAL) CLASSIFICATION SYSTEM (29)

B-cell neoplasms
Precursor B-cell neoplasm
Precursor B-lymphoblastic leukemia and lymphoma
Peripheral B-cell neoplasms
B-cell chronic lymphocytic leukemia prolymphocytic leukemia, small lymphocytic lymphoma
Lymphoplasmacytoid lymphoma, immunocytoma
Mantle cell lymphoma
Follicle center lymphoma, follicular lymphoma
Provisional cytologic grades: I (small cell), II (mixed small and large cells), III (large cells)
Provisional subtype: diffuse, predominantly small cell type
Marginal zone lymphoma
Extranodal (mucosa-associated lymphoid tissue type with or without monocytoid B-cells)
Provisional subtype: nodal (with or without monocytoid B-cells)
Provisional entity: splenic marginal zone lymphoma (with or without villous lymphocytes)
Hairy cell leukemia
Plasmacytoma, plasma cell myeloma
Diffuse large B-cell lymphoma[a]
Subtype: primary mediastinal (thymic) B-cell lymphoma
Burkitt's lymphoma
Provisional entity: high-grade B-cell lymphoma, Burkitt's like[a]
T-cell and putative natural killer cell neoplasms
Precursor T-cell neoplasm
Precursor T-lymphoblastic leukemia or lymphoma
Peripheral T-cell and natural killer cell neoplasms
T-cell chronic lymphocytic leukemia, prolymphocytic leukemia
Large granular lymphocyte leukemia
T-cell type
Natural killer cell type
Mycosis fungoides, Sézary syndrome
Peripheral T-cell lymphomas, unspecified[a]
Provisional cytologic categories: medium-sized cell, mixed medium and large cell, large cell, lymphoepithelioid
Provisional subtype: hepatosplenic γδ T-cell lymphoma
Provisional subtype: subcutaneous panniculitis T-cell lymphoma
Angioimmunoblastic T-cell lymphoma
Angiocentric lymphoma
Intestinal T-cell lymphoma (may be enteropathy associated)
Adult T-cell lymphoma or leukemia
Anaplastic large-cell lymphoma (CD30+, T-, and null-cell types)
Provisional entity: anaplastic large-cell lymphoma, Hodgkin's-like
Hodgkin's disease
Type I. Lymphocyte predominance
Type II. Nodular sclerosis
Type III. Mixed cellularity
Type IV. Lymphocyte depletion
Type V. Provisional entity: lymphocyte-rich classic Hodgkin's disease

[a] These categories are thought likely to include more than one disease entity.

- Yearly incidence of ALL: 9.8/100,000 (children), 12.8/100,000 (adults)
- AML (> 55 years of age) often have chromosome abnormalities associated with progression of myelodysplastic syndromes
- AML (< 55 years of age) often have chromosome abnormalities linked with de novo AML

t(1;14)(p32;q11) (Fig. 32.5X)

- Specific for T-ALL in 10% to 30% of patients
- Often young males with mediastinal mass
- Positive cerebro-spinal fluid and high white count are common
- 1p32 breakpoint in TAL1; 14q11 breakpoint in TCR α or δ (T-cell receptor genes)
- Commercial FISH strategy is not available, but possible to detect TAL1/TCRαδ fusion
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(1;19)(q23;p13) (Fig. 32.5Y)

- 30% of children with Pre-B-cell ALL
- Low leukocyte count
- Cytogenetic variant: t(17;19)(q21-22;p13)
- Poor to intermediate prognostic significance
- 1q23 breakpoint in PBX1; 19p13 breakpoint in E2A
- Commercial FISH strategy is not available, but “home-brew” methods have been reported
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(1;22)(p13;q13)

- Specific for AML-M7 in 25% to 35% of patients
- Found predominantly in infants
- Associated with organomegaly from leukemic infiltration
- Poor prognostic significance
- Commercial FISH strategy is not available
- Gene breakpoints are undefined so molecular tests are not available

t(3;5)(q25.1;q35) (Fig. 32.5F)

- Associated with AML-M6
- Young age
- 3q25.1 breakpoint in MLF1; 5q34 breakpoint in NPM
- Commercial FISH strategy is not available, but possible to detect MLF1/NPM fusion
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(3;21)(q26;q22) (Fig. 32.5G)

- AML, myelodysplastic syndromes, and secondary anomaly in chronic myeloid leukemia
- 3q26 breakpoint in EAP; 21q22 breakpoint in AML1
- Commercial FISH strategy is available to detect break apart of AML1 locus
- Gene breakpoints are undefined so molecular tests are not available

t(6;9)(p23;q34) (Fig. 32.5I)

- 1% to 2% of patients with AML (AML-M2, M4 and rarely M1); refractory anemia with excess blasts
- May be associated with bone marrow basophilia
- Disease onset 20 to 40 years old
- Poor to intermediate prognostic significance
- 6p23 breakpoint in DEK; 9q34 breakpoint in CAN
- Commercial FISH strategy is not available, but possible to detect DEK/CAN fusion
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(8;14)(q24;q32) (Fig. 32.5L)

- 100% of patients with ALL-L3 and Burkitt's lymphoma (different presentations of same disease)
- 5% of patients with adult ALL
- For more information see section on non-Hodgkin's lymphoma

t(8;16)(p11;p13) (Fig. 32.5FF)

- Associated with AML-M4 and M5b
- Found mainly in infants and children
- Associated with disseminated intravascular coagulation (DIC) and erythrophagocytosis
- Poor prognostic significance
- Commercial FISH strategy is not available
- Gene breakpoints are undefined so molecular tests are not available

t(8;21)(q22;q22) (Fig. 32.5M)

- 5% to 10% of AML; 10% to 30% of AML-M2; 7% of AML-M4; 20% of childhood AML
- Disease onset is 25 to 30 years
- Generally good prognostic factor, although long-term survival in children is poor
- 70% of males have associated loss of the Y chromosome (likely no prognostic importance)
- 60% of females have associated loss of the X chromosome (likely no prognostic importance)
- t(16;21)(q24;q22) may be a rare variant
- 8q22 breakpoint in ETO; 21q22 breakpoint in AML1
- Commercial FISH strategy available to detect fusion of ETO and AML1
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(9;22)(q34;q11.2) (Fig. 32.5O)

- “Philadelphia chromosome,” (Ph)
- 5% of children with ALL; 25% to 35% of adults with ALL (usually L2); 1% of AML-M1
- Poor prognostic significance
- 50% of adult ALL and nearly 100% of childhood ALL have fusion gene e1a2
- For more information see section on chronic myeloproliferative disorders

t(10;14)(q24;q11)

- 1% to 3% of patients with T-cell ALL
- 10q24 breakpoint in HOX11; 14q11 breakpoint in TCRαδ (T-cell receptor αδ)
- Commercial FISH strategy is not available, but possible to detect HOX11/TCRαδ fusion
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(11;var)(q23;var)

- Group of translocations with breakpoint at 11q23 and various partner chromosomes
- Mostly children and young adults
- 70% of children <1 year old with acute leukemia; 3% of patients with therapy related AML
- Prognostic significance is poor in ALL and intermediate in AML
- t(4;11)(q21;q23) (Fig. 32.5H) occurs in 5% to 8% of children with ALL who are <1 year of age
- t(9;11)(p22;q23) (Fig. 32.5N) or t(11;19)(q23;p13) (Fig. 32.5HH) occurs in 35% of patients with AML-M5 and 50% of patients with AML-M5a
- t(10;11)(p13;q23) (Fig. 32.5P) occurs in 30% of patients with AML-M4 or M5
- t(X;11)(q13;q23) in T-cell ALL
- Over 30 different chromosome partners described
- 11q23 breakpoint in MLL (mixed lineage leukemia gene)
- 1p32 breakpoint in AF1P; 4q21 in AF4; 9p22 in AF9; 10p13 in AF10; 19p13.1 in ELL; 19p13.3 in ENL, Xq13 in AFX1
- Tandem duplications of exons 2 to 6 in MLL account for 10% of cytogenetically normal AML
- Commercial FISH strategy is available to detect break apart of MLL gene
- Breakpoints in MLL cluster in an 8.3-kb region detected by Southern Blot or RT-PCR analysis

t(12;21)(p13;q22)

- 25% of children with ALL; 3% of adults with ALL
- Good prognostic significance
- Difficult to detect by conventional cytogenetic studies
- Often an unbalanced translocation with loss of abnormal chromosome 12
- 12p13 breakpoint in TEL; 21q22 breakpoint in AML1
- Commercial FISH strategy is available to detect fusion of TEL and AML1
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(15;17)(q22;q21) (Fig. 32.5V)

- Specific for AML-M3 (also known as acute promyelocytic leukemia, APL)
- Accounts for up to 30% to 40% of AML in certain ethnic groups
- 20% patients have a hypogranular or microgranular variants (M3v)
- Median age of onset is 38 years
- Patients frequently present with disseminated intravascular coagulation (DIC)
- Good prognostic significance; respond to All- *trans* -retinoic acid treatment
- 1% of patients have cryptic translocations or variants
- Most common variants include t(11;17)(q23;q21), t(5;17)(q35;q21), t(1;17)(p36;q21)
- 15q22 breakpoint in PML (aka MYL); 17q21 breakpoint in RARα (retinoic acid receptor)
- Commercial FISH strategy is available to detect PML/RARα fusion
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

inv(3)(q21q26) (Fig. 32.6D)

- AML-M2, M4, and M6; 2% of patients with AML
- Frequently associated with thrombocytosis (rare in other forms of AML)
- Poor prognostic significance
- Cytogenetic variants include t(3;3)(q21;q26) (Fig. 32.5CC) and ins(3;3)(q26;q21q26) (Fig. 32.5E)
- 3q21 breakpoint in Ribophorin; 3q26 breakpoint in EVI1
- Commercial FISH strategy is not available, but “home-brew” methods have been reported
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

inv(16)(p13q22) (Fig. 32.6V)

- This anomaly or a variant occurs in 100% of patients with AML-M4Eo
- 25% of patients with AML-M4; 6% of patients with AML
- Clinically associated with bone marrow eosinophilia, lymphadenopathy, and hepatomegaly
- Good prognostic significance
- Most common cytogenetic variant is t(16;16)(p13;q22)
- del(16)(q22) (Fig. 32.6pp) linked with AML-M4Eo, but clinical phenotype may differ
- 16p13 breakpoint in MYH11; 16q22 breakpoint in CBFß (aka PEBP2B)
- Commercial FISH strategy is available to detect break apart of CBFß locus

- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

del(5)(q13q33) (Fig. 32.6F)

- 10% of patients with AML; usually previous myelodysplastic syndromes
- Poor prognostic significance
- See section on myelodysplastic syndromes for more information

del(12)(p12) (Fig. 32.6R)

- 2% of patients with AML, most have M2 or M4
- Associated with basophilia
- Poor prognostic significance
- Frequently associated with monosomy 7
- Gene at 12p13.1 breakpoint is unknown, but TEL or KIP1 (p27 protein) frequently lost
- Commercial FISH strategy available to detect loss of TEL1
- Gene breakpoints are undefined so molecular tests are not available

Hyperdiploidy without apparent structural anomalies

- 25% to 30% of children with ALL, often non-T-cell, non-B-cell
- Neoplastic clones usually have 50 to 60 chromosomes
- Most common trisomies include +4, +6, +10, +14, +17, +18, +20, +21, +X
- Trisomy 21 or tetrasomy 21 occurs in nearly 100% of patients
- Good prognostic significance, especially when +4 and +10 are involved
- Commercial FISH strategy is available using centromere-specific probes to detect aneuploidy
- Molecular strategy is not applicable

Near Haploidy

- 1% of children with ALL
- Neoplastic clones with 26 to 36 chromosomes
- Diploid copies of chromosomes 10, 14, 18, 21 and X or Y are common
- Poor prognostic significance
- Commercial FISH strategy is available using centromere-specific probes to detect aneuploidy
- Molecular strategy is not applicable

Therapy-related leukemia (t-AML) and therapy-related myelodysplasia (t-MDS)(38, 41, 48, 49 and 50)

Three cytogenetic categories: hypodiploid with abnormalities of chromosomes 5 and/or 7, der(1;7) translocations, and t(11;var)(q23;var)

- Among 3,976 patients with hematologic disorders, 121 were hypodiploid with abnormalities of chromosomes 5 and/or 7, 39 had der(1;7) translocations and 29 had t(11;var)(q23;var)
- Up to 20% of patients with aggressive chemotherapy or radiation treatment therapies
- Same chromosome abnormalities associated with exposure to environmental carcinogens
- 10% to 20% of AML
- Chromosomally abnormal clones identified in 90% of patients with t-MDS or t-AML

Hypodiploid and Abnormalities of Chromosomes 5 and 7

- Modal number of chromosomes is <46
- Associated with prior treatment with alkylating chemotherapeutic agents or radiation
- Time from treatment to bone marrow dysfunction is 2 to 5 years
- Patients usually present with myelodysplastic syndromes
- 50% of patients with t-MDS progress to AML in 6 months
- Poor prognostic significance
- Critical region is most likely in 5q31, 7q11-q21 and/or 7q31-q36
- FISH strategy available to detect structural and numeric anomalies of chromosomes 5 and 7
- Molecular strategy is not applicable

der(1;7)(q10;p10) (Fig. 32.5A)

- Unbalanced translocation with loss of the chromosome 7 q-arm and three copies of the chromosome 1 q-arm
- 70% of patients have a therapy-related hematologic disorder
- Associated with prior treatment with alkylating chemotherapeutic agents or radiation
- Time from treatment to bone marrow dysfunction is 2 to 5 years
- Patients usually present with myelodysplastic syndromes and rarely progress to AML
- Pathogenesis may be related to loss of tumor suppressor genes on the chromosome 7 q-arm
- Commercial FISH strategy is available to detect loss of chromosome 7 q-arm and fusion of the centromere of chromosome 1 and 7
- Molecular strategy is not applicable

t(11;var)(q23;var)

- Translocations with breakpoints at 11q23 and various partner chromosomes
- Due to Topoisomerase II inhibitor chemotherapy such as Doxorubicin and Etoposide
- No myelodysplastic syndrome prodrome
- AML develops 1 to 2 years following treatment
- Favorable response to subsequent chemotherapy
- Most common translocations are t(9;11)(p22;q23) (Fig. 32.5N) and t(10;11)(p13;q23) (Fig. 32.5P)
- 11q23 breakpoint in MLL (mixed lineage leukemia gene)
- For more information see section on acute leukemia

Myelodysplastic Syndromes (Table 32.4) (38, 40, 41, 48, 51, 52, 53 and 54)

- "5q- syndrome" included in this section, although not officially recognized as an FAB subgroup
- Overall, 40% of patients with myelodysplastic syndromes have a chromosomal anomaly
- Chromosomally abnormal clones are found in 31% of patients with refractory anemia, 29% with refractory anemia with ringed sideroblasts, 46% with refractory anemia with excess blasts, 50% with refractory anemia with excess blasts in transition, 45% with chronic myelomonocytic leukemia, and 100% with 5q- syndrome
- Many patients with myelodysplastic syndromes progress to acute leukemia

del(5)(q13q33) (Fig. 32.6F)

- "5q- syndrome" accounts for one-third of patients with a 5q- chromosome
  - Subset of young women with 5q- as sole abnormality
  - Small megakaryocytes and abnormal erythropoiesis
  - Good prognosis
  - Chromosome evolution and progression to AML is uncommon
- Two-thirds patients with 5q- have various myelodysplastic syndromes subtypes
  - 50% patients have additional chromosome abnormalities with associated worse prognosis
  - Common variants include del(5)(q31q35) and del(5)(q22q33)
  - Breakpoint at 5q33 occurs in 70% of patients
  - Most patients lack 5q31; candidate genes include EGR1, CSF1R, and IRF1
  - Commercial FISH strategy is available to detect loss of EGR1 and CSF1R
  - Molecular strategy is not applicable

idic(X)(q13) (Fig. 32.6S)

- 0.7% of patients with adult myeloid disorders; specifically associated with refractory anemia with ringed sideroblasts
- Affects only women, mostly >60 years old
- Rarely progresses to AML
- Variants include translocations with breakpoints at Xq13
- Subclones with two copies of the idic(X) are frequent
- ABC7 gene associated with familial refractory anemia with ringed sideroblasts is at Xq13
- Commercial FISH strategy is not available, but probes to detect loss of ABC7 gene is possible
- Molecular strategy is not applicable

i(17q) (Fig. 32.6W)

- Most common isochromosome in hematologic disorders
- Usually associated with complex karyotypes
- Primary anomaly in myelodysplastic syndromes and chronic myeloproliferative disorders
- Isolated i(17q) has poor prognostic significance and progression to AML is frequent
- Pathogenesis most likely related to loss of a tumor suppressor gene such as p53 at 17p13
- Commercial FISH strategy is available to detect the chromosome 17 centromere and q-arm
- Molecular strategy is not applicable

Chronic Myeloproliferative Disorders (Table 32.5) (37, 38, 41, 55)

t(5;12)(q33;p13)

- 2% to 5% of patients with chronic myelomonocytic leukemia
- Associated with myelodysplastic syndromes or chronic myeloproliferative disorder
- Variant translocation partners of 12p13 include 3q26 and 10q24
- 5q33 breakpoint in PDGFRB; 12p13 breakpoint in TEL
- Commercial FISH strategy is available to detect abnormalities of TEL
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(9;22)(q34;q11.2) (Fig. 32.5O)

- "Philadelphia Chromosome," (Ph)
- Ph-chromosome or a variant occurs in 100% of patients with chronic myeloid leukemia
- "Ph-negative CML" does not exist
- Chronic myeloid leukemia also known as chronic granulocytic leukemia
- Variant translocations in 5% to 8% of patients can be complex (involving two or more chromosomes) or cryptic (submicroscopic insertion translocations)
- More than 90% of patients with chronic myeloid leukemia have t(9;22) in all metaphases
- Chronic phase has no other cytogenetic changes
- Myeloid blastic crisis has >50% with additional cytogenetic changes such as multiple copies of Ph-chromosome, +8, i(17q), and +19
- Lymphoid blastic crisis often has anomalies of chromosome 7
- 9q34 breakpoint in ABL; 22q11.2 breakpoint in BCR (breakpoint cluster region)
- Fusion gene usually is b2a2 or b3a2
- Commercial FISH strategies are available to identify BCR/ABL fusion
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis
- For more information on Ph-chromosome in ALL and AML see section on acute leukemia

Lymphomas and Lymphoproliferative Disorders (Table 32.6)

- Classified into non-Hodgkin's lymphoma (T-cell or B-cell) and Hodgkin's disease
- T-cell receptor genes on chromosomes 7 and 14 usually linked with T-cell disorders (Fig. 32.7)

- Light-chain immunoglobulin genes on chromosomes 2 and 22, and heavy-chain immunoglobulin gene on chromosome 14 usually associated with B-cell disorders (Fig. 32.7)

Non-Hodgkin's Lymphoma (Table 32.6) (37, 39, 40 and 41, 56, 57, 58, 59, 60, 61, 62 and 63)

- 80% of patients have detectable chromosome abnormalities

t(2:5)(p23;q35) (Fig. 32.5AA)

- Most likely occurs in 100% of patients with anaplastic large cell lymphoma (Ki-1/CD30+)
- Diverse clinical presentation
- Tetraploidy is associated with poor prognosis
- High frequency in childhood non-Hodgkin's lymphoma
- Variants: t(1;2)(q21;p23), t(1;2)(q25;p23), t(2;3)(p23;q21), t(2;13)(p23;q34), inv(2)(p23q35)
- 2p23 breakpoint in ALK; 5q35 breakpoint in NPM
- Commercial FISH strategy is available to detect break apart of ALK gene
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(3;14)(q27;q32)

- Associated with diffuse large cell lymphoma and 5% to 10% of patients with follicular lymphoma
- Variants include t(3;22)(q27;q11) and t(2;3)(p12;q27)
- 3q27 breakpoint in BCL6; 14q32 breakpoint in IgH
- Commercial FISH strategy is not available, but “home-brew” methods have been reported
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(8;14)(q24;q32) (Fig. 32.5L)

- 100% of patients with ALL-L3 (Burkitt's leukemia) and Burkitt's lymphoma (different presentations of same disease); occasionally, diffuse large cell lymphoma
- May be positive or negative for Epstein Barr virus

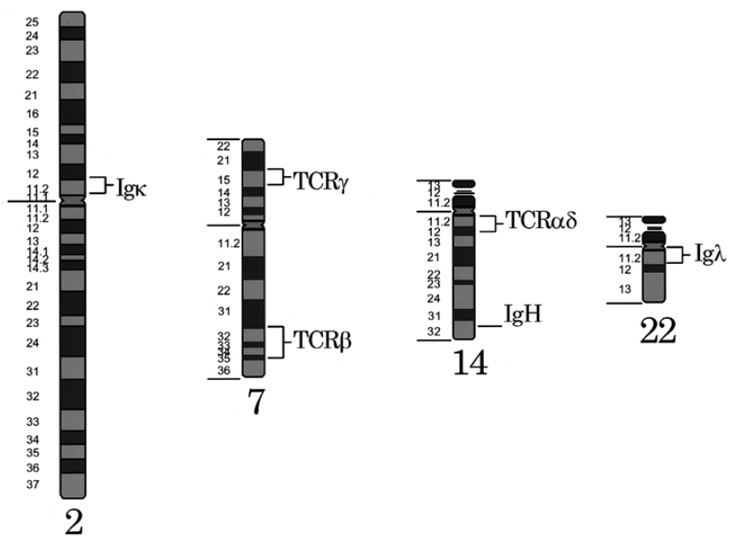

FIGURE 32.7. The immunoglobulin loci on chromosomes 2, 14, and 22; chromosome abnormalities involving any of these sites usually are B-cell disorders. The T-cell receptor (TCR) loci on chromosomes 7 and 14; chromosome abnormalities involving these sites usually are T-cell disorders.

- Variants include t(2;8)(p12;q24) (Fig. 32.5BB) and t(8;22)(q24;q11) (Fig. 32.5GG)
- 8q24 breakpoint in c-MYC; 14q32 in IgH; 2p12 in Igκ; 22q11 in Igλ
- With endemic Burkitt's, the breakpoint is 5′ to c-MYC gene
- Sporadic or AIDS associated Burkitt's, the breakpoint is within c-MYC gene
- Commercial FISH strategy unavailable, but “home-brew” methods to detect c-MYC/IgH fusion reported
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(9;14)(p13;q32)

- Low-grade NHL with plasmacytoid differentiation
- 9p13 breakpoint in PAX5; 14q32 breakpoint in IgH locus
- Commercial FISH strategy is not available, but possible to detect PAX5/IgH fusion
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(11;14)(q13;q32) (Fig. 32.5R)

- 5% to 10% of patients with non-Hodgkin's lymphoma
- Variants include t(11;22)(q13;q11) and t(2;11)(q13;p13)
- Mantle-cell lymphoma
  - 100% of patients with mantle-cell lymphoma
  - 11q13: 80% of breakpoints in major translocation cluster (MTC), 5′ of Cyclin D1 gene (CCND1)
  - 14q32 breakpoint adjacent to IgH enhancer region
- Multiple myeloma
  - Often prodrome of monoclonal gammopathy of undetermined significance (MGUS)
  - 30% to 50% of patients with multiple myeloma (using FISH)
  - 14q32 breakpoint in IgH usually in switch region
  - 70% of patients with multiple myeloma have a breakpoint at 14q32
  - Variants include t(4;14)(p16.3;q32) and t(14;16) (q32;q23)
  - Other translocation partners include chromosomes 6, 8, and 11
  - 11q13 breakpoint in Cyclin D1 gene is variable
  - 1q abnormalities are common secondary anomalies
  - Evolution to plasma cell leukemias is associated with complex cytogenetic abnormalities
- B-cell prolymphocytic leukemia
  - 20% of patients with prolymphocytic leukemia
  - Cases may represent erroneously classified mantle cell leukemia
- B-cell chronic lymphocytic leukemia is not associated with t(11;14)(q13;q32), and when observed in bone marrow or blood, mantle-cell leukemia should be suspected
- 11q13 breakpoint in Cyclin D1 (CCND1, PRAD1, BCL1); 14q32 breakpoint in IgH
- Commercial FISH strategies available to detect fusion of IgH and Cyclin D1
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(11;18)(q21;q21)

- 25% to 50% marginal zone lymphomas (low grade mucosa-associated lymphoid tissue, MALT)
- Good prognostic significance
- 11q21 breakpoint in API2; 18q21 breakpoint in MLT
- Commercial FISH strategy not available, but “home brew” methods have been reported
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(14;18)(q32;q21) (Fig. 32.5S)

- 80% of patients with follicular small-cleaved cell; 39% of patients with diffuse large cell
- Good prognostic significance
- Together with +17, +12, or del(1)(p32p36) denotes poor prognostic significance
- 14q32 breakpoint in IgH; 18q21 breakpoint in BCL2
- Two breakpoints in BCL2 gene: 50% to 60% in MBR (major breakpoint region) and 25% to 30% in MCR (minor cluster region)
- Commercial FISH not available, but “home-brew” methods for BCL2/IgH fusion reported
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

t(14;19)(q32;q13) (Fig. 32.5T)

- B-cell chronic lymphocytic leukemia and small lymphocytic lymphoma (different presentations of same disease)
- Poor prognostic significance
- Most patients less than 40 years old
- Associated with trisomy 12 in 50% of patients
- 14q32 breakpoint in IgH; 19q13 breakpoint in BCL3
- Commercial FISH strategy not available, but possible to detect IgH/BCL3 fusion
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

del(6)(q14q23) (Fig. 32.6I)

- 80% of patients with large cell lymphoma; common in chronic lymphocytic leukemia and T-cell lymphoma
- Good prognostic significance in chronic lymphocytic leukemia
- Candidate gene is MYB
- Commercial FISH strategy not available, but “home-brew” methods for loss of MYB reported
- Molecular strategy is not applicable

inv(14)(q11q32) (Fig. 32.6U)

- 70% of patients with T-cell prolymphocytic leukemia
- Variant: t(14;14)(q11;q32)

- Associated with i(8q)
- 14q11 breakpoint in TCR αδ gene; 14q32 breakpoint in IgH locus
- Commercial FISH strategy in development and “home brew” methods reported
- Defined gene breakpoints are amenable to Southern Blot or RT-PCR analysis

Hodgkin's Disease (Table 32.6) (64, 65)

- Classic Hodgkin's and Reed-Sternberg cells are commonly identified
- 40% of patients with Hodgkin's disease have chromosome anomalies
- No specific chromosome abnormalities described, but recurrent breakpoints include 1p13, 1p36, 2p16-21, 4q25-28, 6q15-21, 7q32-34, 12q22q23, and 19p13

Chromosome Abnormalities That Cross FAB Classification Categories(40, 41, 44, 48, 51, 52 and 53, 55, 66)

del(7)(q22q36) (Fig. 32.6K)

- 9% of patients with AML; myelodysplastic syndromes or t-AML
- Poor prognostic significance
- Commercial FISH strategy is available to detect loss of D7S486 (Elastin gene)
- Molecular strategy is not applicable

Monosomy 7

- Associated with myelodysplastic syndromes and juvenile chronic myelomonocytic leukemia
- Isolated -7 has variable prognostic significance
- Commercial FISH strategy is available to detect loss of chromosome 7 centromere
- Molecular strategy is not applicable

Trisomy 8

- Isolated anomaly in 13% of AML (M2, M4 or M5); 10% of myelodysplastic syndromes; chronic myeloproliferative disorders
- Frequent secondary chromosome anomaly in Ph-positive chronic myeloid leukemia
- Intermediate prognostic significance in AML
- More aggressive as secondary chromosome abnormality
- Commercial FISH strategy is available to detect the chromosome 8 centromere
- Molecular strategy is not applicable

del(13)(q12q22) (Fig. 32.6T)

- 6% of patients with agnogenic myeloid metaplasia
- Associated with myelofibrosis in other disorders such as polycythemia vera and chronic myeloid leukemia
- Secondary anomaly in multiple myeloma, chronic lymphocytic leukemia, and non-Hodgkin's lymphoma
- Critical gene loss may be D13S319 at 13q13
- Commercial FISH strategy available to detect loss of D13S319
- Molecular strategy is not applicable

del(20)(q11q13) (Fig. 32.6Y)

- 2% to 5% of AML; usually prior myelodysplastic syndrome or myeloproliferative disorder
- 6% of patients with polycythemia vera; 1% of patients with myelodysplastic syndromes
- Abnormal erythropoiesis
- Commercial FISH strategy is available to detect loss of D20S108 at 20q12
- Molecular strategy is not applicable

The Chromosome-Breakage Syndromes: Clinical Features, Cytogenetics, and Molecular Genetics

James H. Ray

James German

The so-called chromosome-breakage syndromes are rare, genetically unrelated, and clinically diverse disorders that sometimes are grouped because they share two important features, excessive genomic instability and an increased risk of developing cancer. Most regularly included in the group are Bloom's syndrome (BS), Fanconi's anemia (FA), ataxia-telangiectasia (AT), the Nijmegen breakage syndrome (NBS), xeroderma pigmentosum (XP), and Werner's syndrome (WS).

Each disorder is inherited as an autosomal-recessive trait. In all the disorders except XP, the excessive genomic instability presents itself in cultured but otherwise untreated cells in the form of increased numbers of chromatid and isochromatid gaps and breaks and chromosomal rearrangements. In XP, excessive chromatid breakage occurs only after exposure of cells to ultraviolet (UV) irradiation and UV-mimetic agents. Cells from all the disorders are hyperresponsive to certain chemical or physical agents that damage DNA. Genomic instability has been demonstrated *in vivo* in at least four of the disorders. Although individuals with all the disorders have an increased risk of developing cancer, the distribution of types and sites of cancer is different in each disorder.

Remarkable progress has been made in the last decade in elucidating the molecular and biochemical bases for each of the chromosome-breakage syndromes. The chromosomal location of at least one gene responsible for each disorder has been mapped, the genes have been isolated, and the protein products have been identified. Today, the roles that the proteins play in cellular metabolism are being elucidated, in several cases bringing to light cellular mechanisms not previously known to exist in man.

Here, the clinical features, the cytogenetics, and the molecular genetics of each of the chromosome-breakage syndromes are summarized.

BLOOM'S SYNDROME

Part of "33 - The Chromosome-Breakage Syndromes: Clinical Features, Cytogenetics, and Molecular Genetics"

Clinical Features

BS is the rarest of the chromosome-breakage syndromes. Fewer than 200 affected individuals are known to have been diagnosed since 1954 when the disorder originally was described (1). The incidence of BS in the United States is estimated to be 1/6,331,000. In Ashkenazi Jews it is more common, the incidence having been projected to be 1/60,000; 1 in 107 Ashkenazi Jews in New York City is heterozygous for a BS-associated mutation. Extensive clinical and laboratory records on individuals with BS are maintained in the Bloom's Syndrome Registry, which has made possible an accurate definition of the clinical disorder as well as its complications (2).

Bloom initially described three patients with stunted growth and sun-sensitive telangiectatic erythema of the face (1). Additional features are listed in Table 33.1. The BS fetus is abnormally small, the mean birth weight being 1,906 g for males and 1,810 g for females. Although the postnatal growth rate is normal, both height and weight remain below the third percentile throughout childhood. The vast majority of adults are abnormally short. Men with BS attain an average height of 150 cm; women average 145 cm. Body proportions are normal except for mild microcephaly, dolicocephaly, and a characteristic facies, the result of malar hypoplasia, a relatively prominent nose and ears, and a relatively small mandible. The voice characteristically is high-pitched and squeaky.

Facial erythema typically appears during the first or second summer of life following exposure to the sun. The cheeks and nose, and occasionally the dorsa of the hands and forearms, are affected. The severity of the facial lesion varies greatly and generally decreases with age. Well-circumscribed regions of hypo- and hyperpigmentation — café-au-lait spots — ranging in size from a few millimeters to many centimeters also almost always are observed, and these, in contrast to the limitation of the erythematous and sun-sensitive lesion on the face, are found on the trunk and extremities.

Individuals with BS are immunologically compromised. Most have recurring respiratory-tract infections, specifically otitis media and pneumonia. Abnormally low concentrations of one or more circulating immunoglobulins are observed in 87% of patients. Approximately 12% of the 169 persons followed in the Registry have developed noninsulin-dependent diabetes mellitus. Vomiting and gastrointestinal infections commonly occur during infancy, the former being a result of, in at least some

cases, severe gastroesophageal reflux. Menstruation begins at the usual age in girls with BS but ceases prematurely. Although infertility is the rule, three women have become pregnant and have had normally developed children. Men with BS invariably fail to produce spermatozoa. The average age of individuals with BS at the time of death is 23.6 years, with cancer being the primary cause and chronic lung disease being the cause in a few.

Over 100 cancers have been diagnosed in the 169 individuals under surveillance in the Registry (3). The mean age at the time of cancer diagnosis is 24.4 years. Twenty-nine individuals have developed multiple primary cancers. The cancers in BS are of similar cellular types and arise at similar sites as in the general population; however, in addition to being more common, they arise decades earlier than normal. Included among the cancers that have been diagnosed in BS are acute leukemias, lymphomas, and carcinomas, the latter having arisen most often in the gastrointestinal tract but also in the uterus, breast, larynx, liver, and skin. The rare tumors of childhood and germ-cell tumors also have been observed. Leukemias occur predominately during childhood. Carcinomas appear in late adolescence and predominate thereafter. Cancer has been the cause of death of fully one third of persons with BS.

Cytogenetics

That increased spontaneous chromosome breakage is a feature of BS cells was reported in the mid-1960s (4, 5). Chromosome breakage has been observed in blood lymphocytes and bone marrow cells in short-term culture and in dermal fibroblasts and Epstein-Barr virus-transformed lymphoblastoid cell lines (LCLs) in long-term culture. Chromosome instability manifests itself in cultured but otherwise untreated BS cells in the form of increased numbers of chromatid and isochromatid gaps and breaks, acentric fragments, dicentric and otherwise structurally rearranged chromosomes, telomere associations, and quadriradial configurations (Qrs).

The most characteristic cytogenetic abnormality in untreated cells is the Qr (Fig. 33.1). Qrs in BS typically are symmetrical, consisting of homologous chromosomes associated in a four-armed configuration in which the centromeres are positioned in opposite arms and the opposite arms are equal in length. Qrs result

TABLE 33.1. FEATURES OF BLOOM'S SYNDROME

Clinical
Pre- and postnatal growth deficiency, with relatively normal body proportions
Telangiectatic erythema of face, sun-sensitive
Microcephaly with dolichocephaly
Malar and mandibular hypoplasia
Relative prominence of nose and ears
High-pitched squeaky voice
Hypo- and hyperpigmented areas of skin
Immunodeficiency
Increased otitis media and pneumonia
Bronchiectasia and pulmonary failure
Male infertility; female subfertility and premature menopause
Diabetes mellitus, usually adult onset
Increased incidence of neoplasia of many types and sites
Cytogenetic
Excessive spontaneous chromosomal breakage
Homologous quadriradial configurations
Elevated sister-chromatid exchange frequency
Telomere association

from the exchange of chromatid segments between homologous chromosomes at what appear to be homologous sites; therefore, they are cytological evidence of somatic recombination — somatic crossing-over. The discovery of Qrs in BS was of general biological significance because the exchange of segments between homologous chromosomes may, depending on the segregation pattern of the recombinant chromosomes in subsequent mitoses, lead to the loss of heterozygosity thereby unmasking deleterious recessive genes. Thus, crossing-over is a mechanism by which expression of an altered cellular phenotype can arise in somatic cells.

Increased somatic recombination also has been demonstrated *in vivo* in BS. Multiple chromosome satellite distribution patterns were observed on the group D and G chromosomes in T lymphocytes from an individual who had satellite polymorphisms. A significant percentage of the lymphocytes were homozygous for satellite polymorphisms that constitutionally were present in the heterozygous state in the individual. Also indicative of excessive somatic crossing-over *in vivo* is the finding of an increased incidence of MM and NN erythrocytes in the circulating blood of persons who constitutionally are blood type MN.

In the mid-1970s, a technique was developed that permitted intrachromosomal recombination to be observed (in contrast to the interchromosomal recombination signified by the Qr just discussed). Cells are harvested after growth for two cell cycles in the presence of the thymidine analogue bromodeoxyuridine (BrdU). Slide preparations made from the cultures are exposed to ultraviolet (UV) light and then stained with quinacrine mustard or Giemsa depending on whether fluorescence or light microscopy, respectively, is to be used for viewing the chromosomes. Following treatment with the aforementioned protocol, the chromatids of some chromosomes are differentially stained uniformly along their lengths, one chromatid exhibiting dull fluorescence or pale staining and the other chromatid exhibiting bright fluorescence or dark staining depending on the method of microscopy employed. The sister chromatids of other chromosomes exhibit alternating pale and dark stained regions along their lengths, with the staining patterns of the sister chromatids being mirror images of one another. The points on these latter chromatids at which the staining patterns change represent the points at which exchanges of DNA segments occurred between the sister chromatids of the chromosomes during DNA replication.

When blood lymphocytes from normal (nonBS) individuals are examined using the sister-chromatid exchange (SCE) technique just described, fewer than 10 SCEs/cell are observed (Fig. 33.2A). BS blood lymphocytes, on the other hand, exhibit a 10- to 15-fold increase in the average number of SCEs/cell (Fig. 33.2B) (7). BS is the only human genetic disorder in which BrdU-substituted, but otherwise untreated cells, are known to exhibit an increased frequency of SCE.

As blood lymphocytes from increasing numbers of persons with BS were examined using the SCE technique, an unexpected finding was made, one that was to lead to the discovery of two genetic mechanisms previously not known to be employed in mammalian cells. Some individuals with BS exhibited two populations of cells, one with the high-SCE frequency that is uniquely characteristic of BS and the other with the low-SCE frequency that is observed in normal cells (8). A number of hypotheses were proposed over the years to account for the enigmatic presence of cells with a nonBS (normal) phenotype in persons with a recessive disorder. It was not until the molecular basis for the disorder was identified (see below) that two different genetic mechanisms capable of producing low-SCE somatic cells in persons with BS were discovered: (i) recombination between the two chromosomes 15 within the BLM gene in individuals who were compound heterozygotes (i.e., individuals having mutations at different sites in *BLM*) and (ii) back mutation at *BLM*.

High-SCE BS cells are hyperresponsive with regard to survival and SCE induction following exposure to certain DNA-damaging agents. Chemicals that have been studied include mitomycin C (MMC), monofunctional mitomycin C, 4-nitroquinoline-1-oxide (4NQO), and ethyl methanesulfonate (EMS). BS cells generally only are able to survive exposure to concentrations of chemicals that are an order of magnitude less than normal cells. The number of SCEs induced by a given concentration of a chemical is significantly greater in the already high-SCE BS cells than in normal cells. Survival and SCE induction in the exceptional low-SCE cells in some persons with BS, mentioned above, are comparable to that in normal cells.

BS obligate heterozygotes, who are normally developed and healthy, exhibit normal levels of chromosome breakage and SCE. Some heterozygous men do produce abnormally great numbers of sperm with multiple chromosomal breaks and rearrangements.

Genomic instability in BS also has been demonstrated in several other ways. BS cells are hypermutable: an increased incidence of diphtheria-toxin resistant and hypoxanthine guaninephosphoribosyl transferase (HPRT)-deficient cells have been detected in cultured BS cells. The incidence of HPRT-deficient lymphocytes also is elevated in the circulating blood of persons with BS. In addition, the frequency of erythrocytes mutant at the glycophorin A locus on chromosome 4 is dramatically elevated above normal in BS; increased numbers of M/null and N/null cells and, as mentioned above, increased numbers of MM and NN cells are observed in persons who constitutionally are MN, demonstrating that crossing-over occurs excessively in erythrocyte stem-cell precursors. Increased somatic recombination also has been documented for the HLA-A locus. Increased somatic recombination *in vitro* has been demonstrated by study of polymorphic microsatellite markers in subclones of BS LCLs originally derived from a single EBV-transformed B lymphocyte (i.e., subclones of a clone). Although the microsatellite markers were identical in all cells of a given LCL when it was established by the nature of its origin, the markers that originally existed in the heterozygous state were converted to homozygosity over time as the result of somatic recombination between homologous chromosomes. The frequency of cells with micronuclei also is significantly increased in exfoliated oral mucosal and bladder cells, demonstrating that excessive chromosome breakage occurs *in vivo* as well as *in vitro*.

Genetic Heterogeneity and Complementation

Somatic cell hybridization utilizing cells lines derived from persons with BS representing four distinctive ethnic groups were used to search for evidence of genetic heterogeneity in BS (9).

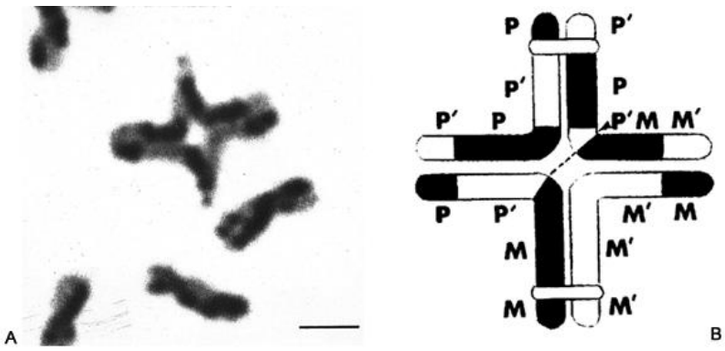

FIGURE 33.1. A: Qr configuration formed between two apparently homologous chromosomes in a BS T lymphocyte. Chromosomes are differentially stained as result of growth for two cell cycles in BrdU-containing medium. **B:** Diagramatic representation of event that led to Qr formation in (**A**). Chromatids arbitrarily have been designated P and P′ for the paternally derived chromosome and M and M′ for the maternally derived chromosome. The presence of P′ segments on P chromatids and P segments on P′ chromatids indicates that exchanges have taken place between the sister chromatids of the paternal chromosome. This also is true for M′ and M chromatids of maternal origin. The presence of M/M′ segments on P/P′ chromatids and P/P′ segments on M/M′ chromatids signifies the exchange of DNA segments between nonsister chromatids of the homologous chromosomes that led to the formation of the Qr. The point at which the nonsister chromatid exchange occurred is designated by the dashed line. Bar represents 2 µm. (From Ray JH, German J. The chromosome changes in Bloom's syndrome, ataxia-telangiectasia, and Fanconi's anemia. In: Arrighi FE, Rao PN, Stubblefield E, eds. *Genes, chromosomes, and neoplasia*. New York, Raven Press, 1981:351–378.)

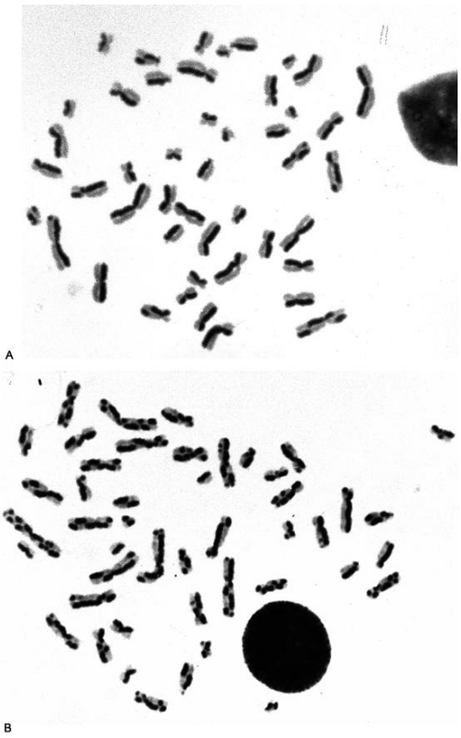

FIGURE 33.2. Differentially stained chromosomes in (A) normal and (B) BS PHA-stimulated lymphocytes demonstrating the dramatically increased SCE frequency of BS cells. Bar represents 10 µm. (From Ray JH, German J. The chromosome changes in Bloom's syndrome, ataxia-telangiectasia, and Fanconi's anemia. In: Arrighi FE, Rao PN, Stubblefield E, eds. Genes, chromosomes, and neoplasia. New York, Raven Press, 1981:351–378.)

The SCE frequency remained elevated in all hybrid cell lines, indicating that mutation at a single locus was responsible for the elevated SCE frequency in all the parental cell lines that were studied. Thus far, molecular genetic studies support the existence of a single locus for BS.

Molecular Genetics

Results of microcell-mediated chromosome transfer experiments, in which normal human chromosomes tagged with the dominant selectable marker for neomycin resistance were introduced into BS cells, provided the first indication that the BS locus was on chromosome 15 (10). Use of structurally rearranged chromosomes further localized the BS locus to the distal part of 15q. That the BS locus was present on chromosome 15 was confirmed by study of an individual with BS who presented with features of both the Prader-Willi syndrome and BS and had maternal uniparental disomy for chromosome 15. The mother was heterozygous for mutation at the BS locus, and her child was homozygous by virtue of having inherited two copies of the segment of her chromosome 15 that carried the *BLM* mutation.

Subsequent to the assignment of *BLM* to chromosome 15, the gene's location was sublocalized by homozygosity mapping. Genotyping of polymorphic DNA markers in persons with BS born to consanguineous parents, taking advantage of the likelihood that the offspring of such unions would have identical mutations at the two BS loci and that DNA sequences closely linked to BLM also would be identical as result of the descent of both chromosomes from a single ancestor, demonstrated tight linkage of *BLM* to the protooncogene *FES*, which was known to map to band 15q26.1 (11). The precise map position of BLM was determined by taking advantage of the low-SCE populations of cells that exist in persons with BS who are the products of nonconsanguineous unions. Previous analysis of polymorphic DNA markers in low-SCE cells from multiple individuals with BS had shown that markers distal to *BLM* were homozygous whereas markers proximal to *BLM* were heterozygous, demonstrating that these individuals were compound heterozygotes, having different mutations at the *BLM* alleles. Intragenic recombination in such individuals can give rise to a wild-type BLM allele, effectively making the cells heterozygous for BS (Fig. 33.3). By comparing polymorphic markers in low-SCE and high-SCE cells from the same individual and determining the precise point at which recombination had occurred giving rise to the low-SCE cells, as indicated by the fact that polymorphic markers changed from exhibiting heterozygosity to exhibiting homozygosity, the map position of *BLM* was identified, and a candidate cDNA was isolated and examined for the presence of mutations (13).

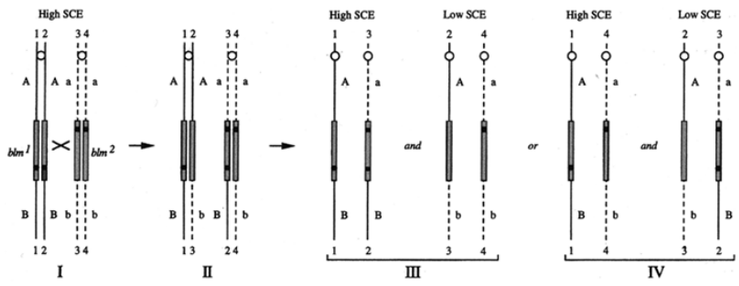

FIGURE 33.3. Model demonstrating how a wild-type BLM allele and low-SCE frequency cells can be generated in an individual with BS by intragenic recombination. **I.** The two chromosomes 15 of a G_2 somatic cell in a BS compound heterozygote are depicted. The mutations in *BLM*, blm^1 and blm^2, are designated by the black dots at different sites in the hatched rectangle. The sister chromatids of the chromosome with the blm^1 mutation are designated 1/1 and 2/2; those of the chromosome with the blm^2 mutation are designated 3/3 and 4/4. The individual is heterozygous for flanking markers designated A/a and B/b. **II**. The G_2 somatic cell in **I** after exchange of segments between nonsister chromatids 2/2 and 3/3. The site of exchange was within *BLM* at a point between blm^1 and blm^2. The resulting BLM locus on chromatid 2/3 (left chromosome 15) is wild type whereas that on chromatid 3/2 (right chromosome 15) has two mutations (blm^1 and blm^2). Flanking markers distal to the point of interchange also are different, being b for chromatid 2/3 and B for chromatid 3/2. Proximal markers remain the same. **III** and **IV**. Alternative chromatid segregation patterns in the subsequent mitosis are depicted. In **III** chromatids 1/1 and 3/2 co-segregate to one daughter cell and 2/3 and 4/4 cosegregate to the other. The daughter cells are homozygous (B/B or b/b) for markers distal to *BLM*. In **IV** chromatids 1/1 and 4/4 cosegregate as do chromatids 2/3 and 3/2. The daughter cells remain heterozygous (B/b) for markers distal to *BLM*. Daughter cells to which chromatids 1/1 and 3/2 or 1/1 and 4/4 cosegregate will maintain the high-SCE frequency characteristic of BS whereas those to which chromatids 2/3 and 4/4 or 2/3 and 3/2 cosegregate will exhibit a low-SCE frequency by virtue of the fact that the BS allele on one chromosome 15 is wild-type. (From Ellis NA, Lennon DJ, Proytcheva M, et al. Somatic intragenic recombination within the muted locus *BLM* can correct the high sister-chromatid exchange phenotype of Bloom syndrome cells. *Am J Hum Genet* 1995:57:1019–1027.)

BLM encodes a 1417 amnio-acid polypeptide with a predicted molecular mass of 159 kDa. The BLM protein exhibits homology to the RecQ helicases, a subfamily of DexH box-containing DNA/RNA helicases. The RecQ helicases are part of a larger group of proteins that contain seven motifs that constitute a highly conserved helicase domain. BLM functions as all 3′ -> 5′ DNA helicases *in vitro*.

Multiple unique BLM mutations have been identified in different individuals with BS. Individuals of Ashkenazi Jewish ancestry share a single mutation, a 6 bp deletion and 7 bp insertion at nucleotide 2,281 BLM, proving that founder effect is responsible for the elevated frequency of BS in that population. More than 60 mutations have been observed in BS individuals of non-Ashkenazi ancestry. Most of the mutations lead to the production of truncated proteins although missense mutations also have been identified.

In spermatogenesis, the BLM protein moves onto the meiotic bivalent during zygotene and pachytene, pointing to a role also in germline recombination.

Prenatal Diagnosis

Determination of the SCE frequency of amniocytes or chorionic villus cells can be offered to couples when both partners are known to be obligate heterozygotes for a BS-producing mutation by virtue of having had an affected child. Use of this technique has permitted the diagnosis BS to be ruled out in a number of pregnancies. It is surprising that only two BS fetuses have been identified among the approximately 20 that have been studied. With the molecular identification of *BLM* and the finding that a single mutation is responsible for BS in individuals of Ashkenazi Jewish ancestry, it has become possible to offer carrier testing and prenatal diagnosis using molecular genetic methods to couples when both partners belong to that ethnic group; such testing is commercially available. Molecular methods also can be employed for couples of non-Ashkenazi ancestry to whom a child with BS has been born when the mutation(s) in *BLM* that they carry has been defined at the molecular level.

FANCONI'S ANEMIA

Part of "33 - The Chromosome-Breakage Syndromes: Clinical Features, Cytogenetics, and Molecular Genetics"

Clinical Features

Fanconi's anemia (FA) occurs with a frequency of 1–3/1,000,000 individuals; approximately 1 in 200 – 300 is heterozygous for mutation at one of the FA loci. Clinical and laboratory records on affected individuals are maintained in the International Fanconi Anemia Registry (14).

The disorder first was described in three sibs with pancytopenia and multiple anatomical defects (15, 16). The phenotype is highly variable, with both intrafamilial and interfamilial differences commonly being observed as well as differences between monozygotic twins. Some individuals exhibit severe anatomical malformations whereas others have none (Table 33.2).

TABLE 33.2. FEATURES OF FANCONI'S ANEMIA

Clinical
Moderate pre- and postnatal growth deficiency
Hyperpigmentation of the skin
Anatomical defects
Absence/hypoplasia of radii and thumbs
Kidney malformation
Strabismus
Micropathalmia
Hypogonadism
Bone marrow hypoplasia
Pancytopenia
Increased neoplasia
Benign and malignant liver tumors
Acute nonlymphocytic leukemia
Cytogenetic
Increased spontaneous chromosomal breakage
Triradial and nonhomologous quadriradial configurations
Hyperresponsiveness to DNA-crosslinking agents

The individual with FA exhibits moderate prenatal and postnatal growth deficiency. Height, weight, and head circumference consistently fall below the fifth percentile. Bruises begin to appear at 5 to 10 years of age, and anemia is diagnosed. In the absence of treatment, the pancytopenia progresses during subsequent years to bone marrow failure. This limits the life expectancy of persons, with 81% dying by 40 years of age.

Hyperpigmentation of various parts of the skin commonly are observed. Approximately 50% of affected individuals have skeletal abnormalities affecting the radial side of the forearms, typically unilateral or bilateral absence or hypoplasia of the radii or thumbs. Kidneys may be missing, misplaced, or horseshoe-shaped, and anomalies of the intestinal tract, central nervous system, and heart sometimes are present. Eye abnormalities include strabismus and micropthalmia. A significant percentage of affected individuals exhibit hypogonadism. Cryptorchidism is observed in approximately 30% of males; spermatogenesis is abnormal, and fertility is significantly reduced. Females, while fertile, may experience menstrual irregularities, secondary amenorrhea, and premature menopause. Hypothyroidism, requiring hormone treatment, is present in some individuals with FA.

Strict adherence to the diagnostic criteria established by Fanconi has led to serious underdiagnosis of FA. As many as one third of affected individuals exhibit only minor phenotypic abnormalities, including height, weight, or head circumference below the fifth percentile, skin pigmentation abnormalities, and/or microphthalmia; therefore, individuals in whom these minor abnormalities are identified should receive appropriate clastogen testing (see below) to determine the appropriateness of FA as a clinical diagnosis.

Treatment of FA consists mainly of blood transfusions and maintenance of bone marrow function by administration of anabolic steroids. While such treatment often is beneficial, bone marrow transplantation now has become the therapy of choice for prolonging the lives of individuals with FA. Marrow from a histocompatible sib and reasonably well-matched placental blood from an unrelated person have served as suitable sources of hematopoietic stem cells.

Early experience with bone marrow transplantation demonstrated that individuals with FA were hypersensitive to the high-dose cyclophosphamide pretreatment regimen and were susceptible

to post-transplant graft-versus-host disease. Modification of the pretreatment regimen to include lower doses of cyclophosphamide followed by thoraco-abdominal irradiation with a moderate dose of 1 – 5 Gy has resulted in improvement of long-term posttransplant survival. Cyclosporin A also now is administered to prevent or lessen the severity of the graft-versus-host disease.

A complication of FA is cancer, which arises in at least 20% of affected individuals. Curiously, the association of FA with predisposition to cancer was not recognized until the mid-1960s. One possible explanation for the delay in recognizing FA as a cancer-associated disease is the fact that during the first several decades after the condition was described affected individuals died early in life from bone marrow failure. In the late 1950s long-term treatment with anabolic steroids began to prolong life. The treatment regimen and/or the aging of the FA population may have contributed to the appearance of cancer. The cancers that do arise, predominantly acute nonlymphocytic leukemia and hepatocellular neoplasms, clearly are completely different in type and distribution from that in the general population.

Obligate FA heterozygotes are not known to be cancer-prone.

Cytogenetics

Chromosome instability was reported to be a feature of FA in the mid-1960s. Schroeder et al. (17) reported that phytohemagglutinin (PHA)-stimulated lymphocyte cultures from affected brothers contained an increased frequency of cells with chromosomal abnormalities. Dermal fibroblast cultures and LCLs also exhibit increased spontaneous chromosome breakage.

The chromosomal aberration frequency in short-term lymphocyte cultures from a given individual with FA may vary over time; the number of cells with chromosomal aberrrations varied from 5% to 42% in a 3-year study of one individual and from 11% to 52% in a 6-year study of another. The frequency of chromosomal aberrations is affected by the concentration of oxygen in which the cells are cultured. Reduction of the oxygen concentration from 20% to 5% significantly reduces the level of chromosome breakage. Further suggestion of a role for active oxygen species in the cellular defect in FA is the finding that antioxidants and the iron chelator desferrioxamine reduce the frequency of spontaneous chromosomal breaks.

The chromosomal abnormalities most commonly observed include chromatid and isochromatid gaps and breaks, acentric fragments, rearranged monocentric chromosomes, and Qrs. Qrs in FA differ from those in BS in that nonhomologous rather than homologous chromosomes typically are involved (Fig. 33.4); therefore, the interchanges in FA would be expected to give rise to cells with partial monosomy, partial trisomy, or balanced translocations depending on the segregation patterns of chromatids in subsequent cell cycles. An increased frequency of cells with endoreduplicated chromosomes also has been observed in cultured cells.

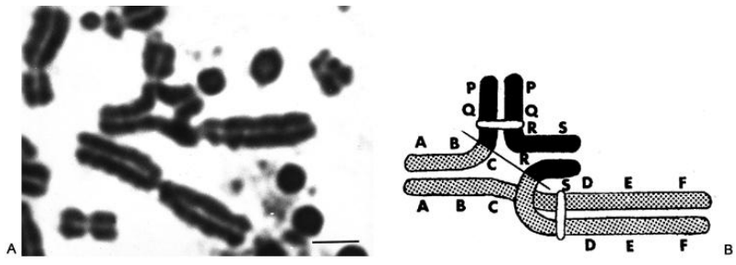

FIGURE 33.4. A: Nonhomologous Qr in FA PHA-stimulated lymphocyte. **B:** Diagramatic representation of event that led to Qr formation in (**A**). Segments on one chromosome are designated ABCDEF; those on the other are designated PQRS. The nonsister chromatid exchange occurred between segments CD on one chromosome and segments QR on the other. The exact point of exchange is denoted by the solid line. Depending on the chromatid segregation pattern in the subsequent mitosis the karyotype of the resulting cells can be either normal, balanced, or unbalanced. For example, if the chromatids containing segments PQCBA and SRDEF cosegregate to one daughter cell and the chromatids containing segments PQRS and ABCDEF cosegregate to the other, the karyotype of the former cell will be balanced and the latter will be normal; however, daughter cells with unbalanced karyotypes will result if the chromatids containing segments PQCAB and ABCDEF cosegregate to one cell and chromatids containing segments PQRS and SRDEF to the other. (From Ray JH, German J. The chromosome changes in Bloom's syndrome, ataxia-telangiectasia, and Fanconi's anemia. In: Arrighi FE, Rao PN, Stubblefield E, eds. *Genes, chromosomes, and neoplasia*. New York, Raven Press, 1981:351–378.)

In addition to displaying an increased frequency of spontaneous chromosomal abnormalities, FA cells exhibit hyperresponsiveness to DNA-crosslinking agents. Exposure to concentrations of DNA-crosslinking agents that have little or no effect on normal cells drastically increases the chromosomal aberration frequency. Agents to which FA cells exhibit hyperresponsiveness include nitrogen mustard (HN2), MMC, long wave UV light in

the presence of 8-methoxypsoralen, cyclophosphamide, cis-diamminedichloroplatinum (II) and (IV), and diepoxybutane (DEB). FA cells respond normally to monofunctional alkylating agents.

The demonstrated hyperresponsiveness to the DNA-crosslinking agents MMC and DEB led to the development of diagnostic tests for individuals with suggestive clinical phenotypes. Soon thereafter, their utility for the prenatal diagnosis of FA in amniocytes and chorionic villus cells was demonstrated (18).

Approximately 15% of persons with FA apparently have two populations of lymphocytes — one that is characteristically hyperresponsive following exposure to DEB and one that responds normally. The finding of two populations of cells with regard to DEB sensitivity is reminiscent of the high-SCE and low-SCE populations of cells that coexist in some individuals with BS who are compound heterozygotes. At least one mechanism that has been shown to account for the existence of cells exhibiting a “wild-type” phenotype in FA is the occurrence of a second mutation in one of the mutant FA alleles that negates the effect of the original mutation on truncation of the encoded protein. The resulting protein, while not being normal in the strictest sense, is able to correct the hyperresponsiveness of FA cells to DNA-crosslinking agents.

In support of *in vivo* genomic instability in FA is the presence of an increased frequency of micronuclei in bone marrow and oral mucosal cells and the presence of an increased incidence of blood lymphocytes mutant at the *HPRT* locus. In addition, the frequency of erythrocytes exhibiting evidence of recombination at the glycophorin A locus is significantly elevated. The ease with which clones of cells with translocations are detected in the bone marrow cells also points to the existence of *in vivo* chromosome instability.

Genetic Heterogeneity and Complementation

The clinical variability observed in FA may be related to the genetic heterogeneity that has been identified (19, 20 and 21). The existence of multiple complementation groups in FA was demonstrated by somatic cell hybridization using LCLs derived from unrelated affected individuals. Use of an FA LCL having two selectable markers, ouabain resistance and HPRT deficiency, permitted selection of complemented somatic cell hybrids based on their abilities to grow in medium containing ouabain, hypoxanthine, methotrexate, and thymidine. In the initial study, two hybrid cell lines exhibited a normal incidence of chromosome breakage and a normal growth response following incubation in medium containing MMC whereas the remaining hybrid cell line exhibited hypersensitivity to MMC typical of FA, establishing the existence of at least two complementation groups — groups A and non-A. In subsequent hybridization studies, the number of FA complementation groups was expanded to eight. Thus, FA is as genetically heterogeneous as XP (see below); however, as has been shown to be the case in XP, most individuals with FA belong to just two or three complementation groups; approximately 67% are FAA; 15% are FAC.

Molecular Genetics

The genes mutated in four of the FA complementation groups have been mapped to four different chromosomal regions, confirming the genetic heterogeneity of the disorder: *FAA* to band 16q24.3; FAC to band 9q22.3; *FAD* to band 3p22 -3p26; *FAG* to band 9p13. The genes for complementation groups A, C, and G have been cloned.

FAC was cloned using functional complementation by electroporated cDNAs of the MMC- and DEB-sensitivity of cultured cells (22). *FAC* spans approximately 80 kb of DNA and consists of 14 exons that encode a 558 amino-acid polypeptide with a 63 kDa molecular mass. The relatively few mutations that have been identified in *FAC* generally lead to truncation or internal deletion of the FAC protein. Although an FAC protein may be produced in cells homozygous for the mutation, the abnormal protein fails to correct the hyperresponsiveness of the cells to MMC, showing that intact carboxy- and amino-terminal domains are required for normal protein function.

The two most common mutations in *FAC* are delG322 in exon 1 and IVS4+4 A to T in intron 4. Additional mutations have been detected in exons 1, 6, and 14. Cells with delG322 and IVS4+4 mutations produce 50 kDa and 55 kDa isoforms of the FAC protein, respectively. The mutation delG322 is found in persons of Northern European ancestry. IVS4+4 occurs predominantly in individuals of Ashkenazi Jewish ancestry; IVS4+4 carrier frequency in the Ashkenazi is estimated to be one in 89. The existence of a founder mutation in this major subgroup of Jewry makes possible complementation group C carrier and prenatal screening.

Data from the Registry suggest that individuals homozygous for delG322 have a relatively mild form of the disorder, with few congenital anomalies and a relatively delayed onset of hematological disease, whereas those homozygous for IVS4+4 have a more severe form, with multiple congenital anomalies and an early onset of hematological complications. Individuals with delG322 mutations tend to survive longer than those with IVS4+4 mutations (14.9 years versus 9.7 years, respectively). Quite surprisingly, the degree of DEB hyperresponsiveness is inversely related to the severity of the disease.

FAC protein is expressed in all cells; it corrects the hyperresponsiveness of complementation group C cells following exposure to bifunctional alkylating agents. FAC is found in the cytoplasm of cells at all stages of the cell cycle regardless of whether the cells have been exposed to bifunctional alkylating agents; this observation makes it unlikely that the protein acts directly on the DNA crosslinks induced by these agents. The protein binds to a complex of cytoplasmic proteins with molecular masses of 60, 50, and 35 kDa. It also binds to cyclin-dependent kinase cdc2, suggesting that is plays a role in G_2/M cell-cycle transition, and to GRP94, a protein expressed in the endoplasmic reticulum with a function in protein transport.

Much less is known about FAA, the protein defective in individuals belonging to complementation group A (23). *FAA* spans 80 kb of DNA and consists of 43 exons that encode a 1,455 amino acid polypeptide with a molecular mass of 163 kDa. The FAA protein contains a nuclear localization signal and a leucine zipper motif, suggesting a nuclear localization; however, early studies indicate that it, like FAC, is located in the cytoplasm.

FAA shares no significant homology with other known proteins. Multiple mutations have been identified in FAA. The mutations generally result in cDNA deletions that lead to the production of truncated proteins.

A candidate cDNA for FAG was identified by its ability to eliminate the MMC sensitivity of complementation group G lymphoblasts (24). *FAG* is identical to *XRCC9*, a human gene that complements the MMC sensitivity of Chinese hamster mutant cell line UV40. Neither FAG nor XRCC9 shares homology with any known protein. The protein product has been suggested to function in DNA postreplication repair or cell-cycle checkpoint regulation.

Prenatal Diagnosis

Prenatal diagnosis has been performed on a large number of pregnancies at risk for FA (25). FA amniocytes and chorionic villus cells exhibit hyperresponsiveness to the chromosome breaking action of DEB just as FA lymphocytes do. Prenatal diagnosis of FA is made, therefore, by demonstrating the characteristic increase in chromatid aberrations and interchanges following exposure of fetal cells to DEB.

