Aerobic Actinomycetes

Michael A. Saubolle

The order *Actinomycetales* includes a vast array of taxonomically heterogeneous genera and species, of which the majority are saprophytic and only a small minority pathogenic. Human infection by this group of organisms is uncommon, and when it occurs, it is most often “opportunistic.” Nevertheless, there has been a recent increase in recognizable infections resulting from aerobic actinomycetes. This increase may in part be the result of shifts in population dynamics, including increasing age and centralization in urban areas, and to the increasing prevalence of chronic obstructive lung disease and immunocompromising conditions such as the acquired immune deficiency syndrome (AIDS).

The aerobic actinomycetes cause a wide spectrum of diseases in humans; clinical presentations and histopathology may differ greatly between taxa, although there often may be significant overlap. In some instances, such as with tuberculosis and leprosy, the role of the aerobic actinomycetes is well known. In others, their role is increasing in scope but is still commonly under-appreciated; their incidence probably is greater than suspected (1, 2, 3, 4, 5 and 6). Initial infection almost always occurs from exogenous sources because these organisms are found rarely as normal microbial flora of humans.

Therapeutic approaches may vary widely depending on specific etiologies.

With the exception of *Mycobacterium leprae*, *Mycobacterium tuberculosis* complex, and the genus *Dermatophilus*, most aerobic actinomycetes exist predominantly as saprophytes. Their presence has been noted in a wide variety of natural as well as man-made environments. Wide variation in the geographic prevalence between species contributes to their diverse epidemiology.

The large number of species present within *Actinomycetales*, together with the confusion and difficulty often associated with their identification, add importance to the laboratory's familiarization with more commonly isolated species. Of the over 40 genera of aerobic actinomycetes, only approximately 18 seem to be of clinical significance (1). The laboratory should be able to differentiate quickly between probable saprophytes and possible pathogens, and to provide guidance to the clinician in interpreting findings and in choosing therapeutic modalities.

GENERAL ASPECTS

Part of "54 - Aerobic Actinomycetes"

Microbiology and Classification

Actinomycetes are prokaryotic bacteria that often elongate or form filaments with tendency toward some degree of true branching; reproduction by formation of spores or fragmentation of the hyphae is normal. Recently, more systematic approaches to classification using chemical and molecular techniques for evaluation, as well as numerical taxonomic means, have provided a better understanding of the relationships between organisms within this group (1, 2). At the general laboratory level, however, morphologic and chemical characteristics help separate these organisms into broad groups and are useful for identification purposes.

Aerobic actinomycetes that produce hyphae, which later fragment into coccal elements to renew the growth cycle, can be considered as “nocardioform.” The term does not, however, imply a close relationship between members of the group. Specifically, the nocardioform actinomycetes show a tendency to produce mycelia that often are transitory or fleeting and that break up quickly into coccoid or bacillary forms. Some genera in this group (*Nocardia*, *Streptomyces*, *Oerskovia*) produce thin substrates or aerial mycelia and may resemble fungi, while other genera (*Mycobacterium*, *Rhodococcus*) have rudimentary or absent mycelia, remaining most commonly in coccoid or short bacillary form (1, 2, 3, 4, 5, 6 and 7). A second group that includes the actinomadurae and streptomycetes, produces spores in or on mycelia. The genus *Dermatophilus* belongs to yet another group of actinomycetes that form mycelia and show division both transversely and longitudinally, producing multilocular, primitive sporangia (3, 4 and 5).

The amino acids, carbohydrates, and lipids found in the cell wall seem to be stable in many genera, and their analysis often is helpful for organism identification. Diaminopimelic acid (DAP) and its stereoisomeric configuration (meso or L-form) together with cell-wall chemotypes further differentiates the clinically significant actinomycetes (3, 4 and 5). However, although useful for taxomic purposes, such studies are normally beyond the capabilities of most clinical laboratories.

Mycolic acids (mycolates) are present in all the genera within the families *Mycobacteriaceae* (*Mycobacterium* and *Tsukamurella*), *Nocardiaceae* (*Nocardia*, *Gordona*, *Rhodococcus*, and *Skermania*), and Corynebacteriaceae (*Corynebacterium*, *Dietzia*, *Turicella*) except for *Turicella* (1). The mycolic acid containing families can be differentiated further by the number of carbons in their mycolates (22–38 in corynomycolates, 34–78 in nocardomycolates, and 60–90 in mycobacterial mycolates). Absence of tuberculostearic acid in the genus *Corynebacterium* separates it from all other genera within the mycolate-containing families (4, 5, 6 and 7).

Traditionally, initial identification of the aerobic actinomycetes

requires recognition of their individual colonial and microscopic morphologies and staining characteristics. Unfortunately, some of the genera frequently resemble each other, and at times it may be hard to differentiate them. Evaluation of growth rates and patterns, delineation of antibiograms, and limited biochemical studies may provide further information as to an isolate's identity (Table 54.1). Newer techniques such as nucleic acid probes, high-performance liquid chromatography (HPLC), macromolecular analysis (e.g., of 16S rRNA and the RNA polymerase gene rpoB), as well as the polymerase chain reaction (PCR) combined with restriction endonuclease analysis have been applied with variable success for the identification of many genera and species (1, 2, 9, 10, 11, 12, 13 and 14).

TABLE 54.1. SELECTED DIFFERENTIAL CHARACTERISTICS OF AEROBIC ACTINOMYCETES ENCOUNTERED IN CLINICAL SPECIMENS[a,b]

Characteristic or Feature	Genus							
	Actinomadura	*Gordona*	*Nocardia*	*Nocardiopsis*	*Oerskovia*	*Rhodococcus*	*Streptomyces*	*Tsukamurella*
DAP isomer type	*meso*	*meso*	*meso*	*meso*	None	*meso*	L	*meso*
Cell wall sugars[c]	Mad	Arab, Gal	Arab, Gal	None	Gal	Arab, Gal	None	Arab, Gal
Size of mycolic acid (No. of carbons)	None	48–66	44–60	None	None	34–64	None	64–78
Acid fastness (weak)[d]	No	Yes	Yes	No	No	Yes	No	Yes
Lysozyme resistance	No	Variable	Yes	No	Yes	Variable	No	Yes
Aerial filament growth	Variable	No	Yes	Yes	No	No	Yes	No
Hyphal fragmentation	No		Yes	No	Yes (motile)	Yes	Variable	

[a] *Mycobacterium* and *Dermatophilus* are not listed because the former is characterized in Table 47.4, and the latter is easily differentiated and rarely encountered in clinical specimens.

[b] Compiled from references 1, 4.

[c] Arab: arabinose; Gal: galactose; Mad: madurose.

[d] Acid-fastness: weak, 0.5% to 1% sulfuric acid in decolorizer; strong, 3% hydrochloric acid in decolorizer.

Diagnostic Procedures

Laboratory Safety Considerations

Laboratories processing specimens for the detection, isolation, and identification of aerobic actinomycetes (especially mycobacteria) should ensure that safety measures are in place and that safety procedures are appropriately implemented, taught and enforced. Classification of practices is based on the potential risk for each laboratory, which in turn depends on factors such as prevalence of mycobacteriosis, number of specimens processed, and prevalence of multi-drug resistant tuberculosis (2).

Normal Biosafety level 2 practices, equipment, and facilities are needed for laboratories at low risk (i.e., those that limit themselves to preparing acid-fast smears and setting up cultures). Class I or II level biological cabinets and aerosol preventive centrifuge bucket covers are necessary for aerosol-generating procedures at the minimum.

Biosafety level 3 practices and Biosafety level 2 facilities are necessary for laboratories that work with *M. tuberculosis* cultures, while Biosafety level 3 practices and facilities are necessary for laboratories at highest risk, including those that have high prevalence of resistant *M. tuberculosis* (2, 15, 16, 17 and 18). Appropriate facilities include a separate, dedicated, controlled-access room maintained at negative pressure relative to the rest of the laboratory. The room should contain a class II laminar-flow biological safety cabinet equipped with a high-efficiency particulate air (HEPA) filtration system, an adequate air draw across the front, and an ultraviolet light for surface decontamination. The cabinet should be inspected and certified at least annually and preferably every 6 months. An autoclave should be present in an adjacent area to decontaminate infectious waste prior to transport to disposal areas. High-speed centrifuges should be equipped with bucket covers and domes to contain possible broken tubes. Electric incinerators rather than Bunsen burners should be utilized to avoid splatters. A container of sand and 95% alcohol or a 5% phenol solution also should be available to clean wires, spades, or loops prior to their insertion in the incinerator.

Personal protective equipment including gloves, National Institute for Occupational Safety and Health (NIOSH)-certified fit-masks or respirators, caps, and gowns should be worn when working with cultures. A protocol should be available regarding the use of a respirator mask, how to conduct fit-testing of the mask, and training of personnel in the use of the respirator. All procedures should minimize aerosol production while maximizing protection from infection by droplet nuclei. All personnel working in the laboratory should be given tuberculin skin tests at least annually for those at low risk and biannually for those at highest risk to elucidate any conversions.

Laboratory Proficiency Considerations

Not all laboratories can be expected to have the facilities, volume, or expertise to work with the aerobic actinomycetes, and especially with the mycobacteria, within adequate safety or proficiency parameters. The College of American Pathologists (CAP) and the American Thoracic Society (ATS) have recommended progressive extents (CAP) and levels (ATS) of proficiency of services for the diagnosis of mycobacterial diseases (2, 15). In general, laboratories with minimum volume of specimens (<10–15 for smears, <20 for culture) requiring mycobacterial workup should utilize the services of reference laboratories capable of documenting proficiency at isolating and identifying mycobacteria. Laboratories performing mycobacterial studies

should be capable of performing smears daily and using modern culture techniques minimizing delay in recovery or susceptibility testing of mycobacteria (17).

Primary Isolation

In most instances, isolation of an agent causing disease is necessary to provide definitive identification and to perform antimicrobial susceptibility studies when such are available or necessary. Specific isolation methods for individual groups of aerobic actinomycetes vary widely. Methods that are optimal for the recovery of groups such as the mycobacteria may not be suitable for groups such as the actinomadura or streptomyces. For some actinomycetes (e.g., *Mycobacterium leprae*), isolation methods are not routinely available, while for others, isolation methods may require selective concentration, decontamination, and/or culture onto specialized media for optimal recovery.

Methods of specimen collection and transport to the laboratory directly influence the detection and isolation of the aerobic actinomycetes. Not all laboratories should be capable of isolation or detection of all genera of actinomycetes. Still, they should be able to provide information to enhance collection techniques and to expedite specimen transportation with minimum delay and maximum quality assurance.

The majority of specimens from mycobacterial or nocardial infections are from the respiratory tract, followed by lymph node tissue, urine, other tissue, and normally sterile body fluids. Specimens from patients with AIDS may include blood and stool. Specimens from actinomycotic mycetomas may include pus, serosanguinous fluid, sinus scrapings, or other biopsy material.

The slower growth of the actinomycetes becomes a problem when other rapidly growing organisms are present in the specimen; such normal or contaminating flora may overgrow the etiologic agent. Collection methods should therefore bypass areas of contamination. In some instances, specimens containing mixed flora should be processed to eliminate the contamination or be inoculated onto selective media to allow the pathogens a chance to grow. All specimens should be refrigerated if not processed within a few hours.

Mailing

The packaging of specimens or cultures to be mailed to reference laboratories must adhere to the Code of Federal Regulations. Screw-cap, watertight tubes must be used. These must be placed within a second watertight container (usually metallic) with enough absorbent material capable of taking up liquid in case of breakage. One or more of these can be packed into containers made of paperboard wood and mailed only after appropriate warning labels are attached (15).

Direct Detection

Microscopic evaluation of specimens can provide rapid information on the presence or absence of: (i) the possible etiologic agent; (ii) infected material characterized by polymorphonuclear or mononuclear leukocytes; or (iii) contamination characterized by squamous epithelial cells. A variety of wet-mount, Gram-stain, or other special stains may be used to detect the aerobic actinomycetes either directly from specimens (sputum, pus, tissue, stool, etc.) or after their decontamination and/or concentration (e.g., specimens for mycobacteria, normally sterile body fluids).

Molecular-based amplification as well as fluorescent-column chromatographic technologies now offer fairly sensitive direct detection methods and provide supplemental capabilities useful in some clinical situations (19, 20, 21, 22, 23, 24 and 25).

Serologic Procedures

The complexity, heterogeneity, and cross-reactivity of antigens among the aerobic actinomycetes have historically precluded the routine use of serologic techniques for diagnosis; in some instances, however, there seems some hope for the future (2, 28). In mycobacterial studies, antigens evaluated have included the 38-kDa antigen, lipoarabinomannan, antigen 60 and the antigen 85 complex (2). Although some reagents currently are available commercially, none have been adequately documented to be sensitive or specific enough for routine clinical use. Antigen capture assays also have been evaluated but cannot be recommended at this time (2, 27, 28).

Skin tests may be of value, both in the mycobacterioses and in actinomycotic mycetoma. Reviews of skin tests and their interpretation and significance can be found elsewhere and are not discussed here (26, 27, 29).

Interpretation of Data

The presence of some genera of aerobic actinomycetes in clinical material is highly associated with an active disease process. Thus, identification of *M. tuberculosis*, *M. leprae*, or *Dermatophilus congolensis* in patients always is considered significant (Table 54.2). Correlation of other groups of actinomycetes, such as the nontuberculous mycobacteria, and nocardia, with disease is more difficult. The environmental prevalence of many actinomycetes, coupled with their low virulence, increases the difficulty of interpreting their causal role in an infectious process.

TABLE 54.2. CLINICALLY SIGNIFICANT AEROBIC ACTINOMYCETES

Genus	Species	More Commonly Associated Infections
Actinomadura	A. madurae and *A. pelletieri* most significant; soil organisms	Mycetoma
Dermatophilus	*D. congolensis* the only spp.; obligate animal parasite	Pustular, exudative dermatitis
Mycobacterium	*M. leprae*, *M. tuberculosis*, *M. bovis* obligate pathogens;	*M. leprae*: leprosy; *M. tuberculosis*, *M. bovis*: tuberculosis
	Nontuberculous mycobacteria (NTM) include a large number of species with potential capability to invade the immunocompromised host; NTM found widely in water, environment	*M. avium* complex, *M. kansasii*, *M. abscessus*, *M. chelonae*, *M. fortuitum* most commonly isolated: associated with pulmonary or infrequently with disseminated disease; rapid growers also associated with localized abscesses post–trauma, foreign body implantation, including lines
Nocardia	Of 11 recognized species, only eight are clinically significant and only six are more frequently isolated in the United States, found in soil, organic debris, and water	*N. asteroides*, *N. farcinica*, *N. pseudobrasiliensis*, *N. nova*: pulmonary, disseminated. *N. nova* is less common and less invasive than others; *N. brasiliensis*, *N. otitidiscaviarum*: localized soft tissue, trauma, but can disseminate
Nocardiopsis	*N. dassonvillei* significant but rare	Mycetoma
Rhodococcus	*R. equi* most commonly associated with disease	Pneumonia, bacteremia most common; endophthalmitis, peritonitis reported
Gordona	*G. bronchialis*, *G. rubroperctinctus*, *G. sputi*, *G. terrae*, and *G. aichiensis* rarely associated with humans; soil, sewage treatment plants	Implicated in primary cutaneous, chronic pulmonary, catheter associated, and brain abscess infections
Tsukamurella	*T. paurometabola* primary spp. of clinical importance	Bacteremias, synovitis in immunocompromised patients, associated also with those undergoing dialysis or with indwelling catheters
Streptomyces	Of a large number of species in this genus, *S. somaliensis* and *S. anulatus (griseus)* most commonly associated with human infections	Mycetoma, abscesses

Therapeutic Considerations

Therapeutic regimens for aerobic actinomycetes vary considerably according to the infecting species, the disease process, and the immunocompetency of the patient. Surgical intervention supplements or supplants antimicrobial therapy in some instances. Although standardized procedures for susceptibility studies do not exist for all genera or species, methods for a few have been developed adequately enough to provide guidance. In other cases, the disease is self-limited, and therapeutic intervention is not normally required (e.g., dermatophilosis).

This chapter focuses on the characteristics of the genera most commonly causing human infections (e.g., *Mycobacterium*, *Nocardia*, and *Rhodococcus*). The genera *Actinomadura*, *Nocardiopsis*, *Streptomyces*, and *Dermatophilus* are only briefly reviewed, while the corynebacteria and the anaerobic and thermophilic actinomycetes are not discussed.

MYCOBACTERIUM

Microbiology and Classification

The genus *Mycobacterium* consists of a diverse group of strongly acid-fast bacilli (AFB) with high lipid content. The lipids in the cell and its wall include waxes with characteristic long-chain (60–90 carbon) mycolic acids.

The diversity in the genus *Mycobacterium* is manifested by variability in morphology, growth rate characteristics, nutritional and temperature requirements, as well as pathogenicity. There are easily over 80 species of mycobacteria currently recognized, but few are more commonly associated with human infections (6, 7, 24). *M. tuberculosis* (MTB), *M. bovis*, *M. africanum*, and *M. leprae* have a high propensity for causing disease and are always considered as pathogens. With the exception of *M. leprae*, the causative agent of leprosy, they all cause classic tuberculosis and form the *M. tuberculosis* complex (Table 54.3). There is presently some doubt as to the individual status of the genus *M. africanum*, which biochemically and by DNA relatedness studies may be indistinct from MTB (2). Mycobacteria that do not belong to the MTB complex have been designated in the past by several names, but the term “nontuberculous mycobacteria” (NTM) is most appropriate.

TABLE 54.3. MYCOBACTERIAL SPECIES MORE COMMONLY ENCOUNTERED IN CLINICAL SPECIMENS IN THE UNITED STATES[a]

Group (Characteristic)	Obligately Pathogenic	Probably or Potentially Pathogenic[b]	Probably Saprophytic Rarely Pathogenic[c]
Tuberculosis complex (slow growth; nonpigmented)	*M. tuberculosis* *M. bovis* *M. leprae*		
Photochromogens (slow growth; light stimulated pigment)		*M. kansasii*, *M. simiae*, *M. marinum*	
Scotochromogens (slow growth; pigmented irrespective of light)		*M. scrofulaceum*, *M. xenopi*, *M. szulgai*[d]	*M. flavescens*, *M. gordonae*
Nonphotochromogens (slow growth, nonpigmented)		*M. avium*, *M. intracellulare*, *M. haemophilum*	M. gastri, M. terrae, M. triviale
Rapid growers (growth within 7 days; nonpigmented)		*M. fortuitum*, *M. chelonae*, *M. abscessus*	*M. smegmatis*

[a] Compiled from 2, 15, 31.

[b] Other potentially pathogenic species include *M. malmoense*, *M. asiaticum*, *M. ulcerans* (obligate pathogen), *M. celatum*, *M. genavense*.

[c] Other rarely pathogenic, commonly saprophytic species: *M. neoaurum*, *M. nonchromogenicum*, *M. parafortuitum* complex, *M. paratuberculosis*, *M. phlei*, *M. thermoresistibile*, and *M. vaccae*.

[d] Photochromogenic at 25°C, but scotochromogenic at 35°C.

Originally, colonial morphology and chromogenicity (carotenoid pigmentation) were used to categorize species of NTM. Additionally, growth rates of species were incorporated into the categorization method to delineate divisional units referred to as Runyon groups. The Runyon groups included the pigmented photochromogens (group I: yellow to orange pigment development after exposure to light; Fig. 54.1) and scotochromogens (group II: pigment development in the dark), the normally colorless nonphotochromogens (group III; Fig. 54.2) and the rapid growers (group IV). This classification was useful, but not completely accurate, because some species' characteristic chromogenicity and growth rates are influenced by other environmental factors such as temperature (2, 15, 29, 30 and 31).

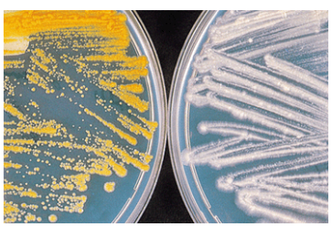

FIGURE 54.1. Colonies of the photochromogen *Mycobacterium kansasii* showing typical formation of carotenoid pigmentation only after exposure to light **(left)** and not when kept in the dark **(right)**.

FIGURE 54.2. Nonpigmented colonies of members of the *Mycobacterium avium* complex.

A second approach to delineation of species of NTM chosen by the ATS uses a clinical classification by type of disease presentation such as pulmonary, lymphadenitis, or cutaneous (30).

The spectrum of biochemical activity of culturable mycobacterial species also provides a tool for classification and identification (Table 54.4). However, results cannot always be depended on because of variability within individual species being studied. Such phenotypic variability becomes a larger problem when the number of biochemical determinations diminishes or the isolate being characterized is rarely isolated (31).

Applications of molecular hybridization techniques (genetic probes) for determination of species relatedness and high-performance liquid chromatography for mycolic acid patterns have facilitated the differentiation of species. Such methods have become more commonly available to clinical laboratories and their routine application has become feasible for cost-effective identification in clinical practice (2, 31). Other molecularly based methods such as evaluation of the hypervariable region of the 16S rRNA gene have provided an understanding to the numerical taxonomy of the mycobacteria. But such methods require molecular sophistication and at present are limited to research laboratories (2, 31).

Esoteric identification methods such as bacteriophage typing and serotyping may have been useful for epidemiologic studies,

but their poor reproducibility and specificity, together with the difficulty of standardizing test systems, have made them unsuccessful as routine tools for evaluation of mycobacterial epidemiology. Such methods have been supplanted by molecular techniques such as RFLP analysis of repetitive insertion sequence IS6110 for *M. tuberculosis* (2), and plasmid typing, rRNA spacer sequencing, and large-restriction-fragment analysis using PFGE for the NTM and other aerobic actinomycetes (32).

TABLE 54.4. MAJOR DIFFERENTIATING TESTS FOR MORE COMMON NONTUBERCULOUS MYCOBACTERIAL ISOLATES[a]

Mycobacterium Species	Nitrate Reduction	Catalase: Semiquantitative	Catalase: Heat Stable	Tween 80 Hydrolysis (5 day)	Tellurite Reduction	Urease	Arylsulfatase (3 day)
M. kansasii	+	+	+	+	V(-)	V(-)	-
M. simiae	-	+	+	-	+	V(+)	-
M. marinum	-	-	-	+	V(-)	+	V(-)
M. scrofulacium	-	+	+	-	V(-)	V(+)	-
M. xenopi	-	-	V(-)	-	V(-)	-	V(-)
M. szulgai	+	+	+	V(-)	V(+)	+	V(-)
M. gordonae	-	+	+	+	-	V(-)	-
M. flavescens	+	+	+	+	V(-)	+	-
M. avium-complex	-	-	V(+)	-	+	-	-
M. gastri	-	-	-	+	V(+)	V(-)	-
M. terrae-complex	+	+	+	+	V(-)	-	-
M. fortuitum	+	+	+	V	V(+)	+	+
M. chelonae	-	+	V(+)	V(-)	V(+)	+	+
M. abscessus	-	+		V		+	+

[a] Compiled from references 2, 15, 31.

[b] Plus signs and minus signs designate the presence or absence, respectively, of a feature or capability in the majority (>80 to 85%) of strains; V indicates variability, while the (+) or (-) signs following the V indicate a greater or lesser percent, respectively, of strains having a feature or capability.

Spectrum of Disease

M. leprae, a pathogenic member of the mycobacteria, is the causative agent of leprosy. The clinical phases of leprosy are broad, ranging from the primary silent (replication of organisms in skin macrophage) and indeterminate (replication in peripheral nerves) phases to the more severe tuberculoid and lepromatous states. Erythematous or hypopigmented skin lesions and damage to peripheral nerves are characteristic and may be progressive, depending on the stage of the disease process (33).

Members of the MTB complex, primarily transmitted person to person via droplet nuclei and the respiratory tract, produce the well-known clinical entity of tuberculosis. In the normal host, MTB remains the primary etiology of pulmonary (85% of cases) as well as of extrapulmonary (15% of cases) tuberculosis in the United States. There is an increased risk of dissemination in the immunocompromised patient. The risk of patients developing clinical disease within the first year of being infected is approximately 5%, but declines thereafter. However, risk of reactivation increases with the decrease of cellular immunity in the elderly.

Primary tuberculosis may be considered an infection of the reticuloendothelial system. The organisms are ingested but not inactivated by alveolar macrophage and polymorphonuclear cells, pass through the lymphatics, and finally enter the bloodstream to reseed the lungs or other sites. Extrapulmonary sites may include lymph nodes (28%), spinal column, as well as meninges (5%), genitourinary tract (13%), bone and joint (10%), peritoneal cavity (4%), and bone marrow. Miliary tuberculosis includes the simultaneous infection of several sites and is seen in approximately 10% of extrapulmonary cases. Pulmonary

disease may be acute and rapidly progressive or chronic with cavitation.

The recent use of the bacille Calmette-Guerin (BCG) vaccine strain of *M. bovis* to treat melanoma or carcinoma of the bladder has increased its recognition as a cause of significant infections in patients undergoing such therapy. Infection is usually limited to the urogenital tract although lymph node involvement has also been noted (31).

The NTM are far less invasive and require an underlying factor in the patient to be able to successfully colonize and cause progressive disease. Members of the *Mycobacterium avium* complex (MAC) and, to a lesser extent, *Mycobacterium kansasii* have a predilection for patients having been immunocompromised by AIDS or malignancy, or for those having chronic pulmonary disease with parenchymal lung damage. Percutaneous trauma (surgery, catheterization, accidental puncture) increases the risk for infection with *M. fortuitum, M. chelonae*, and *M. abscessus* (29, 30, 31 and 32).

Clinical presentation with infection from the NTM primarily includes pulmonary, lymph, and cutaneous/soft tissue sites, but also may involve peritoneal, joint/bone, ocular, gastrointestinal, heart valve, meningeal, and urogenital sites. Dissemination also may occur, especially in the severely immunocompromised host; members of MAC account for the majority of disseminated cases, but other species also may disseminate (29, 30, 31 and 32).

Members of MAC and *M. kansasii* are the most commonly encountered mycobacterial pathogens causing chronic pulmonary disease in the United States. Indistinguishable, indolent but potentially progressive lung disease may occasionally be caused by rapidly growing NTM, *M. xenopi*, *M. simiae*, *M. malmoense*, and *M. szulgai*. Members of MAC have become implicated in the invasion of the gastrointestinal mucosa and dissemination into blood of patients with AIDS; in such patients, the respiratory tract may not be as commonly involved. Interestingly, *M. avium* seems to be more virulent than *M. intacellulare*, accounting for the majority of infections.

Cervical lymphadenopathy, often encountered in immunocompetent pediatric patients, is commonly caused by NTM. Members of MAC are again the most common cause, although *Mycobacterium scrofulaceum* also may be encountered in this setting. Other reported etiologies include *M. kansasii*, *M. haemophilum*, and rarely other NTM (2, 32).

Several species of NTM favor reduced growth temperatures and characteristically infect cooler cutaneous or subcutaneous areas. Localized papulonodular skin lesions at sites contacting unchlorinated fresh or salt water are caused by *Mycobacterium marinum*. *Mycobacterium ulcerans*, encountered primarily in Australia, Africa, and Mexico, causes a subcutaneous infection that can progress to ulceration. *M. haemophilum* has been associated with chronic skin lesions in immunocompromised patients as well as with cervical lymphadenopathy in immunocompetent patients (29, 31, 32).

M. abscessus, *M. chelonei*, and *M. fortuitum* have emerged as major opportunistic pathogens infecting previously traumatized soft tissue such as that associated with penetrating wounds, sternotomies, mammoplasties, percutaneous catheter insertions, and keratitis/corneal ulcerations. These species also have been reported in association with cases of prosthetic valve endocarditis, osteomyelitis, synovitis, meningitis, and disseminated disease (2, 30, 31 and 32).

Other species of NTM (e.g., *Mycobacterium gordonae*, *Mycobacterium flavescens*, *Mycobacterium terrae*, *Mycobacterium asiaticum*, *Mycobacterium gastri*, *Mycobacterium thermoresistibile*, and *Mycobacterium neoaurum*) are commonly considered contaminants in culture and rarely are associated with human disease. Occasional associations with infections in immunocompromised patients, however, have been documented (31).

Epidemiology

The mycobacteria commonly associated with disease in humans and considered always to be pathogenic, are not found free-living in nature, but remain obligate animal parasites. Leprosy and tuberculosis occur worldwide. The former, caused by *M. leprae*, afflicts over 10 million people, especially in third-world or underdeveloped

countries. Person-to-person transmission through contact with intact or abraded skin, as well as by deposition on the nasal mucosa through inhalation is increased by crowded conditions and close contact (33).

In the United States, tuberculosis is caused primarily by *M. tuberculosis*. Control of the prevalence of *M. bovis* in cattle and pasteurization of milk have nearly eradicated infection in humans except as noted above for BCG. Control of *M. tuberculosis* is more problematic, although after a resurgence in the 1980s, the rate of tuberculosis is again declining in most of states. However, continued vigilance and focus by the Public Health infrastructure is necessary to keep the disease on the decline.

Unlike members of the *M. tuberculosis* complex, the NTM are found in the environment, being isolated from soil, water, sewage, house dust, air, and raw milk. Infection of humans occurs by normally unpreventable ingestion, inhalation, or inoculation from environmental sources, and person-to-person spread does not usually occur. Control of the acquisition of infection is extremely difficult (30, 32).

The NTM inhabit a wide variety of ecological niches. Sometimes, their presence in some locations may bring them in closer proximity to a human population and to increased isolation from clinical specimens. Thus, the isolation of members of MAC from water supplied to large metropolitan areas and specific sources in hospitals as well as homes may have clinical implications. These organisms also have been noted in air, water, dust, soil, plants, and animals.

Other members of NTM have been isolated from environmental sources such as soil, water, and dust (rapidly growing NTM), soil, water, milk, and oysters (*M. scrofulaceum*), untreated fresh or salt water (*M. marinum*), and water and animals (*M. xenopi*, *M. simiae*). *M. xenopi* also has been isolated from birds, coastal areas, and human tonsils, while *M. simiae* has been isolated from monkeys. *M. kansasii* has on several occasions been isolated from water, and the fastidious *M. genavense* has been associated with some psittacine birds. Environmental sources for *M. haemophilum*, *Mycobacterium szulgai*, *Mycobacterium malmoense*, *Mycobacterium ulcerans*, and the more fastidious mycobacteria are unknown (2, 30, 31).

In terms of isolation rates, members of MAC have the greatest incidence, followed by *M. kansasii*. Together, the two genera may make up 75% to 85% of all significant isolates of NTM in the clinical laboratory. Members of MAC are less likely to be considered clinically significant than *M. kansasii*. Isolation rates of other NTM drop off sharply with the rapidly growing NTM making up 12% to 15% while the remaining species, in aggregate, making up less than 10% of all isolates.

Specimen Collection

Respiratory Tract

Traditionally, three to five expectorated early-morning sputum samples collected on several different days were considered sufficient to detect mycobacteria. With newer recovery methods such as the BACTEC system (Becton Dickinson Diagnostic Instrument Systems, Cockeysville, MD), limiting sputum specimens to two on separate days is adequate if smear positive. Specimens pooled over a 24-hour period are not acceptable because of their increased contamination and slower recovery rate. Test of cure sputum specimens should be collected for microscopic analysis weekly beginning three weeks after initiation of the therapeutic protocol.

Sputum should originate from deep in the lung, and the patient should be advised on how to cough appropriately. Rinsing the mouth with water may decrease contamination. Screening for upper respiratory tract contamination is not necessary, but there should be evidence of lower tract secretions in the specimen provided (2, 15).

Specimens from patients unable to expectorate sputum may be collected after inducing coughing by nebulization of 5% to 10% saline or by bronchoscopy. Frequently, several expectorated sputum specimens collected a day or two after bronchoscopy enhance the detection of mycobacteria. In some difficult patients, transthoracic needle or open-lung biopsies may be attempted, with the latter method having the best yield. In all cases, the method of collection should be noted on the requisition.

Each specimen should be 5 to 10 mL and may be collected or transported in 50-mL centrifuge tubes. If specimens are to be mailed to a reference laboratory, 1% cetylpyridinium chloride with 2% sodium chloride may be added to the sputum as an initial decontamination step prior to shipping; AFB may survive up to 8 days in transit using this technique.

Gastric Washings

Aspiration of swallowed sputum from the stomach is reserved for patients unable to provide sputum by other means, usually the obtunded or the young. The procedure is performed early in the morning and on an empty stomach. Gastric aspirations should be processed rapidly, or 100 mg of sodium bicarbonate should be added as a buffer.

Normally Sterile Body Fluids

Specimens in this category may include 2 to 5 mL of cerebrospinal fluid (CSF), pericardial or synovial fluids, 10 to 15 mL of peritoneal, bile, paracentesis, dialysis fluid, or pleural fluid, and 3 to 5 mL of exudates. Such specimens should be collected in sterile screw-cap containers. Body fluids may be diluted in saline or a buffer to allow the relatively buoyant acid-fast bacilli to sediment adequately during centrifugation.

Tissue

Surgical biopsies should be submitted in sterile nonbacteriostatic saline to keep them from dehydrating. Larger pieces can be cut up and homogenized in a mechanized tissue grinder or ground in a mortar and pestle. Specimens that cannot be processed immediately may be frozen at -20°C for transport.

Urine

Appropriate cleansing of genitalia should precede collection of the first-morning voided urine specimens. Each specimen should have a minimum of 40 mL. Three to five specimens collected over as many days are normally adequate. 24-hour pooled specimens are not acceptable because acid-fast bacilli may be harmed by long-term exposure to urine. Specimens may be stored for short periods at 4°C.

Sinus Tracts

Caution must be used in collecting drainage material from sinus tracts, which are notorious for being easily contaminated or colonized. Attempts at collecting by needle aspiration or biopsy are preferable. Swabs are poor substitutes for exudates or biopsies, and often will decrease yields. When used, swabs should be inoculated directly to solid or broth media.

Blood

Isolation of mycobacteria from blood is possible, primarily in immunocompromised patients (especially those with AIDS) and such attempts should be reserved for such patients. Blood may be collected in the Isolator lysis-centrifugation system (Merck & Co., Inc., West Point, PA) or inoculated directly into the BACTEC 13A or Myco F Lytic blood culture bottle (Becton-Dickinson, Franklin Lakes, NJ) for mycobacteria. Both of the latter bottles are incubated without further manipulation, while blood in the Isolator tube must be processed according to the manufacturer's instructions and the sediment cultured onto egg or other-based agar media. The sediment should not be cultured in BACTEC 12B medium as this combination may be deleterious to some MAC. Mycobacterium are stable up to 24 hours in these tubes. Blood specimens also may be submitted in tubes containing the anticoagulants heparin or sodium polyanetholsulfonate but not EDTA (2).