The recent isolation of the genes that are defective in FAA and FAC permits molecular prenatal diagnosis to be performed in selected situations. FAC carrier detection and prenatal screening currently are commercially available for individuals of Ashkenazi Jewish ancestry. Molecular prenatal diagnosis of FA in other ethnic groups unfortunately will be limited to families ascertained through the birth of an affected child and in which the mutation(s) has been identified.

ATAXIA-TELANGIECTASIA

Part of "33 - The Chromosome-Breakage Syndromes: Clinical Features, Cytogenetics, and Molecular Genetics"

Clinical Features

Ataxia-telangiectasia (AT) was described independently by Syllaba and Henner (26) and Louis-Bar (27). It occurs with a frequency of 1/20,000 to 1/40,000; approximately 1% of the population is predicted to be heterozygous for an AT-causing mutation.

The individual with AT appears normal at birth; however, neurological signs and symptoms signaling the presence of the disorder appear early in life (Table 33.3). The first is an unsteady gait, which appears between 1 to 3 years of age at the time the child begins to walk. Cerebellar ataxia then progresses during early childhood, and the affected person becomes unable to walk and usually is confined to a wheelchair or the bed by age 10. Speech progressively becomes slurred, and ocular apraxia develops so that the individual has difficulty following objects moved across the visual field. Choreoathetosis is seen in most individuals. Telangiectasia, another clinical sign of AT, also becomes apparent during the first decade of life. Dilated capillaries characteristically are present on the bulbar conjunctiva, the eyelids, the rims of the ears, and the antecubital areas of the arms.

TABLE 33.3. FEATURES OF ATAXIA-TELANGIECTASIA

Clinical
Neurological abnormalities
Cerebellar ataxia
Telangiectasia, bulbar conjunctiva and skin
Ocular apraxia
Choreoathetosis
Slurred speech
Immunodeficiency
Hypoplastic or missing thymus
Hypogonadism (ovarian dysgenesis)
Elevated serum alpha-fetoprotein
Hypersensitivity to ionizing radiotherapy
Increased neoplasia, especially lymphoid
Cytogenetic
Increased spontaneous chromosome breakage
Telomere association
Clones of T lymphocytes with rearranged chromosomes 7 and 14
Hypersensitivity to ionizing radiation and radiomimetic agents

The thymus is hypoplastic or missing in the majority of cases. Immunodeficiency is a common finding but sometimes is not manifested clinically for a number of years. Serum levels of IgA, IgE, and IgG2 are decreased characteristically while IgM, IgG1, and IgG3 concentrations generally fall within normal ranges. Blood T lymphocytes respond poorly to PHA stimulation *in vitro*. The absolute numbers and proportions of circulating T cells commonly are decreased; for example, CD4+/CD45RA+ and naïve T cells sometimes are decreased. Alpha-fetoprotein (AFP), a serum protein that normally decreases rapidly following birth, remains elevated throughout life in most persons with AT. Hypogonadism, and in females even ovarian dysgenesis, is observed relatively commonly.

In one retrospective study the median age at which AT was diagnosed was 78 months. Gait abnormalities had appeared at 15 months of age on average, but the correct diagnosis typically had not been made until after the appearance of telangiectasia at 72 months. Because of the delay in determining that a child has AT, a couple may initiate another pregnancy before it is realized that the first child is so-affected. To permit earlier diagnosis diagnosis of AT, serum AFP determinations would be useful in a child with unexplained and progressive ataxia. The ataxic child with an increased serum AFP concentration (>10 nanograms/mL) then could have a cytogenetic analysis either of T lymphocytes, determining the level of spontaneous chromosome breakage and looking specifically for clones of cells with rearrangements of chromosomes 7 and 14 (see below), or of cultured fibroblasts, examining them for radiosensitivity. The early diagnosis of AT could be beneficial in the medical management of an affected child and also could permit couples to make informed family planning decisions.

An increased risk of developing lymphoid malignancy is an important feature of AT. 10% to 15% of affected individuals develop cancer by early adulthood. Approximately 85% of the malignancies are leukemias or lymphomas (28). T-cell neoplasia may be diagnosed at any age, e.g., T-cell acute lymphocytic leukemia, T-cell lymphoma, or T-cell prolymphocytic leukemia. The increased predisposition to leukemia and lymphoma in AT has been hypothesized to be related to the increased frequency of chromosomal rearrangements that affect the loci that encode T-cell receptors and the immunoglobulin heavy chain (see below). Solid tumors, including hepatocellular carcinoma, ovarian dysgerminomas,

and breast and gastric carcinoma, also have been observed in older survivors.

Treatment of cancer with ionizing radiation led to the discovery that radiosensitivity is a major feature of AT. Treatment employing standard doses of ionizing radiation leads to the development of life-threatening sequelae that are observed in normal individuals only after much higher doses. Radiosensitivity also readily is demonstrated in cultured AT cells.

The question of cancer proneness in carriers of AT mutations, particularly for breast cancer, has yet to be answered. That a degree of radiation hypersensitivity has been reported in cells of AT heterozygotes has raised this possibility. Disruption of the AT locus through mutation or loss of heterozygosity has been reported in a proportion of T-cell prolymphocytic leukemias, B-cell chronic lymphocytic leukemias, and breast cancers.

Cytogenetics

Evidence for genomic instability in AT was reported in 1966 (29). The instability manifests itself in blood lymphocytes in short-term culture in the form of increased numbers of chromatid and isochromatid gaps and breaks, acentric fragments, dicentric chromosomes, and rearranged monocentric chromosomes. Cultured dermal fibroblasts have a breakage frequency even greater than blood lymphocytes. LCLs generally are reported to exhibit a normal level of spontaneous chromosome breakage; however, clones of cells with stable chromosomal rearrangements may be present in such cultures. The frequency of chromosome breakage in freshly aspirated bone marrow has been variable in the few samples that have been examined and reported, being elevated in some samples but normal in others; however, an increased incidence of micronuclei in exfoliated oral mucosal and bladder cells attests to the existence of an increased amount of chromosome breakage *in vivo*.

Telomere association is increased in both interphase and metaphase cells in AT. Telomere shortening, which takes place in normal cells as they age, is reported to be accelerated in AT cells, possibly providing an explanation for the poor growth of cells *in vitro*.

The most characteristic cytogenetic finding in AT is the presence of clones of circulating T lymphocytes that are identifiable as such by the presence of structural chromosomal abnormalities (30, 31). Clones with chromosomal rearrangements are observed in approximately 10% of affected persons. Such mutant clones may account for anywhere from 10% to 95% of the blood lymphocytes. Clones of cells with structurally abnormal chromosomes also have been observed in dermal fibroblasts and LCLs.

The chromosomal rearrangements in the mutant T-cell clones consist principally of translocations and inversions that have taken place in chromosomes 7 and 14 (Fig. 33.5). The distribution of breakpoints on these two chromosomes is nonrandom, specifically affecting bands 7p13, 7q35, 14q11.2, and 14q32.1. The Ig heavy chain locus maps to band 14q32.1 whereas loci for the alpha, beta, and gamma chains of the T-cell receptor map to bands 14q11.2, 7p13, and 7q35, respectively. All of these genes undergo rearrangement in T lymphocytes. Improper reassociation of the DNA sequences of these loci during rearrangement gives rise to the mutant clones of cells with structurally abnormal chromosomes. Examples of translocations observed are t(7;7)(p13;q35), t(7;14)(q35;q11.2) and t(14;14)(q11.2;q32.1) and of inversions are inv(7)(p13q35) and inv(14)(q11.2q32.1). Long-term study of the blood of affected individuals with clonal chromosomal rearrangements has demonstrated that the clones may increase in frequency over time, suggesting that the mutant clones sometimes have a proliferative advantage. Although the role, if any, of such mutant clones in the development of lymphoid cancer is unknown, it is worth noting that rearrangements of chromosome 14 having breakpoints similar to the benign T lymphocyte clones are observed in T-cell lymphocytic leukemia in AT, which suggests that the benign clones may be forerunners of the malignant ones. Alternatively, rearrangements of the same loci found in the benign clones so characteristic of AT may transform the normal lymphocyte into the neoplastic mode from their inception.

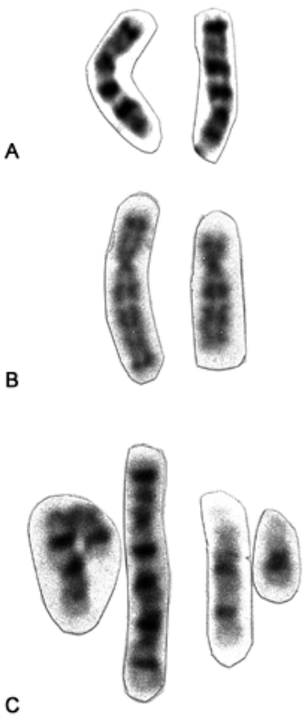

FIGURE 33.5. Partial karyotypes of PHA-stimulated lymphocytes from an individual with AT showing (**A**) inv(7)(p13;q35), (**B**) t(7;7)(p13;q35), and (**C**) t(7;14)(q35;q11.2).

AT cells are strikingly hyperresponsive to the chromosome-breaking action of x-rays and radiomimetic chemicals such as bleomycin. Following irradiation in the G_0 and G_1 stages of the cell cycle cells from normal individuals exhibit increased frequencies of isochromatid gaps, breaks, and interchanges whereas AT cells exhibit increased frequencies of chromatid gaps, breaks,

and interchanges. Following irradiation in the G_2 stage of the cell cycle both normal and AT cells exhibit increased frequencies of chromatid breaks and interchanges; however, the induced aberration frequency is significantly greater in AT. Unirradiated PHA-stimulated AT T lymphocytes exhibit a significantly reduced mitotic index *in vitro* compared to normal cells; following x-irradiation they exhibit significantly less inhibition of mitosis than do normal cells. This results from the failure of AT cells to activate certain cell-cycle checkpoints that normally interrupt DNA synthesis in response to x-irradiation thereby providing cells time to repair DNA damage they have sustained. Unretarded DNA synthesis in AT cells following exposure to x-rays and other radiomimetic chemicals leads to the extensive postradiation chromosomal damage that can be observed cytogenetically.

Genetic Complementation and Heterogeneity

Somatic cell hybridization has been used to demonstrate genetic heterogeneity in AT. The experiments measured radioresistant DNA synthesis in somatic cell hybrids that had been formed by fusion of dermal fibroblasts from individuals with AT from unrelated families. Restoration to normal of DNA synthesis in the x-irradiated hybrid cells was the criterion used for assigning AT cell lines to different complementation groups. Although four complementation groups (A, C, D, and E) were identified in AT (32), molecular techniques have shown the same gene on chromosome 11 to be mutated in each; therefore, the explanation for the existence of multiple complementation groups is obscure.

Molecular Genetics

ATM, the gene for AT, was mapped to chromosome band 11q22 – q23 by genetic linkage studies (33). Microcell-mediated transfer of a normal chromosome 11 tagged with a dominant selectable marker for neomycin resistance into AT complementation groups C and D fibroblasts corrected the radiosensitivity, confirming *ATM*'s location on chromosome 11. ATM was isolated by positional cloning (34). The gene spans 150 kb of DNA and contains 66 exons that produce a 13 kb transcript, which encodes a 350 kDa protein referred to as ATM. ATM is a member of a family of proteins that share a phosphitidylinositol (PI)-3 kinaselike domain at their carboxy termini. ATM also contains a proline-rich region and a leucine zipper motif, suggesting a role in signal transduction. The PI-3 kinases are involved in the regulation of cell-cycle progression, control of telomere length, and response to DNA damage induced by certain DNA-damaging agents.

Mutations throughout *ATM*'s length have been identified in persons with AT. Few recurring mutations have been identified; therefore, most individuals with AT actually are compound heterozygotes, i.e., have different mutations at the two *ATM* loci. DNA haplotyping of unrelated families in whom identical mutations are found generally reveals the families to share a common ancestry. One or more founder mutations have been identified in individuals with AT from Costa Rica, Norway, Poland, Italy, Morocco (in Jews from the Atlas Mountains, now in Israel), Japan, and the United Kingdom. The existence of founder mutations in these populations will provide an opportunity for population screening for AT carrier status.

ATM consistently is mutated in all persons with AT thus far examined regardless of their complementation group, indicating that the basis for the complementation groups does not arise, as had been expected, from mutation at different loci. Most mutations completely inactivate the ATM protein by truncating it, by abolishing its correct initiation or termination, or by deleting large segments. A minority of the mutations result in in-frame deletions and insertions or amino-acid substitutions. Cells from most persons with AT express transcripts for both mutant alleles.

ATM predominantly is a nuclear protein where it interacts with the tumor-suppressor proteins p53 and c-Abl. Following x-irradiation of normal cells the level of tumor-suppressor protein p53 increases in association with a decrease in DNA synthesis. In contrast, AT cells, with their radioresistant DNA synthesis, exhibit a reduced or delayed radiation-induced increase in the level of p53. Interaction of the ATM protein and the protein encoded by c-Abl is thought to alter gene expression in cells. ATM also plays a role in meiosis; by immunofluorescence microscopy, it colocalizes with replication protein A (RPA) along the synaptonemal complex. RPA is a single-strand DNA-binding protein involved in DNA replication, repair, and recombination. The absence of ATM from atm-knockout mice leads to chromosome fragmentation and meiotic arrest in developing gametes. Thus, the functioning of ATM in multiple cellular pathways in multiple cell types may explain the diverse and seemingly unrelated defects that constitute the clinical AT phenotype.

Prenatal Diagnosis

Prenatal diagnosis can be offered to couples in which both partners are obligate heterozygotes for mutation at the AT locus (35). Amniocytes or chorionic villus cells can be examined for increased frequencies of spontaneous and radiation-induced chromosomal aberrations or for radioresistant DNA synthesis. Several affected fetuses have been identified using these methods. With the isolation and characterization of *ATM*, molecular genetic techniques also now can be employed in prenatal diagnosis. Given the fact that few recurring *ATM* mutations have been identified, screening for carrier status is not feasible in most populations; therefore, molecular prenatal diagnosis probably will continue to be limited to couples in which the mutations have been identified following the birth of an affected child.

THE NIJMEGEN BREAKAGE SYNDROME

Part of "33 - The Chromosome-Breakage Syndromes: Clinical Features, Cytogenetics, and Molecular Genetics"

Clinical Features

The Nijmegen breakage syndrome (NBS) was described by Weemaes et al. working in Nijmegen (36). The NBS originally was considered to be a variant form of AT because the two disorders share several major abnormal features (see below). Frequency estimates do not exist for the NBS; it has been identified principally in individuals from eastern and central Europe, in particular among individuals of Slavic ancestry.

Birth weight and length are normal in 70% of newborns; however, poor growth during childhood results in short adult stature (Table 33.4). The body proportions are normal of affected individuals with the exception of the head, the circumference of which falls below the third percentile in 75% of newborns; in the remaining 25% progressive and severe microcephaly develops during the first months of life. The facies is characteristic, consisting of a receding forehead, upslanting palpebral fissures, freckling on the nose and cheeks, a prominent nose, a long philtrum, prominent ears, and a receding mandible. Hair on the head is sparse in half of affected individuals.

TABLE 33.4. FEATURES OF THE NIJMEGEN BREAKAGE SYNDROME

Clinical
Postnatal growth deficiency leading to short stature
Characteristic facies
Microcephaly
Receding forehead and mandible
Upslanting palpebral fissures
Prominent nose and long philtrum
Freckling on nose and cheeks
Prominent ears
Scleral telangiectasia
Immunodeficiency
Recurring respiratory, urinary, and gastrointestinal tract infections
Decreased serum concentrations of IgG, IgA, IgG2, and IgG4
Decreased CD3+ and CD4+ cells
Decreased CD4+: CD8+ cell ratio
Increased incidence of lymphomas
Cytogenetic
Lack of spontaneous chromosome breakage
Circulating clones of T lymphocytes with rearranged chromosomes 7 and 14
Hyperresponsiveness to x-rays and radiomimetic agents

Scleral telangiectasia is observed in some affected individuals, and café-au-lait spots may be present on the skin. Cerebellar ataxia, a cardinal feature of AT, is not a feature of the NBS, and serum AFP levels, which are elevated in AT, are normal.

As in AT, both humoral and cellular immunodeficiency commonly are observed in the NBS. Affected individuals have recurring respiratory tract infections and, frequently also, urinary tract and gastrointestinal infections. Serum levels of IgG, IgA, IgG2, and IgG4 are decreased, and CD3+ and CD4+ cells are decreased in frequency as is the CD4+:CD8+ cell ratio. T lymphocytes exhibit a decreased response to PHA stimulation.

The incidence of cancer is increased. Children have a dramatically increased incidence of lymphomas. Other neoplasms that have been observed include rhabdomyosarcoma, meningioma, glioma, and medulloblastoma. Cancer has been the cause of death of approximately 25% of affected individuals.

Cytogenetics

T lymphocyte cultures from individuals with the NBS have not been reported to exhibit an increased frequency of spontaneous chromosome breakage; however, increased chromatid breakage has been observed in NBS fibroblasts. The most characteristic cytogenetic finding is circulating clones of T lymphocytes with translocations and inversions of chromosomes 7 and 14 (36, 37). These chromosomal rearrangements are strikingly similar to those observed in AT (Fig. 33.5). As in AT, the breakpoints involved in the rearrangements coincide with the location of T-cell receptor and immunoglobulin heavy-chain genes — 7p13, 7q35, 14q11.2, and 14q32.1. The incidence of cells with chromosomes 7 and 14 rearrangements is greater in the NBS than in AT, generally being present in 10% to 35% of T lymphocytes. The most common rearrangement in the NBS is inv(7)(p13q35); whereas inv(14)(q11q32), which commonly is encountered in AT, occurs only rarely.

Both T lymphocytes and dermal fibroblasts are hyperresponsive to ionizing radiation and radiomimetic drugs such as bleomycin. The frequency of chromatid aberrations following x-irradiation during S/G_2 is significantly greater than normal in NBS T lymphocytes. In one study, 70% of NBS T lymphocytes exhibited chromatid aberrations following 1 Gy of ionizing radiation as compared to fewer than 10% of T lymphocytes from a normal individual. As in AT, radioresistant DNA synthesis is increased significantly in NBS lymphocytes and fibroblasts following x-irradiation. After a radiation dose of 40 Gy, the rate of DNA replication is 43% to 78% of that in untreated cells whereas the rate in normal cells is reduced to 17% to 38% of that untreated cells.

Genetic Heterogeneity and Complementation

Early complementation studies utilizing radioresistant DNA synthesis as a marker indicated that the NBS was genetically distinct from AT and suggested that affected individuals fell into two complementation groups, V1 and V2 (32). Later studies, utilizing radioresistant DNA synthesis (38) and induced chromosomal aberrations following x-irradiation (39), identified only a single complementation group. Molecular genetic analysis supports the latter findings (see below).

Molecular Genetics

Microcell-mediated transfer of normal human chromosomes into NBS fibroblasts demonstrated that the NBS gene is in bands 8q21-q24 (38), and this regional assignment was confirmed by linkage analysis (40). The gene was isolated by positional cloning (41, 42). It spans 50 kb of DNA and consists of 16 exons that encode a 754 amino-acid polypeptide with a predicted molecular mass of 85 kDa. The protein, named nibrin, has two conserved domains in the amino-terminal region that are found in cell-cycle checkpoint proteins that function in DNA replication and repair — a fork-head-associated domain and a breast-cancer, carboxy-terminal domain. Nibrin associates with Rad50 and Mre11 in a protein complex that functions in DNA double-strand break repair. The complex possesses manganese-dependent, single-stranded DNA endonuclease and 3′->5′ exonuclease activities. The protein is expressed constitutively in all tissues.

The most common mutation in *NBS* is 657del5, which has been suggested to be a founder mutation in Slavs. All the mutations that have been identified in *NBS* lead to the production of truncated proteins.

Prenatal Diagnosis

Analysis of cultured amniocytes and chorionic villus cells, using radioresistant DNA synthesis as a marker, has proven to be a reliable method for prenatal diagnosis of the NBS (43). Now that the *NBS* gene has been isolated, molecular genetic techniques likely will be used for both carrier screening and prenatal diagnosis in families in which the mutation(s) has been identified.

XERODERMA PIGMENTOSUM

Part of "33 - The Chromosome-Breakage Syndromes: Clinical Features, Cytogenetics, and Molecular Genetics"

Clinical Features

Xeroderma pigmentosum (XP) was described well over a century ago by von Hebra and Kaposi (44). Frequency estimates range from 1 in 100,000 in Japan and North Africa to 1 in 250,000 to 1 million worldwide.

Affected newborns appear normal, but signs of acute sunlight hypersensitivity of the skin appear in infancy or early childhood (Table 33.5). Minimal exposure to the sun results in unusually prolonged erythema, often accompanied by blistering and peeling. Freckling usually develops in sun-exposed areas by two years of age. The skin becomes dry, scaly, and atrophic, and multiple telangiectatic areas develop as the skin sustains continued damage. Actinic keratoses and other benign forms of neoplasia of the sun-exposed areas of the skin appear, followed or accompanied by the development of cancers in 45% of patients.

TABLE 33.5. FEATURES OF XERODERMA PIGMENTOSUM

Clinical
Skin
Excessive erythema following sun exposure
Freckling and keratoses
Excessive dryness, pigmentation, and atrophy in response to sunlight damage
Benign and malignant neoplasms of many types
Eyes
Photophobia
Conjunctival erythema
Chronic inflammation of bulbar conjunctiva
Scarring of the cornea with blindness, in response to sunlight damage
Nervous system
Loss of deep tendon reflexes
Mental deficiency
Cytogenetic
Lack of spontaneous chromosome breakage
Excessive chromosomal breakage in response to ultraviolet light and certain chemicals

Ocular abnormalities also commonly are observed. Photophobia is present in many affected individuals. Some degree of chronic inflammation of the conjunctiva is characteristic, with atrophy and scarring of the eyelids. Blindness often results from the actinic damage to the cornea. Approximately 20% of individuals with XP have neurological symptoms including areflexia, dysarthria, ataxia, and, in some cases, severe mental deficiency. The progressive neurological deterioration is thought to result from accelerated neuronal death.

Skin cancer, principally basal-cell and squamous-cell carcinoma but also melanoma, is increased enormously in XP. The cancers generally are limited to the face, head, neck, eye, and tip of the tongue, regions of the body that receive excessive sun exposure. Melanoma is increased in both sun-exposed and nonexposed areas. Benign and malignant neoplasms also develop on the eyelids. The mean age of appearance of the first skin cancer is 8 years. Although leukemias, lymphomas, brain tumors, and carcinoma of nonintegumentary structures certainly occur in XP (as in other people), they are impressive by their rarity. The expected life-span of XP patients is reduced by approximately 30 years, the main cause of premature death being complications of skin cancer.

Cytogenetics

Unlike in the other chromosome-breakage syndromes, untreated XP cells fail to exhibit an elevated frequency of spontaneous chromosome breakage; however, they do exhibit cytogenetically detectable hyperresponsiveness following treatment with certain DNA-damaging agents (45). When XP cells are exposed to UV-light (254 nm), the induced chromosomal aberration frequency is significantly greater than in comparably treated normal (nonXP) cells. XP cells also are hyperresponsive with respect to cell killing and to the chromosome-breaking action of 4-NQO, N-acetoxy-2-acetylaminofluorene, HN2, decarbamyl mitomycin C (DMMC), aflatoxin B_1, and sterigmatocystin. The hypersensitivity to these chemicals is accompanied by decreased DNA-repair synthesis.

Untreated XP dermal fibroblasts, blood lymphocytes, and LCLs exhibit a normal baseline SCE frequency; however, the SCE frequency of XP cells of some of the complementation groups (see below) is significantly greater than that of similarly treated nonXP cells following exposure to UV-light. XP cells also exhibit hyperresponsiveness with respect to SCE induction following exposure to 4-NQO, HN2, and DMMC; however, they exhibit a normal SCE response to EMS, methyl methanesulfonate, N-methyl-N'-nitro-N-nitrosoguanidine, ethyl nitrosourea, and dimethyl sulfate. The response of XP cells to SCE induction by different classes of chemicals is related to their inability to repair the specific types of DNA damage caused by the chemicals. DNA damage induced by the chemicals that elicit hyperresponsiveness is defectively repaired by XP cells whereas DNA damage induced by chemicals that elicit a normal response is efficiently repaired.

Genetic Heterogeneity and Complementation

Defective DNA repair in UV-irradiated XP skin fibroblasts was reported in 1968 (46). Following exposure to UV-light different levels of nucleotide-excision repair (NER), detected as so-called unscheduled DNA synthesis (UDS), were observed in different individuals with clinical XP, suggesting very early that heterogeneity might exist at the molecular level. To search for genetic heterogeneity, fibroblasts from unrelated individuals with XP were hybridized, the heterokaryons were exposed to UV-light, and the cells then were exposed for a brief time to tritiated

thymidine (47). The amount of UDS in the nuclei of the heterokaryons was compared to that of diploid nonfused cells on the same slide. Parental cells of the heterokaryons that exhibited normal or near-normal amounts of UDS were assigned to different complementation groups whereas parental cells of the heterokaryons that exhibited low levels of UDS comparable to that of unfused cells were assigned to the same complementation group. Seven complementation groups, XPA-XPG, have been identified using this technique. Individuals belonging to the different complementation groups tend to exhibit different disease severities and different amounts of UDS following exposure to UV-light; however, a striking degree of overlap between groups exists for both the phenotype and DNA-repair level. Besides the seven XP complementation groups that are defective at NER, an XP "variant" exists in which NER is normal but so-called post-replication repair is abnormal. XP variants have the classical clinical XP phenotype.

Molecular Genetics

The genes for all even XP complementation groups and the XP variant have been mapped and cloned (48). The chromosomal location of the gene for each complementation group and the function of the gene is shown in Table 33.6. The proteins that are affected in the different complementation groups are involved in nucleotide excision repair (NER). It is by way of NER that the diverse DNA lesions that result from exposure to chemical and physicial agents are repaired. The NER pathway has two components — transcription-coupled repair (TCR) and global-genome repair (GGR). The repair afforded by proteins involved in TCR is limited to DNA lesions produced on DNA strands that are being transcribed at the time the lesion is formed. Other proteins perform GGR, repairing DNA lesions in the remainder of the genome. All XP complementation groups except XPC are defective in both TCR and GGR; XPC has normal TCR but defective GGR.

TABLE 33.6. MOLECULAR GENETICS OF THE CHROMOSOME BREAKAGE SYNDROMES

Syndrome	Complementation Group	Chromosome Locus	Enzyme/Activity
BS		15q26.1	BLM; RecQ helicase with 3′ ->5′ helicase activity
FA	A	16q24.3	Cytoplasmic protein
FA	C	9q22.3	
FA	D	3p22-p26	Cytoplasmic protein interacting with cyclin-dependent kinase cdc2, endoplasmic reticulum protein GRP94, and other 60, 50, and 35 kDa cytoplasmic proteins
FA	G	9p13	Suspected involvement in DNA post-replication repair or cell-cycle checkpoint control
AT		11q22-q23	Phosphitidylinositol 3-kinase
NBS		8q21	Nibrin; component of protein complex that functions in DNA replication and repair
XP	A	9q34	Recognition of pyrimidine dimers
XP	B	2q21	Forms complex with TFIIH; possesses 3′ ->5′ DNA helicase activity
XP	C	3p25.1	Recognition of lesions on transcriptionally inactive DNA and nontranscribed DNA strands of active genes
XP	D	19q13	Forms complex with TFIIH; possesses 5′ >3′ DNA helicase activity
XP	E	11	Recognition of [6-4] photodimers
XP	F	16p13.3	Endonuclease that makes incision 6 nucleotides distal to 3′ end of adduct
XP	G	13q33	Endonuclease that makes incision 22 nucleotides distal to 5′ end of adduct
XP variant			DNA polymerase v
WS		8p21	WRN; RecQ helicase

Repair processes that are induced following the introduction of lesions into the DNA by a damaging agent are complex, requiring the participation of multiple proteins. The proteins that are mutant in the several XP complementation groups represent only a small number of the proteins required for efficient DNA repair. The protein products for XPA and XPE are damage-recognition factors. XPA protein recognizes cyclobutane dimers formed between adjacent thymine residues; XPE protein recognizes [6-4] photodimers formed between adjacent thymine and cytosine residues. XPA protein additionally recognizes cis-diamminedichloroplatinum(II)-induced adducts. The protein products for XPB and XPD associate with other proteins in the transcription factor IIH complex (TFIIH), a high-molecular-weight protein complex that functions in both NER and in the initiation of mRNA transcription by RNA polymerase II. Both XPB and XPD exhibit DNA helicase activity. XPB possesses 3′-> 5′ DNA helicase activity while XPD's activity is 5′-> 3′. The protein products for XPF and XPG exhibit endonuclease activity. They are involved in the incision steps that take place on either side of the DNA adduct before it is removed. Prior to the incision step, ATP-dependent formation of an open DNA structure of approximately 25 nucleotides in size occurs around the adduct. XPF makes an incision six nucleotides distal to the 3′ end of the adduct; XPG makes an incision 22 nucleotides distal to the 5′ end of the adduct. XPF and XPG act at the juncture between double- and single-stranded DNA. The XPC protein product is involved only in GGR. Lesions on transcriptionally inactive DNA sequences as well as on the nontranscribed strand

of active genes serve as its substrate. The 125 kDa XPC protein forms a complex with HHR23B, a 58 kDA protein. The complex is required for the excision of thymine dimers from DNA. XP variant cells exhibit defective post-replication repair. The gene defective in XP variant is DNA polymerase η (49). DNA polymerase η inserts adenine residues on the complementary DNA strand opposite thymine dimers enabling the dimers to be bypassed during replication. Absence of DNA polymerase η in XP variant cells causes DNA replication to be error-prone, leading to the introduction of many mutations.

Prenatal Diagnosis

Prenatal diagnosis for XP is available to those couples known to be at risk because of the birth to them earlier of an affected child (50). Cultured amniocytes and chorionic villus cells are exposed to UV-light, and the amount of UDS in the fetal cells with the suspected diagnosis of XP is compared to that in cells from a control fetus. An abnormally decreased amount of UDS in the suspected fetus confirms the diagnosis XP. Molecular diagnosis, looking for the presence of specific mutations in the fetus, probably will be available in the future at least for families in which the causative mutations in the XP gene have been identified.

WERNER'S SYNDROME

Part of "33 - The Chromosome-Breakage Syndromes: Clinical Features, Cytogenetics, and Molecular Genetics"

Clinical Features

Werner's syndrome (WS) occurs with a frequency of 1 – 22/1,000,000 individuals. The syndrome was described almost a century ago by Werner in a family of two brothers and two sisters who exhibited short stature, premature graying of the hair, cataracts, sclerodermalike skin changes, and hyperkeratotic lesions on the soles of the feet (51). Consanguinity is increased in frequency in parents of affected individuals.

Individuals with WS appear normal throughout childhood and early adolescence (Table 33.7) (52). Short stature, the first symptom to appear, becomes apparent around the time of puberty and is accompanied by low body weight. Average height and weight of adult men with WS is 157 cm and 45 kg, respectively; that of adult women is 146 cm and 40 kg. The trunk is stocky whereas the arms and legs are thin and spindly because of the significant degree of muscle atrophy.

TABLE 33.7. FEATURES OF WERNER'S SYNDROME

Clinical
Short stature
Stocky trunk with thin extremities
High-pitched or hoarse voice
Premature graying and thinning of hair
Cataracts
Scleroderma-like skin changes
Hypogonadism
Decreased fertility
Diabetes mellitus
Atherosclerosis
Increased sarcomas
Cytogenetic
Increased spontaneous chromosomal breakage
Variegated translocation mosaicism

Premature graying of the hair begins in late adolescence, often accompanied by hair loss, particularly on the head, eyelashes, and eyebrows. Axillary and pubic hair also is lost in some patients. Cataracts of the type associated with advanced age develop during the third decade of life and generally are bilateral.

Atrophic skin changes develop during the second decade of life. The sclerodermalike skin changes are noticeable particularly on the face, hands, and feet where the skin becomes tight, shiny, and smooth as result of the replacement of subcutaneous tissue by connective tissue. Hyperkeratoses and calluses develop, particularly on the feet and ankles. The calluses ulcerate and are slow to heal, sometimes making amputation necessary.

The voice is high-pitched or hoarse in approximately half of affected individuals.

Hypogonadism is common. Men generally have small external genitalia while women have infantile external and internal genitalia. Women generally have irregular menses and a premature menopause. Both sexes may be fertile, but fertility apparently is reduced. Sometimes generalized osteoporosis occurs, with involvement particularly of the hands, legs, and feet. Atherosclerosis is common, as is vascular calcification in the lower extremities. Diabetes mellitus is present in approximately 50% of cases.

Individuals with WS have an increased propensity to develop both sarcomas and carcinomas with an overrepresentation of nonepithelial, soft-tissue neoplasia. The most common malignancies are soft-tissue sarcomas, osteosarcomas, melanomas, and thyroid carcinomas; benign meningiomas also occur. Individuals with WS generally die by 47 years of age, the principal causes of death being cancer and vascular accidents.

Cytogenetics

Genomic instability is a striking feature of WS. Although early published cytogenetic reports gave equivocal results, it now generally is agreed that the frequency of spontaneous chromosomal aberrations is increased in both PHA-stimulated peripheral blood lymphocytes and LCLs, as first was reported by Nordenson (53). The most striking cytogenetic feature of WS is the increased frequency of clones of fibroblast cell lines with structurally rearranged chromosomal complements described in 1975 (54). Hoehn et al. reported that 13 of 15 fibroblast cultures established from multiple skin samples taken postmortem from a woman with WS had at least one mutant clone of cells with a unique structural chromosomal rearrangment. Multiple fibroblast cell lines and LCLs established from other persons with WS also have exhibited clones of cells with different structural chromosomal rearrangements.

The term *variegated translocation mosaicism* was coined by Hoehn et al. to describe the existence of multiple clones of cells each having a different structural chromosomal rearrangement in cell lines derived from a single individual. It is unclear whether clones of cells with structurally rearranged chromosomal complements exist *in vivo*; however, the occasional finding of identically rearranged chromosomal complements in different cell lines derived from different biopsies from a single affected individual

supports an *in vivo* origin. The basis for the presence of clonal chromosomal rearrangements in long-term WS cell lines is unclear; however, it may be related to the decreased proliferative response of WS cells *in vitro*.

Fibroblast cultures derived from WS skin have a remarkably shortened life span *in vitro*, typically surviving for only 12.7 population doublings compared to survival for over 50 for normal cells (55). The average cell cycle time of WS cells is prolonged principally because of a longer duration of S.

Genomic instability exists *in vivo* in WS. The frequency of blood lymphocytes mutant at the *HPRT* locus is elevated 8-fold above normal; approximately half of the mutations result from deletions of more than 20 kb of DNA from the *HPRT* locus. *In vitro* DNA ligation studies also have demonstrated that WS cells introduce two to five times more mutations than normal cells during ligation of DNA ends. The mutations mainly are a result of increased numbers of DNA deletions.

Molecular Genetics

WRN, the gene mutated in WS, was mapped to the short arm of chromosome 8 by homozygosity mapping, taking advantage of the fact that both the *WRN* gene locus and its closely flanking polymorphic markers in persons born to consanguineous unions are identical by descent. *WRN* then was isolated by positional cloning (56). The gene spans a genomic region that is at least 100 kb in size and contains 35 exons that encode a 1,432 amino-acid polypeptide.

The function of the WRN protein is unknown. The predicted protein has a central domain containing the seven helicase sequence motifs common to all DNA/RNA helicases, including *BLM*. It shares homology with the RecQ family of DNA helicases. WRN has a nuclear localization signal and has been found only in the cell nucleus. Expression studies have revealed that WRN has an ATP-dependent 3′–> 5′ DNA unwinding activity making it a bona fide DNA helicase. It also has an amino-terminal exonuclease domain with significant similarity to the 3′–> 5′ proofreading domain of *Escherichia coli* DNA polymerase I. Mutations in *WRN* frequently lead to the production of truncated proteins; missense mutations have never been identified. In Japan, where WS is more common than in other countries, analysis of mutations in *WRN* has revealed the existence of a common founder mutation. Elsewhere, persons with WS have different *WRN* mutations so that most of them are compound heterozygotes for the disorder.

Prenatal Diagnosis

With the identification of the gene responsible for WS, prenatal diagnosis now is possible. Prenatal diagnosis probably will be restricted to those families in which the parents are known obligate heterozygotes as result of previously having had an affected child.

SUMMARY

Part of "33 - The Chromosome-Breakage Syndromes: Clinical Features, Cytogenetics, and Molecular Genetics"

Genetically determined genomic instability, first identified in BS, is the subject of basic laboratory investigation in the six rare clinical disorders that comprise the chromosome-breakage syndromes. The chromosome-breakage syndromes differ from one another both clinically and genetically, and their grouping is solely for heuristic purposes. Each disorder is very rare. The pattern of genomic instability in each is unique as are the types and distribution of cancers. It is believed that the explanation for the instability that exists in each disorder will lead to an understanding of various mechanisms by which stability of the genome is maintained. Because of the rarity of the disorders, unraveling the nature of and the basis for the syndromes quite possibly will have a greater impact on human biology that it does on clinical medicine. Yet, the recent attention given this group of rare disorders has resulted in better definition of the clinical syndromes, doubtless of value to affected families.

The past decade has witnessed major advances in our understanding of the molecular bases for the several chromosome-breakage syndromes. The chromosomal locations of 15 of the approximately 20 genes responsible for the disorders have been identified (all except genes for four of the eight FA-complementation groups), and currently the roles that the various newly recognized protein products play in cellular metabolism are subjects of interesting study (Table 33.6). As might have been predicted from the different forms of increased genomic instability that repeatedly have been documented for each of the syndromes, the proteins, which when mutant cause the various syndromes, for the most part have been associated either with DNA replication or with the repair of DNA lesions that are induced following exposure to chemical and physical agents. Some of the proteins interact directly with the damaged DNA; others function indirectly in DNA repair by stimulating the activity of other enzymes. None of the proteins has been identified as being essential for cell survival. Because of the duplicaton that exists in the cell's DNA replication/repair machinery, cells of the chromosome-breakage syndromes are just less efficient at these activities than normal. The multiple activities that some of the proteins have in cells explain how defects in single genes can exert a wide array of phenotypic effects within each of the clinical syndromes. The extensive new information acquired during the study of the chromosome-breakage syndromes has led to a better appreciation of the complexity of the cellular processes that are involved in DNA replication and DNA repair in mammalian cells.

An immediate impact that the advances will have in clinical medicine is in the area of prenatal diagnosis. Prior to the identification of genes responsible for the different disorders, prenatal diagnosis was limited to those families in which couples had been identified as obligate heterozygotes through the birth of an affected child. Individuals belonging to ethnic groups in which one or a very few mutations have been identified, such as blm^{Ash} in BS and IVS4+4 in FA complementation group C individuals who are Ashkenazi Jews, now can learn their carrier status prior to the birth of an affected child. If both partners are carriers of a mutation for a given disorder, prenatal diagnosis can be performed to determine the genetic constitution of the fetus. Testing of carrier status now is commercially available for BS and FA complementation group C individuals of Ashkenazi Jewish ancestry and may become available for ethnic groups in other disorders as founder mutations are identified. Because of the existence

of so many unique mutations in carriers not belonging to specific ethnic groups, recognition that these individuals are obligate heterozygotes for one of the chromosome-breakage syndromes probably will continue to be delayed until the birth of an affected child; once this occurs, family members can be identified unequivocally as being either carriers or noncarriers, and this information can be used in planning future pregnancies.

As a more thorough understanding is gained of how the proteins that are defective in the different syndromes function in normal cells, it may become possible to develop ways to alleviate or eliminate some of the clinical complications that occur during an affected person's lifetime. Such attempts already are being made in FA using genetic engineering and bone marrow transplantation to introduce normal FA genes into affected persons.

34
Solid Tumor Cytogenetics

Fredrik Mertens

Thomas E. Carey

HISTORICAL PERSPECTIVE

Part of "34 - Solid Tumor Cytogenetics"

The discovery of a consistent, specific chromosome abnormality in chronic myelogenous leukemia (CML) in 1960 by Nowell and Hungerford gave birth to the field of cancer cytogenetics. The visibly altered copy of chromosome 22 that they described became known as the Philadelphia chromosome (Ph). This marker, which is the result of a reciprocal translocation between chromosomes 9 and 22, is present in more than 95% of CML cases and is so commonly known that, even among noncytogeneticists and nonhematologists, Ph is regarded as pathognomonic for CML.

In the years following the description of the Philadelphia translocation in CML, multiple specific chromosome changes have been identified in various hematologic neoplasms. Some chromosome abnormalities are highly specific for a restricted set of malignant diseases; e.g., t(15;17)(q22;q11) is found in nearly all acute nonlymphocytic leukemias of the French-American-British (FAB) M3 type, but it has not been reported in other hematologic diseases (see Chapter 29, Basic Cytogenetics). Other rearrangements such as t(8;14), t(2;8), and t(8;22) involving the loci for MYC (c-myc) on chromosome 8 and the immunoglobulin genes on chromosomes 14, 2, and 22 originally observed in Burkitt's lymphoma are common to several types of B-cell neoplasms.

Thus, as described in Chapter 29, specific chromosome changes can be used to distinguish tumors of a specific type (e.g., B-cell leukemias can be distinguished from T-cell leukemias by rearrangements affecting the immunoglobulin genes and the T-cell receptor genes, respectively). Specific chromosome rearrangements in some cases also have been shown to be independent prognostic indicators. For example, t(8;21) (q22;q22) is associated with a relatively good prognosis in acute nonlymphocytic leukemia, whereas t(4;11) (q21;q23) is associated with a poor prognostic outlook in acute lymphocytic leukemia and acute undifferentiated leukemia.

APPLICATIONS OF TUMOR CYTOGENETICS

Part of "34 - Solid Tumor Cytogenetics"

As indicated above, specific chromosome alterations are useful in classifying hematologic tumors according to type. They also may have prognostic significance and, perhaps most importantly, can provide essential clues to the location of genes that may be mutated, lost, inactivated, or aberrantly expressed as a result of (or in combination with) chromosome rearrangements associated with tumor development and progression. This chapter discusses specific chromosome rearrangements that have been identified in a variety of solid human tumors. By the end of the chapter, we hope to have conveyed to the reader a sense of the emerging picture of nonrandom changes in individual solid tumor types. Knowledge of the consistent chromosome abnormalities in solid tumors will serve as a map to the genes that are altered during the neoplastic process. We will illustrate how some cancer-associated chromosome abnormalities have already led to the isolation of genes and the identification of gene products that are not only important in the cancer process but are essential for normal cell growth and development. The elucidation of how gene expression is altered by chromosome rearrangement will provide the basis for predicting the clinical behavior of individual tumors and should lead to the development of novel strategies for cancer treatment and prevention.

METHODOLOGICAL CONSIDERATIONS

Part of "34 - Solid Tumor Cytogenetics"

Although the role of chromosome changes in hematologic cancers is well established, until recently only a small proportion (6% to 13%) of cancer cytogenetic studies concerned solid tumors. Of these, the majority dealt with benign tumors and pediatric tumors, which generally contain relatively few chromosome abnormalities. Therefore, by 1989, only 1% of the published cytogenetic reports about cancer dealt with common epithelial tumors or carcinomas, which represent 80% of all human cancers. In the intervening 10 years, much progress has been made largely as a result of improved cultivation techniques and new methods of genomic evaluation that do not require chromosome preparations from individual tumor samples.

Complicating Factors in the Cytogenetic Analysis of Solid Tumors

To analyze chromosomal integrity with standard techniques, it is necessary to examine the cells during mitosis. However, in a significant proportion of solid tumors, the mitotic index is low, making it difficult to obtain sufficient mitotic cells for cytogenetic

characterization. This is further complicated by the fact that epithelial tumors are surrounded by stromal components that limit access to the mitotic cancer cell populations. This difficulty in gaining access to the tumor cells often results in chromosome preparations that are fuzzy, incomplete, and less than optimal for complete characterization. Compounding these problems, solid tumors usually show multiple chromosome changes, many of which are complex and some of which have been unidentifiable. Solid tumors also frequently have high ploidy with near triploid or tetraploid counts or more, especially in more advanced tumors. Furthermore, carcinomas, which arise from epithelial surfaces such as the upper aerodigestive tract, the gastrointestinal tract, the lower urogenital tract, and the skin, may be contaminated with microorganisms that can destroy even short-term cultures. Additionally, for a thorough cytogenetic examination, analysis of a minimum number of metaphases is necessary, and without adequate recovery of viable tumor cells, it is difficult to accurately determine the consensus karyotype. For many solid tumors, these problems have now been overcome with the development of more effective culture techniques. As a result, the field of solid cancer cytogenetics is expanding rapidly.

Advances in Culture Techniques for Cytogenetic Analysis of Solid Tumors

Advances in culture methodology include the following: careful selection by the surgeon of viable, uninfected tissue for culture; the adequate washing of tumor specimens with antibiotics, including antifungal agents, to prevent microbial outgrowth; improvements in disaggregation techniques; better media formulations for epithelial cells; use of feeder layers; a better understanding and application of growth factors and hormones; the use of decreased serum supplements for certain tumor types and increased serum supplements for others; and the development of methods for removing stromal cell contamination. For disaggregation of solid tumors, probably the most important advance has been in the commercial development of highly purified enzymes, such as collagenase, to break down tumor stroma without damaging the tumor cells. Early preparations contained other proteolytic enzymes that had detrimental effects on tumor cell viability. Currently available purified enzymes effectively digest stromal components and release viable tumor cells in large numbers for direct study and for *in vitro* cultivation. Other improvements have included modifications of culture media, such as supplementation with hormones, particularly hydrocortisone, insulin, and transferrin; the addition of trace elements such as selenium; and the appropriate use of growth factors in the culture media. The elimination of stromal cell contamination by selective trypsinization or by growing tumor cells in soft agar is important, as is the use of irradiated fibroblast feeder layers or the use of extracellular matrix materials such as collagen, fibronectin, or bovine endothelial matrix for better tumor-cell attachment.

In addition to these improvements in culturing, techniques for better chromosome resolution, such as cell synchronization to increase the mitotic fraction, reducing the time of exposure to Colcemid to improve chromosome morphology, and the use of ethidium bromide to maximize chromosome length, have also played a role in obtaining better results in dealing with solid tumors.

In attempting the *in vitro* cultivation of solid tumors, it is important to recognize that methods that have worked for one histologic type are not necessarily effective on other tumor types. For example, standard culture media were ineffective for small cell carcinoma of the lung (SCLC), but great progress was made in the *in vitro* cultivation of this tumor type when a novel medium formulation was used. Use of the HITES medium containing hydrocortisone, insulin, transferrin, estradiol, and selenium, with low (2.5%) or no serum resulted in a 72% success rate for SCLC, which had previously been resistant to culture. For other tumor types such as squamous cell carcinoma (SCC), early misunderstandings regarding their properties may have led to the widely held belief that these tumors were difficult if not impossible to grow *in vitro*. In fact, when appropriate techniques have been employed, success rates exceeding 30% have been routinely obtained in several laboratories. Explant techniques either on plastic or on irradiated feeder cell layers are effective for this tumor type as are careful disaggregation techniques using purified enzymes. Squamous cells are nearly always substrate dependent, probably because they require attachment molecules for mobility and mitotic activity. Because the attachment to substrate is critical to success with SCC, the simple expedient of using only a small volume of media to cover primary explant cultures prevents the tumor fragments from floating away from the substrate and increases the opportunity for squamous cell outgrowth. Another important factor for cultivating SCC and other tumor types is the application of a satisfactory method for removing fibroblasts. Fibroblasts tend to outgrow the tumor cells in early mixed cultures, surrounding and sometimes undermining the epithelial islands. Removing fibroblasts with brief exposures to trypsin-EDTA while monitoring the culture under the microscope to ensure that tumor cells are not detaching eliminates this problem and increases the tumor cell culture success rate. In a few cases, tumor cell islands have been discovered completely buried under sheets of fibroblasts. The tumor cells were not apparent when the culture was viewed under the microscope; if the fibroblasts had not been removed, these tumor cultures might have been discarded. For different tumor types, slightly different methods of cultivation and isolation have been developed. Good reviews of culture techniques for a variety of human tumor cells are presented in the *Atlas of Human Tumor Cell Lines* (eds. Hay, Park, Gazdar, 1994) and in *Human Cell Culture* Vols. 1 and 2, “Cancer Cell Lines” Parts 1 and 2 (J Masters, ed., 1999). A thorough description of the techniques available for obtaining metaphase chromosome preparations from solid tumors is provided in Mandahl (2001).

Advantages Derived from Cultured Tumor Cells

Improved culture methods have increased not only the yield and quality of solid tumor karyotypes but also the accuracy of the characterization of the breakpoints and rearrangements. This is because, in many cases, the tumor cells persist in culture, making additional harvests possible. As a result, it is possible to accurately determine whether a chromosome is missing because of a

random loss from a cell or because monosomy was one of the events in the genesis of the tumor. Similarly, persistent cell cultures can be harvested repeatedly to obtain early-metaphase chromosomes, which are more informative because they are longer and more bands can be clearly discerned.

Cells in culture provide excellent material for special chromosome staining techniques such as C-banding, Q-banding, and silver staining. These techniques are valuable for identifying rearranged chromosomes, for helping the cytogeneticist to determine breakpoints more accurately, for identifying centromeres, and for detecting dicentric chromosomes. Sometimes, C-banding can even help to identify which chromosome of a pair is present in case of monosomy or to determine if both copies might be the same homologue as a result of loss that has been compensated for by duplication and nondisjunction of the remaining chromosome. Silver staining to detect the nucleolus-organizing regions (NORs) of acrocentric chromosomes is valuable for determining if acrocentrics are involved in rearrangements and for distinguishing NORs from homogeneously staining regions (HSRs). This distinction is important because the latter are considered to be indicative of amplified genes. An example of an HSR in a squamous cell carcinoma that contains amplified copies of cyclin D1 is shown in Fig. 34.1. Note that a FISH probe for the cyclin D1 gene stains the entire region of homogeneous staining on the chromosome with the HSR. Hybridization and staining of tumor tissue also can identify amplified gene segments in tumor cell nuclei.

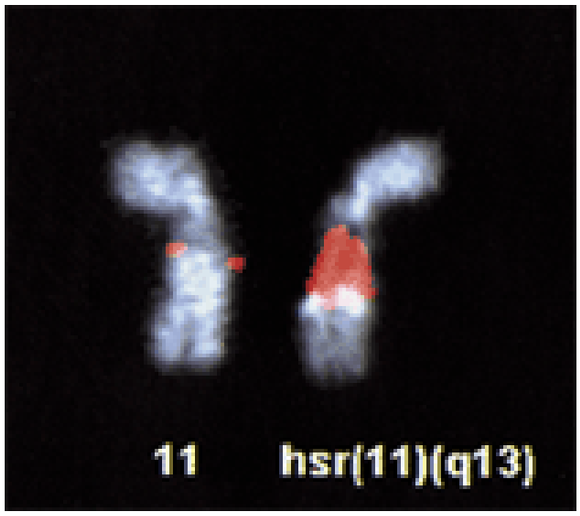

FIGURE 34.1. Partial karyotype from a squamous cell carcinoma of the oral cavity. **Top:** G-banding revealed a homogeneously staining region in band 11q13, (**right**) corresponding to massive amplification of the cell cycle regulatory *CCND1*, as detected by FISH (Courtesy of Dr. Yuesheng Jin, Dept. of Clinical Genetics, Lund University Hospital, Sweden).

In vitro cultures also provide pure populations of tumor cells for studies to further investigate the mechanisms at work at the level of the DNA and RNA molecules in tumor cells with rearranged or deleted chromosomes. Just a few examples of such studies include (i) Southern analysis to detect and study amplified, mutated, or deleted genes, (ii) analysis of simple sequence repeat polymorphisms to detect loss of heterozygosity and homozygous deletion in tumor lines, (iii) Northern analysis to detect aberrant gene expression or inactivation of alleles, and (iv) gene isolation and sequencing to determine the nature of mutations that alter genes or affect gene expression. Finally, cultured cells provide a test system for examining the cell biology associated with altered gene expression.

Controversy Over the Use of Cell Cultures

In spite of the many advantages gained through the use of cultured cells for studies of the genetic changes in cancer, there is controversy over the validity of the karyotypic changes that are defined using cultured cells. Some investigators suggest that culture conditions are not physiologic and may introduce selective pressures that result in clones of cells that are not representative of the *in vivo* tumor population. It also has been suggested that cells grown in culture are unstable and undergo frequent changes or continuous karyotypic evolution *in vitro*.

Addressing the Cell Culture Controversy

To analyze these objections, several points should be considered. As a starting point, it should be noted that following amniocentesis, short-term culture is employed for expanding mitotic cells to detect chromosome abnormalities *in utero* (see Chapter 31), yet accurate results are obtained consistently, suggesting that short-term culture does not routinely introduce karyotypic artifacts. With solid tumors, it is difficult to entirely eliminate some time in culture from the process of karyotyping tumors because it is necessary to harvest mitotic cells to observe the chromosomes in their condensed state. Nevertheless, in some cases it is possible to make “direct preparations” in which karyotypes are prepared from cells released directly from tumor tissue. Direct preparations can serve as controls for evaluating the effects of culture on the tumor populations by comparing results obtained by this method to those obtained after culture. To minimize the possible selective effects of *in vitro* culture, we have also used an “in situ” technique, in which metaphase spreads are prepared from relatively few mitotic cells in short-term cultures by directly treating primary cultures on coverslips with hypotonic solution. In addition, conventional harvests from very early cultures also can minimize selective or evolutionary effects of *in vitro* culture. If random chromosome aberrations arise as a result of *in vitro* culture, then *in vitro* events should accumulate with time in culture. To evaluate this, *in situ* and direct preparations can be compared to early passages and to long-term cultures from the same tumors to document whether *in vitro* changes are significantly skewing the results. In our laboratories, we have observed that the consensus karyotype is represented in both early and later cultures. When a cell culture of an established SCC line was monitored long-term only one chromosome change was detected. In repeated studies over a period that spanned more than 60 *in vitro* passages, a normal 7 was replaced by an i(7p). Even in this case it is possible that the population of cells containing the i(7p) were present all along but were too infrequent to be detected in earlier preparations (Carey et al. 1989). Results from direct preparations, *in situ* preparations on early cultures, and long-term culture have shown that the karyotypes obtained immediately or after days, weeks, and months of *in vitro* culture are remarkably consistent (Worsham et al. 1991). Thus, in our experience, tumor cultures examined after different periods of time in culture nearly always contain the same chromosome rearrangements and the same numerical changes and, in most cases, even maintain similar fractions of near-diploid and near-tetraploid populations. Incidentally, we also have noted that when there are near-diploid and near-tetraploid populations

within the same tumor, each population contains the same rearrangements, and they usually differ from one another only in copy number (Carey et al. 1993, Worsham et al. 1993).

If *in vitro* culture selects for nonrepresentative cell populations with certain rearrangements, then there should be frequent discrepancies between *in vitro* and *in vivo* findings. In earlier studies of leukemias and lymphomas, when the chromosome abnormalities obtained from leukemia cell lines in long-term culture were compared to those found in marrow or blood samples from patients, the same consistent changes and rearrangements for each leukemic type were noted. For example, the original studies of Burkitt's lymphoma showed the same t(8;14) translocation in both fresh specimens and Burkitt lymphoma cell lines.

If tumor cells grown in culture are not representative of the cells that persist in the patient, then we would expect that separate tumor samples from the same patient would represent different clones. When we examine karyotypes from cell cultures taken from primary tumors and metastatic or recurrent tumors from the same donors, the same primary clonal abnormalities are present in both primary and metastatic or recurrent cultures. (For examples of this type of analysis, see the discussion of chromosome changes in squamous carcinomas of the head and neck below). Taken together, these observations support the concept that *in vitro* cultures are a reasonable model of the *in vivo* tumor.

Molecular Allelotyping

It has become possible to detect chromosome losses using polymorphic markers on each chromosome arm. For such studies, it is unnecessary to culture cells for metaphase chromosome analysis. Molecular genetic methods also allow one to determine if karyotypic analyses on cultured tumor cells accurately represent the cells in the tumor specimen. For molecular allelotyping, DNA is harvested from tumor cells and normal cells from the same individual and assessed for loss of heterozygosity using polymorphic markers. Originally this type of analysis employed restriction fragment length polymorphisms (RFLP), but subsequently simple sequence repeat polymorphisms (SSRPs) were discovered that are more numerous and more polymorphic than RFLPs. The simple sequence repeats consist of di-, tri- or tetra-nucleotide repeats that have also been referred to as microsatellite repeat polymorphisms (MSRPs) because satellite DNA surrounding the centromeres also consists of nucleotide repeats. SSRPs appear frequently throughout the genome and have been used very effectively to supplement and confirm consistent chromosome rearrangements identified by conventional cytogenetic methods. Allelotyping employs primer sets that flank individual polymorphic SSRPs that have already been mapped to each chromosome arm. The available sets of primers and SSRPs that are known are very numerous because these have been identified in the course of gene mapping studies and as a by-product of the genome sequencing project. Multiple polymorphic probes are used for each arm of the chromosome to detect loss of heterozygosity (LOH) that corresponds to chromosome deletion. Because the SSRPs on the maternal and paternal chromosome differ in length in 60% to 80% of cases these markers are often informative for evaluating LOH. DNA from normal tissue e.g., normal blood cells and from a tumor-enriched area of the tumor is amplified with the polymerase chain reaction (PCR) using primer sets for an SSRP. These PCR products are separated by size on a DNA sequencing gel. If the repeats are different in the maternal and paternal chromosomes then two bands will be visualized. If one of the chromosomes has been lost in the tumor then only the allele from the intact chromosome will be present in the PCR product. This method has been used to great advantage to define chromosomal regions that have been lost in tumors for which it has not been possible to obtain good chromosome data by karyotyping (Fearon and Vogelstein 1990). Essential to this kind of analysis is good separation of normal and tumor tissue. If normal cells are included in the tumor DNA extractions, there will be significant loss of resolution because the contaminating normal cells contribute a signal from both chromosomes. The allelotyping method has allowed comparison of cell lines to the original tumor tissue from which the lines were established. Frank et al. (1997) compared DNA isolated from 10 head and neck tumors to the cell lines established from each for LOH at multiple polymorphic markers on chromosome arm 18q. In every case the loss or retention of individual alleles was the same in the tumor and the cell line from which it was established. Because multiple markers were assessed in each pair it was also possible to confirm that the breakpoints were the same in the tumor and the cell lines and if part of 18q was retained in the tumor, it was also retained in the cell line. Cell lines also have proved very valuable for defining the minimum region of loss first detected by chromosome studies. Homozygous deletions have been noted to occur in some tumors and these can have the effect of inactivating both copies of tumor suppressor genes. Homozygous deletions affecting both chromosomes are difficult to detect in DNA isolated from tumor tissue because of the presence of contaminating normal cells. Cell lines lack normal cells and can be screened for homozygous deletions using both polymorphic and nonpolymorphic markers such as STS (sequence tagged site) markers. Loss of chromosome 18q arm has been observed by karyotyping in multiple tumor types. Screening pancreatic tumor cell lines for homozygous deletions on chromosome arm 18q resulted in the discovery that *DPC4/SMAD4* is a tumor suppressor gene in pancreatic carcinoma (Hahn et al. 1996). Similarly, screening of human squamous carcinoma cell lines allowed Sun et al. (1999) to define a minimal region of homozygous loss on 8p23.2 that presumably houses a tumor suppressor gene. These observations contribute to the body of data showing that cell lines are highly representative of tumors from which they are derived and strengthen the concept that cytogenetic data obtained from short and even long-term cultures of human tumors accurately portray the situation in the original tumor.

Fluorescence In Situ Hybridization (FISH) — Interphase Cytogenetics and Chromosome Painting

Interphase cytogenetics or chromosome painting, which employs fluorescent, chromosome-specific probes, can be used on cells in interphase to identify individual chromosomes either in tissue sections or in cultures. As discussed above, it is not unusual to obtain only a few metaphase cells in some solid tumors, although there may be abundant interphase cells. Fluorescence *in situ* hybridization (FISH) of chromosome-specific probes to the

nuclei of nonmitotic cells makes it possible to examine the interphase cells for specific genetic changes. For numerical changes, satellite DNA probes that are specific for the centromere of a given chromosome can be used. This method is already effective for characterizing ploidy changes, trisomies, and monosomies, and it may become useful for identifying specific rearrangements as well. As shown in Fig. 34.1 FISH can be used with specific gene probes to detect amplified genes on chromosomes as well as in tumor tissue. Worsham et al. (1993), Worsham et al. (1999) have used FISH to investigate genetic changes in multiple cases of tumor cell lines and the original tumor tissue. Those results have shown identity of both copy number and marker content in tumor tissue and the corresponding cell line. In Fig. 34.2 an example of FISH using centromere specific probes allows the enumeration of chromosome copy number in individual nuclei within tumor tissue (Worsham et al. 1995). In the same study, FISH for a rearranged chromosome was used on a cultured cell line metaphase spread and on tissue sections from both tumors to demonstrate identical clonal origin of synchronous primary tumors in a patient originally thought to have had separate carcinogenic events in the floor of mouth and the pyriform sinus.

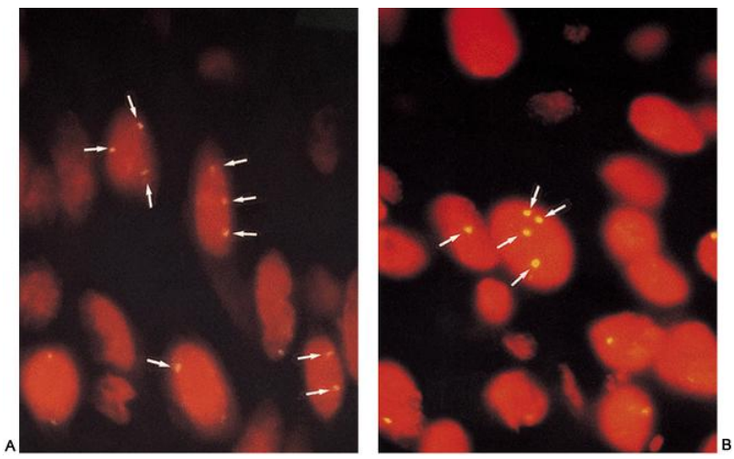

FIGURE 34.2. FISH analysis of a squamous cell carcinoma of the pyriform sinus using centromere-specific probes for chromosomes 7 (**A**) and 17 (**B**). Note that the tumor cell nuclei contain two, three, and four signals each for chromosome in the plane of the photo. (Reproduced from Worsham MJ, Wolman SR, Carey TE, et al. Common clonal origin of synchronous primary head and neck squamous cell carcinomas: analysis by tumor karyotype and fluorescence in situ hybridization. *Human Path* 1995;26:251–261).

Whole chromosome specific probes have been developed and are available commercially. These tools are very useful when a metaphase chromosome spread can be obtained. To detect specific translocations, a mixture of DNA probes for different arms of the chromosomes can be used. An example of multicolor FISH analysis (also called spectral karyotyping) of a hypodiploid myxoid malignant fibrous histiocytoma is shown in Fig. 34.3. Note that the complex rearrangement involving chromosomes 1, 3, 6, and 10 are easily resolved using this technology.

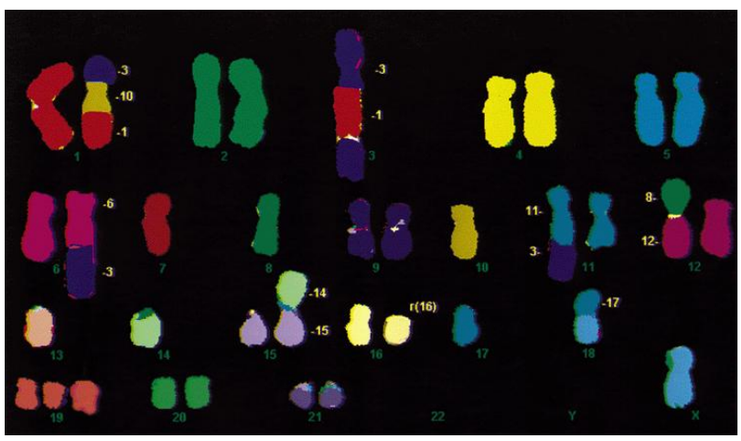

FIGURE 34.3. Complex structural rearrangements in a hypodiploid myxoid malignant fibrous histiocytoma, as detected by multicolor FISH (COBRA FISH, Applied Imaging) analysis (Courtesy of Dr. David Gisselsson, Dept. of Clinical Genetics, Lund University Hospital, Sweden).

Comparative Genomic Hybridization

Comparative genomic hybridization (CGH) combines fluorescence hybridization techniques with a conventional metaphase spread to examine the entire genome from an abnormal cell such as a tumor cell to a normal cell with a normal complement of intact chromosomes. As in the case of allelotyping careful isolation of pure tumor cell DNA is a prerequisite for success. Unlike allelotyping, there is no requirement for normal DNA from the same donor, normal DNA from any individual of the same sex can be used. The DNA from the tumor is labeled by nick translation with biotinylated nucleotides and the DNA from the normal cells is labeled with digoxigenin-labeled nucleotides. These samples are then mixed in equal amounts and hybridized to normal metaphase spreads where the labeled DNA competes for

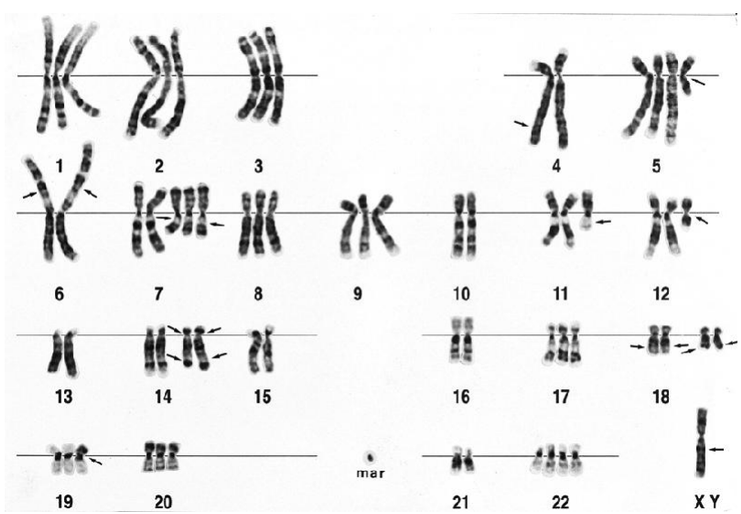

FIGURE 34.4. G-banded karyogram from a pancreatic carcinoma showing multiple numerical and structural rearrangements (Courtesy of Dr. Ludmila Gorunova, Dept. of Clinical Genetics, Lund University Hospital, Sweden).

binding. The hybridization signals are developed with fluorescein-avidin and rhodamine-labeled antidigoxigenin. If there are equal copy numbers in the normal and tumor DNA, then the hybridization signals will be equal and the fluorescein and rhodamine signals will be balanced. However, if there is loss of a chromosome segment in the tumor then the corresponding region of the target metaphase chromosome will be hybridized predominantly with the rhodamine-labeled normal DNA and this will appear red. Similarly if there is a region of chromosomal gain in the tumor, then there will be more hybridization of the corresponding region of the target chromosome with the fluorescein-labeled tumor DNA and this region will appear green. CGH has confirmed results of conventional cytogenetic analysis and has extended the ability to investigate genetic lesions in tumors for which no chromosome spreads can be obtained. Using CGH, Van Dekken et al. (1999) have defined specific regions of gain and deletion in gastroesophageal carcinomas. The current level of technology being developed will use the principle of CGH to assess chromosome gain and loss by hybridization of tumor DNA to gene probes arrayed on slides. As the number of known genes expands it is envisioned that a single hybridization to a gene array chip will identify every example of loss and gain in the entire genome of an individual tumor. The power of this technology will allow customization of therapy to maximize effectiveness based on the genetic changes expressed in an individual patient's tumor.

CYTOGENETIC CHANGES IN SOLID TUMORS

Part of "34 - Solid Tumor Cytogenetics"

Types of Cytogenetic Changes in Solid Tumors

In general, solid tumors from adults and advanced tumors have more numerous and more complicated chromosome changes than hematologic tumors or early pediatric tumors. Many hematological and some pediatric neoplasms are characterized by relatively simple primary abnormalities such as balanced translocations. In contrast, the most common chromosome changes in solid tumors of adults are unbalanced translocations that result in the loss of genetic material (i.e., chromosome deletions). Gains also are frequent and include trisomies of various chromosomes, duplication/amplification of chromosome segments, or amplification of activated protooncogenes. The frequency and extent of ploidy change also is often much greater in solid tumors than in hematologic tumors. An example of a complex karyotype in a solid tumor is shown in Fig. 34.4. This G-banded karyotype from a pancreatic carcinoma shows complex rearrangements, increased copy number of multiple chromosomes, isochromosome formation i(5p) and i(12p), and deletions. In Fig. 34.5, the use of G-banding and FISH to investigate complex alterations in an atypical lipomatous tumor are illustrated. Note that the ring chromosomes contain amplified sequences for both *MDM2* and *CDK4*, genes that can lead to loss of cell cycle control. A summary of the solid tumors known to have clonal chromosome aberrations is given in Table 34.1.

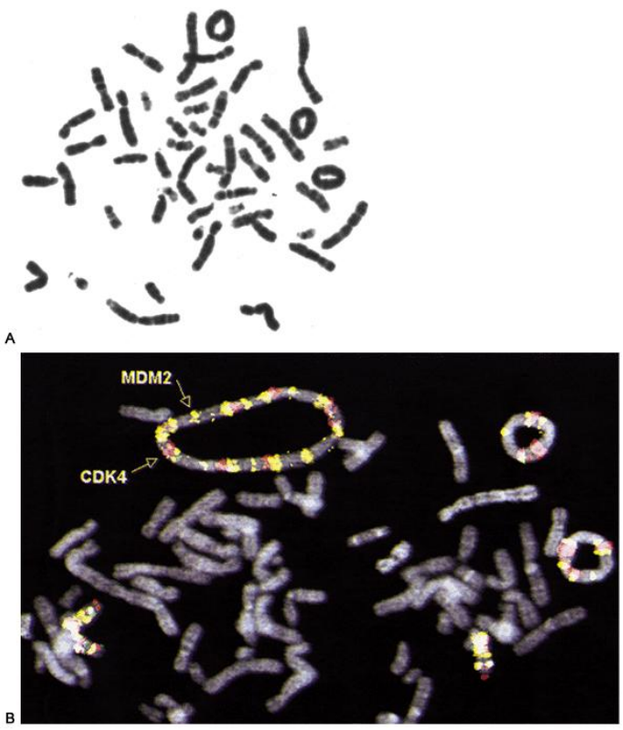

FIGURE 34.5. A: G-banded metaphase spread showing supernumerary ring chromosomes in an atypical lipomatous tumor. These ring chromosomes characteristically contain amplified chromosome 12 sequences (**B**) as shown by two-color FISH using probes for *MDM2* and *CDK4* (Courtesy of Dr. David Gisselsson, Dept. of Clinical Genetics, Lund University Hospital, Sweden).

SIGNIFICANCE OF CHROMOSOME REARRANGEMENTS

Part of "34 - Solid Tumor Cytogenetics"

TABLE 34.1. DISTRIBUTION OF SOLID TUMORS WITH CLONAL CHROMOSOMAL ABERRATIONS BY SITE

Anatomical site	No. of Cases	Anatomical site	No. of Cases
Adrenal gland	112	Parathyroid gland	1
Anus	8	Penis	19
Bladder	142	Peritoneum	8
Brain	1181	Pineal gland	16
Brain stem	23	Pituitary gland	20
Breast	622	Pleura	92
Cerebellum	186	Prostate	180
Eye	198	Salivary glands	364

Translocations, Point Mutations, and Amplification of Protooncogenes

Activation of Protooncogenes

Protooncogenes are normal cellular genes involved in the process of cell replication. When the protooncogenes go awry by any of several mechanisms, the involved cell acquires increased ability to undergo autonomous replication, which results in uncontrolled proliferation. As discussed in Chapter 29, Basic Cytogenetics, in hematological neoplasms, protooncogene activation commonly occurs by chromosome translocations.

Translocations

The classic example of oncogene activation by this type of mechanism is the translocation of the *MYC* protooncogene from chromosome 8 to the immunoglobulin heavy-chain (*IGH*) locus on chromosome 14. As a result of the juxtaposition of *MYC* to the active *IGH* gene, there is increased MYC expression and deregulation of cell growth, driven by the promoter and enhancer elements of the *IGH* gene.

As discussed in Chapter 38, Bone Marrow Transplantation, the translocation of chromosomes 9 and 22 in chronic myelogenous leukemia (CML) provides another example. This translocation fuses the *ABL* protooncogene locus on 9 and a gene locus called breakpoint cluster region (*BCR*) on 22. This translocation

results in the active production of both message and a protein called $P210^{bcr/abl}$ that is similar to the oncogene product of the Abelson murine leukemia virus designated $P160^{gag/v\text{-}abl}$. Both of these rearranged genes encode fusion proteins with deregulated tyrosine-kinase activity. Expression of the $P160^{gag/v\text{-}abl}$ fusion protein induces acute leukemia in mice, and studies from David Baltimore's laboratory demonstrated that mice given murine bone marrow cells transfected with the human P210bcr/abl hybrid construct also develop hematologic tumors and a myeloproliferative disorder that closely resembles CML in humans. This demonstrates most conclusively the significance of the translocation that gives rise to the Philadelphia chromosome.

The consistent translocations in T-cell leukemias have been shown by Carlo Croce and others to often involve the T-cell receptor gene loci and a breakpoint region containing genes that become activated by the translocation. By analogy to the B-cell neoplasms, we can predict that this type of rearrangement involves an active gene, the T-cell receptor, whose promoters and enhancing elements can presumably affect the expression of a gene related to growth regulation on the recipient chromosome. Recent evidence confirms that this is the case and novel genes activated by translocation with the T-cell receptor have been identified.

Based on these observations, it generally is accepted that consistent chromosome rearrangements in cancers are likely to occur at the sites of protooncogenes. Several authors have collected consistent breakpoint data from the literature and compared these sites to known oncogene loci. These comparisons show a strong concordance, which adds further support to the concept that chromosome rearrangements in cancer are functionally related to the cancerous behavior of the tumor cells.

Oncogene Activation

In solid tumors, a major mechanism of oncogene activation appears to be activation by point mutations and gene amplification, rather than activation by translocation. Among the best-studied point mutations and most strongly implicated in the genesis of solid tumors are those of the *RAS* gene family, which consists of three members: *HRAS*, *NRAS*, and *KRAS*. In these cases, specific activating mutations at codons 12, 13, and 61 have been identified. Point mutation of an oncogene has been implicated in the tumorigenesis of several cancers, including bladder (*HRAS*), colon (*KRAS*), pancreas (*KRAS*), lung (*KRAS*), seminoma, and melanoma. *RAS* protooncogene proteins act by binding to GTP, after which the normal RAS product is converted to an inactive form that binds GDP. Point mutations activate *RAS* by eliminating the site necessary for conversion to the inactive GDP-binding form, thus the activated gene product allows unregulated cell growth.

Protooncogene Amplification

Amplifications of HER-2/neu (*ERBB2*), and epidermal growth-factor receptor (*EGFR* or *MYCN*) protooncogenes have been implicated as being prognostically important in neuroblastoma, breast and ovarian cancers, and glial tumors, respectively. Protooncogene amplification also has been reported in several other tumor types as well, but prognostic implications have not been well established in these cases. In neuroblastoma, *MYCN* oncogene amplification has been demonstrated by cytogenetic studies in the form of double minutes (DMs), HSRs, and, more recently, autonomously replicating, small, circular episomes. Double minutes are acentric chromatin bodies that segregate randomly during cell division. When they integrate randomly into a chromosomal

site, an HSR is formed. The size and the number of DMs vary from cell to cell. The presence of DMs in neuroblastoma has been correlated with tumor grade and amplified MYCN expression, which is strongly correlated with rapid tumor progression. In breast cancer and ovarian cancer, amplification and overexpression of the HER-2/neu (*ERBB2*) oncogene has been demonstrated mainly by molecular studies. However, careful examination by cytogenetic methods in a large series of patients might also reveal gene amplification in the form of DMs and HSRs in these two tumor types. As with NMYC in neuroblastoma, there is a correlation between *ERBB2* amplification and elevated *ERBB2* expression and highly malignant behavior in breast cancer and ovarian cancer. In glial tumors, amplification of *EGFR* has been observed in the form of DMs and HSRs, and this is associated with an advanced grade and a poor prognosis.

Chromosome Deletion and Inactivation of Tumor-Suppressor Genes

Activation of an oncogene by translocation, point mutation, or amplification is a dominant phenomenon because malfunction of only one allele is involved in the tumorigenesis. In contrast, inactivation of a tumor-suppressor gene is a recessive mechanism at the cellular level because both alleles must be affected for tumorigenesis. The careful study of tumor-suppressor genes has provided significant insight into the mechanisms that control the cell cycle and into how transforming viruses can induce unregulated cell growth. In cases where there is evidence for genetic losses, one must consider the possibility that loss of a gene that regulates cell growth may have occurred.

CONSISTENT CHROMOSOME REARRANGEMENTS IN SOLID TUMORS

Part of "34 - Solid Tumor Cytogenetics"

In the following survey of the cytogenetic features of solid tumors, the number of references has been limited to recent review articles and, in a few cases, to articles dealing with specific matters of biological or clinical significance. More detailed information about the cytogenetics of solid tumors can be obtained in review articles (Mertens et al. 1997; Mitelman et al. 1997a, Mitelman et al. 1997b), specialized books (Heim and Mitelman, 1995; Mitelman, 1998), or at web sites [Recurrent Chromosome Abberations in Cancer] (http://www.cgap.nci.nih.gov/Chromosomes/RecurrentAberrations); [Mitelman Database of Chromosome Abberrations in Cancer] (http://cgap.nci.nih/gov/Chromosome/Mitelman). Table 34.2, Table 34.3, and Table 34.4 list the numbers of solid tumors by type for which clonal aberrations have been identified.

TUMORS OF THE NERVOUS SYSTEM

Part of "34 - Solid Tumor Cytogenetics"

Tumors of the central nervous system and the surrounding meninges are among the most extensively analyzed solid tumors. Altogether, some 1,500 cases, slightly more than one half of which are gliomas, with clonal chromosomal changes have been reported. In astrocytomas, the most common form of glioma, a nonrandom pattern of chromosomal changes has been established. The karyotypes often are quite complex, with structural rearrangements clustering to chromosome arms 1p, 1q, 6q, 9p, and 19q, and multiple numerical changes, the most common of which are loss of chromosomes X, Y, 10, 13, and 22, and gain of chromosomes 7, 19, and 20. Some of these aberrations, in particular +7, -Y, -10, and -22, may occur as the sole anomalies, suggesting that they may be of particular relevance in the early steps of tumorigenesis. The significance of -Y and +7 as the sole anomalies is, however, debated because both have been detected in nonneoplastic brain tissue as well (Johansson et al. 1993).

Molecular genetic investigations have implicated a great number of oncogenes and tumor suppressor genes in astrocytoma development. Of the suppressor genes that seem to be most commonly deleted and/or mutated — *CDKN2A* in 9p21, *PTEN* in 10q23, *RB1*> in 13q14, and *TP53* in 17p13 — several are located in chromosome segments that characteristically are found

to be deleted at cytogenetic analysis. Frequently amplified oncogenes include *CDK4* in 12q and the epidermal growth factor receptor gene (*EGFR*) in 7p. Amplification of the latter is particularly common in tumors showing double-minute chromosomes, i.e., a cytogenetic sign of gene amplification found in approximately 10% of adult astrocytomas.

Cytogenetic and CGH analyses, as well as molecular investigations, have shown that low-grade astrocytomas have less complex genomic changes than do high-grade tumors, but that the genotypic differences are quantitative rather than qualitative. In a study of 206 patients with gliomas, most of which were astrocytic tumors, the presence of clonal chromosome aberrations was significantly associated with poor clinical outcome. Furthermore, in univariate analysis, rearrangements (most of which were gains and losses, respectively) of chromosomes 7 and 10 were strongly associated with reduced survival (Ganju et al. 1994). In children, low-grade and cerebellar astrocytomas usually have a normal karyotype, whereas high-grade and supratentorial tumors closely resemble the astrocytic tumors in adults. Regarding molecular genetic correlations, *TP53* mutations and loss of 22q material have been found in primary low-grade tumors, whereas most other investigated genes seem to be more commonly involved in high-grade and/or recurrent astrocytomas.

Far less is known about the other main subtypes of glioma, i.e., oligodendrogliomas and ependymomas. The karyotypic pattern among the roughly 50 oligodendrogliomas that have been

Figures obtained in February 1999 from the database for Mitelman's *Catalog of Chromosome Aberrations in Cancer*.

reported to date closely resembles that in low-grade astrocytomas, with predominance of loss of X, Y, and 22, and trisomy 7. The karyotypic spectrum in ependymoma is slightly different: loss of chromosome 22 is the single most frequent change, occurring in one third of the 70 cases that have been reported. The frequent finding of monosmy 22, and the fact that the incidence of ependymomas is higher among patients with neurofibromatosis type 2, makes the tumor suppressor gene *NF2* a possible target suppressor gene. Mutations of *NF2* seem very rare, however, in sporadic ependymomas.

Medulloblastomas, or primitive neuroectodermal neoplasms (PNET), are the most frequent CNS tumors in children. The cytogenetic hallmark of these neoplasms is the presence of an i(17q), which is found in one third of the cases. Other recurrent, but less frequent (about 10%), aberrations include loss of a sex chromosome, del(6q), +7, -10, -17, -22, and double-minute chromosomes. FISH and molecular studies have revealed that most i(17q) actually are isodicentric chromosomes (idic), with a breakpoint in proximal 17p that lies within the critical region for the Smith-Magenis syndrome (Scheurlen et al. 1997). The mechanisms behind the frequent idic(17) formation or the critical outcome of loss of distal 17p remain unknown. However, molecular analyses have shown that *TP53* probably is not the target gene.

Meningioma was the first solid tumor type in which a characteristic chromosome abnormality — monosomy 22 — was detected. At present, more than 500 cases with clonal aberrations have been reported, providing a solid basis for cytogenetic correlations with molecular, histopathologic, and clinical parameters. Cytogenetic and molecular genetic data strongly indicate that loss of chromosome 22 material is a primary event in the development of meningiomas and that more than one gene may be involved. Cytogenetically, loss of one copy of chromosome 22 is seen in three fourths of the cases, often as the sole anomaly. Furthermore, several cases with deletions, typically of the distal half, of 22q have been described, and molecular analyses have pinpointed a commonly deleted region to 22q12-qter. The target gene for many of these rearrangements is *NF2*, located in 22q12, which has been shown to be deleted and/or mutated in the majority of cases. Still, molecular data indicate that some 40% of the cases do not have functional inactivation of the *NF2* gene, suggesting that alternative mechanisms are operative in a substantial subset of meningiomas. Other chromosomes/chromosome arms that have been implicated by cytogenetic or CGH results are X, 1p, 8, 11p, and 14, all of which are nonrandomly lost.

Correlations with clinical parameters have shown that high-grade lesions have more complex karyotypes than do low-grade meningiomas, that abnormal karyotypes are more frequent among suprasellar meningiomas than at other sites, and that recurrent or invasive meningiomas have more complex karyotypes than the benign ones. In particular, loss of 1p and hyperdiploidy seem to be associated with high risk of recurrence (Steudel et al. 1996).

Acoustic neuromas also have been linked to a locus on chromosome 22. This tumor type occurs in both a sporadic form in which tumors are unilateral and a familial form characterized by bilateral tumors. The familial form also is referred to as bilateral acoustic neurofibromatosis or neurofibromatosis type 2 (NF-2). lnitially, NF-2 was thought to be a variant of von Recklinghausen's disease, which also is called neurofibromatosis type 1 (NF-1). However, studies of families with NF-2 have shown that acoustic neuromas are genetically more closely linked to meningiomas than to NF-1. There are two sets of evidence for this distinction. First, some members of the NF-2 pedigrees also develop meningioma, but individuals with NF-1 do not develop acoustic neuromas. Second, consistent loss of alleles from the region of chromosome 22 affected in the meningioma tumors also has been documented in tumor DNA from patients with bilateral acoustic neuroma, even though cytogenetic evidence linking chromosome 22 to acoustic neuromas is sparse.

Retinoblastoma, a rare malignancy that arises from cells of the embryonal neural retina, develops only in infants and young children. In most cases, it is a sporadic disorder, but approximately one third of the tumors are familial, with the predisposition being inherited as an autosomal-dominant trait. Based on clinical differences between sporadic and inherited forms, Knudson (1971) postulated that retinoblastoma develops as a result of two separate mutations of the same gene. In sporadic tumors, both occur somatically, whereas in heritable retinoblastoma the first mutation is present in the germ line and the second is somatic. The identification of constitutional deletions of 13q14 in a subset of retinoblastoma patients led to the molecular identification of the *RB1* gene, which has come to serve as the prototype for tumor suppressor genes. Subsequent molecular analyses have shown that most retinoblastomas have functionally inactivated *RB1* genes, and that introduction of wild-type *RB1* into retinoblastoma cell lines suppresses tumorigenicity.

At the cytogenetic level, 13q14 aberrations are relatively infrequent. Only 10% of the almost 100 cases with clonal aberrations that have been reported have had deletions or unbalanced translocations leading to loss of this band, and an additional 10% have shown monosomy 13. Instead, i(6p), mostly seen as a supernumerary isochromosome, and gain of 1q material are the most common acquired chromosome changes, each occurring in about one-third of the cases. Nothing is known about the significance of these secondary changes.

Roughly 100 uveal melanomas with chromosome aberrations have been reported. The cytogenetic features are quite different from those detected in malignant melanomas of the skin (see below). They usually are near diploid, and the most frequent alterations are monosomy for chromosome 3 and gain of extra copies, usually through isochromosome formation, of the long arm of chromosome 8. These two imbalances tend to be present simultaneously, and are found in approximately 50% of the cases. Also, chromosome 6 is commonly involved (45% of the cases), with deletions of 6q occurring in one third of the cases. Nothing is known about the essential molecular consequences of -3, i(8q), or del(6q). From a clinical point of view, however, it could be noted that -3 and gain of 8q have been associated with ciliary body involvement and poor clinical outcome, suggesting that cytogenetic analysis might add valuable prognostic information (Sisley et al. 1997).

Neuroblastoma arises from postganglionic sympathetic neurons, often in one of the adrenal glands. Although neuroblastoma

cells are notoriously difficult to culture *in vitro*, close to 200 cases with clonal karyotypic changes have been reported. The modal chromosome number has ranged from hypodiploid to hypertetraploid. The most frequent abnormality, found in approximately 75% of the cases, is partial 1p monosomy, with frequent deletion of the region between 1p32 and 1p36. LOH studies indicate a lower — 30% to 40% — frequency of 1p deletions, a discrepancy that may be from selective outgrowth *in vitro* of del(1p) carrying cells. The molecular studies have identified one commonly deleted segment in band 1p36 and, possibly, one additional target for deletions in 1p32. Several candidate tumor suppressor genes for distal 1p have been tested, but so far without any success.

The other cytogenetic hallmark of neuroblastoma is the presence of double minute (dmin) chromosomes or, less frequently, HSRs, found in one third of short-term cultured cells and in even higher frequencies among established cell lines. At the molecular level, the dmin and HSR correspond to large-scale amplification of the *MYCN* oncogene, and it seems as if the gene amplification occurs early in tumorigenesis; if absent at the time of diagnosis, it does not develop during tumor progression.

Cytogenetic deletions of 1p and dmin/HSR/*MYCN* amplification, which typically occur in tumors with near-diploid karyotypes, are more frequent among older children and have been associated with poor clinical outcome, whereas karyotypes with near-triploid chromosome counts usually lack these aberrations and are associated with young age of onset (<1 year) and good prognosis. Using molecular techniques, however, the prognostic significance of 1p deletions has been questioned (Schwab et al. 1996).

CGH analyses have identified frequently lost or gained chromosome segments that have been detected at far lower frequencies after banding analysis of cultured cells. The most striking examples

are gain of 17q, present in 70% to 85% of the cases, and loss of chromosome 14, present in almost one third of the cases.

TUMORS OF THE HEAD AND NECK REGION

Part of "34 - Solid Tumor Cytogenetics"

SCCs account for 90% to 95% of all malignancies in the upper aerodigestive tract. Some 200 cases with clonal abnormalities have been reported after short-term culturing. The majority of these have had fairly complex karyotypes, typically showing a large number of numerical and unbalanced structural rearrangements. The most common imbalances detected at banding analysis are loss of 2q34-qter, 3p, 4p, 4q28-qter, 8p, 9p13-pter, 10p, chromosomes 13 and 14, 15p, 17q23-qter, 18q21-qter, 21p, 22p, and the Y chromosome, and gain of 3q, chromosome 7, 8q, and 11q13. The still relatively few cases that have been analyzed by CGH have shown a similar distribution of gains and losses, albeit at slightly different frequencies. At the cytogenetic level, more than half of the breakpoints involved in structural rearrangements affect centromeres or the near-centromeric regions of the chromosomes. The only euchromatic segments that are repeatedly involved are 1p11–13 and 11q13, the latter often in the form of HSR. FISH studies have shown that the breakpoints in proximal 1p are widely scattered, usually resulting in loss of material from distal 1p, whereas HSR affecting 11q13 (See Fig. 34.1) always represents amplification of the cell cycle regulating *CCND1* gene (Jin et al. 1998a, Jin et al. 1998b). Molecular studies have shown that other genes are also included in these amplicons, but that only *CCND1* and the neighboring *EMS1* gene are consistently overexpressed as a result of the amplification. Frequent inactivation of *CDKN2A* correlates well with the frequent loss of 9p21. The molecular significance of other recurrent changes in SCC is largely unknown.

A subset of SCC have shown fairly simple karyotypes, often

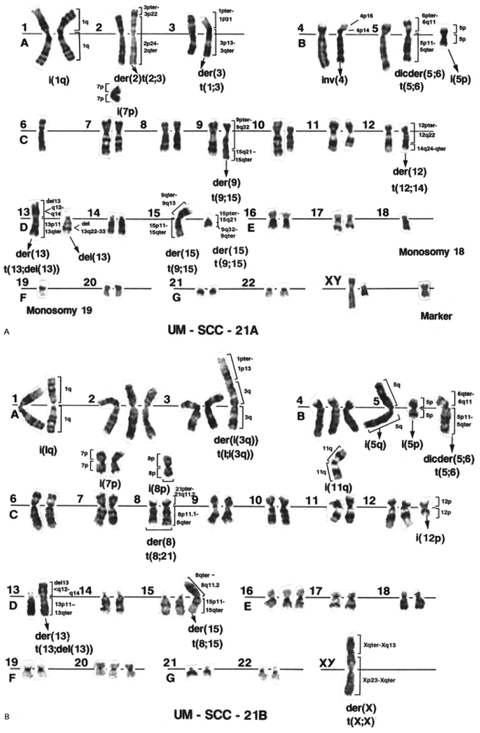

FIGURE 34.6. G-banded karyotypes from head and neck cell lines UM-SCC-21A (**A**) from the primary site and (**B**) UM-SCC-21B from a submental metastasis of a baso-squamous-cell carcinoma showing both common clonal markers and new chromosome changes that arose in each tumor after the two populations separated. The metastatic tumor was removed from the patient 14 months after the primary tumor was excised. Of note, there are numerous changes that arose in the primary tumor that are not present in the cell line from the metastasis demonstrating that the metastatic population had left the primary site long before the surgery on the primary site occurred. *(continued)*

with multiple, unrelated clones, with only a few numerical and/or structural rearrangements. The significance, if any, of these aberrations is questionable. First, established cell lines invariably display more complex changes; second, there are no recurrent rearrangements among the karyotypes with simple structural rearrangements and; third, similar changes have been detected also in nonneoplastic mucosa from elderly individuals (Jin et al. 1997a). Thus, it may well be that most of these changes detected in short-term cultured tumor specimens represent accumulation of genetic damage in stromal or nonneoplastic epithelial cells.

The only thorough evaluation of the clinical significance of cytogenetic findings in SCC showed that complex karyotype in general, and 11q13 rearrangements in particular, were associated with poor clinical outcome (Åkervall et al., 1995). These findings are in line with molecular genetic data indicating that amplification and/or overexpression of *CCND1* confer a poor prognosis. An analysis of a smaller number of stage 3 head and neck cancer patients demonstrated that loss of 18q was significantly associated with poor survival (Pearlstein et al. 1998).

In some cases, tumor progression may be accompanied by chromosomal gains that can obscure the loss of whole chromosomes. Fig. 34.6 presents a set of karyotypes from cultures of a primary tumor and a metastatic tumor in the same patient. UM-SCC-21A is derived from a baso-squamous carcinoma of the skin that was placed in culture more than a year before a metastasis became palpable in the soft tissues of the neck. UM-SCC-21B was derived from that metastatic tumor. The karyotypes show that both tumors are derived from the same clone. Note the presence in both tumors of i(1q), i(5p), t(5;6), i(7p), and t(13;del(13)). However, several changes from the primary tumor are not present in the metastasis and other new changes not found in the primary have developed in the metastatic tumor. Of particular interest are monosomy 6, 18, and 19 in the primary tumor, all of which are represented by two copies in the metastasis. This suggests that these losses occurred with further progression at the primary site after the metastatic population had diverged.

Salivary Gland Neoplasms

The non-squamous cell carcinomas of the head and neck region that arise predominantly from major and minor salivary glands, which include adenocarcinoma, acinic-cell carcinoma, mucoepidermoid carcinoma, adenoid cystic carcinoma, and carcinoma ex pleomorphic adenoma, are less well characterized, with less than 25 informative cases per tumor type. The karyotypes of these malignancies usually are less complex than those typically encountered in SCC. Adenocarcinomas and acinic cell carcinomas often show deletions of 6q and trisomies for chromosomes 7 or 8, in mucoepidermoid carcinomas a recurrent t(11;19)(q14-21;p12) has been described, adenoid cystic carcinomas are characterized by a recurrent t(6;9)(q21-24;p22-24) or del(6q), and carcinomas arising from pleomorphic adenomas usually have structural rearrangements resembling those in pleomorphic adenomas (see below) together with other structural or numerical abnormalities, such as polyploidization, indicating that the malignant transformation often is paralleled by cytogenetically visible clonal evolution.

More than 250 pleomorphic adenomas of the salivary glands with clonal chromosome aberrations have been reported. Three cytogenetic subgroups have been recognized: one third display 8q12 rearrangements, usually as a t(3;8)(p21;q12), 15% have different types of 12q13-15 rearrangements, and the remaining cases have apparently normal karyotypes or simple numerical changes, such as -Y and +8. The molecular consequences of the t(3;8)(p21;q12) recently were clarified. The translocation results in an exchange of promoter sequences between the zinc finger gene *PLAG1* in 8q12 and the constitutively expressed **B**-catenin *CTNNB1* gene in 3p21, which in turn leads to activation of *PLAG1* (Kas et al. 1997). Activation of *PLAG1* through other similar mechanisms also has been demonstrated for some of the variant translocations that are known to occur. The 12q13-15 rearrangements have been shown to involve the *HMGIC* gene, which is commonly rearranged also in a variety of benign mesenchymal tumors (see below). In line with this finding is the observation that adenomas with 12q13-15 rearrangements have a more pronounced stroma component *in vivo* and that cell cultures from these lesions tend to have a more fibroblastlike appearance.

Of the different subtypes of malignant thyroid tumors, only papillary and follicular carcinomas have been investigated in any detail. Still, there are only about 30 cases of each tumor type in the literature. The papillary carcinomas often have a quite simple karyotype, with rearrangements of 10q as the only characteristic feature, found in one third of the cases. The most frequent structural aberration is a paracentric inversion inv(10)(q11q21), which at the DNA level results in a fusion transcript consisting of parts of the *RET* protooncogene in 10q11 and parts of either *PTC1* or *PTC3* in 10q21. Other less frequent mechanisms behind *RET* activation in papillary carcinomas include fusion with *PTC2* through a translocation with chromosome 17.

The follicular carcinomas have had karyotypes of varying complexity, although most have had a chromosome count in the diploid range. Structural rearrangements leading to loss of 3p material is the most common finding. This is in line with molecular studies, which have identified a commonly deleted region in 3p25-pter. A few cases have had karyotypes with simple numerical (+7) or structural rearrangements [del(13q)], indistinguishable from those seen in benign thyroid lesions.

Consistent patterns of chromosome changes have been detected also in benign thyroid adenomas and hyperplasias (Belge et al., 1998). From cytogenetic studies of more than 200 such cases, two main chromosomal subgroups have emerged: one with rearrangements of 19q, accounting for 20% of the cases with clonal changes, and one with a combination of trisomies, almost always including chromosome 7, seen in one third of the cases. Less frequent cytogenetic subgroups are characterized by deletions of 2p or 13q.

Parathyroid adenomas are often characterized by an inv(11) that translocates the parathyroid hormone receptor gene at 11p15 to the region of 11q13. This rearrangement led to the cloning of a gene on the long arm that resides near the BCL1 breakpoint. This gene was originally called *PRAD1* (parathyroid adenoma gene 1). However, when its sequence was elucidated, it was found to be homologous to the cyclin gene involved in cell-cycle progression in xenopus oocytes (Motokura et al. 1991).

Later it was identified as *Cyclin D1*, which is overexpressed in parathyroid tumors with the inv(11). This provides another example in which translocation of an active gene, in this case *PTH*, causes unscheduled expression of a cell regulatory gene (*cyclin D1/CCND1*) as a result of chromosome rearrangement in neoplasia.

TUMORS OF THE BREAST

Part of "34 - Solid Tumor Cytogenetics"

Clonal chromosomal changes have been documented in over 500 breast carcinomas. A wide spectrum of karyotypic changes have been detected among them, with some tumors showing a single numerical or structural alteration and some tumors having highly complex karyotypes with numerous unidentifiable marker chromosomes. Part of these differences may be a result of the analysis of different subsets of breast carcinoma. Initially, mainly pleural effusions from highly advanced-stage carcinomas were used, but with the development of improved cell culture techniques, it also became possible to analyze less aggressive, primary lesions. Another factor influencing the cytogenetic result is the culture technique used; direct harvesting is more likely to yield complex karyotypes, but often fails to provide any information, whereas short-term culturing tends to favor the outgrowth of cells with pseudodiploid or near-diploid karyotypes (Steinarsdóttir et al. 1995).

In spite of these technical problems, a nonrandom pattern of chromosomal aberrations has been detected. No recurrent balanced rearrangement has been detected, but several imbalances are frequent: loss of 1p, 3p, 6q, 8p, 11q, 13q, 16q, and 17p, and gain of 1q and 8q. Some changes have been suggested, on the basis of their appearance both as sole anomalies and together with other aberrations, to be of particular importance in breast cancer development: del(1)(q11-12), del(1)(q42), i(1)(q10), der(1;16)(q10;p10), del(3)(p12-13p14-21), del(6)(q21-22), +7, +8, +12, +18, and +20. However, none of these aberrations is specific for breast carcinoma, and most of them have been identified in benign breast lesions as well (see below). The understanding of the role of these imbalances in breast cancer development is further hampered by the fact that they involve large chromosomal segments, making it difficult to identify the essential molecular genetic consequences.

Several cytogenetic-clinicopathologic correlations have been reported for breast carcinomas, but few have been confirmed in independent studies. It seems, however, as if loss of 16q, as detected by cytogenetic, FISH, or molecular techniques, is associated with node-negative tumors and good prognosis (Hansen et al. 1998; Adeyinka et al. 1999).

Chromosomal aberrations have been reported in almost 100 benign breast lesions (fibroadenomas, phyllodes tumors, adenolipomas, hamartomas, nodular fasciitis, and fibrocystic disease), as well as in prophylactic mastectomies from women with familial predisposition to breast cancer development (Lundin and Mertens, 1998). No disease-specific aberration has been detected among these lesions, almost all of which have displayed a near-diploid chromosome count. Many of the recurrent changes that have been detected, e.g., del(1)(q11-12), der(1;16)(q10;p10), del(3)(p12-13p14-21), del(6q), +7, +18, and +20, coincide with those that have been detected among the invasive breast carcinomas, suggesting that they are not sufficient for malignant transformation. Furthermore, the finding of shared abnormalities in benign and malignant breast tumors and the fact that breast carcinomas often have simple karyotypes imply that cytogenetics is of limited value in the differential diagnosis. One exception would be the phyllodes tumors, where malignant tumors consistently have shown complex karyotypes and the benign variants have had simple karyotypes, which is in line with recent CGH data (Lu et al. 1997; Lundin and Mertens 1998).

The finding of multiple, unrelated cytogenetically abnormal clones is a common phenomenon (up to 50% of the cases after short-term culturing) in both benign and malignant breast lesions. In contrast to other tumors frequently displaying unrelated clones, i.e., skin tumors and head and neck carcinomas, there is a regularity to the pattern of aberrations observed. The significance of such polyclonality is still unclear, but strongly implies that a large proportion of breast tumors are of multicellular origin (Teixeira et al. 1996) or that an early clonal change, which may lack a visible rearrangement, causes genetic instability that drives rapid evolution of clonal diversity. However, like for many other tumors in which multiple clones are observed, most are not long-term survivors and the progressive tumor is a stemline clone. A definite answer to this question of polyclonality will, however, require combined molecular and cytogenetic approaches as well as longitudinal studies with early and late samples of the same tumors.

TUMORS OF THE LUNG

Part of "34 - Solid Tumor Cytogenetics"

The brunt of the cytogenetic information on lung carcinomas stems from the analysis of adenocarcinomas and squamous cell carcinomas. For each of these histopathologic subtypes, approximately 150 cases with clonal aberrations have been reported. The other main categories are large-cell (40 cases) and small-cell lung carcinomas (SCLC, 50 cases), whereas less than 20 informative adenosquamous-cell carcinomas or carcinoids have been published. No aberration specific to any of the different subtypes has so far been described. Generally, all types of lung carcinoma have a highly complex karyotype, with a near-triploid chromosome count and massive numerical and structural changes. The perhaps most conspicuous finding is the frequent loss of 3p material, which initially was thought to be particular for SCLC. Indeed, combined cytogenetic and molecular genetic results indicate that 3p deletions occur in 90% to 95% of all SCLC, but later studies have shown that the majority of non-SCLC also display this aberration. The 3p deletions, which according to chromosome banding analyses have a maximum frequency at bands 3p21-22, are likely to result in the inactivation of a tumor suppressor gene. Despite intensive efforts to identify the putative target gene, no convincing candidate has been identified to date.

Other frequent (at least 25% of the cases) chromosomal imbalances among lung carcinomas include loss of chromosomes X, Y, 4, 9 (in particular 9p), 13, 15, 18, 22, and chromosome arms 1p (1p22-1p36), 6q, 8p, and 17p, and gain of chromosome 7 and chromosome arm 1q. It is still too early to conclude whether any of these imbalances may be particularly characteristic for any of the different histologic subtypes.

Almost 100 mesotheliomas, the major malignancy of pleural origin, with abnormal karyotypes have been described. According to Hagemeijer et al. (1990), who presented the hitherto largest series comprising 30 informative tumors, the cytogenetic findings suggested a dichotomization of the tumors into those with hypodiploid/hypotetraploid chromosome numbers and frequent -4, 9p-, and -22, and those with hyperdiploid karyotypes and frequent 3p-, +5, +7, and +20. No significant association was, however, found between cytogenetic pattern and clinical outcome or histologic subtype of the tumor.

Pulmonary chondroid hamartoma of the lung is a benign neoplasm composed of cartilage, adipose tissue, undifferentiated mesenchymal cells, and epithelium-lined, cleftlike spaces. Almost 200 cases with clonal aberrations have been reported, most of which were part of a large single-institutional series encompassing 191 tumors (Kazmierczak et al. 1999). In that cohort, 70% of the short-term cultured samples showed clonal aberrations, with 21 tumors showing 6p21 rearrangements and 95 tumors showing 12q14-15 rearrangements. The most frequent recurrent translocations were t(12;14)(q15;q24) and t(6;14)(p21;q24). FISH and molecular genetic studies have revealed that the target genes in 6p21 and 12q15 are *HMGIY* and *HMGIC*, respectively, which are rearranged in many other benign mesenchymal tumors (see below). The target gene in 14q24 remains to be identified, but is likely to be the recombination repair gene *RAD51B*, which was shown to be involved in uterine leiomyomas with t(12;14) (Schoenmakers et al. 1999).

TUMORS OF THE GASTROINTESTINAL TRACT

Part of "34 - Solid Tumor Cytogenetics"

The majority of the more than 100 reported ventricular carcinomas, almost all of which were adenocarcinomas, have had highly complex karyotypes. Different research groups have reached slightly different results, and the karyotypes often have included numerous unclassifiable marker chromosomes, making it difficult to evaluate the significance of individual chromosome aberrations. Nevertheless, frequently reported rearrangements include gain of chromosomes X, 8, and 9, loss of the Y, deletions of 3p, 6q, and 7q, isochromosomes for the long and short arms of chromosomes 8 and 5, respectively, and various rearrangements involving 11p.

Of the more than 100 pancreatic malignancies that have been reported to date, the vast majority have been carcinomas of the exocrine pancreas. A review of the cytogenetic data on this tumor type was presented recently by Gorunova et al. (1998). The karyotypes usually are complex with a chromosome number in the triploid-tetraploid range (See Fig. 34.4). Several recurrent changes, all of them leading to imbalances, have been identified: del(1)(q11-12), del(1)(q21), i(1)(q10), del(3)(p11), i(3)(q10), del(4)(q21), del(4)(q25), i(5)(p10), del(6)(q15), i(8)(q10), del(9)(p13), del(11)(p13), dup(11)(q13q23), i(12)(p10), der(13;15)(q10;q10), del(18)(q12), del(18)(q21), and i(19)(q10). Common numerical aberrations include -Y, +2, +7, -18, +20, and -21. These findings are in agreement with CGH and molecular studies, showing frequent loss of 1p, 3p, 6q, 9p, 13q, 15q, 18q, 19p and gain of 5p, 7q, 8q, 11q, 12p, 19q. Several potential target genes for commonly deleted (*CDKN2A* in 9p, *SMAD4* in 18q) or amplified (*CCND1* in 11q, *KRAS2* in 12p, and *AKT2* in 19q) regions have been identified by molecular analyses.

A striking feature of pancreatic carcinomas is the pronounced intratumor heterogeneity seen as multiple related or unrelated clones. In the series of 25 tumors reported by Gorunova et al. (1998), 19 tumors displayed from 2 to 58 clones. As in head and neck carcinomas (see above), unrelated clones usually are near-diploid and sometimes occur together with complex clones. The significance of this cytogenetic polyclonality is unknown.

Very few primary liver tumors have been subjected to chromosome-banding analysis. Hepatoblastomas, the most frequent liver tumor in childhood, have, however, a nonrandom pattern of cytogenetic changes with trisomy 2, or gain of 2q, i(8q), and gain of chromosome 20 as the most common features.

The cytogenetic database on colorectal carcinomas comprises more than 300 cases, mostly adenocarcinomas, with clonal chromosome aberrations. Approximately two thirds of the tumors have displayed a near-diploid chromosome count, often with relatively few numerical and/or structural rearrangements. The remaining one third have had more complex karyotypes, sometimes with more than 100 chromosomes. The most frequent numerical aberrations are gain of chromosome 7 and loss of the Y and chromosome 18 (each detected in 30% to 35% of the cases) followed by trisomy for chromosomes 13 and 20 and monosomy for chromosomes 14, 17, and 22 (each found in 15% to 20%). The most common structural aberrations, all of which lead to loss and/or gain of genetic material, are isochromosomes for the long arms of chromosomes 1, 8, 13, and 17, and deletions of 1p and 17p.

Hereditary non polyposis colon cancer (HNPCC) also known as Lynch syndrome is an inherited predisposition to colorectal cancer that is characterized by microsatellite instability as a result of DNA replication errors (Aaltonen et al. 1993). In initial studies, two chromosome regions were discovered by kindred analysis of inherited linked marker haplotypes. The first region was on chromosome 2p16. In families in which a positive LOD score was not found for this locus, subsequent analysis revealed a locus at 3p21-23. These regions, which are frequently lost in karyotypes from colon cancers as well as other tumors, are the sites of *hMSH2* on 2p (Kohonen-Corish et al. 1995) and *hMLH1* on 3p (Bronner et al. 1994). Hemizygous deletion eliminates the wild-type copy of the gene leaving only the mutated form of the enzyme in the tumor cells, which then have increased DNA replication errors. Mutations of these genes are common in Lynch syndrome patients. Further analysis has led to the identification of other mismatch repair genes. Correction of mismatch repair has been demonstrated *in vitro* by microcell-mediated transfer of a normal chromosome 3 to a human colorectal carcinoma cell line that contains a defect in *hMSH2*. This experiment demonstrates that the defective mismatch genes are responsible for the DNA repair errors and microsatellite instability observed in HNPCC cells (Koi et al. 1994).

Bardi et al. (1995) have reported a correlation between karyotype and tumor grade and site. Structural chromosome aberrations were more common among poorly differentiated carcinomas, whereas well and moderately differentiated carcinomas more often had numerical changes only. Abnormal karyotypes in

general, and complex ones in particular, were more common in rectal tumors than in tumors of more proximal location. Furthermore, it has been suggested that patients with complex tumor karyotypes have a worse clinical outcome than other patients.

In contrast to most other malignancies, carcinomas of the large bowel usually develop through histologically defined premalignant stages, the so-called adenoma-carcinoma sequence. Thus, the study of benign colorectal neoplasms is potentially of utmost importance for our understanding of colorectal tumorigenesis. More than 100 adenomas with clonal abnormalities have been reported. In general, these tumors have had fairly simple karyotypes, but there is a clear tendency for increasing karyotypic complexity with increasing degree of dysplasia. It also should be noted that some cases have displayed highly aneuploid karyotypes. The spectrum of chromosomal gains and losses is very similar to that in colorectal carcinomas, but with gains dominating over losses. The most frequent gains are +7 (50% of the cases), +13 (30%), and +20 (20%), and -18 is the most common monosomy (15%). The breakpoints involved in structural rearrangements cluster to chromosome 1, with loss of distal 1p as the most frequent aberration. Deletions of 1p has in many cases been the sole cytogenetic aberration, indicating that loss of a, so far, unknown gene in distal 1p is of primary importance in colorectal tumorigenesis. Guided by an interstitial deletion of 5q in a patient with familial adenomatous polyposis (FAP, also called familial polyposis coli or FPC), an autosomal-dominant condition in which affected individuals develop hundreds to thousands of colonic polyps led to the discovery of the APC gene at 5q21-q22. The adenomatous polyps are a premalignant condition and nearly all affected patients develop colon cancer by or in their 5th decade. APC mutations are present in at least 95% of FAP families and screening for the mutations can exclude nonaffected family members (Laken et al. 1999).

Many of the chromosome segments that are often involved in imbalances in adenomas and carcinomas are known to harbor genes that from molecular genetic studies have been implicated in colorectal carcinogenesis (Fearon and Vogelstein 1990). Whereas the cytogenetic data may be interpreted to confirm the previous conclusion that it is the net accumulation of genetic changes, rather than the order in which they appear, that is crucial for determining the tumor phenotype, they also show that the molecular picture of colorectal tumor development is far from complete.

TUMORS OF THE GENITOURINARY TRACT

Part of "34 - Solid Tumor Cytogenetics"

Cytogenetic investigations of RCC have resulted in more than 600 reported cases with clonal chromosome abnormalities. Several histopathologic subtypes are recognized, which may be broadly categorized into papillary and nonpapillary RCC. Among the latter, which constitute about 85% of all RCC, the clear cell type is the by far best characterized by chromosome banding techniques. The single most common change (in some series up to 90% of the cases) in this subtype is loss of 3p material. Often this occurs through terminal deletions at bands 3p12-13, but other chromosomal mechanisms, such as interstitial deletions, loss of the entire chromosome, or unbalanced translocations, in particular with chromosome arm 5q, also have been described. Although the cytogenetic data indicate a maximum deletion frequency at band 3p21, molecular investigations suggest that the salient outcome of 3p deletions concerns a more distal locus, i.e., the *VHL* gene in 3p25. This gene, which is causally related to the inherited predisposition to kidney cancer seen in the von Hippel-Lindau disease, is functionally inactivated (lost, mutated, or methylated) in close to 70% of all RCC. Of course, one cannot exclude the possibility that other, more proximal tumor suppressor genes that are deleted concomitantly with the *VHL* gene are of pathogenetic importance, as well. Indeed, loss of heterozygosity studies implicate three distinct, commonly deleted regions: one in 3p13-14, one in 3p21, and one in 3p25-26. Furthermore, similar 3p deletions are common in several other tumor types for which the *VHL* gene is not involved, suggesting that this is a region with several important tumor genes.

Other frequent (more than 15% of the cases) rearrangements in clear-cell RCC include gain of 5q, deletions of 6q, trisomy 7, and loss of chromosomes Y, 8, 9, and 14. Most of these changes probably represent secondary, progression-related alterations, although so far no clear-cut evidence has been provided that the presence or absence of any of them should correlate with clinical outcome. Trisomy 7 presents particular interpretational problems in this context. Not only is gain of one or more copies of chromosome 7 commonly found in the same clone as 3p-, but it can also occur as the sole change, either alone or together with clones carrying 3p- and/or other changes. Furthermore, it has been clearly established that trisomy 7-carrying cells may be present also in nonneoplastic kidney tissue. Thus, the impact of +7 on renal-cell carcinogenesis is presently elusive.

Chromophilic RCC, most of which have a papillary growth pattern, has a distinct cytogenetic profile. The adenomas and low-grade variants usually show only a few numerical changes of which +7, +17 and -Y, are by far most common. In contrast, the more malignant cases display additional trisomies for chromosomes 12, 16, and 20, and loss of the supernumerary chromosome 17 or deletions of 17p. Another subset of malignant papillary/chromophilic RCC is characterized by a pathognomonic t(X;1)(p11;q21), resulting in the fusion of the transcription factor gene *TFE3* on the X-chromosome with the *PRCC* gene on chromosome 1.

Nonrandom karyotypic patterns also have been detected in oncocytomas, one third of which have displayed -Y and -1, chromophobic-cell carcinomas, which usually have hypodiploid chromosome numbers, and collecting duct carcinomas, which are characterized by loss of chromosomes 1, 6, 14, 15, and 22.

Wilms' tumor, the most common renal tumor in childhood, is cytogenetically totally different from adult forms of kidney cancer. Although the inherited forms, and their association with congenital malformations and constitutional mutations in the *WT1* (11p13) gene and *WT2* region (11p15), have gained much attention, more than 95% of the tumors are believed to be sporadic in nature. The karyotypic pattern among the 175 reported cases is clearly nonrandom. Most tumors have had a near-diploid chromosome count. Numerical aberrations mainly involve gain of chromosomes, trisomy 12 being particularly frequent followed by +8, +6, +7, +13, +20, and +17; several of these trisomies

have been detected as the sole karyotypic deviation. Also, structural rearrangements typically result in imbalances, the most common being gain of 1q and loss of 11p. One particular aberration, der(16)t(1;16)(q10-21;q10-13), has been detected in more than 10 cases. The same aberration has been described in many other neoplasms, notably Ewing sarcoma and breast cancer, and probably represents a secondary change. A few cases with triploid-tetraploid karyotypes have been reported, and these tumors tend to have an anaplastic morphology. The same histologic subset, which carries a poor prognosis, also is characterized by *TP53* mutations, which are rare in other subtypes of Wilms' tumor.

A less frequent pediatric kidney tumor is mesoblastic nephroma. Cytogenetically, these low-malignant tumors are characterized by simple numerical changes, the most consistent being +11 followed by gain of chromosomes 8, 10, 17, and 20. The numerical changes, as well as the morphology of the tumors, are essentially identical to those in infantile fibrosarcomas, and it was recently shown that the two tumor types share also a t(12;15)(p13;q25)-associated *ETV6/NTRK3* fusion, which presumably constitutes the primary, tumorigenic event (Knezevich et al. 1998).

No specific chromosomal abnormality has been detected among transitional cell carcinomas of the bladder. Some of the more than 100 reported cases have had a simple karyotype, with only a few numerical and/or structural rearrangements, whereas others have had highly complex changes. Frequent aberrations include various rearrangements of chromosome 1, del(3p), i(5p), trisomy 7, monosomy for or deletion of chromosome 9, and del(10q). Both cytogenetic and molecular genetic data have implicated deletions of 9p and 9q as important in the earliest phases of tumorigenesis, whereas 17p deletions are associated with tumor progression. Cytogenetic studies also have convincingly demonstrated that multifocal uroepithelial tumors usually have a monoclonal origin.

Prostate cancer cells have turned out to be very difficult to maintain in culture, which in part may explain the relative lack of cytogenetic data on this common tumor type. Furthermore, about 100 of the 180 reported cases with acquired chromosome changes have had -Y, +7, and/or a “normal” tetraploid — 92,XXYY — karyotype as the sole anomalies, all of which are of doubtful significance in prostate carcinogenesis. It could be noted, though, that -Y and +7 are common also in samples from benign prostatic hyperplasia. Among the remaining carcinomas, karyotypes of varying complexity have been identified, and it seems as if the structural rearrangements in these tumors cluster to chromosomes 1, 7, 8, and 10. The most consistent outcomes of such rearrangements are deletions of 7q, often in band 7q22, 8p, and 10q. In one study containing a mere 15 cases with clonal aberrations and 42 with normal karyotypes, the former were found to have a significantly shortened survival (Lundgren et al. 1992).

Several series of cytogenetically analyzed ovarian carcinomas have been published, and the literature now contains more than 400 cases, the majority of which were classified as adenocarcinomas, with clonal chromosome abnormalities. Most tumors have had fairly complex karyotypes, with near-triploid or hypodiploid stemlines. The most frequent numerical changes are loss of X, 4, 8, 13, 14, 15, 17, and 22, and gain of chromosome 12, each detected in at least 15% of the cases. Structural rearrangements cluster to chromosomes 1, 3, 6, 9, 11, and 19, leading to loss of 1p, 1q, 3p, 6q, 9p, 11p, 19p, and 19q material.

A few carcinomas have karyotypes with only numerical changes or a single structural rearrangement. Such karyotypes have been associated with well-differentiated tumors, whereas poorly differentiated carcinomas have complex karyotypes. Furthermore, complex karyotypes, as well as several nonrandomly rearranged regions, have been correlated with poor clinical outcome (Taetle et al. 1999). Cytogenetic studies also have shown that bilateral ovarian carcinomas usually have identical karyotypes, strongly implicating that the multifocality is from tumor spreading rather than independent tumorigenesis.

Benign ovarian tumors are less well characterized, but a recurrent pattern of numerical changes, with +12 as the most common variant, has been detected among the roughly 40 cases reported. Trisomy 12, often as the sole anomaly, has been detected in slightly more than one half of the cases, and seems to be particularly frequent in the subgroup of sex cord stromal tumors.

More than 600 uterine tumors with clonal chromosome changes have been reported. The by far most extensively analyzed subtype is leiomyoma, a benign myometrial proliferation, for which information on some 325 tumors exist. Abnormal karyotypes are found in approximately one third of the cases, and several karyotypic subgroups have been established (Morton 1998). The most frequent, each accounting for 10% to 20% of the cases, are characterized by deletions of the long arm of chromosome 7 and structural rearrangements of 12q13-15, the most common being a t(12;14)(q14-15;q23-24), respectively. Cytogenetic and molecular genetic investigations indicate that the minimal deleted segment on 7q maps to 7q21-22, but so far no target gene has been identified. The 12q rearrangements usually involve the *HMGIC* gene, which encodes an architectural transcription factor, leading to aberrant expression of the protein. In contrast to other mesenchymal tumors with frequent aberrations of the *HMGIC* gene, such as lipoma (see below), the breakpoints in leiomyomata often occur upstream of the gene. The importance of altered expression in leiomyomas of proteins belonging to the high mobility group (HMG) family is further emphasized by the fact that a subset of the tumors without involvement of *HMGIC* have rearrangements of band 6p21, harboring the closely related *HMGIY* gene.

The other main subtype of benign uterine tumors, endometrial polyps, also display nonrandom chromosomal changes. These overgrowths of endometrial tissue, for which 25 cases with clonal abnormalities have been described, have at least three different characteristic karyotypic changes. Rearrangements of 6p21, often in the form of a t(6;14)(p21;q24), are the most common, followed by rearrangements of 12q13-15, and deletions of 7q. The cytogenetic picture thus is very similar to the one in leimyomas, and molecular studies have shown that in the polyps, too, the 6p and 12q rearrangements affect the *HMGIY* and *HMGIC* genes, respectively. Most interestingly, a recent FISH study revealed that tamoxifen-induced polyps carry *HMGIC* and *HMGIY* rearrangements that are indistinguishable from those in sporadic polyps (Dal Cin et al. 1998).

The cytogenetic information on malignant uterine tumors is less detailed. The majority of the close to 100 reported endometrial carcinomas, most of which are adenocarcinomas, with clonal chromosome aberrations have had a near-diploid chromosome count, with gain of 1q material, trisomy 10, and deletions of 6q as the most frequent changes. The latter imbalance has been suggested to be particularly frequent among serous papillary, endometrioid, and mixed müllerian endometrial carcinomas. Cytogenetic analysis of a small number of cultured endometrial carcinomas revealed several chromosomal locations that appear to be consistent. These include deletions of distal 18q, rearrangements with breakpoints involving the short arm of chromosome 22, and breakpoints involving 12q. Loss of chromosome 4, deletion 9q and 13q, and a breakpoint on 8p may be associated with aggressive tumors. An example of a karyotype from an endometrial carcinoma containing the common changes is shown in Fig. 34.7.

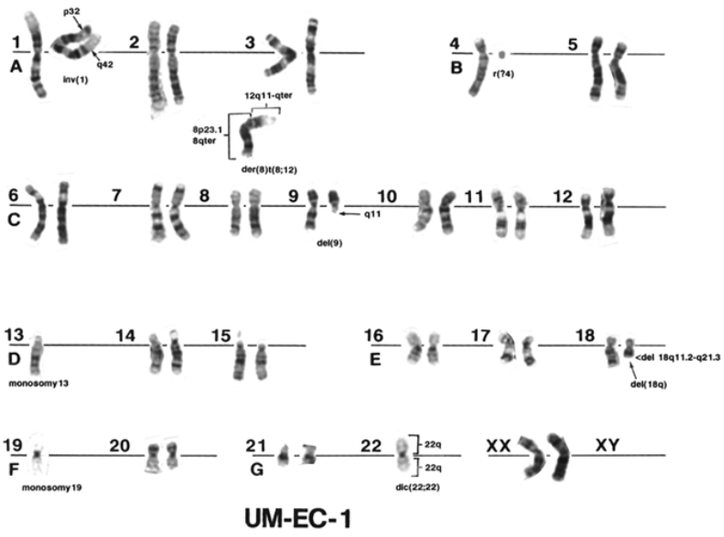

FIGURE 34.7. Karyotype from a hypodiploid endometrial carcinoma demonstrated several of the consistent chromosome changes found in this tumor type. Note that there is monosomy 4, 13, and 19, a pericentric inversion of chromosome 1, del(9q), del(18q), i(22q) and t(8;12) (p23.1;q22). The ring chromosome is most likely derived from the missing chromosome 4. (Reprinted with permission from Grenman SE, Van Dyke DL, Worsham MJ, et al. UM-EC-1, a new hypodiploid human cell line derived from a poorly differentiated endometrial cancer. *Cancer Res* 1988;48:1864–1873.)

Less than 30 malignant uterine tumors showing mesenchymal differentiation have been reported. The leiomyosarcomas have complex karyotypes, usually without any similarities to their benign counterparts, whereas a recurrent t(7;17)(p15-21;q12-21) has been found in stromal sarcomas.

Close to 100 karyotypically abnormal carcinomas of the uterine cervix have been reported. However, many of these karyotypes have been incompletely described, which makes the cytogenetic information an unreliable source for identifying pathogenetically important rearrangements. Recent CGH studies have, however, displayed a nonrandom pattern of imbalances with gain of 3q as the most consistent change, present in two thirds of the invasive cases and one third of *in situ* carcinomas (Kirchhoff et al. 1999). Other frequent (>30% of the cases) changes detected by CGH in invasive carcinomas were gains on Xq, 1q, 5p, 8q, and 15q, and losses on 3p, 4p, 6q, 11q, and 13q.

Squamous-cell carcinomas of the vulva (vulvar carcinoma), are relatively rare tumors, with an incidence of 1 or 2 tumors per 100,000 women. As a result, there are relatively few studies of this tumor type. The etiologic factors for these tumors are not well understood and may differ from squamous cancers that arise at other sites after prolonged exposure to carcinogens. Worsham et al. (1991) studied a consecutive series of six patients and found each tumor to have a unique and complex karyotype. However, there was a surprising degree of similarity in the rearrangements. Five of the six tumors had losses of 3p14-cen, 8pter-p11, 22q13.1-q13.2, and the short arm of the inactive X; the same proportion of tumors had gains of 3q25-qter, band 11q21, and rearrangement breakpoints in 5cen-q12. In this same series, two regions of relative chromosome loss involving 10q and 18q were observed in all four tumors in patients who died from progression of their tumors, whereas the two patients whose tumors did not have these losses were alive and well several years later. In some cases, the loss affected the whole chromosome, but in others there were specific deletions in which the smallest region of loss corresponded to del(10) (q23q25) and del(18) (q22q23). These regions provide targets for additional study as possible sites of genes important in prognosis. An example of a hypotetraploid karyotype from a vulvar carcinoma is presented in Fig. 34.8. Note that many of the regions already mentioned as important in other tumors also are affected in this squamous cancer. For example, i(5p) and loss of 5q as well as loss of 18q are changes in this tumor that are also associated with colon cancer and squamous cancers at other sites such as head and neck.

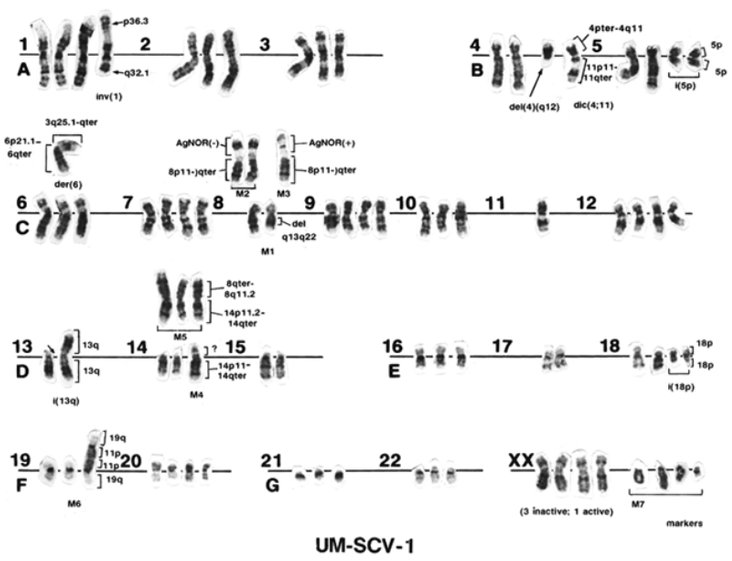

FIGURE 34.8. Representative karyotype from a hypotetraploid squamous carcinoma of the vulva. In this figure, the rearranged chromosomes are identified. Prominent abnormalities against the tetraploid background are the loss of 4q, 5q, 8p, 11 (there is only one intact 11, a total of three copies of 11p, and two copies of 11q), 15, 17, and 18q, as well as the gain of 5p, 8q, 14q, and 18p. (Reprinted from Grenman SE, Van Dyke DL, Worsham MJ, et al. Phenotypic characterization, karyotype analysis and in vitro tamoxifen sensitivity of new ER-negative vulvar carcinoma cell lines, UM-SCV-1A and UM-SCV-1B. *Int J Cancer* 1990;45:920–927.)

Germ-cell tumors (GCT) are a heterogeneous group of neoplasms that may be broadly classified into seminomatous and

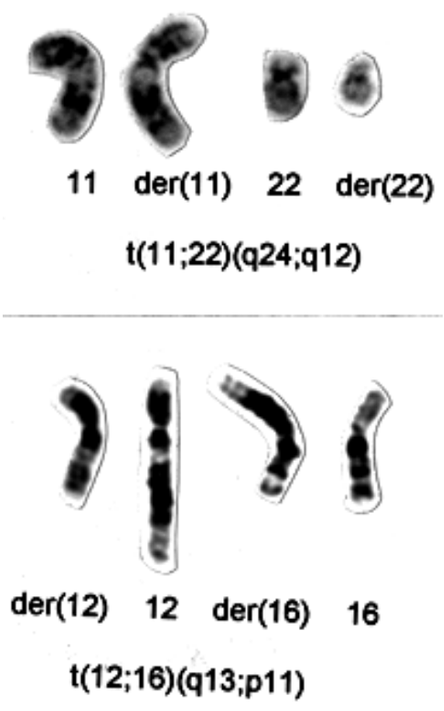

FIGURE 34.9. Partial karyotypes illustrating two sarcoma-associated chromosomal translocations: **(top)** t(11;22)(q24;q12), leading to the *EWS/FLI1* fusion gene, in a Ewing sarcoma, and **(bottom)** t(12;16)(q13;p11), leading to the *FUS/CHOP* fusion gene, in a myxoid liposarcoma.

nonseminomatous tumors. They usually have a testicular or ovarian origin, but are sometimes detected as extragonadal lesions, and may affect all age groups. However, of the more than 350 cases with abnormal karyotypes that exist in the literature, the majority has been testicular GCT from adult men. In this setting, the most frequent aberration, found in more than 80% of cases in some series, is one or more copies of an isochromosome for the short arm of chromosome 12. As the i(12p) usually is supernumerary, together with the fact that other rearrangements leading to gain of 12p sequences have been described, it seems reasonable to assume that the crucial molecular outcome of the isochromosome formation is gain of genes on 12p rather than loss of 12q material. The relevant loci on 12p have not yet been identified, but both cytogenetic and CGH data indicate that these are to be found in the proximal part of 12p (12p11-12). Apart from the i(12p), several other nonrandom chromosomal imbalances have been detected in testicular GCT. In relation to the ploidy level, which usually is near-triploid, gain of 1q, 7p, and chromosome 8, and loss of chromosomes 4, 5, 10, 11, 13, 18, and 19 and chromosome arm 9p have all been detected in at least 30% of the cases.