Stool

Stool specimens are recommended only for the detection of mycobacterial involvement of the gastrointestinal tracts of patients with AIDS and are not generally recommended for routine screening. Swabs are not acceptable. Stool specimens (>1 g) should be submitted in clean containers or in stool transport systems. The stool can be emulsified in 5 mL of Dubos albumin broth and processed like a sputum sample after overnight incubation at 35°C. Fresh specimens not processed immediately may be frozen at -20°C.

Primary Isolation

Specimens considered to contain normal or superinfecting bacterial flora that can overgrow the much slower growing mycobacteria must be processed to remove or decrease the contaminants. Methods for decontamination include strong alkali, acid, or other chemicals to which the lipid-rich mycobacteria are more resistant than other bacteria. However, mycobacteria are also influenced by the decontamination procedure, with only 10% to 80% of their numbers surviving in clinical specimens. Therefore, the most gentle decontamination methods are used as necessary, with harsher methods being reserved for highly contaminated specimens containing organisms such as the pseudomonads, which are more resistant to normal procedures. Procedural steps must be followed carefully to prevent decreased survival of mycobacteria. The high lipid content of mycobacteria is responsible for their greater buoyancy in clinical specimens and especially in liquids and body fluids. Therefore, mucoid specimens such as sputum, or those with high specific gravity or density, must be digested, liquefied, and/or diluted prior to concentration of AFB. Centrifugation must be performed for 15 minutes at a minimum relative centrifugal force of 3,000 × g and preferably at a force approaching 4,000 × g (2, 15).

Most concentration procedures employ combinations of mucolytic agents together with decontaminating agents. The most commonly used agents include *N*-acetyl-L-cysteine or alternatively, dithiothreitol (Sputolysin) as mucolytic agents, combined with 2% sodium hydroxide as a decontaminant. Another acceptable decontamination method incorporates benzalkonium chloride (Zephiran) with trisodium phosphate. Use of oxalic acid combined with a mucolytic agent is beneficial for specimens that are heavily contaminated with Gram-negative rods.

Specimens requiring decontamination and concentration normally include sputum (inclusive of specimens collected by bronchoscopy), urine, gastric aspirates, stool, and contaminated tissue or swabs of pus. Heavy contamination with Gram-negative rods and especially pseudomonads may be expected in sputum from patients with cystic fibrosis or bronchiectasis due to other etiologies.

Decontamination is unnecessary for specimens such as normally sterile body fluids or tissue biopsies that are not expected to be contaminated by normal bacterial flora. If any question as to sterility status of a specimen exists, it may be advisable to first culture a portion of the specimen overnight in nutrient broth or agar to detect bacterial overgrowth prior to processing for AFB.

The laboratory's capability to recover and identify mycobacteria has changed extensively over the past 15 years. The use of newer formulations of liquid media allow smaller amounts of mycobacteria to be detected earlier than by conventional solid medium-based systems. The more rapid recovery rates are enhanced by more sensitive radiometric and fluorescent detection techniques.

Traditional primary isolation media may include nonselective egg-based media, agar-base media, and liquid media or modifications of these to formulate selective media. Egg-based media such as the preferred Lowenstein-Jensen medium usually contain products that make them opaque. Agar-base media such as Middlebrook, 7H10, and 7H11, are clear and therefore help in visualization of early mycobacterial growth; such early detection of colonies is enhanced by using a dissecting microscope. Liquid media include formulations such as the 7H9 broth (2, 15). Selective media normally contain antimicrobial agents to inhibit bacterial and fungal contamination and may include modi-fications of Lowenstein-Jensen media (Gruft modification and mycobactosel) or of 7H10 (Middlebrook medium) and 7H11 (Mitchison's medium).

The BACTEC 12B vial system was the first commercially introduced system that outperformed traditional media. That system had liquid 7H12 broth medium with similar characteristics to the modified, selective 7H11 medium, but with an added C^{14} radiolabeled fatty acid component. Growth in this medium is detected radiometrically by measuring the release of CO_2 by the BACTEC 460 instrument using needles inserted through the top of the vial. The system reduced the time to recovery of mycobacteria by 1 to 3 weeks and increased overall recovery rates of most mycobacteria including many of the fastidious ones (2, 15, 31).

Since the introduction of the BACTEC 460, many other commercial systems have become available, including the Septi-Chek

(Becton-Dickinson), the Mycobacteria Growth Indicator Tube (MGIT; Becton-Dickinson), and the automated, continuously monitoring instruments of the BACTEC 9000 MB system, the BACTEC MGIT 960, the ESP II system (Trek Diagnostics, Westlake, OH), the MB/BacT system (Organon Teknika, Durham, NC) and (presently only in Europe) the MB-Redox system (Biotest, Dreiech, Germany; 2, 34, 35, 36, 37). The newer methods have eliminated the radioisotopes and the needles of the BACTEC 460 system, relying for detection on subculture onto triple media on a paddle (Septi-Chek), fluorescence (MGIT, BACTEC 9000 MB), pressure change in the head space of the bottle (ESP II), a colorimetric CO_2 sensor (MB/BacT), and a redox indicator (MB Redox). Except for the MB Redox system, which has not yet been well evaluated in the United States and the Septi-Chek, the newer systems perform similarly to the BACTEC 460 system, but seem to have slightly higher contamination rates. To maximize recovery, detect mixed cultures, and confirm isolates of *M. tuberculosis* by niacin studies after initial probe identification, the BACTEC 460 or a comparable broth system is recommended together with a solid medium.

Isolation of *M. haemophilum* requires the additional use of chocolate agar or supplementation of media with hemin or 1% ferric ammonium citrate, as well as incubation at 30°C. Isolation of *M. genavense* from blood of patients with AIDS may require inoculation of BACTEC 13A media, extension of incubation to longer than 8 weeks, and supplementation of media with Mycobactin J. The more recently recognized *M. conspicuum* seems to require solid medium incubated at 22°C to 23°C, whereas it can grow in BACTEC broth medium at 35°C to 37°C.

Cultures should be incubated at 35°C to 37°C in 5% to 10% CO_2 in the dark, although the new media systems have their own CO_2 atmospheres and don't require additional supplementation. The radiolabeled BACTEC vials should be incubated at 36 to 38°C for best results. Glass bottles or tubes initially should be kept at a slant with caps loosened to allow CO_2 entry. Plates may be placed in CO_2-permeable polyethylene bags and incubated inverted. LJ slants may be incubated in ambient air after the first 7 to 10 days. Specimens from topical skin lesions, lymph nodes, and the environment should be incubated at both 30°C and 35°C to 37°C to enhance growth of mycobacteria preferring lower temperatures (*M. marinum*, *M. haemophilum*, *M. ulcerans*, and *M. chelonae*). Cultures should be held for 6 to 8 weeks, although 6 weeks is adequate if a BACTEC or comparable system also is used. Examination for growth should occur twice weekly for the first 4 weeks and once weekly thereafter (2, 15, 31).

Identification Methods

The mycobacteria are generally straight or slightly curved rods measuring 0.3 to 0.6 µm × 1 to 4 µm. Mycelia are observed rarely, and when produced, fragment easily into coccobacillary units.

On subculture to traditional agar media, growth rate differentiates the mycobacteria: rapid growers require less than 7 days for visual recognition under optimal conditions; slow growers require more than 7 days. With additional use of pigmentation and some key biochemical studies, it is possible to identify most of the more common clinical isolates.

Members of the strictly pathogenic MTB complex are slow growers and, having buff-colored colonies, are considered nonpigmented. Selection of key tests for this group of organisms should include production of niacin and heat-stable catalase as well as evaluation for nitrate reduction. Susceptibility to thiophen-2-carboxylic acid hydrazide (TCH) further differentiates *M. bovis* from MTB (2, 15).

Nontuberculous mycobacteria may be initially characterized by growth rate and to some degree by their pattern of pigment production (old Runyon groups). *M. chelonae* and *M. fortuitum* are not considered pigmented, but may have carotenoid pigments. A few species of NTM may have varying characteristics of pigment production, thereby limiting the usefulness of the Runyon classification. Thus, on occasion, *M. szulgai* may show scotochromogenicity at 35°C and photochromogenicity at 25°C; rarely, scotochromogenic strains of the normally photochromogenic *M. kansasii*, as well as slightly pigmented strains of nonphotochromogens, may be encountered.

Identification of species may be accomplished using the following key biochemical tests (2):

I. Photochromogens: pigment, nitrate reduction, Tween 80 hydrolysis, arylsulfatase (3 day, 28°C), growth at 28°C, niacin, and semiquantitative catalase;
II. Scotochromogens: nitrate reduction, semiquantitative catalase, Tween 80 hydrolysis, urease, arylsulfatase (3 day, 42°C), 5% NaCl tolerance, growth at 52°C, and photoactive pigment at 25°C;
III. Nonphotochromogens: niacin, nitrate reduction, semiquantitative catalase, Tween 80 hydrolysis, urease, NaCl tolerance, arylsulfatase (3 day);
IV. Rapid growers: nitrate reduction, 5% NaCl tolerance (28°C), arylsulfatase (3 day), semiquantitative catalase, 68°C catalase, MacConkey agar with crystal violet, iron uptake (28°C), and utilization of sodium citrate, inositol, and mannitol.

Thorough descriptions of test methods and extensive biochemical reaction keys have been published (2, 15, 31).

Infrequently used at present, the BACTEC 460 system also has been used to successfully differentiate between members of the MTB complex and the NTM. The NAP (*p*-nitro-α-acetylamino-ß-hydroxy-propiophenone) differentiation test uses the characteristic inhibitory capacity of NAP against isolates of MTB complex and its incapability to inhibit the NTM. Using this system the two groups can be differentiated within 5 days of isolation.

Introduction of genetic probes has allowed for rapid and specific identification of many mycobacteria. These probes are directed at mycobacterial ribosomal RNA and are available for specific identification of members of the MTB complex as a whole, of *M. avium*, *M. intracellulare*, *M. kansasii* and *M. gordonae* (AccuProbe; Gen-Probe, San Diego, CA). Sensitivities and specificities of the probes for isolate identifications are greater than 99%, although rare cross-reactions have been reported between the *M. tuberculosis* complex probe and *M. terrae* and *M. celatum* complex (2). They cannot distinguish between *M. tuberculosis*, *M. bovis*, *M. africanum*, and *M. microti*, although this does not normally present a dilemma except with *M. bovis* (inclusive of the BCG

strains), which may be isolated in the laboratory. The probes can be used on isolates grown in broth or on solid culture media and their use in conjunction with the newer liquid broth based isolation systems makes them rapid, cost-effective and a practical means for identification of the most commonly isolated, clinically relevant mycobacteria. Such applications have significantly reduced the time to detection and identification of the mycobacteria. However, poor sensitivity precludes their use for direct mycobacterial detection in specimens at this time (2, 15, 31).

Other molecular means for identification of the mycobacteria have included sequencing using the hypervariable regions of the 16S rRNA gene (16S rDNA), 16S rRNA, and RNA polymerase gene (*rpo*B; 2, 14). A number of studies have used PCR amplification of a variety of genes followed by enzymatic restriction fragment length polymorphism analysis (RFLP) to identify the mycobacteria (11, 12, 13). PCR of the 65-kDa heat shock protein-encoding gene followed by RFLP looks promising in its ability to be clinically applicable in the near future (2).

Immunologic probes using radioimmunoassay, ELISA, and immunoblot technology have not been applied extensively in clinical laboratories but have in the past shown some promise as inexpensive alternatives for rapid mycobacterial identification.

Gas-liquid chromatography (GLC) for short-chain fatty acids has shown to be a promising tool for mycobacterial identification but is limited by its presently limited database and by its inability in many circumstances to provide species level identification without biochemical test supplementation. Reverse-phase HPLC for analysis of mycolic acids as bromophenacyl esters provides the most distinct patterns for individual species identification (31). The latter method is especially useful for the identification of the NTM. However, GLC and HPLC methods require organisms grown in culture, are more complex and require extensive equipment set-up and training of personnel; they are useful alternatives for larger reference laboratories that may see a plethora of unusual isolates (2, 15, 31).

Direct Detection

Microscopy

For direct microscopic detection of mycobacteria, centrifugation of specimens such as CSF, urine, and homogenized sputum at a minimal 3,000 × g is recommended to increase yield. Pellicles found on CSF specimens should be cut and a portion smeared for staining. However, routine direct staining of urine, CSF, and bone marrow specimens may not be necessary and is not recommended (unless perhaps if the patient is suspected of having AIDS), because the yield in such specimens is negligible (2, 15).

All smears may be air dried and heat fixed on an electric hot plate at 50°C for approximately 30 minutes. In most instances, light (thin) smears should be prepared, as material from these has a lower tendency to flake off during staining. Care must be exercised with all unstained slides because any AFB present may still be viable.

Rapid and sensitive stain results can be achieved through concentration of sputum by means of cytocentrifugation of sputum which is first liquefied and decontaminated by addition of 5% bleach (equal volume). These specimens, however, cannot be then used for culture (2).

The high lipid content of the mycobacteria allows them to retain certain basic dyes better than other bacteria even after treatment with acid-alcohol. This characteristic provides the mycobacteria with the trait of being “acid-fast” (Fig. 54.3). Although they share acid-fastness to some degree with nocardia and rhodococci, the latter two show much less ability to retain the dyes.

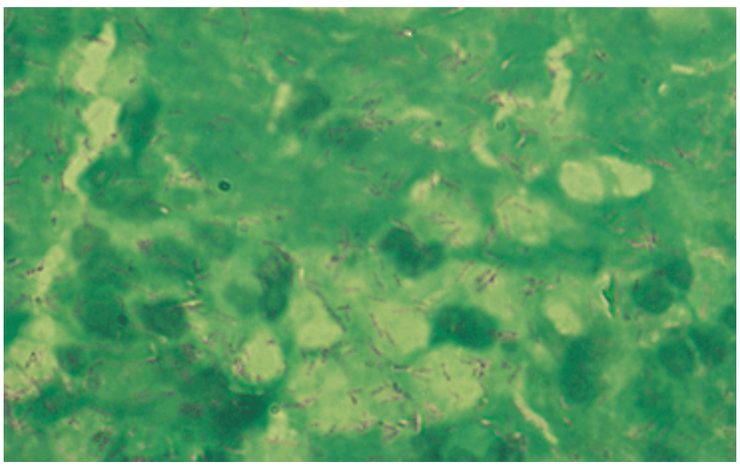

FIGURE 54.3. Acid-fast bacilli in a direct Kinyoun stain of synovial fluid yielding *Mycobacterium haemophilum*.

Several staining methods are available, including those using the aniline dye carbolfuchsin (Ziehl-Neelsen and Kinyoun stains) or fluorochrome dyes auramine O in conjunction with a counterstaining rhodamine. The auramine fluorochome stain has the same specificity as those using aniline dyes, but is a more sensitive method. Smears may be scanned for brightly fluorescing rods against a dark background at lower power (25× or 40× objectives). A mercury vapor or a halogen lamp (in an epifluorescent microscope) may be used as light sources in conjunction with appropriate filters. Although useful for scanning smears, the fluorochrome method has several problems, including inability to provide morphologic detail or to stain some isolates of rapidly growing mycobacteria (2, 15).

Of the two methods using carbolfuchsin, Kinyoun's method is simpler to perform because constant heating of the smear is not required. Otherwise, Kinyoun's cold stain and the Ziehl-Neelsen stain are comparable, decolorizing with a strong acid-alcohol (e.g., 95% ethanol and 3% hydrochloric acid). Examination of smears prepared by both methods requires use of 100× objectives and oil immersion.

The same characteristics that afford the mycobacteria acid-fast properties contribute to the difficulty of staining them by other stains, especially by the Gram method. Gram-stained preparations usually do not detect mycobacteria. However, in smears with heavy concentration of organisms, the rods may appear as poorly stained, beaded Gram-positive bacilli, or as “ghost” outlines that have taken up neither crystal violet nor safranin.

When scanning smears stained by carbolfuchsin (high magnification), at least 300 fields should be examined. Smears stained by the fluorochrome method may be scanned at a lower magnification, viewing at least 30 fields (2). Positive fluorochrome stained smears may be restained by the Kinyoun

method to better evaluate morphology if necessary. The immersion oil objective lens should be wiped clean after viewing a positive slide to avoid the chance of contamination of negative smears by carryover of AFB in the oil from the positive slide. Members of the MTB complex will typically be 2 to 8 µm long and may be slightly curved, whereas members of the NTM may have a banded appearance (*M. kansasii*) or have a pleomorphic morphology (*M. avium*). However, definitive identification cannot be made on microscopic morphology alone. Reporting of positive slides should include some form of quantitation to allow interpretation of the smears (e.g., using the fluorochrome stain at a magnification of 250X: if no AFB seen, report = no AFB seen; 1 to 2 AFB/30 fields or 1 sweep = doubtful, repeat specimen needed; 1 to 9 AFB/10 fields = 1+; 1 to 9 AFB/field = 2+; 10 to 90 AFB/field = 3+; >90 AFB/field = 4+) (2, 15). Full descriptions of methods and reporting formats may be found in references 2 and 15.

Other Means of Detection

Newer methods for the direct recognition of mycobacteria in specimens include HPLC analysis using a more sensitive fluorescent detection column and genomic amplification strategies using PCR or other nucleic acid amplification assays (2, 19, 38).

Of the PCR assays described, the majority are “home-brews” and not available commercially. Many of these use the IS6110 DNA insertion sequence which separates *M. tuberculosis* complex from other mycobacteria. Although home brew testing may be available through research facilities or private reference laboratories, care must be exercised when using such facilities because no standards exist and methods may vary widely.

A few amplification assays have been Food and Drug Administration (FDA)- approved and are commercially available as packaged kits; the first to become approved were the *Mycobacterium Tuberculosis* Direct Test (MTD test by GenProbe) and the AMPLICOR MTB assay (Roche Molecular Systems, Branchburg, NJ). The MTD test is based on transcription-mediated amplification of rRNA while the AMPLICOR assay relies on PCR methodology (2, 21, 24). Additionally, strand-displacement amplification, ligase chain reaction, Q-beta replicase-amplified assay, and nucleic acid sequence-based amplification assay have been introduced and are in the midst of evaluations (23).

Sensitivity of PCR and other nucleic acid amplification methods, both commercial and home brew, approaches 95% for smear positive sputum specimens, but varies between 40% to 80% for smear negative ones. Although not FDA approved for nonrespiratory specimens, some of the direct amplification methods have been evaluated on other specimen types such as CSF for tuberculosis with promising success (20). The clinical utility of direct amplification assays depends on the probability or heightened clinical suspicion for tuberculosis with each individual case. Studies should be limited to cases in which results would directly affect antituberculosis therapy, isolation procedures, or would limit further diagnostic testing (25).

Detection of mycobacterial antigens by immunoassay or of species-specific DNA or RNA sequences by gene probes presently is not adequately sensitive to recommend their routine application. These methods are no more sensitive than direct microscopy.

Interpretation of Results

Care must be exercised in interpreting results of direct smears of specimens and culture. Sensitivity and specificity of procedures are less important on the whole than are their accuracy for positive and negative prediction. The overall sensitivity and specificity of direct detection of AFB in sputum of patients with tuberculosis has been reported to be 22% to 80% and greater than 99%, respectively. Although good, the predictive value of a positive smear depends on the prevalence of disease. Furthermore, it is often difficult to microscopically differentiate between organisms belonging to the MTB complex and the NTM. Sensitivity and the capability of acid-fast smears to predict the absence of AFB in specimens are notoriously poor. Sensitivity can be increased by using auramine-rhodamine, by concentrating specimens (especially by cytocentrifugation), and by examining multiple specimens (2, 15).

Cross-contamination of culture tubes also has been known to occur, and care must be exercised to reduce or discover such a possibility. Inoculation order of tubes should be documented and positivity of consecutive (or closely following) specimens evaluated carefully for the possibility of carry-over contamination. All information derived from laboratory studies must be correlated to patient and clinical considerations (2, 15)

Multiple species may be present in a few infectious cases. Great care must be taken to ascertain that multiple morphologies are not present in primary broth cultures. Confirmation of the identity of an isolate identified as *M. tuberculosis* complex by genetic probe directly from a broth culture is still essential; this can be readily accomplished by documentation of niacin production using growth from the primary LJ slant.

Because the NTM are so commonly associated with the environment, their isolation from clinical specimens, especially sputum, does not immediately equate them with the etiologic agent of disease. The American Thoracic Society has proposed diagnostic criteria for relevance of *M. avium*, *M. kansasii*, and *M. abscessus* in respiratory tract secretions which are summarized below (30):

I. If three sputum or bronchoscopic washing specimens are available over the previous 12 months,
   a. 3 positive cultures (even if smears are negative), or
   b. 2 positive cultures plus one positive smear.

II. If only one bronchoscopic washing is available for evaluation,
   a. Positive culture (any quantity) with few (2+) or more organisms seen on direct smear, or
   b. Few (2+) or more colonies grow on primary solid media.

III. If sputum or bronchial washings are non-diagnostic or another process cannot be excluded,
   a. Positive biopsy (transbronchial or lung), or
   b. Compatible histopathology (granuloma or AFB on smear) and positive sputum culture.

Risk factors in the host, together with failure to identify other pathogenic etiologies, may provide additional clues. The usefulness of the histopathological evaluation of a specimen for documentation and correlation of the infectious process cannot be overstressed. Although these criteria were created to facilitate diagnosis of infections caused by the NTM, they also are useful for

suspected nocardial and other actinomycotic infections (2, 15, 30).

Therapeutic Considerations

Leprosy, tuberculosis, and the nontuberculous mycobacterioses require different treatment protocols. On one side of the spectrum, disease may be localized and self-limited (e.g., localized granuloma caused by *M. marinum*) or may require surgical excision alone (e.g., cervical lymphadenitis caused by *M. avium*, *M. scrofulacium*, or *M. haemophilum*). On the other side, they may require multiple drug regimens over an extended period of time (e.g., extensive pulmonary disease caused by resistant *M. tuberculosis* or *M. avium*).

Treatment of leprosy has depended on the stage of the disease. Dapsone and rifampin remained the primary agents for the tuberculoid stage (paucibacillary), while addition of clofazimine was recommended during the lepromatous stage (multibacillary). Ethionamide or prothionamide may be used in place of clofazimine (33). Newer agents that seem bactericidal to *M. leprae* but for which less experience has accumulated include minocycline, clarithromycin, and ofloxacin.

Antituberculosis therapy is dependent on susceptibility of the isolate and on the state of the disease process. Resistance, especially to isoniazid (INH), but also to multiple agents (multi-drug resistant *M. tuberculosis*, MDRTB) has increased. Variables associated with resistance include prior antituberculous therapy, patient's original country of residence, and his or her duration of stay in the United States. An increased incidence of resistance has been especially prominent in asiatics and hispanics and in several inner-city locations in the United States (2, 15, 39). Therapeutic protocols for tuberculosis have been recommended by the ATS in reference 39. In all cases initial treatment should include at least isoniazid, rifampin and pyrazinamide. When resistance is suspected ethambutol and/or streptomycin should be added. If resistance or adverse drug reaction is noted, the second-line of antituberculous agents can be considered and consists of para-aminosalicylic acid, ethionamide, cycloserine, capreomycin, kanamycin, amikacin, ciprofloxacin, ofloxacin, and rifabutin (2, 39, 40).

The final choice of agents of *M. tuberculosis* is aided by *in vitro* susceptibility studies which should be performed on every initial isolate and repeated if the sputum continues to grow MTB after 3 months of therapy (2, 40). Methods for such studies have been well established and determine the percent of bacilli in a population that are resistant to an agent. A poor clinical outcome is predictable with an agent to which more than 1% of bacilli in any single population are resistant. Thus, the proportional susceptibility method determines the percent of resistant organisms within a population being studied. Middlebrook 7H10 or 7H11 agar, impregnated with antituberculous agents at specific concentrations, is overlaid with inocula of known size. The plates are read quantitatively after an appropriate incubation period, with resistance being defined as growth of more than 1% of the initial inoculum as measured on the control plate (40).

The BACTEC radiometric system also has been applied to study *in vitro* susceptibilities of *M. tuberculosis* against INH, rifampin, ethambutol, and streptomycin with good results. Testing with pyrazinamide is more problematic because of the need to maintain a lower pH in the media. The BACTEC vial susceptibility testing system is a modification of the conventional proportion method, using radiolabeled Middlebrook 7H12 broth and radiometric measurements of growth. The amount of growth (as indicated by changes in the growth index) in the media with known drug concentrations compared with that in the control bottle has been correlated to the presence or absence of resistance in 1% of the inoculum (2, 40).

The conventional studies, as well as those using the radiometric system, may be performed on culture isolates (indirect method) or directly on concentrated specimens (direct method) in which AFB have been seen on smear. Care must be used in interpreting direct tests because of variables present, and results should be verified by indirect studies (40).

Many of the nontuberculous mycobacterioses are not amenable to antimicrobial therapy with antituberculous agents. Most clinically significant NTM are resistant to the first-line antituberculous agents. *M. kansasii*, alone, being commonly treatable with protocols using rifampin together with isoniazid and ethambutol or streptomycin, is only slightly more difficult to treat than *M. tuberculosis* (30). Members of MAC, however, are notoriously resistant and often require regimens combining more than four agents as described in the ATS guidelines (30). Surgical intervention is often recommended for localized disease, especially lymphadenitis.

The rapidly growing mycobacteria are also difficult to treat, being primarily resistant to conventional antituberculous agents. Approaches to therapy often include surgical intervention and debridement of localized infection together with antimicrobial therapy consisting of multiple agents. *M. fortuitum* usually is susceptible to amikacin, ciprofloxacin, sulfonamides, imipenem, cefoxitin, and clarithromycin, and variably susceptible to doxycycline. *M. abscessus* generally is susceptible to clarithromycin, amikacin, and cefoxitin, and has variable susceptibility to imipenem and ciprofloxacin. *M. chelonae* usually is susceptible to tobramycin, clarithromycin, and amikacin, and is variably susceptible to imipenem, doxycycline, and ciprofloxacin.

Historically, conventional *in vitro* susceptibility studies of NTM have had poor predictive value because antimicrobial concentrations for the evaluation of clinical usefulness have not been established. Recent evidence, however, indicates that such studies using microbroth dilution or the gradient strip (Etest, AB BioStrip, Sweden) can be helpful with certain drug selections noted below in the ATS guidelines (30):

I. *M. kansasii*: test rifampin only, and only if patient fails empiric or prophylactic therapy with that agent.
II. *M. avium*: test clarithromycin only, and only if patient fails empiric or prophylactic therapy with that agent.
III. *M. abscessus*, *M. chelonae*, *M. fortuitum*: test for susceptibility to amikacin, doxycycline, imipenem, fluoroquinolones, sulfonamides, cefoxitin, clarithromycin, and tobramycin (*M. chelonae* only).

Suceptibility studies of other NTM-drug combinations are not standardized and not normally recommended.

NOCARDIA

Part of "54 - Aerobic Actinomycetes"

Microbiology and Classification

The genus *Nocardia* historically has contained a very heterogeneous group of organisms, primarily because species identification was based solely on morphologic criteria. Presently, the genus has been restructured with many species being reassigned to new or other genera (*Gordona*, *Actinomadura*, *Nocardiopsis*, *Oerskovia*, and *Rhodococcus*), leaving it more homogeneous (1, 3, 4 and 5, 41). The nocardia possess a type IV cell wall, meso-DAP, arabinose and galactose, but may be differentiated from the mycobacteria by the former's shorter chained (40- to 60-carbon) mycolic acids.

The genus *Nocardia* presently has eleven well defined species of which eight are of clinical importance (*N. asteroides*, *N. farcinica*, *N. brasiliensis*, *N. pseudobrasiliensis*, *N. otitidiscaviarum*, *N. nova*, *N. transvalensis*, and *N. brevicatena* complex). Characterization of the recognized nocardial species is based on a multitude of morphologic and physiological determinants that usually can provide an identification to the species level. *N. asteroides* contains two subgroups that differ in several characteristics and DNA homologies, whereas *N. transvalensis* contains four such subgroup taxa. Because much of the earlier literature did not diffentiate between *N. asteroides* (sensu stricto), *N. farcinica*, and *N. nova*, these three species have often been described as part of the *N. asteroides* complex (2).

Spectrum of Disease

In the United States, the nocardia are commonly considered opportunistic pathogens seen primarily in immunocompromised patients, in those receiving long-term corticosteroid therapy, or in those who have undergone traumatic percutaneous abrasions. Nocardial infections are especially prevalent in patients with parenchymal lung damage resulting from chronic lung disease. Unlike the mycobacteria, nocardial lesions are typically suppurative in nature, with progression to acute necrosis and abscess formation. Granulomatous lesions are rarely formed.

N. asteroides, *N. farcinica*, *N. nova*, *N. brasiliensis*, *N. pseudobrasiliensis* and *N. otitidiscaviarum* are the most common species associated with human infection. *N. transvalensis* and *N. brevicatena* are seldom encountered. Primary manifestations include pneumonia, localized abscess, brain abscess, bacteremia, peritonitis, synovitis, and other localized or disseminated infections.

N. asteroides, *N. farcinica*, *N. pseudobrasiliensis*, and *N. nova* are most commonly associated with pulmonary and (in the case of the first three species) disseminated disease, and less frequently with direct soft-tissue infection. *N. transvalensis*, which is encountered rarely in the United States, has a tendency to cause localized infection, although it can disseminate. In contrast, *N. brasiliensis* and *N. otitidiscaviarum* frequently involve soft tissue. However, both species occasionally may cause systemic and pulmonary disease. Lymphocutaneous sporotrichoid infections also may be encountered, especially with *N. brasiliensis*. Outside the United States, *N. brasiliensis*, *N. otitidiscaviarum*, and *N. transvalensis*, are associated with actinomycotic mycetoma, a localized, progressive, yet chronic infection of skin and soft tissue (1, 3, 8, 42, 43). The organisms are probably introduced into subcutaneous tissue through traumatic inoculation via thorns or splinters, with extremities being involved most frequently. Infected sites swell, and lesions may progress to form draining sinus tracts. Small white granules often may be present in the draining material, representing masses of nocardial cells compacted together. Such mycetomas are seen characteristically in older soft tissue infections.

Epidemiology

The clinically significant nocardial species normally reside as saprophytes in soil and may be associated with plant material as well as water, air, and dust. Their geographic distribution is probably responsible for the variation in species' prevalence in association with disease. The most common species, *N. asteroides* complex, are found throughout the United States, although it is the author's personal observation that numbers seem higher in the southwest. *N. brasiliensis* is commonly associated with tropical areas, although in the United States it also seems to have a higher prevalence in the southwest and southeast. *Nocardia otitidiscaviarum* is an infrequent isolate from soil throughout the world, while the environmental source of *N. transvalensis* has yet to be elucidated (1).

The majority of *N. asteroides* complex and *N. pseudobrasiliensis* infections in the United States are acquired via the respiratory tract, although traumatic inoculation may also occur. Person-to-person transmission of nocardiosis is uncharacteristic, but acquisition in small clusters of patients in close proximity to each other suggests that possibility, but does not rule out environmental exposure in a specific locale (44, 45). *N. brasiliensis* is primarily acquired percutaneously, although respiratory acquisition is possible. Infection with this genus, as with *N. otitidiscaviarum*, is usually primary and is most frequently seen in the normal host.

Diagnostic Procedures

Specimen Collection

The same principles used for mycobacteria specimen collection can be used for nocardia specimens. Respiratory specimens are the most common, but tissues, other normally sterile body fluids, as well as pus, exudates, and even blood may yield nocardia in the right clinical setting. Storage at colder temperatures may be deleterious to some nocardia (1).

Primary Isolation

Nocardia are able to grow on most readily available routine media such as 5% sheep blood and chocolate agars, Mueller-Hinton agar, tryptic soy agar, various broths, Sabouraud dextrose agar, brain-heart infusion agar, and Lowenstein-Jensen agar. Unfortunately, overgrowth of the nocardia by more rapidly growing bacteria and fungi in heavily contaminated clinical specimens is a common problem (1, 3, 4 and 5).

TABLE 54.5. PHENOTYPIC DIFFERENTIATION BETWEEN THE CLINICALLY SIGNIFICANT SPECIES OF *NOCARDIA*

Characteristic	*N. asteroides (sensu stricto)*	N. farcinica	N. nova	N. brasiliensis	N. pseudobrasiliensis	N. otitidiscaviarum	N. transvalensis
Decomposition of:							
Casein	No	No	No	Yes	Yes	No	No
Xanthine	No	No	No	-	-	Yes	No
Hypoxanthine	No	No	No	-	-	-	Yes
Adenine	-	-	-	No	Yes	-	-
Arylsulfatase (14 day)	No	No	Yes	-	-	-	-
Acid from L-Rhamnose	No	Yes	-	-	-	-	-
Growth at 45°C	Variable	Yes	No	No	No	Variable	No

Compiled in part from reference 1.

Because of the overgrowth problem, several primary plating media, including selective media, should be used to optimize isolation.

Selective buffered charcoal yeast extract agar (BCYE) used for legionellosis, as well as Thayer-Martin, Lowenstein-Jensen, and Sabouraud dextrose agars may be used in conjunction with routine blood or chocolate agar plates to isolate nocardia selectively. Selective media may be inhibitory to some nocardia and should not be used alone.

A paraffin-baiting technique, using sterile carbon-free broth and a paraffin-coated glass rod, has been described and is reported to almost double isolation rates for nocardia. The method relies on the propensity of nocardia to invade and use the paraffin on the glass rod as a growth medium. However, the technique has not been popular in clinical laboratories because of its cumbersome nature and longer time to recovery. Pretreatment and processing of contaminated specimens with N-acetyl-L-cysteine or other decontaminating methods used for the mycobacteria are deleterious to the nocardia. Such treatment can significantly decrease viability and should not be used as a primary isolation method. However, isolates can survive in some instances, and nocardia can be isolated in the mycobacterial section of the laboratory (1).