The i(12p) chromosome seems to be only slightly less common (40% of the cases) in extragonadal GCT in adults, but far less so in pediatric GCT. Instead, the majority of the pediatric tumors have had quite simple karyotypes with only a few numerical and/or structural rearrangements. This pattern resembles the situation in ovarian GCT in adult women. Most of these tumors have been classified as mature or immature teratomas and have recurrently shown trisomies for chromosomes 3, 8, 12, and 14.

SKIN TUMORS

Part of "34 - Solid Tumor Cytogenetics"

Clonal chromosomal aberrations have been described in less than 50 basal cell carcinomas. Almost all of them have shown a near-diploid chromosome count, which is in line with flow cytometry data. In general, simple numerical changes, in particular +18, +9, +20, +7, and +5, predominate (Jin et al., 1998c). The only chromosome arm that appears to be nonrandomly involved in structural rearrangements, usually deletions, is 9q. These deletions are likely to be part of the functional inactivation of the *PTCH* gene, a tumor suppressor gene. *PTCH* is lost or inactivated in both sporadic and familial basal cell carcinomas as determined by molecular genetic methods. Interestingly, a recurrent t(9;16)(q22;p13) has been found in three cases (Jin et al. 1997b). Whether this translocation represents another mechanism for *PTCH* deregulation remains to be elucidated.

Merkel-cell carcinoma is a rare, aggressive skin tumor of neuroendocrine origin. Only 25 cases with clonal chromosome aberrations have been reported, and no specific change has been detected among them. Chromosomes 1 and 11 have been most frequently involved, but apart from implicating the potential importance of deletions of distal 1p, the cytogenetic data are, so far, not helpful in directing future molecular studies.

Approximately 100 malignant melanomas of the skin with clonal chromosome abnormalities have been reported. In contrast to uveal melanomas (see above), most cases have had very complex karyotypes, which may reflect the fact that a large subset of the tumors has been highly advanced metastatic lesions (Thompson et al. 1995). Balanced structural aberrations occurring in more than one case are rare. Instead, the karyotypes are dominated by chromosomal imbalances, in particular gain of chromosome 7 and chromosome arms 1q, 6p, and 8q, and loss of chromosomes 3, 10, and 16 and chromosome arms 6q, 8p, and 9p, all of which have been detected in at least 15% to 40% of the cases. Trent and his coworkers noted a consistent t(1;6) (p22,q12-q21;q11-q13) in several melanomas and after review of the literature observed that band region 6q11-q13 was consistently the recipient of non-reciprocal translocations from several other chromosomes as well. These included (in order of frequency) two regions of chromosome 1 (p22,q12-q21), chromosomes 5, 3, 4, and 17. Subsequent analysis has led to the cloning and the identification of a gene identified by subtractive hybridization of expressed sequences suppressed by chromosome 6 transfer in human melanoma cells. *AIM1*, (absent in melanoma 1) is a novel non-lens member of the ß-γ crystallin superfamily (Ray et al. 1997) that is localized to 6q21. *AIM1* expression reverses tumorigenicity in melanoma cells and represents a candidate tumor suppressor gene associated with consistent 6q rearrangement. The only other imbalance for which a candidate target gene has been identified is loss of distal 9p. Band 9p21 harbors the tumor suppressor gene *CDKN2A* (*MTS*/*p16*), which is inactivated through deletion, mutation, or hypermethylation, in a large subset of sporadic melanomas. Furthermore, *CDKN2A* also is known to be constitutionally mutated in several kindreds with familial predisposition to malignant melanoma.

BONE AND SOFT TISSUE NEOPLASMS

Part of "34 - Solid Tumor Cytogenetics"

The group of musculoskeletal neoplasms comprises a wide variety of histopathologic entities that clinically cover the spectrum from totally innocuous lesions to highly aggressive malignancies. Because of the relative ease with which the cells from these mesenchymally or neuroectodermally derived tumors may be propagated *in vitro*, the cytogenetic literature is quite extensive, with roughly 1,000 cases with clonal changes having been reported for both the benign and the malignant variants. The interest in cytogenetic analysis of these tumors also has been spurred by the finding of highly consistent, sometimes pathognomonic, karyotypic patterns in many of them. Still, however, each histopathologic entity remains poorly investigated, and only for lipomas, liposarcomas, osteosarcomas, rhabdomyosarcomas, and synovial sarcomas have more than 100 cases with clonal chromosome aberrations been published. For recent, more detailed reviews of the karyotypic findings in musculoskeletal tumors, see Mandahl (1996), Sreekantaiah (1998), and Mandahl et al. (1999).

The clinical and biological variation among the musculoskeletal neoplasms is reflected by their karyotypes. The malignant tumors, the sarcomas, may be broadly dichotomized into one group characterized by specific, balanced translocations, and one group typically showing massive chromosomal rearrangements leading to recurrent, but nonspecific, chromosomal gains and losses. The former group includes myxoid liposarcoma, synovial sarcoma, clear-cell sarcoma, alveolar rhabdomyosarcoma,

extraskeletal myxoid chondrosarcoma, Ewing sarcoma, desmoplastic small-cell round-cell tumor, and infantile fibrosarcoma (Table 34.5). In all of these sarcoma types, the characteristic translocation leads to the creation of a fusion gene, which in turn will encode a novel hybrid protein. Because one of the two genes involved in each translocation always encodes a transcription factor, it is believed that the oncogenic effect is exerted by influencing the expression of other genes. Examples of consistent translocations in liposarcoma and Ewing's sarcoma are illustrated in Fig. 34.9. Also some unbalanced rearrangements are strongly associated with certain sarcoma types, such as the presence of one or more supernumerary ring chromosomes in dermatofibrosarcoma protuberans, parosteal osteosarcoma, and other sarcomas of low or borderline malignancy (Table 34.5).

TABLE 34.5. BONE AND SOFT TISSUE TUMORS WITH CHARACTERISTIC CHROMOSOMAL FINDINGS

Tumor Type	Chromosomal Aberrations	Molecular Genetic Aberrations
Sarcomas		
Alveolar rhabdomyosarcoma	t(1;13)(p36;q14)	*FKHR/PAX7* fusion
	t(2;13)(q35;q14)	*FKHR/PAX3* fusion
Clear-cell sarcoma	t(12;22)(q13;q12)	*EWS/ATF1* fusion
Dermatofibrosarcoma	r(17;22)	*COL1A1/PDGFB* fusion
protuberans	t(17;22)(q22;q13)	
Desmoplastic small-cell, round-cell tumor	t(11;22)(p13;q12)	*EWS/WT1* fusion
Extraskeletal myxoid	t(9;22)(q22;q12)	*EWS/CHN(TEC)* fusion
chondrosarcoma	t(9;17)(q22;q11)	*RBP56/CHN(TEL)* fusion
Ewing tumors	t(2;22)(q33;q12)	*EWS/FEV* fusion
	t(7;22)(p22;q12)	*EWS/ETV1* fusion
	t(11;22)(q24;q12)	*EWS/FLI1* fusion
	t(17;22)(q12;q12)	*EWS/EIAF* fusion
	t(21;22)(q22;q12)	*EWS/ERG* fusion
Infantile fibrosarcoma	+8,+11,+17,+20,	
	t(12;15)(p13;q25-26)	*ETV6/NTRK3* fusion
Myxoid liposarcoma	t(12;16)(q13;p11)	*FUS/CHOP* fusion
	t(12;22)(q13;q12)	*EWS/CHOP* fusion
Parosteal osteosarcoma	supernumerary ring chromosomes	amplification of 12q sequences
Synovial sarcoma	t(X;18)(p11;q11)	*SYT/SSX1 or SYT/SSX2* fusion
Benign Tumors		
Adipose-tissue tumors		
-atypical lipomatous tumors	supernumerary ring chromosomes or giant markers	amplification of 12q sequences, including *MDM2*
-hibernoma	rearrangements of 11q13	deletion of 11q13 sequences, including *MEN1*
-lipoblastoma	rearrangements of 8q11-13	rearrangements of *PLAG1*
-lipoma	rearrangements of 6p21 or 12q13-15	rearrangements of *HMGIY* and *HMGIC*
	t(3;12)(q27-28;q14-15)	*HMGIC/LPP* fusion
-spindle cell/pleomorphic lipoma	del(13q), del(16q)	unknown
Osteocartilaginous exostoses	del(8)(q24)	loss of *EXT1*
Schwannoma	del(22q), -22	loss of *SCH (NF2)*

The subgroup characterized by more complex karyotypes comprises the majority of the sarcomas, including, e.g., leiomyosarcoma, malignant fibrous histiocytoma, embryonal rhabdomyosarcoma, malignant peripheral nerve-sheath tumors, chondrosarcoma, and osteosarcoma. Although no specific aberration has been detected among these sarcomas, they all show nonrandom, but largely overlapping, patterns of chromosomal gains and losses. For none of the recurrent imbalances has the crucial molecular consequence been pinpointed, but, as for other tumor types, it is assumed that repeatedly deleted regions indicate the location of tumor suppressor genes, and that frequently amplified regions harbor dominantly acting oncogenes.

The benign musculoskeletal tumors are as cytogenetically heterogeneous as the sarcomas (Table 34.5). However, they usually have near-diploid chromosome counts with only a few structural and/or numerical aberrations, distinguishing them from many of their malignant counterparts. The lipomatous tumors may serve as a good example of the excellent correlations that exist between histopathologic and cytogenetic subgroups: ordinary lipomas typically show translocations involving 6p21 or 12q13-15, lipoblastomas are characterized by rearrangements of 8q11-13, pleomorphic and spindle cell lipomas show deletions of 13q and/or 16q, hibernomas have rearrangements of 11q13, and atypical lipomatous tumors have supernumerary ring chromosomes and/or giant marker chromosomes. Also for some of the benign lesions, the molecular consequences of the chromosomal rearrangements have been clarified. For instance, the 6p21 and 12q13-15 rearrangements, usually translocations, in lipomas lead to the disruption, sometimes through fusion with other genes, of the *HMGIY* and *HMGIC* genes, respectively.

NONNEOPLASTIC LESIONS

Part of "34 - Solid Tumor Cytogenetics"

The interpretation of cytogenetic findings in cell cultures from suspected solid tumors presents problems that are rarely encountered in the analysis of neoplastic hematologic disorders. While

the detection of clonal, acquired chromosome abnormalities in a peripheral blood or bone marrow sample, with the well-known exception of -Y in elderly men, is a highly reliable sign of neoplasia, chromosomal changes in other tissues do not necessarily represent neoplastic cells. Although relatively few studies on the cytogenetic picture in tissue samples from adults without neoplasia have been conducted, preliminary data do indicate that accumulation of chromosome damage might be a common phenomenon also in nonneoplastic cells. Not only have clonal changes, in particular numerical changes, been detected in normal brain, kidney, lung, synovia, and oral mucosa tissue, but there also is an emerging picture that somatic mutations, as detected at the chromosome level, may be nonrandomly associated with proliferative lesions that traditionally are regarded as nonneoplastic. For instance, in osteoarthritis, a degenerative joint disease characterized by cartilage destruction, synovial hyperproliferation, and bony outgrowths known as osteophytes, close to 90% of osteophytes and 95% of synovial samples show clonal chromosome aberrations (Mertens et al. 1996). Even more peculiar, almost all of them have the same abnormality, i.e., trisomy 7, and it has been established that the trisomic cells, compared to diploid cells, have an increased proliferative capacity *in vitro*. Furthermore, some 10% of the cases have breakpoints in 12q13-15, and it has been shown by FISH that these rearrangements may lead to disruption of the *HMGIC* gene in a way that seemingly is indistinguishable from what is thought to be essential in the pathogenesis of a large variety of benign mesenchymal neoplasms (Broberg et al. 1999). Finally, in rheumatoid arthritis, another inflammatory joint disease characterized by trisomy 7, molecular genetic studies have shown frequent *TP53* mutations and altered expression of several oncogenes, features that otherwise are associated with malignant cell proliferation (Aupperle et al. 1998). Thus, it can no longer be argued that somatic mutations are restricted to tumor cells.

How then, should one interpret the frequent finding in some tumor types, notably those of epithelial origin, of pseudodiploid karyotypes with a single or only a few numerical and/or structural changes? As has been shown to be the case in squamous cell carcinomas of the head and neck region and in breast carcinomas, the cytogenetic finding is often at odds with flow cytometric, molecular, or CGH data, which clearly demonstrate the presence of a highly aneuploid cell population within the same tumor specimen (Persson et al. 1999). Bearing in mind that most tumor samples used for cytogenetic analysis contain a mixture of tumor parenchymal and stromal cells and, furthermore, that it is impossible to distinguish between these two cell types after hypotonic treatment and fixation, one possible interpretation of the discrepancies would be that the clonal chromosome aberrations sometimes could be part of the stroma. Whereas this seems to be a reasonable explanation for some tumors, e.g., head and neck carcinomas, the consistency of the detected aberrations in tumor samples and the lack of such aberrations in normal tissue, argue against this hypothesis for other tumors, such as breast carcinomas. The alternative explanation would be that the tumor is composed of more than one, related or unrelated, neoplastic cell population. However, the majority of the data from studies looking specifically at this question indicate monoclonal origin. Most probably, these questions regarding the significance of some genetic findings cannot be resolved until they are addressed by combined cytogenetic, molecular genetic, and immunohistochemical approaches.

CLINICAL SIGNIFICANCE OF CYTOGENETIC FINDINGS IN SOLID TUMORS

Part of "34 - Solid Tumor Cytogenetics"

Ultimately, there are two aims with characterizing the cytogenetic profiles of solid tumors. First, the hope is of course that by learning more about the chromosomal mechanisms that are operative in tumor development one will also obtain a better understanding of the cellular processes that distinguish the neoplastic cells from their normal progenitors. This, in turn, would open up possibilities for designing new treatment strategies, or perhaps even preventing malignant transformation. Second, even before such detailed knowledge about the genetic features of tumor cells has accrued, the cytogenetic results could be useful as diagnostic and prognostic markers. Certainly, genetic investigations, be they at the chromosome or DNA level, are already an integral part of the battery of diagnostic tools that are employed in the classification of small cell, round cell tumors in children, and during recent years the relevance of cytogenetic analysis in the differential diagnosis of musculoskeletal tumors has become increasingly acknowledged. Other situations where cytogenetic analysis may be of help in providing a specific diagnosis or in distinguishing between malignant and benign tumors are discussed in a recent review article by Mitelman et al. (1997b). A few relevant examples are provided below.

Differential Diagnosis

Small cell and round cell tumors in children pose a considerable diagnostic dilemma because it is often impossible to make a diagnosis based on histology alone. The presence of a specific translocation, t(11;22), will make a definite diagnosis of Ewing's sarcoma, whereas the presence of a 1p deletion will establish the diagnosis of neuroblastoma. Similarly, neuroblastoma can be distinguished from Askin's tumor and neuroepithelioma by the presence of t(11;22) in the latter tumors. For a long time, neuroepithelioma and Askin's tumor were considered to be atypical neuroblastomas and were treated accordingly. However, because, like Ewing's sarcoma, they contain t(11;22), they since have been reclassified as primitive neuroectodermal tumors, and they now receive the more favorable therapy used for Ewing's sarcoma.

The presence of a specific change, t(12;16), can be used to make the diagnosis of a subset of liposarcomas, i.e., myxoid liposarcoma. Even though the distinction between benign and malignant tumors is clear in most soft-tissue tumors, the t(12;16) also can be utilized to make this distinction because the benign tumors have chromosome 12q13 involvement but do not show the chromosome 16 involvement. Abnormalities in chromosomes 2, 13, and 1 can be used to distinguish rhabdomyosarcoma from other neuroepithelial tumors. A specific translocation, t(2;13), might even distinguish the alveolar subtype.

Cytogenetics has been clearly underutilized in the area of diagnosis of malignant disease in body fluids such as pleural and peritoneal effusions. Several studies have provided evidence for the correlation between the presence of a clonal abnormality and the presence of neoplastic cells. Thus, cytogenetic analysis can be a useful adjunct to standard cytology in the differential diagnosis of neoplasia versus inflammation or other causes.

Prognostic Implications

In bladder cancer, chromosome abnormalities were recognized as predictors of clinical outcome even before the banding era. Banding techniques have refined the accuracy of identifying chromosome changes in this tumor type, and some specific changes, such as the deletion of 11p, have been shown to be associated with tumor progression. In general, low-grade, noninvasive bladder tumors have diploid karyotypes with few markers, and the higher-grade, invasive tumors have polyploid karyotypes with multiple marker chromosomes. The presence of marker chromosomes also is correlated with recurrence and mortality. Patients whose tumors did not have marker chromosomes had only a 5% rate of recurrence and achieved a 5-year survival rate of 90%, whereas patients whose tumors had markers had a 50% recurrence rate and a 5-year survival rate of only 75%. Thus, the karyotype can be a prognostic indicator in bladder cancer.

In neuroblastoma, the presence and the copy number of double minutes (*MYCN* amplification) has clinical implications. Patients with low-grade tumors and low copy number of double minutes have a much better likelihood of survival compared to patients with high-grade tumors and higher double minutes. Even among patients with high-grade tumors, those with low numbers of double minutes do well compared to those with high numbers. In general, patients with *MYCN* amplification also have chromosome 1 deletions, and this group of patients has the poorest prognosis.

Another prognostic indicator already mentioned above is the amplification of HER-2/neu (*ERBB2*) oncogene at the DNA, mRNA, and protein level that has been correlated with a shortened disease-free interval and decreased overall survival in breast and ovarian cancers. Of particular interest is that this prognostic indicator has now led to the development of a new therapeutic agent consisting of a humanized anti-HER2/Neu antibody. This agent shows great promise as it has caused regression and inhibition of tumor progression even in far advanced cases of metastatic disease.

In colon cancer, tumors from the left side often have more genetic changes, including chromosomal as well as allelic losses, than tumors from the right side. These genetic changes are correlated with disease-free interval and ultimate survival. Interestingly, loss of chromosome arm 18q has been linked to poorer prognosis in colon cancer. Using microsatellite markers and DNA from formalin-fixed, archived tumors, the investigators found that LOH on 18q was linked to poorer survival within stage II and stage III patients. For stage II patients, 5-year survival was 93% in cases where there was no LOH on 18q but only 54% in cases with LOH. Similarly for stage III, the 5-year survival decreased from 52% to 38% if 18q LOH was present.

In head and neck squamous-cell carcinoma, LOH on distal 18q also is associated with poorer survival. In multivariate analysis LOH on 18q was the strongest predictor of decreased survival when compared to age, black race, male gender, advanced stage, tumor histology, and the presence of neck disease. Of these indicators, only black race and advanced stage also were significant (Pearlstein et al. 1998). In head and neck cancer, rearrangement affecting 11q13 also is associated with reduced survival compared to those cases without 11q13 chromosome change (Åkervall et al. 1995). Many of these cases are likely a result of CCND1 amplification, which also is associated with poorer outcome.

In principle, there is no reason to expect that the cytogenetic profile would be less informative for solid tumors than for hematologic malignancies, but the database needed to validate such an assumption is presently far too limited. As a general phenomenon, however, it seems, not unexpectedly, as if the degree of cytogenetic complexity is correlated with clinical outcome (Mitelman et al. 1997b). Significantly shortened survival for patients with complex tumor karyotypes compared to patients whose tumors display only simple abnormalities has been reported for carcinomas of the breast, colon, head and neck region, kidney, ovary, and pancreas. These findings should be kept in mind when considering the many reports, usually including far less than 100 patients, claiming prognostic relevance for a particular chromosome or gene abnormality. Furthermore, with few exceptions, none of the reported correlations between cytogenetics and clinical outcome has been corroborated in independent series. Bearing in mind that some tumor types are rare and that many of them now are analyzed only by alternative techniques, it may well turn out to be difficult to reach any firm conclusions regarding the prognostic importance of cytogenetic findings in solid tumors unless several cytogenetic laboratories combine their results.

36 Molecular HLA Typing

37 HLA: Applications

38 Bone Marrow Transplantation

As details of the molecular and immunological phenomena known collectively as HLA continue to unfold, application of these in clinical medicine, in forensics, and in a myriad of other areas follow close behind. Indeed, sometimes the details get in the way of seemingly beneficial applications, but these ultimately sort themselves out, and our understanding continues to evolve. Thus, the chapters on HLA methods and applications, modified and updated, are herewith presented with the full knowledge that, as in the past, changes are afoot. Current practices and procedures are widely used and lead to useful interpretations with effective results in clinical medicine as well as in research. The certainty that evolving knowledge will produce methodological changes in the near future does not detract at all from their importance as clinical tools and their fruitfulness in research.

HLA testing has evolved over the years through a variety of different methods. Some of these have persisted, with minor variations, for a long time. Given the diverse nature of the demonstrated structural differences between the class I, II, and III HLA antigens, it is not surprising that a number of diverse typing methods should be required to identify them. These methods are subject to constant review and are revised when it is appropriate. The methods presented here are those in use at the time of writing, but it should come as no surprise that variations of these may become standard. The use of lymphocytotoxicity is diminishing, as is the use of DNA probes. Use of reference strands — heteroduplexing — is emerging as a possible method. Class III antigens are found to be burgeoning with polymorphisms, but the role of these, clinically, remains unclear.

Newer specificities, identified by polymerase chain reaction–sequence-specific primer (PCR-SSP) techniques or by sequence-based typing (SBT) are increasingly in use, providing exquisite matching. The use of other methods, leading to less exquisite matching is on the wane. Yet, given the increased use of immunomodulation, and immunosuppression in solid organ transplantation, it may well be that the extreme exquisiteness becoming possible in HLA complex matching is not required for clinical success in these areas. This, however, does not diminish the need for maximum precision in HLA typing given its many other roles. As has always been the case with HLA, as we hone our understanding of the major histocompatibility complex ever more sharply, the need for more precise typing methods will be the driving force behind the development of these methods.

Chester M. Zmijewski

Organ transplantation has long held fascination for scientists of many persuasions. Workers in diverse specialties have been attracted to this area for many reasons and it has burgeoned into activity requiring input from these diverse specialties. Attempts to transplant tissues and organs for the purpose of studying oncogenesis or ageing were thwarted by the failure of the engrafted tissues or organs to thrive in the body of the host. Characteristically grafts of skin exchanged between animals belonging to the same species begin to heal shortly after surgery. Blood vessels from the host extend into the grafted tissue and circulation is established. After 10 to 12 days, the vessels become occluded, circulation ceases, and necrosis begins. This culminates in the formation of an eschar and rejection of the graft at about day 14.

When skin grafts were exchanged between animals of the same inbred strain, which are akin to identical twins, healing occurred without incident and survived for the life of the animal. However, grafts exchanged between animals of different strains were rejected as expected. Finally, the F1 offspring from the mating of two different inbred strains would accept grafts from animals of either parental strain. On the other hand, either parent rejected grafts from an F1 donor. This offered experimental evidence indicating the phenomenon of graft rejection was under genetic control.

As early as 1944, Medawar clearly demonstrated that the “homograft” (currently referred to as “allograft”) reaction had an immunologic basis (1). He showed that although the rejection of skin did occur in 14 days, a second graft from the same donor was rejected much more rapidly. Such a secondary response implied immunologic memory. Furthermore, subsequent grafts were rejected even more rapidly until finally a situation took place in which vascularization failed to occur giving rise to a so-called “white graft.”

Microscopic examination of biopsies taken from the site of these grafts revealed the presence of a large number of small lymphocytes clustered around capillary venules, inflammatory cells, and, in the case of white grafts, massive thrombi with relatively little lymphocytic involvement.

Based on these observations and other experiments involving the generation of tolerance, Medawar postulated that there existed a set of alloantigens under genetic control that are present on donor tissues and recognized by the host. The host mounts an immune response to these antigens, which is not unlike a delayed hypersensitivity response consisting of immune lymphocytes as effectors. Upon continued exposure to antigen or after repeated challenges, antibodies directed against these antigens are formed. Indeed, it was eventually demonstrated that the features of the white graft were caused primarily by circulating antibodies that had been formed in response to previous grafts. This was the origin of the idea of histocompatibility antigens, which were first described by Snell on inbred strains of mice and later by Dausset, Payne, Van Rood, and others, in humans (2, 3).

Histocompatibility antigens were conceived as being a set of alloantigens, i.e., tissue surface antigens that differ among members of the same species, which were significant only as targets for the allograft reaction. However, shortly after their definition, it became clear that these antigens, which are controlled by a genetic complex referred to collectively as the Major Histocompatibility Complex (MHC), are involved in immunologic self recognition and therefore have a much deeper biologic function. It is now clear that histocompatibility antigens serve as self-recognition molecules. In this capacity, they help to trigger the T-cell–dependent immune response and actively participate in the immune elimination of cells infested with foreign substances.

The antigens of the HLA system comprise the histocompatibility antigens in man. The genetic complex controlling the production of these antigens is located on the distal one third of the short arm of chromosome 6. Counterparts of this system exhibiting the same general characteristics have been found in all mammalian species studied to date and are similarly genetically controlled. For example, the mouse equivalent, called H-2, is found on mouse chromosome 17. This system has been studied extensively and continues to serve as a model for the investigation of basic questions in immunology centered on immune responsiveness and tolerance. Among the other species in which the MHC systems have been studied are horses (ELA), cows (BLA), cats (FLA), dogs (DLA), rats (RtLA), and rhesus monkeys (RhLA).

GENETICS AND SPECIAL FEATURES OF HLA

Part of "35 - HLA: Structure, Function, and Methodologies"

Genes of the HLA Complex

The HLA region on chromosome 6 is composed of a set of very closely linked loci. The general arrangement of these loci is

shown in Fig. 35.1 (4). This region extends over approximately 4 centimorgans of DNA or about 4×10^6 base pairs, and contains more than 200 genes. The particular combination of HLA alleles found on an individual chromosome is known as an HLA haplotype. The genetic complex can be divided into three major regions, each of which controls the production of molecules that have distinct biologic functions. These are called class I, which encompasses the HLA-A, -B, and -C loci; class II, which includes the HLA-D region loci HLA-DR, DQ, and DP; and class III, which are loci whose gene products are molecules that belong to the complement system and include C2, C4, and Bf as well as the cytokines referred to as tumor necrosis factors (TNF). The class II region also includes the genes for the TAP-1 and TAP-2 peptide transporter, the LMP genes that encode proteasome subunits, and the gene encoding the DMα and DMß chains. The function of DM genes is to catalyze peptide binding to HLA class II molecules. The DOA and DOB genes, which encode the DO molecule, a negative regulator of DM, are also related to the class II genes. A listing of the loci in the HLA region arranged in order from the telomeric to the centromeric end is given in Table 35.1 (5).

TABLE 35.1. NAMES FOR GENES IN THE HLA REGION, ORDERED FROM TELOMERE TO CENTROMERE

Name[a]	Molecular Characteristics
HLA-F	Class I – like molecule
HLA-G	Class I – like molecule
HLA-H	Class I pseudogene
HLA-A	Class I α-chain
HLA-J	Class I pseudogene
HLA-E	Class I – like molecule
HLA-C	Class I α-chain
HLA-B	Class I α-chain
HLA-DRA	DR α chain
HLA-DRB1	DR ß1 chain determining specificities DR1, DR2, DR3, DR4, DR5 etc.
HLA-DRB2	pseudogene with DR ß – like sequences
HLA-DRB3	DR ß3 chain determining DR52 and Dw24, Dw25, Dw26 specificities
HLA-DRB4	DR ß4 chain determining DR53
HLA-DRB5	DR ß5 chain determining DR51
HLA-DRB6	DRB pseudogene found on DR1, DR2 and DR10 haplotypes
HLA-DRB7	DRB pseudogene found on DR4, DR7 and DR9 haplotypes
HLA-DRB8	DRB pseudogene found on DR4, DR7 and DR9 haplotypes
HLA-DRB9	DRB pseudogene, isolated fragment
HLA-DQA1	DQ α chain as expressed
HLA-DQB1	DQ ß chain as expressed
HLA-DQB3	DQ ß-chain-related sequence, not known to be expressed
HLA-DQA2	DQ α-chain-related sequence, not known to be expressed
HLA-DQB2	DQ ß-chain-related sequence, not known to be expressed
HLA-DOB	DO ß chain
TAP2	ABC (ATP binding cassette) transporter
LMP7	Proteasome-related sequence
TAP1	ABC (ATP binding cassette) transporter
LMP2	Proteasome-related sequence
HLA-DMB	DM ß chain
HLA-DMA	DM α chain
HLA-DOA	DO α chain
HLA-DPA1	DP α chain as expressed
HLA-DPB1	DP ß chain as expressed
HLA-DPA2	DP α-chain-related pseudogene
HLA-DPB2	DP ß-chain-related pseudogene

[a] Gene names given in bold type have been assigned since the 1996 Nomenclature Report.

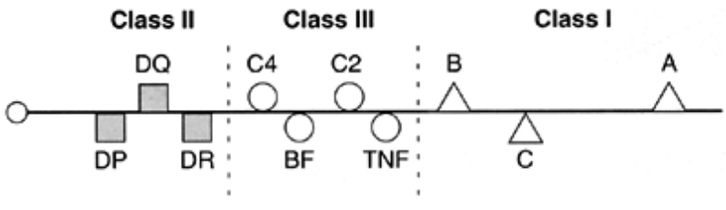

FIGURE 35.1. A diagrammatic representation of the distal third of the short arm of human chromosome 6 carrying the major loci of HLA. The region is divided into three areas that control the production of the class I, class II, and class III molecules.

Other Genes with Specialized Immune Functions Encoded in the HLA Region

Although the most important known function of the HLA gene products is the processing and presentation of antigens to T cells, many other genes map within the region; some of these are known to have other roles in the immune system, but many have yet to be characterized functionally. In addition to the highly

polymorphic HLA class I and class II genes, there are a several HLA class I genes encoding variants of these that show little polymorphism. Some of these genes function to inhibit cell killing by NK cells, a role played by several class I HLA molecules. Such a role has been suggested for HLA-G, which is expressed on fetus-derived placental cells. These cells express no HLA class I molecules and the expression of HLA-G may protect the fetus from the attack by either CD8 T cells or NK cells. Likewise, HLA-E has a specialized role in the recognition of NK cells. HLA-E binds to a very restricted subset of peptides, derived from the leader peptide of other HLA class I molecules. It is known that these peptide:HLA-E complexes can bind to CD94, one of the receptors on NK cells. HLA-E recognition by NK cells blocks killing. The class I and class II regions also contain a number of pseudogenes, i.e., genes that are not expressed as detectible peptides. These genes currently are under study as possible regulators of the intensity of immune responses.

HLA Polymorphism

The HLA system is highly polymorphic. Indeed it is one of the most polymorphic genetic systems in man. Associated with each of the loci is a set of alleles, each of which gives rise to the production of a unique antigenic specificity that is expressed on the cell surface and that can be detected by specific antibodies and/or immunologically activated T cells. The recognizable antigens of the HLA system are shown in Table 35.2 (6). The nomenclature for the alleles of the HLA system has been established and is controlled by a select committee of the World Health Organization (WHO). The antigen name is composed of a letter designating the locus e.g., A, B, C, DR, DP, DQ, and a number. Originally, before it was known that multiple loci controlled HLA, the numbers were assigned in the order of their discovery. Therefore, some inconsistencies occur such as 1, 2, and 3 assigned to the A locus, 5, 7, and 8 assigned to B, and then 9, 10, and 11 reverting to A. The more recently described antigens now follow in logical sequence. Another noticeable peculiarity is the absence of antigens 4 and 6 from the original list. These numerical assignments were reserved for some very special antigens that did not seem to follow the accepted patterns of inheritance or serology. Since then, they have been shown to be so-called “supertypic” or public antigens, which will be described in a subsequent section and are now called Bw4 and Bw6.

In some of the older literature, certain HLA specificities may carry a number prefixed with a “w.” In previous versions of the HLA nomenclature, this prefix stood for “workshop” and indicated a provisional designation pending confirmation based on extensive serologic testing. This was often a very labor-intensive process that was clouded by the fact that the antisera used for the testing were frequently multispecific. Further, these antisera were products of an immune response and as such carried the expected individual variations associated with such responses.

Current practice calls for serologic specificities to be named based on their correlation with an identified DNA sequence (6). Therefore, there is no need for provisional designations because the new antigenic specificities will have a primary biochemical definition that is devoid of serological vagaries. The “w” prefix, however, is retained in the case of the Bw4 and Bw6 epitopes to distinguish them from alleles; as well as the C locus specificities to distinguish them from the complement components.

The new system of nomenclature also allows for the differentiation between the currently accepted classic serologic splits and what are better termed allelic variants. Thus, for example, B51 and B52 are splits of the B5 specificity, distinguishable serologically,

while B*5101 and B*5102 are allelic variants of B51, discernable by biochemical techniques. (Alleles are designated by the locus letter followed by an asterisk and the allele's number.) Currently, however, new serologically defined splits that are a result of epitopes corresponding to combinations of alleles are not given official names. A comprehensive listing of serologically defined specificities and their allele equivalents has been published by Hurley et al. (7).

The individual loci of the HLA complex are tightly linked. Therefore, genetic recombination or crossing over is a rare event, occurring for the most part no more than 1% of the time between A and B and between B and DR and 0.6% between A and C and 0.2% between B and C. Thus, the alleles of the HLA system for the most part are inherited *en bloc* from each parent as a unit called a haplotype.

Fig. 35.2 shows the typical inheritance pattern of the HLA antigens in a hypothetical family with six siblings. Each of the first four siblings is different with respect to the HLA antigens he or she has inherited, however the group can be divided into pairs that share either identical maternal or identical paternal chromosomes. However, the fifth sibling must be identical to one of the others, because there are only four combinations possible. Thus, in any family having more than one sibling, there is a one in four chance that two siblings will be HLA-identical and a one in two chance that they will share one haplotype.

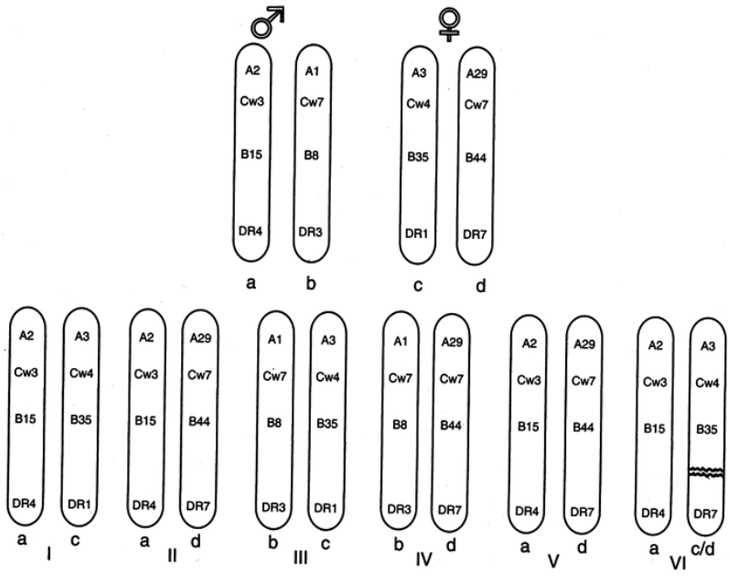

FIGURE 35.2. A pedigree of a family consisting of two parents and six siblings. The HLA haplotypes are labeled c and d. Siblings I through IV represent the different combinations. Sibling V is HLA-identical to sibling II. Sibling VI carries a maternal haplotype that is a recombinant in which the A, C, and B loci come from chromosome c and the DR locus comes from chromosome d.

The HLA-identical siblings in a family may be identical without being identical twins. The same combinations of gametes bearing the MHC of chromosome 6 may be expected in 25% of all offspring on the basis of chance combination alone. Nevertheless, the relatively low frequency of genetic recombination within the HLA region resulting from tight linkage is the phenomenon that permits transplantation between siblings other than identical twins.

Although recombination in the HLA system is an infrequent event, it does occur and usually between the B and the DR loci. An example of this type of recombination is given by sibling six in Fig. 35.2. In this case, offspring number six is identical to siblings numbered four and five with respect to class I antigens but differs with respect to class II antigens. Such recombination can have important clinical implications for transplantation.

Highly polymorphic multilocus systems such as HLA usually are found in the population at large in a state of genetic equilibrium. This equilibrium is such that the frequency with which two or three alleles from the linked loci occur together in a single haplotype is equal to the product of the individual gene frequencies in the population being observed. Although this holds true to a certain extent in the HLA system, there are some notable exceptions. The phenomenon of genetic disequilibrium or more properly gametic association is one of the hallmarks of the HLA system.

Gametic associations are regularly found between certain alleles of A and B, C and B, B and DR, and DR and DQ. In addition, there are instances where certain haplotypes contain even those sequences controlling the class III antigens in a unique gametic

Reference tables of two-locus haplotype frequencies for all MHC marker loci. In: Albert ED, Baur MP, Mayr WR, eds. *Histocompatability testing 1984*. New York: Springer-Verlag, 1984:677–755.

association, forming an extended haplotype. The measure of gametic association is given by the expression, "Δ" or delta and represents the difference between the calculated and observed frequencies of the haplotype. Some of the more prominent gametic associations are listed in Table 35.3 (8).

Information about gametic association is important. For example, it can be used to predict the presence of antigens that are difficult to detect. The products of the HLA-C locus are very difficult to detect using conventional serological techniques even though biochemical techniques have been used to detect as many as 61 allelic variants at this locus. The antigens appear to be weak and the antisera produced in response to them often are multispecific. For this and other reasons, the gene products of the C locus have not been considered in some clinical situations such as solid organ transplantation. However, because of the strong association of some C locus antigens with certain B locus antigens, it often is possible to predict the occurrence of the former whenever the later antigen is detected.

The cause of gametic association is unknown (9). Usually, this condition is found in biologic systems with alleles that have undergone recent mutation and not yet had an opportunity to reach equilibrium. This does not appear to be the case with the HLA system. The gametic associations observed extend throughout widely divergent populations. Such a finding implies that simultaneous and identical mutations that have not yet reached equilibrium occurred in these widely separated populations. This is a highly unlikely event.

In the mouse system, there is a set of genes at the telomeric end of the MHC region that preferentially inhibit recombination in haplotypes that carry them, thereby favoring gametic association (10). A search for a similar set of genes in man has been underway but thus far has been without reward. Genes have been found telomeric to HLA-A that give rise to putative MHC molecules. However, their function does not appear to be equivalent to that found in rodents.

Another theory often proposed to explain such a finding is selective advantage. With respect to HLA, this is difficult to rationalize because many of the haplotypes in gametic association also are associated with certain diseases. As will be discussed subsequently in more detail, the common haplotypes HLA-A3,B7 and HLA-A1,B8 are strongly associated with multiple sclerosis and myesthenia gravis, respectively. Although this is far from a convincing argument for advantage, some proponents of the idea point out that there may be other very beneficial genes associated with these haplotypes that by far outweigh the occasional detrimental effects and therefore do offer some advantage to the organism.

As with many of the other alloantigens such as the blood groups of the human red cells, the alleles of the HLA system have gene frequencies that vary from one population to the next. The variability exists not only among the different races but also among various ethnic groups. Some of the more prominent differences in gene frequencies are shown in Table 35.4 (11). Key frequencies of antigens common to all three racial groups or peculiar to a given group are listed in bold type. Thus, some antigens may be present in high frequency in whites but altogether absent in Asians. Other antigens may be present in blacks in fairly high frequency and virtually absent from whites. Although not shown, such distinctions may be present among various ethnic populations within the same race. Thus there may be certain antigens that are characteristic of eastern Europeans such as the Poles and Russians that are rarely found among the English. Similar analogies in antigen distribution may be found among the various black tribes of Africa and among various Asian peoples such as the Japanese, Chinese, and Koreans.

[a]From Baur MP, Danilovs JA. Population analysis of HLA-A, B, C, DR and other genetic markers. In: Terasaki PI, ed. *Histocompatability Testing 1980*. Los Angeles: UCLA Tissue Typing Laboratory, 1980:955–993.

Although the majority of the HLA alleles present in whites have been discovered as evidenced by gene frequencies that total almost 100%, the same may not be true of the other races. In considering the HLA-A and -B loci, one would expect that an individual should have at least four antigens. Two HLA-A antigens, one from each parent, along with two HLA-B antigens inherited in the same fashion. In testing African-American families, for example, it is not uncommon to find individuals who appear to lack one or more HLA antigens. It usually is clear from the familial pattern of inheritance that the individuals in question are not homozygous for a given allele and therefore phenotypically express it only once but rather they have inherited

what appears to be an undetectable characteristic, a so-called “blank.” The obvious explanation for such a finding is that the individual has a gene that causes the expression of an antigen that cannot be detected with the currently available battery of anti-HLA antisera. Indeed, studies of such individuals among African-Americans have revealed the existence of unique HLA antigens. Similar race-specific antigens have been reported in the Asiatic populations as well as other ethnic groups. Many of these new alleles recently have been defined by DNA-based typing techniques (12, 13).

These antigens become an important consideration in transplant programs associated with large metropolitan hospitals. The random organ donor population available to such institutions as well as their patient populations will be composed of racial minorities. Therefore, knowledge of these special antigens and the ability to detect them are essential. In addition, a knowledge of the variation in the gene frequency of HLA is important because it can have an effect on the ability to find an HLA-matched random cadaveric donor from the general population in a given geographic area. It might be very difficult to locate a suitable donor for a black patient with one or more unique antigens in some Midwestern city populated primarily with whites of Scandinavian ancestry. Numerous other examples could be cited for other regions of the United States that have a blend of peoples with widely divergent racial and ethnic backgrounds. For this reason, a system of organ sharing on a national basis needs to be employed in order to give patients the maximum potential for obtaining a well-matched graft.

HLA Class I Null Alleles and Their Significance in Transplantation

The importance of HLA class I null alleles was reported during the 11th and 12th International Histocompatibility Workshops and Conferences (14). New HLA class I null alleles usually are formed by conversion or recombination between pairs of existing alleles or genes and only rarely by point substitution. New HLA-B alleles are formed at a higher rate than HLA-A or -C, with HLA-A evolving new alleles somewhat more rapidly than -C. The indigenous populations of Latin American countries have evolved many more HLA class I alleles than their counterparts in North America, a difference that primarily is a result of the HLA-B locus. In the populations of South America, older HLA-B alleles have been, to a considerable extent, replaced by newer recombinant alleles. This reveals the general trend for allele turnover and demonstrates that 10,000 to 35,000 years (the estimated time that human populations have lived in America) can be sufficient to replace a founding set of HLA-B alleles by a derived set of recombinants.

Although inactivated HLA null alleles (such as A*24 null) only differ from the common functional allele (A*2402) by a single nucleotide change, the potential effects of such changes on function and histocompatibility are great. For example, if an A*2402 solid organ was transplanted into an A*24 null recipient, the recipient's immune system would recognize it as a completely incompatible class I antigen against which potent alloreactivity and cytotoxic T-cell responses could be made.

The Complexity of HLA Serologic Cross-Reactivity

The majority of antigens in the HLA system can be detected by means of serologic methods employing specific antibodies. One of the characteristic phenomena that has been observed when using anti-HLA alloantibodies is the frequent appearance of serologic cross reactivity. This is a condition in which an antiserum previously shown to react with one particular HLA specificity, upon further testing is shown to react either wholly or partially with another specificity. An example of this is shown in Table 35.5.

TABLE 35.5. CROSS-REACTIVITY RESULTING FROM SHARED EPITOPES

				Reaction With:		
HLA Specificity	Epitopes	Possible Antibodies	Observed Specificity	B5	B35	B18
B5	1, 2, 3	Anti-1 Anti-2 Anti-3	Anti-B5	+++	+	+
B35	1, 4, 5	Anti-1 Anti-4 Anti-5	Anti-B35	+	+++	+
B18	3, 6, 5	Anti-3 Anti-6 Anti-5	Anti-B18	+	+	+++

The occurrence of serologic cross reactivity is most easily attributed to the presence of a mixture of antibodies having specificities directed against several but perhaps related antigens. However, this does not appear to be the cause of cross reactivity in the HLA system (15). Usually, the repeated absorption of the HLA antiserum in question with cells bearing one of the specificities totally removes all reactivity for the other specificity. Such a finding indicates that the antiserum is truly monospecific and establishes that the cross reactivity may be attributable to factors at the level of the antigenic determinant, a conclusion supported by the results of experiences with *in vivo* immunization. In some cases, an antigenic challenge with a given primary antigen may result in the development of antibodies that react with another antigen not present in the immunizing dose. Furthermore, an attempt to immunize an individual with an antigen that he/she is lacking but that is cross reactive with one of his/her own antigens may not result in an immune response.

The phenomenon of antigenic cross reactivity is from the sharing of specific epitopes on the antigenic molecule. It is a regular feature of the HLA system whose antigens may be arranged in “cross reactive groups” (CREGS). The most prominent CREGS of the HLA-A and -B loci are shown in Fig. 35.3.

CREGS are important in that they allow for greater latitude in donor-recipient HLA matching and at the same time may be used to predict potential problems with graft outcome. For example, transplantation or platelet transfusion within a CREG often can be performed without eliciting any great uncontrollable immune response. By the same token, if a patient is shown to

have an antibody of a particular specificity, it is possible that under the proper circumstances his or her serum will react as well with tissues bearing other antigens within in the same CREG.

As the techniques and reagents for clinical HLA typing became more sophisticated, CREGS became less important and greater emphasis was placed on typing and matching for discreet specificities. However, recently, matching strategies based on CREGS are resurfacing. A number of investigators are exploring the possibility of CREG matching as a way to find cross-match compatible donors for patients who have developed HLA antibodies to a large number of specificities as a result of transfusion or previous transplant. Some success has been achieved by means of this approach.

The so-called public and private specificities of the HLA system are a special type of CREG and constitute a prominent feature of the antigens in the HLA system. Public antigens are specific epitopes that are found associated with each of the different specificities of an entire family of HLA molecules. Two such public specificities are the HLA-Bw4 and Bw6, mentioned previously. As the HLA system unfolded, it became clear that many of the antisera belonging to a number of investigators in the field and supposedly detecting a variety of different antigens were in fact detecting a similar set of antigens that could be given an HLA designation. However, the supposedly allelic antigens 4^a and 4^b originally described by van Rood did not appear to fit the scheme. Further investigation revealed that 4^a and 4^b were not products of antithetical allelic genes but rather were found associated with all antigens of the HLA-B locus. Because these specificities cross the boundaries of all of the other specificities of this locus, they were envisioned as public specificities.

In contrast to public specificities, which tend to group antigens into large categories, private specificities tend to divide the groups. For example, the specificity HLA-A9 has two private, serologically detected specificities, HLA-A23 and A24. Cells expressing either of these antigens will react not only with anti-HLA-A23 or A24 antisera but also with anti-HLA-A9. Thus the private specificities are true specificities in their own right. In addition HLA-A23 and A24, each have a different gene frequency in whites and in blacks indicating that they probably arose from a common ancestral gene after the divergence of the races.

BIOCHEMISTRY OF HLA

Part of "35 - HLA: Structure, Function, and Methodologies"

In the previous section, the HLA chromosomal region was divided into sections that controlled the production of three different types of molecules that were called class I, class II and class III. Each of these is unique in terms of its tissue distribution, biochemical structure, and biologic function.

Class I molecules are expressed constitutively on the surface of all nucleated cells in the body with the possible exception of the cells of the central nervous system. They can be demonstrated readily on mature lymphocytes, granulocytes, monocytes, platelets, epithelial cells, endothelial cells and fibroblasts grown in culture. However, they are not found as normal components of the surface of mature human erythrocytes.

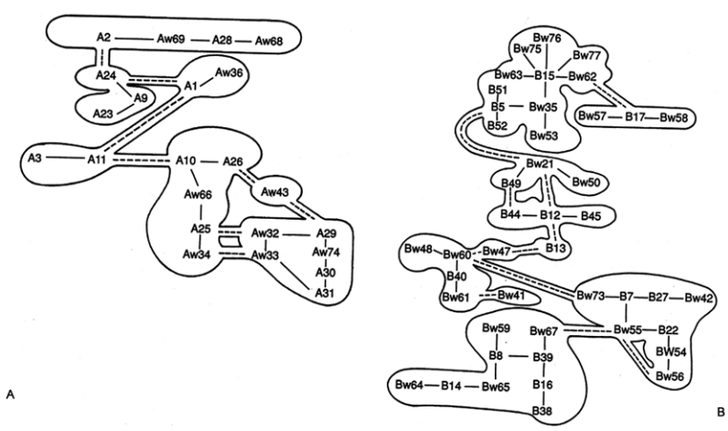

FIGURE 35.3. The prominent cross-reactive groups (CREGs) of the HLA antigens. The CREGs of the HLA-A antigens are shown in **A** and those of the HLA-B antigens in **B**. The antigens form tightly bound clusters that are strongly cross-reactive. In addition, some weaker cross-reactivity shown by the dotted lines exists between the clusters.

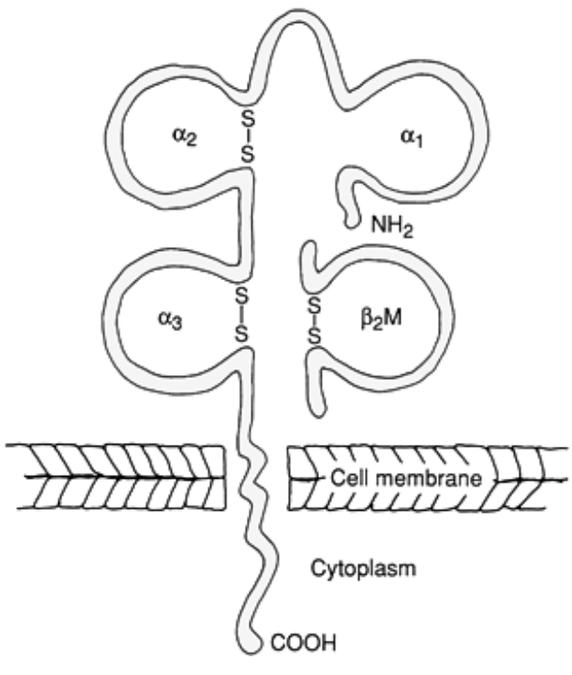

FIGURE 35.4. A diagrammatic representation of the HLA class I molecule. The α chain carries the specificity. It is always found in association with ß2-microglobulin.

Soluble HLA Antigens (sHLA)

There have been numerous reports that class I antigens may be found on red blood cells in humans just like their murine counterparts, the H-2 antigens. These observations are best explained by the finding that free HLA antigens are present as soluble substances in the plasma. Most likely they are shed from the surface of nucleated cells and maybe even from maturing erythroblasts. Occasionally, these soluble class I HLA antigens may become attached to the surface of mature red cells as they float freely in the plasma (16). It is highly unlikely that the antigens can be synthesized by anuclear mature red cells.

The amount of soluble HLA in blood transfusion products is significant. Red cells tested 30 days after collection and platelets from a single blood unit were shown to contain significant concentrations of HLA class I molecules. Such preparations completely inhibited mixed lymphocyte reactions and the cytotoxic activity of alloreactive T cells, suggesting an important biological role for sHLA molecules. However, the addition of anti-HLA class I monoclonal antibodies to the red blood cell preparations abolished their inhibitory effect. In addition, these molecules have a very practical value in the laboratory; forming the basis of a series of ELISA based techniques that can be used for antibody detection. These will be described in Chapter 36, Molecular HLA Typing.

HLA Class I and Class II Molecular Subunits and Three-Dimensional Structures

The class I MHC molecules, Fig. 35.4, consist of heterodimers composed of two, noncovalently linked polypeptide chains. The larger of the two, the α chain, is glycosylated and has a molecular weight of approximately 45kD. It is produced as a direct result of genetic information within the MHC and bears amino-acid sequences that are part of the allospecific epitopes. The α chain is anchored in the lipid bilayer of the cell membrane. This form of attachment allows the molecule to move freely on the surface of the cell and is loose enough to permit shedding.

The smaller, ß2-microglobulin chain does not penetrate the cell surface. It has a molecular weight of 12kD. Its production in man is controlled by nonpolymorphic genes found on chromosome 15. Thus, the two polypeptides that form class I HLA antigen are produced independently and associate posttranslationally to produce the final molecule. The presence of ß2-microglobulin is required to maintain the stability of the class I molecule and it has been found to be an integral part of such molecules from all species studied.

An analysis of the amino-acid sequence of the α chain has shown that it is divided into five domains consisting of three extracellular regions, α1, α2, and α3, a transmembrane domain, and a cytoplasmic domain. The α2 and α3 domains each have intrachain loops held by disulfide bonds having strong sequence homology to immunoglobulin domains. The α1 domain is not held in a loop and contains a glycosylation site at position 86. The amino-acid sequencing of α chains from MHC antigens of different specificities and even from different species shows a remarkable degree of conservation in some of the domains (17). Most of the variability occurs in the α1 and α2 domains, which are the regions expressing allospecificity. The transmembrane domain consists primarily of hydrophobic amino acids with some highly charged residues that may help anchor the molecule. The cytoplasmic domain contains serine residues that may be phosphorylated and could be involved in intracytoplasmic signaling. The associated ß2-microglobulin consists of a single domain formed by one disulfide loop. It is associated with the heavy chain through interaction with the α3 domain.

The class I molecule has been crystallized and its structure deduced by radiograph diffraction and computer-assisted analysis. (18) The resultant image shown diagrammatically in Fig. 35.5 is a globularlike structure containing an immunoglobulinlike groove that could act as a peptide-binding site. The α1 and α2 domains combine to form a structure composed of two a helices that form the walls of the groove and a ß-pleated sheet that forms the floor.

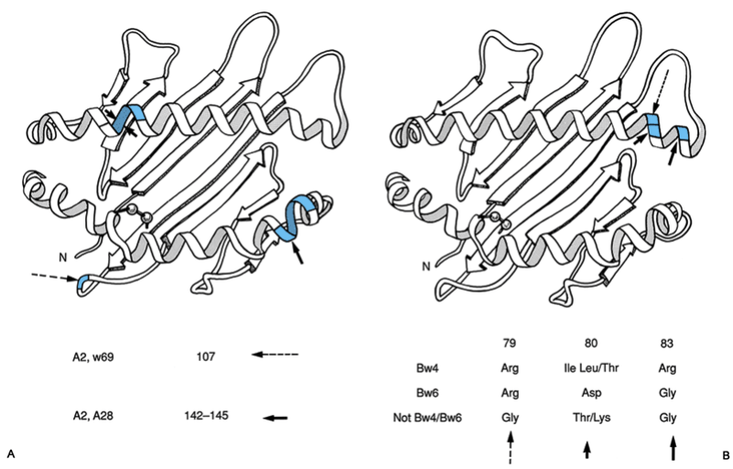

FIGURE 35.5. Diagrams of the structure of HLA molecules derived from the study of crystals showing the location of amino acid residues comprising HLA-specific epitopes. The epitopes of HLA-A2 are shown in **A**, and the amino acids forming HLA-Bw4 and Bw6 are shown in **B**. (Reprinted from Parham P, Lawlor DA, Slater RD, et al. HLA-A, B, C: patterns of polymorphism in peptide binding proteins. In: Dupont B, ed. *Immunobiology of HLA, II*, New York: Springer-Verlag, 1989:17.)

Amino-acid sequence analysis of the α chains of class I molecules of different HLA specificities has revealed the presence of at least 20 residues of high variability (17). Most of these differences are localized in exposed surfaces of the outer domain of the molecule, and in the peptide-binding groove in particular. The polymorphic residues that line the peptide-binding groove determine the peptide-binding specificity of the different HLA molecules.

Peptides bind to HLA class I molecules through specific anchor residues. The amino-acid side chains of these residues anchor the peptides by binding in pockets that line the peptide-binding groove. Polymorphism in HLA class I molecules affects the amino acids lining these pockets and thus their binding specificity. As a consequence, the anchor residues that bind to each allele are different. The set of anchor residues that allows binding to given antigen is called a sequence motif.

Linear sequences identifying residues critical to the expression

of allospecificities are found in the helices of the α1 and α2 domains as well as external portions of the ß-pleated sheet. Other polymorphic amino-acid residues that cannot be defined by alloantibodies can be identified by DNA-based techniques as discussed in Chapter 36, Molecular HLA Typing.

These findings explain certain phenomena that confounded serologists working in the HLA system. The public specificities Bw4 and Bw6 are the result of amino-acid substitutions in residues 79 to 83 of the α1 domain. Asparagine at position 80 is essential for the expression of the Bw6 epitope while arginine at position 83 is responsible for the Bw4 specificity. These amino-acid positions are different from those that confer the private specificities. Therefore, the so-called inclusion of private specificities within public ones can be explained because the HLA molecule has several epitopes in different locations.

The finding that within the HLA-A2, A28, Aw69 CREG a combination of three epitopes is required for the expression of HLA-A2, could be the basis for cross reactivity. While all three epitopes are required for the expression of A2, the expression of A28 depends only on residues at positions 142 to 145 and Aw69 at position 107.

In contrast to class I antigens, the class II antigens that include the products of the HLA-DR, DQ, and DP loci are limited in their distribution. In general, these antigens do not appear to be constitutive products of nucleated cells. Rather they are produced in conjunction with an immune response by means of lymphokines such as IL-2 and γ-interferon.

Most regularly, the class II antigens are found on B-lymphocytes, monocytes, macrophages, endothelial cells, Langerhans cells and activated T-cells. However, they also may be induced in other types of cells such as renal epithelial cells and pancreatic ß cells by means of lymphokines. The latter finding has led to the formation of an hypothesis regarding a possible mechanism for autoimmunization with subsequent tissue damage and disease.

Class II antigens, Fig. 35.6, are heterodimers consisting of two noncovalently linked polypeptide chains, each of which is a product of separate genes in the HLA region. The chains each have two external domains, a transmembrane portion anchored in the lipid bilayer of the cell wall and a cytoplasmic domain. One of the chains, the α chain, has a molecular weight of 34kD and only its α2 domain is arranged as disulfide loop. It bears structural homology to the constant region of immunoglobulin. The α chains of DR molecules are not polymorphic. Therefore, all of the DR specificities share identical α chains. However, the α chains of DQ molecules have some degree of limited polymorphism.

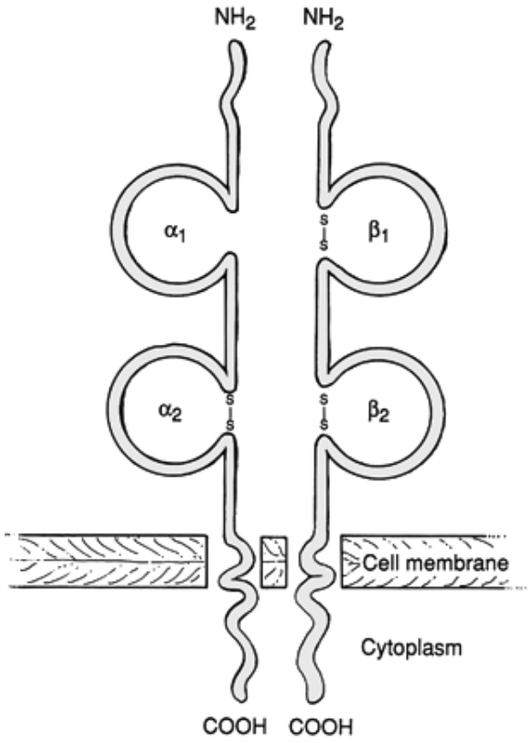

FIGURE 35.6. A diagrammatic representation of the HLA class II molecule. The carboxy-terminal ends of both the α and the ß chains are embedded in the lipid bilayer of the cell membrane.

The second polypeptide or ß chain has a molecular weight of 29kD. It is highly polymorphic in all class II molecules and carries sequences appropriate to the allospecificity in three hypervariable regions of its ß1 domain situated between residues 9–13, 26–33, and 67–74. In contrast to the α chain, both the ß1 and ß2 domains contain disulfide loops. Glycosylation sites are found in the α1, α2 and ß1 domains, which are not involved in the allospecificity of the intact molecule (19).

The crystal structure of the HLA-DR molecule shows that it is folded very much like the HLA class I molecule. The major differences lie at the ends of the peptide-binding cleft, which are more open in the HLA-DR molecules. The main consequence of this is that the ends of a peptide bound to any class I molecule are substantially buried within the molecule, wheras the ends of a peptide bound to HLA-DR are not (20). Different allelic variants of HLA class II molecules also bind different peptides; but the more open structure of the HLA class II peptide-binding groove, and the greater length of the peptides bound in it, allow a greater variety of peptide binding. It is therefore more difficult to predict specific peptides that might bind to HLA class II molecules.

Within the DR region, the DRB1 gene encodes for the DRß1chain, which determines the DR private specificities DR1, DR2, DR3, DR4, DR5, etc. The DRB3, B4, and B5 genes encode for the DRß3, ß4, and ß5 chains, which determine the DR52, DR53, and DR51 specificities, respectively. Originally, the DR52 and DR53 specificities were thought to be supertypic or public antigens similar to the class I antigens Bw4 and Bw6 because they were always found along with one of the other DR specificities. DR3, 5, 6, and 8 associate with DR52 and DR4, 7 and 9 with DR53. This is not the case. Rather, the observed phenotypic association occurs because of the tight linkage and almost absolute gametic association between the two ß chain loci involved (21).

The DQ antigens were likewise thought to be public specificities of DR because DR1, 2, and 6 are associated with DQ1; DR3, 7 with DQ2 and DR4, and 5 with DQ3. However, this too is the result of gametic association.

The posttranslational binding of the α and ß chains in the formation of the DQ heterodimers offers some interesting possibilities. In the heterozygous individual, there are two α chain genes for DQ, one from each parent. These may be different because the responsible genes exhibit at least limited polymorphism. In addition, there are two different DQ ß chain genes. It is possible for the products of genes in the *trans* position to associate posttranslationally as shown diagrammatically in Fig. 35.7. Therefore, a paternal DQ α chain could associate with a maternal DQ α chain, giving rise to a hybrid molecule. Such a molecule would display the maternal DQ allospecificity because this is controlled by the ß chain. However, the specificity of this molecule arising from the complementarity of the two chains could be entirely unique to antigen recognition cells and contribute to further polymorphism.

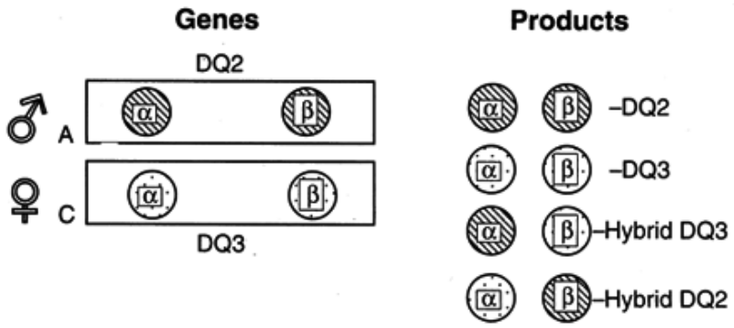

FIGURE 35.7. A scheme showing how the posttranslational combination of DQ α and ß chains in a DQ-heterozygous individual can result in four different molecules.

The early studies of the HLA system additionally defined a set of antigens that could only be detected in a biological assay called the mixed lymphocyte culture (MLC). These antigens correlated with polymorphic class II antigens when analyzed in families and were called HLA-D. A whole list of these specificities was identified and many are still found in the table of current antigens. It is now recognized that the HLA-D specificities are controlled by the DR alleles. However, they may be different than those recognized serologically.

It is clear that immune cells are more robust than antibodies in their ability to detect very small molecular differences. Thus two DR ß chains coming from two different individuals and having identical DR epitopes but differing by only a single amino-acid substitution in another part of the molecule, could not be distinguished by anti-DR antibodies. However, the cells expressing these chains could be recognized by other cells. Differences such as this and their impact on class II antigen detection will be considered in the section dealing with biochemical techniques.

BIOLOGICAL FUNCTION OF HLA GENES

Part of "35 - HLA: Structure, Function, and Methodologies"

The biologic function of the molecules of the MHC has been the subject of a great deal of basic research. In studying the biology

of the immune response in rodent systems, it became clear that the response to certain well-defined antigens was under genetic control (22). Furthermore, it could be demonstrated that the genes responsible for this function could be mapped to the MHC region of the chromosome.

In vitro experiments designed to study the immune response at the cellular level showed that both antigen presentation and antigen destruction by immunologically transformed cytotoxic cells was restricted by the MHC antigens (23). For example, cytotoxic lymphocytes induced in response to challenge with influenza virus can kill only other cells infected with such a virus if two conditions are met. First, the virus has to be antigenically identical with the one used for induction. Second, the MHC of the infected cell to be destroyed has to be identical to the MHC of the cell that harbored the immunizing virus. The primary biologic role of the class I antigens that make up the HLA-A, -B and -C repertoire described in this section is to function in such a capacity. Their behavior as alloantigens in transplantation by serving as the targets of the allograft response is secondary activity of iatrogenic origin.

Class II molecules function biologically in antigen presentation. *In vivo*, pathogens and other foreign substances are processed by antigen-presenting cells and delivered to specific T-cell receptors on immunologically competent lymphocytes in the context of class II antigen. The T-cell receptor must recognize both the foreign antigen and the self class II molecule in order to transmit a signal. Therefore, class II antigens play a very important role in the initiation of the immune response. Furthermore, in this context, they can act in the capacity of controlling the response.