Primary media should be incubated aerobically at 35° for up to 2 to 3 weeks. Cultures also may be set up simultaneously at 25°C, especially if the identity of the potential pathogen is not suspected. Although CO_2 enhancement of nocardial growth has been reported, experience has shown that CO_2 is not necessary for initial isolation of fresh isolates. Cultures should be examined every 2 days for the first week and at least twice weekly thereafter. Clear media are superior for early microscopic recognition of nocardial colonies, which often can be distinguished by their filamentous appearance and possible aerial mycelia. Colonies most frequently are chalky white, turning yellow-orange with age.

Identification

Nocardial isolates may be recognized once the colonies reach a size that will show their chalky aerial mycelia. These are best observed under a dissecting microscope. Commonly, young colonies are pure white, turning to an orange color with age. Staining will show Gram-positive to stippled, branching rods, or occasionally coccobacilli indicative of hyphal fragmentation. A certain percentage of the population of organisms from a colony will stain acid-fast when a weak acid decolorizing solution (0.5% to 1% sulfuric acid) is used with the modified Kinyoun stain.

Resistance of nocardial isolates to lysozyme differentiates them from other streptomycetes. Although the rhodococci may have a variable response to lysozyme, they are normally less acid-fast than nocardia, and their colonies are commonly salmon-pink. The nocardia and rhodococci can further be presumptively differentiated by their susceptibility to vancomycin and erythromycin. Presence of aerial hyphae in the *Nocardia* also differentiates that genus from all other related species (2).

Clinically significant species of nocardia may be differentiated by testing hydrolysis of casein, xanthine, and hypoxanthine; arylsulfatase production; growth in L-rhamnose; and adenine decomposition (Table 54.5 and Table 54.6). Schematic flow charts and a full review of characteristics have been described recently by Brown, McNeil, and Desmond (2).

TABLE 54.6. ADDITIONAL STUDIES TO DIFFERENTIATE THE SPECIES *N. ASTEROIDES*, *N. FARCINICA*, AND *N. NOVA*

Test	% Positivity (P) or Susceptibility (s)		
	N. asteroides	*N. farcinica*	*N. nova*
Growth at 45°C (3 days)	43 P	100 P	5 P
Rhamnose	10 P	80 P	5 P
Acetamide	17 P	80 P	0 P
Arylsulfatase	5 P	0 P	75 P
Cefamandole (S:>20 mm)	95 S	7 S	100 S
Tobramycin (S:>20 mm)	83 S	0 S	17 S
Erythromycin (s:>30 mm)	2 S	0 S	100 S

[a] Compiled from Wallace RJ, Brown BA, Tsukamura M, et al. Clinical and laboratory features of *Nocardia nova*. *J. Clin Microbiol* 1991; 29:2407–2411, and Schiff TA, McNeil MM, Brown JM. Cutaneous *Nocardia farcinica* infection in nonimmunocompromised host. *Clin Infect Dis* 1993; 16:756–760.

More definitive identification sometimes requires evaluation of whole-cell hydrolysates and the isolates' utilization of a variety of organic compounds. These more definitive studies are not commonly available and are not normally needed for most identifications. Identification at the molecular level also has helped define species using PCR, genetic hydridization, and sequence of 16S rRNA studies. These are beyond the capability of the normal laboratory and appropriate reference laboratories should be sought when clinically indicated.

Direct Detection

The nocardia may frequently be detected in routine Gram-stained smears of specimens as long, delicate, branched, beaded to Gram-positive filaments (Fig. 54.4). Shorter rods and coccal

forms are also possible. The Gram stain is probably the most sensitive stain for the detection of these organisms. Although the nocardia have “weak” acid-fast properties, they do not complex the basic dyes as tenaciously as the mycobacteria, and they require a milder acid-alcohol wash. Thus, a modified Kinyoun stain using 0.5% sulfuric acid decolorizer will stain 60% to 90% of nocardia in specimens. Not all nocardia within a single population or specimen will stain acid-fast (partial acid-fastness), and the property may be lost through aging of cultures. A modified auramine-rhodamine stain also may be used to provide an opportunity for detection by fluorescent microscopy.

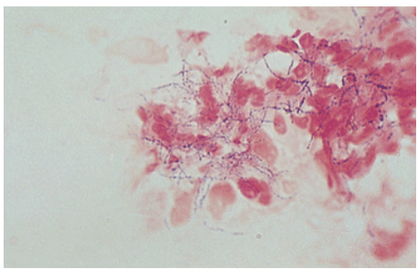

FIGURE 54.4. Direct Gram stain of sputum showing delicate, branched, beaded to Gram-positive filaments characteristic of *Nocardia* species (original magnification of 1,000 X).

Unlike material from actinomycetomas, specimens from respiratory, cutaneous, and systemic nocardiosis usually do not contain actinomycotic sulfur granules. When present, granules may be crushed between two slides and observed by wet mount or by Gram stain for typical branching filaments. A modified acid-fast stain may then be performed for identification. Negative stains, however, cannot rule out nocardial organisms. The Gram-Weigert, Brown and Brenn, and modified acid-fast stains may all detect actinomycetes in tissue and sulfur granule preparations, whereas the hematoxylin and eosin stain will not (1, 3, 41).

Therapeutic Considerations

Sulfamethoxazole-trimethroprim (SXT) and the sulfonamides together with minocycline, amikacin, and imipenem remain the drugs of choice for nocardiosis. Combination therapy with either amikacin or imipenem plus SXT often is recommended for disseminated and central nervous system infections. Treatment should be prolonged for a minimum of 2 to 12 months depending on the severity and progress of the infection. Recovery or improvement is normally best in pulmonary or localized soft tissue infections and worst in disseminated disease (8). Described alternative agents include the third-generation cephalosporins, amoxicillin-clavulanic acid combination, and the fluoroquinolones, although their activity *in vitro* against the nocardia has been variable.

The variable response of *N. asteroides* to a number of antimicrobials suggests that isolates be tested *in vitro* for specific guidelines (1, 8). Although methods for susceptibility studies of the nocardia have not officially been standardized, microbroth dilution, disk agar diffusion, gradient strip agar diffusion, and radiometric broth bottle determinations of MICs or susceptibilities have been well described (46, 47 and 48).

The broth-microdilution test system using cation-supplemented Mueller-Hinton broth and the radiometric broth BACTEC vial system correlate fairly well the disk diffusion method (46, 47 and 48). The broth microdilution and gradient strip methods are practical for application in many laboratories. Results must be noted as being nonstandardized. Further study is needed to confirm clinical applications and correlations with outcomes.

RHODOCOCCUS, *GORDONA*, AND *TSUKAMURELLA*

Part of "54 - Aerobic Actinomycetes"

Microbiology and Classification

Members of this group of organisms are diverse in their morphology and growth patterns. Their grouping and identification are based primarily on cell wall constituents (being those of type IV, with mycolic acid sizes ranging from 32 to 66 carbons in length) as well as biochemical criteria.

Considered originally as rhodochrous strains of the genus *Mycobacterium*, the rhodoccocci were placed in a separate genus in the 1970s. A redefining of the genus *Rhodococcus*, with removal of several species to the genus *Gordona* and renaming of one species as *Tsukamurella*, has left nine species intact. The rhodococci contain 34 to 52 carbon mycolic acids, no mycobactins, and eight isoprene dehydrogenated menaquinones. Only one species, *Rhodococcus equi*, has been isolated from humans and is associated with human infection (1, 49, 50). Other species not associated with disease in humans include *R. coprophilus*, *R. erythropolis*, *R. fascians*, *R. globerulus*, *R. marinonascens*, *R. rhodnii*, *R. rhodocrous*, and *R. ruber*.

The genus *Gordona* was reintroduced in 1988 to accept transfer of several species from the genus *Rhodococcus* based on molecular studies and characterized by differences in mycolates (48 to 66 carbon atoms) as well as presence of nine isoprene units in the dihydogenated menaquinoes. Presently, the species in this genus associated with human disease include *G. bronchialis*, *G. rubroperctinctus*, *G. sputi*, *G. terrae*, and *G. aichiensis*. Species not associated with humans include *G. amarae*, *G. hydrophobica*, and *G. hirsuta* (1, 49, 50).

Tsukamurella paurometabola is the primary species in the genus named after Tsukamura (in 1988), who in 1971 first studied the organism isolated from sputum. Four other species alloted to this genus include *T. inchonensis*, *T. pulmonis*, *T. tyrosinosolvens*, and *T. wratislaviensis* (1).

Spectrum of Disease

Rhodococci and related genera *Gordona* and *Tsukamurella* rarely are involved in human disease, but seem to be increasing in their role as opportunistic pathogens in the immunocompromised host.

Primarily a pathogen of livestock, *R. equi* is the species most commonly associated with human infections in this group. The organism has been implicated with pulmonary disease, including lung abscess and cavitation, often concomitantly with bacteremia in patients with neoplastic disease or on immunosuppression (5, 51).

Separate reports have implicated *R. equi* in localized infection of a cervical lymph node as well as in endophthalmitis (52). The organism also may cause disease in patients with implanted Hickman catheters or in those with AIDS (53).

Infections caused by *Gordona* species are very rare, and colonization or contamination of specimens may occur. These species have been implicated in primary cutaneous infection (*G. terrae*), chronic pulmonary infection (*G. aichiensis*, *G. bronchialis*, and *G. rubropertincta*), catheter-associated bacteremia, and a brain abscess (1).

The genus *Tsukamurella* also is a rare opportunistic pathogen, having been associated with immunocompromised patients and those undergoing dialysis and with indwelling catheters; bacteremias have been documented on several occasions (1).

Epidemiology

The rhodococci may be found in a number of environmental locations, especially soil, but also fresh water, marine habitats, the gut of some arthropods, and feces of herbivores, swine, and fish. The presence of fecal contamination significantly increases the multiplication of the organisms in the soil. Isolation of the organism from sputum and central lines suggests its acquisition from air or dust, which may be inhaled or may contaminate medical devices. Often however, patients do not have a history of exposure to animals (53). Corticosteroids and immunocompromising conditions enhance patient susceptibility to clinically manifested infection (1, 4, 49, 53).

Gordona also are well distributed in nature, with various species being isolated from soil, aeration tank foam in sewage treatment plants, biofilters from waste gas treatment, and sputum. *Tsukamurella* species, which prefer cooler growth temperatures, have been isolated from soil, sludge and arthropods (1, 4).

Diagnostic Procedures

Specimen Collection

Follow the same guidelines given for the nocardia. Bacteremia may be present during rhodococcal and related organism infection of immunocompromised patients and of long-term indwelling lines.

Primary Isolation

On culture plates, colonies of *Rhodococcus equi* initially are clear to white, nonhemolytic, rounded, and frequently mucoid and often turn salmon-pink to red within 2 to 5 days (Fig. 54.5.). Pigmentation may vary from red to cream. Growth is good between 15°C and 40°C, but is slow, often requiring several days for visual observation. Microscopically, the organisms are Gram-positive and coccobacillary or bacillary, resembling other coryneform bacteria. A small number of cells within a population may be stained by the modified Kinyoun weak acid-fast stain, contributing to their being confused with fragmented nocardial cells. Unlike the nocardia, however, rhodococci are susceptible to vancomycin and erythromycin *in vitro*.

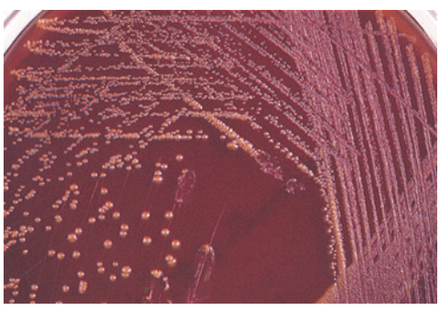

FIGURE 54.5. Colonies of *Rhodococcus* species with typical salmon-pink to red pigmentation (shown on sheep blood agar).

In addition to colonial and microscopic recognition, the rhodococci may be preliminarily recognized and identified by biochemical characteristics using API Coryne system (bioMerieux, Maarcy l'Etoile, France), API ZYM, and the VITEK GPI card (bioMeriux Vitek, Hazelwood, MO) (53). Supplemental tests may include the presence of *equi* factor (CAMP-like test), catalase, urease, lipase, oxidase, orthonitrophenyl-ß-D-galactopyranoside (ONPG), growth on MacConkey agar, and hydrolysis of xanthine, tyrosine, hypoxanthine and gelatin (53). Definitive identification is difficult and may require cell analysis for meso-DAP, arabinose, and galactose, as well as more extensive physiological and molecular testing (1, 4, 5, 7, 51, 52 and 53).

Direct Detection

The rhodococci are seen typically as Gram-positive short rods or coccobacilli and are confused frequently with the diphtheroids. Although having partially acid-fast properties, these organisms are seen less frequently as being acid-fast than the nocardia. The organisms do not have characteristic morphologies that would lead one to suspect them as being rhodococci on direct Gram stain. However, the histopathology in bronchial secretions may show characteristic pleomorphic Gram positive bacteria engulfed by polymorphonuclear leukocytes. Microabscesses, pseudotumors and malakoplakia (granulomatous inflammation) also may be evident by histopathology (1).

Therapeutic Considerations

The rhodococci normally are susceptible to erythromycin, rifampin, vancomycin, the aminoglycosides, penicillin G, and doxycycline. Because of the organisms' intracellular nature, the combinations of erythromycin or imipenem with rifampin seem to act synergistically. Fluoroquinolones have been suggested as alternative therapy, but resistant strains have been noted in Asia (53). Duration of therapy is uncertain, although many weeks may be required because relapses may occur after shorter periods. Surgical intervention also may be necessary in instances. Standardized susceptibility tests are not available, although NCCLS guidelines for the coryneform bacteria may be applied (1, 3, 7, 49, 53, 54).

ACTINOMADURA, *DERMATOPHILUS*, *NOCARDIOPSIS*, AND *STREPTOMYCES*

Microbiology and Classification

Species within the genus *Actinomadura* share a chemotype III cell wall and contain the sugar madurose. These organisms are Gram-positive rods that do not fragment and produce both substrate and aerial branched hyphae. They can be distinguished easily from *Dermatophilus* morphologically. Originally classified in the genus *Nocardia*, the *Actinomadura* were later given individual genus status. The genus contains 26 species, of which three (*A. madurae*, *A. pelletieri*, and *A. latina*) are clinically significant. Previous members such as the species *dassonvillei* were found to lack madurose and were transferred to the genus *Nocardiopsis* (1, 4).

The genus *Dermatophilus* contains but a single species, *Dermatophilus congolensis*, an obligate animal pathogen with meso-DAP and madurose as major cell-wall components. The organism characteristically divides by transverse, longitudinal, and horizontal septation of the mycelium, leading to the formation of motile zoospores. A tough, gelatinous capsule is formed surrounding the branching vegetative mycelium at points of division where zoospores mature, representing a multilocular sporangium (1, 55).

Nocardiopsis contains seven species, only one of which really may be considered pathogenic (*N. dassonvillei*). The organisms produce characteristic chains of arthrospores which fragment from aerial as well as substrate hyphae, contain meso-DAP and a chemotype III cell wall, but lack mycolates (1, 3).

The genus *Streptomyces* contains a large number of frequently poorly defined species of sporoactinomycetes with cell-wall type I (L-DAP, glycine but no sugar). Of all the species present in this genus, only *Streptomyces somaliensis* and *Streptomyces anulatus* (*griseus*) are commonly associated with human disease (1, 3).

Spectrum of Disease

Infectious manifestations of members of the genera *Actinomadura*, *Nocardiopsis*, and *Streptomyces* are primarily limited to the formation of localized, suppurative, mostly chronic lesions. These mycetomas occur commonly in parts of the body coming into frequent contact with soil or that may be abraded or traumatized. The most common human pathogens are *A. madurae*, *A. pelletieri*, and *S. somaliensis*, and less frequently, *S. griseus* and *N. dassonvillei*. The organisms gain entry into subcutaneous tissues through slight or imperceptible breaks in the skin. A painless nodule forms, becomes fluctuant, and usually forms a sinus tract through which pus is discharged. Draining pus often contains pigmented granules made up of filamentous, compacted microcolonies of the organism and ranging in color from white to yellow (*A. madurae* and *S. somaliensis*) or red to pink (*A. pelletieri*). Additional nodules and sinus tracts form over time, with fibrous tissue eventually deforming the areas involved. Unchecked, progression of the lesions may involve connective tissue, muscle, and bone. The immune response to actinomycotic infections characteristically is pyogenic. The disease remains localized. Hematogenous spread is encountered rarely (except with nocardia), although spread via the lymphatics to involve lymph nodes is possible (26, 42, 43).

D. congolensis, the only species in the genus, causes streptrotrichosis in animals; this dermatophilosis is a pustular, exudative dermatitis affecting many wild and domestic animals, especially sheep, cattle, and horses. The organism is found obligately on animals, never having been isolated from the environment. It may be transmitted to humans, either directly through contact with infected animals or possibly through bites by arthropods that may carry infective zoospores. Infection, however, probably requires some form of dermal abrasion because *Dermatophilus* is not invasive. Presenting either as multiple pustules or as a desquamative keratitis of the hands and forearms, the infection usually is self-limiting in humans (1, 4, 55).

Epidemiology

The clinically significant species of *Actinomadura*, *Nocardiopsis*, and *Streptomyces*, primarily soil inhabitants, have diverse geographic prevalences, although none is common in the United States. Mycetomas caused by *A. madurae* are cosmopolitan, although tending to be more frequent in tropical or subtropical regions. The organism is isolated frequently in North and South America, Africa, and Asia. *A. pelletieri* has a predilection for areas with heavy rainfall and is more restricted to areas of Africa and South America (26, 42). *S. somaliensis* prefers arid regions, sandy soil, with vegetation consisting of thorny plants. It therefore causes mycetomas most frequently in Africa, Mexico, and portions of South America, although it may be found in other continents as well.

Dermatophilus is an obligate parasite associated with livestock and other feral animals. Direct contact of abraded skin with material such as skin or hair of diseased animals carrying infective zoospores is the normal route of transmission. The disease is uncommon in the United States (1, 55).

Diagnostic Procedures

Specimen Collection

Biopsy of deeper tissue is preferred for the evaluation of actinomycotic mycetomas, because surface material may be contaminated or colonized. Other specimens may include pus, drainage fluid, or sinus scrapings either from open lesions or from aspirates.

Specimens for diagnosis of *Dermatophilus* infections include material from unopened pustules, exudates, biopsies, scrapings, and scabs. Specimens should be submitted in sterile tubes or in adequate volume on premoistened sterile swabs and should be kept at room temperature (1, 55).

Primary Isolation

Culture methods for the actinomadurae, the nocardiopsis, and the streptomycetes are similar to those for the nocardia. The actinomadurae may at times be difficult to isolate from clinical specimens. The former, together with the streptomycetes, may not grow on all of the media described for the nocardia, but may produce small colonies on nocardia selective agars. Thus, such media should be supplemented by other routine media as outlined

for the nocardia, as well as by Sabouraud dextrose agar, both with and without chloramphenicol (0.05 mg/mL). Incubation should be at 26°C as well as at 35° for up to 3 weeks (1, 3).

Isolation of *Dermatophilus* is difficult, but may be accomplished by inoculating the specimens onto beef infusion-blood agar and incubating for up to a week aerobically at 35°. Plates also may be incubated in the presence of 5% to 10% CO_2. Specimens with heavy contamination may require selective processing, employing either animal passage or the predilection of zoospores for CO_2 (55).

Identification

Members of the genus *Actinomadura* normally are slow-growing, with colonies that are glabrous or waxy, heaped, and either white to cream (*A. madurae*) or pink to coral red (*A. pelletieri*) in color. Microscopically, they are Gram-positive, non–acid-fast, bacillary organisms with branching vegetative mycelia. The mycelia of the two clinically important species only rarely fragment and usually do not produce aerial forms. Streptomycetes, on the other hand, are fast-growing and produce colonies similar to those of the actinomadurae.

Simplified differential identification schemes may include cell-wall analysis for the presence of meso-DAP and madurose in the actinomadurae, of meso-DAP without characteristic sugars in nocardiopsis, and of L-DAP in the streptomycetes. *A. madurae* and *A. pelletieri* can be differentiated by the red coloration of the latter's colony (1, 26).

Dermatophilus may be recognized as tiny, pitting colonies after incubation for 24 hours, turning orange within 2 to 5 days with ß-hemolysis evident in areas of heavy growth. The single species in this genus can be identified by the characteristic microscopic morphology, which is similar to that seen in clinical specimens. Colonial growth is optimal at 37°C when enriched media are used, and production of aerial mycelium is promoted by 10% CO_2. Whole-cell hydrolysate analysis for DL-DAP and madurose, together with casein and starch hydrolysis may help in furthering identification of a few strains, but such studies are rarely needed (55).

Direct Detection

In cases of mycetoma, biopsy or drainage material should be examined for granules, which usually are hard and of variable sizes (1, 26). The granules should be washed with sterile saline and then examined microscopically after emulsification in a drop of 10% potassium hydroxide or after crushing between two slides. They also can be stained by the Gram method to visualize the tangled filamentous forms of the actinomycetes, thereby differentiating them from the broader, cross-walled mycelia of the fungi. A positive modified acid-fast stain also can differentiate between the nocardia and the actinomadura and streptomyces; however, negative stains also may occur with the nocardia. As with the nocardia, the Brown and Brenn's modification of the Gram stain and the Gram-Weigert stain will detect the aerobic actinomycetes in tissue (1, 26, 42, 43).

Direct detection of *Dermatophilus* is best accomplished using the Giemsa stain of submitted smears or tissue. The Gram-stain and methylene blue wet mount also may be useful. The organisms typically show 2 to 5 µm wide, branched filaments with transverse and longitudinal division. Packets containing coccoid cells may be present (55).

Therapeutic Considerations

Actinomycotic mycetoma responds to antimicrobial therapy, although regimens of several months' duration are necessary to curb relapse. Surgical debridement may enhance healing. Streptomycin sulfate, usually combined with another agent, is commonly suggested. The second agents recommended may be dapsone for *A. madurae* and *S. somaliensis*, and SXT for *A. pelletieri*. SXT also has been suggested for streptomycetes not initially responding to dapsone. Susceptibility studies are not recommended routinely (42, 43).

Infection with *Dermatophilus* normally is self-limited, and systemic therapy usually is not required.

OTHER ACTINOMYCETES

Part of "54 - Aerobic Actinomycetes"

Other actinomycetes of some medical importance include the genera *Oerskovia*, *Micromonospora*, and the three thermophilic genera *Saccharomonospora* spp., *Saccharopolyspora* spp., and *Thermoactinomyces* spp. These genera, however, are encountered rarely in clinical laboratories and are well described elsewhere (1).

Interesting characteristics of the oerskoviae include their being facultative anaerobes, having the ability to fragment into motile bacillary elements, and having a yellow pigment. Additionally, morphologic characteristics, absence of DAP and mycolates, and presence of type VI cell wall constituents, with lysine and galactose as major components, separate the oerskoviae from other aerobic actinomycetes (5). Found primarily in soil and plant debris, these organisms occasionally have been reported to cause infections in humans, usually in association with traumatic inoculation or contamination of indwelling foreign objects (56).

SUMMARY AND CONCLUSIONS

Part of "54 - Aerobic Actinomycetes"

Many of the aerobic actinomycetes have gained increased prominence as pathogens at a time when the number of patients with immunocompromising conditions also is on the rise. Sophisticated medical technology together with newer diseases that induce immunodeficiency are at least partially responsible. Added recognition of the infective capability of the aerobic actinomycetes and better understanding of their epidemiology, clinical course, and susceptibilities to antimicrobial agents are paramount to rapid diagnosis and better patient care. Molecular identification and typing techniques will bring a better understanding of the interrelatedness of the various genera and species in these groups of organisms. Clinical laboratories must become aware of the role played by the aerobic actinomycetes in disease and must recognize when identification, susceptibility testing, and therapeutic or surgical interventions are necessary.

Antimicrobial Susceptibility Testing

Carl L. Pierson

Antimicrobial susceptibility test results are regarded by most clinicians as vital information for the rational selection of antimicrobics to treat an established infection or to prevent an infection. Unfortunately, few clinicians who use susceptibility test results understand the methods used to generate them and, more importantly, the limitations of using such *in vitro* procedures to predict efficacy in their patients. With new antimicrobics being added almost yearly to the physician's armamentarium with their varied antimicrobial spectra, pharmacokinetics, and pharmacodynamics, the complexity of choosing and administering an appropriate therapeutic agent has increased dramatically. In addition, our expanding knowledge regarding the number and complexity of antimicrobic resistance mechanisms is requiring the testing laboratories to add or modify testing procedures to detect such mechanisms. Therefore, clinical pathologists and microbiologists must work closely with the infectious disease specialists and pharmacists within a medical care setting to provide meaningful reports with interpretations to assist in this selective process. Quality assurance indicators designed to monitor how clinicians use laboratory information often reveal where false assumptions are being made from a laboratory report, e.g., “the antibiotic with the lowest minimum inhibitory concentration (MIC) is the one to use.” Clinical pathologists and microbiologists must continue to stay abreast of the laboratory testing methods being used and their clinical relevance, and must interact with the clinicians using this information to produce useful reports leading to appropriate drug utilization.

The clinical relevance of *in vitro* susceptibility results is not altogether clear in many instances. Bacterial pathogens declared “susceptible” to an antimicrobic selected for therapy may be treated effectively in an immunocompetent patient, but the drug may be ineffective in an immunocompromised patient or if the infection occurs in a poorly vascularized anatomic site. Most studies that attempt to correlate treatment success with *in vitro* susceptibility fail to show a positive correlation; however, there frequently is a positive correlation between organisms that test resistant and treatment failure (1, 2, 3 and 4). Therefore, the apparent value of the susceptibility test is to monitor for organism resistance or declining susceptibility to selected antimicrobics.

The developmental history of susceptibility test methods has been reviewed (5). Much effort has gone into developing testing standards to provide consistent interlaboratory results. Drs. Hans Ericsson and John Sherris worked with an international team to publish the International Collaborative Study report in 1971 (6). These remarkable studies laid the groundwork upon which most subsequent work on test standardization for disk diffusion and broth dilution techniques was done. In the United States, this continuing task has been taken up by the National Committee for Clinical Laboratory Standards (NCCLS) subcommittee on antimicrobial susceptibility tests, which publishes testing standards and supplemental updates for these standards on a periodic basis. NCCLS Subcommittees have been formed to develop methods for performing other special tests such as the minimum bactericidal concentration (MBC) test and the serum bactericidal test (SBT), which, by consensus approval, could become approved standards.

Microbiology specimens submitted for routine bacteriologic culture usually arrive in the laboratory accompanied by a requisition for “culture and susceptibility.” This implies that a susceptibility test is to be done if a possible pathogen is isolated that is known to vary in its susceptibility to antimicrobics commonly used for treatment, and methods exist to perform and interpret the test. Organisms that typically show no variation in susceptibility to the recommended drugs of choice need not be tested, e.g., to date *Streptococcus pyogenes* has always tested susceptible to penicillin when testing is done appropriately. Other pathogens may need to be treated empirically without the benefit of susceptibility testing either because the *in vitro* results are known not to reflect the clinical response to therapy with a drug or because the laboratory has no way of interpreting the results obtained from such a test. An example of the former would be the activity of cefotetan against *Stenotrophomonas maltophilia*; an example of the latter would be the activity of ampicillin against *Bacillus cereus*.

TABLE 55.1. LABORATORY RESPONSIBILITIES FOR PERFORMING ANTIMICROBIAL SUSCEPTIBILITY TESTS

Select isolates to be tested
Select antimicrobics to test
Perform tests using standardized procedures whenever possible
Assist with interpretation of nonstandardized tests
Report results
Accurately
Timely
Selectively

As antimicrobics became available for clinical use, a method of determining which agents needed to be tested and/or reported against appropriate bacteria had to be developed. The current NCCLS documents M2-A7 (standards for the disk diffusion method) and M7-A5 (standards for dilution methods) offer suggested groupings that can be used to limit the number of drugs requiring testing based on drug class and probability of obtaining like results (7, 8). Suggestions also are offered for selective reporting of results to encourage the use of less expensive yet effective antimicrobics. If an organism shows resistance to a

first-tier antimicrobic, another one of a similar class that shows good activity can be reported from a secondary tier. Antimicrobics approved for use by the hospital formulary committee should be used as a guide for drug selection. Consultation with local infectious disease specialists who utilize the laboratory also can offer valuable assistance on drug selection and drug concentrations to test, but, to promote interlaboratory uniformity in testing, NCCLS standards should be followed unless there are overriding local circumstances to the contrary. Whenever an alternative method is used, it should be justified, and the clinician should be notified that a nonstandardized method was used. Under such circumstances, NCCLS interpretations should not be used, and it may be necessary to report the result without an interpretation. The areas of responsibility for the performance of susceptibility testing that rest with the microbiology laboratory are listed in Table 55.1.

COMMON IN VITRO ANTIMICROBIAL SUSCEPTIBILITY TESTS

Part of "55 - Antimicrobial Susceptibility Testing"

There are at least a dozen different laboratory test methods in use to determine organism susceptibility to various antimicrobics (Table 55.2 and Table 55.3) but only a few are used with any frequency in most clinical microbiology laboratories doing such testing on a routine basis. In addition, reference laboratories also may perform susceptibility tests for mycobacteria, fungi, and certain viruses.

TABLE 55.2. FREQUENTLY USED *IN VITRO* SUSCEPTIBILITY TESTS

Dilution tests
Broth microdilution
Agar
Semiautomated
Diffusion tests
Disk (aka Kirby Bauer)
Fixed gradient (Etest or epsilometer)
Spot tests (e.g., ß-lactamase)

To date, there are four susceptibility testing standards issued by the NCCLS:

M7-A5 *Methods for Dilution Antimicrobial Susceptibility Tests for Bacteria that Grow Aerobically*, 4th ed. (2000);

M2-A7 *Performance Standards for Antimicrobial Disk Susceptibility Tests*, 6th ed. (2000);

M11-A4 *Methods for Antimicrobial Susceptibility Testing of Anaerobic Bacteria*, 4th ed. (1997); and

M27-A *Reference Method for Broth Dilution Antifungal Susceptibility Testing of Yeasts* (1997).

In addition, a supplement — M100-S10 *Performance Standard for Antimicrobial Susceptibility Testing*; Ninth Informational Supplement (2000), provides updated tables for standards M7-A5 and M2-A7. These tables are updated annually.

NCCLS publications for other susceptibility testing procedures are available but have not been given standard status to date. Still, they contain valuable information regarding the state of the art. These publications include:

M21-A *Methodology for the Serum Bactericidal Test* (1999); Approved Guideline

M23-T3 *Development of In Vitro Susceptibility Testing Criteria and Quality Control Parameters* (1998); Tentative Guideline

M24-T *Antimycobacterial Susceptibility Testing* for Mycobacterium tuberculosis (1995); Tentative Guideline

M26-A *Methods for Determining Bactericidal Activity of Antimicrobial Agents* (1999); Approved Guideline, and

M38-P *Reference Method for Broth Dilution Antifungal Susceptibility Testing of Conidium-Forming Filamentous Fungi* (1998); Proposed Standard.

Broth Microdilution Minimum Inhibitory Concentration Test

The broth microdilution minimum inhibitory concentration (MIC) test provides a quantitative measurement (in µg/mL) of the lowest concentration of an antimicrobial agent that inhibits the growth of a bacterium. The reader is advised to consult the NCCLS standard M7-A5 for a detailed description of procedures for this test method (8).

Selected antimicrobics can be obtained either from the pharmaceutical manufacturer, the U.S. Pharmacopeia, Rockville, MD, or a commercial distributor. Only standardized powders or liquids specifying specific activity and expiration date are to be used. The agents are dissolved in appropriate solvents, finally diluted to appropriate concentrations and distributed into the wells of molded microtiter plates (Fig. 55.1). The filled plates can be either frozen at -70°C or desiccated and stored at room temperature. The concentrations selected for each agent are determined by the achievable blood (or urine) concentrations obtained with recommended dosage schedules and routes of administration. Traditional MIC panels contain a two-fold dilutional series of concentrations for

each agent, ranging from easily achievable concentrations in blood (or urine)(susceptible) to those that usually are unachievable (resistant). Because of the large number of antimicrobics available for testing, some panels are designed as “breakpoint panels” that limit the number of dilutions used to the minimum necessary to provide interpretive information. This allows for more drugs to be tested per panel. Other drugs are present in single concentrations and may be used primarily for screening for one-point levels of resistance.

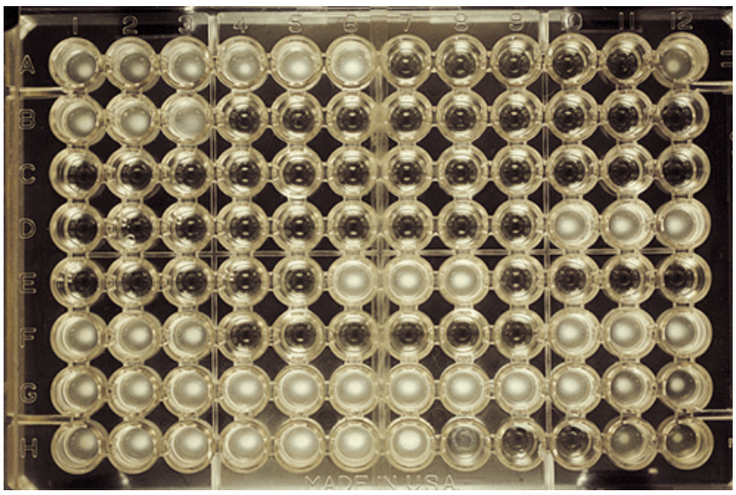

FIGURE 55.1. Microdilution minimum inhibitory concentration (MIC) tray showing growth endpoints using indirect lighting.

Frozen panels must be defrosted and subsequently inoculated with the test organism, making sure that the inoculum volume does not exceed more than 10% of the final volume in each well. Usually 1 to 5 µL of inoculum is added to 100 µL of diluted antimicrobic solution in each well. Alternatively, the drug concentration in each well can be prepared and stored at twice the final desired concentration and diluted two-fold with the diluted inoculum. Dessicated panels usually are rehydrated and inoculated simultaneously by suspending the appropriate number of organisms directly in the rehydrating growth medium.