Effects of HLA Polymorphism on Antigen Recognition by T-cells

HLA polymorphism affects antigen recognition by T cells, both indirectly, by controlling peptide binding, and directly, through contacts between the T-cell receptor and HLA molecule itself. Because the HLA genotype restricts the antigen specificity of T cells, this effect is called MHC restriction. MHC restriction is a critical feature of antigen recognition by most functional classes of T cells.

Some of the polymorphic amino acids on the HLA molecules are located on the a helices flanking the peptide-binding cleft in such a way that they are exposed on the outer surface of the peptide-HLA complex and can be contacted directly by the T-cell receptor. Therefore, when T cells are tested for their ability to recognize the same peptide bound to different HLA molecules, they readily distinguish the peptide bound by HLA^{a} from the same peptide bound to HLA^{b}. Thus specificity in a T-cell receptor is defined by both the peptide and by the HLA molecule binding it. This restricted recognition can be caused by differences in the conformation of the bound peptide imposed by the different HLA molecules rather than by direct recognition of polymorphic amino acids on the HLA molecule itself. Thus HLA restriction in antigen recognition reflects the combined effect of the peptide binding, and of direct contact between the HLA molecule and the T-cell receptor (24).

HLA Polymorphism Determines the Range of Antigens to Which the Immune System Can Respond

As different HLA molecules bind different peptides, the T cells responding to a given protein antigen presented by several different HLA molecules usually will be able to recognize different peptides. In rare cases, a protein will have no peptides with a suitable motif for binding to any of the MHC molecules expressed on the cells of an individual. When this happens, the individual fails to respond to the antigen.

As pointed out previously, such failures in responsiveness to simple antigens were first reported in inbred animals, where they were called immune response (Ir) gene defects. Rodent model systems clearly demonstrated that these genes can be mapped to the MHC and were the first clue to the antigen-presenting function of the MHC molecules. Subsequently, it was shown that the Ir genes encode MHC class II molecules. Ir genes and associated defects are easily recognized in inbred strains of mice because the mice are homozygous for all their MHC genes and thus express only one allelic variant from each locus. In humans, the polymorphism of HLA molecules guarantees a sufficient number of different HLA molecules in a single individual to make this type of nonresponsiveness unlikely.

The polymorphism at each HLA locus can potentially double the array of different HLA molecules expressed by an individual; because most individuals are heterozygotes. Polymorphism offers the additional advantage that different individuals in a population will differ in the combination of HLA molecules they express and will therefore present different sets of peptides from each pathogen. This makes it unlikely that all individuals will be equally susceptible to a given pathogen and its spread will therefore be limited. That exposure to pathogens over an evolutionary time scale can select for expression of particular HLA alleles is indicated by the strong association of the HLA-B53 allele with recovery from a potentially lethal form of malaria. This allele is very common in the people from West Africa, where malaria is endemic and rare in parts of the world where malaria is uncommon.

Recognition of Allogeneic HLA Molecules by T Cells

The discovery of MHC restriction has helped explain the phenomenon of nonself MHC recognition in graft rejection. Transplanted tissues or organs from donors bearing HLA molecules that differ from those of the recipient are reliably rejected. The rapid and very potent cell-mediated immune response to the transplanted tissues results from the presence in any individual of large numbers of T cells that are specifically reactive to particular nonself or allogeneic HLA molecules. *In vitro* MLC studies have shown that 1% to 10% of all T cells in an individual will respond to stimulation by cells from any allogeneic individual. This type of response is called alloreactivity because it represents recognition of allelic polymorphism on allogeneic HLA molecules.

Before the role of MHC molecules in antigen presentation was understood, it was a mystery why so many T cells should recognize

nonself MHC molecules. However, once it was learned that T-cell receptors have evolved to recognize foreign peptides in combination with polymorphic MHC molecules, alloreactivity became easier to explain. Experiments with T cells from animals lacking MHC class I or class II molecules have shown that the ability to recognize MHC molecules is inherent in the genes that encode the T-cell receptor, rather than being dependent on selection for MHC recognition during T-cell development. It is thought that the alloreactivity of mature T cells reflects the cross-reactivity of T-cell receptors normally specific for a variety of foreign peptides bound by self-MHC molecules.

The Class III MHC Gene Products

The class III MHC gene products include complement components: C2, Factor B, and C4 and the cytokines: TNF-α and -ß (lymphotoxin) that have important functions in the immune response. The function of these genes will be discussed in Chapter 37.

CLASSICAL TECHNIQUES FOR DETECTING HLA ANTIGENS

Part of "35 - HLA: Structure, Function, and Methodologies"

Serologic Techniques

The classical serologic techniques for the detection of HLA antigens of class I are based on the microlymphocytotoxicity method originally developed by Terasaki and McClellan (25, 26). This is a complement-mediated serologic assay in which peripheral blood lymphocytes are first mixed with an antiserum containing specific anti-HLA antibodies. After a period of incubation, complement is added and the mixture further incubated. If the lymphocytes carry the HLA antigen against which the antibodies in the antiserum are directed, an antigen-antibody reaction will occur, which activates the complement. The ensuing enzymatic cascade culminates in membrane damage that ultimately kills the lymphocytes. A positive reaction is ascertained by examining the cell suspension for cell death. This can be accomplished in a number of ways including phase contrast microscopy coupled with the use of supravital stains.

A number of variations of this general method have been developed to increase its sensitivity and/or simplify and improve the method used to distinguish live cells from dead ones. These will be described later.

The target cells of choice for HLA typing are the small lymphocytes of the peripheral blood. These cells fully express all of the class I antigens. They can be isolated and purified and easily remain stable during *in vitro* manipulation.

Separation is accomplished by layering diluted whole blood over a solution of Ficoll-Hypaque that has a specific gravity corresponding to the density of small lymphocytes. This is 1.077 to 1.080. The resultant gradient is centrifuged allowing the mononuclear cells consisting primarily of lymphocytes to settle at the Ficoll-blood interface. The erythrocytes and granulocytes being denser settle to the bottom of the tube while most of the platelets remain floating in the uppermost layer (Fig. 35.8).

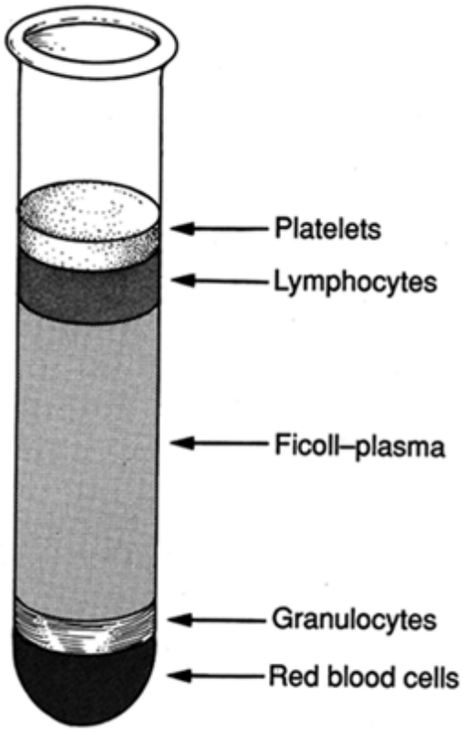

FIGURE 35.8. The gradient formed after the centrifugation of whole blood layered on a mixture of Ficoll-Hypaque. (From White TJ, Arnheim N, Erlich HA. The polymerase chain reaction:L the basic technique. *Trends Genet* 1989;5:6.)

Isolated small lymphocytes consist of a mixture of T cells and B cells. Such a suspension is perfectly adequate for the detection of class I HLA-A, -B, and -C antigens because these are well represented on all subsets of lymphocytes. However, in order to identify Class II HLA-DR and DQ antigens that are expressed primarily on B cells, an enrichment or purification of this subpopulation is required.

A number of techniques are available for the purification of B cells (27). All take advantage of one or more specific properties of T cells and B cells. These include the ability of T cells to form rosettes with sheep erythrocytes, and the adhesive properties of B cells. Monoclonal antibodies to T cell differentiation antigens together with complement also can be used to purify B cells.

Source of Typing Sera

The antisera used for HLA typing are available from a number of commercial sources both as bulk reagents and on prepared typing trays. The prepared trays are the most economical because they contain a wide range of antisera capable of detecting the majority of clinically relevant antigens. In addition, much of the initial quality control on the finished product has been performed by the manufacturer. Bulk sera, on the other hand, need to be selected according to some predetermined criteria based on their specificity and then dispensed into the typing trays. Finally, extensive primary quality-control procedures need to be carried out in order to ensure that the reagents are working and that the assortment of sera selected can accurately identify an individual's HLA phenotype.

The majority of typing sera used for the detection of class I and class II HLA antigens are derived from the sera of multiparous women. HLA antibodies are produced frequently as a result of alloimmunization during pregnancy (28, 29). Approximately 25% of para iii or greater have them in their serum. This event does not result in any harm to the fetus even though these antibodies are almost exclusively IgG and capable of crossing the placenta. Most

likely the protection is afforded by the placenta, which carries the fetal tissue antigens and acts like a sponge to absorb the antibodies. In fact, placentae are a rich source of HLA antibodies.

Anti-HLA antibodies may be produced as the result of other forms of exposure to antigenic stimuli including transplantation and blood transfusion. The method developed for the production of monoclonal antibodies has been employed to make some anti-HLA reagents (30). Although this procedure was initially fraught with difficulty, it currently shows very promising results. The clinically significant allospecific epitopes on the antigen molecules have been better defined and the procedure for monoclonal antibody production including antigen preparation and clonal selection has become more sophisticated. As a result, some of the newer reagents appear to be quite specific in their ability to distinguish clinically significant HLA types; yet they offer all of the advantages of a monoclonal reagent. For example, they are specific for either class I or for class II antigens. Thus, B-cell separation is not required to type for HLA-DR. In addition, they are free of many interfering substances found in human sera containing alloantibody; thereby allowing for the development of novel and perhaps more rapid techniques for HLA typing.

The antisera used for HLA typing regardless of their source are quite different than the alloantisera used for typing in other systems such as the red cell blood groups. One of the vagaries associated with them is illustrated by the observation that over the years very few sera directed apparently against the same specificity have been shown to be exactly identical when tested on a cell panel from a large number of donors. In other words, each serum is bound to give both false-negative and perhaps false-positive reactions with the lymphocytes of various individuals. Thus, because of the nature of the antisera, several examples of each must be used for the optimum definition of each specificity.

Over the years, various descriptive terms have been coined to describe these phenomena. Some of them are derived from the habit of most investigators to conveniently represent the reactivity of a serum by means of a histogram or serogram as shown in Fig. 35.9. The test cells are listed along the side, the sera across the top, and each block represents the reaction of a single serum with a single cell. The positive reactions are represented by a solid block while the negatives are assigned by a dash. The cells are arranged so that those expressing the key antigen, graphed on the left side of the diagram, are at the bottom of the chart. In this type of an illustration, a serum giving false-positive reactions will cause its serum bar to be longer than the occurrence of the antigen. Therefore, such sera were often referred to as “LONG.” On the other hand, sera that tend to give false-negative reactions result in reaction bars that are shorter than the occurrence of the antigen. These sera were called “SHORT.”

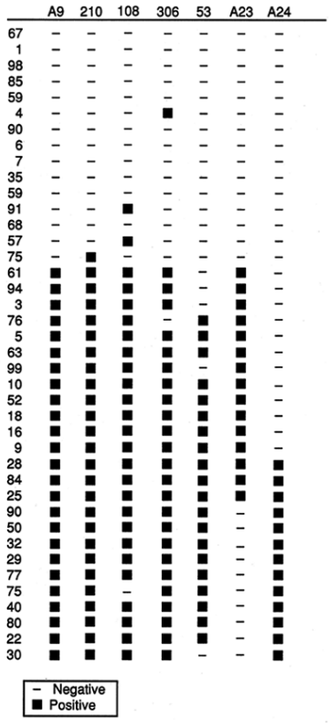

FIGURE 35.9. A serogram showing the reaction patterns of four sera reacting with cells positive for HLA-A9. The occurrence of the A23 and A24 antigens among the cells of the panel is shown in the last two columns. Serum 108 is “long” and serum 53 is “short” compared to the index specificity, HLA-A9.

Absorption studies performed using the cells giving the false-negative reactions with short sera often showed that they were able to fully absorb the specific antibody from such sera. Still, they failed to give a positive cytotoxicity reaction. A finding of this type has been called CYNAP (cytotoxicity negative, absorption positive). This phenomenon may be the result of a number of factors including poor antigen expression on the cell at the time of the test, low antibody affinity, or the presence of anticomplementary factors in the cell preparation or the antiserum containing the antibodies.

Fig. 35.9 also shows the reaction patterns of the public specificity HLA-A9 along with the private specificities HLA-A23 and A24. The pattern is such that the private specificities are “INCLUDED” in the public one. The practice of resolving the reaction patterns of anti-HLA sera into serograms has resulted in a

wealth of information relative to the relationship of the various specificities to each other. It formed the basis from which many of the features of the system could be defined and served as a template for further studies at the level of molecular biology and biochemistry.

The complement source used in the microlymphocytotoxicity test is normal rabbit serum. The sera from a large number of different animal species have been tested for their usefulness in cytotoxicity and the rabbit was found to be the best. This is because of the fact that normal rabbits naturally produce a small amount of antihuman antibody in response to environmental stimuli. These antibodies act in synergy with anti-HLA antibodies to promote rapid and efficient complement activation. Currently, a number of commercial sources supply excellent rabbit complement. As a matter of fact, some suppliers of reagent anti-HLA sera provide complement specifically tailored for use with their reagents. Still, it is considered good laboratory practice to quality control each new lot of complement. In this way, consistency of testing and therefore typing results can be assured. In addition, adequate positive and negative controls must be employed with each test.

The standard microlymphocytotoxicity test is performed in specially designed plastic trays containing wells with optically flat bottoms (Fig. 35.10). In practice, the wells first are filled with biologically inert mineral oil, which is used to retard the evaporation of the minute volumes of reactants. One microliter of antiserum-containing antibodies is added to the bottom of the well followed by 1 µL of cell suspension containing approximately 2,000 cells.

FIGURE 35.10. A standard 55 × 80 mm tray used for HLA typing. The reactions are carried out in the individual wells, whose contents can be observed from below by means of an inverted microscope. (Courtesy of Robbins Scientific Corporation, Sunnyvale, CA.)

This mixture is incubated at room temperature for 30 minutes to allow the antibodies in the serum to react with antigens on the cell surface. At the conclusion of the incubation, 5 µL of rabbit complement are added and the reaction further incubated for 60 minutes at room temperature. During this period, complement is activated by the antigen-antibody complexes at the cell surface resulting in cell death. At this point, a solution of Eosin-Y dye is added to stain the cells and make the test easier to read. Finally, a solution of neutralized formalin is added to stop the reaction and preserve the architecture of the cells.

The reaction is read using an inverted microscope equipped with phase contrast illumination. Under these conditions, live lymphocytes appear as clear, glistening, small, round cells not too different from red cells. For this reason, it is imperative to remove as many red cells from the final cell suspension as possible. The red dye used for staining penetrates the cells but can be excreted by live ones giving them a golden tone on a light red background. The dead cells cannot excrete the dye and therefore stain with an intense maroon color. They appear as dark, opaque, swollen cells with prominent nuclear detail (Fig. 35.11).

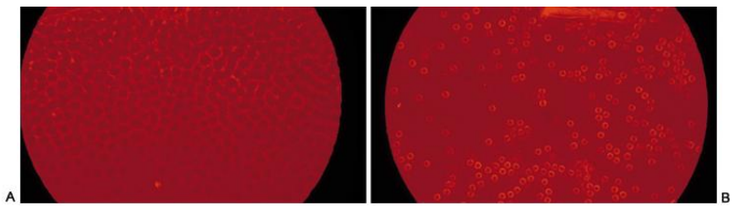

FIGURE 35.11. Microscopic appearance of the lymphocytotoxicity reaction. **A:** A positive reaction. The cells have taken up the eosin Y dye. They are swollen and have prominent nuclear detail. **B:** A negative reaction. Most of the cells appear clear, glistening, and refractive.

The reaction is scored by determining the percentage of cell death in each well. In practice, skilled workers estimate the percentage of cell death by trained optical-pattern analysis. The results are expressed according to the grading scheme shown in Table 35.6. A score of eight is maximum but the reaction is considered positive with a score of six. A negative is defined by a score of one.

TABLE 35.6. CYTOTOXICITY SCORING

Score	% Cell Death	Interpretation
1	0–10	Negative
2	10–25	Possibly negative
4	25–50	Possibly positive
6	50–80	Positive
8	80–100	Strong positive

In the performance and the reading of this type of test, which depends so heavily on a biological end point, there is always the possibility of some doubtful reactions. These are indicated by the scores of four and two. A score of four usually is interpreted to mean, “I don't know; but I think it's positive.” A score of two means, “I don't know; but I think it's negative.” Although this may seem to be somewhat subjective, it does have precision. Skilled workers are remarkably consistent in coding these reactions and very little if any variation is observed between duplicate readings performed by the same or by different individuals.

More Sensitive Microlymphocytotoxicity Tests

There are a number of variations to this basic test, which were introduced in attempts to make it more sensitive (31). The first of these, which is known as the Amos Mod technique, calls for the cells to be washed with tissue-culture fluid after their initial incubation with antiserum. This modification is based on the fact that the source of antiserum is frequently a patient whose serum may contain factors that bind complement nonspecifically. These could be aggregated gamma globulins, antigen-antibody complexes, or even the products of bacterial contaminants in stored sera. Any of these materials could deplete the system of complement and lead to false-negative reactions. Therefore, their elimination prior to the addition of complement effectively increases sensitivity.

Another modification that increases the sensitivity of the standard microlymphocytotoxicity test is based on the use of an anti-human globulin reagent (32). The reagent of choice in this case is directed against the light-chain of human IgG. An anti-κ containing serum is the most popular. The underlying principle of this modification is different from that of classical antihuman globulin or Coombs tests used in red-cell serology in which antiheavy-chain reagents are used. In this case, the antiglobulin serum serves as a source of additional Fc fragments to interact with those on bound anti-HLA to help activate complement rather than as an antibody bridge to promote agglutination. Using this approach, it is possible to achieve complement activation even with a relatively small number of anti-HLA antibody molecules bound per cell; thereby giving extreme sensitivity.

These procedures are most useful in those cases in which patients' sera are used as a source of potential anti-HLA antibody, such as in cross-matching, described in Chapter 37, HLA: The Major Histocompatibility Complex-Applications. However, this and other modifications should be avoided when using commercial typing sera that have been standardized according to routine methods. The direction circulars accompanying such products should be followed exactly.

Other Microlymphocytotoxicity Tests

A totally different approach to determining cell death in the microlymphocytotoxicity test is given by a technique called cytofluorochromasia (33). This technique is based on the fact that living lymphocytes possess esterases in their cytoplasm. One of these enzymes is capable of converting the colorless compound, fluoresceine diacetate, into fluoresceine, which glows with a green fluorescence under ultraviolet (UV) light. In the test procedure, the lymphocyte suspension is pretreated with fluoresceine diacetate before any exposure to antibody. Then the cells are incubated, first with antibody and then with complement, in the usual fashion. The reaction is read with an inverted microscope equipped with a UV light source and the appropriate excitation filters. Under these conditions, only the live cells can be seen glowing with an apple-green fluorescence. The fluorescent compound leaks from the dead cells and leaves them colorless. Therefore, the degree of fluorescence is proportional to the number of live cells remaining. A totally dark well indicates 100% cell death and a positive test. A negative reaction is given by a well filled with glowing cells. To improve the accuracy of reading and subsequent interpretation, the dead cells can be counterstained with ethidium bromide, a red fluorescing compound that can penetrate the damaged membranes of dead cells and stain their nuclei.

An interesting variation of this technique was developed by van Rood and his colleagues, which can be used to test for class II HLA antigens without the bother of preparing suspensions of pure B cells (34). The principle is based on the fact that B cells express immunoglobulins on their surface.

A cell suspension prepared from peripheral blood containing both B cells and T cells is treated with a predetermined dose of a reagent containing goat antihuman immunoglobulin antibodies, which have been conjugated with fluorescein diisothiocyanate. This reagent reacts with the immunoglobulins expressed on the B cells, effectively coating them with a fluorescent compound. In addition, the reagent cross-links the immunoglobulins expressed on the cell surface causing them to form a cap that migrates to one pole of the cell.

The microlymphocytotoxicity test is performed in the usual way with the exception that ethidium bromide is added as the final stain instead of eosin. This dye will penetrate the damaged walls of dead cells and will stain their nuclei. Live cells having intact membranes exclude this material leaving their nuclei unstained.

The reaction is read using a UV microscope equipped with filters capable of exciting both green and red fluorescence. Under these conditions, dead B cells will fluoresce red with green caps, live B cells will have only green caps, dead T cells will be red but with no caps, and live T cells will be colorless (Fig. 35.12).

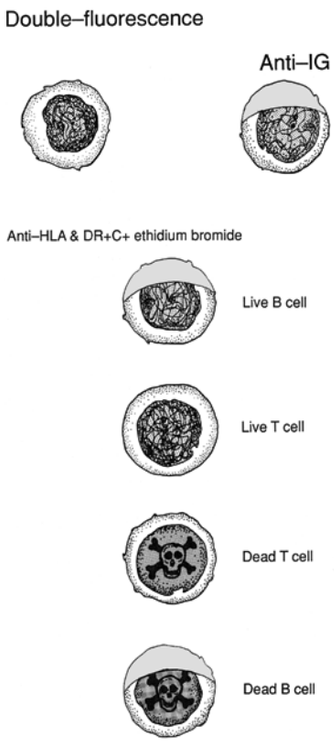

FIGURE 35.12. Double-fluorescence microlymphocytotoxicity.

The fluorescent methods offer no advantage over the standard cytotoxicity procedures with respect to sensitivity and carry the disadvantage of requiring specialized equipment. However they are somewhat easier to read by the untrained and form the basis for automated readers that employ photomultipliers for detecting fluorescence intensity. Using this type of instrumentation, the readings can be directed to computer programs that automatically assign the serologic HLA types.

Importance of Quality Control in HLA Typing

As with any laboratory procedure, meticulous attention must be paid to quality control. In the microlymphocytotoxicity system, the various components are especially fragile and susceptible to denaturation. Care must be excercised in making cell suspensions to ensure maximum viability at the outset. Collection procedures call for room-temperature storage and handling of blood specimens collected in preservative free heparin or ACD.

The anti-HLA antibodies found in the sera of patients and specific reagent donors are for the most part IgG immunoglobulins. Although examples of IgM antibodies have been described, they are usually the exception rather than the rule. IgG antibodies are the products of a well-developed, mature immune response that has completed undergoing an isotype switch.

They are remarkably stable molecules and under ideal experimental conditions have been shown to retain their activity even after storage at room temperature for several days. The storage conditions imposed on antisera are not in place to preserve the antibodies from denaturation, but rather to minimize the formation of “anticomplementary” factors consisting of substances such as aggregated gamma globulins, protein complexes, and microbial products that can interfere with the complement-dependent cytotoxicity reaction. Therefore, in order to assure maximum reactivity, storage temperatures need to be carefully monitored and maintained within the specified limits.

Controls need to be used with each test to assure a minimum viability of 90% at the start, and maximum viability with a negative control serum. A positive control must be included to assure that the complement is working and that the cell suspension being used is susceptible to its action.

Complement must be controlled carefully. Each new lot of complement should be compared with a previous lot to determine its optimum working titer. This assay should be performed using several antisera having different specificities and antibody titers to demonstrate that the new source of complement works with equal facility with both strong and weak sera. In addition, because complement has a natural denaturation time, which is related to temperature, storage temperatures for this reagent must be monitored carefully.

The anti-κ antiserum used in the antiglobulin modification of the standard procedure needs to be controlled in much the same manner as complement. Each new lot should be tested along with a previously used working lot to determine its optimum working dilution. It should be aliquoted in small volumes to avoid repeated freezing and thawing.

Finally, in performing quality control on the cytotoxicity procedure, the proficiency of the operator performing the test cannot be overlooked. This test is highly dependent upon individual skills, especially those required for reading the test. These skills must be monitored carefully by the periodic performance of blind repeats of HLA typings and the duplicate reading of tests by more than one individual. Readings should differ by no more than a single score value.

Limitations to Serologic HLA Typing in Non-Caucasian Populations

Since the 1972 International Histocompatibility Workshop, it has been appreciated that HLA alleles exist specific to particular ethnic groups. However, serologic typing with its reliance on white alloantisera has tended to underestimate ethnic differences and the number of such alleles. Thus, the serologic typing does not detect a large number of alleles found in human populations, and it is in nonwhite populations that the inaccuracies and insensitivities

in serologic typing are the greatest. The extent of the ethnic diversification of HLA molecules will continue to be unveiled as population studies and molecular typing venture to various ethnic groups.

Several HLA specificities are difficult to define unambiguously with serology. The antigens in the B15 serologic group are an example of antigens inconsistently defined. In practice, an individual carrying the HLA-B*1508 allele might be assigned an HLA-B62 serologic type in one laboratory and an HLA-B75 serologic type in an another. Furthermore, defined antigens such as HLA-A74, -A80,-B81 and -B82 may lack serologic reagents for definition and may be missed.

In addition to alleles that are undetected, patterns of serologic cross-reactivity do not always reflect the underlying structural relationships between alleles. One example is HLA-B45, a common antigen in blacks. By serology, this antigen is closely related to HLA-B44 and the pair can be distinguished by their association with the Bw4 and Bw6 epitopes. In contrast, nucleotide sequences show that B44 and B45 are only distantly related, with B45 being much closer in structure to HLA-B50.

Serological Typing for HLA Null Class I Alleles

Although the difference between null and normal subtypes of an allele has the potential to produce major histoincompatibility in certain transplant situations, the overall relevance of HLA class I null alleles will depend upon their frequency within the population of patients and donors. The number of HLA null alleles that have emerged from DNA-based testing is impressive and seems to be preferentially found in particular populations (e.g., Native Americans and natives of Northern Ireland).

Comparison of serological and DNA typing is the best approach for the identification of HLA class I null alleles, and the need to define the null alleles provides a compelling reason for maintaining serological typing while the DNA-based typing methods are implemented and refined. The nucleic acid sequences that characterize some of these null alleles may not be in the genetic region normally targeted by DNA typing; thus, without serologic information, these null alleles may go undetected. However, once a null allele is identified by serology and characterized by nucleic acid sequencing to identify the source of the lack of expression, the null allele then can be readily detected in subsequent individuals by DNA testing procedures alone. The frequency of yet undetected null alleles is not known. It is expected to be low and will likely vary in different populations.

HLA class II Antigens Identified by the Mixed Lymphocyte Culture

The mixed lymphocyte culture (MLC) is a method that was used to investigate Class II HLA antigens. It is based on the observation that when populations of lymphocytes from two different individuals are mixed in culture, the cells from one individual are able to recognize foreign antigens on the cells of the other and to respond to these antigens by undergoing blastogenic transformation (35).

The antigens recognized in this reaction are Class II HLA antigens. Originally, they were called HLA-D and were believed to be recognizable only by lymphocytes. When the HLA-DR antigens were detected serologically on the surface of B lymphocytes, it became clear that they were the source of antigenic stimulation of MLC reactivity. Nevertheless, as will be described later, the serologically defined specificities alone could not fully explain cellular reactivity. This had to await until the true molecular diversity of the class II region was revealed by studying it at the DNA level.

In order for the MLC reaction to occur, there must be a difference between the HLA DR antigens of the two cell populations. Discrepancies in the HLA-A and/or -B antigens alone will not result in stimulation. However, cytotoxic T lymphocytes (CTL), which are directed against class I antigens, are generated as a by-product of this reaction.

In the normal MLC, 5 days of culture are required for the cells from a given individual to respond to the antigens of another individual and undergo blastogenesis. However, if this reaction is allowed to continue until all of the stimulating cells are expended, the multiplying responding cells return to a mature steady state. A rechallenge with fresh stimulating cells from the original donor will result in a brisk blastogenic response within the first 24 hours. This is a secondary response and takes place because the responding cells have been primed to recognize the stimulating antigen.

TECHNIQUES OF MOLECULAR BIOLOGY APPLIED TO HLA TYPING

Part of "35 - HLA: Structure, Function, and Methodologies"

Many new techniques, originally developed for use in molecular biology and described in detail in Chapter 36, have been applied recently to the study and elucidation of the HLA system. Some of these techniques have resulted in data that contribute significantly to a better understanding of the system. Others are in the process of being used for special applications in diagnostic and forensic laboratories.

One biochemical method shown to be very useful is two-dimensional gel electrophoresis, a technique that has been applied extensively to the investigation of the ß chains of DR molecules. It is possible to test a group of individuals whose cells express HLA-DR4; but who stimulate and respond to each other in the MLC. Electrophoretic and isoelectric focusing studies have shown that cells from individuals belonging to HLA-DR4 can be sorted by this method into groups corresponding to their reaction patterns in the MLC. In this method, lymphocytes are cultured in the presence of 35S methionine, which biosynthetically labels the HLA gene products. The harvested cells are lysed and their HLA molecules immunoprecipitated with monoclonal antibody directed against epitopes present on the constant region of the DR ß chain.

The immunoprecipitated molecules are first separated on a gel containing a pH gradient according to their isoelectric point. The focusing gel then is transferred to an electrophoretic gel and further separation according to size and electrical charge takes place in a second dimension that is 90° to the first. The resulting radioactive spots are developed by exposure to photographic

[b] IEF = Isoelectric focusing.

film. A typical result is shown in Fig. 35.13. Each DR molecule separates into several spots. The invariant α chain forms a single large spot. The ß chains, however, usually separate into three spots that reflect different levels of the glycosylation of individual metabolically labeled molecules. This technique, coupled with the DNA methods described below have been applied to the study of DRß chains from other DR specificities. The relationship between HLA-DR detected serologically and class II specificities detected by means of lymphocyte interactions are now becoming clearer. The various HLA-D types are a result of specific DRB1 alleles, some of which are shown in Table 35.7. Several of these alleles may result in the production of ß chains with identical epitopes recognizable by anti-DR antibody and at the same time distinctly different epitopes recognizable by lymphocytes.

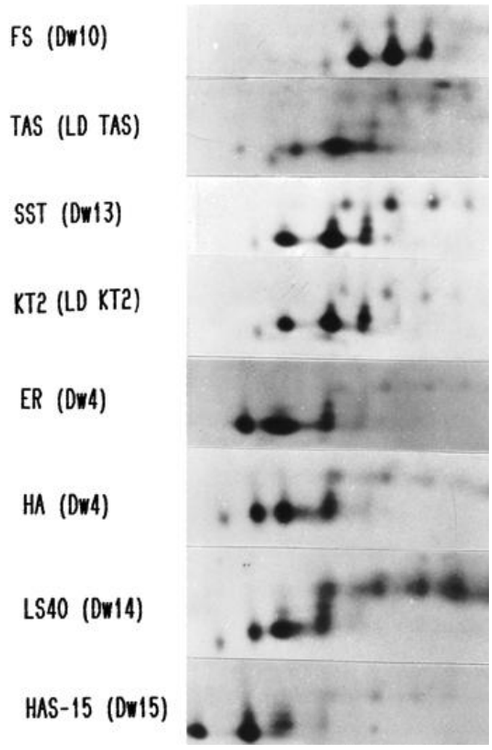

FIGURE 35.13. Two-dimensional gel electrophoresis of immunoprecipitated DR4 molecules. The ß chains appear as three separate spots as a result of differences in glycosylation. The chains migrate in different areas depending on their individual amino-acid composition. Even though these examples all behave serologically as DR4, they have different HLA-D specificities. (Reprinted by permission of Elsevier Science Publishing Co., Inc. from Monos DS, Mickelson E, Hansen JA, et al. Analysis of DR and DQ gene products of the DR4 haplotype in patients with IDDM: possible involvement of more than one locus. *Hum Immunol* 1988;23:289–299. Copyright 1988 by the American Society for Histocompatibility and Immunogenetics.)

Isoelectric focusing alone has been used to study the HLA-A and -B molecules. For the most part, this technique has been able to detect all of the common class I variants currently detected serologically. These are listed in Table 35.8.

HLA typing also can be accomplished at the DNA level and by direct sequencing. Such molecular methods are an important area that has revolutionized HLA typing and presented a great deal of new data about HLA polymorphism. It will be discussed in detail in Chapter 36.

These DNA-based methods are particularly useful in the clinical setting for the HLA class II typing of patients whose B cells are present in low numbers or difficult to isolate for other reasons. Such situations may be encountered in very young children, patients with hematologic disorders such as aplastic anemia or various forms of leukemia, and in patients undergoing chemo- or immunosuppressive therapy. Frequently, patients such as these are being considered for bone-marrow transplantation in which class II identity is essential. Prior to the development of this approach, many repeat serologic and MLC tests had to be performed, which more often than not yielded poor results.

Biochemical methods have contributed a great deal to a better understanding of the HLA system. In particular, they have helped to explain some of the inconsistencies that were experienced by earlier workers. For example, the original discovery of antibodies reactive with HLA antigens on B cells heralded a serologic solution to the lengthy and troublesome MLC. With the greatest confidence, the new HLA-DR antigens were assigned numbers corresponding to the then-defined HLA-D types because they were considered equivalent. Yet this enthusiasm was soon dampened when it became apparent that quite often lymphocytes from unrelated individuals who had identical HLA-DR types stimulated and responded to each other in the MLC. Information obtained using two-dimensional gel electrophoresis and RFLP analysis (Fig. 35.14 and Table 35.8) has revealed that the ß chains conferring a given DR specificity may differ slightly in other areas along their length. Lymphocytes can detect these differences resulting in MLC reactivity among cells with the same DR type but differing in their DR ß molecules.

The isolation, crystallization, and DNA sequencing of the class I molecules has afforded an explanation for the way in which the HLA-Bw4 and Bw6 antigens are related to the rest of the HLA-B series. These studies have shown that the amino-acid sequences responsible for the Bw4 and Bw6 specificities are located at positions 79 and 83, whereas the private specificities are controlled by amino acids at positions 107 and 142 to 145 (see Fig. 35.5).

Studies at the genomic level have extended our knowledge of the relationship between the public antigens and the private specificities. In addition, it has explained why cells from two individuals bearing identical serologically defined DR specificities might stimulate each other in the MLC. Thus, the investigation of HLA at the molecular level has revealed many secrets of this system including the concepts of cross reactivity, inclusions, multispecific antisera and antibody production to antigens presumably not present in the challenging dose. These are now clear when viewed from the standpoint of shared epitopes.

The DNA-Based Molecular Methods Compared to Serologic and Culture Techniques

The DNA-based molecular methods are certainly more accurate than the routine serologic and culture techniques that were the standard since the inception of HLA typing. For example, as mentioned earlier, typing based on DNA sequencing has revealed the true polymorphism of HLA-C that escaped detection by cytotoxicity techniques. In one study, as many as 19 previously undetected alleles were described (36).

The use of molecular methods for the determination of class II HLA types in donor selection for bone marrow transplantation has become routine. In addition, this method is being applied to class I typing as well. It would appear that the molecular techniques may replace serologic methods in all forms of transplantation. Indeed, current investigative efforts are concerned with making the methods more efficient, easier, and quicker to perform so that they can be applied readily to the clinical laboratory. A key issue to be resolved before this can become routine is the fact that molecular methods are able to distinguish a large number of polymorphisms in the HLA. At this time, little is known about the true clinical significance of these minor antigenic differences that may be represented by only one or two amino-acid substitutions. However, this is an area currently under investigation in the area of bone-marrow transplantation. For kidney transplantation in which such high-resolution typing may not be necessary, it is possible to employ a low-resolution typing from which cosmic HLA types such as HLA-A10 or HLA-DR4 can be inferred. This will be discussed in more detail in Chapter 37.

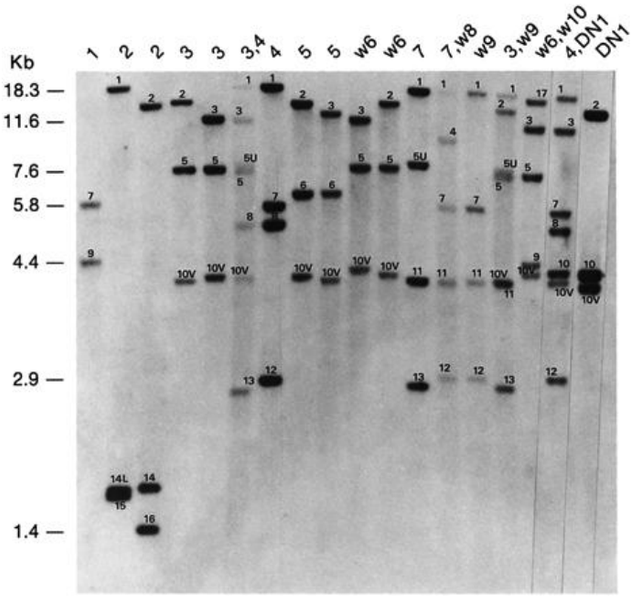

FIGURE 35.14. The RFLP patterns of the different DR specificities. The bands are numbered to indicate the pattern found within each DR antigen. The DNA was cut using the restriction enzyme TaqI, and the patterns were developed using a DR [backwards E] probe. Molecular HLA Typing

Marcelo Fernández-Viña

Kai Cao

Derek Middleton

Class I and class II genes of the major histocompatibility complex (MHC) encode cell surface glycoproteins whose main biological function is binding and presentation of antigenic peptides to T-lymphocytes. These molecules play an important role in self—nonself recognition as well as in tolerance and rejection of allografts. The class I MHC region spans approximately 1,600 to 2,000 kb of DNA and contains a number of highly homologous genes including those encoding classical HLA class I antigens: HLA-A, HLA-B, and HLA-C. These molecules are highly polymorphic and are found on the surface of nearly all nucleated cells (1, 2, 3 and 4).

Conventionally, identification of HLA class I polymorphism and typing of these allo-antigens has been performed by serological methods. A hallmark in HLA typing is the high degree of serological cross-reactivity between specificities that in some instances may hinder the assignment of some alleles. Inaccuracy in the typing of some HLA phenotypes may arise because of poor quality and a limited supply of or lack of some serological reagents (5, 6, 7 and 8). Similarly, some particular amino-acid variations that introduce HLA microheterogeneity can be detected by T-lymphocytes and not by serological reagents.

The biochemical structure of class I and class II alleles has been elucidated. The class I molecules are heterodimers composed of a polymorphic heavy-chain subunit encoded by genes in the MHC complex on chromosome 6 with a nonvariable light chain subunit (ß-2-microglobulin) that is encoded by a gene located outside the MHC (chromosome 15) (1, 3). Class II molecules are heterodimers as well. Both α and ß subunits are encoded in the MHC. There are differences in the level of polymorphism of the genes encoding these subunits. For example, the gene encoding the DR α subunit is virtually nonpolymorphic while the genes encoding the subunits of DQ and DP molecules present a considerable degree of polymorphism (1, 3).

The heavy chain of the class I molecules comprises three extracellular domains and a transmembrane/cytoplasmic domain; in contrast, each of the class II subunits comprises two extracellular domains and a transmembrane/cytoplasmic domain. In general, most of the differences in the amino-acid sequences of different HLA alleles are found in the distal membrane domains (α-1 and α-2 domains of the class I molecules and α-1 and ß-1 domains of the class II molecules) (1, 9). The genes encoding the subunits of the HLA molecules are discontinuous, containing coding (exons) and noncoding (introns) segments. The class I genes contain 8 exons while the class II genes contain 6 or 7 exons (1, 10).

With the advent of gene cloning nucleotide sequencing, most of the alleles of HLA class I and class II loci have been characterized and the nucleotide and amino-acid differences between HLA alleles have been identified (11). The vast majority of the nucleotide polymorphism occurs in exon-2 of the class II genes and exons 2 and 3 of the class I genes. These exons encode for the distal membrane domains of the class I and class II molecules. Polymorphisms in these exons correlate with the HLA specificites defined by serologic and cellular methods.

Analysis of the differences between alleles of various homologous loci showed that alleles of the same locus share nucleotide sequences that are absent in alleles of other loci. Locus-specific sequences can be found in coding (exons) and noncoding regions (introns). The comparison of alleles of the same locus shows that the distinguishing nucleotide differences between alleles are restricted to some segments or regions of the gene (variable regions) (1, 12). Most of the allelic variation of the class I genes resides in exons-2 and 3 (encoding for the α-1 and α-2 domains), while most of the class II variation occurs in exon-2. DNA based methods to type for HLA alleles have therefore focused in the analysis of nucleotide variation occurring in both exons 2 and 3 of the class I genes and exon-2 of the class II genes. The nucleotide sequences in exon 2 of selected DRB1 alleles is shown in Fig. 36.1 (13, 14).

The application of DNA-based procedures has increased the accuracy of HLA typing and led to the identification of serologically undetected alleles and of many subtypes of many serological specificities. The methods used include DNA amplification and hybridization with oligonucleotide probes (SSOP), amplification with sequence-specific primers (SSP, ARMS) and sequence-based typing. Typing of HLA class II alleles by molecular methods are firmly established and have been incorporated in the routine; more recently, molecular approaches of PCR-based DNA typing have been applied to HLA class I typing including PCR-based DNA sequencing (15, 16, 17, 18, 19 and 20), PCR using sequence-specific primers (SSP) (21, 22, 23 and 24), and sequence-specific oligonucleotide probes (SSOP) (25, 26, 27, 28, 29 and 30).

MOLECULAR METHODS APPLIED TO TYPING OF HLA ALLELES

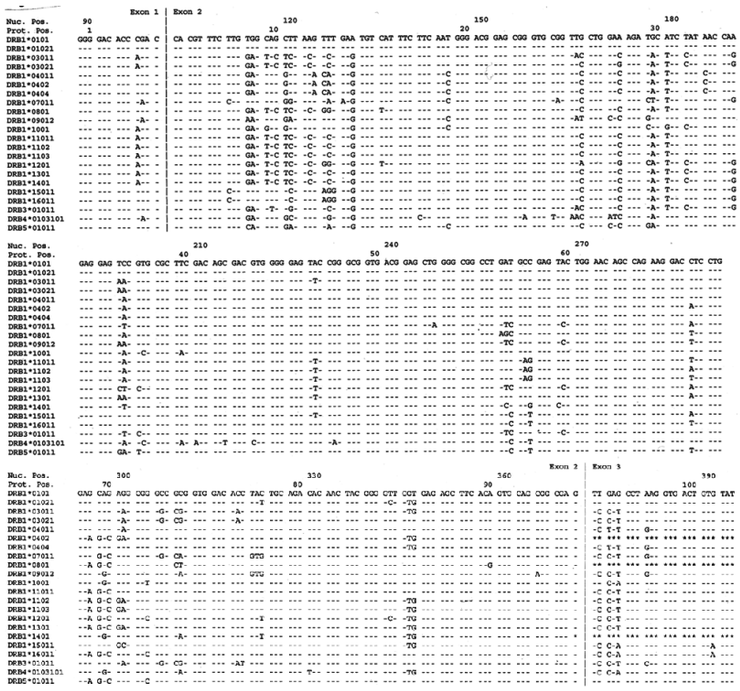

FIGURE 36.1. Exon 2 nucleotide sequence alignment of selected DRB alleles. Complete exon-2 and flanking segments of exons 1 and 3 of representative DRB alleles are shown. Nucleotides are grouped in triplets corresponding codons (protein position). The nucleotide sequence shown corresponds to the cDNA sequence. In the genomic organization of DRB genes, exons are separated by noncoding DNA stretches (introns). The first nucleotide of codon 5 is encoded in exon 1, while the second and subsequent nucleotides are encoded in exon 2. This pattern corresponds to the mRNA splicing pattern observed for other exons from eukaryotes. Polymerase chain reaction primers used for amplification of genomic DNA may span partially both intron and exon sequences. The top sequence corresponds to DRB1*0101. Dashes in other alleles indicate identical nucleotides in the corresponding positions; nucleotide differences are shown by the letter of the corresponding nucleotides. Asterisks (*) indicate that the nucleotide sequence has not been determined (Codons 95–102). In naming HLA alleles in general, the first two digits correlate with the serologic equivalency (e.g., DRB1*0101 and DRB1*01021 type serologically as DR1) and the next two digits indicate differences in nonconservative substitutions. A fifth digit is used to distinguish alleles with identical amino-acid sequence and different only by silent nucleotide substitutions. The nucleotide positions in which alleles of the DRB loci differ from each other are clustered in regions (hypervariable regions) separated by long DNA stretches in which the nucleotide sequences are identical in almost all alleles. The most noticeable hypervariable regions span codons 9–13, 26–38, 57–60, 67–77 and 85–86. Notice that many alleles with similar serotype (e.g., DRB1*0101 and DRB1*01021) differ by a few nucleotide substitutions; DNA stretches containing the distinguishing nucleotide substitutions are found in other alleles (see DRB1*01021 and DRB1*1201 in the stretch spanning codons 78–86) as well.

TABLE 36.1. GENERIC AND GROUP-SPECIFIC (ALLELE GROUP DRB1*01) PRIMERS USED FOR AMPLIFICATION OF EXON 2 OF DRB ALLELES

Amplification Type	Intron-Exon	Nucleotide Sequence[a]	Orientation

[a] Nucleotide sequences of oligonucleotide primers used for amplification of DRB alleles. Primer pairs were selected to match the sequences of alleles of the locus (generic primers) or groups of alleles (group-specific primers).

[b] A mixture of primers is required to amplify all the DRB alleles. Note Codon 8 in Figure 36.1 which shows similarity of DRB1*07011, *15011, and *16011 (and their difference from *0101) necessitating the use of a different primer in the mixture.

[c] Relative positions are shown as codons for nucleotides from exons. The sequences shown in Figure 36.1 can be used for comparison. Please notice that the sequence alignment in Figure 36.1 shows only coding DNA (exon sequences). Therefore, for comparison with Figure 36.1, the exon segments of the primer should be used. The nucleotide sequence of the forward primers can be visualized directly; the sequence of the reverse primers can be matched by converting the sequence to the complementary nucleotide and by inverting the orientation of the complementary bases.

[d] For amplification of the DRB1*01 alleles, group-specificity is obtained with the forward primer 2-DRBAMP-1; the nucleotide sequence of this primer matches only DRB1*01 alleles; in bold and underlined are shown polymorphic nucleotide positions.

The development of novel molecular techniques has allowed the direct detection of nucleotide substitutions encoding amino-acid differences that determine the differential immunologic characteristics of the HLA antigens. There are many molecular methods available to define the HLA alleles. The ability to amplify DNA segments by the polymerase chain reaction (PCR) greatly facilitates the application of molecular techniques in the routine laboratory tests. PCR-based methods may be broadly classified into three categories: (i)those that generate a product containing internally located polymorphisms that can be identified by a second technique, e.g., PCR sequence-specific oligonucleotide (SSO) probing, PCR-RFLP, PCR followed by sequencing (SBT), (ii)those in which the polymorphism is identified directly as part of the PCR process, although there are postamplification steps, e.g., PCR sequence-specific primer (SSP), and (iii) conformational analysis in which different mutations generate specific conformational changes in PCR products. These are identified by electrophoretic analysis e.g., heteroduplex analysis, single-strand conformation polymorphism (SSCP), denaturing-gradient gel electrophoresis (DGGE) and temperature-gradient gel electrophoresis (TGGE).

The use of a specific technique will depend on the laboratory's requirements. Clinical urgency and requirement, sample numbers, availability of equipment, staff skills, and budget will influence the choice. Some laboratories, depending on their needs, may use a combination of methods. All techniques need to be updated continually to allow for the detection of newly discovered alleles. According to the clinical application, high- or low-resolution typing may be required. Kidney transplant candidates, for instance, do not necessarily have to be typed at a high-resolution level, because only the “broad” serological specificities (DR1-DR10) usually are taken into consideration for organ allocation. For bone marrow transplantation purposes, high-resolution typing is required.

STEPS FOR MOLECULAR TYPING

Part of "36 - Molecular HLA Typing"

In order to achieve molecular typing by any of the most commonly used procedures (SSP, SSOP, and SBT) three general steps are followed: (i) extraction of genomic DNA, (ii) amplification of the genes of interest, and (iii) detection of the sequence polymorphisms that define the alleles.

DNA Extraction

Generally, HLA typing is performed from genomic DNA extracted from nucleated cells, usually blood specimens. A few micrograms of genomic DNA are sufficient to perform complete molecular typing of all HLA loci at the highest resolution level. The purity of the DNA extracted may be an important factor for successful results. Usually, short PCR fragments (less than 300 base pairs) are amplified easily, and a simple salting-out method may be sufficient to achieve successful amplification; however, longer fragments may require higher purity. In general, amplification of exon-2 (approximately 270 bp) of HLA class II is sufficient to achieve the highest resolution level. For typing HLA class I, both exons 2 and 3 and the intervening intron (fragment longer than 900 bp) are amplified by a single pair of primers.

DNA Amplification

DNA is amplified by repeating thermal cycling of the PCR mixture. This mixture contains genomic DNA, dNTPs, primers, Taq DNA polymerase, and the corresponding buffer. This mixture is subject to repeated cycles in which the sample is subject to the following steps: (a) heating to 94°C to 96°C for denaturation of double-stranded DNA, (b) cooling down to the corresponding annealing temperature of the primers used, and (c) warming up again to 72°C in which the Taq DNA polymerase primed by the annealed primers has its optimal activity to incorporate the complementary nucleotides to the single-stranded DNA.

The DNA copies obtained after one cycle of amplification serve as template to be copied in the following cycles. This process allows one to obtain an exponential growth of the PCR products. In order to achieve exponential growth, both DNA strands of the same fragment need to be amplified. Therefore, primers for both strands should be designed and the fragment amplified will include the intervening segment between both primers. The number of PCR cycles and the incubation times at each temperature depend on the length and GC content from both the fragment to be amplified and the primers used. The dNTPs are added in excess and should not be a limiting factor for the efficiency of the PCR reaction.

PCR Primers

The PCR primers are selected to be complementary to sequences of the fragment to be amplified. These usually are 18 to 25 bp and the orientation of the sequence from 5′ to 3′ because the DNA polymerase adds the complementary nucleotides in this orientation. The selection of primers is crucial to the success of the procedure; the nucleotides at the 3′ end of the primer are crucial to achieve the desired specificity and efficiency. Usually, nucleotide mismatches with the target sequence in the middle or at the 5′ end are tolerated and DNA amplification with primers mismatched with the target sequence in those areas can be achieved. On the contrary, nucleotide mismatches at the 3′ end of the primer do not allow the DNA polymerase to extend the complementary sequence. This feature of the DNA polymerase is used to select the primers with the correct specificity.

When amplification of all alleles of a locus is desired, then a common sequence to all of them is selected and this must be different from other homologous loci. In some cases, the primers are selected to amplify a single allele or a group of alleles; because both primers are required to achieve exponential amplification, then specificity of a particular segment can be achieved by either of the two primers. Table 36.1 shows the nucleotide sequences of forward and reverse primers designed for amplification of all DRB alleles (DRB generic) and for amplification of selected groups of alleles [group-specific primers (GS)]. The DRB forward and reverse generic primers match the sequences of all

DRB alleles in the 3′ end of the primer while one or both GS primers match the sequences of only a group of alleles.

Detection of the Sequence Polymorphisms That Define the Alleles

Identification of the HLA alleles carried by a particular individual is accomplished by the detection of nucleotides present in one allele and absent in others. Because most of the distinguishing nucleotide substitutions are not unique to a particular allele, alleles usually are typed by analyzing several polymorphic positions, and the allele assignment is made by the reactivity pattern.

The most common methodologies used to detect nucleotide sequence polymorphism of HLA alleles include SSP (or amplification with group/allele specific primers), sequence specific oligonucleotide probes (SSOP) hybridization and sequenced based typing (SBT).

Sequence-Specific Primers

In this procedure, sets of primer pairs are used to amplify genomic DNA of samples. The primer pairs (both reverse and forward primers) included in each set match sequences of HLA alleles or groups of alleles of the HLA locus to be typed. In addition to the allele/GS primer pair, each tube contains an amplification control (AC) primer pair. The primers of AC match conserved sequences of a selected gene and are used to control the efficiency of the amplification reaction. The PCR products obtained with each primer pair are run in an agarose gel and stained with ethidium bromide. The gel then is visualized under ultraviolet (UV) light. The presence or absence of bands corresponding to PCR products obtained with each allele/GS primer pair is scored. Valid negative scores are those in which the band corresponding to the AC is visualized and that of the allele/GS primer pair is not observed. In these reactions, the molecular weight of the band visualized also is used to assign the scores. The expected size of each band corresponds to the distance (number of nucleotides) between both primers. Usually, the AC band has a larger size than that of the allele/GS primer pair. The AC band is a required control because longer DNA fragments are more prone to fail. Therefore, the presence of the AC band and the absence of the allele/GS band allow confident determination of the negative reaction scores. Patterns of amplifications with each set of primer pairs are analyzed to make the assignment of the corresponding genotype.

Usually, molecular typing by SSP methods is performed with a limited number of primer pairs that identify groups of alleles of a particular locus. Most of the approaches developed identify groups of alleles that belong to the same serologic group. Once these groups are identified, additional SSP reactions are selected to distinguish the alleles within each group.

The SSP methodology is relatively easy to perform and results are obtained within a few hours. However, with increasing numbers of alleles, high resolution typing of a large number of samples may become unwieldy because it involves the performance of many PCR reactions.

HYBRIDIZATION WITH SSOP

Part of "36 - Molecular HLA Typing"

These methods involve the specific amplification of HLA alleles of a particular locus in the HLA region by the PCR, immobilization of PCR products onto nylon membranes, and the subsequent

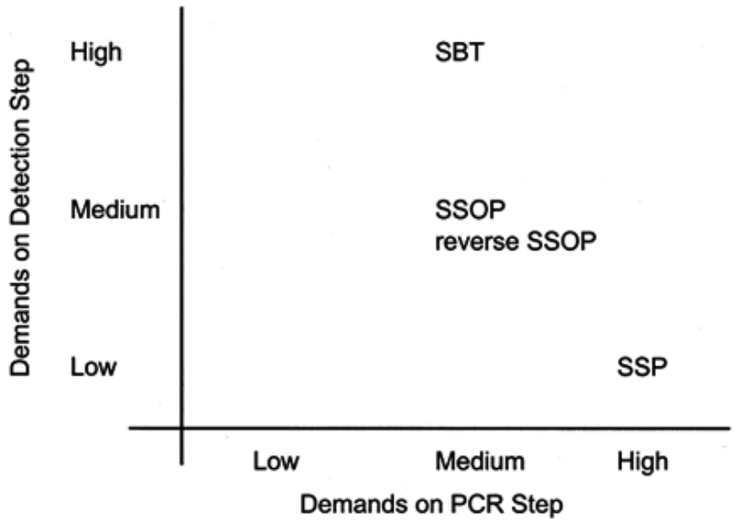

FIGURE 36.2. Comparison of the technical, equipment, supply, and skill demands of various molecular methodologies applied in typing of HLA alleles. Abbreviations: SBT, sequence based typing; SSOP, sequence-specific oligonucleotide probes; SSP, sequence-specific primers.

TABLE 36.2. COMPARISON OF SOME CLASS I DNA TYPING METHODS

Method	Resolution	Advantages	Disadvantages
SSP[a]	Medium	Rapid	Controls
	(High)	single samples	Large number samples
Reverse	Medium	Rapid	Multitiered for high resolution
SSOP[b]	(High)	Single samples	
SSOP[2]	Medium	Robust	Slower
	High	Flexible	Batch mode
		Inexpensive in large volume	Expensive in small volume
SBT[c]	High	Highest resolution	Slower
		Definitive standard	Labor intensive
			Capital costs

[a] SSP: Sequence Specific Primers.
[b] SSOP: Sequence Specific Oligonucleotide Probes.
[c] SBT: Sequence Based Typing.

probing of this product with sequence SSOP. The vast polymorphism of the HLA system results from conversion events whereby small nucleotide sections of one allele (usually no more than 100 bases long) are transferred to another allele. Thus, many of the sequences tend to be shared by alleles and not to be allele-specific. Therefore, several sequence-specific probes must be used to identify a particular allele. In order to differentiate the alleles, a battery of probes is required and it is the pattern of reaction with these probes, which distinguishes the HLA alleles.

The so-called “PCR SSOP forward format” involves PCR amplification of several samples with the same primers. Then, the PCR products of different samples are blotted onto replicate nylon membranes. Each replicate membrane then is hybridized individually with each SSOP. Each SSOP contains radioactive or nonradioactive labels. The excess SSOP then is rinsed off the membranes followed by stringent wash steps in which the SSOP is removed from dots that contain PCR products that do not match its nucleotide sequence. Finally, either an autoradiogram or a colorimetric reaction detects each SSOP.

The SSOP are designed to match the sequence of a particular allele or groups of alleles. Under controlled hybridization and washing conditions, SSOP that match completely a target sequence are detected and SSOP with a single nucleotide mismatch do not sensibly hybridize. Usually, the SSOP are 6 to 19 nucleotides long and their sequence is chosen in a manner that the polymorphic nucleotides are centered. The specificity of the hybridization is achieved by adjusting the hybridization and washing conditions. Usually, SSOP that tend to display cross-hybridization give more specific hybridization if the salt concentration in the wash step is lower or if the stringent wash is performed at a higher temperature.

Several detection systems may be used. One of them consists of labeling the probes with digoxigenin (DIG) and detecting the presence of hybridization of these probes to an identical sequence present in the PCR-amplified HLA allele of an individual by adding an antidigoxigenin antibody conjugated with alkaline phosphates (ALP). The ALP then acts on a chemiluminescent substrate and the light emitted is detected by autoradiography. Other procedures involve the direct conjugation of the SSOP with alkaline phosphatase or horseradish peroxidase. Either a chemiluminescent substrate or a colorimetric substrate can be used for detection. An alternative labeling procedure involves the incorporation of a radioisotope in the SSOP.

The “forward dot blot” SSOP procedure is advantageous because many samples can be tested simultaneously. However, it is time consuming and may be unwieldy in typing samples that require a rapid turn around time. Other hybridization methods used to test single samples in a short period of time have been developed. One of them includes a “reverse format” SSOP procedure in which many SSOP are immobilized on a single solid support (nylon strips) and exposed to hybridization with the PCR products that are in a liquid phase. The latter procedure involves the labeling of the PCR product for detection of hybridization. Another oligonucleotide hybridization-based procedure for testing simultaneously multiple SSOP with a single sample involves hybridization in 96-well plates. In this procedure, PCR products produced with biotin-labeled primers are immobilized on avidin-coated trays and hybridized to a different SSOP in each well. The SSOP are tagged with digoxigenin or labeled with an enzyme. Detection of hybridization is performed with colorimetric substrates.

As a consequence of the large degree of sharing of sequences between alleles of the same and homologous loci, PCR SSOP methods may be performed in sequential tiers to accomplish the highest level of typing resolution.

COMPARISON BETWEEN CLASS I AND CLASS II TYPING SYSTEMS

Part of "36 - Molecular HLA Typing"

The slight differences between typing systems for HLA class I and class II alleles reside in the nature of their diversity. HLA class II genes, in particular DRB loci, present a large number of homologous genes carried by the same chromosome; as a result of the multiloci sequence homology, the selected primers for PCR amplification of all alleles of one locus coamplify alleles of other loci as well. So far, no primer pairs that amplify exclusively exon-2 of all DRB1 alleles have been described. In DRB, many coamplified alleles of various loci share nucleotide sequences in polymorphic areas that require probing. The extensive sharing of sequences very often results in patterns that correspond to several genotypes (ambiguity).

A widely used approach for typing HLA DRB alleles involves a multiple-step procedure. This approach includes an initial step in which the loci and or groups of alleles carried by a sample are identified. If the resolution level required is not achieved in the first step, then locus or group-specific amplifications are performed and the PCR products are probed with the corresponding sets of SSOP to achieve the desired resolution. In general, the highest level of nucleotide polymorphism in HLA class II loci resides in exon-2; in this exon are encoded the distal membrane, α-1 or ß-1, domains of the α and ß subunits, respectively, of the class II molecules. In general, analysis of the nucleotide variations in this exon is sufficient to achieve allele-level typing or to identify polymorphisms that are likely to be relevant in clinical histocompatibility.

In contrast, typing alleles at HLA class I loci requires a different approach. In spite of the many homologous genes and pseudogenes, it has been possible to identify locus-specific sequences. These served as the basis for design of PCR primers that amplify all alleles of the locus to be tested without the co-amplification of alleles of other homologous loci.

The class I genes present high levels of nucleotide variation in two exons (2 and 3). Generally, the molecules corresponding to alleles of the same class I loci present differences in either the α-1 or α-2 domains or in both domains. The exons-2 and -3 of HLA genes encode these domains, and both exons must be analyzed to achieve HLA class I typing. Therefore, the PCR primers selected for HLA class I typing must encompass segments spanning both exons. Locus-specific primers are used to obtain PCR products spanning exons-1, -2, and -3, and the intervening introns 1 and 2 for HLA-A and -B. A shorter segment spanning introns 1 to 3 is obtained with the primers selected for HLA-C amplification. The primers selected are consistently efficient in amplifying all alleles of a particular locus.

The “forward dot blot” approach uses PCR products that are immobilized to membranes; the double-stranded PCR products

then are denatured by alkali and no reconstitution of the double strands occurs after this treatment. Therefore, reannealing of the long PCR fragments obtained with the selected primers does not prevent optimal hybridization with SSOP. In other dot-blot formats, like the reverse-dot-blot assays, the secondary structures of long PCR fragments may cause hindrance to the annealing to some oligonucleotide probes.

For high resolution typing of HLA class I alleles, oligonucleotide probes designed to match almost all sequence segments encoding polymorphisms in exons-2 and -3 of HLA-A, -B, and -C are used. The chosen sequences are 19 nucleotides or less, and the variable nucleotides are centered. These probes were tested under various hybridization and washing conditions to select the optimal conditions for specificity. For SSOP in which it was not possible to determine consistently specific and robust hybridization conditions, they were redesigned or shortened.

TYPING OF HLA ALLELES BY NUCLEOTIDE SEQUENCING (SBT)

Part of "36 - Molecular HLA Typing"

The direct identification of the complete nucleotide sequence of the HLA alleles carried by a sample provides the most accurate procedure for typing. Currently, HLA typing using automatic nucleotide sequencers has a widespread application. Usually, the dideoxy chain termination method is the most widely used approach. Detection of the sequencing fragments usually is performed utilizing fluorescent dyes. Different laboratories use fluorescent primers and/or tagged nucleotides. The use of multiple dyes usually facilitates the performance of electrophoresis. For SBT typing, the same primers used for SSOP-based methods can be used to amplify the HLA genes; the PCR products obtained with these primers then can be sequenced. In order to obtain a more accurate typing, both DNA strands (forward and reverse) are sequenced.

Typing of HLA-A, -B, and -C usually involves the simultaneous amplification and sequencing of both alleles carried by a particular sample, and heterozygous nucleotide assignments are made for each particular position. For loci that do not have unique specific sequences (e.g., DRB loci coamplified with generic primers) the PCR products sequenced are those obtained with allele/GS primer. Otherwise, multiple-base assignments could be made at certain polymorphic positions. As observed in SSOP typing, some heterozygous genotypes result in the same sequencing pattern; these combinations usually are resolved by performance of GS amplification that enables physical separation of the alleles of a sample.

Even though nucleotide sequencing may be technically more demanding than other procedures, SBT presents the advantages over the other procedures because of the relatively fast (24 to 48 hours) turn-around time. In addition, SBT generally achieves allele-level resolution. However, this procedure may be unwieldy for typing large numbers of samples.

COMPARISON OF DNA TYPING METHODS USED FOR TYPING HLA ALLELES

Part of "36 - Molecular HLA Typing"

In principle, the methodologies mentioned above can be used for typing alleles at any locus of the HLA region. Therefore, the choice of methodology used in a particular laboratory will be made based on work volume, equipment, and reagent costs as well as on requirements of personnel training and skills. Usually, most of the technical demands are in the performance of various steps of the procedure and in the interpretation of the data. Fig. 36.2 compares the levels of complexity in the performance of the DNA amplification and detection/interpretation steps. As previously described, the SSP-based tests require the use of several primer mixes and therefore the number of thermocyclers in a laboratory may present a limitation for testing large number of samples. On the other hand, the SSP results are easy to interpret. The other methodologies in contrast require one or a few DNA amplification reactions for typing of the alleles of a single locus, and are highly demanding in the detection (SSOP) and interpretation steps (SBT).

ADVANTAGES AND LIMITATIONS OF THE DNA-BASED TYPING METHODS

Part of "36 - Molecular HLA Typing"

Molecular typing techniques such as PCR-SSOP, SSP, and SBT provide a strong typing tool for typing the highly polymorphic HLA genes, especially those of class I and class II. These methods have advantages because of greater accuracy and a higher level of resolution compared with serological typing. For high volume typing, SSOP methods seem to be the most convenient and powerful methods to use because a large number of specimens can be tested simultaneously. Various levels of resolution for alleles of HLA class I and class II loci can be achieved by using selected sets of SSOP or SSP. A summary of the advantages and resolution offered by each procedure is presented in Table 36.2. This table also presents the disadvantages and limitations inherent to each procedure.

DELINEATION OF THE TYPING SYSTEMS, TRENDS AND FUTURE STRATEGIES

Part of "36 - Molecular HLA Typing"

It is likely that as more alleles are discovered, more ambiguities will be found and the performance of group-specific amplification

(GSA) will have to be applied more often. In order to make the HLA class I typing process more efficient, the procedure may have to be redesigned to a higher frequency of ambiguities. This process may include the performance of an initial screening for heterozygosity at a few polymorphic segments; once heterozygosity is identified, then GSA with selected primers may allow separation of the alleles. Either PCR-SSOP or SSP may be used for the screening procedure for heterozygosity. If the SSP approach is chosen as the initial step, the PCR-SSP products obtained could be further analyzed by hybridization with SSOP or by nucleotide sequencing.

APPROACHES FOR TYPING OF NOVEL POLYMORPHISMS

Part of "36 - Molecular HLA Typing"

The method for typing HLA class I alleles described here is based on the analysis of exons-2 and -3 while for typing class II alleles only exon-2 is analyzed routinely. Recently, new polymorphisms outside these exons have been described and several pairs of alleles have been found to differ only by substitutions in the new variable segments. In fact, some of the nucleotide substitutions in the novel polymorphic site result in a termination codon that results in nonexpression of the alleles carrying them (31, 32, 33, 34, 35 and 36). Therefore, in spite of identical exon-2 and exon-3 nucleotide sequences, some pairs of HLA class I alleles will differ in their expression pattern. Other mutations that alter HLA expression have been described in intronic splicing sites (36) and in the promoter regions. Typing strategies for mutations outside exons-2 and -3 will require further development. The methodologies described here may be supplemented by the performance of additional amplifications to probe for the expression variants by either SSP or SSOP when ambiguities including these alleles are identified. Alternatively, new PCR primers that amplify DNA segments including exons-2 and -3 and spanning the areas containing the mutations that affect expression may be developed.

The current trend in HLA typing is to replace the serological methods that detect the expressed products by genomic testing procedures. However, not many extensive population studies in which serologic and molecular testing have been performed in parallel have taken place. Therefore, it is possible that novel null-alleles remain to be identified. Until such studies have been completed, serological testing should not be completely omitted from clinical histocompatibility testing because alleles typed only at the genomic level may contain undetected expression defects. It has been shown that HLA mismatches influence the outcome of allogeneic transplants and this effect is highly relevant in bone marrow transplantation. In clinical histocompatibility testing, assumptions made about the expression of some alleles, when in fact the corresponding are not expressed, may result in the introduction of undetected HLA mismatches.

The aim of typing at the intermediate-resolution level is to identify groups of alleles at a level that yields at least the same information as that obtained by serologic methods. The dot-blot procedure is well suited for typing large numbers of samples. This is a highly accurate procedure and therefore may replace serologic typing of volunteers of bone-marrow donor registries. It is likely that still newer methodologies will enhance the performance of molecular testing by improving turn-around time, ease of performance, and level of resolution. Some of the currently used PCR primers and the target sequences chosen for analysis also may prove useful for development of new approaches for HLA typing.

TRANSPLANTATION: SOLID ORGANS

Part of "37 - HLA: Applications"

The critical need for allogeneic renal transplantation as a therapeutic modality in end-stage renal disease served as the impetus for the investigations that led to the rapid discovery and understanding of the HLA system.

The concept of donor-recipient matching for histocompatibility antigens prior to transplantation is founded on the same principles underlying those used for the selection of blood for transfusions. An allograft is rejected as a result of an immune response directed against alloantigens expressed on the graft that are absent from the host. Matching for the most prominent antigens should result in some abrogation of the antigenic stimulus, resulting in a response that is more amenable to control by immunosuppressive drugs. It is recognized that exact matching for all possible antigens may be a practical impossibility. However, closer matches for major antigens will result in lesser degrees of antigenic challenge and therefore will require lower levels of immunosuppressive drugs, resulting in better overall outcomes.

Renal Transplantation

Renal transplantation is carried out successfully using two groups of donors as sources for allografts. The first of these are living donors, usually relatives of the patient, who have two functioning kidneys, are in good health, and consent to donate. This practice has been extended to include living nonrelated donors such as spouses. The second source is from cadaveric donors who were in reasonable health before death and whose kidneys were not affected by the fatal disease or circumstances of death. The most suitable donors in this category are victims of head trauma or other situations that result in irreversible brain damage.

There are advantages and disadvantages to the use of each of these types of donors, and each presents a different set of problems with respect to matching. Although the HLA system automatically comes to mind in the consideration of donor-recipient matching for transplantation, its importance is not exclusive. The strongest and probably most significant transplantation antigens in humans are the antigens of the ABO blood group system (1). These antigens, in addition to being present on erythrocytes, are fully expressed in all tissues of the human body with the exception of those of the central nervous system. In addition, all people possess antibodies against the antigens (of the ABO system) they lack, developed as a result of natural environmental stimuli. These antibodies have the potential of reacting with antigens expressed on the vascular endothelium of the donor organ and can result in a hyperacute rejection similar to the white graft reaction described earlier. Therefore, matching for ABO within the same general guidelines used for blood donor selection is an essential prerequisite for organ transplantation.

The HLA matching of living related donors is performed with respect to the sharing of haplotypes containing the HLA-A, HLA-B, and HLA-DR antigens. Data excerpted from the United Network for Organ Sharing (UNOS) transplant registry are shown in Table 37.1 (2). The overall 1-year survival among 1,013 patients with grafts matched for both haplotypes was 96.6% and the survival at 5 years was 85.9%. Among 1,872 patients with grafts matched for only one haplotype, the 1-year survival was slightly lower (95.3%) and the 5-year survival was only 73.4%. The overall graft survival in blacks was lower than in whites. UNOS data indicate an overall 1-year graft survival of 93.7% in whites versus 91% in blacks. At 3 years, the difference is greater with a graft survival of 86.2% in whites and 76.2% in blacks. From these data, it is clear that HLA typing has a significant influence on the survival of kidneys from living, related donors.

TABLE 37.1. LIVING RELATED KIDNEY GRAFT SURVIVAL ACCORDING TO HAPLOTYPE MATCHES[a]

Level of HLA Mismatch	N	1 Year Survival %	N	3 Year Survival %	5 Year Survival %
0	1013	96.6	4179	91.2	85.9
3	1872	93.0	6605	83.1	73.4

[a]Data from United Network for Organ Sharing 1998 (2).

The striking difference in the overall outcome of transplantation between whites and blacks is noteworthy. These differences, which have been observed not only with living, related donors but with cadaveric donors as well, cannot be readily explained. The inability to type for certain antigens prevalent only in blacks plays no part in the cases of living, related donors because they are matched for haplotypes derived from family studies. However, so-called center effects, physiology, and lack of patient compliance have been cited as possible contributory causes.

The center effect must be considered whenever analyzing data of this type, which have been collected in a central registry from a large number of individual transplant centers. The effect originates from a collection of events that may exert a significant influence on outcome but that are not attributable to the condition being measured, for example, HLA matching. These influences

would include such factors as surgical technique, standards for organ harvesting, immunosuppressive protocols, clinical condition of the patient prior to transplantation, nursing care, socioeconomic status of the patient, patient compliance, postgraft monitoring, and assessment of clinical condition. Interestingly enough, this collection of factors, which contribute to the center effect and therefore may obfuscate the interpretation of collated data to some extent, may have a marked effect on the results from a single center. Thus, any single center might appear to show either a very high or a very low correlation of graft survival with typing. Therefore, the analysis of pooled data from a large number of patients gives the best picture because the center effect is minimized.

HLA matching appears to have an effect on long-term graft survival of kidneys from cadaveric donors. The data from the UNOS registry (2), shown in Table 37.2, indicate a 1-year graft survival, which is not very different in cases involving a complete match from those that are completely mismatched. However, after 5 years, the gap in percent survival widens. In an earlier analysis of long-term survivors of kidney transplantation from cadaveric donors, the average half-life of grafts was 10.1 years for those with no HLA-A or -B mismatches and 6 years for those with no HLA antigens in common. When both HLA-A, -B and HLA-DR matching are considered, the results are clearly superior, with patients receiving organs with zero mismatches for the entire constellation of HLA antigens and achieving a graft survival half-life of 11.3 years compared to a half-life of 6.3 years for grafts that were completely mismatched for HLA-A, -B and DR (3).

TABLE 37.2. CADAVER KIDNEY GRAFT SURVIVAL ACCORDING TO HAPLOTYPE MATCHES[a]

	1 Year Survival	5 Year Survival
Level of HLA Mismatch	%	%
0	95.2	82.1
1	96.1	82.2
2	94.8	82.0
3	95.0	81.8
4	94.9	81.0
5	94.4	80.1
6	93.8	78.8

[a]Data from United Network for Organ Sharing 1998 (2).

HLA matching is especially beneficial in second transplants and in patients with preformed antibodies (4). Patients matched with their donors for both DR antigens (disregarding any HLA-A, -B matching) have a 1-year survival of 83% versus 76% for those with one match and 74% for those with no matches. At 5 years, 64% of the fully matched grafts are still functioning while only 55% of those with one or no matches survive. Matching for the HLA-A and -B antigens in addition to HLA-DR has an enhancing effect. In the study cited, the patients matched for both HLA-DR antigens achieve a 1-year graft survival of 87% if they also are matched for a single HLA-A antigen and a single HLA-B antigen versus 74% for those with no HLA-A or -B match. Additional analyses have confirmed these findings and have shown that HLA-A, -B matching has a significant effect on long-term graft survival (5). Interestingly, the same study revealed that HLA-DR matching alone does not improve long-term graft survival even though it appears to have an effect during the early period after transplantation.

A donor-recipient matching scheme is being evaluated that is based on the matching for the relevant immunogenicity of shared epitopes in AB and DR (6). The examination of the antibodies from 50,000 pregnancies revealed that most of the specificities were directed against public and private specificities defined by molecules with shared epitopes (7). Furthermore, this analysis allowed the calculation of an immunogenicity score for each specificity, based on the chance of immunization. This immunogenicity score varied by more than 10 times between different specificities. In addition, the shared epitopes based on the cross-reactivity between different DR types could be defined. This approach to matching is receiving a great deal of attention and is being supported by the ever-increasing understanding of the HLA antigens at the amino-acid level (8). Hopefully, this should lead to a better definition of allowable mismatches like those that are routinely applied to the choice of blood for transfusion.

Still another sophisticated procedure for donor-recipient matching is being explored at the peptide level. Using a computer-generated table of peptides unique to each HLA specificity, Takemoto and Terasaki (9) used this system for matching. They claim that this approach was more effective in identifying patients with extremely poor outcomes than conventional techniques. Although such a tool is far from practical in its present state of development, it may offer new insights to the problem.

Under ideal circumstances, it would be most desirable to obtain donors who are perfectly matched with respect to all six HLA antigens of the recipient. In spite of the polymorphism of the HLA system, some haplotypes are more prevalent in the population than others. Therefore, in certain cases, it is possible to find exact matches, even among random donors. Unfortunately, this can take time, and for many patients with end-stage renal disease, the time needed to find an exact match may not be available. For this reason, each case must be evaluated individually, and compromises based on both scientific and clinical judgment must be made.

The analysis of data such as those presented earlier has led to the development of a hierarchy of matching: A,B,DR >B,DR >A,DR >DR >B >A. A convenient way to select a recipient for any given random donor is based on the awarding of points. The points assigned by UNOS for the various degrees of matching are given in Table 37.3. In addition to HLA matching, this scheme also allows for the awarding of points for other factors related to the quantity of preformed anti-HLA antibody in the recipient serum and the length of time on the waiting list.

TABLE 37.3. UNOS POINT SYSTEM FOR ORGAN SHARING

Degree of HLA Matching	Points
0 B or DR mismatch	7
1 B or DR mismatch	5
2 B or DR mismatches	2
PRA-> 80	4

Graft Rejection

Solid-organ graft rejection can take place as one of three different types or a combination. The most common types can be defined as follows.

Hyperacute rejection. The improved new crossmatching techniques greatly diminished the incidence of hyperacute rejection. Hyperacute rejection occurs when a kidney is transplanted into a recipient with preformed cytotoxic antibodies against donor class I or more rarely, class II HLA antigens. It also occurs when engraftment is attempted between ABO-incompatible individuals.

Hyperacute rejection happens so rapidly that transplanted organs may become visibly devitalized while the patient is still on the operating table. There is no effective treatment for this type of rejection. A hyperacutely rejected kidney should always be removed

Accelerated rejection. Accelerated rejection occurs within the first two to five posttransplant days. This form of rejection is thought to be a result of an amnestic response to donor tissue resulting from prior sensitization to donor alloantigens. Accelerated rejection may be mediated by cytotoxic T cells, anti-HLA alloantibodies, or both and often is associated with vasculitis or T-lymphocyte infiltration of renal vessels. The prognosis of these early rejection episodes is poorer than that seen with acute cellular rejection. Accelerated rejection rarely occurs in patients receiving antilymphocytic antibodies for induction immunosuppression. This fact emphasizes the central role of lymphocytes in its occurrence.

Acute cellular rejection. Acute cellular rejection occurs in 20% to 60% of renal transplant recipients. It occurs usually in the first 3 months following engraftment and is most common in the 2nd and 3rd weeks posttransplant. Mild acute cellular rejection is marked by diffuse mononuclear cellular infiltrates and lymphocytic infiltration of tubular structures. It usually is treated by the administration of large doses of immunosuppressive drugs.

Other Solid Organs

In contrast to the kidney, donors of nonpaired organs such as the heart and liver must be of cadaveric origin, although single hepatic lobes from living donors have been used. Furthermore, in these cases, clinical considerations play a very prominent role because, unlike the kidney patient who can be supported on dialysis, end-stage coronary and liver diseases are not amenable to long-term maintenance therapy. In the case of these organs, ABO compatibility and size are the two most important considerations. Size is especially important because these grafts must fit when placed orthotopically and also must be capable of handling the physiologic burden of the recipient. Speed is essential, as preservation techniques either are not developed or are very critical. For these reasons, there is little time for prospective donor-recipient matching based on HLA.

Pancreas and Kidney-Pancreas Transplantation

Pancreas is transplanted both as a solid organ and as dissociated islet cells. Both of these tissues are exceptionally susceptible to the action of HLA antibodies, isolated islet cells somewhat more. The greatest success is obtained when pancreas and kidney from the same donor are transplanted simultaneously. Therefore, the same HLA matching criteria used for the selection of kidneys are employed.

Vascularized pancreas grafts have assumed an increasingly important role in the treatment of insulin-dependent diabetes mellitus (IDDM). Simultaneous kidney-pancreas is gaining acceptance as a viable alternative to kidney transplant alone in diabetic transplant recipients because of its ability to provide superior glycemic control and an improved quality of life. Although morbidity is still higher after simultaneous kidney-pancreas transplant compared to kidney transplant alone, the addition of the pancreas does not appear to jeopardize the kidney transplant. The most common complication, rejection, does not appear to adversely influence long-term kidney allograft survival compared to solitary kidney transplantation.

Cardiac Transplantation

Retrospective studies on the significance of HLA matching in cardiac transplantation are controversial. Some data appear to support a positive effect from DR matching, while others indicate no apparent effects from such matching (10, 11). Recent data suggest that pretransplant antibodies to HLA antigens appear to have an effect on outcome. It appears that patients with positive cross-matches to HLA antigens do more poorly than patients whose cross-matches are negative. In addition, positive B-cell

cross-matches have been reported as the cause of early rejection. Experience gained from the evaluation of renal transplantation suggests that the myriad of factors associated with cardiac patients is even more complicated. This contributes significantly to the center effect, requiring the study of many more cases before any meaningful conclusions can be reached. The relationship of the donor HLA status to that of the recipient generally is not determined prospectively, and therefore, allocations schemes for heart are not based upon HLA matching criteria as they are for kidney transplant.

The constraints of donor-ischemic time and unpredictability of donor availability do not permit prospective matching. However, several studies have shown correlation between the degree of HLA mismatch and acute rejection, allograft vasculopathy, and survival. Indeed, HLA mismatch and other potential risk factors for rejection were analyzed using multivariate analysis of data from 27 institutions participating in the Cardiac Transplant Database Research between 1990 and 1992. The few patients with zero, one, or two mismatches had a 54% freedom from rejection at 1 year versus only a 36% freedom from rejection in those patients with three or more HLA mismatches.

Screening for anti-HLA antibodies is very important in heart transplant candidates. Some studies have indicated the need to use sensitive techniques such as flow cytometry or ELISA for the detection of anti-HLA antibodies. If a heart transplant candidate has preformed panel-reactive anti-HLA antibodies, a T-cell cross-match should be performed using a sensitive technique. In general, if the panel-reactive antibody (PRA) is less than 10%, donor allocation can be accomplished without a prospective cross-match. The presence of PRA prior to sensitization is associated with the poorer outcome and might dictate a more aggressive immunosuppressive regimen.

Liver Transplantation

In liver transplantation, clinical considerations are even more important than in heart transplantation; as a result, a careful prospective study has never been attempted. However, data from retrospective studies performed at the largest liver transplant center in the United States are showing some interesting, although somewhat ironic, results. They seem to suggest that HLA matching for DR has a reverse effect; that is, patients with grafts poorly matched for class II antigens appear to do better than those with well-matched grafts (12).

This finding seems to parallel results from rodent models of endocrine organ transplantation. In these systems, it has been suggested that the graft failure stems from the ability of the cells in the matched tissue to act as antigen-presenting cells to the host immune system. Class II antigen expression by the nonlymphoid cells being transplanted may be induced by IL-2 and interferon gamma released during the normal inflammatory stages of the transplant procedure. Class II identity with the host allows these cells to act as antigen-presenting cells. The antigens being presented are thought to be minor histocompatibility antigens expressed on the donor cells that are absent from the host. If this is indeed the cause of the failure of DR-matched livers in humans, it could lead to a better understanding of human minor histocompatibility antigens (13).

Some of the more recent data on liver transplantation seem to suggest that this organ appears to be quite resistant to the action of anti-HLA antibodies. Patients who demonstrate the presence of preformed antibody against donor antigens fail to exhibit hyperacute rejections. They do undergo rejection episodes. However, these can be controlled and reversed with aggressive immunosuppressive therapy (14).

Lung Transplantation

Lung transplantation is one of the most recent therapeutic modalities currently being practiced. It is performed in a relatively few centers and as a result data are lacking relative to the significance of HLA matching. As in heart transplants and liver transplants, clinical considerations are paramount. Nevertheless, as in all solid organ transplants, matching for the ABO blood groups is essential. The very best pretransplant strategy is to obtain an HLA antibody profile of the patient that is as complete as possible. It has been noted that antibodies to class II major histocompatibility complex (MHC) antigens can be particularly dangerous to this type of graft. Therefore, it is extremely important to screen for such antibodies in these patients, determine their specificity, and select donors accordingly, prior to organ harvest.

Special Immunologic Considerations in Pediatric Transplantation

A significantly greater percentage of children under the age of six suffer graft failure after their first rejection episode than do older recipients. There is evidence that young children have heightened immunologic reactivity; because children under the age of 15 years are more likely to develop anti-HLA antibodies in response to blood transfusion. Thus, presensitization is a significant predictor of poor graft outcome. Highly sensitized children can wait inordinately long periods for a crossmatch-negative transplant, and this wait can represent a problem for small children who often tolerate dialysis poorly.

Significance of Alloantibodies

A very important consideration in the selection of a donor of any solid organ is the antibody status of the recipient. Preformed antibodies in the serum of the recipient directed against donor antigens can have a deleterious effect on the outcome of transplantation. Consequently, presence of such antibodies must be ascertained prior to donor selection. Antibodies to HLA antigens are produced by recipients awaiting transplantation in response to a number of different stimuli, including blood transfusion and previous transplantation. The dose of challenging antigen is presented differently in each of these situations. This results in a variety of different immune responses that may vary with respect to the quantity, biochemical affinity, and in some cases the predominant immunoglobulin class of the antibodies produced as well as their specificity and persistence. In addition to developing alloantibodies, some patients awaiting renal, heart, or pancreas transplants may have produced a variety of autoantibodies as a result of their primary disease or pregraft therapeutic modalities.

In marked contrast to the well-developed and sharply defined response obtained in alloimmunization of pregnancy, the immunologic response to a clinical allograft is somewhat impaired. Under these circumstances, the antibody producer is an unhealthy individual whose immune system has been compromised as a result of disease; this unhealthy immune system has been further compromised deliberately by immunosuppressive drugs. This doubly impaired immune system is then presented with an antigenic challenge as a single bolus containing a large variety of antigenic specificities. The result is a broad polyclonal response directed against a host of cross-reactive antigens, some of which may not even be represented on the graft.

The quality of the antibody response to blood transfusion may be classified as falling somewhere between that of pregnancy and that of transplantation. In this case, the subject is an unhealthy individual whose immune system may be somewhat depressed as a result of uremia, but the patient has not been pharmacologically immunosuppressed. The antigen is introduced intravenously, a route that is optimal for tolerization by soluble HLA antigens shed from the cellular components of the transfusion. On the other hand, the number of antigen-bearing cells, leukocytes, and platelets in a unit of packed red blood cells is relatively small and decreases even further with time after the unit is drawn. As a result, multiple transfusions of units of blood are required to constitute an adequate antigenic dose. These units come from different blood donors whose cells display a variety of private specificities. The antigens that are most readily recognized by the immune system, therefore, are those directed against public specificities shared by the donors and those directed against private specificities that occur with relatively high frequencies in the general population. Patients undergoing transfusion routinely produce a spectrum of antibodies, including anti-HLA-A, -B, -C, and -DR.

The antibodies produced as a result of either of these challenges are IgG and IgM, though the IgG antibodies are frequently of low affinity. They are directed against a variety of HLA antigens and tend to react with the public specificities of the HLA cross-reactive groups. In addition, IgM antibodies with very broad specificities may be produced as well. Current data seem to indicate that, with some exceptions, these antibodies tend to disappear with time, and, in the case of transfusion-induced antibodies, fail to reappear upon secondary challenge (15).

Antibodies to class I HLA antigens can be directed specifically against private specificities or public specificities. Antibodies with private specificities are clinically relevant and are directed against epitopes formed by a unique amino-acid sequence that forms a single specificity. Antibodies to public specificities, on the other hand, define various cross-reactive groups. They have been the subject of a great deal of study to establish their importance in clinical transplantation.

Antibodies to the class II HLA antigens DR and DQ appear to be clinically significant with respect to adversely affecting graft survival. On the other hand, other antibodies that preferentially react with B cells but that have no apparent specificity for class II or class I MHC antigens may have little or no clinical significance. Many of these antibodies are composed of IgM immunoglobulin and react preferentially at 20°C or below. They are not very stable and can be inactivated by treatment with dithiothreitol (DTT) or other similar reducing agents (16).

Autoantibodies occasionally may be found in the sera of pretransplant patients who are suffering from diseases with a heightened immune response such as lupus nephritis. They tend to react with a patient's own cells in *in vitro* serologic tests and may sometimes have HLA specificity (17). In addition, autoantibodylike substances may be produced in response to certain drugs such as hydralazine or procainamide. These may not be true antibodies at all; they may be aggregated γ globulins or other macromolecules.

Autoantibodies appear to play no role in transplantation rejection, but they serve as an indicator of a patient's abnormal immune status and frequently interfere with the interpretation of serologic tests for alloantibody detection. Most often these antibodies are IgM and react preferentially at room temperature or below. However, their thermal amplitude is occasionally higher and they will react at 37°C. For the most part, such antibodies can be inactivated with DTT or removed by absorption with the patient's own cells.

Alloantibody Screening

Testing for donor-reactive antibody has been a routine part of histocompatibility evaluation for transplantation. Clinical benefits include: (i) the identification of unacceptable antigens; (ii) the detection of unreported or unrecognized sensitizing events; (iii)the selection of appropriate crossmatch techniques and interpretation of results; and (iv)the provision of an estimation of the likelihood of finding a crossmatch-compatible donor. Federal standards under Clinical Laboratory Improvement Amendments (CLIA) regulation, *Code of Federal Regulation* (CFR) 4933.1265, stipulate that sera from potential transplant recipients must be screened for preformed anti-HLA antibodies at the time of initial typing and, thereafter, following sensitization events. Laboratories must have a program to periodically screen serum samples from each patient.

Until recently, the federal standards required the use of lymphocyte targets for the detection of anti-HLA antibodies. However, in 1998 the Health Care Financing Administration (HCFA) ruled that solid phase immunoassays could be used for antibody screening, provided that each laboratory had documented validation of the assay's equivalent or superior sensitivity to cytotoxicity assays.

Screening procedures used in the pretransplant patient for antibody detection and identification must be designed to take all of the aforementioned characteristics into consideration. The approach is designed to uncover the total antibody content of a patient's serum and its characteristic reaction patterns. This information then is used to render a judgment regarding the interpretation of the pretransplant test between the serum of the patient and the cells of the donor with respect to the suitability of a given donor-patient combination. Therefore, it is essential to fully ascertain all of the properties of any antibodies involved. Are they public, private, or auto? Are they class I or class II? Do they react by the standard testing method, or do they require enhanced antiglobulin procedures? Finally, what is their expected frequency of positive reactions with the general population?

From these data, much important information may be derived, including an estimate of the likelihood of finding a cross-match–compatible donor among the random cadaver population in a given region. This, in turn, serves as the basis for a prediction of the waiting time for a given patient on the list. Additionally, from these data it is possible to predict the HLA types of donors who are likely to cause a positive cross-match and thus avoid unnecessary testing. Finally, the data derived permit the selection of optimal serologic cross-matching methods to ensure maximum sensitivity for antibody detection as well as the interpretation of any unexpected positive or equivocal results

Antibody Screening by Cytotoxicity (CDC) Methods

The patient's serum to be screened is tested serologically against a panel of cells whose antigenic composition has been predetermined according to rigorous standard typing criteria. The distribution of positive reactions is compared with the distribution of each of the known HLA antigens in the cell panel. The specificity of the antibody in the serum is equivalent to the antigenic specificity in the panel that most closely matches the distribution of positive reactions. The match will hardly ever be exact, because most frequently the sera contain a mixture of antibodies. In addition, the sera may contain a heterogeneous population of antibody molecules that have a spectrum of affinities for antigen. As a result, although the observed pattern may be similar to that for a particular antigen distribution, discrepancies will occur and a certain degree of uncertainty will be experienced.

The serologic methods used in screening patient sera should be the most sensitive available. One of the purposes is to learn as much as possible about the reactivity of a given patient's serum during a time of relative leisure and to predict how it will behave in the cross-match procedure performed under more stressful conditions and time constraints.

Ordinarily, the screening is performed using panels of purified T cells for the detection of class I antigens and purified B cells for the detection of class II antigens, as well as the patient's own cells to detect autoantibodies.

The practice of treating all sera prior to screening and cross-matching with dithiothreitol (DTT) to eliminate bothersome and clinically insignificant reactions from IgM antibodies has been advocated. Although this practice saves some time, it masks the presence of IgM antibodies and occasionally may dilute weak IgG antibodies, thus inhibiting their activity beyond their threshold of detectability. It is preferable to recognize that the serum of a particular patient may contain an IgM antibody so that it can be dealt with accordingly and the serum's reactivity interpreted intelligently.

Antibody Screening by Solid-Phase Immunoassays

Solid-phase immunoassays employ solubilized HLA antigens coupled to a solid matrix. The solubilized antigens are obtained after detergent solubilization of membrane antigens from pools of cells or from established cell lines. The solid matrix may be either the polystyrene wells of microtiter plates or latex beads. Coupling of the antigens to the matrix is accomplished by a “Capture antibody” consisting of an anti-HLA, class-specific antibody or by a chemical bond. Patient serum samples are incubated with the antigen-matrix and then washed to remove unbound antibodies. Specific antibody binding then is assessed by the addition of antihuman immunoglobulin conjugates. Conjugates used as reporter molecules for these assays usually are either enzymes that are used for enzyme-linked immunoassays (ELISA) or fluorochromes for immunofluorescent assays using flow cytometry as described below (18, 19).

In the ELISA assays, enzymes such as peroxidase or alkaline phosphatase permit visual detection of specific binding when their appropriate substrate is added. Cleavage of the substrate yields a chromogenic reaction product that can be visualized. In addition to the initial evaluation performed by laboratories to ensure the compatibility, equivalence and reproducibility of ELISA assays, each test run must include proper controls including those for nonspecific binding to verify the accuracy. In addition, patient sera must be tested at dilutions optimal for the assay in use. Results are dependent upon the optical density (OD) observed in the test wells. Cut-off values for reactivity above that of known negative controls must be established for each assay.

With some commercially available ELISA assays, computer software programs are available that allow the derivation of PRA values from the pattern of raw scores of ODs observed in the test wells. Assignment of antibody specificity for a given HLA antigen is performed by statistical programs in the software that determine the degree of concordance between the reactivity of a serum sample and the presence or absence of antigen. However, final results should still be reviewed by an experienced technologist familiar with cross-reactive epitope groups (CREGs) and linkage disequilibrium.

The complement-dependent cytotoxicity (CDC) assays have a number of disadvantages including the requirement for large panels of viable cells to cover all HLA specificities, the subjective reading of the tests, and the difficulty in differentiating HLA specificities in the presence of non-HLA cytotoxic antibodies. The solid-phase immunoassay offers several advantages in that it detects antibodies specific to HLA antigens, provides increased objectivity and reproducibility, it eliminates the need for a viable lymphocyte cell panel and can be performed in the face of immunosuppressive drugs, cytotoxic pharmaceuticals, and monoclonal antibodies. In addition, ELISA assays can be automated and thus, can provide significant cost savings and achieve faster turn around time. The clinical significance of the antibodies detected by solid-phase assays recently was investigated and showed a strong correlation with transplant rejection and clinical outcome. Some reports suggested that ELISA-detected anti-HLA is more clinically informative than CDC-PRA and correlates with the delineation of pre- and posttransplant immunologically high-risk allograft recipients.

Statistical Analysis of Antibody Screening Data

To interpret the results, the reaction patterns are normally analyzed using statistical methods that allow for a measure of this

uncertainty. If the level of uncertainty is small, being a result of chance alone, the similarity observed between the reactions of the serum and the distribution of an antigen in the cell panel probably is real. On the other hand, if the level of uncertainty is large, then the differences may be real and the plausibility of similarity diminishes. The most frequently used statistic for this purpose is the 2 × 2 contingency chi-square test.

The following is an example of a 2 × 2 analysis showing the comparison of the reactions of serum S.J. with the distribution of HLA-B7 in the test cell panel.

		HLA-B7 +	HLA-B7 −	
Serum S.J.	+	43	2	45
	−	3	27	30
		46	29	75

The theoretical distribution of X^2 against which the computed value will be compared is a continuous distribution. The data, on the other hand, lead to a discontinuous distribution of computed X^2 values. In practice, it is customary to correct for continuity by employing the Yates correction factor (20). For the example given above, the corrected X^2 is computed as follows:

$$X^2_{\text{CORRECTED}} = \frac{([(43\cdot27) - (3\cdot2)] - [0.5\cdot75])^2\, 75}{(45\cdot30\cdot46\cdot29)} = 52.01$$

If the two events — namely the occurrence of the antigen and the positive reactions of the serum — are independent, then the X^2 value will be low. On the other hand, if the occurrence of a positive reaction depends on the presence of the antigen in a given cell (or, stated another way, the antibody defines the specific antigen in the panel), then the X^2 value will be high and will approach the number of cells tested (75 in this example), but will never quite reach it. In addition, the customary use of the Yates correction factor to correct for discontinuity further lessens this chance. The hypothesis that the serum is detecting the given antigen in the panel is accepted or rejected depending on the probability corresponding to the calculated X^2 value obtained from a table of the X^2 distribution for 1 df (degree of freedom). When the X^2 is low, the probability of independence between reaction patterns and specificity is high. When the X^2 is high, the probability is low. A probability in the range of 0.01 to 0.001 or less indicates that the serum reaction patterns most likely correspond to the antigen distribution pattern. In the example given above, the probability is less than 0.001. Therefore, the hypothesis that the serum S.J. most likely contains antibodies with HLA-B7 specificity may be accepted.

In practice, these calculations are performed with the aid of computer programs. The X^2 values are then ranked. Frequently, sera will give high values with more than one antigen because they are multispecific. A crude approximation of the range of specificities that is adequate for clinical work can be obtained by performing a careful examination of the antigen distribution among the cells in the panel and the resultant X^2 values that are significant. Extensive screening against highly selected cell panels to confirm the specificities implied by the initial studies is usually not performed for diagnostic purposes in pretransplant patients. A careful consideration of the preliminary screening data along with the HLA type of the patient and the typing data of the previous grafts, if any, usually will give a good indication of the HLA antigens to be avoided in future grafts.

The knowledge of the specificity of antibodies in patients' sera is essential in making a sound decision regarding the suitability of a given donor for a particular patient. In addition, it serves as the basis for computing a predictive measure of the possibility of finding a suitable donor among the cadaveric organs available from the general population. The predictive value is given by the percent or PRA. It is computed from the frequency in the local population of the antigens defined by the patient's serum when it was tested and gives a reasonable reflection of how the sera might be expected to react in cross-matches with donors from the random population. Over the years, this value has become a standard parameter for judging a patient's transplantability and is used as one of the criteria that govern a patient's clinical management.

In summary, antibody screening can be defined as the systematic examination, under controlled conditions, of a serum for its content and immunoglobulin type of antibodies directed against surface antigens of nucleated cells, and the analysis of the resultant data. The information sought from these data determines the methods and extent of the systematic examination and the resultant data analysis.

The useful information required for patient antibody screening includes an exhaustive characterization of the antibody reactivity under a variety of very sensitive serologic methods, a general feeling for the scope and range of its reactivity with an array of different specificities, and a measure of the frequency of its reactivity with cells from the random population expressed as PRA.

Donor-Specific Cross-Matching

Donor-specific HLA antibodies in the serum of a recipient prior to transplant are especially significant. Such antibodies can readily combine with antigens on the grafted organ immediately after a blood supply is established and result in hyperacute or accelerated graft rejection. This can be avoided by performing a pretransplant cross-match in which a serum sample from the recipient is tested against lymphocytes obtained from the intended donor. A negative cross-match is an essential prerequisite for the performance of a transplant.

The serum sample from the patient must be one that best represents a sampling of the patient's anti-HLA antibody repertoire at the time the transplant will be performed. Ideally, this should be one collected just prior to surgery. Quite frequently, however, this may not be possible because of practical considerations. For example, the test itself is time consuming: if the intended recipient is not readily available to provide a serum sample, donor organ ischemia time might be prolonged to the point where irreversible damage could occur. Similarly, the recipient is usually one of several candidates; therefore the identity of the actual recipient might not be known. For these reasons, serum samples

are collected from potential recipients of cadaveric organs at monthly or more frequent intervals, especially those coinciding with the peak of an immunizing event such as a blood transfusion. These samples are carefully preserved in the frozen condition to be used for cross-matching with a potential donor.

Standard immunologic dogma dictates that once a patient formed an HLA antibody it would be of significance even after it had disappeared from the serum. Such antibodies might remain at undetectable levels or could be rapidly produced in a secondary response upon reexposure to antigen. Consequently, historical serum samples containing the maximum levels of antibody reactivity should be used routinely in cross-matches along with current samples. A positive historic cross-match would be considered to be a contraindication to transplantation with that particular donor. There is some controversy regarding the point that this does not hold true in cases in which HLA antibodies disappear prior to a first transplant (15). Nevertheless, it is worthwhile to consider that in such cases, the antibodies developed before the graft are most likely the result of exposure to HLA antigens present in blood transfusions. Apparently, the response produced to such an immunization does not result in long-term immunologic memory. Therefore, positive cross-matches with historical sera are frequently disregarded in such cases. On the other hand, in cases involving transplant immunization such as found in cases awaiting a second or third transplant, the reactions of historically positive sera with the potential donor are most important (16, 21). It seems that patients immunized or in conjunction with a previous graft develop strong immunologic memory and can produce a brisk secondary response when rechallenged with the offending antigen.

Traditionally, the cross-match is performed using a sensitive modification of the microlymphocytotoxicity test. Many centers employ the antiglobulin technique; others opt for an extended incubation of the antibody-lymphocyte mixture; still others favor some modification incorporating one or more wash steps prior to the addition of complement. However, any method selected should be capable of detecting the varieties of antibody found in the patient's serum during the pretransplant antibody screening. Thus the importance of pretransplant screening cannot be overemphasized. This procedure allows a detailed and accurate assessment of the antibody repertoire carried by the patient in a relatively leisurely manner rather than under the stresses associated with a cadaveric donor organ harvest and the overzealous anticipation of a possible transplant.

When using a cadaveric donor, the lymphocytes of choice are prepared from excised lymph nodes or a section of spleen obtained in conjunction with organ harvesting. The nodes should be kept moist after their removal and during delivery to the laboratory. Some workers advocate the use of peripheral blood from the potential donor in order to save time. This is a debatable point. The peripheral blood cells of patients who have been kept on life support systems may be unsuitable for use in the cytotoxicity test for a number of reasons, including the effects of antemortem steroids administered to reduce cerebral edema. Consequently, uninterpretable results may often be obtained, requiring the tests to be repeated. Thus, little time is saved and the expense of duplicate work is incurred.

It is best to perform the cross-match using pure T cells as targets (22). This is good practice, because anti-HLA class I antibodies are the most frequently encountered and the most clinically significant. In addition, many types of patients such as those with lupus erythematosus, certain diabetics, and others often demonstrate nonspecific autoreactivity. This is most frequently directed against B cells and seems to have no clinical significance. If mixtures of T and B cells are used in the cross-match with the sera of such patients, they would give a positive result. Therefore, a transplant would be denied because of a false-positive reaction.

In contrast to nonspecific B-cell antibodies, those directed against class II HLA antigens are of definite clinical relevance; associated with increased graft rejection and graft loss. In addition, positive B-cell cross-matches have been implicated in early rejection of both cardiac and lung transplants. Pretransplant HLA class II antibody screens should be designed for their detection and identification. In addition, cross-matches with the serum of patients containing such antibodies should be performed using suspensions of B cells.

Application of Flow Cytometry Techniques in Potential Solid Allograft Recipients

The application of flow cytometric techniques in the pretransplant work-up of potential solid allograft recipients has grown rapidly during the past decade. One of the most important applications is the flow cytometric crossmatch (23, 24). CDC is adequate for routine crossmatching in that it detects most antibodies that are responsible for hyperacute graft rejection. However, this method does not detect low concentrations of antibodies that may not be the cause of hyperacute rejection; but nevertheless may be responsible for an accelerated rejection of the graft.

Several reports have shown that low levels of alloantibodies, undetectable by CDC, could be detected by flow cytometry. This technique is more sensitive since it is not dependent on complement binding. In these studies, renal transplant recipients exhibiting a negative CDC assay but a positive flow cytometric cross-match were more likely to experience early accelerated rejection episodes, an increased number of such episodes and early graft failure. The patient groups more likely to experience this type of rejection were those individuals who were previously alloimmunized from a rejected transplant, multiple pregnancies, or multiple blood transfusions. Thus the flow cytometric cross-match may be important in identifying a subgroup of patients who would be at increased risk for graft failure or for a more complicated posttransplant clinical course.

The flow cytomeric cross-match offers additional advantages over CDC. It can identify IgG antibodies specifically without the additional treatment of patient's serum with DTT. Furthermore, cell viability is not as critical for the flow cytometric cross-match because the dead cells can be gated-out by light scatter and/or viability stains. Furthermore, it is unnecessary to prepare separate suspensions of T cells and B cells; because these can be identified by specific monoclonal antibodies. Finally, the interpretation of the flow cytometric cross-match tends to be more objective in that CDC assays rely on the visual scoring of stained cells that can be influenced to a significant degree by reader bias.

Reagents

The most critical reagent for the flow cytometric cross-match is the secondary antibody. This reagent is used to identify the human

immunoglobulin that is specifically bound to the target cell. Thus, the reagent selected should provide optimum specificity with low background staining. In addition, the secondary antibody must not cross-react with mouse or horse immunoglobulins. Importantly, each lot of secondary antibody should be tested using a checkerboard titration to determine the optimum working dilution. Depending upon the cell population to be evaluated, appropriate monoclonal secondary antibodies are selected based on their specificity for the desired cluster antigen and their fluorochrome tags. Most laboratories utilize a fluorescein-conjugated secondary antibody.

The flow cytometric cross-match requires both a positive and a negative control serum. The most common sources of target cells are mononuclear cells derived from peripheral blood, lymph nodes, or spleen. Only a small number of cells is needed. One of the important variables is the ratio of patient's cells to the volume of patient's serum used in the test. Increasing the volume of serum used per tube or decreasing the number of cells per tube will increase the sensitivity. Thus, it is important that the laboratory establish its staining protocol and strictly adhere to methods that provide the accuracy and consistency of cell and serum concentrations and volumes.

Critical Points in the Flow Cytometric Crossmatch Procedure

As indicated above, the ratio of serum volume to number of cells is important because it can affect the sensitivity of the assay. A second point relates to the number of wash steps used following the primary antibody incubation. Washing is done in order to ensure that residual immunoglobulins are removed prior to the addition of the secondary antibody. Insufficient washes may result in a weak or even a false-negative cross-match. A third point relates to the nature of the secondary antibody used. It is important that the anti-human immunoglobulin reagent does not cross-react with mouse immunoglobulins because the directly conjugated monoclonal antibodies used to define T- and B-cell populations are of mouse origin. Cross-reactivity with these immunoglobulins will render the crossmatch uninterpretable. Finally, in preparing patient and control sera it is useful to airfuge (100,000 g for 15 min.) all sera prior to testing. This type of ultracentrifugation removes immunoglobulin aggregates that may produce nonspecific background staining, particularly with B cells, because of Fc receptor binding.

Standards and Controls

Each laboratory must establish its own set of standards and controls for the performance and the interpretation of the flow crossmatch. The choice of adequate controls is very important. Care must be taken to ensure that the normal human serum selected for use as a negative control is free of any anti-HLA antibodies. This reagent can be either a pooled or a single-donor serum. However, it must be tested thoroughly with a number of different normal cell donors to ensure that the reagent has no reactivity with human lymphocytes.

The positive control is usually a pool of sera from patients who are known to have high levels of anti-HLA antibodies. Such a pool can be diluted several fold and stored for use. This reagent should be used at a dilution that yields a reasonable shift in fluorescence (displacement between 100 and 300 channels) that is below a level of saturation.

Despite the potential of flow cytometry to provide quantitative data, the flow cytometry cross-match is used mostly as a semiquantitative test; i.e., negative, weak, or strong positive. Fluorescent intensity results may be expressed as either channel shift or fluorescence ratio and can show a high degree of variability among different laboratories. Using a cutoff value of two standard deviations, one can define a channel value that can be used as a discriminator for positivity.

Alternative methods also can be used including the utilization of semi-quantitative methods for determining the relative immunofluorescence of the attached molecules. Using a mixture of beads, each with a different level of fluorescence, one can perform a relative calibration of the flow cytometer. Subsequent channel values then can be converted to the number of Molecules of Equivalent Soluble Fluorochrome (MESFs). Results then are reported in MESF units and the determination of positive is made by indicating a minimum MESF value above which a cross-match is considered positive. At present, it is uncertain whether results expressed as MESF units are more advantageous and whether they can reduce the variability among laboratories than results expressed as channel shift. The American Society for Histocompatibility and Immunogenetics has published standards for the performance of flow cytometric cross-match for transplantation.

Results and Interpretation

Data acquisition is performed usually after setting gates around lymphocyte populations. Post acquisition analysis is performed next by gating on a selected fluorescence specific for T- or B-cell populations. In a three-color cross-match, fluoresceine isothiocyanate (FITC) can be used as the conjugate for the anti-IgG reagent; in conjunction with phycoerythryn-conjugated CD20 (specific for B cells) and PerCP (Peridinin Chlorophyll protein)-conjugated CD3 (specific for T cells). Following acquisition of lymphocyte-gated data, individual regions are set around CD3- and CD20-positive cells. This is performed by displaying a dot plot of CD3 versus CD20 (Fig. 37.2). Subsequently, analysis of the FITC staining can be made by displaying a single parameter histogram for the CD3 region or from the CD20 region (Fig. 2). Following completion, the median channel value for each cell population is recorded. This three-color combination allows for the simultaneous detection of alloantibodies reacting with T cells and B cells and eliminates background staining from NK cells and monocytes. Each laboratory must establish its own cutoff for determining the magnitude of channel displacement to be considered a positive result.

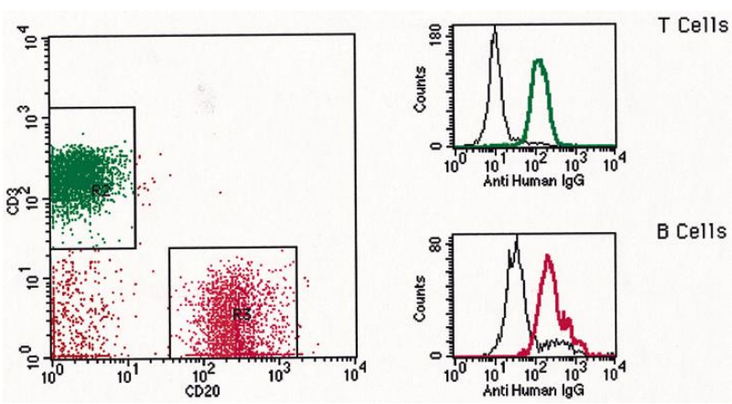

FIGURE 37.2. Three-color flow cytometric crossmatch. **Left:** Dot-plot displaying CD-20 PE staining of B cells (x axis) versus CD3-PerCP staining of T cells (y axis). **Right:** single parameter histogram of T and B cells. Staining fluorescence with the normal human serum control is shown in black; staining fluorescence observed with a positive serum sample is shown in green and red color for T and B cells respectively (Becton Dickinson FACSCalibur Cytometer; 4-decade log scale; 1056-channel resolution; CellQuest analysis).

One of the general problems in evaluating the significance of crossmatching by any technique is in the establishment of anti-HLA antibody specificity. Thus, in addition to crossmatching, routine antibody screening also should be performed by sensitive techniques that can detect antibodies specific to HLA class I and class II antigens. This knowledge is key to interpreting cross-match results. The second problem is the determination of the clinical relevance of a positive flow cytometric crossmatch.

Knowledge of the patient's clinical history is most important. There certain individuals who, under appropriate immunosuppression, could achieve a good transplant outcome despite a positive-flow cytometric cross-match. Thus a positive-flow cytometric cross-match will not always constitute a contraindication to transplantation. The identification of this type of patient depends heavily on the patient's sensitization history, as well as biological and clinical parameters.

In addition to the cross-match, flow cytometry also can provide very useful information on routine antibody screening. Significant levels of anti-HLA antibodies can be detected by flow cytometry in patients whose cytotoxic PRA was 0%. Flow cytometric PRA can be performed using pooled cells that are selected based on their CREG antigens. More recently, a microparticle assay utilizing purified HLA class I and HLA class II proteins coated onto beads has been used successfully to detect antibodies to HLA class I and class II antigens. Class I and class II beads can be admixed so that patient serum can be simultaneously assessed for the presence of class I and/or class II. Newer configurations of the microparticles have been designed recently, which can identify the specificity of the antibodies.

Evaluation of Tolerance to Donor HLA Antigens and Post Transplant Monitoring

Recipient's T cells can recognize allogeneic HLA molecules by two distinct routes: either directly as intact molecules or indirectly as peptides produced as a result of antigen processing. The direct recognition pathway is thought to be the primary mediator of acute allograft rejection and can be observed as antidonor mixed-lymphocyte culture and cell-mediated lympholysis reactivity exhibited by the recipient's T cells. Experimental work to date has shown that indirect presentation of allogeneic MHC molecules can occur not only *in vitro* but also *in vivo* where it can influence graft rejection. The precise role of this route of antigen presentation is yet to be established, although there is strong circumstantial evidence that this pathway is important in the initiation of chronic or late graft rejection and the induction of unresponsiveness following allogeneic transfusion. Late in the transplanted organ's course, donor MHC class II positive-passenger lymphocytes will have been depleted from the graft, but cells expressing MHC class I and class II alloantigens are likely to be shedding these antigens into the circulation. Recipient antigen presenting cells (APC) would then be able to process these allo-MHC molecules and present them as peptides to recipient CD4+ T cells. This would result in the activation of cellular and humoral effector mechanisms. That such a scenario highly likely is evidenced by the fact that tolerizing strategies targeting T cells that recognize MHC antigen indirectly are being explored as possible therapeutic and/or prophylactic modalities.

The development of useful immune or surrogate markers of tolerance to donor HLA antigens that are measurable by standardized and reliable biological assays is very desirable. Such markers should be capable of measuring the effect of immunomodulating intervention on clinical outcome in transplantation. The measure of immune responses should include the

quantitation of lymphocyte responsiveness to donor alloantigens using methods such as proliferation assays, cytotoxicity activity, *de novo* antibody production, and cytokine secretion.

Several assays are available that can be used in monitoring the posttransplant immune status of patients receiving solid organ grafts. These include the monitoring of the levels of anti-HLA antibodies directed against graft antigens, the monitoring of the appearance of various forms of soluble HLA antigens discussed below, as well as several cellular assays.

Although antibody screening is a mandatory pretransplant procedure, antibody screening also is useful for posttransplant monitoring. The advent of antibody detection using soluble HLA antigens and ELISA or flow cytometric techniques has allowed for the reliable detection of all classes of anti-HLA antibodies in the posttransplant period. These methods circumvent the constituents found in post-graft sera that make the cytotoxicity procedure unreliable. These include such elements as immunosuppressive drugs and anticomplementary proteins.

The data being accumulated thus far using ELISA techniques indicate that screening for newly formed HLA antibody may be a useful procedure for graft monitoring. It has been demonstrated that the production of HLA antibody directed against graft antigens is correlated with the incidence of severe graft rejection episodes that can lead to decreased graft survival. This allows for the identification of patients at risk and allows for the more rapid employment of therapeutic steps to prevent excessive damage to the graft.

Cellular assays might include the monitoring of graft-infiltrating cells obtained from biopsy material and can be accomplished by evaluating *in vitro* lymphocyte growth in response to IL-2. Another assay might consist of measuring the number of T cells participating in the indirect pathway of allorecognition. This can be measured by limiting dilution analysis of the precursor frequency of $CD4^+$ cells recognizing synthetic allopeptides that correspond to polymorphic regions of the mismatched donor MHC class II antigens.

Currently, the use of assays such as the ones described is experimental. Data collected from retrospective studies strongly suggest that this type of monitoring should be highly useful in the management of the posttransplant patient. Such assays would be a more direct indication of the patient's response to the allograft at the level of the immune response. Current monitoring strategies consist of biochemical assays to measure graft physiology and in most cases, graft biopsies. Such biopsies are invasive and may be subjective and prone to error. In addition, once the biopsy is positive the damage to the graft already has occurred. Therefore, immunologic assays would be superior. However, rigorous prospective studies are needed to evaluate the clinical utility of these assays.

Soluble HLA Antigens and Their Peptides

The relationship of soluble HLA (sHLA) proteins to the graft-host relationship is a double-edged sword. On one hand, several laboratories have demonstrated tolerance to allograft following the pretreatment of experimental animals with soluble forms of MHC class I and class II antigens, or derivative donor allopeptides. Soluble specific HLA complexes cause allospecific $CD8^+$ T cells to undergo apoptosis *in vitro*. It was recently suggested that this could be relevant for tolerance induction after liver transplantation. Hepatocytes are an important source of sHLA class I molecules, which *in vivo* may induce apoptosis of alloreactive T cells in a similar way. It now appears that sHLA may be part of an elaborate system for regulation of cytotoxic T lymphocyte (CTL) by soluble forms of membrane bound HLA proteins that may be involved in the maintenance of peripheral tolerance (26). Furthermore, soluble HLA-C molecules can form complexes with the NK receptor. This interaction leads to inhibition of the NK cells (25).

On the other hand, there is evidence for donor-specific HLA class I antigen release in organ transplant patients as an indicator of transplant rejection. ELISA measurements of serum for sHLA class I mismatched antigens in patients with acute or chronic rejection showed increased serum levels of donor sHLA-A and -B in heart, lung, and kidney recipients. No detectable donor sHLA (over pretransplant background) could be found in the sera of nonrejecting recipients. However, not all rejections in all patients lead to detectable soluble donor HLA release (27). The reason for this remains unknown.

Recent studies have suggested a possible explanation for the “good” versus “bad” soluble HLA proteins. Biochemical studies using the western blot technique to define the molecular weights of various forms of sHLA class I released in liver transplant recipients, indicated that a proteolytic cleavage mechanism might be operative in acute rejection. Metalloenzymes on the membrane of the graft parenchymal cells might be responsible for the release of rejection-associated soluble HLA molecules. These soluble β_{2m}-free truncated forms of HLA class I molecules are highly susceptible to proteolysis and, because they contain polymorphic donor peptide sequences, would be a readily available substrate for spreading the T helper cell alloresponse. In contrast, the β_{2m}-associated forms that are released by well functioning organ allografts, may promote allograft tolerance by inhibiting “direct pathway” CTL responses, while activating a suppressive “indirect pathway” T-cell response to a few immunodominant epitopes.

Clinical Immunosuppression

A discussion of laboratory testing in organ transplantation would not be complete without describing some of the pharmacological approaches to immunosuppression, their sequelae, mode of action, and possible laboratory monitoring. In transplantation, there are three main uses of immunosuppressants: to (i) induce initial acceptance of a graft (induction therapy) using heavy doses to prevent rejection and favor the tolerance response; (ii) to reverse a rejection episode (acute-rejection therapy) using heavy doses to reverse an established rejection and; (iii) for maintenance, using moderate doses to prevent rejection but preserve host defense mechanisms.

Several immunosuppressive drugs are used in transplantation, all of which can be toxic by virtue of the induction of immunodeficiency. This may result in infection as well as certain malignancies such as skin cancer, and B-cell lymphoma. In addition, many of these drugs may have a direct deleterious effect on nonlymphoid cells such as kidney or bone-marrow stem cells. The

list of the currently approved immunosuppressants includes azathioprine (AZA), corticosteroid, Cyclosporine (CsA), Tacrolimus (FK506), Atgam (Upjohn, Kalamazoo, Michigan), anti-CD3 (OKT3), and mycophenolate mofetil (Table 37.4).

TABLE 37.4. CLASSIFICATION OF IMMUNOSUPPRESSIVE AGENTS

Pharmacological Agents	
1. Immunophilin binding drugs	a) calcineurin inhibitors: cyclosporine[a], FK-506[a]
	b) calcineurin independent actions: rapamycin
2. Inhibitors of cell division/nucleotide metabolism	a)nonselective antiproliferative and cytotoxic drugs: azathioprine[a], cyclophosphamide[a]
	b)lymphocyte-selective specific drugs: mycophenolate mofetil[a]
3. Corticosteroids[a]	
Biological Agents	
1. Antibodies	a) polyclonal antilymphocyte: horse anti-thymocyte globulin[a], rabbit antilymphocyte or antithymocyte globulin
	b) murine monoclonal: anti-CD3 (OKT3)[a], anti-CD4 (OKT4), anti-LFA, anti-ICAM
	c) humanized monoclonals: anti-IL-2R α chain
2. Fusion proteins	CTLA4Ig, IL-2 toxin
3. Cytokine and cytokine receptors	
4. Peptide therapy	

[a] Agents released in the United States of America

AZA is a purine analog and an antiproliferative agent that suppresses the proliferation of activated B and T lymphocytes. It now is used most often as a supplement to CsA, but was used widely along with steroids for maintenance immunosuppression before the introduction of CsA. The major nonimmune toxic side effect of AZA is marrow suppression. Other important side effects include hepatotoxicity and the usual immunodeficient toxicity.

Corticosteroids are used for maintenance immunosuppression as well as for treatment of acute rejection episodes. The pharmacological effects of steroids are complex and their mechanism of action is not fully understood. The side effects of corticosteroids are numerous, dose-dependent, and contribute significantly to the morbidity of transplant patients.

CsA is a natural cyclic amino acid peptide, isolated from fungi. It has been an essential component in most immunosuppressive protocols in transplantation. FK506 can now be substituted. CsA acts by binding to cyclophilins and the resultant CsA-cyclophilin complex is the active drug. This complex inhibits calcineurin (CN), a serine protein phosphatase. Inhibition of CN prevents or reduces the activation of several CN-dependent transcription factors such as IL-2 and other cytokine genes, as a result, CsA inhibits the transcription of several T-cell cytokines and the proliferation of T cells. The most important nonimmune side effect of CsA is nephrotoxicity, which may be confused with rejection in renal transplant recipients. Levels of this drug in patients' sera must be carefully monitored biochemically to ensure that optimum but not excessive blood levels are maintained.

Tacrolimus (FK506) is a macrolide antibiotic. Its mode of action is analogous to CsA. FK binds to an immunophilin, FK-binding protein. The resultant complex then interacts with CN and inhibits its action in the same manner as CsA. FK is much more potent and toxic than CsA. It has been used most extensively in liver transplantation as an alternative to CsA. There is currently no definitive evidence that FK is more effective than CsA in renal transplants for patient and graft survival, but clinical trials are in progress.

Atgam is a horse serum containing polyclonal antilymphocyte antibodies. The immunosuppressive activity of Atgam is mediated through the depletion of circulating T lymphocytes. Atgam also blocks the function of T cells and inhibits their proliferative activity. Because Atgam severely impairs cellular immunity, patients treated with Atgam are prone to develop opportunistic infections and malignancies. Other important side effects include skin rash, serum sickness, leukopenia, and thrombocytopenia.

OKT3 is a murine monoclonal antibody against the CD3 complex of molecules on the surface of T cells. OKT3 was released for the treatment of acute rejection, where it is very effective. It also has been widely used for induction immunosuppression in sensitized patients and in patients with delayed graft function. However, concern over the emergence of early proliferative disease in patients treated with OKT3 has somewhat limited its prophylactic use. The immunosuppressive effects of OKT3 are mediated mainly through the depletion of circulating T lymphocytes and modulation and removal of CD3 molecules from the cell surface, thereby making the T cells nonfunctional. The most common side effect of OKT3 is the cytokine-release syndrome. This is characterized by fever, chills, nausea, diarrhea, and myalgia. As with Atgam, OKT3 therapy significantly impairs cell-mediated immunity. As a result, patients receiving OKT3 also are predisposed to opportunistic infections and malignancies. Patients undergoing Atgam and/or OKT3 therapy should subjected to the regular monitoring to assess the number of T cells in their circulation.

Mycophenolate mofetil is a new immunosuppressive agent that has recently been introduced in transplantation. Its active metabolite is mycophenolic acid (MPA). It selectively inhibits lymphocyte proliferation and has been developed as a replacement for AZA. *In vitro*, MPA has been shown to inhibit antibody formation and inhibit cytotoxic T-cell generation. In clinical trials, the incidence of acute rejection in patients treated with

mycophenolate mofetil is reduced by 40% to 50% as compared to placebo or AZA. It is hoped that by reducing the incidence of early graft rejection, mycophenolate mofetil also may improve the long-term outcome of the renal transplant recipients. The major side effects are gastrointestinal. In contrast to AZA, mycophenolate mofetil does not induce nephrotoxicity, hepatotoxicity, or significant bone-marrow suppression.

There has been some controversy regarding the benefit of HLA matching in the era of newer modalities of immunosuppression. This occurred first when cyclosporine, a remarkable immunosuppressive drug that made liver transplantation a reality was introduced. However, even then studies showed that HLA matching could improve kidney graft survival by 10% to 15%. Therefore, even with the use of powerful new immunosuppressives graft survival could be improved even more by donor selection based on HLA matching (Table 37.5).

TABLE 37.5. SELECTIVE MATCH GRADES FOR PLATELET TRANSFUSION[a]

Match Grade	Extent of HLA Matching	Example		
A	Four HLA-A,B antigen match	A2,30,B12,7	→	A2,30,B12,7
B1U	One HLA antigen is unknown	A2,?,B12,7	→	A2,30,B12,7
B2U	Two HLA antigens are unknown	A2,?,B12,?	→	A2,30,B12,7
B1X	One antigen is cross-reactive	A2,30,B12,**27**	→	A2,30,B12,7
B2X	Two antigens are cross-reactive	A2,**33**,B12,**27**	→	A2,30,B12,7
BUX	One antigen unknown, one cross-reactive	A2,**?**,B12,**27**	→	A2,30,B12,7
C	One major antigen mismatch	A2,30,B12,**5**	→	A2,30,B12,7
D	Two or more major mismatches	A2,**10**,B12,**5**	→	A2,30,B12,7

TRANSPLANTATION: BONE MARROW AND STEM CELLS

Part of "37 - HLA: Applications"

The HLA system is of vital importance in bone marrow transplantation. This subject will be covered in detail in Chapter 38.

PLATELET TRANSFUSION

Part of "37 - HLA: Applications"

Patients receiving repeated infusions of platelet concentrate over long periods of time frequently become refractory. They fail to achieve an incremental increase in their platelet count proportional to the number of platelets transfused. It has been shown that this condition results from the development of antibodies frequently produced in response to class I HLA antigens expressed on the surface of platelets. HLA class II antigens play no role in this phenomenon.

The use of HLA-matched platelets is beneficial in many of these cases for achieving normal platelet survival in the immunized patients and the prevention of immunization in the immunologically virgin patient (28). However, exact HLA matching for platelet transfusion may not be possible for practical reasons. Fortunately, not all HLA antigens are expressed on platelets with equal strength. Furthermore, it has been shown that matching for some of the antigens as outlined in Table 37.5, together with matching for CREGs is adequate to achieve successful clinical results (29).

The selection of the type of matched product — whether matched for private antigens or matched for CREGs — depends entirely upon the patient. Platelet recipients can be divided into three groups. The first consists of patients who are nonresponsive and never become refractory. The second group are those who become refractory to random donor platelets but tolerate HLA-matched products. These may be further subdivided into those who require HLA-identical products from siblings and those in whom platelets matched according to the schemes outlined above result in adequate increments and provide adequate hemostatic function. The third group are those who become refractory very quickly after a minimal number of random units and cannot tolerate even very well-matched platelets.

Another strategy for obtaining good platelet survival in refractory patients is based on good antibody screening and identification. Extensive antibody screening using either cytotoxicity or ELISA techniques is carried out on patient serum samples collected over a period of time. All of the antibody specificities are identified and listed. Platelet donors are selected who carry none of the specificities against which the patient has antibodies. Using this scheme, the data indicate a good *in vivo* response for HLA nonmatched but antibody-compatible platelets as opposed to antibody-incompatible platelets (30). This system appears to achieve the best results except in those patients that are refractory for reasons unknown.

DISEASE ASSOCIATION

Part of "37 - HLA: Applications"

The association of HLA types with various diseases has been the subject of intense investigation (31). Originally discovered as a chance observation and later enforced by the finding of a strong association between ankylosing spondylitis and the presence of the infrequent antigen HLA-B27, this line of investigation has led to a clearer understanding of some of the disease processes themselves. For example, diabetes mellitus has been reclassified into two distinct types. Juvenile-onset, insulin-dependent diabetes, or type I diabetes mellitus, is strongly associated with HLA; whereas type II or maturity-onset diabetes shows no apparent association. As a result of these findings it is now recognized that each of these types is a clinically distinct disease entity with its own pathogenesis.

In discussing the concept of HLA and disease, it is important to recognize the distinction between association and linkage. It is tempting to speculate that the reason for the observed relationships

between the occurrence of a given disease and the presence of a particular HLA antigen is linkage. However, linkage implies a formal genetic analysis of family inheritance patterns and indicates that two loci are situated closely enough on the chromosome to allow crossing over to occur less than 50% of the time. With the exception of diseases that exhibit familial tendencies, most of the studies carried out with respect to HLA and disease have been population studies that do not permit formal genetic analysis.

Indeed, such analyses have shown that genes responsible for hemochromatosis, for deficiencies in 21-hydroxylase (resulting in congenital adrenal hyperplasia), and for C2 are linked to HLA. Further studies resulting from these observations have revealed that the loci for 21-OH and C2 are not only linked to the MHC but are within the MHC itself. However, the majority of diseases studied in this manner exhibit association rather than linkage. Association of a particular HLA antigen with a certain disease is a statistical event established by comparing the frequency of the antigen in the disease population with its frequency in the normal population. The normal population in this case should consist of random individuals matched for racial composition with the disease population. A comparison is made using the X^2 statistic in a 2 × 2 contingency table and corrected for the number of antigens tested.

The strength of the association can be obtained by calculating the relative risk (RR) or the statistical chance that a patient with a certain disease will have the given HLA antigen. This may be computed either by the method of Woolf (32) or that of Haldane (33). Both of these are shown in the example given below. This example demonstrates the steps in the analysis of data obtained in a hypothetical study of the incidence of the antigen HLA-B27 among 40 patients suffering from ankylosing spondylitis and 904 normal control subjects.