Time-kill kinetic assay

Several different growth media have been used to assess antimicrobic activity. Some nutritionally fastidious bacteria (e.g., *Haemophilus influenzae*) require the addition of supplementary growth factors (9). Others may require higher concentrations of cations to express resistance characteristics not seen otherwise (10, 11 and 12). Serum or serum components may be added to show the effects of protein-binding on antimicrobic activity (13, 14 and 15). For routine testing, however, the growth medium selected for use in MIC testing in the United States is Mueller-Hinton broth (MHB) that contains a final concentration of 20 to 25 mg/L of Ca^{2+} and 10 to 12.5 mg/L of Mg^{2+} described as cation-adjusted Mueller-Hinton broth (CAMHB). These cation concentrations are especially important when testing the activity of certain aminoglycosides against *Pseudomonas aeruginosa* (11). To optimize the expression of resistance to oxacillin in staphylococci, the CAMHB also must contain 2% NaCl (12, 16). The pH of the medium must fall within the range of 7.2 to 7.4 (17).

Bacteria to be used for inoculation can be harvested from either solid media or broth culture. The organism's phase of growth appears to have little effect on the results, but it is important to have a relatively fresh culture to assure that a high percentage of the bacterial cells are viable (e.g., ≤24-hour culture). Initially, a portion of four to five similar colonies from a pure culture or from colonies well isolated on a plate are to be harvested and suspended in water and the turbidity adjusted to match that of a 0.5 McFarland turbidity standard or an optical density (O.D.) of approximately 0.08 @625 nm. This provides an approximate starting concentration of 10^8 viable cells/mL. This suspension must be further diluted in CAMHB to achieve a concentration such that the final concentration in the microdilution well will be about 5×10^5 CFU/mL. Although this concentration is somewhat arbitrary, it has been determined that when inoculum concentrations substantially higher than this are used, e.g., 10^7 CFU/mL, false-resistant results can be obtained; lower inoculum concentrations can yield false-susceptible results (18). A sample from the growth control well of an inoculated MIC panel should be removed and a colony count performed to document that the viable inoculum concentration is within the acceptable range. Inoculated panels are to be incubated 18 to 24 hours at 35°C in a room-air incubator. CO_2 incubators are not to be used unless necessary to achieve growth because the CO_2 increases the acidity of the growth medium, which can significantly alter the activity of certain antimicrobics, e.g., erythromycin. A full 24-hour incubation time is recommended when testing *Staphylococcus aureus* for oxacillin resistance. These resistant organisms are frequently slow-growing, and “heteroresistant” strains, i.e., when only a small number of cells express resistance, they may be difficult to detect with shorter incubation times (12). It may be

necessary to incubate coagulase-negative staphylococci up to 48 hours to detect oxacillin resistance. A full 24-hour incubation time also is necessary to optimally detect vancomycin resistance in enterococci. Rapid-growing mycobacteria and *Norcardia* spp. also may be tested for susceptibility using this method, but they usually require 3 to 4 days of incubation prior to reading (19, 20).

Panels are read by holding them over a light source that provides indirect background lighting. This type of illumination is optimal for detecting faint buttons of growth at the base of the wells. All panels are to have a growth control well that contains no antimicrobic, and an uninoculated sterility well that contains no antimicrobic. Both control wells should be examined prior to assessing the rest of the panel. The sterility well should show no evidence of growth, and the growth control well should show obvious growth that is consistent with the pattern of growth expected for the organism type inoculated. Gram-positive cocci usually form a discrete button at the bottom of the well, whereas Gram-negative bacilli frequently grow in a more diffuse pattern, although neither of these characteristics is absolute. If the control wells do not appear as expected, the reading of the panel should be aborted and the isolate retested.

If the control wells are acceptable, each series of dilutions of an antimicrobic should be examined for an endpoint where the lowest concentration in the antimicrobic series has completely inhibited the growth of the inoculated organism. This concentration is recorded for each antimicrobic tested. Most endpoints are quite easy to determine; some, especially certain bacteriostatic drugs, may not produce a sharp endpoint, and exhibit a "trailing effect." With experience, an endpoint usually can be determined where there is a sharp (≥80%) decrease in the amount of growth seen.

Specific control strains must be tested at least weekly to monitor drug concentrations in the panels and to assure that the technique being used to set up the panels is adequate to obtain accurate results. Quality control (QC) guidelines are available from the NCCLS (M23-T3). Currently, there are four strains that are recommended for routine quality control of MIC panels:

S. aureus, American Type Culture Collection (ATCC) 29213 (ß-lactamase positive);

Enterococcus faecalis, ATCC 29212;

Escherichia coli, ATCC 25922; and

P. aeruginosa, ATCC 27853.

Additional strains should be tested when certain drugs or specific bacteria are to be tested:

E. coli, ATCC 35218 when ß-lactam/ß-lactam inhibitor combinations are being tested (ß-lactamase positive);

H. influenzae, ATCC 49247 or 49766 when testing an *H. influenzae* isolate; and

Neisseria gonorrhoeae, ATCC 49226 when testing an isolate of *N. gonorrhoeae*.

All of the above strains are available from the ATCC, Rockville, MD. The ideal control strain would yield an MIC that is in the intermediately susceptible range for the drug being monitored. Unfortunately, many of the new broad-spectrum antimicrobics are highly active against the older control strains and produce MICs that are much lower than the lowest concentration being tested. New, stable, resistant control strains are needed for these drugs to provide adequate QC.

The MIC results are to be reported in µg/mL and an interpretation given for each drug as to whether the MIC falls within the range considered by the NCCLS standard to be susceptible, intermediately susceptible, or resistant. Infections caused by organisms that yield intermediately susceptible results still may be treated effectively by the drug if higher dosages can be administered or if the drug is known to concentrate within the infected locus such as in urine or bile. When organism-drug combinations are tested and no interpretations are available, no interpretations should be given until there is enough clinical evidence to show that an interpretation is justified. As mentioned previously, attempts should be made to limit the number of drugs reported to those that offer a more limited yet good spectrum of activity and are less expensive to purchase and administer.

Agar Dilution Method

The reader is referred to the section on the testing of anaerobes for a description of this method.

Disk Diffusion Method

This method, commonly referred to as the Kirby-Bauer test, provides a qualitative measure of the ability of an antimicrobic to inhibit the growth of a rapidly growing bacterium. The disk diffusion method was the first standardized susceptibility method available and remains a very useful method despite the continuing shift of laboratories to either the microdilution MIC method or a semiautomated procedure.

Disks containing a given concentration of an antimicrobic are placed on a confluently inoculated agar plate and incubated for 16 to 24 hours. At the end of the incubation period, zones of growth inhibition are measured across the disk diameter and recorded to the nearest millimeter (Fig. 55.2). The results are interpreted as susceptible, intermediately susceptible, or resistant by using the interpretive tables provided in the NCCLS standard M2-A5 (7). No quantitative results can be given with this method.

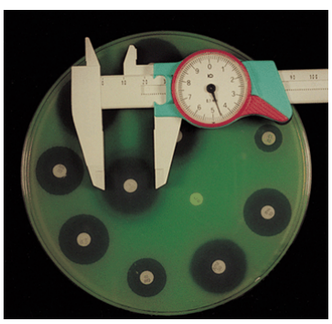

FIGURE 55.2. Measuring zones of inhibition around antimicrobic disks using a micrometer.

For routine disk diffusion testing, most clinical laboratories use plastic culture dishes with diameters of 150 mm that have been filled with Mueller-Hinton agar to a depth of 4 mm. Cation supplementation usually is unnecessary because the agar itself contributes adequate amounts of Ca^{2+} and Mg^{2+}, and the companies providing the media now monitor their products and supplement them when necessary. The media can be supplemented with other products such as horse blood, which supplies thymidine phosphorylase and allows for more accurate measurement of trimethoprim and sulfamethoxazole activity, which are inhibited by the presence of thymidine (21). Blood-supplemented plates often are necessary to obtain adequate growth of some fastidious organisms such as some streptococci and diphtheroids (9). To test *N. gonorrhoeae*, the NCCLS standards recommend the use of GC agar instead of Mueller-Hinton agar. The 150 mm plates can accommodate about 12 individual susceptibility disks; the actual number depends on the anticipated

size of the zones of inhibition, which should not overlap. This size is partly dependent on the concentration of the drug in the disk and the diffusion characteristics of the drug through the agar. Drugs such as penicillin can produce very large zones of inhibition when testing very susceptible organisms, whereas others such as most aminoglycosides produce relatively small zones but can still be considered clinically effective. The agar plates can be maintained at 4°C for up to the given expiration date. Regardless of the date, however, the agar surface should be smooth, level, and of the correct depth (4 mm) prior to placing a plate into service. No condensation should be apparent on the plate surface after the plate has been allowed to reach room temperature.

Inoculum preparation is similar to that previously described for MIC preparation. The tops of four to five well-isolated uniform colonies are touched with an inoculating loop and used to inoculate 4 to 5 mL of a nutrient broth (e.g., TSB or BHI). The broth is incubated at 35°C to 37°C for sufficient time to allow the growth to reach a tubidity equal to or greater than a 0.5 McFarland turbidity standard (ca. 1-2 × 10^8 cfu/mL) and subsequently diluted if necessary with broth to be equivalent to this standard. An acceptable alternative method is to remove sufficient fresh growth from a nonselective agar medium to obtain adequate tubidity. A nontoxic swab is immersed into the broth, swirled to eliminate air bubbles, and the excess fluid pushed out of the swab by rotating it against the wall of the tube above the fluid level. The swab is used to streak the agar plate for confluent growth. Care must be taken not to over- or underinoculate the plate because this can alter the resulting zone of inhibition (22). A correctly inoculated plate will reveal individual but closely packed colonies with careful inspection of the plate after incubation.

Filter paper disks containing designated amounts of an antimicrobic can be obtained from either the manufacturer or several commercial supply firms. They usually are supplied in sealed cartridges with a desiccating agent to assure dryness. Moisture can decrease potency. It is necessary to put the disks in a non–self-defrosting freezer for long-term storage and keep a working supply in a refrigerator under desiccation. The disks should be allowed to warm to room temperature prior to opening them for use.

The disks must be placed onto the surface of the inoculated agar plate no later than 15 minutes after inoculation. Once applied, they cannot be repositioned because the antimicrobic begins to diffuse immediately. The plates are to be incubated in a non-CO_2 incubator at 35°C for 16 to 18 hours unless otherwise specified. After this time, the zone of inhibition can be measured to the nearest mm and the results interpreted following the appropriate NCCLS Standard table. Generally, supplements should be added only when necessary to obtain adequate growth. Certain fastidious organisms such as *H. influenzae, N. gonorrhoeae*, and *S. pneumoniae* will require blood supplements and a 5% to 7% CO_2 atmosphere to grow. Whenever media supplements are used, appropriate control strains must be tested to assure proper test function and interpretation of results.

The determination of disk diffusion interpretation is based on correlating MIC results with corresponding zone diameters. These are inversely proportional; i.e., as the MIC increases, the zone diameter of inhibition decreases. When a variety of organisms with varying susceptibilities to an antimicrobic are tested by both methods and the results plotted with the increasing MIC results on the *y* axis and the increasing zone sizes in millimeters plotted on the x axis, a regression curve with a negative slope is obtained (Fig. 55.3). Depending in large part on the pharmacokinetics of the drug, interpretive zone sizes can be determined that correspond to those used for interpreting MIC results. For various reasons, this correlation does not always exist and discrepant results can occur. Nevertheless, commercial products have been developed that use such regression analysis to calculate an MIC from zone size data. An example is the BioMIC (Giles Scientific, Inc., New York, NY), which uses an imaging system and computer to display the plate image on a computer monitor and marks the zone of inhibition around each disk (Fig. 55.4). This zone can be adjusted, if necessary, by the technologist prior to entering the data into the system. The computer then records the zone size and calculates the MIC based on stored regression data. Studies have been published correlating the calculated MIC with the standardized microdilution methods (23).

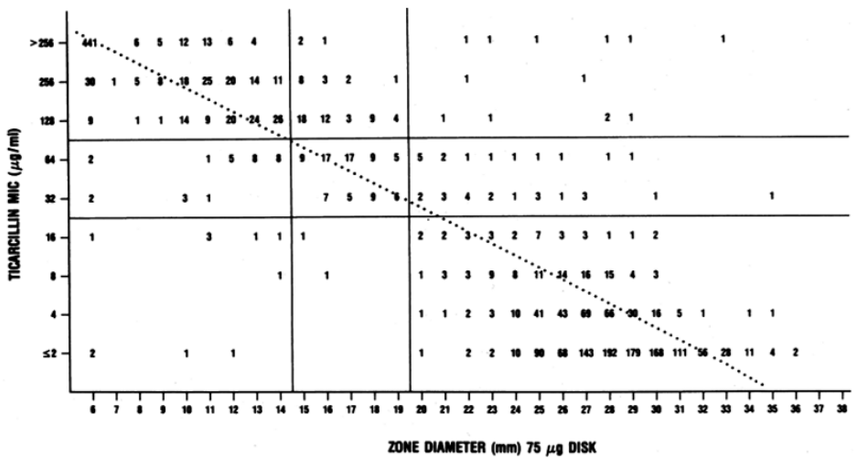

FIGURE 55.3. Regression analysis of *Enterobacteriaceae* susceptibility to ticarcillin. Broth microdilution minimum inhibitory concentrations (MICs) *(y-axis)* are plotted against zones of inhibition *(x-axis)* obtained by disk diffusion. Horizontal and vertical lines represent current breakpoints for interpretation of test results. (Reprinted with permission from Barry A, Fuchs P, Gerlach E, et al. Antimicrobial. *Agents Chemother*. 1992;36:139.)

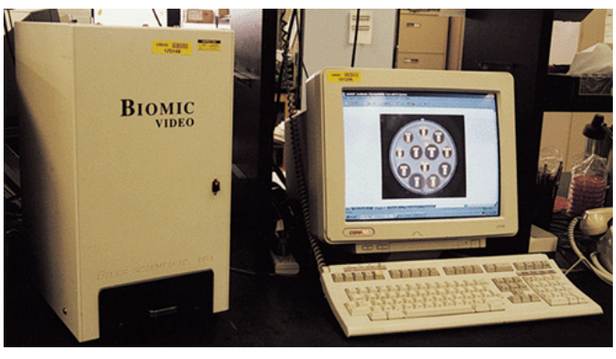

FIGURE 55.4. The BioMIC System showing on-screen zone measurement.

A new test method has been developed recently called the E Test (AB Biodisk, North America, Inc., Piscataway, NJ), which is a modification of the disk diffusion test but provides an MIC result (24, 25 and 26). This test is set up in the same way as the disk diffusion test except that, in place of the disks, one uses 5-mm × 50-mm plastic strips having a continuous, fixed gradient of antimicrobic immobilized on one side and an MIC interpretive scale corresponding to 15 two-fold MIC dilutions on the other side. After incubation, the zone of inhibition takes the shape of an ellipse. The MIC is read at the point where the zone intersects the MIC scale on the strip (Fig. 55.5). Studies show this method to give greater than 95% agreement with the standardized broth microdilution method (27).

Again, most testing laboratories are opting to use methods that provide an MIC result rather than the disk-diffusion test. It should be noted that both methods provide clinically useful information. Under most clinical situations, the interpretive result is all that is needed for the choice of antimicrobic (28, 29). There also are advantages to the use of each method. With the disk diffusion method, it is easy to substitute one disk for another. Unless you prepare your own MIC trays, you are dependent on a commercial provider for the drug profiles available. It also is easier to spot contamination and low-level resistance than it is with the broth microdilution method. However, the disk-diffusion method is approved for use only with rapidly growing organisms, whereas the broth-microdilution method can be incubated for longer periods of time and, therefore, can be used to test slower growing nonfermenters, anaerobes, and even the rapid-growing mycobacteria (27, 30, 31). It also lends itself more readily to automation with prepared trays having long outdates. MBCs cannot be done using agar diffusion techniques.

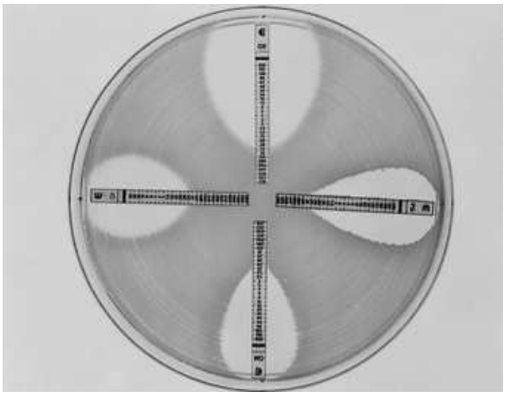

FIGURE 55.5. The E-test. Elliptical zones of inhibition around antimicrobic-impregnated strips. The minimum inhibitory concentration (MIC) is read from the on-strip scale where the zone touches the side of the strip.

SUSCEPTIBILITY TESTING OF ANAEROBIC BACTERIA

Part of "55 - Antimicrobial Susceptibility Testing"

Although testing standards exist for anaerobes (NCCLS M11-A4), it is now recommended that most clinical laboratories consider limiting the frequency of such testing (32). Empiric choice of agents shown by clinical trials to be effective against pathogenic anaerobes is usually sufficient. Susceptibility testing of anaerobes is indicated primarily in situations where the infection did not respond to recommended therapy or for periodic screening of local isolates to assess the relative activity of recommended antimicrobics (33, 34).

Various methods have been used, but none appear totally adequate for the testing of all pathogenic anaerobes. An agar dilution method has been chosen as the reference method, but it is not a convenient method for most clinical laboratories to use. The reader is referred to the M11-A4 standard for details on this method. In brief, antimicrobics are made up from standard powders, as mentioned earlier, and added to melted Wilkins-Chalgren agar supplemented with hemin and vitamin K_1 to achieve the desired concentration. The molten agar is immediately poured into Petri plates and allowed to solidify and the surface to dry after reaching room temperature before inoculation. Wadsworth Brucella blood agar using 5% laked sheep blood, has been suggested as an alternative medium and appears to support the growth of a broader range of anaerobes. MICs may average about one dilution higher with this medium. Thioglycollate broth enriched with hemin and vitamin K_1 is inoculated with a fresh isolate taken from an anaerobic blood agar plate and incubated to obtain turbid growth. The growth is adjusted to obtain a concentration such that 10^5 CFU are deposited onto the surface of the agar in the form of a spot.

Several organisms can be tested on each plate containing a specific antimicrobic concentration. The concentrations recommended for testing for each agent are given in the standard but should span the physiologically achievable range with maximum dosage. The aforementioned procedures can be done under aerobic conditions, but following inoculation, the plates must be incubated at 35°C to 37°C under anaerobic conditions for 48 hours before determining endpoints. The endpoint is the lowest concentration tested that inhibits growth of the isolate. Some inoculum spots may show a haze or one to two colonies of reduced size compared to the growth control, but should be ignored. If trailing occurs, the endpoint is read at the concentration where a major decrease in colony count or size occurs. The result is interpreted as either susceptible or resistant. No intermediate or moderately susceptible catagories exist, because the maximum dosage is recommended for the treatment of anaerobic infections.

Most laboratories testing anaerobes use a broth microdilution method. The methodology is quite similar to that described for testing organisms that grow aerobically; however, some significant differences exist. Various test media have been used including Schaedler's, West-Wilkins, brain heart infusion, and Wilkins-Chalgren broth. None are capable of supporting the growth of all anaerobes that one may want to test. Any of these can be used so long as the control strains respond appropriately. The recommended control strains are:

Bacteroides fragilis, ATCC 25285;

Bacteroides thetaiotaomicron, ATCC 29741;

Clostridium perfringens, ATCC 13124; and

Eubacterium lentum, ATCC 430555.

It is recommended that at least two of these control strains be run with each batch of tests or at least weekly. The inoculum is prepared as described for the standard agar dilution, but the final concentration should be about 10^6 CFU/mL in each dilution well. The inoculum volume should not exceed 0.01 mL, and the final volume in each well should not be less than 0.1 mL. The incubation time should be 48 hours under anaerobic conditions. The endpoint should be the lowest concentration of each drug dilutional series that shows either no growth or significantly reduced growth compared to the growth control well. It has been noted that the MICs obtained by broth microdilution usually run about one dilution lower than those obtained by agar dilution.

Older studies refer to a disk elution technique where disks containing a given concentration of an antimicrobic were added to a given volume of test medium and time was allowed for the antimicrobic to elute into the medium (35). Usually, only one concentration was tested, and the isolate was considered either sensitive or resistant depending on whether or not it was inhibited. This technique is no longer recommended by the NCCLS, especially when testing cephalosporins.

The ß-Lactamase Test

The ß-lactamase test is a rapid, sensitive procedure for screening isolates for resistance to ß-lactamase-susceptible antimicrobics. The genetic ability of bacteria to produce small amounts of ß-lactamase is universal as it is needed for normal cell wall development. However, certain bacteria are capable of producing sufficient quantities of these enzymes to effectively neutralize the killing capacity of certain ß-lactam antimicrobics before they can

reach vulnerable “penicillin-binding proteins” that serve as their primary targets. The genetic information coding for these enzymes can be carried on plasmids or integrated into the chromosome. The reader is referred to Bush et al. (36) for a comprehensive review of the ß-lactamase and their current classification. Some ß-lactamases are produced constitutively and others must be induced to produce detectable amounts (37, 38). Irrespective of the method of production, if a ß-lactamase is detected, all susceptible ß-lactam antimicrobics are considered to be ineffective against the organism. This type of resistance spawned the development of many new ß-lactam drugs that either are inherently resistant to ß-lactamase inactivation or are coupled with specific enzyme inhibitors that irreversibly bind with the enzyme to render them inactive.

Three methods have been used in the clinical laboratory for the detection of ß-lactamases: acidometric, chromogenic cephalosporin, and iodometric.

The acidometric method takes advantage of the enzyme's hydrolytic action on the ß-lactam ring, producing penicilloic acid, which has an additional carboxyl group. This causes the pH of the medium to decrease sufficiently to cause the pH indicator to change color. A convenient technique is to draw a solution containing penicillin and a pH indicator into a capillary tube and subsequently to stab one or more colonies with the end of the tube creating an organism plug that makes contact with the solution. If ß-lactamase is produced, the solution adjacent to the plug will begin to become acidic. This method is easy and quite inexpensive but may not react with certain enzymes that are more specifically active against cephalosporins than against penicillins.

The chromogenic cephalosporin method currently is considered the optimal method because it appears to react with all classes of ß-lactamases known to date. This method takes advantage of the chromogenic properties of specific cephalosporins that change color when hydrolyzed. A disk containing a chromogenic cephalosporin, e.g., nitrocefin or cefesone, is wetted with water or saline and the test organism is removed from an agar plate and streaked onto the disk surface. If an isolate is a ß-lactamase producer, it will cause a color change, usually within minutes but it may take as long as 1 hour for some staphylocci. Impregnated disks or cartridges are available from commercial sources (39, 40).

The iodometric method is seldom used in clinical laboratories but can be a very sensitive method for detecting penicillinases. The method relies on the ability of penicilloic acid to function as a reducing agent, converting iodine to iodide. When a solution containing penicillin, iodine and starch is inoculated with a penicillinase-producing bacterium, the iodine is reduced to iodide and the starch solution changes from a blue-black color to colorless.

Organisms that are tested routinely for ß-lactamase production are *H. influenzae* and anaerobes such as nonfragilis *Bacteroides* spp., *Fusobacterium*, and *Clostridium* spp. The vast majority of staphylococci produce a penicillinase that is readily detectable following induction, but the incidence is so high that few laboratories bother testing for the few isolates that are nonproducers. *Moraxella catarrhalis*, *N. gonorrhoeae*, and *Enterococcus* spp. are tested infrequently by most laboratories. *M. catarrhalis* usually is positive and both *N. gonorrhoeae* and *Enterococcus* spp. are rarely positive. Certain Gram-negative facultative anaerobes also produce ß-lactamases that render specific antimicrobials inactive. Such activity results in high MICs, and it usually is not necessary to specifically test such isolates for ß-lactamase production.

Certain Gram-negative bacilli such as *Enterobacter cloacae* may only produce a ß-lactamase following induction with a specific ß-lactam antimicrobic such as cefoxitin or imipenem. The clinical significance of this is uncertain at present; however, certain strains may convert to constitutive enzyme production, which is clinically significant (37, 41, 42).

Inducible strains can be detected using a modification of the disk diffusion test. At the time of inoculation, a disk containing a low concentration of an inducing antimicrobic is placed just outside the zone of inhibition normally obtained with an enzyme-susceptible antimicrobic. After incubation, the shape of the zone of inhibition is noted. If no enzyme is induced, the shape of the zone will remain circular; however, if induced ß-lactamase is produced in the presence of the inducing agent, the zone will become flattened at the side adjacent to the inducing disk (Fig. 55.6). Such a test usually is necessary only when an appropriate organism appears to be susceptible *in vitro* but resistant *in vivo* and a potentially inducing antimicrobic is being administered in addition to the ß-lactamase-susceptible drug.

FIGURE 55.6. Evidence of the induction of ß-lactamase by the disk-diffusion technique. The zones of inhibition are flattened adjacent to the central disk containing an inducing agent.

RESISTANCE SCREENING PLATES

Part of "55 - Antimicrobial Susceptibility Testing"

Agar plates containing a specified concentration of a single antimicrobial agent are frequently used to screen selected organisms for resistance to the agent.

S. aureus isolates can be screened for resistance to oxacillin using a CAMHA plate containing 4% NaCl and 6 µg/mL of oxacillin. Each isolate's concentration is adjusted to match a 0.5 McFarland standard and spotted onto the agar plate and incubated at 35°C for a full 24 hours prior to examination for growth. All isolates testing resistant are to be reported as resistant

to all other ß-lactam antimicrobics. This method is not approved for screening coagulase-negative staphylococci (43).

E. faecium and *E. fecalis* can be screened for vancomycin resistance in a similar way by spotting the prepared inoculum onto a brain-heart infusion agar plate containing 6 µg/mL of vancomycin (44, 45). Isolates that screen resistant should be confirmed by performing a standard microdilution MIC test. This same plate can be used to screen *S. aureus* isolates for increased resistance to vancomycin (46, 47). *S. pneumoniae* isolates can be screened for resistance to penicillin by confluent inoculation of a standard 5% sheep blood MHA plate and application of a 1 µg oxacillin disk followed by 20- to 24-hour incubation in a 5% CO_2 atmosphere (48). Isolates yielding a inhibitory zone size of >20 mm are considered susceptible to penicillin; those yielding zones of <19 mm must be further tested by microdilution MIC or Etest to confirm resistance.

DETECTION OF EXTENDED-SPECTRUM ß-LACTAMASE-PRODUCING ISOLATES

Part of "55 - Antimicrobial Susceptibility Testing"

In the mid-1980s, reports began appearing in the literature of certain enteric Gram-negative bacilli, primarily *E. coli* and *Klebsiella* spp., demonstrating resistance to various extended-spectrum cephalosporins (49). Further investigations revealed that these organisms carried mutated TEM and SHV plasmids that coded for ß-lactamases capable of hydrolyzing extended-spectrum cephalosporins but were inhibited by the ß-lactamase inhibitors such as clavulanic acid and remained susceptible to cephamycins, carbapenems, and cephem class drugs. These enzymes are called extended-spectrum ß-lactamases or ESBLs. Unfortunately, organisms carryings ESBLs may test susceptible *in vitro* to one or more of the third generation cephalosporins but usually the zone of inhibition is smaller and the MIC is somewhat higher than is typically seen for truly susceptible organisms (50, 51 and 52). ESBLs also have been found in other members of the *Enterobacteriaceae* (53, 54). Various methods have been used to detect isolates expressing ESBL resistance but recently the NCCLS has established a standardized method for this purpose (7). Most testing laboratories monitor one or more of three ß-lactam antimicrobics for reduced activity against isolates of *E. coli* and *Klebsiella*: ceftazidime, aztreonam, and/or cefpodoxime. If reduced activity is detected by either disk-diffusion or MIC, a confirmation test is to be performed that involves testing the isolate's relative susceptibility to both ceftazidime and cefotaxime with and without the addition of clavulanic acid. If either the zone of inhibition increases by >5 mm or the MIC decreases <3 two-fold dilutions when clavulanic acid is added, the isolate is declared an ESBL-producing strain and it is reported as resistant to all cephalosporins and monobactams (Fig. 55.7). Isolates testing susceptible to cephamycins, carbapenems, cephems, and ß-lactam/inhibitor combinations should be reported as susceptible. AB Biodisk (Solna, Sweden) has produced a dual gradient strip with either cefotaxime or ceftazidime at one end of the strip and the same drug with a fixed concentration of clavulanic acid at the opposite end (26). When placed on an inoculated agar, an elliptical zone of inhibition could be produced at each end. If an MIC ratio of drug:drug + clavulanic acid is >16:1, the isolate is declared and ESBL-producer (Fig. 55.8).

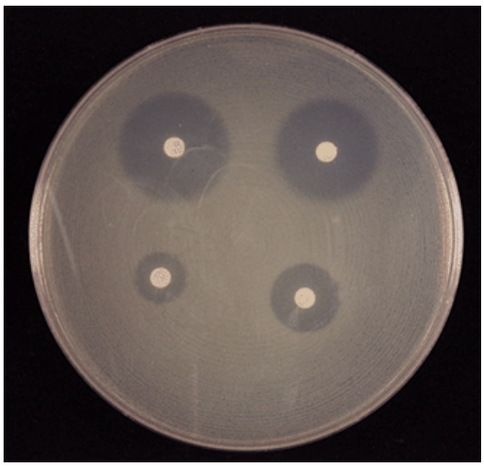

FIGURE 55.7. Extended-spectrum ß-lactamase disk test. Zones of inhibition with and without the addition of clavulanic acid to standard cefotaxime and ceftazidime disks.

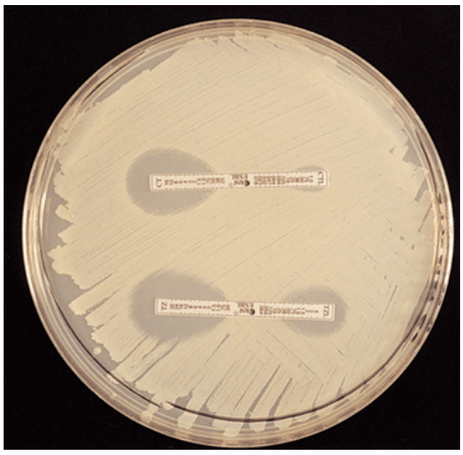

FIGURE 55.8. Etest ESBL test strips. A concentration gradient of either cefotaxime or ceftazidime is on the left side of each strip and the same drug plus a fixed concentration of clavulanic acid is on the right side of each strip.

OTHER TESTS TO DETECT DRUG-INACTIVATING ENZYMES

Part of "55 - Antimicrobial Susceptibility Testing"

Relatively rare isolates of *H. influenzae* produce choramphenicol acetyltransferase, which renders them resistant to chloramphenicol (55). A 10-minute disk or tube test is available to detect this enzyme. Most laboratories do not perform this test unless a strain

of *H. influenzae* capable of producing this enzyme has been detected in the community or there is a treatment failure.

Aminoglycoside-modifying enzymes can be detected by testing for enzyme-substrate activity or, more recently, by specific DNA probes but, to date, these tests are performed only in research settings (56, 57).

Semiautomated Susceptibility Testing

Several instruments have been introduced that facilitate susceptibility testing; a few approach full automation and usually perform organism identification procedures as well (58, 59). Two systems have been used extensively in clinical microbiology laboratories: the Vitek System (AMS) (bioMerieux Vitek, Inc., Hazelwood, MO)(60, 61) and the MicroScan System (Dade MicroScan, Inc., West Sacramento, CA)(62). Briefly, each system is composed of three major components: a module that serves as an incubator/reader; a computer with a keyboard that allows data/command entry and controls all system functions; and a printer to provide hard copy. Prepared susceptibility test panels, usually provided in the dried form for longer shelf life, are packaged to be run only on the designated system. Most companies provide several different formats to choose from, or they can customize panels at extra cost. The test isolate is prepared by diluting the suspension in an inoculating medium to obtain a designated turbidity. This inoculum is used to simultaneously hydrate and inoculate the panels. This is done either by hand-held disposable transfer devices, mechanical inoculators or a vacuum unit. Once inoculated, the panels are appropriately labeled and accessioned in the computer for subsequent tracking. The panels are then loaded into the incubator/reader. The panels are “read” by the instrument at periodic intervals using light emitting diodes or fiberoptics as light sources, coupled with detectors to monitor changes in turbidity in each well. Incubation times vary, depending on the system, from 3.5 hours using fluorogenic substrates to 18 hours with conventional substrates. As each test is finalized, the position becomes available for another panel. Systems in clinical use have been evaluated for accuracy by comparing results with the standardized reference methods (63, 64).

Testing errors have been categorized as very major, major, or minor. A very major error occurs when the test system calls an isolate susceptible to an antimicrobic, but the reference system calls it resistant (false-susceptible). A major error occurs when the test system calls an isolate resistant, and the reference method calls it susceptible (false-resistant). Minor errors result when the interpretation varies between susceptible and intermediately susceptible or between resistant and intermediately susceptible relative to the reference method. The FDA requires the manufacturer to recommend to the user of a system that an alternative method should be used whenever a drug/bug combination produces a very major error more than 1.5% of the time or a major error more than 3% of the time. Through software modifications, most approved systems now produce acceptable and reproducible results, but some problems still occur, especially with slow-growing and fastidious bacteria, oxacillin-heteroresistant staphylococci, and gentamicin-resistant enterococci (65). Systems that report results within 5 to 6 hours may have difficulty detecting resistance in isolates that produce inducible ß-lactamase. Such systems also have difficulty detecting low-level vancomycin resistance in enterococci mediated by the *vanB* gene (66).

Sites using such systems report improved reproducibility of results and a modest savings in personnel time, although usually not enough to free up a technologist for other duties. Two-way interfaces help to limit the amount of data input necessary during accessioning. The system's computer is able to generate useful summary reports and susceptibility trend analyses. Programs can be added allowing for input of pharmacy data and compares the susceptibility of the patient isolate to the antimicrobics being administered and flags instances when the organism appears resistant to the antimicrobic(s) being given.

To date, these systems are not fully automated. The inoculum must still be prepared by hand and the panels inserted into the system. No system has been free of major error; therefore, each testing site must maintain a backup system or use a reference laboratory to obtain results for specified bug/drug combinations. Some panels cannot be read manually in the event of a system malfunction. The primary motive for going to an automated system is to increase accuracy, efficiency, and to realize a cost savings. To date, these systems have had only a modest favorable impact. The manufacturers of these systems are actively addressing these concerns, and substantial improvements in performance have been made since the first introduction of these systems into clinical laboratories.