	HLA-B27 +	HLA-B27 −	
DISEASE	[a] 35	[b] 5	[a+b] 40
CONTROL	[c] 67	[d] 837	[c+d] 904
	[a+c] 102	[b+d] 842	[n] 944

$$X^2 = \frac{(ad - bc)^2 n}{(a + b)(c + d)(a + c)(b + d)} =$$

$$\frac{[(35)(827) - (5)(67)]^2(944)}{(40)(904)(102)(842)} = 254.9$$

$$RR = \chi = \frac{ad}{bc} = \frac{(35)(873)}{(67)(5)} = 87.4$$

according to the method of Woolf; and

$$RR = X = \frac{[2(a + 1)][2(d + 1)]}{(2c + 1)(2b + 1)}$$

$$= \frac{(2)(35 + 1)(2)(837 + 1)}{(2)(67 + 1)(2)(5 + 1)} = 73.9$$

according to the method of Haldane. The X^2 value of 254.9 is highly significant and indicates that the higher incidence of HLA-B27 among the patient population is not the result of chance. In this example, both populations were tested only for the presence or absence of HLA-B27; consequently no corrections are required. However, when studying a disease for the first time, it is customary to test for a battery of HLA antigens. Because one would expect that some deviation from the normal distribution of antigen frequencies could occur from chance, the X^2 is corrected by dividing it by the number of antigens that were tested.

The RR of 87.4 given by the method of Woolf agrees with that published. The method of Haldane is designed to correct for small sample sizes and gives a value of 73.9. This is slightly less than the published value but is nevertheless quite significant in terms of its order of magnitude.

Associations have been shown to be of two types. Those in which the disease is associated with class I antigens are shown in Table 37.6. Those having strong associations with class II antigens are given in Table 37.7. Interestingly, the diseases have a strong immunologic flavor, being either diseases of the immune system itself or having autoimmunity as their underlying theme.

TABLE 37.6. SOME PROMINENT ASSOCIATIONS OF DISEASES WITH CLASS I ANTIGENS[a]

Disease	HLA	RR
Idiopathic hemochromatosis	A3	6.77
Vitiligo (Yemenites)	B35	13.9
Acute anterior uveitis	B27	10.4
Ankylosing spondylitis	B27	87.4
Reiter's disease	B27	37.0
Duodenal ulcer	B35	2.7
Subacute thyroiditis (de Quervain)	B35	13.7
Psoriasis vulgaris	Cw6	13.3

TABLE 37.7. SOME PROMINENT ASSOCIATIONS OF DISEASES WITH CLASS II ANTIGENS[a]

Disease	HLA	RR
Allergy (Ra 5 response)	DR2	19.0
Multiple sclerosis	DR2, DQ6	4.1
Narcolepsy	DQ6	>38
Celiac disease	DQ2	>250
Goodpasture's disease	DR3	15.0
Insulin dependent diabetes	DQ8	14
Systemic lupus erythematosus	DR3	2.6
Rheumatoid arthritis	DR4	9
Insulin dependent diabetes	DR4	15.4
Pemphigus vulgaris	DR4	14.4
Juvenile rheumatoid arthritis	DR8	8
Pernicious anemia	DR5	5.4
Nephrotic syndrome (steroid responsive)	DR7	5.9

[a]From Zmijewski CM. HLA and disease. *CRC Crit Rev Clin Lab Sci* 1984; 20:285–370.

Of particular note are rheumatoid arthritis (RA) and IDDM or type 1 diabetes. These diseases have been studied extensively at the molecular level and have yielded a great deal of innovative information. Both RA and IDDM are strongly associated with DR4. However, in the case of RA the association appears to be with the

DR molecules themselves; whereas in IDDM the association may be because of interactive effects of both DR and DQ loci (34).

HLA-associated diseases are caused by an interplay of different genes and environmental factors, in which HLA complex genes most often confer the strongest genetic predisposition. This can be illustrated by taking type 1 diabetes as an example. The concordance rate for this disease among monozygotic twins is between 35% to 50%. However, the concordance rate among HLA identical siblings is approximately 15% to 25%, compared to approximately 1% for siblings differing at both HLA haplotypes. This indicates that genes in the HLA complex are the most important for genetic predisposition, an idea that is consistent with the results of a genomewide search for susceptibility genes (34, 35).

Several autoimmune diseases seem to be associated primarily with peptide-presenting HLA molecules. As an example, susceptibility to develop RA is strongly associated with the DRB1*0401, *0404, *0405, and *0408 alleles (see Fig. 35.1). On the other hand, DRB1*0402 is not associated with RA and may instead confer protection. Interestingly, these genes all encode a very similar stretch of amino acids at DRß chain residues 67 to 74, with one important exception. At residue DRB71, the former genes encode the positively charged amino acids lysine or arginine. In contrast, DRB1*0402 encodes negatively charged glutamic acid at this position. Residue 71 points inward towards pocket four of the peptide-binding cleft of DR molecules. It may thus play a critical role binding peptides to the DR molecule. This suggests a direct involvement of given peptide-presenting DR molecules in the pathogenesis of RA (34 and references therein).

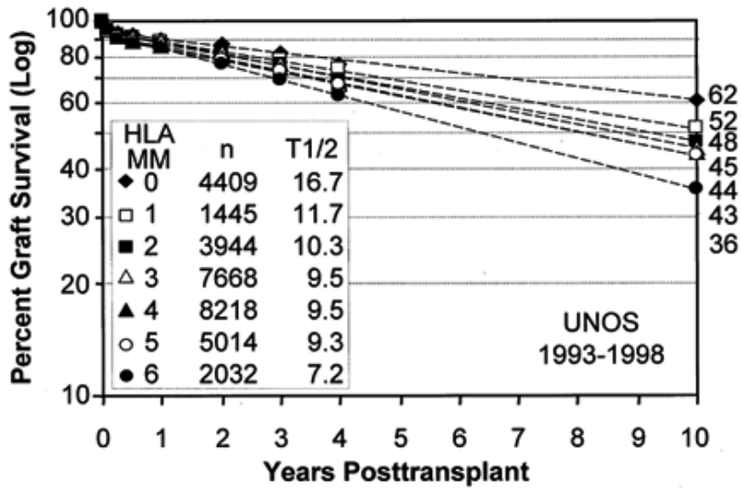

FIGURE 37.1. Survival of cadaveric kidneys according to HLA matching assuming a constant failure rate after the first year for all cadaver transplants performed between 1993 and 1998. This is based on UNOS Scientific Registry Data as of March 1999. Provided by M Cecka.

Similarly, in type 1 diabetes it appears that both susceptibility and protection are associated primarily with some class II HLA molecules. Because of the strong linkage disequilibrium that exists between genes in the HLA complex, it often is difficult to dissect the genes primarily involved in the disease from those genes that are secondarily involved due to gametic association. Susceptibility and protection are thought to be the result of the occurrence of certain HLA-DQ heterodimers. In most populations a stronger susceptibility to type 1 diabetes is found in DR3,DQ2/DR4,DQ8 heterozygotes, than in DR3,DQ2/DR3,DQ2 or DR4,DQ8/DR4,DQ8 homozygotes. Furthermore, disease susceptibility can be observed in patients from different populations who have combinations of the same DQA1 and DQB1 genes in either the *cis* or in the trans position. The susceptibility associated with the DQ heterodimer is strongly influenced by the accompanying DR4 antigen in the haplotype. Susceptibility is usually seen when the DRB*0405, *0402 or *0401 code for DR4. In contrast, little susceptibility but rather protection against the development of the disease is observed when either DRB*0406, *0403 or *0404 code for the accompanying DR4 antigen (34 and references therein).

It currently is believed that HLA-associated predisposition to develop type 1 diabetes is mainly determined by the combination of DQ and/or DR molecules of a particular individual in whom certain DQ and DR4 molecules appear to be most characteristic (34, 35). This may explain differences between populations with respect to susceptibility associated with particular DQ or DR molecules. For example, in most white populations, DQ8 is associated with susceptibility because it frequently occurs together with susceptibility-associated DR4 subtypes. In contrast, in the Chinese susceptibility may not be associated with DQ8 because in this population DQ8 often occurs together with the protective DRB*0406 or *0403 molecules.

Many of the HLA-associated diseases are associated with HLA molecules that share certain pockets in their peptide-binding clefts, which may play a critical role in determining which autoantigen-derived peptides can be bound. As discussed previously, the susceptibility-associated DR molecules in RA may preferentially bind an arthrithogenic peptide at pocket four that contains a negatively charged amino-acid residue. In diabetes, the DQ molecules associated with susceptibility often share an amino acid other than aspartic acid at position 57 on the DQß chain that is located in pocket nine of the peptide-binding cleft (36, 37). On the other hand, those DQ molecules associated with protection carry aspartic acid at this position. Although there are exceptions to this rule, the importance of positively or negatively charged amino-acid residues at position 57 suggests an important role for pocket nine of DQ molecules in the binding of pancreatic ß-cell–derived peptides; thereby conveying either susceptibility or resistance.

The biological mechanisms underlying the associations between HLA antigens and various diseases is not understood. A number of possibilities have been suggested, including antigenic mimicry, faulty immune response, or other susceptibility genes in gametic association with HLA. Each of these can be supported with a good deal of positive evidence. However, in each case there is an equally impressive body of contradictory evidence. Some of the newer approaches at the molecular level are producing an explanation for this most intriguing mystery.

PARENTAGE TESTING

Part of "37 - HLA: Applications"

The extensive polymorphism of the HLA system makes it a powerful tool in the resolution of litigation resulting from disputed parentage (38). The method is based on the logical genetic premise that cell membrane antigens or any other readily discernible phenotypic markers cannot appear in an offspring unless they are present in either or both of the parents. Applying this premise to the resolution of paternity, it can be concluded that if the putative father lacks an antigen expressed by the child that could not have been inherited from the mother (the obligatory gene), he is excluded from consideration as the biological father of that child. This is referred to as a first-order exclusion and is positive evidence that the accused man is not the father.

If the accused man expresses the obligatory characteristic he cannot be excluded. However, this finding does not offer proof that he is indeed the true father; it merely offers evidence against an exclusion. Nevertheless, based on the findings, a probability of the likelihood of his being the true father can be calculated. It is in this arena that the HLA system demonstrates its great potential.

The calculations used to compute the probability of true paternity are based on the frequency of the obligatory gene or combination of genes in a population of random individuals of the same race as the accused. Because the HLA system is so polymorphic, the frequency of ‘each combination usually is very low. Thus, if an accused does indeed have the obligatory gene or combination of genes, it is a simple probability calculation to show how likely he is to be the biological father.

In practice, the HLA system is used in conjunction with a number of red cell blood group systems, including ABO, Rh,

MNSs, Kell, Duffy, and Kidd. The cumulative probability is computed and used to assess the likelihood of paternity. Using all of these systems results in a greater than 95% exclusion of falsely accused males.

Currently, the use of red-cell systems and HLA has been supplanted in most jurisdictions by the use of DNA markers. The markers used are found in numerous loci in the genome and have been found to be extremely polymorphic in various populations. Their frequencies have been studied extensively and allow for exclusion rates of up to 99.9%. Under such conditions paternity can be almost proved.

The HLA system has many applications in transplantation, in platelet transfusion, in the study of the immunogenetics of disease and in forensic matters such as parentage testing. Nevertheless, its most important biological function is probably in the orchestration of the immune response through self-recognition. As such, it is the only polymorphic alloantigenic system in humans whose function is known.

Bone Marrow Transplantation

Patrick G. Beatty

BACKGROUND

Part of "38 - Bone Marrow Transplantation"

Goals of Marrow Transplantation

For over 50 years, radiation and/or chemotherapy has been used in the treatment of malignant diseases (1, 2). Although these modalities can induce complete remissions, these remissions often were of short duration. Efforts to escalate drug and/or radiation doses in hopes of effecting a cure were frustrated by organ toxicity, particularly bone marrow damage. Despite these limitations, careful clinical studies led to the development of regimens capable of curing a substantial proportion of patients with Hodgkin's disease (3) and childhood acute lymphoblastic leukemia (4). However, for most patients, cure was impossible, as treatment doses capable of destroying the malignancy also would destroy marrow function.

Experiments carried out in secret during World War II, and openly afterwards, pointed towards a possible solution for the dose limiting toxicity of chemoradiotherapy. It was shown that lethally irradiated mice could be rescued with either spleen cells or marrow cells from a syngeneic animal (5, 6, 7). This observation led to the concept that patients with cancer might be cured of their malignancy by delivering very high-dose therapy, then rescuing them from the resulting hematologic toxicity by giving them normal bone marrow hematopoietic stem cells collected from another individual. Clinical experiments were carried out in desperately ill patients in the mid-1950s, delivering high dose radiation followed by intravenous infusion of marrow from another person (8). Although there were some cases of transient engraftment, there were no long-term survivors: all patients died either of transplant-related complications or relapsed malignancy (9). However, these endeavors did demonstrate that human marrow could be obtained and infused without ill effects to either donor or recipient. More successful were two transplants carried out in two patients with leukemia, each of whom had an identical twin (10). Each patient received total body irradiation, and then a marrow infusion from his/her identical twin. Both twins apparently engrafted, but unfortunately, both quickly relapsed with their leukemia.

It was clear from these early human experiments that marrow transplantation was more difficult than initially imagined. Indeed, there were no further clinical trials until the beginning of the appreciation of the importance of the human histocompatibility complex, HLA, and the evolving ability to test in a rudimentary fashion for the antigens encoded by the complex. Thus, in 1968, three children with congenital immunodeficiency diseases were transplanted from HLA-matched siblings (11, 12, 13). All three patients are currently alive and well nearly 30 years later (14). Shortly thereafter, Dr. E. Donnall Thomas treated a series of patients with advanced leukemia, using high-dose chemoradiotherapy followed by marrow rescue from HLA-identical siblings (15). Although there was a high death rate from transplant-related complications and relapse, a small percentage of these otherwise incurable patients was rendered disease-free, and remain so more than 20 years later. These encouraging early successes led to the systematic development of the clinical art and science of marrow transplantation, with gradual improvements taking place in the control of infections, the understanding and control of graft-versus-host-disease (GVHD), the delineation of optimal treatment protocols, the recognition of the importance of performing the transplant early in a patient's disease course, and perhaps most important, the development of an increasing ability to define histocompatibility differences between patient and donor (16, 17, 18, 19, 20, 21). These developments led to the gradual acceptance of marrow transplantation as the cost-effective treatment of choice for many otherwise fatal hematologic diseases (22).

Indications for Marrow Transplantation

There are four general indications for marrow transplantation: to replace a diseased myeloid and/or lymphoid system; to provide rescue from high dose chemoradiotherapy given for treatment of a malignancy; to deliver anticancer immunotherapy; and to effect therapy for defective genes.

The replacement of a diseased or damaged organ is analogous to solid organ transplantation. Indeed, replacement of a genetically defective immune system was the first successful indication for transplantation; and transplantation still remains the most effective therapy for a wide range of these disorders, including severe combined immune deficiency, Wiskott-Aldrich syndrome, and any other genetic or acquired disease that causes potentially fatal damage to either lymphoid or myeloid cells (23). In addition to the genetic syndromes, there is a spectrum of acquired diseases that may or may not have a defined etiology, such as chloramphenicol-induced severe aplastic anemia, accidental radiation damage after incidents such as the Chernobyl disaster, or

idiosyncratic reactions to a wide range of medications (24). A substantial proportion of acquired myeloid or lymphoid damage appears to be immunologically based, which occasionally can be cured or ameliorated with immunosuppressive therapy, without need for complete replacement by marrow transplantation (25). The majority of patients with nongenetic marrow/lymphoid failure appear to have no inciting cause. Whatever the etiology, all these defects can be approached by administering cytotoxic agents, then delivering healthy bone marrow from another individual. The results of such transplants generally are excellent. For instance, patients who suffer from newly diagnosed severe aplastic anemia, and who receive immediate transplant from an HLA-identical sibling, can expect long-term, disease-free survival rates above 90% (26).

The second and most common indication for transplantation is for treatment of chemotherapy-sensitive malignant disease. The approach to a patient who is known to have a chemoradiosensitive malignancy is to deliver potentially curative cytotoxic therapy at a level also known to be marrow ablative. These patients then are rescued with marrow from an appropriate donor, be it an HLA-matched sibling, an HLA-mismatched relative, or an HLA-matched or mismatched unrelated donor. The first disease successfully approached in this manner was acute leukemia. Patients with either acute lymphocytic or acute myelocytic leukemia were given high dose chemoradiotherapy, then rescued with marrow from an HLA-genotypically matched sibling. Although the early death rates were extremely high, approximately 10% of these patients became long-term, disease-free survivors (15). As understanding evolved concerning transplant complications, the death rate dropped to the point where it was possible to consider transplantation of patients who had fatal diagnoses, but who were still in remission. This led to a dramatic increase in the survival rates for patients with diagnoses such as acute myelocytic leukemia in first remission and chronic myelocytic leukemia in chronic phase (27, 28). Other malignant diseases that now are routinely approached with allogeneic marrow transplant include non-Hodgkin's lymphoma, Hodgkin's disease, multiple myeloma, myelodysplastic syndrome, and indeed any malignant disease of the hematopoietic system which is known to be therapy responsive, but is not usually curable with conventional dosing (29, 30, 31, 32).

The third indication for marrow transplantation, anti-cancer immunotherapy, only became evident after years of experience. As the marrow inoculum contains a complete immune system, it can potentially effect a potent immunotherapeutic effect on residual malignant cells. Although the mechanism has not been worked out, it has long been noted that there is a correlation between an increased incidence of GVHD and a decreased risk of leukemia relapse (33, 34). When efforts were aimed at decreasing the incidence of GVHD, such as depleting T-cells from the marrow inoculum, there was often an increased risk of malignancy relapse (35). Conversely, there have been numerous attempts to harness this graft-versus-leukemia effect by attenuating or even eliminating the standard post transplant GVHD prophylaxis (36). Generally these efforts have been fruitless: although there may be a decrease in the relapse rate, in most studies this was counteracted by an increased death rate from acute or chronic GVHD. More recently, clinical researchers are studying the effects of T-lymphocytes given several weeks after transplant in hopes of separating in time the graft-versus-leukemia effect from the GVHD effect (37). One hypothesis is that T-cells given at the time of transplant are more likely to cause GVHD because of the inflammatory cytokine milieu secondary to the chemoradiotherapy conditioning regimen.

The fourth indication for marrow transplantation is to administer gene therapy. As described for the first indication, bone-marrow transplantation can be curative for genetic defects of the hematopoietic system: the mechanism is simply the obliteration of the defective gene as it exists within the hematopoietic cell, and substitution of a normal gene, carried by a normal hematopoietic cell. It has been shown that diseases that do not at first glance appear to be related to the hematopoietic system can be cured by this approach (38, 39). For instance, the mucopolysaccharide deficiency diseases often involve macrophage function defects, which allow buildup of toxic products in the liver, brain, or other organs (40). These can be cured by introducing macrophages with a normal gene, as part of replacing the entire hematopoietic system with a marrow transplant. In the future, it may be possible to directly manipulate the diseased gene within a hematopoietic stem cell, and/or substitute a normal gene (41).

The Allogeneic Response in Marrow Transplantation

The major allogeneic marrow transplantation complication, which requires such detailed and precise histocompatibility testing, is that of GVHD (42). Whereas with other types of organ transplantation, graft rejection is the major issue in marrow transplantation, where an intact immune system is transplanted into a patient's body, it is necessary to consider immune reactivity in two vectors: graft-versus-host and host-versus-graft. In most patients who receive a marrow transplant, particularly those being treated for an underlying malignancy, treatment of that malignancy is so immunosuppressive that the chance of the patient's immune system surviving with sufficient strength to reject a marrow graft is minimal. However, and perhaps partly because of this extraordinarily high dose of chemoradiotherapy, there is a very high probability that the incoming immune system will recognize the antigens in the patient's body and cause severe or even fatal reactions. Although skin, liver, and gut are the most commonly afflicted organs, any organ of the body can be damaged. The immunogenetic nature of this reaction is most clearly demonstrated by the observation that GVHD is far less commonly seen when genotypically identical twins are used as donors (43). Further, the incidence of GVHD increases with increasing HLA disparity (44). However, although generalizations can be made about the relative risks given certain levels of disparity, GVHD risk for individual patients cannot be reliably predicted. Indeed, patients with no HLA disparities can have fatal GVHD, and patient/donor pairs with one or more major HLA differences can have none. Additional non-HLA factors that may be implicated in GVHD risk include concurrent infections (45); the recent delivery of high-dose chemoradiotherapy (with its “cytokine storm”); and the influence of non-HLA antigens, namely the minor histocompatibility antigens (46, 47, 48).

With the recognition of GVHD as the major barrier to wider use of bone marrow transplantation, major efforts have been made to ameliorate the problem. However, attempts at this have led to other, sometimes unexpected, complications. As mentioned above, it has been demonstrated that patients who survive GVHD are less likely to have a relapse of their underlying malignancy, the so-called graft-versus-leukemia effect. Another unexpected problem that became apparent when efforts were made to decrease GVHD is an increased risk of graft rejection (49, 50). Although the mechanism is not entirely clear, it appears that some GVHD may be required to obliterate the remnants of the host immune system, and hence render it incapable of rejecting the incoming marrow inoculum.

Although GVHD affecting the skin, liver, and gut is the most visible manifestation of the syndrome, the most common cause of death in patients with GVHD is infection (45). It appears that the phenomenon of GVHD disregulates the immune system, to the extent that it is incompetent to recognize pathogens. Furthermore, as the treatment of GVHD involves nonspecific immunosuppression, the patient's vulnerability increases.

Even if the patient and donor are genotypically matched for HLA, there remains a substantial risk of GVHD. The antigens that elicit GVHD in HLA-matched siblings are by definition “minor histocompatibility antigens.” Characterization of these antigens is just beginning (51, 52). It is unclear, particularly in humans, how many antigens there are, where they are encoded in the genome, and whether the same loci are important for each donor/patient pair (53, 54, 55, 56).

HLA-MATCHED SIBLINGS

Part of "38 - Bone Marrow Transplantation"

Histocompatibility Assessment

In determining the most appropriate histocompatibility assessment for a patient who is a candidate for marrow transplantation, it is necessary to consider the availability and relevance of three different categories of donors, usually in the following order of preference: HLA genotypically identical siblings, HLA mismatched relatives, and matched or mismatched unrelated donors.

In the late 1960's, the art of histocompatibility testing had advanced to the point where it usually was possible to define the segregation of HLA alleles within a family (57). As it was then just becoming appreciated, all of the elements of the major histocompatibility complex in humans (HLA) are encoded on a short stretch on the short arm of chromosome 6, and hence are inherited *en bloc*. Thus, with a relatively limited and primitive set of serologic reagents, plus cellular methodology, it was possible to determine which if any siblings had inherited the same two HLA haplotypes from their parents.

The goal of histocompatibility assessment when screening for an HLA-matched sibling donor is straightforward: identify which, if any, siblings have inherited the same HLA haplotypes from their parents. This requires typing all siblings, and if possible, both parents for HLA-A, -B, and -DR. Currently, it is most cost effective to type for HLA-A and -B by serologic methodology, and for HLA-DR by molecular methodology. As discussed below, the use of a mixed lymphocyte culture or other cellular-based technology has been made unnecessary by the precision of the new molecular methods.

Early in the development of histocompatibility testing, it became obvious that if cells from two siblings that are known to be HLA-identical are mixed, the cells would remain quiescent and would not divide (58). However, if there was a disparity between siblings for HLA-DR, there was a rapid development of blasts and cell division, which could be monitored easily by measuring tritiated thymidine uptake. This proved to be a useful test in the early days of HLA typing, when it often was difficult to clearly establish haplotype segregation. Thus, if a patient and a prospective donor were clearly negative in a mixed lymphocyte culture, but there was strong reactivity elsewhere in the family, the patient and donor could be presumed to be HLA genotypically matched. However, with the increasing precision of DNA typing, it is now possible to demonstrate with virtual certainty how haplotypes segregate within a family, thus making the MLC test obsolete for that purpose. Other cellular crossmatching tests include measurements of precursor frequency by a limiting dilution analysis (59). There is some indication that these tests might be capable of picking up minor histocompatibility antigen differences, but this has not been definitively demonstrated. Other more complicated tests include mixing donor lymphocytes with irradiated patient T-lymphocytes, then taking the subsequent cells and layering them upon patient fibroblast lines, and demonstrating fibroblast destruction (60). This does appear to be somewhat predictive of minor antigen disparity in HLA-matched siblings, but the cumbersome nature of the test, and the time involved for developing results, have led to limited acceptance of this method.

Minor Histocompatibility Antigens

Once HLA haplotype segregation has been established in a family, and it has been demonstrated that the patient and donor are genotypically HLA matched, it can be concluded that to any given level of discrimination, they are matched for all known HLA alleles and indeed for any antigens that have been encoded in that region but that have not yet been described. Thus, the risk of GVHD must be ascribed entirely, by definition, to minor histocompatibility antigens (61, 62). Although the existence of segregating non-HLA antigen systems can be well demonstrated in animal models, precise definition of the antigens has proven elusive (46, 47 and 48, 51, 52, 53, 54, 55 and 56). Because of the peculiar biology of these antigens, it has been difficult to develop reliable testing. It appears that the minor antigen is expressed on the cell surface as a degraded peptide fragment bound to a specific HLA molecule. These peptides can be readily recognized only by T-lymphocytes, which coordinately recognize both peptide and adjacent HLA amino-acid residues. Thus, it has proven virtually impossible to develop antibodies capable of recognizing these antigens. Recently, sophisticated biochemical methodology involving removing the peptides from the HLA binding groove has allowed sequencing of some of these peptides (51, 56). It appears they are fragments of various proteins that do not necessarily have any connection to the immune system. Another approach to the identification of minor histocompatibility antigens is by using genetic linkage analysis. Gubarev et al. (63, 64) describe localization

of two distinct loci, which encode minor histocompatibility antigens. T-lymphocyte clones were isolated from a patient with GVHD, and each tested against lymphoblastoid cell lines derived from numbers of large, genetically mapped pedigrees, each of which had been transfected with the appropriate HLA-restricting element (in this case HLA-B7). Each family member was phenotyped for presence or absence of the minor antigen by a cytolytic T-cell lysis assay, and a computer linkage analysis performed. Each clone localized a gene to within 30 to 60 centimorgans on chromosomes 11 and 22.

It will take considerably more effort to fully catalog these antigens, identify the loci that encode them (65, 66, 67 and 68), and determine the number of alleles per locus. Only when this has been accomplished will it be possible to first develop clinical testing methodology, and then ultimately determine how many loci exist, their degree of polymorphism, and which loci might be most important.

HLA MISMATCHED RELATIVES

Part of "38 - Bone Marrow Transplantation"

Histocompatibility Assessment

Given the genetics of the HLA system, specifically a 50% chance that two siblings have inherited the same haplotype from each parent, the total probability that any two siblings are HLA identical is 25%. Given the current average family size in the United States of 2.7 siblings, one of whom is the patient, there are 1.7 siblings to choose from. Therefore, the approximate probability that the average U.S. patient will have an HLA match within the family is 30% to 35%. The remainder of the patients who otherwise might have been considered for transplant must look beyond their siblings. For those patients who do not have an HLA-matched sibling within the family, it is reasonable to consider transplantation from a family member who shares one haplotype and is variably mismatched on the nonshared haplotype. The clinical data clearly indicate that with increasing disparity for HLA, whether it is the A, B, or DRB1 locus, there is increased risk of GVHD (44). The first goal of histocompatibility testing in such cases is to determine that patient and donor share one HLA haplotype by inheritance. With respect to the two nonshared haplotypes, the problem of positively identifying each antigen at each locus is obviously significantly more complex than that of simply identifying haplotype segregation. Thus, it becomes critically important to have reagents that are of sufficient quality to unambiguously define each antigen, so as to be certain of whether the patient is either matched or mismatched for that locus with the prospective donor. Ability to carry out this kind of testing evolved several years after the initial ability to define haplotypes; hence, there was a delay in testing the hypothesis that transplants from HLA mismatched relatives can be successful.

Thus, the histocompatibility assessment when considering HLA-mismatched relatives is considerably more complex than that involved when only HLA-matched siblings are considered. First, one must establish HLA haplotype segregation within the family: this requires testing for HLA-A, -B, and -DR. Once it is clear which family members share by inheritance one HLA haplotype, attention can be turned to the nonshared haplotypes. As these haplotypes, by definition, are not shared by inheritance, it is important to define with the greatest possible precision all antigens at each relevant locus (see below). Currently, this would include testing for HLA-DR and -DQ using molecular methodology; testing for HLA-C preferably by molecular methods; and testing for HLA-A, and -B currently by serology, but hopefully in the near future by molecular methods. As some HLA disparity can be presumed, it is critical to test by the lymphocytotoxicity assay for presence of patient-antidonor anti-HLA-specific antibodies. Although it is not clear whether such antibodies directly contribute to graft rejection, it is clear that a correlation exists (69). Perhaps these antibodies are surrogates for a more generalized increased alloreactive state.

Relative Impact of HLA Disparities

Determination of the relative importance of particular HLA loci to GVHD can be most readily accomplished in large cohorts of patients, treated in a similar fashion, in whom there is only one locus different between patient and donor. An early analysis carried out in Seattle showed no substantial difference in the risk of GVHD, whether the mismatched locus was HLA-A, -B, or the serologically defined -DR locus (44). More recently, using more precise molecular typing technology, Servida et al. from Seattle (70) have reported that disparity for HLA-DRB1 incurs a significantly greater risk for GVHD than disparity for HLA-A or HLA-B. There was a trend for lower GVHD risk for HLA-A disparity as opposed to HLA-B disparity.

It is possible that different modes of patient immunosuppression posttransplant might have an impact upon the relative hierarchy of risk of various loci. The current standard of care will accept a donor who differs for one of three loci: HLA-A, -B, or -DR. Although in such instances there is an increased risk of GVHD, there is not necessarily a substantial impact upon survival, mostly because of an increased graft-versus-leukemia effect. The relevance of HLA-C, -DQ, and -DP remains unclear in this setting. The use of two or three loci-disparate donors is controversial: because there is clearly an increased risk of GVHD, use of such donors therefore should be confined to clinical research trials attempting to ameliorate the inherent allogeneic risks (71, 72, 73).

HLA MATCHED/MISMATCHED UNRELATED DONORS

Part of "38 - Bone Marrow Transplantation"

Histocompatibility Assessment

When considering unrelated donors, the difficulty of positively identifying each antigen increases. Here we assume that there is no sharing of HLA haplotypes by inheritance. Thus, it is necessary to positively identify both alleles at each relevant HLA locus. Furthermore, it is not enough to simply determine match versus mismatch; one must also be certain of the exact allele designation as the patient has literally millions of possible donors to choose from (74), and it is clinically important to optimize this choice. For instance, there may be some mismatches that are less dangerous than others.

It quickly became apparent in the mid-1980s that the serologic

and cellular testing technologies were insufficient for optimal unrelated donor/patient matching. This has led to the rapid development of DNA-based allele-level typing, initially for class II (HLA-DR, -DQ, -DP) (75), and more recently for class I (HLA-A, -B, -C) (76, 77). It has become clear that DNA-based typing is far more accurate and reproducible than were previous methodologies (78, 18). It is likely only a matter of time before the cost of DNA typing lowers to the point at which this testing methodology completely supplants other technologies.

In considering transplantation using unrelated donors, it must be recognized that as opposed to the situation with related donors, the degree of match can only be presumed to extend to the level of resolution of the typing technology employed, and the number of loci tested. For instance, in considering HLA-matched siblings, if the patient and donor are both HLA-B12, and if these antigens can be demonstrated to be on a shared haplotype, they can be presumed to match; thus, it is immaterial whether the antigen can be split to demonstrate whether it is HLA-B44 or HLA-B45. In the case of an unrelated patient/donor pair where, of course, there are no haplotypes shared by inheritance, all such antigens need to be split to the limits of current technology, as they could be mismatched for these alleles. Thus it is necessary to carry out complete testing of all clinically relevant loci. Particularly as there now have been several additional loci demonstrated to be polymorphic in humans beyond HLA-A, -B, -C, and -DR, and particularly as the technology of HLA typing has advanced to the point that there are now dozens or even over a hundred alleles identified at each locus, it has become important to attempt to determine a hierarchy of importance of loci in the human allogeneic response. Addressing these questions requires a very large body of clinical data with precision typing. Only now are sufficient numbers of patients available to perform this expensive analysis (79, 80). Further, for most complete assurance for validity of this type of analysis, it is best to study patient/donor pairs in which there is only one locus difference. It appears safe from the available clinical data to date to conclude that the HLA-A, -B, and -DRB1 loci are of importance. There now are data that demonstrate that the HLA-DP locus has little, if any, significance in clinical GVHD (81). Disparity for HLA-DQ, however, appears to correlate with risk for AGVHD (82). The HLA-C locus is in the process of virtually complete redefinition using DNA typing (77, 83). Because of methodologic problems with serology related to the relatively low expression of HLA-C locus antigens, and their extensive cross reactivity with HLA-B locus alleles, it has always proven difficult to obtain reliable typing. With the availability of DNA-based methodology, a number of new alleles have been identified, and many of the old antigens have been split or redefined. The hypothesis has been raised that the HLA-C locus may have some importance in natural killer cell function, and perhaps some importance in graft rejection (84, 85).

In unrelated donor transplantation, the use of DNA-based technology for class II typing has virtually eliminated the use of serology because of its extreme accuracy and precision. Indeed, comparisons between DNA and serology in reliable laboratories have shown a very substantial error rate for HLA-DR serology (78, 86, 87, 88, 89 and 90). As most class I alleles now have been sequenced, it can be expected that DNA-based typing for the HLA-A, -B, and -C loci soon will move from the research and development phase into widespread application. It then will be instructive to reexamine the issue of the impact of minor HLA polymorphisms upon clinical outcome in light of using these far more precise tools (92, 93, 94 and 95).

The precise DNA-based technology to be utilized is still not resolved (75, 96). Initially, analysis of restriction-fragment-length-polymorphisms (RFLPs) was used; but this technology proved to be often insufficiently informative, expensive, and cumbersome. The invention of the polymerase chain reaction (PCR) led to the development of a number of related technologies exploiting differences or similarities at the DNA base-pair level. Which of these technologies will ultimately be selected for use in clinical practice will likely depend upon a compromise between cost, precision, and accuracy.

Cellular crossmatching technology initially was developed to help identify HLA-matched siblings; however, it has proven to be particularly unreliable in unrelated transplantation (97, 98 and 99). The explanation likely revolves around the fundamental issue in unrelated transplant, namely that the patient and donor can be expected to have only phenotypic, but not genotypic, identity. Thus, when cells from two HLA genotypically identical siblings are mixed in culture (MLC), one can expect virtually zero reactivity. However, even if a patient and an unrelated donor are fully matched for HLA-A, -B, and -DR, it is likely that there will be some disparities, which would be detectable in an MLC test. This low level of activity is complicated further by the fact that patient cells cannot be expected to be normally reactive, as a result of patient's underlying disease or the treatment thereof. When results of MLC testing have been analyzed carefully in unrelated transplantation, the assay has been found to be both poorly reproducible, and most significantly, virtually completely nonpredictive for development of GVHD. On the other hand, it is clear that high resolution HLA-DRB1 testing is very predictive of GVHD (100). As a result, the use of the MLC test has been virtually abandoned in this setting.

Impact of HLA Polymorphism on Finding Donors

Given the extreme polymorphism of HLA, and the large number of different loci (Table 38.1), it might seem foolhardy to hope that any given patient might be able to find a fully matched unrelated donor (101, 102 and 103). This problem has been operatively overcome by simplifying assumptions, and by considering the biology of the HLA system. It was presumed a decade ago that the most relevant loci would be HLA -A, -B, and -DRB1, although it is yet to be proven that this assumption is entirely valid. Indeed, given the increased risk of GVHD in transplantation using unrelated donors, it is quite possible that this assumption may be proven partially wrong. However, even assuming that these three loci encode the only antigens of importance, there are still an enormous number of possible HLA phenotypes. The biology of HLA, however, makes the possibility of finding an HLA match more manageable. As previously noted, HLA antigens are encoded on one small portion of the short arm of chromosome 6. As crossovers are infrequent, one can presume that HLA antigens are evolutionarily selected as a complete haplotype,

are inherited as a haplotype, and are preserved as a haplotype, a phenomenon termed “linkage disequilibrium.” Within different racial groups, certain haplotypes are far more common than would be expected by chance alone. The reason for this is unclear, but it might be postulated that this phenomenon is related to the evolutionary selection of individuals with haplotypes that protect against specific endemic diseases in their region of the world. Thus, for instance, among whites, the HLA-A1, -B8,-DR3 haplotype is extremely common. Perhaps an individual who possessed that haplotype would have had a high chance of surviving the Plague or smallpox in the Middle Ages. The relevance for our purpose is that a person with such a haplotype has a high chance of finding a donor even from amongst a relatively small file of volunteers. However, it appears that the majority of patients will have haplotypes that are neither particularly common nor in linkage disequilibrium. Thus, in order to have a reasonable probability of finding a well-matched donor, it is necessary to have available a very large file of HLA-typed potential donors. In the United States there are over 2.5 million donors available, with another 1 million available worldwide (104). Currently, approximately 65% of patients can find an acceptable donor (105). However, it is clear that patients belonging to racial groups that are not well represented in the registries have a dramatically decreased probability of finding a donor. This is not only because of the different distribution of HLA antigens and haplotypes within different racial groups: for African-Americans there appears to be an additional problem, namely that those peoples descended from those currently living in Africa appear to be far more polymorphic for HLA than are other racial groups (105). A hypothesis for this is the origin of humanity in Africa, with other racial groups who have migrated out of Africa passing through a genetic “bottleneck,” and thus having limited diversity. In any case, the implication is that in order to find HLA-matched donors for African-Americans, it will be necessary to recruit far more donors than are needed for other racial groups. Obviously, for these racial groups in particular, the development of technology to allow successful HLA-mismatched transplants from unrelated donors will be particularly important.

TABLE 38.1. HLA POLYMORPHISM (106)

Based on Number of Alleles Shown at Each Locus						
A	*B*	*C*	*E*	*G*		
142	285	99	5	14		
DRA	*DRB1*	*DRB3*	*DRB4*	*DRB5*	*DRB7*	
2	225	20	9	13	2	
DQA1	*DQB1*	*DPA1*	*DPB1*	*DMA*	*DMB*	*DOA*
20	42	17	81	4	65	8
Considering All Loci						
No. of possible haplotypes: 1.02×10^{23}				No. of possible genotypes: 1.04×10^{46}		
Only Considering HLA-A,B,DRA,DRB1						
No. of possible haplotypes: 1.82×10^{7}				No. of possible genotypes: 3.32×10^{14}

Continued advancements in the field of hematopathology, particulary studies based on characterization of genetic abnormalities as well as progress made in automation, have resulted in major changes in clinical diagnosis and management of patients. The following chapters will provide an understanding of the basic approach to diagnosis of various disorders related to hematopoietic disorders. As a discipline of clinical pathology, hematopathology requires expertise in a variety of areas including instrumentation, clinical laboratory analysis, and traditional microscopic skills. These skills actually place hematopathology in the unique position of bridging the clinical laboratory sciences and anatomical pathology. Although the basic foundation of hematopathology remains unchanged, the technological advances that have characterized the field of medicine over the past decade have also changed diagnostic approaches in hematopathology. Indeed, the hematopathologist is now challenged with mastering both the traditional skills of laboratory medicine and morphology and newer diagnostic modalities and instrumentation. The medical community has embraced these new technological advancements and already incorporated some into the routine patient management.

The key to becoming a successful hematopathologist depends on the incorporation of these newer diagnostic modalities as well as expertise gained in traditional morphologic skills. During the past decade, many clinical and laboratory studies have validated the efficacy of utilization of new assays in hematopathology. Based on these studies and their documented successes in patient management, healthcare providers are increasingly incorporating this knowledge in their daily practice. Therefore it becomes crucial for physicians to be aware of both traditional as well as newer modalities available in the laboratory.

Hematopoiesis and the Hematopoietic Growth Factors

Stephen G. Emerson

INTRODUCTION

Part of "39 - Hematopoiesis and the Hematopoietic Growth Factors"

All of the cells observed in the adult peripheral blood derive from the bone marrow, arising through an extraordinary process termed hematopoiesis. This process results in the maintenance of the wide variety of distinct blood cells, despite the fact that each blood cell variety has its own distinct lifespan in the circulation. Our current understanding of this process is embodied in a theory called the stem-cell model of hematopoiesis. This model forms the foundation for truly all of our present thinking about normal hematopoiesis, pathologic hematologic disease states, and hematologic therapies.

Stem-Cell Theory

Unlike other tissues of mesodermal origin, which as a rule have little turnover in their constituent cell populations, the cellular components of the blood are constantly undergoing cell death and replacement by new cells. While red blood cells last approximately 4 months in the circulation, platelets last only about 1 week and granulocytes less than 10 hours. It is estimated that every day 1×10^{11} blood cells are lost to wear and tear and are replaced with an equal number of new blood cells. To fulfill the continual need for replacement blood cells, hematopoiesis occurs actively throughout our lifetimes. As a result, the blood-forming tissues are among the most mitotically active, along with the gastrointestinal epithelium and epidermis. The recognition of this high turnover rate for blood cells has led to the development of the stem-cell theory of blood cell development and maintenance, or hematopoiesis (1). This chapter discusses this theory in detail, as well as its implications for clinical practice.

Hematopoietic Growth Factors

One of the most exciting advances in the study of hematopoiesis in the last decade has been the study of the role of hematopoietic hormones in the control of the process of blood-cell differentiation. These hematopoietic hormones, also known as hematopoietic growth factors, appear to control every step in the process of the development of new blood cells. At the present time, we know principally a group of such hematopoietic growth factors that are stimulatory to hematopoietic stem cells and their progeny. However, some inhibitory factors have been discovered and appear to play an equally important role in the negative control of this process. Other hormones that are felt to have primarily nonhematopoietic functions also are known to affect the process of the production of new blood cells. This chapter concisely describes the role of both stimulatory and inhibitory hematopoietic growth factors.

Hematopoietic Microenvironment

The term hematopoietic microenvironment refers to the “stromal” elements of the organs in which hematopoiesis occurs, that is, the cellular and noncellular elements that do not directly give rise to the blood cells but rather provide a solid three-dimensional structural matrix in which the hematopoietic stem cells and their progeny proliferate and differentiate until they migrate into the blood stream. The role of the hematopoietic microenvironment in the control of the development of blood cells is believed to be of paramount importance in the process of hematopoiesis. Both the stromal cells and their secreted matrix proteins appear to influence the process of hematopoiesis as profoundly as the soluble, secreted hematopoietic growth factors, and a summary of current understanding of the contribution of the hematopoietic microenvironment is included in this chapter.

HISTORICAL CONSIDERATIONS

Part of "39 - Hematopoiesis and the Hematopoietic Growth Factors"

Early Studies

The scientific study of hematopoiesis is a recent phenomenon. Although the cellular nature of blood was discerned by van Leeuwenhoek and reported in 1674, it was not until the middle of the 19th century that interest was aroused in the origin of the cellular components of blood. The earliest observations on hematopoiesis were the studies of Weber and Kolliker, who determined in 1846 that, in the fetus, the liver is the principal site of hematopoiesis. In 1868, two scientists working independently, Ernst Neumann and Giulio Bizzozero, discovered that in the adult, erythropoiesis, the process of the differentiation of red blood cells, occurs within the bone marrow, with subsequent release of newly formed erythrocytes into the bloodstream. Bizzozero also recognized that white cells were formed in the bone

marrow, and he coined the term “platelet” for thrombocytes. The origin of the blood platelets from megakaryocytes in the bone marrow was not uncovered until 1906, however, when James Homer Wright, the inventor of the stain used most frequently for blood and hematopoietic tissues, noted the shedding of platelets from the cytoplasm of megakaryocytes.

The identification of the bone marrow as the principal hematopoietic organ in the adult was followed, at the close of the 19th century and the first half of the 20th century, by a proliferation of various theories of the cellular origin of blood cells. While it was universally understood during that time that the various blood cells must derive from some sort of ancestral cell or cells, the nature of the precursor cell(s) remained highly controversial.

Two basic theories were advanced, each with highly opinionated proponents, and each with a myriad of variations. The first theory, the monophyletic theory, postulated that all different forms of blood cells were derived from a common ancestral cell, the totipotent hematopoietic stem cell. The term totipotent indicated its capability of differentiating into any and all of the various forms of blood cells. The monophyletic theory was first proposed by Artur Pappenheim at the turn of the century (2) and was supported vigorously by some of the most prominent medical scientists of this century, including the Russian anatomists/embryologists Vera Dantschakoff and Alexander Maximow, Maximow's pupil William Bloom, and Hal Downey, a hematologist and the editor of an important work called the *Handbook of Hematology*.

In opposition to the monophyleticists, a second group arose, the polyphyleticists, who posited the existence of independent lines of hematopoietic cell development for various types of blood cells. For example, Paul Ehrlich, the first to apply histologic staining techniques to the study of blood tissues, proposed the “dualist” theory, viz., that granulocytes derived from a primitive “myelocyte,” whereas the lymphocytes had a completely separate origin (3). Others who were considered polyphyleticists included the Swiss hematologist Otto Naegeli, Robert Schilling of the University of Wisconsin, and Florence Sabin. Each described various modifications of the polyphyletic theory, all of which, however, basically revolved around the notion that the different morphologically recognizable lineages of blood cells derived from different populations of precursor cells that did not have the capability of giving rise to several different types of blood cells.

Experimental evidence to settle this vexing issue did not come until the middle of the 20th century, when evidence of the multilineage capability of hematopoietic stem cells was convincingly demonstrated in transplantation experiments in lethally irradiated mice (4, 5). The monophyletic viewpoint has now largely been vindicated, and at the present, most experts in hematopoiesis agree on the existence of a totipotent hematopoietic stem cell that has the capability, as a single cell, of giving rise to cells of all the different lineages of blood cells, including lymphoid, myeloid (granulocytes and monocytes/macrophages), erythroid (red blood cells), and megakaryocytic lineages (6).

HEMATOPOIESIS IN THE EMBRYO AND FETUS

Part of "39 - Hematopoiesis and the Hematopoietic Growth Factors"

Role of the Yolk Sac

The fertilized egg first develops the beginnings of blood tissue while still in the embryonic stage (7). The first step toward the development of blood tissue is thought to occur in the yolk sac, where undifferentiated cells called mesoblasts are found and are believed to migrate there from the primitive streak of the embryo. The mesoblasts are highly mitotically active, and will subsequently differentiate into cells that are clearly related to the mature blood cells of the adult, called “primitive erythroblasts,” as well as into cells called primitive endothelial cells, which give rise to vascular channels in the yolk sac. Within hours after migration, the yolk-sac mesoblasts have generated, by a process of cell division and differentiation, primitive erythrocytes, primarily nucleated but including a minority that are nonnucleated, all of which acquire hemoglobin and thus lend a reddish color to the clumps of yolk-sac cells where blood-cell formation is occurring. The clumps of hemoglobinized cells are visible to the naked eye, hence the name “blood islands” to describe these localized areas of embryonic hematopoiesis in the yolk sac. Megakaryocytes also are found in the blood islands and are presumably derived from the mesoblasts. Other mesoblasts appear to differentiate into a type of cell called the “hemocytoblast.”

A second stage of hematopoiesis in the yolk sac occurs in the embryos of some mammals. In human embryos, this second stage is present but is not as vigorous as in rabbits, the mammal in which the embryogenesis of blood cells has been most extensively studied. In the second stage of yolk-sac hematopoiesis, hemocytoblasts differentiate into “definitive” erythroblasts, which subsequently acquire hemoglobin and are called “definitive” or “secondary” normoblasts. These may lose their nuclei by a process of extrusion and become “definitive” erythrocytes. Vascular channels form in the blood islands, and eventually connect to form a network of blood vessels. This network of primitive blood vessels early on contains the primitive erythroblasts and hemocytoblasts, and later definitive erythroblasts and erythrocytes. By the end of the third week of embryonic development in the rabbit, all the hematopoietic activity of the blood islands has subsided and the process of hematopoiesis has gradually shifted to the liver.

The Embryonic Body Mesenchyme

A minor role in early embryonic hematopoiesis is played by primitive mesenchymal cells in the body cavity itself, particularly in the head mesenchyme. Small numbers of mesenchymal cells of the body cavity develop into erythroblasts, megakaryocytes, granulocytes, and phagocytic cells analogous to their counterparts in the adult. Quantitatively, the number of cells produced is small, and large accretions of blood cells similar to the blood islands of the yolk sac do not form in the body cavity mesenchyme. The small clusters of blood cells that do form quickly degenerate and no further blood formation occurs here to any significant degree after the third week. However, the formation of blood cells in the mesenchyme is illustrative of the fact that mesenchymal cells have potential for differentiation into hematopoietic cells, and this potential may in theory reside with mesenchymally derived cells throughout life.

Emergence of the Liver As the Principal Site of Hematopoiesis in the Embryo

Beginning at around the 12-mm stage of the human embryo, blood formation is seen to occur in the embryonic liver. The liver

soon becomes the dominant site of hematopoiesis and remains active in hematopoiesis until birth. As the endodermal cords of the liver primordium grow into the septum transversum, they encounter wandering mesenchymal cells with the appearance of lymphocytes. These lymphocytoid-wandering cells are subsequently trapped between the primordial liver endodermal cords and the endothelial cells of ingrowing capillaries. They give rise to hemocytoblasts similar to those of the yolk sac. These hemocytoblasts soon form foci of hematopoiesis similar to the blood islands of the yolk sac, wherein secondary erythroblasts are formed in large numbers, which subsequently divide and differentiate into definitive erythrocytes through the progressive acquisition of hemoglobin and loss of the cell nucleus. Although definitive erythrocytes may be seen in the liver at the 12-mm stage, they do not emerge into the circulation in any great numbers until much later. Thus, by the 70-mm stage, the majority of circulating erythrocytes in the embryo are secondary (definitive) erythrocytes.

Megakaryocytes also appear to form from the hemocytoblasts in the embryonic and fetal liver. Granulocytic cells are found in the embryonic liver, but they appear to develop not from the hemocytoblasts but perhaps directly from the lymphocytoid-wandering cells themselves. The embryonic liver is not the dominant site of hematopoiesis for long, being replaced in importance by the embryonic bone marrow beginning around the 25- to 30-mm stage in the human.

The Embryonic Bone Marrow and Myelopoiesis

Bone formation in the embryo occurs at varying times for different bones. The earliest bones to form are the long bones of the appendicular skeleton. Initially, a cartilaginous model of each bone is formed. The central core of the diaphysis of each long bone subsequently becomes ossified, and soon an area of bone resorption develops followed by the ingrowth of mesenchymal cells from the periosteum. These mesenchymal cells are accompanied by the ingrowth of capillaries. The mesenchymal cells continue to increase in number by continued influx of other mesenchymal cells as well as by division of those already within the newly forming marrow cavity. They also elaborate a noncellular ground substance, or “stroma,” which fills the developing marrow cavity. Cells identical to the hemocytoblasts of the liver and yolk sac develop from these early marrow mesenchymal cells. As in the yolk sac and liver, these give rise to megakaryocytes and erythroid cells. However, there is a second population of cells, called the “lymphoid-wandering cells,” which appear nearly identical to lymphocytes. These cells predominate in the population of cells in the very early marrow cavity, and are thought to give rise to myeloid cells, including neutrophils, basophils, and eosinophils. The embryonic marrow differs markedly from the earlier centers of hematopoiesis in that the generation of these myeloid cells is especially vigorous and dominates the embryonic marrow hematopoietic activity. The process of formation of the early myeloid cells, or “myelopoiesis,” occurs first in the central portion of the marrow cavity and spreads outward from there to eventually include the entire marrow cavity. Erythropoiesis occurs slightly later in the embryonic marrow and generally is admixed with the process of myelopoiesis. Small foci of erythropoiesis thus can be seen among the many maturing cells of myeloid lineage. After birth, hematopoiesis ceases in the liver, and the bone marrow continues to be the principal site of hematopoiesis for the remainder of life.

Hematopoiesis in the Spleen of the Embryo and Fetus

The last major site of hematopoiesis to form in embryonic life is the spleen. Although the spleen itself forms much earlier, wandering mesenchymal cells do not begin to invade the spleen until around the 70-mm stage in humans. These then differentiate into typical hemocytoblasts, which give rise to cells of primarily erythroid lineage. The spleen is thus a center of erythropoiesis until the time of birth, when erythropoiesis gradually ceases. Although some myelopoiesis occurs in the embryonic and fetal spleen, it is relatively insignificant in comparison. Much later, during the fifth month of gestation, the white pulp of the spleen forms by the differentiation of mesenchymal cells that have grouped around the splenic arterioles. The formation of the splenic lymphocytes appears to occur as a process completely separate from the origin of erythropoiesis in this organ.

Other Sites of Hematopoiesis in the Embryo and Fetus

The embryonic thymus develops as an outgrowth of the third branchial pouch. The thymic epithelium is invaded by wandering mesenchymal cells, which begin multiplying rapidly and differentiating into lymphocytes. During this process, small numbers of erythroid and myeloid cells are formed in the thymus, but the primary process is that of lymphopoiesis. The lymphocytes formed in this organ will constitute a distinct class of lymphocytes with a special function: that of cell-mediated immunity.

The lymph nodes develop as outpouchings from the primitive lymphatic vessels, which become surrounded by accretions of mesenchymal cells. Subsequently, these seem to round up and become similar in appearance to the lymphocytes of the adult. A few of the mesenchymal cells give rise to cells of other lineages, such as erythrocytes, granulocytes, and megakaryocytes, but this is a transitory phenomenon, and, as in the thymus, the principal process is that of lymphopoiesis.

Summary of Embryonic and Fetal Hematopoiesis

In all the hematopoietic organs of the embryo and fetus, a similar process takes place. Wandering mesenchymal cells are attracted to a particular site, by processes still not clearly understood, and become transformed into cells recognizable as hematopoietic precursors. These embryonic hematopoietic precursors appear to be capable of multilineage differentiation, but at any one site, the process of hematopoiesis may be dominated by the formation of a particular lineage, presumably under the influence of the local environment. The various sites of embryonic hematopoiesis seem to be active only at specific times during development and follow a pattern of programmed involution, except for the bone marrow, which continues as the

principal location of hematopoiesis in the adult, and the lymph nodes, spleen, thymus, and other lymphatic tissues, which continue to be active in lymphopoiesis.

HEMATOPOIESIS IN THE ADULT

Part of "39 - Hematopoiesis and the Hematopoietic Growth Factors"

After birth, the major site of hematopoietic activity shifts gradually from the liver and spleen to the bone marrow cavities of nearly all bones of the axial and appendicular skeleton. The marrow acquires a reddish color like that of blood once hematopoietic activity begins, reflecting the vigorous production of erythrocytes that contain hemoglobin. The bone marrow cavity serves primarily as a site for the production of nonlymphoid blood cells, whereas lymphopoiesis in the adult occurs primarily in the spleen, lymph nodes, thymus, and the gut-associated lymphoid tissue, including the tonsils, adenoids, and Peyer's patches. Thus, when examined with the light microscope, the adult marrow will be seen to be composed primarily of erythroid and myeloid precursor cells, together with scattered megakaryocytes and a population of cells known as “stromal cells,” which are crucial for the maturation of the precursor cells and release of the fully differentiated cell types into the circulation.

As each individual ages, the marrow of bones of the appendicular skeleton gradually loses its red appearance and is transformed into yellow marrow, a reflection of the progressive replacement of hematopoietic tissue by adipose tissue. Thus, by early adulthood, the long bones no longer bear red marrow but are completely replaced by nonhematopoietic yellow marrow, and the primary sites of red marrow are confined to the sternum, ribs, vertebrae, and pelvis. Although the stimulus for this progressive transformation of red to yellow marrow is unknown, in pathologic conditions associated with vigorous hematopoietic activity, the transformation may fail to take place and the red marrow may actually expand into bones not normally associated with hematopoietic activity, such as the diploic cavities of the cranial bones. The liver, spleen, and lymph nodes also may be locations of “extramedullary hematopoiesis” in such situations. An extreme example occurs in individuals with thalassemia major, a disease in which erythropoiesis is unusually brisk throughout life, resulting in a characteristic expansion of the marrow spaces of all the cranial bones and long bones and enlargement of the liver and spleen. This is so pronounced that the diploe of the calvarium has a characteristic “hair-on-end” appearance in radiographs of the skull as a result of expansion of the marrow space, and maxillary hyperplasia results in a characteristic facies with prominent cheekbones and malocclusion of the teeth because the maxilla is disproportionately larger than the mandible.

THE STEM CELL MODEL OF HEMATOPOIESIS

Part of "39 - Hematopoiesis and the Hematopoietic Growth Factors"

The cell that gives rise to all other types of blood cells, the stem cell, is so rare that it has never been clearly morphologically identified. Rather, the existence of stem cells is inferred by functional assays that demonstrate the ability of single cells to generate multiple hematopoietic lineages. Thus, stem cells currently are defined not by their appearance but by their function (8). Stem cells are known to be extremely rare cells, although quantifying them is somewhat imprecise as a result of different degrees of rigor applied to the definition of what constitutes a stem cell. The most generous estimate is that stem cells occur in human bone marrow with a frequency of one per 1 million nucleated bone marrow cells, while more conservative estimates place this figure at one per 10 million.

The tremendous production rate of hematopoietic cells requires that the bone marrow produce as many cells as it contains roughly every other day. To maintain this rate throughout life, the bone marrow must contain cells that have the ability to generate vast numbers of mature cells continuously, that is, without losing the ability to do so. This *self-renewal* ability is critical to the concept of the stem cell. Presently, there are two theories as to how this might occur. According to the first theory, every stem-cell division is asymmetric, producing one undifferentiated stem cell and one more differentiated cell that is committed to producing mature blood cells (9). In the second theory, each stem cell division produces either two additional stem cells or two more mature cells. The stem cell pool is thus maintained not by precise asymmetric divisions within each stem cell, but rather by a balance between the number of stem-cell divisions yielding more stem cells and divisions yielding more mature cells.

At the point the stem cell leaves the self-renewing pool to populate the differentiating pool, it is still an unrecognizable blast cell with the capacity to produce cells of all lineages. With each subsequent division, the daughter progenitor cells become more and more restricted in their commitment to the production of specific blood-cell lineages. That is, if one isolates progenitor cells and permits them to propagate and differentiate, they will generate collections of cells that are of only one or a few lineages. The more differentiated the progenitor cell, the fewer lineages are produced and the smaller the number of cells produced (10). These concepts, which have been supported by several decades of *in vivo* and *in vitro* experiments, have now defined the hierarchical stem-cell model of hematopoiesis (Fig. 39.1).

The Hematopoietic Microenvironment

If maintained in a simply nutritive environment, stem cells will die without differentiating or dividing. To support the process of hematopoietic self-renewal and differentiation, stem cells and their progeny must be maintained in the close proximity of nonhematopoietic mesenchymal cells, called *stromal cells*. These cells, which are composed of a heterogeneous group of fibro-blasts, endothelial cells, and adipocytes, line the endosteal surfaces in the bone marrow cavity. These cells appear to supply two closely related requirements for the hematopoietic cells, soluble hematopoietic growth factors and membrane-bound attachment molecules (11).

The *hematopoietic growth factors (HGF), or colony-stimulating factors (CSFs)* are a class of glycoprotein hormones that obligately regulate the division and differentiation of hematopoietic cells. These hormones are required for survival, proliferation, differentiation, and function of all the hematopoietic cells. Although initially discovered as spontaneously secreted products of T-cell tumors, it is clear that these hormones are normally the products of bone marrow stromal cells as well as T lymphocytes and monocytes.

CSFs are produced in a two-tiered process. First, small amounts of certain CSFs — interleukin 6 (IL-6), granulocyte-macrophage colony-stimulating factor (GM-CSF), and stem-cell factor (SCF) — are produced constitutively by bone-marrow stomal cells, probably in response to stimulation by plasma proteins. The production of these CSFs is responsible for basal hematopoiesis, maintaining blood counts in the normal ranges (12).

CSF secretion is greatly increased above the basal levels in response to infection. Bacterial and viral products activate monocytes, which then secrete interleukin 1 (IL-1), tumor necrosis factor a (TNFα), and granulocyte colony-stimulating factor (G-CSF), as well as their own macrophage colony-stimulating factor (M-CSF). These products, in turn, stimulate additional CSF secretion. IL-1, together with antigenic stimulation of specific receptors, activates T cells to secrete GM-CSF and interleukin 3 (IL-3) (13). IL-1 and TNFα each stimulates fibroblasts and endothelial cells in the bone marrow stromal microenvironment to increase their secretion of IL-6 and GM-CSF, and also to secrete large quantities of G-CSF (Fig. 39.2) (14). These cytokines thereby directly increase the numbers of circulating neutrophils, monocytes, and plasma cells as well as activating these same mature cells. The generation of each specific lineage of mature blood cells is in this manner regulated by a specific set of hematopoietic growth factors. Although the sets of hematopoietic growth factors that induce specific mature blood-cell subsets overlap, each is characteristically distinct.

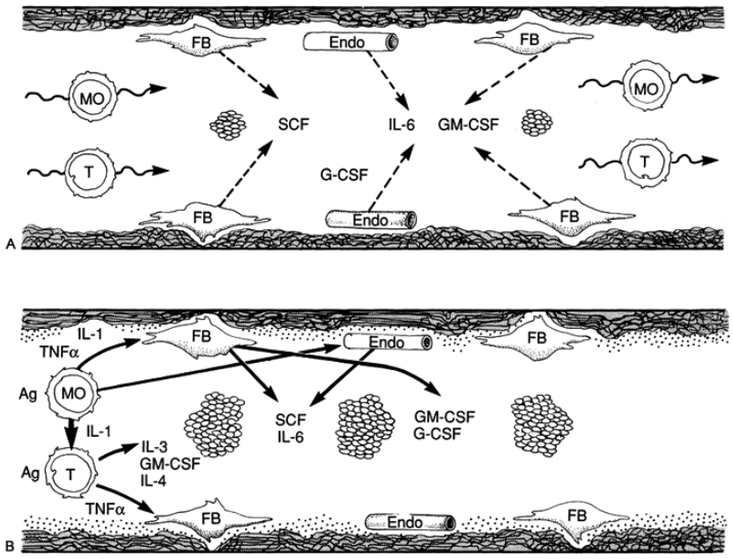

FIGURE 39.1. A: Basal hematopoiesis. **B:** Antigen-amplified hematopoiesis.

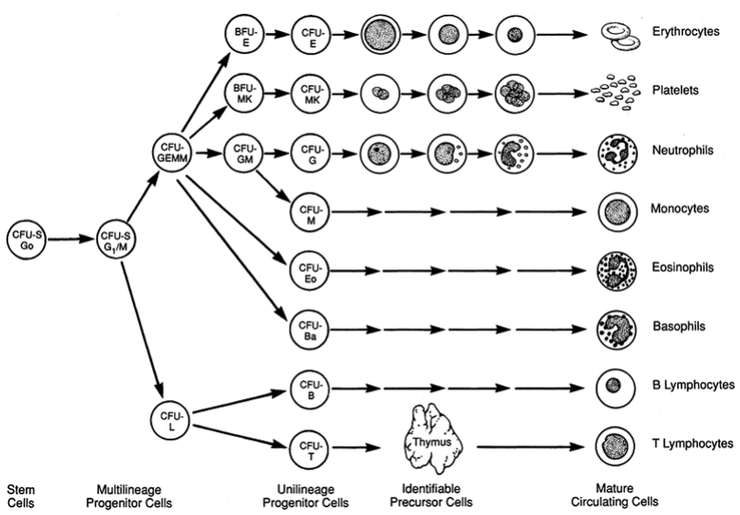

FIGURE 39.2.

Erythropoiesis

The final stages of erythroid differentiation are regulated largely by *erythropoietin*, a glycoprotein produced in response to tissue hypoxia in the fetal liver and adult kidney. Of the 18 or so cell divisions that take place during the time that a stem cell generates a mature red blood cell, the final eight to 10 divisions are strongly induced by erythropoietin. The transcription of the erythropoietin gene in renal peritubular endothelial cells and hepatoblasts is regulated by oxygen-sensitive transcription factors that upregulate gene expression with declining O_2 delivery. Overproduction of erythropoietin, observed in some cases of renal-cell carcinoma and hepatoma, leads directly to erythroid polycythemia.

The preceding cell divisions, which give rise to erythropoietin-sensitive erythroid progenitor cells, are largely erythropoietin-independent. These proliferation and maturation events are instead induced by granulocyte-macrophage colony-stimulating factor (GM-CSF) and *stem-cell factor (SCF)*, both of which are produced locally within the marrow microenvironment by bone-marrow stromal cells. In addition, these steps can be amplified specifically by the secretion of interleukin 3 (IL-3) by activated T lymphocytes (15).

Granulopoiesis

Much like erythroid differentiation, the final stages in neutropoiesis and monopoiesis are induced by *granulocyte colony-stimulating*

factor (G-CSF) and *macrophage colony-stimulating factor (M-CSF)*, respectively. The early divisions, which direct multipotential progenitors to become committed to individual lineages, are regulated by the synergistic interactions of GM-CSF, SCF, and IL-3. As described above, while there is a constant level of basal secretion of CSF by the bone-marrow stromal fibroblasts that line the marrow endosteal surfaces, the secretion of GMCSF and G-CSF is dramatically upregulated in the presence of inflammation in response to the secretion of IL-1 and TNFα by monocytes.

For the production of eosinophils, *interleukin 5 (IL5)* and, to a lesser extent, IL-3 and GM-CSF, play major inductive roles. Basophils and mast cells are directly stimulated by SCF and IL-3. In both of these instances, the initial afferent signals that trigger the release of these cytokines is not yet well understood.

Megakaryopoiesis

The earliest stages in the development of megakaryocytic progenitor cells also appear to be induced by IL-3 and GM-CSF, in conjunction with SCF. What induces the later stages of megakaryopoiesis is not yet certain, but recent evidence suggests that thrombopoietin (TPO) and interleukin 11 (IL-11) play important roles (16). IL-11 and TPO also play roles in the terminal budding events that lead to increased platelet counts.

B Lymphopoiesis

As with the myeloid lineages, the development of B cells begins by the differentiation of pluripotent stem cells into undifferentiated but committed B-cell progenitors. The initial stages in the proliferation and differentiation of these B-cell progenitors are induced by *interleukin 7 (IL-7)* and SCF. Once recognizable pre-B cells and B cells are generated, further differentiation and divisions are induced by stimulation through the immunoglobulin antigen receptor, through the F_cg receptor, and through stimulation by soluble *interleukin 4 (IL-4)* and interleukin 6. Once antibody-producing plasma cells are generated, additional proliferation as well as antibody secretion is stimulated by IL-6 and GM-CSF.

T Lymphopoiesis

Once pre-T cells undergo the complex processes of negative and positive selection in the thymus that generate self/nonself discrimination, the resulting mature T cells are subject to antigen- and cytokine-induced activation and expansion. Stimulation with interleukin 2 (IL-2) as well as antigen leads to preferential

expansion of CD8 T cells, while direct stimulation of the antigen receptor TCR/CD3 along with CD28 leads to preferential activation of CD4 cells.

CLINICAL USE OF HEMATOPOIETIC GROWTH FACTORS

Part of "39 - Hematopoiesis and the Hematopoietic Growth Factors"

Since the first human hematopoietic growth factors were cloned and isolated 8 years ago, preclinical and clinical trials have rapidly led to their introduction into the clinic for routine and experimental use. At the present time, erythropoietin, G-CSF, GMCSF, and IL-11 have all been approved for human use by the Food and Drug Administration (FDA), while IL-3, SCF, and IL-6 have begun phase I and II trials.

Erythropoietin

The *anemia of renal failure* is directly responsive to treatment with erythropoietin. Doses of 50 U/kg three times weekly lead to prompt reticulocytosis, as long as the patients have sufficient iron, folate, and B_{12} stores and have no other source of ongoing inflammation. The only side effect of such treatments is hypertension, if the hemoglobin level rises too high. The introduction of erythropoietin therapy in this manner has made thousands of renal dialysis patients nontransfusion dependent and has greatly improved the quality of their lives (17).

Other anemias, such as in the setting of chronic diseases such as cancer, autoimmune immunodeficiency syndrome (AIDS), and rheumatologic diseases, can also respond to erythropoietin. However, the doses required are higher (150 U/kg or more three times weekly), and even at high doses the responses are variable. In general, the higher the baseline erythropoietin level circulating in the patient's plasma, the less the chance of response to erythropoietin therapy.

A third, growing area of application of erythropoietin therapy is to *autologous donation* of red blood cells prior to elective surgery. By administering erythropoietin under a controlled setting, hematologists can stimulate a mild erythrocytosis, which then allows safe phlebotomy and storage. In this way, it is possible to stimulate and store several units of red blood cells prior to any elective surgery, thus eliminating the need for and risk of allogeneic red-cell transfusion. The only limitations on this therapy are the organizational abilities of hematologists and blood banks. Given the large fraction of blood products that go for urgent and emergent surgeries, allogeneic donation and blood transfusion will still be essential. However, for an increasing fraction of cases, autologous, erythopoietin-stimulated donation and transfusion will be the preferred route for transfusion support.

Granulocyte Colony-Stimulating Factor

When the peripheral neutrophil count is depressed, increased levels of circulating G-CSF can be detected by sensitive assays such as enzyme-linked immunosorbent assay (ELISA). However, the amount of G-CSF produced is suboptimal to stimulate rapid granulopoiesis. Therefore, if additional G-CSF is supplied as a pharmaceutical, the neutrophil count will recover more rapidly and to a higher level. The first major setting in which G-CSF therapy has been applied has been in *chemotherapy-induced neutropenia*. Delivery of G-CSF subcutaneously, in a dosage of 4 to 10 (μg/kg/day), beginning approximately 1 week following chemotherapy, helps lessen the severity of chemotherapy-induced nadirs. Controlled studies have now shown that such treatment helps prevent infections and hospitalizations. Similarly, if patients suffer an infection during a chemotherapy-induced neutropenic nadir, therapy with G-CSF will accelerate their recovery from the nadir. The only side effect observed with G-CSF is bone pain, which occurs in 10% to 15% of patients and can be controlled easily with analgesics.

Pharmacologic doses of G-CSF are also effective in raising the neutrophil count in several cases of chronic neutropenia, such as congenital neutropenia (Kostmann's disease), idiopathic neutropenia, and immune-mediated neutropenias, such as thyroglobulin-lymphoproliferative disease (18). In these cases, however, the doses of G-CSF required can be substantially higher, and the responses are not as uniform.

Granulocyte-Macrophage Colony-Stimulating Factor

Like G-CSF, GM-CSF increases the neutrophil count *in vivo*. However, it has a substantially broader range of activity and also increases the monocyte count and eosinophil count as well. Increases in reticulocytes and platelets also have been reported, but these are less reliable. Given its broad spectrum of activity, GM-CSF has been approved by the FDA for *acceleration of recovery of hematopoietic function following bone-marrow transplantation*. In this setting, GM-CSF clearly shortens the time to recovery, resulting in notably decreased morbidity of the transplantation procedure (19).

In addition, GM-CSF almost certainly has the same salutory effect as G-CSF in preventing and treating chemotherapy-induced nadirs. Although it is possible that its spectrum of side effects (chills, fevers, third-spacing of plasma) might make its use in this setting more problematic than G-CSF, at this time there has been no side-by-side comparison of GM-CSF and G-CSF in any setting.

One recent application of GM-CSF and G-CSF that deserves particular notice is that of progenitor-cell mobilization. In the first trials of GM-CSF, it was found that while the density of bone marrow progenitor cells rose slightly, the density of circulating progenitor cells rose dramatically, often 50- to 100-fold over baseline. Later, very similar data were obtained for G-CSF (and the same is probably true for IL-3 and SCF as well) (20). Based on these data, several bone-marrow transplant centers have used decreasing numbers of peripheral blood leukapheresis collections (from a baseline of eight to 10 down to two to four) to successfully support reengraftment following autologous peripheral blood transplantation. Although there are many questions remaining regarding the cause and the meaning of this effect, as well as the role of progenitor-cell mobilization in transplantation, the application of hematopoietic growth factors to “hemotherapy” in transplantation medicine will be an exciting venue in the decade ahead.

Interleukin-11

Although GM-CSF, IL-3, and IL-6 each have megakaryocytic colony stimulating activity *in vitro*, they have little if any thrombopoietic effect in humans when administered *in vivo*. IL-11, in contrast, does not raise platelet count when administered to patients who became thrombocytopenic following high dose cytotaxin and adriamycin chemotherapy (21). However, the effect of IL-11 is not as uniform as that observed with G-CSF and GM-CSF for neutropenia, so its use to date in the clinic has been more limited.

Stem cell factor (SCF) has to date had little *in vivo* success as a thrombopoietic agent. In contrast, SCF may be more useful as an adjunct to G-CSF for the mobilization of hemotopoietic progenitors and stem cells. However, it should be realized that both SCF and IL-11 are very new drugs, and the full ranges of their clinical utilities are still being determined.

Peripheral Blood and Bone Marrow: Morphology, Counts and Differentials, and Reactive Disorders

Curtis A. Hanson

This chapter covers a variety of topics, all included under the broad category of laboratory hematology. This area is really the substantive, day-to-day component of any routine clinical hematology laboratory. Such a laboratory must have a solid foundation in (a) basic morphologic identification of peripheral blood and bone marrow cells; (b) the complete blood count (CBC) and its components; (c) the differential leukocyte count; (d) basic hematology instrumentation and automation, as related to the CBC and differential count; and (e) a variety of miscellaneous, hematology-associated assays, such as reticulocyte count and erythrocyte sedimentation rate (ESR).

In addition to these morphologic and technological considerations, the laboratorian must have an understanding of the clinical disorders, both benign and malignant, associated with abnormalities of the CBC and differential leukocyte count. Conversely, the interpretation of hematologic data by the clinician must be based on an awareness of how the data were generated and how to avoid the production of spurious results. Thus, to gain the greatest clinical benefit from hematologic studies, a mutual understanding of both the laboratory and clinical components is required.

This chapter is divided into three broad areas: (a) peripheral blood and bone marrow morphology, as this is the basis for understanding normal hematopoiesis as well as clinical hematologic disease; (b) blood cell counting, including the CBC and its components, as well as the differential leukocyte count, reticulocyte count, and the ESR; and (c) nonmalignant disorders of white blood cells, including quantitative increases or decreases in any white blood cell count (WBC) component, benign morphologic disorders, and functional disorders of leukocytes.

PERIPHERAL BLOOD AND BONE MARROW MORPHOLOGY

Part of "40 - Peripheral Blood and Bone Marrow: Morphology, Counts and Differentials, and Reactive Disorders"

The morphologic evaluation of the peripheral blood and bone marrow involves the evaluation of all components of each sample. Examination of the peripheral blood must therefore consist of evaluating the erythrocytes (red blood cells), leukocytes (white blood cells), and platelets (thrombocytes). The leukocyte component consists of five basic cell types: neutrophils, lymphocytes, monocytes, eosinophils, and basophils. Neutrophils, eosinophils, and basophils can also be referred to as granulocytes or polymorphonuclear leukocytes (PMNs). Among neutrophils there are both segmented and band neutrophil types. Each of these different cell components has a particular morphologic appearance, as well as having unique and essential cellular functions.

Peripheral Blood

Neutrophil (Segmented). The segmented neutrophil is an intermediate-size cell (10 to 15 μm) with three to five nuclear segments. Each of the segments is connected by a thin filament. The nuclear chromatin of the neutrophil is coarsely clumped, with no visible nucleoli. The cytoplasm of the neutrophil contains abundant small, azurophilic (secondary) granules that vary in size (Fig. 40.1).

Neutrophil (Band). The band neutrophil is slightly larger than the segmented neutrophil and has a U-shaped nucleus with coarsely clumped chromatin. Instead of a thin filament separating the lobes, as seen in the segmented neutrophils, a band neutrophil has a much thicker band connecting the nuclear segments. This defining criterion is somewhat vague and has led to significant variability and lack of reproducibility between technologists in determining band counts (see the subsection on neutrophilia in this chapter). Cytoplasmic granulation is identical to that found in the segmented neutrophil.

Lymphocyte. The lymphocyte is a round- or oval-shaped cell that varies from small (7 to 10 μm) to intermediate (10 to 20 μm) in size. The nucleus is usually round to slightly indented or folded, having smooth, mature chromatin; parachromatin is not typically visible. Nucleoli are faint. Cytoplasm will vary from scant to abundant and pale blue to basophilic in color. Occasional azurophilic granules may be identified. These granulated lymphocytes are thought to represent either natural killer cells or lymphocytes with cellular cytotoxic action.

Monocyte. The monocyte is an intermediate to large cell (15

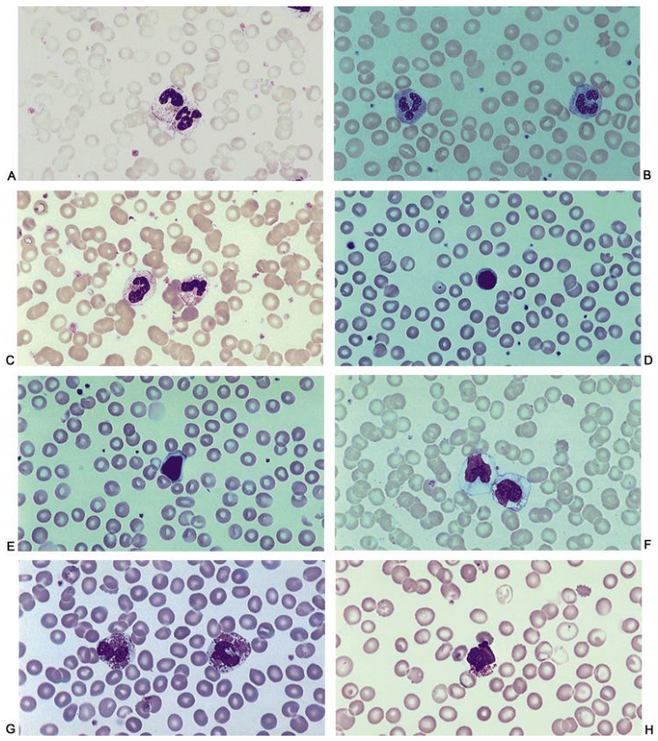

FIGURE 40.1. Peripheral blood smear from a normal individual. **A, B**, Segmented neutrophil; **C**, band neutrophil; **D, E**, lymphocyte; **F**, monocyte; **G**, eosinophil; **H**, basophil.

to 20 μm) with an indented and irregularly folded nucleus. The nucleus consists of what has been described as “raked” chromatin. Nucleoli are typically not seen. The cytoplasm of a monocyte is “dirty,” being grayish blue and occasionally having fine to very small azurophilic granules. Occasional vacuoles may also be identified.

Eosinophil. The eosinophil is an intermediate-size (10 to 15 μm) cell characterized by large, refractile, reddish orange granules. These eosinophilic granules are much larger than those found in neutrophils and are quite distinct in appearance. The nucleus is typically segmented into two or occasionally three lobes. The nuclear chromatin is coarsely clumped with no visible nucleoli.

Basophil. The basophil is similar in size to the neutrophil and eosinophil and contains characteristically large, round, blue-purple granules spread over the nucleus and cytoplasm. This granulation frequently obscures the nuclear features of the cell. The nucleus may contain from one to three lobes and typically has no visible nucleolus. The chromatin of the basophil is slightly different from the chromatin of an eosinophil or neutrophil and is not as coarsely clumped as those two cells. Rather, the basophil nuclear chromatin is smooth, having little visible parachromatin.

Bone Marrow

Granulopoiesis

The normal cellular maturation of the erythrocytic, granulocytic, and monocytic sequence is illustrated in Fig. 40.2. The maturation of the granulocytic series is characterized by sequential steps of reductions in nuclear and cytoplasmic volume, progressive clumping of nuclear chromatin, nuclear lobulation and segmentation, and the sequential loss and gain of primary and secondary granules, respectively (Fig. 40.3). The cells in the first half of the morphologic differentiation scheme (myeloblasts, promyelocytes, and myelocytes) are capable of replication and of undergoing mitosis. The cells in the latter half of myeloid differentiation (metamyelocyte, band neutrophil, segmented neutrophil, eosinophil, and basophil) cannot divide and undergo mitosis.

Myeloblast. The myeloblast is the youngest identifiable cell in the granulocytic series. Myeloblasts are medium-size cells (12 to 16 μm), having high nuclear:cytoplasmic ratios, finely reticular chromatin, and prominent nucleoli. The scant cytoplasm is deep blue and will show rare to few primary, azurophilic granules.

Promyelocyte. The promyelocyte is the largest cell of the granulocytic series, measuring 15 to 22 μm. The prominent azurophilic primary granules are the characteristic feature of this cell. Its nucleus remains round to oval, having fine to perhaps slightly condensed chromatin and typically one to two nucleoli. The amount of cytoplasm in the promyelocyte is slightly more than is found in the myeloblast and is basophilic to pale blue in color. No secondary granules are identified. The primary granules typically overlie both the cytoplasm and the nucleus. At the junction between promyelocyte and myelocyte development, the secondary granules appear in the cytoplasm as a pale, yellowish blush, typically in the Golgi area. It may be difficult to appreciate the specific secondary granules; rather, the early secondary granules give a “patchy,” light blue appearance to the cytoplasm.

Myelocyte. The myelocyte is slightly smaller than the promyelocyte with a central to eccentrically located, round to oval nucleus. The chromatin of the nucleus has begun to clump, but no definite indentation in the nucleus has occurred. Nucleoli are absent or inconspicuous. A moderate amount of cytoplasm is present. The cytoplasm of the myelocyte contains both primary and secondary granules. The secondary granules will appear pink to light blue or purple on a Wright-Giemsa stain. The Golgi hof may be quite prominent in these cells. The amount of cytoplasm relative to the nucleus is increased compared with the promyelocyte stage.

Metamyelocyte. The metamyelocyte is the first stage beyond the mitotically active stages of granulopoiesis. The metamyelocyte is only slightly larger than the mature neutrophil (10 to 18 μm) and shows a slightly indented or kidney bean–shaped nucleus. Chromatin is quite dense with no nucleolus evident. Obviously, secondary granules at this point are quite prominent and far outnumber the larger, darker, primary granules.

Neutrophil/Eosinophil/Basophil. The band and segmented neutrophils, eosinophils, and basophils were previously discussed.

Monocytopoiesis

Monocytes and macrophages constitute the so-called mononuclear phagocyte system (Fig. 40.2). These cells arise from committed stem cells capable of generating either monocytic or granulocytic precursors. After differentiation into mature monocytes, circulating monocytes may eventually migrate to target tissues, where they become macrophages. These macrophages may be present in multiple tissue sites, including the spleen, liver, and lungs.

Monoblast. The monoblast is a large cell (14 to 22 μm) with a round, eccentrically placed nucleus. The nucleus has fine chromatin and prominent nucleoli. There is relatively abundant cytoplasm for such a large, blastic-appearing cell, with certainly more cytoplasm than a typical myeloblast. The cytoplasm is pale blue and may rarely contain some faint azurophilic granules.

Promonocyte. The promonocyte is a poorly defined cell, intermediate between a monoblast and a mature monocyte. Like the monoblast, the promonocyte is a large cell with an indented to slightly irregular nucleus. Nuclear folding does not reach the degree of indentation seen in the mature monocyte and thus is intermediate between a monoblast and a monocyte. The nucleus typically shows one to two faint nucleoli. The nuclear chromatin has begun to show slight condensation and a coarseness beyond that of the typical monoblast. The cytoplasm retains the gray-blue color of a monocyte and typically shows some fine azurophilic granules and occasional vacuoles.

Monocyte. The monocyte was discussed previously.

Erythropoiesis

The process of erythropoiesis begins at the pluripotent stem cell through the intermediate stages to the committed erythroid stem cell unit (Fig. 40.1). The earliest identifiable component of the erythroid series is the pronormoblast. This cell undergoes sequential divisions through the basophilic normoblast to eventually

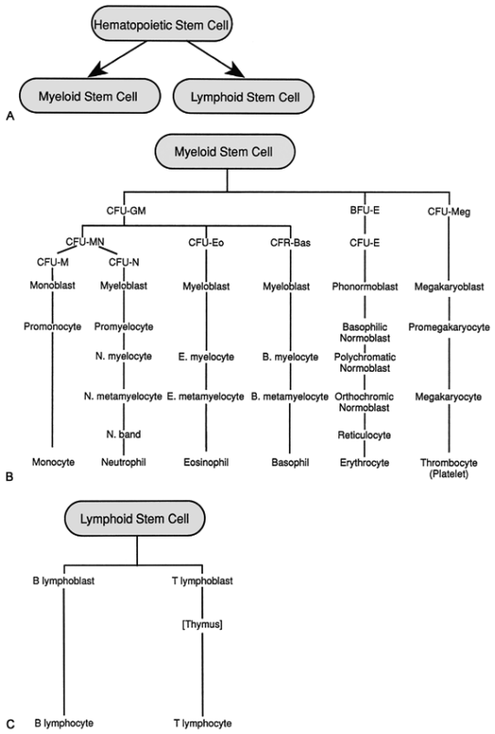

FIGURE 40.2. Schematic line drawing of the normal. **A**, Hematopoietic; **B**, myeloid; **C**, lymphoid maturation sequence. CFU, colony-forming unit; BFU, burst-forming unit; GM, granulocyte/monocyte; M, monocyte; N, neutrophil; Eo, eosinophil; Bas, basophil; E, erythroid; Meg, megakaryocyte.

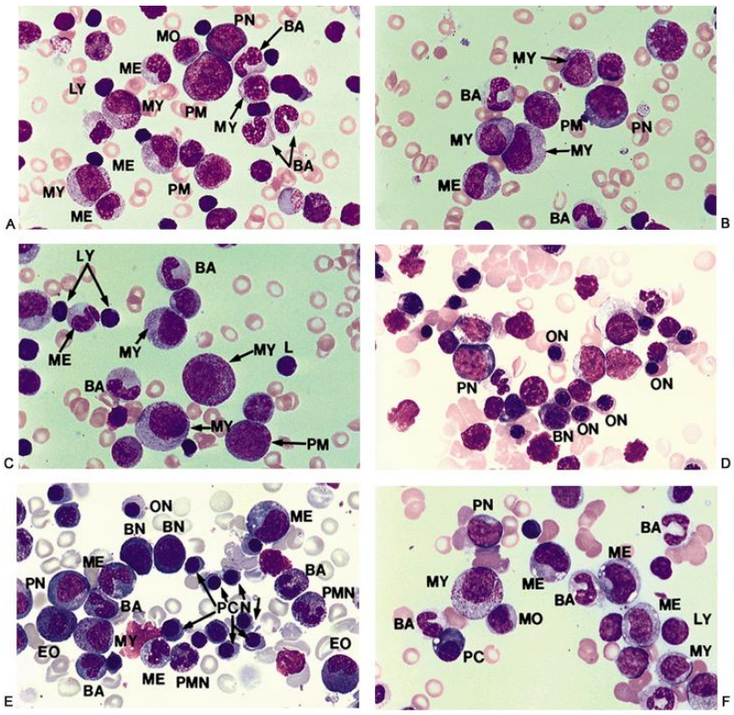

FIGURE 40.3. A–F: Photomicrographs of bone marrow aspirate smears show erythroid and granulocytic maturation. the reticulocyte and a mature red blood cell. Each division results in a decrease in cell size, nuclear condensation, nuclear pyknosis, and eventual extrusion of the nucleus and hemoglobinization of the cytoplasm. The morphologic characteristics of the normal erythroid series are noted below.

Pronormoblast. The pronormoblast is the largest erythroid precursor (15 to 22 μm), having a uniformly round to slightly oval nucleus. The chromatin is finely reticular with one to two prominent nucleoli. The cytoplasm is deeply basophilic and scant in quantity. There is typically a well-defined chromatin rim around the nucleus.

Basophilic Normoblast. The basophilic normoblast is decreased in size (10 to 16 μm) relative to the pronormoblast, having slightly more cytoplasm and a slightly more condensed chromatin pattern. Nucleoli are inconspicuous. The cytoplasm retains the deeply basophilic color seen in the pronormoblast.

Polychromatophilic and Orthochromatic Normoblast. These two cell types constitute the final two sequences of nucleated erythroid

precursors in the bone marrow. They continue to show the reduction in size seen in erythroid differentiation (10 to 15 μm and 8 to 12 μm, respectively). Hemoglobinization becomes evident at these stages as the cytoplasm turns from basophilic to blue-gray to grayish pink and eventually to a definite reddish-orange color. The nucleus shows further chromatin condensation and becomes quite pyknotic in appearance in the orthochromatic stage.

Reticulocyte. The reticulocyte is the first stage of erythroid development that lacks a nucleus. The cytoplasm has a slight gray-blue tinge to the prominent orange-staining color. Vital staining (e.g., with new methylene blue) will show fine basophilic reticulum in the red blood cell, which is the defining feature of a reticulocyte. This represents residual RNA, remaining from previous precursor stages.

Lymphopoiesis

Lymphocytes play an important role in antigen recognition and the subsequent immune response. The earliest lymphocyte precursors undergo the initial maturation steps in the bone marrow before migration to extramedullary sites; lymphocytes can be antigenically and functionally split into B- and T-cell types (Fig. 40.1). The T-lymphocyte precursors migrate from the bone marrow to the thymus, where further differentiation and maturation occur. The thymus provides an appropriate environment such that immunocompetent T lymphocytes are produced. It is in the thymus that T-cell selection occurs, a process whereby cells that would react with “self” are removed; cells that express the preferred T-cell receptors and antigens and have appropriate histocompatibility recognition antigens are selected for further differentiation. From the thymus, mature T lymphocytes are released to the peripheral lymphoid tissues, including the paracortical regions of lymph nodes, the periarteriolar regions of spleen, and other nonlymphoid sites such as in the mucosa of the gastrointestinal tract and pulmonary tree.

The other major component of the lymphoid system is the B lymphocyte. B cells differentiate to maturity within the bone marrow. The normal development and differentiation of B cells begin at the hematopoietic stem cell, go through the early stages of B-cell differentiation while still in the bone marrow, acquire surface immunoglobulin as mature B lymphocytes, and end with plasma cell production of cytoplasmic immunoglobulin. As the mature B cells are released from the bone marrow, they migrate to B-cell areas of lymph nodes and spleen, such as the follicles, mantle zones, and medullary regions. Other B-cell areas include the follicles and follicular areas of mucosa-associated lymphoid tissue.

Lymphopoiesis can be accurately and precisely defined by immunophenotyping studies, which detect surface antigens present at various stages of lymphoid development. Morphology offers a limited perspective of lymphopoiesis and can identify only the lymphoblast, lymphocyte, and plasma cell components.

Lymphoblast. The lymphoblast is a small- to intermediate-size cell (8 to 15 μm) with a round nucleus and scant cytoplasm. The chromatin is fine but slightly coarser than that found in myeloblasts. It has inconspicuous to prominent nucleoli and no observable cytoplasmic granules.

Lymphocyte. The morphology of the lymphocyte was discussed previously.

Plasma Cell. The plasma cell is a small cell (7 to 10 μm) with an eccentrically placed nucleus. The nucleus has coarsely clumped chromatin that has been described as resembling a clock face. The cytoplasm is a basophilic, cornflower-blue color and has a prominent, perinuclear hof.

Megakaryopoiesis

Megakaryopoiesis involves a much different morphologic sequence of differentiation than the other myeloid cell lines (Fig. 40.1). The megakaryoblast is closely related to the early erythroid precursor and morphologically has some resemblance to a primitive pronormoblast. Erythropoietin, which stimulates bone marrow erythroid production, also stimulates megakaryopoiesis and the production of platelets. The megakaryoblast undergoes endomitosis, which involves chromosomal division without cytoplasmic and cellular division. As endomitosis and nuclear segmentation occur, recognizable megakaryocytic precursors can be identified. Endomitosis continues until the megakaryocyte contains 8, 16, or 32 nuclear lobes. This process is accompanied by an increase in cell size and cytoplasm. Eventually the cytoplasm becomes more granular, and small platelets, which are membrane-bound portions of granular cytoplasm, break off and eventually enter the circulation.

Megakaryoblast. The megakaryoblast is a poorly defined cell that may not be easily recognizable as a distinct entity within a normal bone marrow. It may either be a small blast (8 to 15 μm) or much larger in size (18 to 30 μm). The megakaryoblast has a round to oval nucleus, prominent nucleoli, and variable amounts of blue to deeply basophilic cytoplasm. The chromatin may be finely reticular in larger cells or dark and dense in smaller cells.

Megakaryocyte. The megakaryocyte is the largest nucleated cell within the bone marrow and ranges in size from 35 to 100 μm. The megakaryocyte typically has a multilobated nucleus with 8, 16, or 32 nuclear lobes. No nucleoli are evident. The cytoplasm appears light blue and contains finely dispersed granules.

BLOOD CELL COUNTING

Part of "40 - Peripheral Blood and Bone Marrow: Morphology, Counts and Differentials, and Reactive Disorders"

The complete hematologic evaluation of a peripheral blood sample can provide important clinical and diagnostic information about the three major components of the peripheral blood: (a) the erythrocytes or red blood cells, (b) the leukocytes or white blood cells, and (c) the platelets. These studies are useful in screening patients for potential hematologic disorders as well as providing diagnostic information for specific diseases as described in this and other chapters of this section.

The process of performing a basic hematologic analysis of peripheral blood involves four primary steps: (a) collection and processing of the peripheral blood sample, (b) determination of the CBC, including cell concentrations and red blood cell indices, (c) determination of the differential WBC (either automated or manual); and (d) blood film examination for potential morphologic changes/abnormalities. Although these steps are

discussed in some detail here, it may not be appropriate or necessary to perform all four steps on all samples. Rather, there must be appropriate use of laboratory resources according to the presenting clinical indications.

Specimen Collection and Processing

The handling and processing of blood samples can be a forgotten component in providing quality results for the hematology laboratory. Table 40.1 lists some of the preanalytic and analytic errors that can affect hematologic results. Understanding these potential sources of errors is essential knowledge for both laboratorians and clinicians. These include specimen collection, choice of anticoagulant, specimen clotting, storage temperature, time between acquisition and analysis, hemolysis, adequate specimen mixing, hyperlipemia, and other metabolic/biochemical abnormalities. Recognition of these factors by laboratory personnel is essential in providing accurate clinical hematologic data for their clinical colleagues.

TABLE 40.1. THE COMPLETE BLOOD COUNT (CBC): SOURCES OF SPURIOUS RESULTS

CBC Component	Causes of Spurious Increase	Causes of Spurious Decrease
White blood cells (WBC)	Cryoglobulin Heparin Monoclonal proteins Nucleated red cells Platelet clumping Unlysed red cells	Clotting Smudge cells
Red blood cells (RBC)	Cryoglobulin Giant platelets High WBC (>50,000/μL)	Autoagglutination Clotting Hemolysis (*in vitro*) Microcytic red cells
Hemoglobin (Hb)	Carboxyhemoglobin (>10%) Cryoglobulin Hemolysis (*in vivo*) Heparin Hyperbilirubinemia Lipemia Monoclonal proteins	Clotting
Hematocrit (Hct) (automated)	Cryoglobulin Giant platelets High WBC (>50,000/μL) Hyperglycemia (>600 mg/dL)	Autoagglutination Clotting Hemolysis (*in vitro*) Microcytic red cells
Hematocrit (microhematocrit)	Hyponatremia Plasma trapping	Excess ethylenediaminetetraacetic acid Hemolysis (*in vitro*) Hypernatremia
Mean corpuscular volume	Autoagglutination High WBC (>50,000/μL) Hyperglycemia	Cryoglobulin Giant platelets Hemolysis (*in vitro*) Microcytic red cells Swollen RBC
Mean corpuscular hemoglobin	High WBC (>50,000/μL) Spuriously high Hb Spuriously high RBC	Spuriously low Hb Spuriously high RBC
Mean corpuscular hemoglobin concentration	Autoagglutination Clotting Hemolysis (*in vitro*) Hemolysis (*in vivo*) Spuriously high Hb Spuriously low Hct	High WBC (>50,000/μL) Spuriously low Hb Spuriously high Hct
Platelets	Cryoglobulin Hemolysis (*in vitro* and *in vivo*) Microcytic red cells Red cell inclusions White cell fragments	Clotting Giant platelets Heparin Platelet clumping Platelet satellitosis

Venipuncture/Anticoagulants

Peripheral blood for hematologic tests is typically obtained from a venipuncture specimen. Blood may also be drawn from pricking the fingertip, heel, great toe, or earlobe. The blood should be collected into a tube containing an anticoagulant and thoroughly mixed. The choice of anticoagulants for hematologic studies include ethylenediaminetetraacetic acid (EDTA) (sodium or potassium salts), trisodium citrate, and heparin, with EDTA being the standard anticoagulant of choice for hematologic studies. Citrate and EDTA are, in effect, calcium chelators and thus remove calcium, which is an essential ingredient for the coagulation

process. Heparin inhibits thrombin formation by complexing with antithrombin III.

EDTA specimens may produce significant morphologic artifacts on blood films if allowed to stand for more than 2 to 3 hours, although instrument analysis is stable for as long as 8 hours at room temperature. If analysis cannot be performed within 8 hours, clinical specimens can be refrigerated for as long as 24 hours at 4°C with little degradation of instrument results. Specimens with EDTA kept at room temperature for more than 8 hours may show an artifactual increase in the mean corpuscular volume (MCV) and a decrease in both the mean corpuscular hemoglobin concentration (MCHC) and ESR.

Citrate is most commonly used for coagulation and special platelet studies but may be useful for routine hematologic studies if EDTA-dependent platelet agglutination is present; blood counts should be increased by a factor of 1.1 if citrate is used to account for the sample dilution that occurs with the use of sodium citrate. Heparin is a sufficient anticoagulant for red blood cell analysis but may cause clumping of platelets or leukocytes. These imitations of available anticoagulants have basically mandated that most hospital-based hematology work be performed on-site and that referral hematologic specimens be acquired within a relatively short time of analysis to minimize laboratory and morphologic artifact.

Complete Blood Count

The CBC is the backbone of any hematologic evaluation. The CBC includes a determination of (a) red blood cell data, such as total red blood cell count (RBC); hemoglobin/hematocrit; red blood cell indices, including MCV, MCHC, and mean corpuscular hemoglobin (MCH); and the red cell distribution width (RDW); (b) white blood cell data; and, usually, (c) platelet count and, sometimes, mean platelet volume (MPV). A differential WBC may also be part of a routine CBC in some laboratories, although a more judicial use of the differential count is probably warranted.

The CBC in the broadest sense can provide important baseline information about the functional state of the bone marrow. Recognition of a "-penia," or deficiency of a blood component, is indication of either a marrow-production problem or peripheral destruction activity. Likewise, a "-cytosis," or elevation of a blood component, could indicate either a normal marrow response to a peripheral stimulation or the peripheral manifestation of an uncontrolled malignant proliferation. Thus, in general, the CBC is useful in broadly screening for hematologic disease (Table 40.2). The hemoglobin and/or hematocrit quantify the degree of anemia or polycythemia and the MCV/MCHC/RDW can be useful in further subclassifying the type of anemia (e.g., normocytic, microcytic, macrocytic). The WBC can provide diagnostic or follow-up information regarding either a benign response or malignant process (see later in this chapter). Obtaining a platelet count is the first step in the evaluation of the hemostatic process. Any of the CBC components can be useful in monitoring patient responses to therapy (e.g., iron, vitamin B_{12}/folate, marrow toxicity owing to drugs, chemotherapy).

TABLE 40.2. INDICATIONS FOR ORDERING THE COMPLETE BLOOD COUNT

Ambulatory population	
General population (screening)	Not useful
Specific subgroups (e.g., pregnant women, elderly, immigrants.)	Possibly useful
Hospital population	
No abnormality suspected	Rarely useful
Hematologic abnormality suspected	Useful
Repetitive testing	Useful in some patients at appropriate intervals

The appropriate ordering of the CBC is not something that has been seriously debated in the medical literature. Indeed, the role of the CBC has been considered a virtual icon in the evaluation of hospitalized as well as ambulatory patients. The challenge to the medical community will be to develop practice parameters for CBC utility in various patient settings. The CBC as a screening device in the ambulatory setting has limited utility in the general population because of the low prevalence of asymptomatic disease that would be detected by a routine CBC. Indeed, even the detection of mild asymptomatic abnormalities with the CBC, such as mild anemia, may not offer any real clinical benefit to the patient. Screening of particular subgroups, such as pregnant women, institutionalized geriatric persons, and possibly immigrants from Third-World countries, may be useful because the prevalence of hematologic disease is higher in those groups than in the general population. However, no studies have been done in these groups to justify the benefit of CBC screening for disease.

It is in hospitalized patients that the routine CBC has been most abused both as an admission screen and as a repetitive follow-up test. If no hematologic abnormality is suspected clinically, the CBC is rarely useful on patients admitted to a hospital. Those clinical situations in which a routine CBC would be of questionable value include elective surgeries in which only minor blood loss is anticipated, for patients undergoing minor diagnostic procedures, and for patients who have no clinical indication of a hematologic abnormality. If, however, a hematologic abnormality is suspected clinically, the CBC is obviously indicated and may be useful in confirming either a primary or reactive hematologic disorder that may have an impact on disease diagnosis and management.

It is also difficult to document the effectiveness of repetitive CBC testing. Unfortunately, it has become common practice to order repetitive CBCs (e.g., daily) for patients for whom no benefit may be gleaned. If a patient clinically responds to treatment for a hematologic disease, then ordering a repetitive CBC would not be beneficial unless there is indication that such treatment has not been effective. This aspect of defining appropriate testing intervals for the CBC has not been studied extensively and remains a major challenge.

Table 40.2 provides a summary of the utility and indications for obtaining a CBC. Although laboratories have generally not sought to control the flow of CBC samples, it seems inevitable that some limitation of its use will evolve as health care cost containment grows in importance. The greatest challenge to laboratorians will be devising practice standards that outline more effectively the indications for routine and follow-up CBCs for both hospitalized and ambulatory patients.

Hematology Analyzers/Instrumentation

Clinical hematology laboratories have undergone significant changes in the arena of automation as technological advances have continually evolved. The era of manual CBC determinations has thankfully ended, with automated blood analysis now a routine part of virtually all hematology laboratories. Automated red blood cell and white blood cell counters emerged in the clinical laboratories in the 1960s. The addition of platelet counters, seven-parameter CBC analyzers, and three-parameter differential leukocyte counters appeared in the 1970s. The 1980s were characterized by single, stand-alone instruments capable of performing 10-parameter CBCs. The greatest change in the hematology laboratory came in the latter part of the 1980s and the early 1990s with the development of more sophisticated and accurate leukocyte differential counters. Changes that have emerged over the past few years include bar-code readers, closed-tube sampling, automated sampling systems, and “walk-away” analysis stations. Bar-code readers have allowed for efficient and high throughput of specimens and provide more accurate patient and specimen identification. Closed-tube sampling has been a tremendous benefit in this era of universal precautions and the recognition of high-risk blood samples. The “walk-away” features of many instruments has been made possible because of the built-in mixing systems as well as simple robotics for specimen aspiration and handling.

It is improbable that more clinically relevant parameters will be extrapolated from the CBC. Therefore, one would predict that the next decade or two will show advances and changes related to two areas: increasing automation and walk-away capabilities of the instrument with the eventual use of robotics to handle and process specimens and increasing use of computer analytic capabilities to control utilization of hematologic testing as well as providing more innovative ways to display and interpret laboratory data.

One can envision the evolution of robotic techniques that would allow specimens to be transported from a central receiving area to the hematology instrument based on appropriate specimen bar coding. Technologist interaction would be needed at the point of troubleshooting or manual slide making (another potential automated area). The power of today's computers to store and analyze large clinical databases will also permit the evolution of autoverification of patient results. In addition, by interrogating the patient database, computer capabilities may allow the laboratorian better control over the utilization of the CBCs and differential WBCs; in particular, controlling the frequency of repetitive CBCs and differential WBCs. Last, more sophisticated laboratory information systems will, it is hoped, allow the laboratories to present their data in a more meaningful clinical fashion. For example, the capability to present data graphically or in combination with results from other laboratories (for example, hemoglobin values with Coombs' test, transfusion record, and bilirubin) could be a major enhancement in how laboratory data are interpreted clinically.

Total RBC

For most medical technologists, the hemacytometer is merely a reminder of how technology has improved their lives. It is safe to write that virtually all modern laboratories use some form of automated counting to determine the total RBC. Nearly all modern instruments use either electrical impedance methods or laser light-scatter characteristics to determine the RBC. Although frequently ignored in the evaluation of a CBC, the RBC is the basis for calculating the hematocrit, MCH, and MCHC. In addition, the RBC may have value by itself when attempting to distinguish iron deficiency anemia from thalassemia in patients with an unknown microcytic anemia. In iron deficiency, the RBC diminishes in proportion with the hemoglobin concentration. This is in contrast with thalassemia, in which the RBC may be normal to increased relative to the degree of anemia as shown by the hemoglobin value. Several mathematical formulas have been derived in an attempt to distinguish these disorders more accurately; none has proved perfect, and most have been too complex to remember. A simple formula reported by Baker and Cornbleet (1) takes the MCV divided by the RBC; a value greater than 13 favors iron deficiency and a value less than 13 favors thalassemia.

Automated counting methods for red blood cells have been based primarily on electrical impedance or light-scattering techniques. These methods allow both the counting of total cells and determining the cell size (i.e., the MCV) of the red blood cells. Analyzer from the Beckman Coulter, Inc., Fullerton, California uses the electrical impedance method, whereas light-scattering techniques have been pioneered with the Bayer Advia, Tarrytown, New York analyzers. The electrical impedance method requires that cells pass an aperture through which a current is passing. As the cells cross the electrical current, the change in the electrical resistance that can be detected is proportional to the cell size. In light-scattering techniques, photomultiplier tubes detect changes in light scatter as the cells pass through a flow cell. Various cell types can be distinguished from these light-scatter characteristics based on cell size and granularity.

Very few clinical situations will result in false elevations or decreases in the total RBC. Red blood cell autoagglutination and extreme red blood cell microcytosis may lead to spurious decreases in the reported total RBC. In the latter case, the small red blood cells may be counted as large platelets and not be included in the red blood cell histograms, whereas autoagglutination can result in the red blood cell “clump” being counted as a single cell. Conversely, very high WBCs as well as cryoglobinemia may both lead to false elevations in total RBC. High WBCs, typically if greater than 100.0×10^9 cells/L, can significantly add to the total RBC, whereas normal WBCs have little impact on the total RBC.

Hemoglobin

The primary function of the red blood cell is transporting oxygen and carbon dioxide. Hemoglobin within the cell takes up oxygen within the lungs and releases it in tissues in exchange for carbon dioxide. This regulated delivery and control of oxygen and carbon dioxide exchange is obviously an extremely vital component of the mammalian system. The role of oxygen delivery depends on the binding of hemoglobin to oxygen. The equilibrium between oxygen and hemoglobin varies according to oxygen tension (PO_2). This dissociation curve (the so-called oxygen

TABLE 40.3. HEMOGLOBIN DERIVATIVES: ABSORPTION MAXIMAS

Hemoglobin	Abbreviation/Terms	Maxima (nm)
Hemoglobin	Hb	431,555
Oxyhemoglobin	HbO_2	415,542
Carboxyhemoglobin	HbCO	420,539
Sulfhemoglobin	SHb	—
Carboxysulfhemoglobin	SHbCO	—
Hemiglobin	Hi/methemoglobin	406,500

Modified from van Assendelft OW. *Spectrophotometry of haemoglobin derivatives*. Assen, The Netherlands: Royal Van Gorcum Ltd., 1970.

dissociation curve) demonstrates the saturation process of hemoglobin relative to the conditions found in both lung (binding of oxygen) and peripheral tissue capillaries (release of oxygen).

Hemoglobin constitutes more than 90% of the red blood cell and is composed of two pairs of globin chains ($\alpha 2B_2$) and four heme groups containing ferrous iron. A decrease in hemoglobin concentration is referred to as an anemia, whereas an increase in hemoglobin concentration is called polycythemia. Some clinical conditions can lead to the formation of oxidized hemoglobin (for example, Heinz body anemias); this oxidized hemoglobin is called methemoglobin, which has a reduced capacity for carrying carbon dioxide. Sulfhemoglobin is an uncommon form of hemoglobin that results from the addition of sulfur to the hemoglobin molecule during the process of oxidation. Sulfhemoglobin cannot carry oxygen and typically accounts for less than 1% of all hemoglobins. Clinically, sulfhemoglobin has been reported in some patients receiving sulfa-based drugs, as well as in some patients with clostridium bacteremia. Carboxyhemoglobin normally accounts for less than 1% of the overall hemoglobin concentration and is produced during the process of heme metabolism to bilirubin.

The interaction of carbon monoxide and hemoglobin deserves specific mention. The affinity of carbon monoxide to hemoglobin is much greater than with oxygen (more than 200 times greater). Thus, even small concentrations of carbon monoxide in the air will preferentially bind to hemoglobin and thus prevent oxygen exchange and transportation. Acute carbon monoxide poisoning is the most dramatic cause of elevated carboxyhemoglobin levels. Long-term carbon monoxide exposure as a result of smoking, or smoke exposure, may also lead to elevation of carboxyhemoglobin and a "left shift" in the oxygen dissociation curve. The differentiation of these various hemoglobin derivatives is classically based on spectrophotometric determination. The various hemoglobins have particular absorption spectra, shown in Table 40.3.

Hemoglobin is most commonly determined by spectrophotometry in modern instrumentation using a cyanomethemoglobin procedure; this is the standard method by which virtually all hematology instruments measure hemoglobin. This procedure involves oxidizing all hemoglobin to methemoglobin by using excess ferric iron (potassium ferricyanide). Excess cyanide ions (potassium cyanide) subsequently leads to the formation of cyanated methemoglobin (which maximally absorbs light at 540 nm). Other forms of hemoglobin besides cyanomethemoglobin, including hemoglobin, oxyhemoglobin, carboxyhemoglobin, and methemoglobin, will also absorb light at 540 nm (Table 40.3). Falsely elevated (real or apparent) hemoglobin absorbances can occur owing to hyperlipemia, fat droplets (associated with hyperalimentation), hypergammaglobulinemia, cryoglobulemia, or a leukocytosis (more than 50.0×10^9 cells/L). Improperly collected blood specimens (venipuncture or fingerstick) can also cause falsely elevated (hemoconcentrate) or falsely decreased (hemodilute) levels. Other laboratory methods for the determination of hemoglobin have been based on detecting oxyhemoglobin or by detecting the iron content of whole blood. Neither method is widely performed because of the lack of standardization or the inherent complexity of the process.

The automated determination of hemoglobin has bypassed many of the inherent errors of manual hemoglobin detection. However, variation in results can still occur from a variety of situations. As discussed earlier, sample collection problems or specimen abnormalities (e.g., hyperlipemia) can give falsely elevated or decreased hemoglobin levels. Hemoglobin concentrations are reported in grams per deciliter or grams per liter and vary according to age, gender, and ethnic background (Table 40.4). Cord blood or newborn capillary blood can be more concentrated (as much as 2 g/dL) than venous blood; premature infants have lower hemoglobin values than term infants. The average hemoglobin concentration drops dramatically during the first month of life and does not significantly increase until after puberty. Adult females have hemoglobin values of 1.0 to 2.0 g/dL lower than adult males. It also has been recognized that blacks of both genders have slightly lower mean hemoglobin levels than whites. All this normal variation mandates that different normal ranges be utilized for reporting hematologic results and that the clinical interpretation of CBC findings be done in conjunction with all appropriate clinical findings.

TABLE 40.4A. COMPLETE BLOOD COUNT: NORMAL VALUES

Age	Hb[a] (g/dL)	Hct (%)	RBC ($\times 10^{12}$-L)	MCV (fl)	MCH (pg)	MCHC (g/dL)	RDW (%)

Hematocrit

The hematocrit is simply the ratio of the volume of the red blood cells to the volume of the whole blood. Although hematocrits can be determined directly by centrifugation ("spun" hematocrits), most hematocrits are now calculated directly from the RBC and MCV: hematocrit = RBC (cells/L) × MCV (liter/cell) (Table 40.5). Thus, any factor leading to spurious errors in RBC or MCV determination will also lead to spurious hematocrit results. Because the hematocrit is thus derived from two separate factors and all their sources of error, it should be clear that the hematocrit is a less accurate measure of anemia than the direct determination of hemoglobin concentration.

Manual or spun methods for determining hematocrits are still used in some circumstances and are based on centrifuging capillary blood tubes at 10,000 to 15,000*g* to separate the fluid and cell components of the blood. Spun hematocrits may give spuriously high results if a significant concentration of plasma becomes trapped in the red cell layer. This phenomenon can be found in samples with polycythemia, macrocytosis, spherocytosis, hypochromic anemias, and red blood cell fragment disorders (such as sickle cell anemia or burn patients). Improper mixing and excessive dilution with anticoagulant can also lead to inaccurate spun hematocrit levels.

Red Blood Cell Indices

The red blood cell indices are a key component of the CBC. These include the MCV, MCH, and MCHC, which are used to determine the size, cellular hemoglobin, and hemoglobin concentration of the red blood cells, respectively. The MCV is the most useful of the red blood cell indices and is especially important in classifying anemias as either normocytic (normal MCV), microcytic (decreased MCV), or macrocytic (increased MCV) (see Chapter 41 for more details). The MCV is determined by the distribution of the red blood cell histogram (Fig. 40.4). The mean of the red blood cell distribution histogram, based on electrical impedance, is the MCV and the coefficient of variation (or sometimes the standard deviation) is the RDW (discussed later).

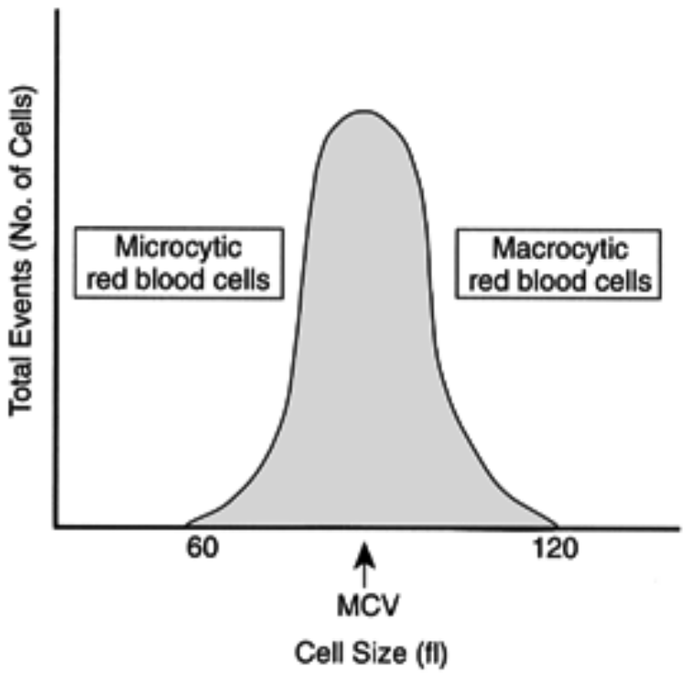

FIGURE 40.4. Red cell distribution histogram from an automated blood analyzer. The number of events counted (*y* axis) is plotted versus the cell size or volume (*x* axis). The median value of the histogram distribution is the mean corpuscular volume (MCV) of the sample. The coefficient of variation (or in some cases, the standard deviation) is equivalent to the red cell distribution width. Microcytic red blood cells, large platelets, and debris fall to the left portion of the curve, and macrocytic red blood cells, and small leukocytes fall to the right.

The MCH is the hemoglobin concentration per cell and is calculated from the hemoglobin and RBC (Table 40.5). It is of little use clinically and typically follows the movement of the MCV value. The MCHC is the average hemoglobin concentration per total red blood cell volume (Table 40.5) and is of minimal diagnostic use. A decrease in MCHC provides little clinical information and may not be noted until, for example, late in the course of an iron deficiency anemia. An increased MCHC is indicative of instrumentation or specimen problems and is a useful tool in the quality-control process. When MCHCs (hemoglobin/hematocrit) were determined manually (before automated instruments were widely used), a low MCHC was more commonly encountered in iron deficiency. This erroneous finding was the result of spuriously elevated spun hematocrits with the plasma trapping seen in microcytic anemias. Thus, the MCV is the only one of its red blood cell indices that provides consistently

TABLE 40.5. COMPONENTS OF THE COMPLETE BLOOD COUNT

CBC	Traditional Units	International Units
Hemoglobin	g/dL	g/L
Hematocrit	dL/dL (%)	L/L (%)
Red blood cells (RBC)	10^6 cells/μL	10^{12} cells/L
White blood cells	10^3 cells/μL	10^9 cells/L
Platelet count	10^3 plt/μL	10^9 platelets/L
Mean corpuscular volume (MCV)	fl/cell	fl (10^{-15}L/cell)
Mean corpuscular hemoglobin (MCH)	pg/cell	pg (10^{-12}g)/cell
Mean corpuscular hemoglobin concentration (MCHC)	g/dL	g/L
Derived CBC Values		
Hematocrit (Hct) (L/L;%) = [MCV (in liters per cell)] × [RBC (in cells/L)]		
MCH (pg/cell) = [HB (in g/L)] / [RBC (in cells/L)]		
MCHC (g/dL) = [Hb (in g/dL)] / [Hct (in L/L)]		

CBC, Complete blood count.

useful clinical information, with the MCH and MCHC useful primarily for quality-control purposes.

Red Cell Distribution Width

The RDW provides some insight and quantification into the variation in red cell size, or anisocytosis. It is derived from the red blood cell histogram and represents the coefficient of variation (or, in some cases, the standard deviation) of the red cell histogram distribution curve (Fig. 40.4). Bessman et al. (2) proposed a system of classifying anemias based on RDW and suggested that it may be a more sensitive indicator of a change in cell size than purely the MCV (Table 40.6). In general, an elevated RDW has been associated with anemias from various deficiencies such as iron, vitamin B_{12}, or folate. This is to be contrasted with the normal RDW that classically characterizes the microcytic anemias seen in thalassemia. However, as in most laboratory tests, this single red blood cell parameter has been shown to have more than its share of false positives and false negatives relative to this classification scheme. Indeed, some cases of thalassemia may have an elevated RDW, and cases with anemia of chronic disease that have slightly lower MCVs appear to have slightly elevated RDWs; myelodysplastic syndromes and some malignancies may also be associated with elevated RDWs. Thus, the RDW must be interpreted in conjunction with other CBC data in interpreting the abnormal hemogram.

TABLE 40.6. UTILITY OF RDW AND MCV IN CLASSIFICATION OF ANEMIA

MCV	RDW Normal	RDW High
Low	Thalassemia trait	Iron deficiency
	Transfusion	S-ß-thalassemia
	Chemotherapy	Hemoglobin H
	Malignancy	RBC fragmentations
	Hemorrhage	
	Hereditary spherocytosis	
	Posttraumatic splenectomy	
Normal	Normal	Transfusion
	Chronic disease	Early iron, B_{12}, or folate deficiency
		Homozygous hemoglobinopathy
		Myelofibrosis
		Sideroblastic anemia
High	Aplastic anemia	Folate deficiency
	Liver disease	B_{12} deficiency
		Cold agglutinin
		Hemolytic anemia
		Chemotherapy

RDW, red cell distribution width; MCV, mean corpuscular volume; RBC, red blood cell.

WBC—Total

The total WBC (or leukocyte count) consists of the PMNs (segmented and band forms), lymphocytes, monocytes, eosinophils, basophils, and potentially any other circulating hematopoietic cells. Historically, nucleated red blood cells are not included and are typically subtracted from the total WBC. WBCs are performed on EDTA-anticoagulated blood. With automated hematology counters, the total WBC, like the total RBC, is determined by either electrical impedance methods or light-scatter techniques. Hemacytometers are not used routinely in hematology laboratories for the WBC but may be used if the automated counters fail to provide accurate results, such as in leukopenic or leukemic patients. In either method, the red blood cells are lysed before the determination of the WBC.

The WBC can provide important diagnostic and monitoring information in patients with primary hematologic disease or acute/chronic infectious processes. The WBC also provides appropriate therapeutic data after administration of chemotherapy, radiation therapy, or antimicrobial agents. Because the WBC is composed predominantly of PMNs, any change in the total WBC typically reflects a change in the total PMN count. However, the WBC by itself is neither highly sensitive nor specific for an acute or chronic infectious process. In other words, an elevated WBC should not be considered as evidence of an infectious process unless there is clinical evidence of such and, conversely, a low WBC does not rule out an infectious process when clinical findings favor an infectious process. Other causes of elevated WBC include trauma, surgery (24 to 48 hours after), hemorrhage, delivery, tissue necrosis, and corticosteroids and other medications.

Heparinized blood should not be used for determining the WBC because of its interference with lysing reagents and its association with platelet agglutination in some specimens. As mentioned previously, citrate anticoagulant may be useful in cases with EDTA-dependent platelet agglutination; a correction factor of 1.1 is needed to account for the extra volume of anticoagulant used.

With the electrical impedance method, the red blood cells are first lysed and the remaining white blood cells pass through a narrow aperture, one cell at a time, which changes the electrical current across that opening. The change in current is proportional to the cell number and cell size. As with the total RBC, light-scatter characteristics may be used to determine the WBC as the light scatter relates to cell size and cellular content. As with any CBC component, various clinical and specimen characteristics may lead to spurious WBC results. Nucleated red blood cells, cryoglobulin, platelet clumps, large platelets, and unlysed red blood cells may all lead to false elevations of the total WBC. As mentioned previously, nucleated red blood cells are usually excluded from the corrected WBC; the following formula is used: corrected WBC = (measured WBC × 100)/[100 + (*n* red cells/100 white cells)].

White Blood Cell Count—Differential

The differential WBC (or differential leukocyte count) remains one of the most frequently performed tests in the clinical hematology laboratory. Until the early 1970s, the only accepted method for performing a differential count was microscopic examination of a Romanowsky-stained peripheral blood smear. Traditionally, the differential WBC includes the counting and categorization of typically 100 white blood cells based on morphologic criteria, with the results being expressed as a percentage of each cell type identified. Absolute concentrations of the various cell types are calculated by multiplying the percentage by the total WBC. In addition to the differential count, morphologic evaluation of the smear provides the opportunity to evaluate morphologically all components of the peripheral blood, including red blood cells, white blood cells, and platelets. This is a key advantage of the manual differential in that it allows the detection of a variety of disorders that might otherwise be lost in a totally automated system.

The manual performance of a differential count, i.e., the manual differential, is a time-consuming, labor-intensive, and relatively expensive procedure in this era of technological advances and automation. In addition to these technical and administrative disadvantages, the traditional manual differential count has other medical and scientific limitations, including poor sensitivity, specificity, and predictive value; it is imprecise because of sampling error and statistical probabilities and is prone to subjective judgmental errors. Nonetheless, the manual differential count has remained the gold standard of differential WBCs.

To interpret accurately the morphologic features of a peripheral blood film, several technical steps are required. First, the film must be well made with a good “feathered” edge and preferably with space around all slide edges. There should be a uniform distribution of cells and uniformly distributed Wright's or Wright-Giemsa stain. Although these basic requirements seem rather obvious, they can be easily forgotten in the laboratory, which can lead to inaccurate differential counts.

The area behind the feather edge of the blood film is the site of accurate counting. In this area, the red cells should show typical central pallor without being clumped. The smear is examined in a logical pattern, moving from one edge to another. Typically, 100 consecutive white blood cells are identified and classified by the morphologic reviewer. Other morphologic abnormalities are also noted during this process.

It is important to realize the statistical impact that a 100-cell count has on overall differential accuracy. The greater the number of cells counted, the greater the statistical precision of a differential count. Table 40.7 illustrates the 95% confidence interval limits for various blood cell percentages as determined by the total cell count obtained. Basically, the fewer cells that are counted, the less precise the blood cell percentage is. This is especially true with the cells that account for relatively lower percentages, as would be seen with neutrophil bands, monocytes, eosinophils, and basophils. For example, a band count of 5% obtained at one time would not represent a statistically significant change in the percentage of bands compared with a 10% count the following day if a 100-cell differential count is performed. This can be contrasted to obtaining either a 500- or 1,000-cell differential count in which a change from 5% to 10% would be considered statistically significant. In addition to this statistical variation dependent on total cell counts obtained, one must keep in mind the large number of errors that can result from inadequately collected or processed blood samples, poor-quality blood films, inconsistent staining, or judgmental errors by the technologist or physician performing the differential count. All these components emphasize the deficiencies of the manual differential count. Thus, the historical reliance on the manual differential count as the gold standard of the hematology laboratory must be viewed skeptically, considering the major sources of error that can potentially contribute to the determination of the differential WBC.

TABLE 40.7. CONFIDENCE LIMITS (95%) FOR PERCENTAGES OF CELLS REPORTED IN A MANUAL DIFFERENTIAL COUNT

% Reported	*n* = 100	*n* = 1,000	*n* = 10,000

Modified from Rümke CL, Bezemer PD, Kuik OJ. Normal values and least significant differences for differential leukocyte counts. *J Chron Dis* 1975;28:661–668.

Because of the significant limitations of the differential WBC, the clinical hematology laboratory has incorporated the use of numerous instruments with the capability to perform differential WBCs. Two basic methodologies have been used as automated differential counters in the clinical laboratory. These are digital

image analysis systems based on cell recognition from a stained blood smear and the determination of different leukocyte cellular characteristics that permit separation into subtypes by using various flow cell–related techniques. This latter methodology has become the standard in automated differential counts and is based on the use of either electrical impedance or light-scattering techniques.

Automated differential leukocyte counts as performed by modern hematology analyzers are more accurate, more precise, more economical, faster, and safer than traditional manual differential counts. Although the goal of any automated differential leukocyte counting system is to replace the manual differential count, this has not been fully accomplished in the clinical laboratory. The automated differential WBC is superior to the manual differential count in many aspects, but in some cases it fails to provide important morphologic detail that only the manual differential/review can provide. For example, red cell morphologic findings, categorization of immature granulocytes, and recognition of intracellular or extracellular organisms (e.g., malaria) can be accurately identified only on a manual smear. Thus, all modern clinical hematology laboratories have to deal with how an automated differential leukocyte count can be incorporated into the routine practice of that particular laboratory.

Most laboratorians would agree that the initial differential count for every patient, whether hospitalized or ambulatory, should be performed by automated methods. The key to successful implementation is based on the ability of the instrument to recognize both quantitative and qualitative abnormalities and to flag particular cases for further review. These flagged results may then lead to either a manual differential count or at least a manual review of the stained blood smear. Figure 40.5 demonstrates an approach to incorporating automated differential counts with manual reviews to best meet the patient's needs while still maintaining appropriate utilization of laboratory resources. It is the ability to recognize these qualitative abnormalities that determines the success of an automated differential count in a particular laboratory. The laboratorian must expect a false-negative rate that approaches 0%, while enduring a false-positive rate that is not too high. Obviously, the kinds of patients evaluated by a clinical hematology laboratory and the overall percentage of abnormal differential counts will also influence the degree of success of the automated differential. Thus, the type of instrument, the flagging criteria chosen, and the patient population served by the laboratory will determine the role of automated differential counts.

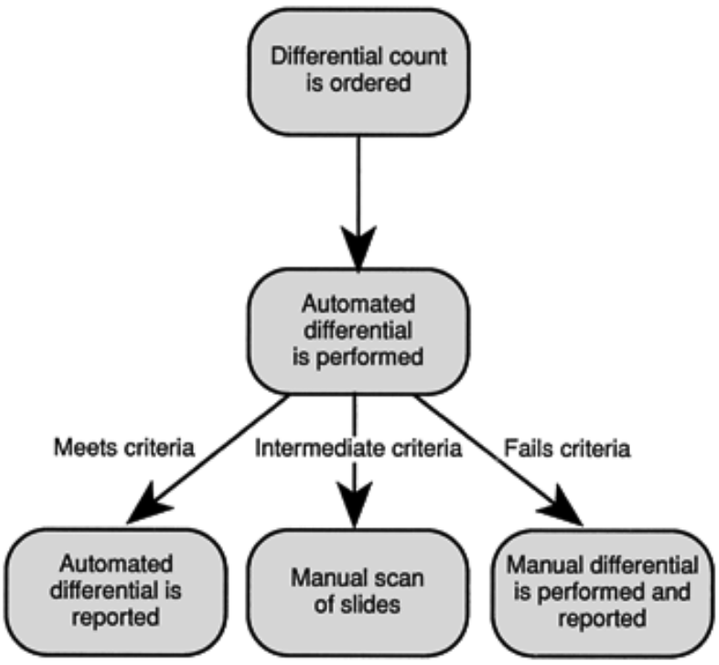

FIGURE 40.5. Schematic drawing shows the laboratory logistics of incorporating automated leukocyte differential counts, manual differential counts, and slide scanning.

Several hematology analyzers are available for the clinical laboratory. Each one approaches the issue of automated differentials in slightly different ways, but all use a single-cell flow apparatus that allows interrogation of each individual cell for a variety of potential characteristics. These characteristics permit separation of the various cell types. Technicon's H6000, H1, and H2 analyzers are flow cytometers that use myeloperoxidase cytochemistry coupled with light-scattering characteristics. Others, including Coulter's STKS, and TOA's Sysmex NE8000, use a combination of electrical impedance, low-frequency conductivity, and light-scattering characteristics to categorize white cells. Other newer analyzers, including the Cobas Argos 5 Diff by Roche, uses electrical impedance, cytochemistry, and optical absorbance,

and the CelDyn 3000 from Abbott uses a complex multiangle, light-scattering technology to categorize white cells. As mentioned previously, image analysis–based systems have not survived their introduction and are no longer being actively marketed to the clinical laboratories.

The blood cell histograms as produced by the modern automated hematology analyzers provide a wealth of information about the CBC and differential count. However, these scattergrams and histograms have not gained popularity among clinicians for various reasons. It is neither important nor necessary for clinicians to review routinely these histograms, but laboratorians may find the histograms invaluable for quality-control purposes as well as for evaluating difficult diagnostic cases and recognizing problem cases that need further review. Figure 40.6 provides examples of histograms from the Coulter STKS automated analyzer and depicts the typical distribution of the various peripheral blood components.

Additional parameters that can be generated by the Technicon analyzers include the mean peroxidase index, which is a measure of the myeloperoxidase staining intensity of neutrophils. Low levels of peroxidase index indicate a myeloperoxidase deficiency; the clinical importance of an elevated mean peroxidase index, however, has not been clarified. In addition, the Technicon also determines a lobularity index for neutrophils. A decreased lobularity index suggests less neutrophil lobulation and, therefore, a granulocytic left shift.