INFREQUENTLY USED ANTIMICROBIC SUSCEPTIBILITY TEST METHODS

Part of "55 - Antimicrobial Susceptibility Testing"

Because of the complexity of performing and interpreting the following special susceptibility tests, it is advisable that such requests be routed through a laboratory director accompanied by a pathology consultation. The director should ascertain why the test is being ordered and determine if the test being requested is appropriate or if the information needed can be better obtained using a different, less expensive methodology.

The Minimum Bactericidal Concentration Test

Under special clinical circumstances, it may be warranted to determine the minimum antimicrobic concentration necessary to kill the organism. This information usually is unnecessary if the infected patient is immunocompetent. In that case, both bacteriostatic and bactericidal drugs appear to be effective therapeutic agents. However, patients who are leukopenic, have defects in cell-killing capacity or have endocarditis may benefit from receiving treatment with a bactericidal agent (67, 68 and 69). Certain organisms may be inhibited by low concentrations of an antimicrobic but require much higher concentrations to be killed. This can be determined by the minimum bactericidal concentration (MBC). Bactericidal tests should only be done using drugs that are known to have bactericidal activity against the isolate being tested. At present, there is no standardized test procedure, but

the NCCLS subcommittee has released an approved testing guideline (M26-A).

For efficiency, the MBC should be requested at the same time that the routine susceptibility test is requested, especially if the routine method is a broth MIC test. The endpoint being sought is the lowest concentration of antimicrobic that kills at least 99.9% of the viable inoculum after 18 to 24 hours of incubation. This endpoint is used because it is difficult to kill 100% of the organisms. A small number of "persisters" survive, probably from low metabolic activity. To obtain this information, the exact number of viable organisms used for inoculation must be known. Also, because the cidal activity of many antimicrobics is dependent on active cellular metabolic activity, the test must be performed using actively growing bacterial cells.

The isolate to be tested is inoculated into a nutrient broth and allowed to grow at 35°C to 37°C until it reaches late log phase. The growth must be adjusted to obtain an estimated final concentration in each well of about 5×10^5 CFU/mL. A sample is further diluted and plated for viable colony count. The rest of the setup is the same as with the routine microdilution MIC.

Following the reading of the MIC, all wells of drug(s) being tested that show no visual growth must be sampled by removing an aliquot and using it to inoculate a nutrient agar plate. The inoculum should be spread out over an area of at least 5 cm^2 to provide isolated colonies. The inoculated plate is then incubated long enough to obtain visible colonies and the number of colonies counted. Care must be taken to sample an adequate volume from each well. The endpoint is the drug concentration that is able to kill at least 99.9% of the original inoculum (5×10^5 CFU/mL). Accordingly, the residual viable organism concentration must be 500 CFU/mL or less. To detect 500 CFU/mL, one would have to plate an undiluted volume of 0.01 mL to obtain five colonies.

The 99.9% kill endpoint remains controversial because there are no convincing clinical studies showing that concentrations that kill 99% or even 90% of inoculated organisms result in more frequent treatment failure. Another area of controversy is the meaning of in vitro tolerance. The working definition of tolerance is when the MBC:MIC is greater than or equal to 32:1. For example, enterococci frequently show tolerance to the cidal activity of vancomycin. Therefore, vancomycin is not effective when used alone for the treatment of endocarditis from *Enterococcus* species (70). The results obtained are very technique-dependent, and laboratories not using consistent methods will get variable results with the same isolate. Another phenomenon seen with this technique is the "paradoxical" or Eagle effect, where killing is seen with lower antimicrobic concentrations but less killing with higher concentrations (71). The higher drug concentrations are thought to inhibit various enzymatic steps required to kill the organism resulting in a bacteriostatic condition. With rapid dilution of the drug, the organisms remain viable.

The MBC has been performed with both micro- and macrodilution techniques using volumes of 0.01 mL and up to 5 mL/assay tube, respectively. Discrepant results are frequently obtained between these two methods depending on the technique used. The current NCCLS approved guideline for bactericidal tests advocates using the microdilution technique to enhance reproducibility and convenience, but there are no clinical data to support the use of one method over the other.

The Serum Bactericidal Test

The serum bactericidal test (SBT) measures the level of cidal antimicrobial activity in patient serum directed against the patient's isolate. The result is expressed as the highest serum dilution that retains the ability to kill 99.9% of the inoculum (72). The NCCLS has published an Approved Guideline for this test, M 21A. Sera are collected when the concentration of the antimicrobic(s) being administered is either at its peak, at its nadir, or at both times. For test interpretation, both the time and route of drug administration and the time that the blood was drawn must be accurately documented. Serial doubling dilutions of the serum are prepared using Mueller-Hinton broth containing 50% normal human serum as the diluent yielding dilutions from 1:2 to 1:256. The inoculum is prepared in the same way as described for the MBC test. A quantitative viability count is necessary to document the starting inoculum concentration. After 18 to 24 hours of incubation, each tube or well is examined for visible growth. All tubes showing no growth are sampled by removing and plating an aliquot and counting the number or colonies after overnight incubation and the 99.9% killing endpoint determined. If both peak and trough sera were assayed, there is usually a significant drop in titer with normal drug clearance.

Test interpretation remains a problem (73). If the patient is being treated for endocarditis, clinicians may want the nadir (trough) titer to stay above 1:8 (74). For the treatment of staphylococcal osteomyelitis using oral therapy, they may want to see high peak titers indicating good absorption of the drug from the gastrointestinal tract and patient compliance with dosage orders. The number of requests for SBTs remains low in most tertiary care centers and is used primarily for cases of endocarditis and osteomyelitis being treated with drug combinations or for patients being switched from parenteral to oral therapy (75).

Selected tests methods have been used to test for antimicrobical interaction but none have proven to be strongly predictive of clinical outcome and, therefore, are infrequently ordered despite the frequency with which drug combinations are used clinically (76, 77 and 78).

Disk Approximation Synergy Test

Disk Approximation is the least complex method to be used as a screening method to assess how two drugs interact when combined *in vitro*. The test is performed in two stages. The first stage is to perform a routine disk diffusion test to obtain the zone of inhibition radius for the drugs to be tested. The second stage is to repeat the setup but place the disks such that one would expect to obtain a small zone of growth (e.g., 4 mm to 5 mm) between the two zones of inhibition produced around each disk if there was no drug interaction. After an adequate incubation time, the area between the two disks is examined for any distortion in the zone of inhibition. If no growth is seen between the two disks, this is evidence

for possible drug synergy. If a zone is blunted, this may be evidence of drug antagonism or enzyme induction (Fig. 55.7).

Time-Kill Kinetics Test

As performed, the MBC and the SBT measure the number of surviving organisms at one time point, usually after 24 hours of exposure to varying concentrations of the drug. The time-kill kinetic assay measures the rate of killing while being exposed to a single drug concentration, usually one that is physiologically achievable at standard dosage (79). Tubes containing Mueller-Hinton broth with and without the test antimicrobic(s) are inoculated with the test organism at an estimated viable concentration (documented by colony counts at the time of inoculation) and maintained at 35°C during the testing period. Aliquots are removed at periodic intervals, usually at 2, 4, 8, or 12 and 24 hours, and plated to determine the number of viable organisms at each time point. The results are plotted using semilog paper or standard graph paper after calculating the $\log_{10}$ of each data point. The viable concentration (in CFU/mL or $\log_{10}$ CFU/mL) is plotted along the y-axis as a function of time on the x-axis. Drugs showing more complete and/or rapid rates of killing may be more efficacious in treating infections occurring in individuals with low immunocompetence.

The time-kill kinetic assay is currently thought to be the best method to study in vitro drug synergy. As the term implies, drugs that act in synergy with one another are more efficient in killing than either one alone acting independently (80). The cidal activity of each drug must be tested as well as the combination. If more than one concentration of either drug is tested, the testing complexity becomes geometric. A combination is considered to be acting in a synergistic manner when the viable count is reduced at least 100-fold compared with the most actively cidal drug of the pair (Fig. 55.9).

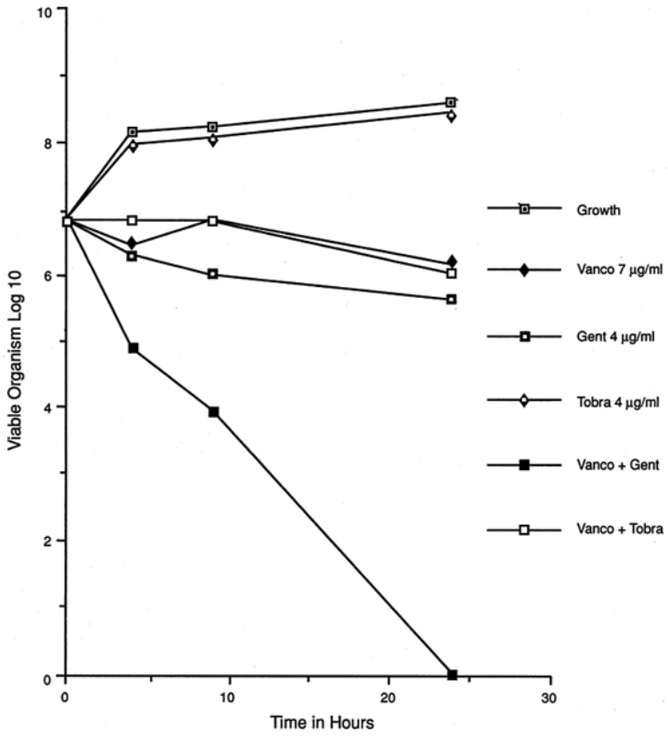

FIGURE 55.9. Time-kill kinetics. Rate of bactericidal activity of single and combined agents on *Enterococcus faecium*. Synergistic killing is occurring with the combination of vancomycin plus gentamicin.

Checkerboard Microdilution Test

An alternative method of performing drug synergy studies is the "checkerboard" microdilution technique (81). A standard 96-well microtiter tray is loaded horizontally with increasing concentrations of drug A, and vertically with increasing concentrations of drug B so that as one scans the plate from lower left to upper right, both drugs in each well are present in increasing concentrations that span the therapeutic range from easily achievable (susceptible) to unachievable (resistant) (Fig. 55.10). Each drug also is present in either a row or column as a single agent to determine the MIC and MBC of each agent without the other being present. The wells are inoculated with the test organism prepared as just described and the plate incubated for 18 to 24 hours.

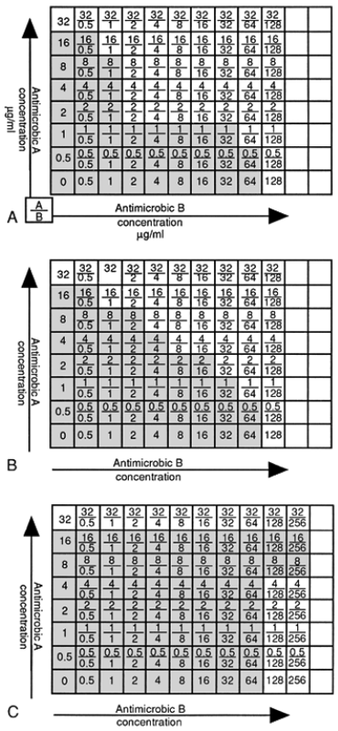

FIGURE 55.10. "Checkerboard" technique for determining antimicrobic interaction. (**A**) Drug synergy. (**B**) Additive effect. (**C**) Drug antagonism.

Because both drugs are present at their lowest concentrations at the lower left, one would expect growth to occur in this region of the plate. As one progresses toward the upper right, however, a point is reached for each dilutional series where no visible growth occurs. If one marks the first well of the lowest concentrations in each row and column where no growth is seen and connects these marks with a continuous line, a crude isobologram is produced, the shape of which connotes the test results. If the line bows substantially toward the lower left, the two drugs are expressing synergy; if it bows substantially toward the upper right, the two drugs are antagonistic; if the line is essentially straight, the effects are additive. A more practical method of interpretation is to express the results as a fractional index. The concentration of drug A necessary to inhibit or kill the organism in any row or column is divided by the concentration needed to do the same without drug B present. This is the fractional inhibitory or cidal concentration (FIC) of drug A (FIC_A). The same is done for drug B to obtain the FIC_B. The two factional concentrations are added together to obtain the fractional index.

$$\frac{A}{\mathrm{MIC_A}} + \frac{B}{\mathrm{MC_B}} = \mathrm{FC_A} + \mathrm{FC_B} = \mathrm{FI}$$

There are several possible choices of combinations to choose for calculating the index. Thus, the logical choice is to select those concentrations that are within the lower physiological range for each drug. If the index is 0.5 or less, the drugs are acting with synergy. As the index increases, the drug interactions progress from additive to indifferent to antagonistic.

Molecular Techniques for Diagnosis of Infectious Diseases

Frederick S. Nolte

Since the publication of the first edition of this book significant changes have occurred in the practice of diagnostic molecular microbiology. Chief among them is the widespread application of nucleic acid amplification techniques to the diagnosis and management of patients with infectious diseases. The advent of commercially available test kits has facilitated the use of this technology in the clinical laboratory. Molecular microbiology has emerged as the leading area in molecular pathology in terms of both numbers of tests performed and clinical relevance. This technology has reduced the dependency of the clinical microbiology laboratory on culture-based methods and created new opportunities for the clinical laboratory to impact patient care. This chapter will cover amplified and nonamplified probe techniques, postamplification detection and analysis, clinical applications of these techniques, and the special challenges and opportunities that these techniques provide for the clinical laboratory.

NUCLEIC ACID PROBES

Part of "56 - Molecular Techniques for Diagnosis of Infectious Diseases"

Nucleic acid probes are pieces of DNA or RNA labeled with radioisotopes, enzymes, or chemiluminescent reporter molecules that can bind to complementary nucleic acid sequences with high specificity. Probes range from 15 to thousands of nucleotides in size, however synthetic oligonucleotides (<50 nucleotides) are the most commonly incorporated into commercial kits. The probes can be designed to identify microorganisms at any taxonomic level (e.g., genus, species, or subspecies). A number of commercially available DNA probes have been developed for direct detection of pathogens in clinical specimens and identification of pathogens after isolation by culture.

The commonly used formats for probe hybridization includes liquid-phase, solid phase, and in situ hybridization. The leading method used in clinical microbiology laboratories is a liquid-phase hybridization protection assay (Gen-Probe). In this method a single-stranded DNA probe labeled with an acridinium ester is incubated with the target nucleic acid. Alkaline hydolysis follows the hybridization step and probe binding is measured in a luminometer after addition of peroxides. In a positive sample, the acridinium ester on the bound probe is protected from hydrolysis and upon addition of peroxides emits light. The hybridization protection assay can be completed in several hours and does not require removal of unbound single-stranded probe or isolation of probe-bound double stranded sequences (1).

In solid-phase hybridization, target nucleic acids are bound to nylon or nitrocellulose and hybridized with a probe in solution (2). The unbound probe is washed away and the bound probe is detected by means of fluorescence, luminescence, radioactivity, or color development. Although solid-phase hybridization is a powerful research tool, the length of time required and the complexity of the procedure limit its application in clinical practice.

In situ hybridization is another type of solid-phase hybridization where the nucleic acid is contained in tissues or cells affixed to microscope slides and is governed by the same basic principles (3). In most clinical applications, formalin-fixed, paraffin embedded tissue sections are used. The sensitivity of *in situ* hybridization is limited by the accessibility of target nucleic acid in the cells.

In general, the application of nonamplified probe techniques to direct detection of pathogens in clinical specimens is limited to those situations where the number of pathogens is great because of the poor analytical sensitivity of these techniques. These include Group A streptococcal pharyngitis and genital tract infections with *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. These techniques are used to their best advantage in culture confirmation assays for mycobacteria and systemic dimorphic fungi. These culture confirmation tests have a positive impact on patient management by providing rapid and accurate diagnoses for these slowly growing, often difficult to identify pathogens.

NUCLEIC ACID AMPLIFICATION TECHNIQUES

Part of "56 - Molecular Techniques for Diagnosis of Infectious Diseases"

The development of the polymerase chain reaction (PCR) by Mullis and colleagues (4) was a milestone in biotechnology and heralded the beginning of molecular diagnostics. Although PCR is the best developed and most widely used nucleic amplification strategy, other strategies have been developed and several have commercial potential. These strategies are based on target, probe, or signal amplification. Examples of each category will be discussed in the sections that follow. These techniques have sensitivity unparalleled in laboratory medicine, have created new opportunities for the clinical laboratory to impact patient care,

and have become the new gold standards for laboratory diagnosis of several infectious diseases. Table 56.1 compares the features of the nucleic acid amplification methods.

TABLE 56.1. NUCLEIC ACID AMPLIFICATION METHODS[a]

Method	Category	Manufacturer	Amplification System	Temperature Requirement	Nucleic Acid Target	Key Reference
PCR	Target	Roche	DNA polymerase	Thermal cycle	DNA (RNA)	(4)
TMA	Target	Gen-Probe	RT, RNA polymerase, RNase H	Isothermal	RNA (DNA)	(11)
NASBA	Target	Organon-Teknika	RT, RNA polymerase, RNase H	Isothermal	RNA (DNA)	(10)
SDA	Target	Becton-Dickinson	Restriction endonuclease, DNA polymerase	Isothermal	DNA (RNA)	(13)

bDNA	Signal	Bayer	Branched DNA probes	Isothermal	DNA, RNA	(24)
Hybrid capture	Signal	Digene	anti-DNA-RNA hybrid antibody	Isothermal	DNA, RNA	(28)

[a] Adapted from reference (66.)

Target Amplification Techniques

All of the target amplification systems share certain fundamental characteristics. They are enzyme-mediated processes, in which a single enzyme or multiple enzymes synthesize copies of target nucleic acid. The amplification products in all of the techniques are defined by two oligonucleotide primers that bind to complementary sequences on opposite strands of double-stranded targets. All result in the production of millions to billions of copies of the targeted sequence in a matter of hours, and, in each case, the amplification products can serve as templates for subsequent rounds of amplification. Because of this, all of the techniques are sensitive to contamination with product molecules that can lead to false-positive reactions. False-positive reactions because of product cross-contamination has impeded the routine use of techniques in the clinical laboratory.

Polymerase Chain Reaction

PCR is a simple, *in vitro*, chemical reaction that permits the synthesis of essentially limitless quantities of a targeted nucleic acid sequence. This is accomplished through the action of a DNA polymerase, that under the right conditions, can copy a strand of DNA. At its simplest, a PCR consists of target DNA, a molar excess of two oligonucleotide primers, a heat-stable DNA polymerase, an equimolar mixture of deoxyribonucleotide triphosphates (dATP, dCTP, dGTP, and dTTP), $MgCl_2$, KCl, and a Tris-HCl buffer. The two primers flank the sequence to be amplified, typically <100 to several hundred bases, and are complementary to opposite strands of the target.

To initiate a PCR, the reaction mixture is heated to separate the two strands of target DNA, and then cooled to permit the primers to anneal to the target DNA in a sequence specific manner. The DNA polymerase then initiates extension of the primers at their 3′ ends toward one another. The primer extension products are dissociated from the target DNA by heating. Each extension product, as well as the original target, can serve as a template for subsequent rounds of primer annealing and extension.

A PCR cycle consists of denaturation and annealing. At the end of each cycle, the PCR products are theoretically doubled. Thus, after n PCR cycles the target sequence can be amplified 2^n-fold. The whole procedure is carried out in a programmable thermal cycler that precisely controls the temperature at which the steps occur, length of time that the reaction is held at the different temperatures and the number cycles. Ideally, after 20 cycles of PCR, a million-fold amplification is achieved and after 30 cycles, a billion-fold. In practice, the amplification may not be completely efficient because of failure to optimize the reaction conditions or the presence of inhibitors of the DNA polymerase. In such cases, the total amplification is best described by the expression $(1+e)^n$ where e is the amplification efficiency ($0 \geq e \leq 1$) and n is the total number of cycles.

Reverse transcriptase-PCR

PCR as it was originally described was a technique for DNA amplification. Reverse transcriptase-PCR (RT-PCR) was developed to amplify RNA targets. In this process complementary DNA (cDNA) is first produced from RNA targets by reverse transcription, and then the cDNA is amplified by PCR. As originally described RT-PCR employed two enzymes, a heat-labile RT such as avian myeloblastosis virus reverse transcriptase (AMV-RT), and a thermostable DNA polymerase. Because of the temperature requirements of the heat-labile enzyme, cDNA synthesis had to occur at lower temperatures. This presented problems both in terms of the nonspecific primer annealing and inefficient primer extension because of formation of RNA secondary structures. These problems have been largely overcome by the development of a thermostable DNA polymerase derived from *Thermus thermophilus* that under the proper conditions can function efficiently as both a RT and a DNA polymerase (5). RT-PCRs using this enzyme are more specific and efficient than previous protocols using conventional, heat-labile RT enzymes. Commercially available kits (Roche) employing this single enzyme technology are available for detection of hepatitis C virus (HCV) RNA and for quantitation of human immunodeficiency virus type 1 (HIV-1) and HCV RNA in clinical specimens.

Nested PCR

Nested PCR was developed to increase both the sensitivity and specificity of PCR (6). It employs two pairs of amplification

primers and two rounds of PCR. Typically, one primer pair is used in the first round of PCR of 15 to 30 cycles. The products of the first round of amplification are then subjected to a second round of amplification using the second set of primers that anneal to a sequence internal to sequence amplified by the first primer set. The increased sensitivity arises from the high total cycle number and the increased specificity arises from the annealing of the second primer set to sequences found only in the first round products, thus verifying the identity of the first round product. The major disadvantage of nested PCR is the high rates of contamination that can occur during the transfer of first round products to the second tube for the second round of amplification. This can be avoided either by physically separating the first- and second-round amplification mixtures with a layer of wax or oil, or by designing single-tube amplification protocols. In practice, the enhanced sensitivity afforded by nested PCR protocols is required rarely in diagnostic applications, and the identity of an amplification product usually is confirmed by hybridization with a nucleic acid probe.

Multiplex PCR

In multiplex PCR, two or more primer sets, designed for amplification of different targets, are included in the same reaction mixture (7). With this technique, more than one target sequence in a clinical specimen can be coamplified in a single tube. The primers used in multiplexed reactions must be selected carefully to have similar annealing temperatures and to lack complementarity. Multiplex PCRs are proven more complicated to develop and are less sensitive than single primer set PCR reactions.

Quantitative PCR and Reverse Transcriptase PCR

A linear relationship may exist between the quantity of input template and the amount of amplification product. However, because the final amount of PCR product depends on exponential amplification of the initial quantity of template, minor differences in amplification efficiency may lead to very large and unpredictable differences in the final product yield (8). The tube-to-tube differences may depend on sample preparation and nucleic acid purification procedures, presence of inhibitors, and thermal cycler performance. For these reasons, simple quantitation of amplified product and the use of external standard reference curves do not provide reliable quantitation of the template initially present in the sample.

A variety of PCR-based strategies have been developed to accurately quantitate DNA and RNA targets in clinical specimens. It generally is accepted that a competitive PCR (cPCR) approach is the most reliable and robust.

The basic concept behind cPCR is the coamplification in the same reaction tube of two different templates of equal or similar lengths and with the same primer binding sequences. Because both templates are amplified with the same primer pair, identical thermodynamics and amplification efficiency are ensured. The amount of one of the templates must be known and, after amplification, products from both templates must be distinguishable. Different types of competitors have been used in cPCR, but in general, those competitors similar in size and base composition to the target work most effectively. RNA competitors should be used in quantitative RT-PCRs to address the problem of variable RT efficiency.

The yield of PCR product is described by the equation, $Y=I(1+e)^n$, where Y is the quantity of PCR product, I is the quantity of template at the beginning of the reaction, *e* is the efficiency of the reaction, and *n* is the number of cycles. In cPCR, this equation is written for both templates, as follows: competitor, $Y_c=I_c(1+e)^n$; and target, $Y_t=I_t(1+e)^n$. Because *e* and *n* are the same for both the competitor and target, the relative product ratio Y_c/Y_t directly depends on their initial concentration ratio I_c/I_t and the function, $Y_c/Y_t=I_c/I_t$, is linear.

A single concentration of competitor is sufficient, in theory, to quantitate an unknown amount target without the use of a standard curve. However, because analysis of two template species present in a sample at widely different amounts may be difficult and imprecise in practice, cPCR using several concentrations of competitor within the expected concentration range of the target were generally performed. However, this approach provided no more accurate results than the use of a single concentration of competitor in a recent study of different approaches to standardization of cPCR (9). The commercially available quantitative PCR and RT-PCR assays or cytomegalovirus (CMV), HIV-1, and HCV (Roche) all use a single concentration of a competitor to determine the initial concentration of the target.

Transcription Amplification Methods

Nucleic acid sequence-based amplification (NASBA) and transcription mediated amplification (TMA) both are isothermal RNA amplification methods modeled after retroviral replication (10,11 and 12). The methods are similar in that the RNA target is reversed transcribed into cDNA and then RNA copies are synthesized using an RNA polymerase. NASBA uses AMV-RT, RNase H, and T7-RNA polymerase while TMA uses a RT enzyme with endogenous RNase H activity and T7-RNA polymerase.

Amplification involves the synthesis of cDNA from the RNA target with a primer containing the RNA polymerse promoter. RNase H then degrades the initial strand of target RNA in the RNA-cDNA hybrid. The second primer then binds to the cDNA and is extended, resulting in the formation of double-stranded DNA containing the T7 RNA polymerase-binding sequence. Both strands can serve as transcription templates for the RNA polymerase that generates multiple copies of single-stranded RNA (both sense and anti-sense). These RNA product molecules reenter the cycle with subsequent formation of more double-stranded cDNAs that can serve as templates for more RNA synthesis. A billion-fold amplification of the target RNA can be achieved in less than 2 hours with this method.

Transcription-based amplification systems have several strengths including no requirement for a thermal cycler, rapid kinetics, and the single-stranded RNA product does require denaturation prior to detection. Also, single-tube clinical assays and an RNA product that is more easily degraded than DNA, may help minimize contamination risks. Limitations include the poor performance with DNA targets and concerns about the stability of complex, multi-enzyme systems. TMA-based assay for

detection of *Mycobacterium tuberculosis* (Gen-Probe), *C. trachomatis* (Gen-Probe), HCV (Gen-Probe, Bayer), and HIV-1 (Gen-Probe), are commercially available. A NASBA is commercially available (Organon-Teknika) for the detection and quantitation of HIV-1 RNA.

Strand Displacement Amplification

Strand displacement amplification (SDA) is an isothermal DNA amplification technique that consists of a target generation step followed by an exponential amplification phase that replicates the target sequence through a series of primer extension, nicking, and strand displacement steps (13, 14). This conceptually complicated amplification method was initially plagued by nonspecific amplification products. However, the use of organic solvents to increase the stringency of primer binding and heat stable enzymes have effectively addressed this problem (15). Clinical applications of SDA are being developed by Becton Dickinson and include assays for *M. tuberculosis* and *C. trachomatis*. A quantitative RT-SDA assay for HIV-1 RNA also has been described (16).

Probe Amplification Methods

Probe amplification methods differ from target amplification in that the amplification products contain only a sequence present in the initial probes. Ligase chain reaction (LCR)(17), Qbeta replicase (18) and Cleavase/Invader technology (19) are all examples of probe amplification methods with commercial potential. To date, only the ligase chain reaction has had a significant impact on the clinical microbiology laboratory.

Ligase Chain Reaction

In a standard ligase chain reaction (LCR), two oligonucleotide probes hybridize adjacent to one another on each of the denatured target DNA strands such that a “nick” is formed. A thermostable DNA ligase then seals the “nick” by joining the 3′ end of one probe and the 5′ end of the other. Each ligated product, as well as the original target, can serve as a template in subsequent rounds of denaturation, annealing, and ligation resulting in an exponential accumulation of products (17, 20).

A modification of this technique called gapped LCR (G-LCR) differs from standard LCR in that a short gap is formed after annealing of the probes to the template. The gap is filled by a thermostable DNA polymerase and the resulting nick then is ligated by the DNA ligase (21). Although LCR is convenient and easily automated, control of contamination with ligation products may prove difficult. A combination G-LCR kit for detection of both *C. trachomatis* and *N. gonorrhoeae* is commercially available (Abbott Laboratories, Chicago, IL).

Signal Amplification Methods

In signal amplification methods, the concentration of probe or target does not increase. The increased analytical sensitivity comes from increasing the concentration of label molecules attached to the target nucleic acid. Multiple enzymes, multiple probes, multiple layers of probes, and reduction of background noise have been used to enhance target detection (22). Target amplification systems generally have greater analytical sensitivity than signal amplification methods, but technological developments, particularly in branched DNA assays, have lowered the limits of detection to levels that may rival target amplification assays in some applications (23).

Signal amplification assays have several advantages over target amplification assays. In signal amplification systems, the number of target molecules is not altered and, as a result, the signal is directly proportional to the amount of target sequence present in the clinical specimen. This reduces concerns about false-positives because of cross-contamination and simplifies the development of quantitative assays. Because signal amplification systems are not dependent on enzymatic processes to amplify target sequences, they are not affected by the presence of enzyme inhibitors in clinical specimens. Consequently, less cumbersome nucleic acid extraction methods may be used. Typically, signal amplification systems employ either larger probes or more probes than target amplification systems and, consequently, are less susceptible to errors resulting from target sequence heterogeneity. Finally, RNA can be measured directly without the synthesis of a cDNA intermediate.

Branched DNA

The branched DNA (bDNA) signal amplification system is a solid phase, sandwich hybridization assay incorporating multiple sets of synthetic oligonucleotide probes (24). The key to this technology is the amplifier molecule; a bDNA molecule with 15 identical branches, each of which can bind three labeled probes.

Multiple target-specific probes are used to capture the target nucleic acid onto the surface of a microtiter well. A second set of target-specific probes also bind to the target. Preamplifier molecules bind to the second set of target probes and up to eight bDNA amplifiers. Three alkaline phosphatase-labeled probes hybridize to each branch of the amplifier. Detection of the bound labeled probes is achieved by incubating the complex with an enzyme-triggerable substrate, dioxetane, and measuring the light emission in a luminometer. The resulting signal is directly proportional to the quantity of target in the sample. The quantity of target in the sample is determined from an external standard curve.

Nonspecific hybridization of any of the amplification probes and nontarget nucleic acids leads to amplification of the background signal (noise). To reduce the hybridization potential to all nontarget the non-natural bases, isocytidine (isoC) and isoguanosine (isoG), were incorporated into the amplification probes of the third generation bDNA assays (25). IsoC and isoG bases pair with each other but not with any of the four naturally occurring bases (26). The use of isoC and isoG probes in bDNA assays increases target-specific amplification without a concomitant increase in background, thereby, greatly enhancing the detection limits. The detection limit of the third generation bDNA assay for HIV-1 RNA is 50 copies/mL. bDNA assays for the quantitation of hepatitis B virus (HBV) DNA, HCV RNA, and HIV-1 RNA are commercially available (Bayer). The System 340 platform for bDNA assays automates the incubation, washing, reading, and data processing.

Hybrid Capture

The hybrid capture system is a solution hybridization antibody capture assay that uses chemiluminescent detection. The target DNA in the specimen is denatured and hybridized with a specific RNA probe. The DNA-RNA hybrids are captured by antibodies specific for DNA-RNA hybrids that are coated onto the surface of a tube. Alkaline phosphatase-conjugated antihybrid antibodies bind to the immobilized hybrids. The bound antibody conjugate is detected with a chemiluminescent substrate and the light emitted is measured in a luminometer. The intensity of the emitted light is proportional to the amount of target DNA in the specimen. Hybrid capture assay for detection of human papillomavirus (HPV) (27) and CMV (28) in clinical specimens are commercially available (Digene).

POSTAMPLIFICATION DETECTION AND ANALYSIS

Part of "56 - Molecular Techniques for Diagnosis of Infectious Diseases"

Gel Analysis

Visualization of amplification products in agarose gels after electrophoresis and ethidium bromide staining was the earliest detection method. After gel electrophoresis DNA may be transferred to a nitrocellulose or nylon membrane and hybridized to a specific probe to increase both the specificity and sensitivity of detection. Membranes with bound radiolabeled probes are placed in proximity to radiograph film and the hybrids are visualized as dark bands. Enzyme-labeled probes can be visualized through either light or color production after the addition of the appropriate chemiluminescent or chromogenic substrates. Many of these nonisotopic approaches are at least as sensitive as isotopic methods and are faster and the labeled probes more stable. Although gel electrophoresis and blotting remain important research tools, these techniques are being replaced by faster and simpler methods in the clinical laboratory.

Single-strand conformation polymorphism (SSCP) and restriction fragment length polymorphism (RFLP) analysis have been used to ascertain information about the base composition of the amplification products visualized in the gel. In SSCP analysis PCR product is denatured and then subjected to electrophoresis in a nondenaturing gel (29). Variations in the physical conformation of the PCR products are related to the base composition and are detected by differential gel migration. This technique has been used successfully to detect mutations causing rifampin resistance in *M. tuberculosis* (30).

RFLP analysis employs restriction endonucleases to cleave amplification products at specific recognition sites. The fragments are separated by electrophesis and the resulting banding pattern provides information about the nucleic acid sequence. When coupled with a hybridization reaction, RFLP analysis can also provide information about the location and number of loci homologous to the probe. Both SSCP and RFLP analysis of short products may soon be replaced by direct DNA sequencing as this technology improves and the costs drop.

Colorimetric Microtiter Plate Systems

Colorimetric microtiter plate (CMP) systems are convenient alternatives to traditional blotting techniques for detection of amplified products. In these systems amplified product is captured in microtiter plate wells by specific oligonucleotide probes coating the plastic surface. Bound product is detected by a color change that takes place after addition of an enzyme conjugate and the appropriate substrate. These systems resemble enzyme immunoassays and use microtiter plate washers and readers commonly found in clinical laboratories. CMP systems are more practical and faster than traditional membrane hybridization techniques described above.

Several variations are commercially available. In one popular approach, biotinylated primers are used to amplify the target and the biotin containing PCR product is denatured and added to the microtiter well. After hybridization with a capture probe, bound product is detected with a streptavidin-enzyme conjugate and a chromogenic substate (31). Enzyme conjugated-antibodies directed against double-stranded DNA also have been used detect PCR product in another CMP system (32). Another approach uses digoxigenin-dUTP to label PCR product and enzyme-conjugated antidigoxigenin antibodies to detect the captured product (33).

Automated Detection Systems

Target and probe amplification assays consist of three major steps: specimen processing, nucleic acid amplification, and product detection. The amplification and detection steps have proven the easiest to automate. Unfortunately, sample processing usually is the most labor-intensive step and represents the biggest challenge for manufacturers of automated test systems.

The COBAS system (Roche) automates the amplification and detection steps. The Abbott LCx systems automates the detection of G-LCR products. Organon Teknika manufactures automated sample preparation and detection systems for NASBA assays. All of the major manufacturers are developing high-throughput, fully automated, nucleic-acid analyzers. One example, the TIGRIS system (Gen-Probe), can reportedly process 500 nucleic acid detection tests in 8 hours.

Real Time PCR

Real-time PCR describes methods by which the target amplification and detection steps occur simultaneously in the same tube. These methods require special thermal cyclers with precision optics that can monitor the fluorescence emission from the sample wells. The computer software supporting the thermal cycler monitors the data throughout the PCR at every cycle and generates an amplification plot for each reaction.

In its simplest format, PCR product is detected as it is produced using fluorescent dyes that preferentially bind to double-stranded DNA. SYBR Green I is one such dye that has been used in this application (34). In the unbound state, the fluorescence is relatively low, but when bound to double-stranded DNA the fluorescence is greatly enhanced. The dye will bind to both the specific and nonspecific PCR products. The specificity of the detection can be improved through melting curve analysis. The specific amplified product will have a characteristic melting peak at its predicted melting temperature (T_m) whereas the primer dimers and other nonspecific products should have different T_m or give broader peaks (35).

The specificity of real-time PCR also can be increased by including hybridization probes in the reactions mixture. These probes are labeled with fluorescent dyes or with combinations of fluorescent and a quencher dyes. In the 5′ nuclease PCR assay (Taqman), the 5′ to 3′ exonuclease activity of Taq DNA polymerase is used to cleave a nonextendable hybridization probe during the primer extension phase of PCR (36). This approach uses dual-labeled fluorogenic hybridization probes. One fluorescent dye serves as reporter and its emission spectra is quenched by the second fluorescent dye. The nuclease degradation of the hybridization probe releases the reporter dye resulting in an increase in its peak fluorescent emission. The increase in fluorescent emission indicates that specific PCR product has been made and the intensity of fluorescence is related to the amount of product (37).

Fluorescence resonance energy transfer (FRET) is the basis of another approach to real-time PCR (38). This method requires two specially designed sequence-specific oligonucleotide probes. These hybridization probes are designed to hybridize next to each other on the product molecule. The 3′ end of one probe is labeled with a donor dye and the 5′ end of the other probe is labeled with an acceptor dye. The donor dye is excited by an external light source and instead of emitting light, transfers its energy to the acceptor dye by a process called FRET. The excited acceptor dye emits light at a longer wavelength than the unbound donor dye, and the intensity of the acceptor dye light emission is proportional to the amount of PCR product.

Real-time detection and quantitation of PCR product also can be accomplished using molecular beacons (39). Molecular beacons are hairpin-shaped oligonucleotide probes with an internally quenched fluorophore whose flurorescence is restored when they bind to a target nucleic acid. They are designed in such a way that the loop portion of the probe molecule is complementary to the target sequence. The stem is formed by the annealing of complementary arm sequences on the ends of the probe. A fluorescent dye is attached to one end of one arm and a quenching molecule is attached to the end of the other arm. The stem keeps the fluorophore and quencher in close proximity such that no light emission occurs. When the probe encounters a target molecule, it forms a hybrid that is longer and more stable than the stem, and undergoes a conformational change that forces the stem apart and causes the fluorophore and quencher to move away from each other, restoring the fluorescence.

Real-time PCR methods decrease the time required to perform nucleic acid assays because there are no post-PCR processing steps. Also, because amplification and detection occur in the same closed tube, these methods eliminate the post-amplification manipulations that can lead to laboratory contamination with amplicon. In addition, real-time PCR methods lend themselves well to quantitative applications because analysis is performed early in the log phase of product accumulation.

Direct Sequencing

The combination PCR and dideoxynucleotide chain termination methods can be used to determine DNA sequence in clinical samples (40). There are two platforms currently used for sequencing PCR products: electrophoretic separation on polyacrylamide slab gels or glass capillaries, and DNA microarrays. Fluorescent dye terminator chemistry and laser scanning in a polyacrylamide gel electrophoresis format has been the standard in electrophoretic separation technology. However, the recent application of capillary electrophoresis techniques to the separation of PCR and dideoxy chain termination products has streamlined the sequencing process by eliminating some of the labor intensive steps (41).

Although direct sequencing of PCR products using electrophoretic technology is a powerful research tool, its routine use in the clinical laboratory depends upon development of high throughput systems with integrated data bases and data analysis software. One such system for HIV-1 drug resistance genotyping is currently in clinical trials (Visible Genetics).

DNA MICROARRAYS

Part of "56 - Molecular Techniques for Diagnosis of Infectious Diseases"

DNA microarrays are produced by attaching or synthesizing hundreds or thousands of oligonucleotides to a solid support. A labeled amplification product is hybridized to the probes and hybridization signals are mapped to various positions within the array. If number of probes is sufficiently large, the sequence of the PCR product can be deduced from the pattern of hybridization with the aid of computer software. A number of manufacturers are developing DNA microarrays and the instrumentation required to acquire and analyze the data.

One of the most developed approaches marries advances in synthetic nucleic acid chemistry with photolithography, a process used in the manufacture of semiconductors for the computer industry. This approach uses light to direct the synthesis of short oligonucleotides on a silica wafer (42). On a 15-mm square chip, thousands of individual sites or features can be established. At each feature, specific oligonucleotides are assembled, one nucleotide at a time, by light-activated chemistry.

The DNA chip is incubated in a flow cell with DNA product that has been fragmented and labeled with a fluorophore. After hybridization, a scanning laser confocal microscope evaluates the surface fluorescence intensity of the chip. Automated scanning by the microscope requires only a few minutes to acquire an image of the entire surface of the chip, and the computer software analyzes the fluorescent image and determines the nucleic acid sequence of the PCR product. A DNA chip based on this technology for the detection of HIV-1 drug resistance mutations is commercially available (Affymetrix).

DNA microarrays hold much promise for molecular diagnostics, however, the current technology has several limitations including the complexity of fabricating the microarrays, limited availability, and high test cost.

CLINICAL APPLICATIONS

Part of "56 - Molecular Techniques for Diagnosis of Infectious Diseases"

Molecular methods have created new opportunities to the clinical microbiology laboratory to impact patient care in the areas of initial diagnosis, disease prognosis, and monitoring response to therapy. However, in most cases the new molecular tests supplement rather than replace the conventional diagnostic tests and add significant expense to laboratory budget. As a consequence, only those clinical applications that add true value to the overall diagnostic strategy will stand the test of time.

Detection of Slowly Growing and Unculturable Pathogens

With the development of molecular methods, the clinical microbiology laboratory is no longer solely reliant on the traditional culture methods for detection of pathogens in clinical specimens. Culture-based methods have long been the “gold standard” for infectious disease diagnosis but, in several diseases, nucleic acid based tests have replaced culture as the gold standard. Hepatitis C, pertussis, and genital infections with *C. trachomatis* are some examples of diseases in which nucleic acid-based tests are the new gold standards for diagnosis. This technology has been used to its best advantage in situations where the traditional methods are slow, insensitive, expensive, or not available. These techniques work particularly well with fragile or fastidious microorganisms that may die in transit or be overgrown by contaminating flora when cultured. It is beyond the scope of this chapter to review all of the possible applications or to provide a compendium of methods for detection of various pathogens. The reader is directed to other excellent resources for this information (43, 44).

Opportunities to actually replace culture for bacterial pathogens in routine practice are limited by the need to isolate the organisms for antibiotic susceptibility testing. In those applications where culture actually has been replaced by nucleic acid testing the pathogens are of predictable susceptibility and consequently, routine susceptibility testing is not performed e.g., *N. gonorrhoeae* and *C. trachomatis*.

Molecular methods have had the biggest impact in clinical virology where the molecular approaches are often faster, more sensitive, and more cost-effective than the traditional approaches. The diagnosis of enteroviral meningitis, herpes simplex virus encephalitis, and diagnosis of CMV infections in immunocompromised patients are examples of clinical relevant and cost effective applications of nucleic acid based tests. There are greater opportunities to replace the conventional methods in virology than in bacteriology because the culture-based methods are costly and antiviral susceptibility testing is not routinely performed. In those situations where antiviral susceptibility testing is required, it is amenable to molecular approaches.

Perhaps the greatest impact of molecular methods has been in the discovery of previously unrecognized or unculturable pathogens. During the past 15 years, a number of infectious agents were first identified directly from clinical material using molecular methods (Table 56.2). HCV, the principal etiologic agent of what was once known and non-A, non-B hepatitis, was discovered in 1989 thorough the application of molecular cloning techniques by investigators from the Centers for Disease Control and Prevention and the Chiron corporation (45). Cloning and analysis of the HCV genome led to production of viral antigens that now serve as the basis of the specific serological tests used to screen the blood supply and for diagnosis of hepatitis C. Currently, RT-PCR is used to detect, quantitate, and genotype HCV in infected individuals. To date, HCV has resisted all attempts at *in vitro* cultivation.

TABLE 56.2. EXAMPLES OF HUMAN PATHOGENS FIRST IDENTIFIED FROM CLINICAL SPECIMENS USING MOLECULAR APPROACHES[a]

Disease	Pathogen	Reference
Non-A, non-B hepatitis	Hepatitis C virus	(67)
Bacillary angiomatosis	*Bartonella henselae*	(68)
Whipple's disease	*Tropheryma whippelii*	(46)
Hantavirus pulmonary syndrome	Sin nombre virus	(69)
Kaposi's sarcoma	Human herpes virus 8	(70)

[a] Adapted form reference (47)

Tropheryma whippelii, the causitive agent of Whipple's disease, is another example of an unculturable microorganism which was initially identified by molecular methods (46). It was discovered by the use of broad-range PCR, in which primers directed against conserved sequences in the bacterial 16S ribosomal RNA gene. Sequence analysis of the PCR product and comparison with known 16S ribosomal RNA gene sequences were used to characterize the organism and establish its disease association. This approach provides a new paradigm for discovery of unrecognized pathogens and will be of value in other diseases with features that suggest an infectious etiology (47).

HCV and *T. whippelii* are two of the best examples of an important new principle in infectious diseases. A etiologic agent can be detected and characterized, and its disease association established long before its existence can be substantiated by traditional culture and serologic methods.

Disease Prognosis

Molecular techniques have created opportunities for the laboratory to provide important information that may predict disease progression. Probably the best example is HIV-1 viral load as a predictor of progression to acquired immune deficiency syndrome (AIDS) and death in infected individuals. This was first demonstrated in 1996 as part of a multicenter AIDS cohort study (48). These investigators showed that the risk of progression to AIDS and death was directly related to the magnitude of the plasma viral load at study entry. Plasma viral load was a better predictor of disease progression than the number of CD4+ lymphocytes. Subsequent studies have confirmed that baseline viral load critically influences disease progression.

Subtyping of certain viruses by molecular methods also may have prognostic value. Subtyping respiratory syncytial viruses may provide information about the severity of infection in hospitalized infants, with those infected with group A viruses having poorer outcomes (49). HPV causes dysplasia, intraepithelial neoplasia, and carcinoma of the cervix in women. HPV type 16 and 18 are associated with high risk of progression to neoplasia while types 6 and 11 are associated with a low risk of progression (50). Different genotypes of HCV have their own distinct global distributions and associations with progression to chronic infections and hepatocellular carcinoma (51).

Response to Therapy

Molecular methods have been developed to detect the genes responsible for resistance to single antibiotics or classes of antibiotics in bacteria and in many cases are superior to the phenotypic, growth-based methods. The detection of methicillin resistance in staphylococci, vancomycin resistance in enterococci, and rifampin resistance in *M. tuberculosis* are examples

where molecular methods are used to supplement the growth based methods (52). However, it is difficult to imagine, given our current state of knowledge of molecular genetics of antimicrobial resistance and the technological limitations, a genotypic approach to routine antimicrobial susceptibility testing of bacteria that would rival the phenotypic methods in terms of information content and cost.

Molecular techniques are playing an increasing role in predicting and monitoring patient response to antiviral therapy. The laboratory may have a role in predicting response to therapy by detection of specific drug resistance mutations, determining viral load, and by genotyping.

Both viral load and genotype are independent predictors of response to combination therapy with interferon and ribavirin in chronic HCV infections (53). Those patients with pretreatment viral loads of >2 million copies/mL or with genotype 1 infections have poor sustained response rates. Patients with type 1 infections require a full 48 weeks of combination therapy for maximum response whereas those patients infected with other genotypes do not benefit from therapy beyond 24 weeks duration. Therefore a simple genotype determination could spare those infected with genotypes other than 1 the discomfort and expense associated with an additional 24 weeks of therapy.

Drug resistance mutations in HIV-1 RT and protease genes lead to lower sensitivity to antiretroviral agents and are an important cause of drug failure (54). In a recent randomized clinical trial, genotypic resistance testing was found to have a significant benefit on virological response when choosing therapeutic alternatives (55). Although more data are need to document the clinical benefit of assays for detection of drug resistance mutations, these assays are likely to be used routinely to predict response to antiretroviral drugs.

Quantitative tests for HIV-1 RNA are the standard of practice for guiding clinicians in initiating, monitoring, and changing antiretroviral therapy. Several commercially available HIV-1 viral load assays have been developed and guidelines for their use in clinical practice have been published (56). Viral load assays have also been used in monitoring response to therapy in patients chronically infected with HBV and HCV (57, 58).

SPECIAL CONCERNS

Part of "56 - Molecular Techniques for Diagnosis of Infectious Diseases"

The unparalleled analytical sensitivity of nucleic acid amplification techniques coupled with their susceptibility to cross contamination present unique challenges to the routine application of these techniques in the clinical laboratory. There are special concerns in the areas of specimen processing, workflow, quality assurance, and interpretation of test results. Additional information can be found in the National Committee for Clinical Laboratory Standards (NCCLS) document MM3-A, Molecular Diagnostic Methods for Infectious Diseases; Approved Guideline (59).

Specimens

Specimen collection and processing are as critical for molecular microbiology tests as they are for culture-based tests. However, techniques designed to preserve and recover viable organisms may not be optimal for nucleic acids. Specimen processing for nucleic acid amplification tests should efficiently recover target nucleic acid from the specimen, ensure its integrity, and remove amplification inhibitors. Specimen processing also should concentrate the nucleic acid into a small volume of fluid that is compatible with the amplification reaction and address any biosafety concerns. Most specimen processing protocols for nucleic acid amplification tests require that the target DNA or RNA be extracted and partially purified. A wide variety of conventional methods and commercial kits are employed. Specific recommendations for processing vary with the target nucleic acid, the specimen, and the test method.

Prevention of Cross-Contamination

All of the target and probe amplification methods are subject to false-positives because of cross contamination with amplicon and target nucleic acid. Special laboratory design, practices, and workflow are necessary to reduce the possibility of cross contamination. The molecular diagnostic laboratory must be able to accommodate four basic functions: reagent preparation, sample processing, reaction set-up, and product detection. Ideally, these functions should be done in four physically separated areas. However, because of space constraints, separate workstations for these functions within the same room are often used. Regardless of the degree of physical separation, each workstation should have dedicated equipment and supplies. Additional containment measures include controlled airflow, vestibule entrances to the rooms, and the use of dead-air boxes at the workstations. Nucleic acid amplification tests should not be performed in areas of the laboratory used for cultivation of the target organisms because of concern about cross contamination with the target. The need for strict physical isolation of the workstations is less for those applications that include amplicon inactivation methods or use closed systems.

Unidirectional workflow is another means to reduce the possibility of cross-contamination. The workflow is should always be from those areas free of contaminating nucleic acids to those areas that are likely to be contaminated, proceeding from the reagent preparation area to the amplification area, and then finally to product detection area. Flow of personnel in the opposite direction should be discouraged. In addition to unidirectional workflow, a number of other routine preventive measures have been described including the use of aerosol barrier pipette tips, single use reagents, diluted bleach to wipe down counters, and low copy number positive controls (60, 61).

One of the most effective measures for controlling false-positive PCRs from amplicon cross-contamination is use of dUTP and uracil *N*-glycosylase (UNG) to modify the PCR product and selectively destroy any carried-over product from a previous reaction, respectively (62). With this amplicon inactivation method, dUTP replace dTTP in the reaction mixture and results in amplicon with deoxyuracil residues in thymidine resides. This unnatural DNA is chemically distinct from the target DNA and the UNG present in the reaction mixture cleaves any carried over product DNA at the uracil residues destroying its template activity. Target DNA is unaffected by UNG and new product can be synthesized because the UNG is thermally denatured at the elevated temperature used to denature the target and initiate the

PCR (63). Other methods include of amplicon inactivation include, ultraviolet (UV) light irradiation, use of photochemical cross-linkers, and hydroxlamine treatment (64, 65).

Quality Assurance

The number of nucleic acid amplification tests cleared by the FDA for diagnostic use is relatively small and limited to a few pathogens (Table 56.3). Tests for herpes simplex virus (HSV) DNA in cerebrospinal fluid (CSF) of patients suspected of having HSV encephalitis or enteroviral RNA in CSF of children with aseptic meningitis, and for HCV RNA in serum of patients with hepatitis are some examples of tests that are used routinely for diagnostic purposes, but for which there are no kits cleared by the Food and Drug Administration (FDA). Laboratories that develop assays "in house" must take responsibility for the appropriate validation and verification of the test performance. These activities are more demanding than described in CLIA'88 for FDA-cleared kits and are outlined in the NCCLS document 3A (59).

TABLE 56.3. NUCLEIC ACID AMPLIFICATION TESTS CLEARED FOR *IN VITRO* DIAGNOSTIC USE BY THE FDA

Test	Method (Manufacturer)
Chlamydia trachomatis	PCR (Roche), LCR (Abbott), TMA (Gen-Probe)
Neisseria gonorrhoeae	PCR (Roche), LCR (Abbott)
Mycobacterium tuberculosis complex	TMA (Gen-Probe), (PCR Roche)
Human immunodeficiency virus type 1	Quantitative RT-PCR (Roche)
Cytomegalovirus	HCA (Digene)

FDA, Food and Drug Administration

Proficiency testing is extremely important in molecular diagnostic laboratories because of the number of nonstandardized tests that are in routine use. Unfortunately, organized proficiency testing programs in this area are not well developed. The College of American Pathologists has offered an ungraded molecular microbiology survey over the past several years. The Centers for Disease Control and Prevention has on-going proficiency testing programs in HIV-1 viral load and *M. tuberculosis* testing. These programs and published reports of investigator-initiated proficiency testing studies all demonstrate that increased standardization is needed and that the laboratory performing the test is relatively more important than the test methodology. In the absence of an organized proficiency-testing program, the laboratory can design its own internal program or arrange to send samples to laboratories using similar methods.

Interpretation of Results

Molecular diagnostic tests often are more sensitive than culture methods that traditionally have been considered the gold standards for diagnosis. In these situations, the sensitivity and specificity of the molecular tests is defined in clinical rather than laboratory terms. Also, because molecular methods bring new capabilities to the clinical microbiology laboratory, they can lead to the definition of new disease states. Interpretation is even more problematic in this situation because the molecular methods may have no acceptable standard to use in a comparative evaluation.

The simple detection of an organism's DNA in clinical specimen does not guarantee its viability or its association with a disease process. Dead organisms may contain amplifiable DNA and, as a result, nucleic-acid–based tests are not useful as tests of cure for bacterial infections. Detection of an organism's nucleic acid sequence in a normally nonsterile body site may indicate colonization, contamination, or infection.

Interpretation of molecular diagnostic test results must take into consideration the factors that can lead to both false-positive and false-negative results. Assays using carry-over prevention formats and multiple negative controls decrease the likelihood that false positive results will be reported. Assays with internal positive controls increase the likelihood of detecting false-negatives due to sample inhibition and lead to increased confidence in negative results.

Culture methods usually are designed to recover all of the common pathogens that are likely to be found in particular specimen, whereas, molecular methods usually are designed for a single agent. Panels of single-target molecular tests and multiplexed reactions often are required to provide the same broad range of pathogen detection offered by culture.

Role of the Clinical Microbiology Laboratory in Hospital Epidemiology and Infection Control

Daniel J. Diekema

Michael A. Pfaller

The clinical microbiology laboratory is responsible for identifying pathogenic microorganisms in clinical specimens as accurately and rapidly as possible, thereby assisting clinicians in the timely diagnosis and treatment of infected patients. Hospital epidemiologists and infection control practitioners are charged with monitoring, preventing, and controlling the spread of infections in the hospital environment. Because preventing hospital-acquired (nosocomial) infections first requires the ability to detect infections when they occur, the clinical microbiology laboratory is inextricably linked to the infection control program at any hospital. In this chapter, we will discuss the impact of nosocomial infections, outline the organization of the hospital infection control program, and describe the important role of the clinical microbiology laboratory in the prevention and control of nosocomial infection.

NOSOCOMIAL INFECTION

Part of "57 - Role of the Clinical Microbiology Laboratory in Hospital Epidemiology and Infection Control"

Definition

A nosocomial infection is one that is acquired in a hospital or healthcare facility (i.e., the infection was not present or incubating at the time of admission). Although each individual infection must be considered in light of its usual incubation period, for most bacterial infections an onset of symptoms more than 48 hours after admission is evidence for nosocomial acquisition. An infection acquired in the hospital or healthcare facility may not be recognized until after discharge. These infections are still considered to be nosocomial. This is especially true for surgical wound infections. Because hospital stays are shorter now than ever before, infection control practitioners must devise strategies for postdischarge surveillance in order to accurately monitor nosocomial infection rates.

Infection Rates and Predominant Pathogens

Approximately 5% to 10% of inpatients acquire an infection during hospitalization. The urinary tract is the most commonly involved site, comprising 35% to 40% of all nosocomial infections. Surgical wound infections are the next most frequent nosocomial infection (20%), followed by lower respiratory tract (15%) and bloodstream (5% to 10%) infections (Fig. 57.1).

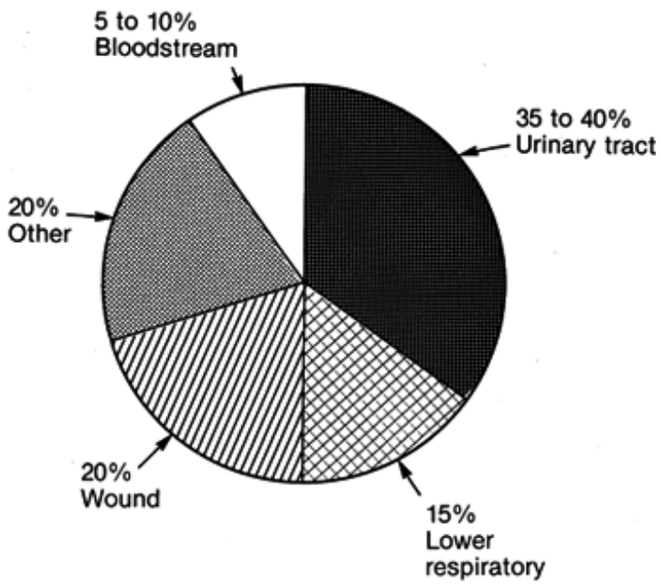

FIGURE 57.1. Nosocomial infections by site.

Table 57.1 lists the five most common bacterial pathogens causing various nosocomial infections in U.S. hospitals surveyed in the Centers for Disease Control and Prevention's (CDC) National Nosocomial Surveillance Survey (NNIS) (1, 2). The past two decades have seen a gradual shift in spectrum of nosocomial pathogens from Gram negative to Gram positive organisms, and the emergence of *Candida* spp. as a major problem (3). An important factor associated with the emergence of the staphylococci and enterococci as nosocomial pathogens has been their increasing resistance to most commonly used antimicrobial agents (4) (Table 57.2).

Morbidity, Mortality, and Cost

Nosocomial infections are estimated to be responsible for thousands of deaths annually, and likely contribute to thousands more (5, 6). Because patients with the most severe underlying illness also are those most vulnerable to nosocomial infection, it is very difficult to estimate the proportion of crude or overall mortality that is directly attributable to nosocomial infection. Studies have been performed that attempt to carefully control for as many confounding variables as possible, in order to estimate *attributable* mortality. These studies have demonstrated that the attributable mortality of nosocomial bloodstream infection was 14% for those because of coagulase-negative staphylococci (7), 31% and 37% for those because of vancomycin-susceptible and -resistant enterococci (8, 9), respectively, and 38% for infections from *Candida* spp. (10) (Table 57.3).

Nosocomial infections also cost the healthcare system billions of dollars annually, primarily through increasing hospital costs and length of stay (LOS). At the University of Iowa, we have demonstrated a median excess LOS of 8 and 30 days for nosocomial bloodstream infections resulting from coagulase-negative staphylococci and *Candida* spp., respectively (7, 10). Nosocomial

bloodstream infections in the intensive care unit have been associated with an excess LOS of 24 days and excess hospital costs of $40,000 per survivor (11). Surgical wound infections result in an excess LOS of over 7 days and an increase in hospital costs of over $3,000 per infection (12).

Organism	Percent Resistance by Year				
	1990	1992	1994	1996	1997–1998
Enterococcus spp	<1	5.6	8	16–17	18
S. aureus	20–25	20–25	-	26	25–45

Adapted from reference 63.

TABLE 57.1. DISTRIBUTION OF THE FIVE MOST COMMON NOSOCOMIAL PATHOGENS ISOLATED FROM THE FOUR MAJOR INFECTION SITES IN THE INTENSIVE CARE UNIT, JANUARY 1986–APRIL 1997, NNIS[a]

Infection Site	Pathogen	Percent of Total at Each Infection Site
Bloodstream		
	CoNS	33.5
	S. aureus	13.4
	Enterococcus spp.	12.8
	C. albicans	5.8
	Enterobacter spp.	5.2
Pneumonia		
	P. aeruginosa	17.4
	S. aureus	17.4
	Enterobacter spp.	11.4
	K. pneumoniae	6.7
	H. influenza	4.9
Surgical Site		
	Enterococcus spp.	15.3
	CoNS	12.6
	S. aureus	11.2
	P. aeruginosa	10.3
	Enterobacter spp.	9.5
Urinary Tract		
	E. coli	19.2
	C. albicans	14.4
	Enterococcus spp.	14.1
	P. aeruginosa	11.2
	K. pneumoniae	5.8

[a] National Nosocomial Infections Surveillance System (1). CoNS, coagulase negative staphylococci

Although certain nosocomial infections are secondary to the use of devices or procedures that compromise normal host barriers to infection, many nosocomial infections are preventable. The Study of the Efficacy of Nosocomial Infection Control (SENIC) indicated that the presence of an active surveillance and infection control system was associated with a 32% decrease in nosocomial infection rates, while the absence of such a program was associated with an 18% increase in nosocomial infections (13). Clearly, the activities of an effective infection control program save hospitals money and, more importantly, improve patient care.

THE HOSPITAL INFECTION CONTROL PROGRAM

Part of "57 - Role of the Clinical Microbiology Laboratory in Hospital Epidemiology and Infection Control"

The hospital infection control program is generally directed by a physician-epidemiologist and enforced by the infection control committee. The program should include surveillance of nosocomial infections, continuing education of medical staff, control of infectious diseases outbreaks, protection of employees from infection, and advice on new products and procedures. The clinical microbiology laboratory has a role to play in each of these important activities.

Infection Control Committee

The infection control committee is responsible for reporting and evaluating nosocomial infection data and for drafting and implementing policies, procedures, and guidelines pertinent to the practice of infection control. The committee should be multidisciplinary, with representatives from all departments, including clinical microbiology. Every hospital also must have a working infection control staff, composed of one or more infection control practitioners supervised by the physician-hospital epidemiologist. These professionals are responsible for collecting data concerning nosocomial infections and providing it to the committee. The committee should meet every 1 to 2 months, depending upon the size of the hospital, to review hospital-specific nosocomial infection data and to formulate policy. Other responsibilities of the committee include review of technical information about new products, devices, or procedures pertinent to infection control, and institution of all necessary control measures in the event of an outbreak or other infection control emergency.

The clinical microbiologist has an important role on the infection control committee. Few, if any, of the other infection control committee members will have a background in diagnostic microbiology. The clinical microbiologist therefore provides expertise in the interpretation of culture results, advice about the appropriateness and feasibility of microbiological approaches to an infection control problem, and input regarding the laboratory resources necessary to accomplish the goals of the committee. Equally important is what the clinical microbiologist takes back to the laboratory: namely, the ability to better plan for epidemiologic investigations and surveillance efforts, and important insight into the practical problems confronting the hospital infection control program.

One of the most important contributions of the clinical microbiologist is to inform the infection control committee of the strengths and limitations of methods employed to detect and characterize nosocomial pathogens. He or she should describe the potential impact on infection control of any change in methods for detection, identification and susceptibility testing of nosocomial pathogens. The committee should also be made aware of the budgetary and personnel constraints under which the laboratory operates, to ensure that they do not expend valuable laboratory resources unless there is a clear epidemiologic indication to do so.

TABLE 57.3. ATTRIBUTABLE MORTALITY OF NOSOCOMIAL BLOODSTREAM INFECTION FROM SELECTED PATHOGENS

Organism	Mortality Among Cases (%)	Mortality Among Matched Controls (%)	Attributable Mortality (%)	Reference
CoNS[a]	31	17	14	7
Enterococcus spp.	43	12	31	8
VRE[b]	67	30	37	9
C. albicans	57	19	38	10

[a] Coagulase-negative *Staphylococcus* spp.

[b] Vancomycin-resistance *Enterococcus* spp.

Nosocomial Infection Surveillance

Although costly and time-consuming, systematic surveillance of nosocomial infections is important for many reasons. By monitoring the frequency and types of nosocomial infection, the infection control program may detect outbreaks, evaluate compliance with infection control guidelines, provide data for policy development, and monitor the impact of any infection control interventions on nosocomial infection rates. Additionally, surveillance is a requirement of national and state accrediting agencies. One of the most important aspects of surveillance is the timely feedback of infection rates to health care providers, along with suggestions for improvement and reemphasis of existing infection control practices. In any case, the existence of an active nosocomial infection surveillance program is associated with a reduction in infection rates (and their consequent morbidity and mortality) (13, 14).

Because surveillance consumes more time than any other single infection control activity (15), it is essential that the most efficient surveillance system be employed. The most complete and accurate surveillance program would employ daily chart reviews of all hospitalized patients, an approach that is obviously not practical in any but the smallest of hospitals. Limited resources should be focused in the highest risk areas (intensive care units, hematology-oncology, burn units, organ transplant wards), and various screens can be used to increase efficiency. Microbiology reports, nursing care plans (Kardex), antibiotic orders, radiology reports, temperature charts, and discharge diagnoses all can be used to determine which charts should be reviewed further.

Review of microbiology reports probably is the most common method for case finding used routinely in the performance of nosocomial infection surveillance. Review of microbiology reports alone compares favorably to more comprehensive ward-based surveillance (16, 17). Yakoe et al. (18) recently reported that review of microbiology data alone was both more resource efficient and as effective as applying the CDC/NNIS definition for detecting nosocomial bloodstream infection. Laboratory-based surveillance allows for the efficient review of large amounts of data, and medical information systems can enhance surveillance further by linking data from many sources, including pharmacy (antimicrobial use), laboratory, radiology, billing (diagnostic codes), and even nursing notes (temperature charts, care plans).

Although review of microbiology reports is an essential part of surveillance, these data alone will not detect all outbreaks or infections. The sensitivity and specificity of laboratory-based surveillance is heavily dependant upon both the frequency of culturing and the quality of the specimens received by the lab. Optimal surveillance will include a combination of the above data screens (for example, nursing care plan and microbiology reports) to help determine which charts deserve further review. The frequency of surveillance of specific hospital units should be determined in each hospital by infection control practitioners, based upon available resources, prevailing infection rates and other factors. The University of Iowa has validated a surveillance strategy using primarily microbiology reports and nursing care plans (Kardex), and found the sensitivity and specificity to be 81% and 98%, respectively (19).

Education

Communication is the cornerstone of effective infection control. Combining reminders about good infection control practice along with regular feedback on nosocomial infection rates is one effective way to educate health care providers. Infection control practitioners also require continuing education, and one area for special emphasis should be clinical microbiology. Regular laboratory rounds to review laboratory results, discuss ongoing infection control problems, and plan investigative efforts in outbreak settings serves to educate both microbiologists and infection control practitioners about each other's areas of expertise. The infectious diseases consultant(s) and any other interested clinicians also should be invited to participate in these rounds to add further clinical insight.

ROLE OF THE MICROBIOLOGY LABORATORY IN INFECTION CONTROL

Part of "57 - Role of the Clinical Microbiology Laboratory in Hospital Epidemiology and Infection Control"

Now that we have given a broad overview of the general structure and activities of the hospital infection control program, we

will focus on the most important specific roles played by the microbiology laboratory in the day to day practice of infection control. We will discuss the challenges of accurate reporting of identification and susceptibility results, the importance of timely reporting of data, and the specialized studies sometimes required in the setting of an outbreak of infection.

Accurate Identification and Susceptibility Testing of Nosocomial Pathogens

The expanding spectrum of organisms that colonize and infect seriously ill patients continues to challenge the ability of the clinical microbiology laboratory to accurately identify and characterize nosocomial pathogens. Many common nosocomial pathogens are easily detected and identified (e.g., *Staphylococcus* spp., *Enterococcus* spp., *Candida* spp., and the Enterobacteriaceae). However, many nonfermentative Gram-negative organisms (e.g., *Burkholderia* spp., *Stenotrophomonas* maltophilia, *Acinetobacter* spp.), fungi (e.g., *Aspergillus* spp., *Fusarium* spp., nonalbicans *Candida* spp.), and viruses also cause nosocomial infections and can be more difficult to identify.

Specimen Handling

The ability of the laboratory to accurately identify nosocomial pathogens requires that adequate, high-quality specimens be received from the clinical services (discussed in more detail in Chapter 50). Any inappropriate specimens (wrong transport media, leaking containers, undue delay from collection to transport) should not be processed. Specimens also should be examined microscopically whenever possible to help judge quality and assist in the interpretation of results. For example, a nasopharyngeal wash specimen for detection of respiratory syncytial virus (RSV) antigen that has no cellular material is likely to produce a falsely negative test result. Gram stain of sputum specimens also is extremely useful as a screen to determine which are contaminated with oropharyngeal secretions and therefore not likely to be of value in the diagnosis of respiratory tract infection (20). Careful monitoring of specimen quality and enforcement of strict criteria for acceptance of clinical specimens ensures that the most accurate, least misleading microbiological data are reported to the clinician and infection control practitioner. Because many nosocomial pathogens also are common colonizing organisms and culture contaminants (e.g., coagulase-negative staphylococci), specimen collection and handling can have an impact on nosocomial infection rates. In addition, improper handling and contamination of culture specimens in the laboratory can lead to pseudo-outbreaks of infection (21, 22), which expend valuable time and resources.

Rapid Diagnostic Testing

The past decade has seen the increasing development of rapid diagnostic testing using molecular or immunologic methods, independent of culture. The speed with which these methods produce accurate results can have important implications for infection control. For example, a variety of methods now are available for rapid detection of RSV in respiratory secretions (23), *Clostridium difficile* in stool (24), *Mycobacterium tuberculosis* in respiratory specimens that are smear-positive for acid-fast bacilli (AFB) (25), and *Legionella pneumophila* serogroup 1 in urine (26). A positive result from any of these tests may allow for more rapid institution of appropriate isolation precautions and/or early investigation of potential outbreaks. Of course, indiscriminant use or poor quality control of a rapid diagnostic test can lead to errors, including a series of falsely positive tests resulting in a pseudo-outbreak (27). Additionally, the infection control practitioner must be educated regarding the negative predictive value of some rapid tests (e.g., nucleic acid amplification for *M. tuberculosis* in AFB smear negative patients), which may not be sufficiently high to allow for discontinuation of previously instituted isolation precautions.

Another example of a rapid test with implications for infection control is a new, rapid ELISA for the detection of antibodies to the human immunodeficiency virus (HIV) (HIV, Murex, Single Use Diagnostic System (SUDS) HIV 1/2) (28). The high sensitivity and excellent negative predictive value of this test may assist the infection control practitioner in counseling a health care worker who sustains a blood or body fluid exposure to a source patient who tests negative by the rapid test. Again, however, the limitations of this rapid test should be communicated to infection control practitioners. If the source patient has recent (within the past 6 months) risk behaviors for HIV acquisition, any test for antibodies to HIV may be falsely negative because the patient may not have yet mounted a detectable immune response.

Finally, the most widely available rapid diagnostic test is the microscopic examination of Gram-stained material. This procedure provides information rapidly and may detect and presumptively identify organisms of epidemiologic importance that may not be apparent on routine culture. Thus, the microbiology laboratory should make sure that infection control personnel are aware of the results of the Gram stain, as well as culture, for epidemiologically important specimens.

Automated Identification and Susceptibility Testing

Most laboratories have the capability to identify microorganisms to species level and perform antimicrobial susceptibility testing (AST). Conventional macro- and microbroth dilution AST have been replaced in many laboratories by automated commercial systems, which are convenient, less labor intensive, more rapid, and more standardized than is currently the case with in-house methods (29, 30). In general, the performance of most of the automated identification and susceptibility testing systems is as good as the conventional manual methods. Accuracy of 90% to 95% relative to conventional methods are reported routinely for both identification and susceptibility testing (29,30,31,32 and 33). The widespread availability of these systems has provided an improved level of performance and standardization among laboratories and allows many laboratories to perform microbiologic testing that otherwise would have had to be sent out to reference laboratories.

The limitations of many of these automated AST systems, in particular those using short (3- to 5-hour) incubation periods, have become increasingly apparent in recent years. As new pathogens and new resistance mechanisms evolve, it has become necessary to supplement automated systems with additional

methodologies to guard against significant errors for some organism/antimicrobial combinations. In general terms, these are organisms that display heteroresistance to ß-lactam antibiotics, inducible resistance mechanisms, or high mutation rates to drug resistance. In many cases, these resistance mechanisms may become apparent only after an incubation period longer than the 3- to 5-hour interval used by many rapid automated systems. For example, many commercial systems are not satisfactory for detecting penicillin resistance in pneumococci (34), and may underestimate glycopeptide resistance among enterococci (35). In addition, some systems have had problems in accurately detecting oxacillin resistance among *Staphylococcus* species (36) and have not adequately detected extended-spectrum ß-lactamase production among certain Enterobacteriaceae (29, 37). Conversely, some systems have reported false resistance to imipenem and aztreonam among Gram-negative rods (38).

As these problems are brought to the attention of the manufacturers of these systems, improvements can be made in the instrumentation, panels, or software programs to improve accuracy. This process of ongoing independent evaluation of automated systems and feedback to responsive industry representatives is extremely important. Unfortunately, in the era of managed care and shrinking laboratory resources fewer laboratories can perform rigorous internal evaluations of new technology. Unrecognized problems in identification or susceptibility testing (e.g., inaccurate detection of glycopeptide-resistance among enterococci or oxacillin resistance among staphylococci) have obvious, major ramifications for infection control. Namely, serious problems and even outbreaks can go unrecognized, or conversely, infection control resources can be diverted toward spurious resistance problems.

Three of the most problematic resistances emerging as causes of nosocomial infection include extended-spectrum ß-lactamases (ESBLs) and stably derepressed Bush-Jacoby-Medeiros group 1 cephalosporinases among Enterobacteriaceae (39, 40), glycopeptide resistance among enterococci (41) and staphylococci (42, 43), and penicillin resistance among *S. pneumoniae* (44) and viridans-group streptococci (45). Effective infection control efforts obviously depend upon the ability of the laboratory to detect these epidemiologically important resistant pathogens. The laboratory director must keep up with current literature regarding the ability of automated systems to detect emerging resistances, and the need for any additional methods to detect or confirm resistance patterns. The Etest, a stable antimicrobial gradient method, has performed satisfactorily for susceptibility testing of fastidious species and for many other organism/drug combinations that have proven problematic for some automated systems (33, 46–48).

Reporting of Laboratory Data

Results of cultures and antimicrobial susceptibility testing are an important data source for infection control and usually are reviewed daily by infection control practitioners. Additional important information can be obtained via direct communication between laboratory and infection control personnel during regular laboratory rounds (e.g., issues of infection versus colonization, or the extent to which specimens should be worked up for epidemiologically important organisms).

Additionally, some culture results warrant an early phone call from the laboratory to the infection control practitioner to ensure that appropriate control measures are implemented. Examples include positive blood or normally sterile site cultures for *Neisseria meningitidis*, smears, or cultures positive for AFB, isolation of the enteric pathogens *Salmonella* or *Shigella*, and the isolation of certain antimicrobial resistant pathogens such as methicillin-resistant *S. aureus*. Additionally, the detection of new or unusual pathogens (e.g., *Legionella* spp., vancomycin-resistant Gram-positive organisms) also should be reported promptly to the infection-control practitioner.

Routine microbiology laboratory results should be readily accessible to laboratory personnel, clinicians, and infection-control practitioners. In most cases, results are stored in a computer database, facilitating retrieval and analysis. Information stored should include specimen type, date of collection, patient identification, hospital number, hospital service, ward location, organisms identified, antimicrobial susceptibility test results, and the results of any specialized testing performed (e.g., typing). This information can be of great value in establishing a baseline for nosocomial infection rates for the analysis of trends or outbreaks.

Both clinicians and infection-control workers may benefit from periodic summaries of selected microbiology results. These results should be organized into frequency of isolation of various nosocomial pathogens by anatomical site and hospital service. The tables generated should summarize antimicrobial susceptibility test results, thereby assisting clinicians in their choice of empiric antimicrobial therapy. Including cost information for the most commonly used antimicrobials also may be appropriate.

Specialized Studies for Outbreak Investigations

When the infection control team detects a cluster or outbreak of nosocomial infection, they must act promptly to define the extent of the outbreak, learn the mode of transmission of the pathogen, and instititute appropriate control measures. The clinical microbiology laboratory must provide appropriate support during this time. Because the demands on the laboratory may be great during outbreak settings, advance preparation should be performed. Laboratory personnel should communicate regularly with infection control practitioners regarding the types of outbreaks that have occurred in the past, and what laboratory resources would be required should such outbreaks occur in the future. The extra costs associated with outbreak investigations also should be anticipated by hospital administration and calculated into annual budgets if possible. Costs should not be borne by the laboratory or charged to individual patients involved in the outbreak.

Molecular Typing in the Outbreak Setting

Outbreaks of nosocomial infection often result from exposure of a number of hospitalized patients to a common source or reservoir of a pathogenic agent (e.g., a healthcare worker colonized with *S. aureus*, water from a hot water tank colonized with *Legionella*

spp.). The organisms causing the outbreak in these cases all derive from a single strain (i.e., they can be said to be clonally related). The hospital epidemiology program therefore may request that the microbiology laboratory characterize potential outbreak strains to determine their genetic relatedness. In the appropriate clinical setting, species identification and antimicrobial susceptibility testing (antibiogram) may provide strong evidence for an epidemiologic link. However, because nosocomial pathogens also are frequently colonizing flora or normal environmental flora, more sensitive methods of strain delineation are often necessary (49,50 and 51). For this reason, most phenotypic typing methods (e.g., AST, biochemical profiles, bacteriophage susceptibility patterns, multilocus enzyme electrophoresis profiles), which discriminate poorly among strains, have been replaced almost completely by genotypic or DNA-based typing methods (49,50 and 51).

The cost-effective application of genotypic typing methods requires that they be used only for well-defined epidemiologic objectives. These objectives include: (a) determination of the extent of an outbreak, (b) determination of the mode of transmission of nosocomial pathogens, (c) evaluation of the efficacy of preventative measures, and (d) monitoring of infection in high risk areas (e.g., intensive care units), where cross-infection is a recognized hazard.

The ideal genotypic typing system should be standardized, reproducible, stable, sensitive, broadly applicable, readily available, inexpensive, and of proven value in epidemiologic investigation. Table 57.4 summarizes the characteristics of several DNA-based typing methods. Pulsed-field gel electrophoresis (PFGE) and certain polymerase chain reaction (PCR)-based typing methods perform well for a wide array of nosocomial pathogens and are the molecular typing methods most frequently used to investigate nosocomial infections and outbreaks. Further discussion of the relative advantages and disadvantages of the many available typing systems is beyond the scope of this chapter and has been well summarized in several recent reviews (49,50,51,52 and 53).

TABLE 57.4. DNA-BASED METHODS FOR EPIDEMIOLOGICAL TYPING OF MICROORGANISMS

Method	Substrate	Principle Characteristics	Examples
Plasmid fingerprinting	Plasmid DNA	Technically simple and inexpensive; potentially unstable because of loss of plasmids; may be augmented by restriction endonuclease digestions	*S. aureus*, coagulase-negative staphylococci, *Klebsiella* spp., *Serratia* spp., *Enterobacter* spp.
Restriction endonuclease analysis of chromosomal DNA with conventional electrophoresis	Chromosomal DNA	Reproducible and broadly applicable; complex banding patterns; very difficult to interpret	*Clostridium difficile, Enterococcus faecium, S. aureus*
Restriction-fragment length polymorphism (RFLP) analysis with nucleic acid probes	Chromosomal DNA	Includes insertion sequence analysis and ribotyping; broadly applicable; multistep process; automated system available; limited discriminatory power (ribotyping)	*M. tuberculosis, S. aureus, C. albicans*, Enterobacteriaceae
Pulsed-field gel electrophoresis	Chromosomal DNA	Broadly applicable; excellent reproducibility and discriminatory power; employs rare cutting restriction enzymes to generate large band DNA fragments (10–800 kb); fewer bands; slow turnaround time; expensive equipment	Staphylococci, enterococci, Enterobacteriaceae, *Pseudomonas* spp., *Candida* spp.
Polymerase chain reaction (e.g., RAPD, rep-PCR, CFLP, AFLP: see reference 52 for details)	Chromosomal DNA	Rapid and relatively easy to perform; universally applicable when random primers are used (RAPD); moderate to good discriminatory power	*S. aureus, C. difficile*, Enterobacteriaceae, *Candida* spp.

From reference 22.

RAPD, Random Amplified Polymorphic DNA; rep-PCR, repetitive extragenic palindromic–polymerase chain reaction; CFLP, cleavase fragment length polymorphism; AFLP, amplified fragment length polymorphism

Regardless of the typing system employed, several general principles should be emphasized. A valid comparison between two or more isolates can be difficult unless the samples are run under the same conditions, and usually on the same day with the same reagents. Additionally, in order to make valid conclusions about the epidemic strain during an outbreak, one must demonstrate that control isolates from epidemiologically unrelated patients and/or environmental sources are different from the outbreak strain (51, 54). Finally, regardless of the method used, if molecular typing is applied indiscriminately or without sound epidemiologic reasoning, the information gleaned often will be conflicting and confusing.

Unfortunately, because the methodology, nomenclature, and reference strains have not been standardized, it is not usually possible to compare molecular typing results obtained by different methods or different laboratories (53). Sophisticated computer-based analysis systems and fully automated molecular typing systems (e.g., Riboprinter, Qualicon, Wilmington, DE) are first steps toward standardization and quantitative analysis of molecular typing results (55), and some early standards and guidelines for the interpretation of typing results have been developed (56).

Of course, it is impossible to provide infection control practitioners with supplemental testing like molecular typing if the appropriate isolates have not been saved. The laboratory should plan ahead with infection control and save all epidemiologically important isolates. Decisions about the number and type of isolates to be banked and the duration of storage will differ from hospital to hospital based upon available resources. Certainly all isolates from blood and other normally sterile sites (e.g., cerebrospinal fluid) as well as multiply antibiotic-resistant strains from any site should be saved for a period of several months to years.

Cultures of Hospital Personnel and Environment

Investigating an outbreak of nosocomial infection may require culture of many specimens from patients, hospital personnel, and the environment. The use of selective media (i.e., media which inhibits growth of organisms other than those of epidemiologic interest) or differential media (i.e., media that results in distinctive colonial features of the target organism) can significantly reduce laboratory workload and expedite specimen processing in these circumstances. Likewise, enrichment cultures may be necessary to detect specific pathogens that may be present in low numbers, such as methicillin-resistant *S. aureus* (57). Given the resources required to process these cultures, it is imperative that they be obtained only when epidemiologically indicated.

Cultures of medical devices and the environment (surfaces, air, water) should be performed rarely and only when the evidence suggests involvement in the transmission of a nosocomial pathogen. Various potential sources and their appropriate culture methods are outlined in Table 57.5. Although the use of such cultures is frequently entertained, it should be emphasized that the cultures are labor intensive, nonstandardized, difficult to interpret, and rarely provide useful information.

TABLE 57.5. CULTURE OF POTENTIAL SOURCES OF CROSS-INFECTION IN NOSOCOMIAL INFECTION OUTBREAK[a]

Source	Culture Method	Comment
Blood products	Broth culture incubated aerobically and anaerobically at 30°–32°C for 10 days	Following transfusion reaction; obtain simultaneous blood cultures by venipuncture
Parenteral fluids and intravenous devices	Broth or membrane filter method	Culture needle, catheter, administration set, fluid, closure; obtain blood culture
Environmental surfaces	Swab-rinse or impression plate	No evidence that any particular level of contamination correlates with nosocomial infection
Tubes and containers	Broth-rinse or swab-rinse with semiquantitative plating	At least two colonies of each morphologic type should be picked for identification
Disinfectants and antiseptics	Plating of serial dilutions of the product with and without specific neutralizers	Organisms usually nonfermenting Gram-negative aerobic bacilli
Respiratory therapy equipment	Broth-rinse or swab-rinse	Only in situations of high endemic or epidemic levels of nosocomial respiratory infection
Air	Mechanical air sampler (preferred); settling (plates (poor)	No uniform agreement on acceptable levels of contamination; lack of correlation with infection
Water and ice	Membrane filter	Poor correlation of culture findings with illness
Hands of personnel	Broth-bag: 10–20 mL nutrient broth in sterile plastic bag. Wash hands in broth and plate semiquantitatively	May confirm the mechanism of cross-infection; impress the importance of hand washing

[a] Cultures to be performed only if clearly indicated by epidemiologic data. From reference 62.

Because the hands of healthcare workers are such an important vehicle for transmission of nosocomial pathogens from patient to patient, hand cultures are sometimes useful in confirming the mechanism of cross-infection during an outbreak investigation (58). A sensitive method of culturing hands to detect transient or resident flora is the broth-bag technique. The subject vigorously washes both hands in 10 to 20 mL of nutrient broth (supplemented with Tween 80, sodium thiosulfate, and lecithin to neutralize any residual antiseptics), and an aliquot of the broth is then plated onto selective and nonselective media and observed for growth of the pathogen of interest (59).

As a general rule, routine cultures of hospital personnel and the environment should not be performed. Exceptions include routine monitoring of sterilization, infant formula, and other hospital-prepared products; blood components prepared in an “open” system; hemodialysis fluid; and disinfected equipment. Sampling activities that have been identified specifically as unnecessary because of high cost and lack of clinical or epidemiologic benefit include routine culturing of patients or hospital personnel, routine sampling of commercial patient-care items, in-use testing of antiseptics and disinfectants, random culturing of blood units, and routine culturing of respiratory therapy equipment, peritoneal dialysate, and air. These routine cultures are a burden to the laboratory and seldom, if ever, provide useful information or lead to specific interventions (60, 61). They only should be done with appropriate epidemiologic indications or as part of an educational program (e.g., routine broth-bag hand culturing in the intensive care unit to reinforce good handwashing practices).

CONCLUSION

Part of "57 - Role of the Clinical Microbiology Laboratory in Hospital Epidemiology and Infection Control"

The clinical microbiology laboratory is an essential component of an effective hospital epidemiology and infection control program. The changing spectrum of nosocomial pathogens and the rapid development and application of new technologies in the diagnostic laboratory require ongoing cooperation and collaboration between the laboratory and infection-control personnel. Appropriate application of the newer methods for detection, identification, and typing of nosocomial pathogens will enhance the effectiveness of infection control efforts. A good working relationship between the clinical microbiologist and hospital epidemiologist has a positive influence on both laboratory and infection control operations and facilitates the investigation and control of nosocomial infection problems.

Autopsy Microbiology

Mary J. Reznicek

Franklin P. Koontz

Autopsies are one of the most powerful learning tools the field of medicine has in its armamentarium for understanding disease. They are performed for a variety of reasons: to gain additional information into the pathogenesis of disease, to identify clinically unsuspected disease processes, and to correlate premortem clinical diagnoses with postmortem diagnoses. The autopsy is a valuable teaching tool and quality control measure that works most efficiently when there is open communication between the primary physician and the pathologist. This ensures that valuable information is exchanged between both parties to facilitate a greater understanding of disease processes.

Despite the advent of the antibiotic era, infection has remained a significant cause of death in the United States. Therefore, the ability to identify an infectious process at autopsy is crucial. The diagnosis of an infectious disease at autopsy, like the diagnoses made in living patients, can be accomplished by positive cultures, tissue histology, and serologic procedures. These tests can be utilized singly or in combination.

Postmortem cultures can be a very useful component of the postmortem examination. They can be utilized to detect infections not suspected clinically, such as mycobacterial or fungal infections. They also can be useful in pinpointing the source of a known sepsis. For example, the discovery at autopsy of a *Staphylococcus aureus* psoas muscle abscess in a patient with known *S. aureus* sepsis and no other potential sites of bacterial seeding would certainly make the abscess the most likely source. Culturing also can be useful as a quality control measure to assess the effectiveness of antimicrobial therapy. As a quality control measure, the identification of an unsuspected infectious process can also help clinicians identify, in a retrospective fashion, other tests that might have aided in the premortem identification of an infection.

All of the knowledge gained by postmortem culturing is dependent on the utilization of proper methods to collect and process samples. This would include proper cooling of the body after death, avoiding lengthy delays in the performance of an autopsy, the use of sterile culturing techniques, and the use of good interpretive skills to correlate the clinical history, culture results, and the gross and histologic findings.

MICROBIOLOGY OF AUTOPSY TISSUE

Part of "58 - Autopsy Microbiology"

The use of cultures in autopsy microbiology is controversial, and opinions vary on its usefulness. Several basic questions concerning the validity of postmortem cultures have been discussed in the literature. Most of these questions center around the basic question of whether a dead human body with its own inherent normal bacterial flora is suitable for culturing. More specifically, these questions are:

1. Does agonal or postmortem bacterial invasion occur?
2. What effect does the postmortem interval have on culture results?
3. Are human viscera sterile?

Two theories exist that support the idea that autopsy material is unsuitable for culture: the theories of *agonal invasion* and *postmortem invasion*. The theory of agonal invasion states that the diminished vitality of the dying body predisposes it to disseminated infection. The theory of postmortem invasion suggests that bacteria multiply and migrate throughout the body after death. Potential sites of dissemination include the normal flora of the oropharynx, which can seed the lung and blood, and normal gastrointestinal (GI) tract flora, which can seed the liver, spleen, and blood.

Both of these theories promote the concept that increasing numbers and types of organisms would be seen after death. Similarly, one would expect that the number of positive cultures would increase in direct proportion to the postmortem time interval. However, this concept does not appear to be valid if one considers several studies that illustrate that the postmortem interval has no effect on the number of positive cultures at autopsy (1,2,3,4,5,6 and 7). The postmortem interval in these studies ranged from 14 to 48 hours, and bodies were placed in a cooler at 4° to 5°C soon after death. There was no increase in positive autopsy cultures as the postmortem interval increased. In contrast, Carpenter and Wilkins (8) conducted a retrospective study of 2,033 autopsy cases that showed a rise in postmortem positive cultures with increasing postmortem intervals up to 18 hours. Unfortunately, because the distribution of cases between short and long delay intervals was not provided, the conclusions of this study are open to question. Overall, the majority of the published evidence suggests that, if proper cooling of the body takes place and the autopsy is performed in a timely manner, agonal or postmortem invasion (if either exists) should not produce false-positive culture results.

The high frequency with which positive cultures are isolated from autopsy tissues that clinically and pathologically appear

normal has raised the question of whether human viscera are sterile. This question has sparked controversy about the increasing numbers of cadaver organs harvested for transplant. A study of 148 surgical biopsies (excluding skin and GI tract) showed that approximately 28% were culture-positive (2). Because the samples were surgical biopsy specimens, one cannot argue that agonal or postmortem invasion played any role. Considering the transient bacteremias that are known to occur in individuals undergoing dental or urologic procedures, it is not surprising that human viscera may not be sterile at any given time. In healthy individuals, these numbers of circulating bacteria are likely to be too small to result in clinical disease. In interpreting a positive postmortem culture result, one must be careful not to equate a positive culture with disease without first correlating the culture results with the clinical history and histologic findings. A positive culture result may be *valid* in light of the above discussion, but the determination of its clinical significance is of major importance in ascertaining its contribution to the cause of death.

Knapp and Kent (1) addressed this issue and suggested that low levels of bacteria may be present in noninfected organs at the time of autopsy. They showed by quantitative cultures that less than 10^5 organisms per milliliter in lung tissue correlated with the absence of pulmonary disease by autopsy histology and, conversely, more than 10^5 organisms per milliliter in lung tissue correlated with clinical and pathological pneumonia.

It is imperative to understand that the data and concepts expressed in the above discussion are totally dependent upon proper culturing techniques at the time of autopsy. Although the “sterile autopsy technique” suggested by O'Toole et al. (4) is impractical for routine use, DeJongh et al. (3) have described a more practical technique. This technique is described in detail elsewhere in this chapter (see Specimen Collection and Transport, below).

Avoiding contamination of tissues with fluids introduced into the body cavities at the time of dissection is an important aspect of culturing. One study by Silva and Sonnenwirth (7) reported that blood cultures obtained from the heart through a closed chest were more likely to yield significant results than those obtained from an exposed right atrium. They also showed that bowel manipulation increased the number of positive cultures. Contamination of postmortem cultures with normal flora from the bowel or nasopharynx can lead to significant problems. However, these can be controlled by strict adherence to protocols or procedures adapted for the care and handling of the cadavers from the moment of death to the completion of the autopsy.

SPECIMEN COLLECTION AND TRANSPORT

Part of "58 - Autopsy Microbiology"

Preparation

Before beginning the autopsy, it is imperative to fully review the patient's chart. The value of the autopsy is directly proportional to the preparation by the prosector. The information contained in the patient's chart can be used to ascertain the clinical questions that need to be answered by the autopsy. Areas of the hospital record that are particularly helpful include current hospital notes, transfer notes, and past discharge notes, which often provide an excellent review of the patient's medical history. Radiology examinations such as radiographs, computed tomography (CT) scans, and white blood cell (WBC) scans will often point out areas of suspected infections. For example, when the clinical note states “suspected pancreatic pseudocyst,” the CT scan may be helpful in describing the exact location of the cyst and the size. If the prosector is unsure of the clinical questions, it can be extremely helpful to consult with the physician who managed the patient. This is strongly recommended in every autopsy case and can often provide more recent data that may not be evident in the chart.

In reading the patient's record, it is important to delineate those cases in which infection was thought to play a clinically important role and those cases in which the cause of death is unknown and infection is a possible cause. In the former situation, the prosector should study clinically suspicious areas of infection by gross and microscopic examination and possibly by culture. Autopsy data, whether gleaned from gross observation, histologic examination, or microbiological culture, serve as quality control mechanisms for antemortem concepts. The autopsy can clarify these concepts regardless of whether the findings are positive or negative. For example, the clinicians and the radiologist may suspect a right lower lobe pneumonia in a patient who dies a few days later. The prosector, by reading the chart, knows this information and, despite the gross findings of dependent congestion and a lack of consolidation in the right lung, can obtain samples of that area for microbiological culture and histologic examination. By doing so, the prosector can adequately address the antemortem diagnosis of pneumonia. Additional information can be gleaned from the hospital record relative to the use of antimicrobial therapy. This information could be critical in evaluating the effectiveness of specific antimicrobial therapy.

Diagnosing an unsuspected infection when the cause of death is unknown is also a responsibility of the prosector. It is important to consider doing cultures in this situation. It is relatively easy to culture during the autopsy; however, the chance is lost after the tissue has been placed in formalin and the cadaver has been taken to the funeral home. For example, a 35-year-old male is admitted to the hospital with severe congestive heart failure, and he dies before a workup is performed. No definite etiology for the congestive failure is known. The clinical differential includes cardiomyopathy, myocardial infarction, *cor pulmonale*, and myocarditis. Histologic sections of the heart show scattered inflammatory cells indicative of a myocarditis. In this case, confirmatory viral cultures would not only add strength to the diagnosis of myocarditis but also would give valuable epidemiologic information. Similar information also can be supplied by specific serologic tests. If antemortem tests were performed for specific antibodies, postmortem serum should be submitted for convalescent titers.

In reviewing the hospital record, it is important to ascertain whether the patient may have had an infectious disease that would place individuals present at the autopsy at risk, such as tuberculosis, hepatitis, and acquired immune deficiency syndrome (AIDS). In cases of suspected tuberculosis, PPD results and sputum culture results may be informative. For hepatitis, elevated liver function tests or a previous history of transfusion or drug abuse should be noted. If AIDS is suspected, the patient's human

immunodeficiency virus (HIV) status and personal risk history should be determined. The presence of multiple opportunistic infections, such as *Pneumocystis carinii* pneumonia and/or atypical mycobacterial infection, in an otherwise normal host, or an unknown cause of death, also should arouse suspicions. Although universal precautions are recommended for all autopsies, particular caution should be exercised in instances where infectious diseases are suspected. In such cases, it is best to limit the number of people in the autopsy suite, thereby decreasing the number of people possibly exposed. In addition, consideration might be given to limiting the autopsy to areas of clinically suspected disease. For example, in a patient who died of fulminant hepatitis, there may be no reason to examine the brain except for completeness. In these cases, limiting the autopsy may be indicated.

Culturing

The extent of postmortem culturing is a problem that has never been specifically addressed. If only one area is to be cultured, the spleen and heart blood are favored as reliable sites. However, additional cultures from other areas such as lungs and kidneys will more accurately reflect the spectrum of bacteria affecting the patient. The clinical history and the gross appearance of the organs at autopsy also can help the prosector to decide how many postmortem cultures are necessary. For example, in a patient with a clinical history of sepsis, cultures of heart blood and spleen should be taken even if gross organ appearance is normal. If both sites grow identical organisms, a diagnosis of sepsis is supported.

In transplant patients and other immunocompromised hosts, special diligence must be shown. In the event of an established disseminated infection, it is clinically important to identify the site of entry of the infection and/or the primary organ of involvement that may be seeding the rest of the body. Entry sites other than the typical respiratory route include indwelling catheters, Hickman catheters, skin wounds, and nasal lesions. Extensive culturing in these patients is recommended to document the dissemination of the infection and to identify possible sources of infections.

The extent of culturing not only refers to the number of cultures but to the types of cultures as well. In immunocompromised patients, the use of special viral, fungal, or mycobacterial cultures in addition to routine bacteriology should be considered. These special cultures must be clearly requested on the test requisition form because they are not routinely performed on autopsy specimens in most laboratories.

The use of cultures should not be discounted because of antemortem antimicrobial therapy (8,9,10,11 and 12). Some studies have shown that antibiotics per se do not influence the number of positive cultures at autopsy. In addition, the availability of resin bottles or other antibiotic removal devices for blood cultures also may help increase this yield. In patients who have received antimicrobial therapy, postmortem cultures can assess the effectiveness of the drug.

As previously discussed, the techniques employed in obtaining postmortem cultures clearly affect the usefulness of the results. A more practical technique, described by DeJongh et al. (3), compares very favorably with those used in autopsies performed under strict sterile operative conditions. This technique, as it applies to blood, urine, CSF, and tissue, includes the following steps:

1. After making the initial incisions, visually inspect the cavities for fluid accumulations that can be cultured immediately before manipulation. Gently inspect organs for areas suspicious for infection. Consider culturing organs that are *clinically* suspected of harboring infection.
2. Dry the area to be cultured by searing with a hot steel spatula while keeping the organ elevated away from any secretions. Avoid dripping gloves that may contaminate the surface after it has been sterilized.
3. For tissue culture, remove a 1-cm^3 portion of tissue with sterile forceps and blade and place it in a sterile Petri dish that has been identified properly with the patient's name, the culture site, and the specific type of culture desired (e.g., viral and fungal).
4. For blood culture, aspirate blood from the right atrium with a sterile syringe and inject 10 mL into aerobic and anaerobic blood culture bottles whose surfaces have been sterilized. Consider using a resin culture bottle if the patient has been on antibiotics. In cases of suspected fungemia, centrifugation lysis blood tubes (Isolator, DuPont) may be used.
5. To obtain urine for culture, aspirate urine directly from the bladder with a sterile syringe and inject it into a sterile tube.
6. CSF fluid for culture can be obtained from the lateral ventricle through the *corpus callosum* after the skull cap is removed or by cisternal tap through the skin. Both methods are adequate when performed aseptically.
7. Cultures of abscesses and granulomata should be obtained from both the center and the peripheral wall of the lesions. Depending on the disease, the organisms can be in either location.
8. Use different sets of sterile instruments for each culture/site.
9. If the microbiology laboratories are not all in one location, divide the specimens aseptically for the bacteriology, mycology, TB, and virology laboratories. The specimens should be delivered promptly to the microbiology laboratory.

Thus, by careful sampling, surface decontamination, and handling of tissues, one can obtain postmortem cultures that are useful in assessing the importance of infection in the death of a given patient.

It is very important to adequately fill out the laboratory requisitions. Tissue from surgical specimens may be automatically plated for bacteriology, anaerobes, and fungi; however, autopsy cultures, because of their low yield, may not get the same treatment. It is important to let the microbiology laboratory know what is suspected. For example, if you clinically suspect an organism that has special growth requirements, like *Haemophilus*, that information must be relayed to the laboratory to ensure proper handling of the specimen.

Tissue specimens for viral culture should be placed in transport media and kept at 4°C if any delay in transport to the laboratory is anticipated. If a longer delay (more than 48 hours) is anticipated, the specimen should be snap frozen in liquid nitrogen. Slow freezing may kill some unstable viruses. In suspected viral syndromes, the virus may be excreted in body fluids and thus may be present

in urine and feces as well as in the organ of primary interest. Culturing multiple areas may result in higher yield (Table 58.1).

TABLE 58.1. SPECIFIC BODY SITES FOR VIRAL CULTURING

Syndrome	Specimens
Respiratory	Lung, tracheal swab
CNS	Brain, spinal cord, CSF, feces
Cardiac	Heart, nasopharyngeal swab, feces, pericardial fluid
Liver	Liver, nasopharyngeal swab, feces, blood
GI	Feces, GI tract

CNS, central nervous system: CSF, cerebrospinal fluid: GI, gastrointestinal

One procedure that can be performed immediately in the morgue is a touch preparation of the infected organ. A Diff-Quick (Fisher Scientific) or Giemsa stain set-up and a microscope can be kept in the morgue. This procedure can permit the rapid identification of yeast, molds, or granulomatous inflammation and thereby help direct the extent and type of culturing (see Fig. 58.6). It also presents the opportunity to give rapid feedback to the clinician while the clinical situation is still fresh in his or her mind.

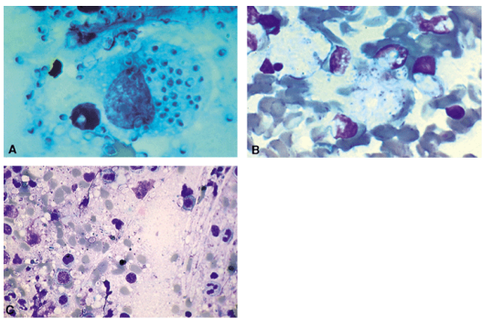

FIGURE 58.6. A: Touch preparation from a lymph node with internal structure of Histoplasma (Diff-Quick, ×1,000, oil). **B:** Touch preparation from a lung with internal structure of *Pneumocystis carinii* (Diff-Quick, ×1,000, oil). **C:** Touch preparation from a spleen containing *Candida* showing effects of amphotericin therapy (ghost pseudohyphae) (Diff-Quick, ×400).

Specimen Processing

Autopsy culture specimens should be processed by the laboratory in much the same way as clinical specimens. These techniques already have been described in previous chapters. However, in processing these specimens, the general philosophy is to avoid picking up less meaningful data. Broth cultures can be avoided because the low levels of organisms at autopsy are unlikely to be clinically significant. Culture plates that grow multiple organisms also are unlikely to be significant in most clinical situations.

Additional microbiological methods that can be applied include print culture (13), immunofluorescence, DNA probes, and polymerase chain reaction (PCR) (14). In general, these methods involve additional laboratory time and expensive reagents. Print cultures involve pressing culture media directly against the block of tissue to be cultured. The print cultures then can be directly correlated to the presence of an inflammatory response in the tissue section, allowing a rough quantitation of organisms to be made. A similar principle was advocated by Knapp and Kent (1) 12 years earlier when they compared quantitative cultures of lung tissue with Gram stains of tissue imprints and histologic sections. The advantage of this technique is the ability to directly correlate culture information to histologic sections. In both studies, contaminants were readily identified by the low numbers of organisms grown in culture (1) or by the pattern of growth. For example, in the print culture method, contaminating bacteria are generally restricted to the edges of the culture imprint (13).

At present, rapid diagnostic methods such as DNA probes and immunofluorescence should be reserved for autopsy cases in which an organism is suspected clinically and pathologically despite negative routine laboratory cultures and tissue sections. Special techniques also may be necessary for organisms that cannot be easily cultured or identified by routine histologic stains, such as *Rickettsia*.

Special histologic stains on formalin-fixed autopsy tissue also can be performed alone or in combination with cultures to diagnose an infectious process. Which special stains to order can often be determined by the routine hematoxylin and eosin (H&E) stain, which provides information as to the type and degree of cellular host response. These host responses can be divided into the broad categories of acute inflammation, chronic inflammation, and granulomatous inflammation, and the identification of one of these can alert the prosector to search for the presence of an organism that characteristically elicits that type of host response (Table 58.2).

TABLE 58.2. HOST TISSUE REACTIONS TO ORGANISMS

Host Tissue Reaction	Organisms
Acute inflammation	Routine bacteria, actinomyces, *Nocardia, Blastomyces, Candida*, and herpes virus
Chronic inflammation	Viruses, *Pneumocystis*
Granulomatous inflammation	Mycobacteria, *Cryptococcus, Histoplasma, Coccidioides, Candida*
Caseous necrosis	Mycobacteria, *Histoplasma, Coccidioides*
Thrombosis	*Aspergillus*, Zygomycetes, *Fusarium*

Several characteristic host reactions can be identified. Infection with *Pneumocystis* can produce honeycombed, intraalveolar material seen in immunocompromised patients as well as the interstitial plasma cell infiltrates seen in patients with intact immune systems. Viruses such as *cytomegalovirus* and herpes simplex, when they occur on a mucosal surface, may cause necrosis and ulceration with acute inflammation. Other viruses may only elicit chronic inflammation. Areas of infarction with vascular thrombosis should suggest the possibility of *Aspergillus* or *Zygomycetes*.

In general, the host response is a reflection of the status of the patient's immune system. For example, a patient with a competent immune system forms a *caseous granuloma* around an organism such as *Mycobacterium* tuberculosis. Few organisms, if any, can be identified in these lesions. In patients with AIDS or chronic immunosuppression, well-formed granulomata usually are not found. The response may range from ill-formed collections of histiocytes to only scattered histiocytes. In these cases, abundant organisms usually are seen within histiocytes.

After developing a differential diagnosis as to the type of infectious process, the proper histologic stain can be selected. Table 58.3 lists the most commonly employed histologic stains and the organisms they demonstrate (Fig. 58.1,Fig. 58.2,Fig. 58.3,Fig. 58.4,Fig. 58.5,Fig. 58.6 and Fig. 58.7). Under ideal circumstances, these results can be correlated to positive culture results.

TABLE 58.3. COMMONLY USED HISTOLOGICAL STAINS TO DEMONSTRATE ORGANISMS IN TISSUES

Stain	Organism	Example
Hematoxylin and eosin	Viral inclusions (specifically CMV, *herpes*, adenovirus, rabies); Toxoplasma; dematiaceous (pigmented) fungi; other fungi (*Aspergillus*, Zygomycetes)	CMV (Fig. 53.1 *A*) *Herpes* (Fig. 53.1 *B*) Adenovirus (Fig. 53.1 *C*) *Toxoplasma* (Fig. 53.1 *D*)
	Demonstrates cellular response	*Aspergillus* (Fig. 53.1 *E*)
Gomori's methenamine silver nitrate (GMS)	Fungi (yeast and mycelial forms); *Pneumocystis*	*Histoplasma* (Fig. 53.2 *A*) *Candida* (Fig. 53.2 *B*) *Aspergillus* (Fig. 53.2 *C*) *Blastomyces* (Fig. 53.2 *D*)
Periodic acid–Schiff (PAS)	Fungi (yeast and mycelial forms), especially good for sporotrichosis, *Blastomyces*, and Zygomycetes	*Blastomyces* (Fig. 53.3 *A*) *Zygomycosis* (Fig. 53.3 *B*) *Coccidiodes* (Fig. 53.3 *C*)
Acid fast stains (AFB, Fite, Kinyoun)	Mycobacteria, Nocardia, (Fite—*Mycobacterium* leprae)	Mycobacteria (Fig. 53.4)
Gram	Most bacteria, including Actinomycetes Also stains fungi, especially on touch preparations	*Nocardia* (Fig. 53.5)
Giemsa (Diff-Quick)	*Ricksettsia, Pneumocystis* (will stain internal structure), fungi	*Histoplasma* (Fig. 53.6*A*) *Pneumocystis* (Fig. 53.6*B*) *Candida* (Fig. 53.6*C*)
Mucicarmine	*Cryptococcus* (mucin positive capsule)	*Cryptococcus* (Fig. 53.7)
Warthin-Starry	Spirochetes, *Bartonella* spp.	

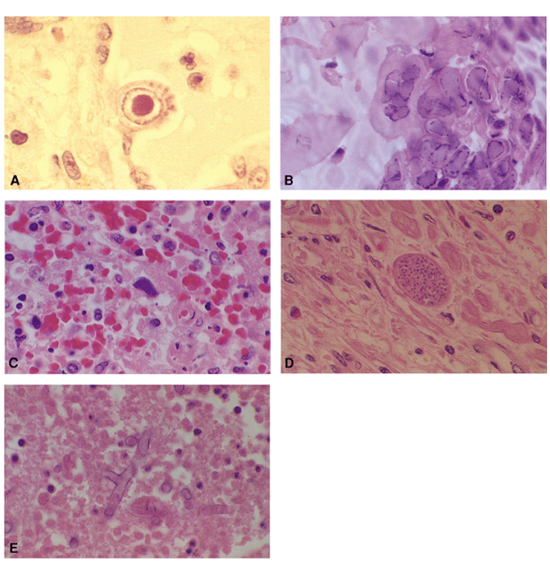

FIGURE 58.1. A: Lung tissue with characteristic “owl's-eye” *cytomegalovirus* nuclear inclusion and cytoplasmic inclusions (H&E, ×1,000, oil). **B:** Esophageal tissue with herpes virus intranuclear inclusions with multinucleation (H&E, ×1,000, oil). **C:** Lung tissue with a “smudged” intranuclear inclusion characteristic of adenovirus (center H&E, ×1,000, oil). **D:** Heart tissue with an intramyocardial *Toxoplasma* cyst (H×E, ×1,000, oil). **E:** Lung tissue with invasive *Aspergillus* (H&E, ×1,000, oil).

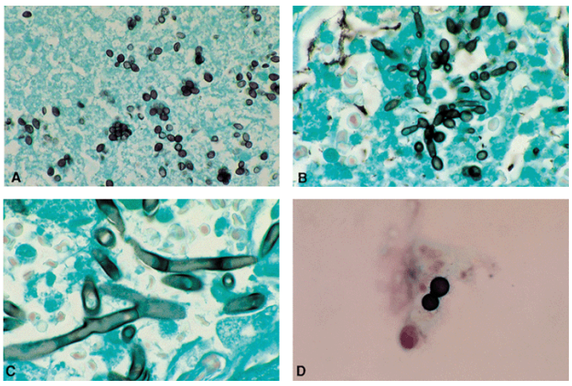

FIGURE 58.2. A: Lung granuloma with *Histoplasma* organisms (GMS, ×1,000, oil). **B:** Lung tissue with invasive *Candida* and characteristic pseudohyphae with pinching at the septae (GMS, ×1,000, oil). **C:** Lung tissue with invasive *Aspergillus* and characteristic true septae (no pinching) and 45° angle branching (GMS, ×1000, oil). **D:** Cytology bronchial specimen with broad-based bud of Blastomyces (GMS, ×1,000, oil).

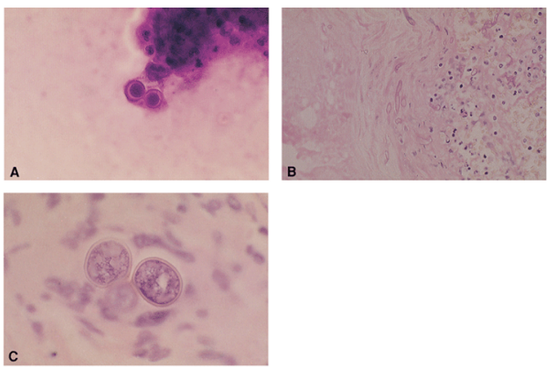

FIGURE 58.3. A: Cytology bronchial specimen with internal structure of *Blastomyces* (PAS, ×1,000, oil). **B:** Sinus vessel wall containing characteristic pleomorphic ribbon appearance and absence of septae in zygomycosis (PAS, ×2,000). **C:** Lung granuloma with *Coccidiodes*spherule (PAS, ×1,000, oil).

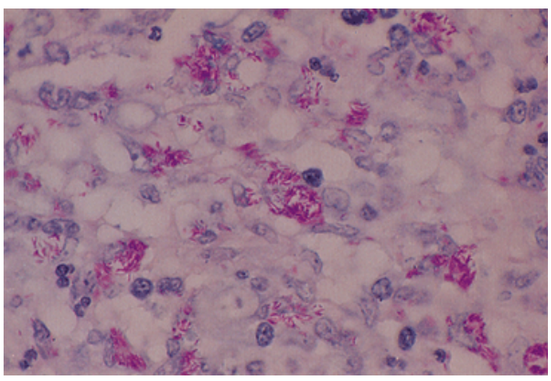

FIGURE 58.4. Lymph node tissue with acid-fast positive rods within histiocytes characteristic of *Mycobacterium avium-intracellulare* (AFB, ×1,000, oil).

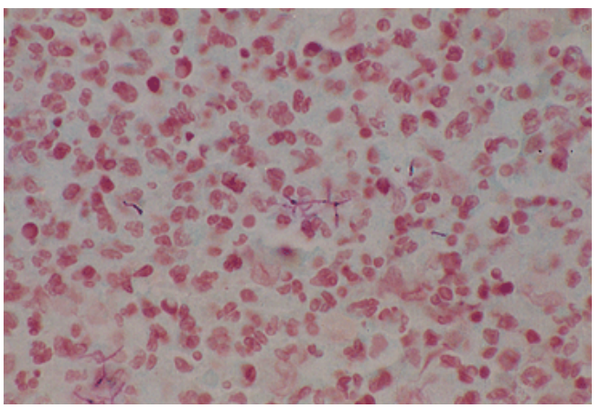

FIGURE 58.5. Skin abscess tissue with Gram-variable, right-angle branching, filamentous bacteria characteristic of *Nocardia* (Gram, ×1,000, oil).

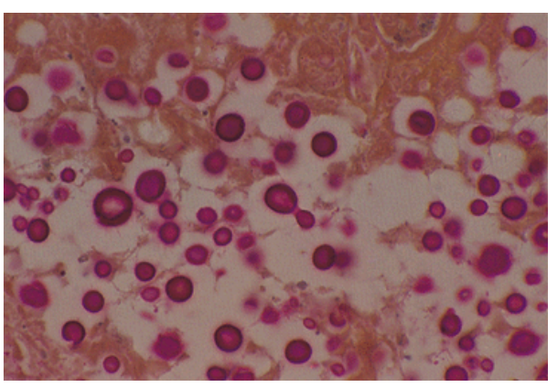

FIGURE 58.7. Liver granuloma with characteristic variably sized budding yeasts surrounded by a mucoid capsule (mucicarmine positive) characteristic of Cryptococcus (mucicarmine, ×1,000, oil).

It is important to remember that histological stains complement each other. The H&E stain provides information about the type of host response, and the Gomori methenamine silver (GMS) stain acts as a good screening tool for the presence of fungi. With the GMS stain, the fungus stains black on a green background, but host response is not demonstrated. Therefore, correlation between the GMS and H&E stains will provide information about both host response and the presence of organisms. A combination stain utilizing GMS with an H&E counterstain will provide both sets of information and, coincidentally, photographs well (Fig. 58.8).

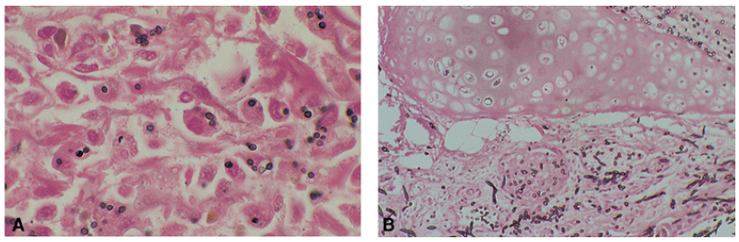

FIGURE 58.8. GMS with H&E counterstain preparation showing: **A:** *Histoplasma* organisms within histiocytes (×400). **B:** *Aspergillus* invading through bronchial cartilage (×200).

INTERPRETATION OF POSTMORTEM CULTURE RESULTS

Part of "58 - Autopsy Microbiology"

A common sense approach to the evaluation of autopsy microbiology includes the correlation between clinical history, culture results, and tissue histology. Determining which results represent contamination versus true infections can be difficult; however, when the patient's clinical history, culture results, and tissue histology are considered jointly, this job becomes much simpler. The literature indicates only fair correlation, at best, between premortem and postmortem cultures. In a study by Wood et al. (12), a positive correlation of 76% was noted when antemortem and postmortem blood cultures were compared with anatomical evidence of infection in 62 autopsy cases. In a study by Koneman and Davis (10) comparing only antemortem and postmortem cultures, the results were less inspiring; no correlation was demonstrated between antemortem and postmortem cultures in 42%, 63%, and 52% of sputum-lung, urine-kidney, and blood-heart cultures, respectively. A more recent publication by Wilson et al. (15) on the utility of postmortem blood cultures created some controversy. The results of their study of 111 autopsies reported that better than half of the positive postmortem blood cultures were from patients whose cause of death was not related to an infection. Conversely, of the 20 patients with antemortem microbemia, seven yielded the same organisms at autopsy, 10 yielded multiple contaminants, and three had blood culture isolates different than antemortem blood cultures. They believe that postmortem blood cultures rarely, if ever, provide information not previously known, or provide any pathophysiologic clarification, or detect errors in therapy or patient management. These results were subsequently challenged by Silver (16) and Nichols (17) in the Letters to the Editor Section of that journal. In practice, the degree of correlation is largely dependent on the ability of the prosector to select the correct areas to sample for culture, to use the correct technique to procure the samples, and to delineate the insignificant results from the clinically important ones. The following sections suggest an approach to the interpretation of positive culture results from blood, tissues, and fluids.

Positive Blood Cultures

1. Interpret positive cultures carefully. Could the organism be a contaminant? Some of the common contaminants in morgues include *Staphylococcus epidermidis, Streptococcus* species, *Corynebacterium* species, *Pseudomonas fluorescens/putida,* and other environmental organisms, such as *Flavobacterium* species. Contamination also is indicated if an excessive number of days (more than 5 to 7) is required for the blood culture bottle to become positive or if only one of two bottles is positive.
2. Did the spleen culture or other tissue cultures grow the same organism as the blood culture? Having the same organism cultured from multiple sites certainly strengthens an argument for sepsis.
3. Could the antemortem clinical course be consistent with sepsis? Patients with sepsis often have a rapid downward course with fever and hypotension.

Positive Tissue or Fluid Cultures

1. Were organisms demonstrated on tissue sections or on Gram stains of homogenized tissue at the time of culture? Given the large number of organisms required to be able to demonstrate even one organism histologically per high power field, it is not surprising that one is frequently unable to demonstrate organisms in tissue stains. However, if organisms that are detected in tissue or on a Gram stain from culture material correlate with the culture results, it will significantly strengthen a diagnosis of infection.
2. Is a host response present that is consistent with the proposed infection? Growth of multiple organisms in a lung culture that is confirmed by tissue Gram stain without evidence of tissue reaction or inflammation most likely indicates agonal aspiration of stomach contents and not a pneumonia. Gross findings of a consolidated lobe of lung with microscopic findings of an acute intraalveolar inflammatory infiltrate and a positive culture of *Streptococcus pneumoniae* are classic findings typical of pneumonia. Limited inflammatory responses may occur in immunosuppressed patients; in these cases, tissue responses such as cell necrosis, fibrinous exudate, and cellular atypia may be indicative of infection.
3. How well do the autopsy findings correlate with the antemortem diagnosis? For example, the isolation of poliovirus from the stool of a patient who died at age 2 of congenital heart disease may raise the question of premortem administration of polio vaccine rather than actual infection. Polio vaccine is a live attenuated vaccine, and virus can be cultured from stool for several weeks in patients receiving the oral vaccine.

By correlating the clinical findings, the autopsy histology findings, and the results of microbiological cultures, under- or overinterpretation of the findings can be avoided. Items that should definitely be addressed in the autopsy report include the confirmation of clinically suspected infections, the adequacy of antemortem antimicrobial therapy, the findings of a clinically unsuspected infection, and the inability to demonstrate a clinically suspected infection.

Methods to determine the adequacy of antimicrobial therapy may include susceptibility testing of the postmortem isolate to the antibiotic given antemortem. This information may be very important epidemiologically, especially in an intensive care unit situation in which multiple patients may be colonized or may later develop infections with the same organisms.

CONCLUSIONS

Part of "58 - Autopsy Microbiology"

The use of microbiological techniques in autopsy pathology can be an important part of the postmortem examination. Infections continue to play a major role in causing significant morbidity and mortality. The confirmation or discovery of infections at autopsy is an important duty of the pathologist. While it can be argued that at times the results of microbiological studies are more confusing than helpful, careful correlation with the patient's clinical history and microscopic pathology often clarifies difficult

cases. It is important to recall that postmortem culturing is affected by many variables, including culturing techniques, gross observational skills, adequate tissue sampling, antimicrobial therapy, possible contamination by normal flora, and the possibility that viscera may not be sterile. Thus, the finding of positive cultures should not be equated with infection unless supported by clinical and histopathological evidence. Understanding the strengths and weaknesses of postmortem culturing will help ensure that results are interpreted correctly. Although postmortem culturing has certain limitations, this should not preclude its use by pathologists.

Diagnostic Virology

Karen C. Carroll

James C. Overall Jr.

Viruses continue to be among the most intriguing and important emerging pathogens. Molecular techniques have clearly added to our understanding of viral pathogenesis and have made rapid viral diagnosis and viral quantitation possible. In addition, the past decade has seen an explosion in new antiviral therapies. All these advances should dispel myths that viral diagnosis is neither timely nor clinically useful.

In 1998, 19,916 specimens were submitted for viral culture or antigen detection to the diagnostic virology laboratory at the Associated Regional and University Pathologists, University of Utah Medical Center. Twenty percent were positive, with a mean turnaround time for positive results of 1.4 days. The 20% of specimens positive for a virus compares favorably with the 5% reported rate for positive blood cultures (1). The 1.4-day mean time to positive test results includes confirmed specific identification of herpes simplex virus (HSV), cytomegalovirus (CMV), influenza A and B viruses, respiratory syncytial virus (RSV), adenoviruses, and varicella-zoster virus (VZV) and presumptive identification of an enterovirus. The particular methods used to detect and identify these viruses are described in this chapter. For more technical detail about specific viruses, please see references 2,3,4,5,6,7,8,9,10 and 11.

Table 59.1 lists the antiviral agents [other than those used for the treatment of human immunodeficiency virus type 1 (HIV-1)] licensed for use as of 2001 and the viruses against which the drugs are active. The most recent agents to be approved are the neuraminidase inhibitors for the treatment of influenza A and B (12). Equally exciting is the agent pleconaril, currently in clinical trials, with activity against the enteroviruses (13). Note that the drugs are very selective, i.e., clinically active against only one or a few viruses. Therefore, a specific viral diagnosis must be made to select the proper drug. For more detailed information about antiviral agents, the reader is referred to references 14,15 and 16.

TABLE 59.1. LICENSED ANTIVIRAL AGENTS (NON–HIV-1)—1999

Generic Drug	Brand Name	Viruses	
		Proved	Possible
Amantidine	Symmetrel	Influenza A	
Rimantidine	Flumadine	Influenza A	
Zanamivir	Relenza	Influenza A, B	
Oseltamivir	Tamiflu	Influenza A, B	
Acyclovir	Zovirax	HSV, VZV, CMV	EBV, herpes B
Valacyclovir	Valtrex	HSV, VZV, CMV	
Ganciclovir	Cytovene	CMV	HSV, VZV, EBV, HHV-8, herpes B
Penciclovir		HSV	
Famciclovir	Famvir	HSV, VZV	HBV
Foscarnet	Foscavir	CMV, HSV, VZV including acyclovir resistant	HHV-8, HIV-1
Cidofovir	Vistide	Ganciclovir resistant CMV	Acyclovir resistant HSV, HPV
Ribavirin	Virazole	Lassa fever, hantavirus, HCV	RSV, parainfluenza, influenza A, B, measles, Sin Nombre virus
Lamivudine	Epivir	HBV, HIV	
Interferon alfa	Several	HBV, HCV, HHV-8, HPV	Hepatitis D

HBV, hepatitis B virus; HSV, herpes simplex virus; VZV, varicella-zoster virus; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV-8, human herpesvirus type 8; HIV, human immunodeficiency virus; HPV, human papilloma virus; HCV; hepatitis C virus.
Modified from references 12–16.

VALUE OF SPECIFIC VIRAL DIAGNOSIS

Part of "59 - Diagnostic Virology"

There is value in making a specific virologic diagnosis, not only for the individual patient but also for the community and hospital. For the patient, assistance in the decision to initiate antiviral therapy has already been mentioned. In addition, identification of a particular virus in a patient can result in the discontinuation of unnecessary antibiotic therapy and shorten the duration of hospitalization. For example, in the infant admitted with a diagnosis of meningitis and given oral antibiotic therapy before admission, culture of an enterovirus from the cerebrospinal fluid (CSF) can discriminate between (a) partially treated bacterial meningitis requiring as long as 10 days of hospitalization and intravenous antibacterial therapy and (b) viral meningitis, for which patients can be managed symptomatically and often discharged after a few days (17,18). Identification of a viral agent often enables cessation of unnecessary diagnostic tests (e.g., in a patient with a fever of unknown origin) and provides a more accurate prognosis, both acute and long term.

At the community level, identification of a specific viral disease (e.g., measles) can aid in the recognition of illness in subsequent patients and in the institution of preventive measures (e.g., vaccine). In the hospital setting, detection of a particular virus can allow more rational use of infection control measures. For example, influenza virus is known to be transmitted by small particle aerosol, requiring a separate room and respiratory isolation (19). In contrast, RSV is transmitted by direct contact or large droplet aerosol and needs only good hand washing (20) and use of gloves and gown (21). Diagnosis of a particular virus will enable rational use of antiviral prophylaxis in selected situations. For example, if an index case of influenza A is identified in a nursing home patient, use of amantadine or rimantadine in the other residents and staff of the facility for a 2- to 3-week period can prevent serious illness (22).

Finally, at least two studies have demonstrated the cost-effectiveness of rapid diagnosis of respiratory virus infections in hospitalized pediatric patients (23,24). A reduction in antibiotic use was seen in both studies and a decrease in hospital stay and laboratory utilization was found in the study by Woo et al. (24).

APPROACH TO VIRAL DIAGNOSIS

Part of "59 - Diagnostic Virology"

There are two major approaches to the diagnosis of a viral infection: virologic and serologic. The virologic approach includes (a) isolation of infectious virus in cell culture or in laboratory animals, (b) detection of viral antigen by immunologic methods such as immunofluorescence assay (IFA) or enzyme immunoassay (EIA), (c) identification of viral particles by electron microscopy (EM), and (d) detection of viral nucleic acid. The serologic approach includes (a) demonstration of a fourfold or greater rise in antiviral antibody using acute and convalescent sera and a variety

of methods that measure predominantly immunoglobulin (Ig) antibody and (b) demonstration of virus-specific IgM antibody in a single late acute or early recovery phase serum.

As is true for any diagnostic test, the timing, quality, and handling of the specimen are critical for an accurate diagnosis. For the virologic approach to diagnosis, it is important to obtain specimens during the acute infection from the site of disease. For example, samples collected after bacterial and fungal cultures have returned negative results and the patient has begun to recover are unlikely to yield infectious virus. A positive viral culture from a stool specimen in a patient with suspected viral meningitis (instead of CSF) may provide misleading results.

SPECIMEN COLLECTION AND TRANSPORT

Part of "59 - Diagnostic Virology"

The optimal specimens vary depending on the site of disease. Lesions that can be sampled with a swab include vesicles or ulcers on the skin or mucous membranes, the urethra, and the cervix. Several different synthetic swabs, such as Dacron or rayon, on a plastic or aluminum shaft with an accompanying transport tube are commercially available (25,26). For culture of infectious virus, calcium alginate, charcoal-impregnated swabs and swabs on wooden shafts should be avoided (8,25,26). Calcium alginate binds to the virus, rendering it noninfectious, particularly if the swab is left in the transport medium (25,26 and 27). Calcium alginate also inhibits the polymerase chain reaction (PCR) (26).

For pediatric respiratory illnesses, several investigations have shown that the nasopharyngeal (NP) aspirate or nasal wash provides a better yield of virus than a NP swab (28,29 and 30). The NP aspirate is obtained by passing a suction catheter into the posterior nasopharynx, a procedure that usually elicits coughing up secretions from the lower respiratory tract. Gentle suction is applied with a device that allows the respiratory secretions to be delivered into a trap vial or tube. If insufficient respiratory secretions are obtained, 2 mL of nonpreservative saline can be instilled in the opposite nostril, and the suction process repeated. Nasal-wash specimen collection is accomplished by aspirating 3 mL of saline into a suction bulb with a snout. The saline is instilled into one nostril and immediately aspirated back into the suction bulb. In adults, the usual recommended specimens for respiratory viruses are a throat swab or a throat wash with viral transport media (8,11). It might be, however, that a NP aspirate or nasal wash is the preferred specimen in adults also because most respiratory viruses replicate preferentially in columnar epithelial cells located primarily in the posterior NP and in the lower respiratory tract. Aspirates, sputum, bronchoalveolar lavage (BAL) samples in volumes exceeding 0.5 mL can be placed directly in a sterile container and sent to the laboratory. Volumes less than 0.5 mL should be placed into 2 to 3 mL of transport media (8).

For stool specimens, fresh stool is preferable to a rectal swab (8,11). Body fluids other than blood, such as urine specimens and CSF, should be obtained using sterile procedures. Small volumes (0.5 mL) should be placed in viral transport media.

Several viruses are present in the blood during acute infection, and isolation/detection of virus from this body fluid can be an important indicator of disease. Several viruses are associated with white cells, including CMV, HSV, HIV, and the enteroviruses (Coxsackie, echo, polio). HIV is found in lymphocytes and macrophages (31), whereas CMV is associated with neutrophils and, to a lesser extent, macrophages (32). The enteroviruses can be isolated from plasma as well as from white cells (33). The optimal blood fraction for HSV has not been well delineated. Because the particular virus being sought may not be clearly known, it may be optimal to process blood specimens to obtain both neutrophil and mononuclear cell fractions by gravity sedimentation

or by separation techniques that provide both fractions (34). There is limited direct information on the optimal anticoagulant for blood specimens: heparin, ethylenediaminetetraacetic acid (EDTA), or acid citrate dextrose. One investigation demonstrated no difference between heparin and EDTA-anticoagulated blood in the recovery of CMV (34). Recovery rates of HIV from blood were higher with EDTA than heparin-anticoagulated blood (35). Because it is also known that heparin can inactivate the herpesviruses *in vitro* (36), it seems reasonable to recommend the use of EDTA (purple top) tubes. EDTA is also an acceptable transport for molecular assays such as hybridization and PCR.

For small-volume samples and biopsies of tissues or when there is concern about labile infectivity for particular viruses (e.g., RSV or VZV), commercially available tubes or vials with transport media should be used. Ideally, the viral transport system should be isotonic, contain protein, antibiotics, and buffer to control pH and should be nontoxic to cell culture, antigen detection, and molecular assays. Two reports (37,38) evaluate the viability of frequently isolated viruses in several commercially available viral transport systems. Although several systems are comparable in terms of virus stability, Multi-Microbe Media (M-4) (MicroTest, Inc., Snellville, GA) can be used to culture chlamydia, urea plasma, and mycoplasma as well.

The optimal temperature for storage and transport of specimens for viral culture and antigen detection is 4°C (refrigerator or wet ice temperature). Most viruses will be stable for 2 to 5 days at this temperature (25,37,39). Freezing at -20°C (ordinary freezer temperature) destroys or significantly reduces infectivity of virtually all viruses. If specimens must be stored for longer than 3 to 4 days, an ultra-low temperature freezer (-70°C) should be used, and the specimen transported to the virology laboratory on dry ice.

VIROLOGIC METHODS IN VIRAL DIAGNOSIS

Part of "59 - Diagnostic Virology"

Viral Isolation

Isolation of infectious virus in tissue cell cultures remains one of the most commonly used methods to detect viruses. Because not all culturable viruses will grow in a single cell line, several different types of cells are required. The cells that may be used during the winter season to isolate respiratory viruses include primary rhesus monkey kidney, Madin-Darby canine kidney, Hep-2 (a human epithelial carcinoma cell line), buffalo green monkey kidney continuous cell line, and a human fibroblast cell. These are different from the cells used for the summer/fall enterovirus season: primary rhesus monkey kidney, Hep-2, buffalo green monkey kidney, RD (a human rhabdomyosarcoma cell line), and a human fibroblast cell. Many viruses will demonstrate a cytopathic effect (CPE) within a few days, whereas some may take as long as a week or two. Some viruses do not cause typical CPE and are identified by the adsorption of red blood cells to the surface of virus-infected cells in the culture (e.g., hemadsorption for the influenza and parainfluenza viruses). For some viruses, such as several of the Coxsackie A viruses and Colorado tick fever virus, mouse inoculation is required.

With cell culture systems, presumptive identification of a particular virus or virus group (e.g., HSV or RSV or an enterovirus) can be performed within a few or several days based on the CPE: characteristics, time of onset, and cell type in which it occurs. This presumptive identification can be greatly facilitated if the test requisition slip contains the important information requested: source of the specimen (e.g., swab of a genital ulcer or a conjunctival swab rather than an unidentified swab source) and clinical diagnosis (e.g., genital herpes, influenza, aseptic meningitis).

Confirmation of a specific virus or serotype of a virus (e.g., HSV-2, influenza A H3N2, echovirus 11) requires use of immunologic methods with antibody of known specificity. In recent years, fluorescein or peroxidase-conjugated monoclonal antibodies (MABs) have become available commercially to detect viral antigen in cell cultures, e.g., HSV (40,41,42,43 and 44), CMV (45,46,47 and 48), VZV (49), RSV (50,51 and 52), influenza A and B (53), the parainfluenza viruses (54), and the adenoviruses (55). To identify the specific serotype of influenza A or B, inhibition of hemagglutination by specific serotype antisera is used. For confirmation of a specific Coxsackie or echovirus serotype, neutralization of CPE with pools of antisera and then individual antisera is still required (56).

The technique of centrifugation of the patient specimen onto the cell monolayer on a coverslip in the bottom of a shell vial followed by staining for viral antigen with MAB after 1 or 2 days of incubation has significantly reduced the time required to detect and confirm a number of viruses (44,47,52,53,55). The centrifugation step shortens the time required for replication of the virus and production of viral antigen in cell cultures. For more slowly growing viruses such as CMV, the use of MAB against nonstructural proteins produced early in the replication cycle [i.e., immediate early antigen (EA) or EA] allows detection of virus even before CPE can be observed (47). Table 59.2 compares the times to detection for several viruses using the shell vial centrifugation/viral antigen staining (SVC/VAS) method versus conventional CPE. The time to detection and confirmation is much faster with the SVC/VAS method with every virus listed. For example, with CMV, the SVC/VAS method detects 50% of the total positives in 1 day and 90% in 2 days, whereas it requires 10 days to detect 50% with conventional CPE. Many diagnostic virology laboratories, therefore, use the SVC/VAS technique, particularly for detection of CMV.

TABLE 59.2. VIRUS IDENTIFICATION: CENTRIFUGATION PLUS STAIN VERSUS CONVENTIONAL CYTOPATHIC EFFECT

	Centrifugation + Stain		Conventional CPE	
Virus	**Days in Culture**	**Percentage Detected**	**Days in Culture**	**Percentage Detected**
HSV	1	96, 99[a, c]	1	50[b]
CMV	1	55[c]	10	50[c]
CMV	2	95[c]		
VZV	2	90[d]	5	50[d]
Adenovirus	2	97[e]	4	50[d]
Influenza	2	60[f]	4	50[e]

CPE, cytopathic effect; HSV, herpes simplex virus; CMV, cytomegalovirus; VZV, varicella-zoster virus.

The major viruses detected by isolation in cell culture include HSV, CMV, RSV, influenza A and B, the parainfluenza viruses, the adenoviruses, the enteroviruses (Coxsackie A and B, echo, polio), and VZV. Although animal isolation is rarely done at commercial diagnostic virology laboratories, this may be required to isolate some viruses (e.g., Colorado tick fever and many of the Coxsackie A viruses). Animals for isolation of viruses are available at some state health laboratories.

There are several advantages to using isolation of infectious virus as the method of diagnosis. First, a broad range of viruses can be detected. For example, from a respiratory secretion specimen, a number of different respiratory viruses can be isolated, whereas an antigen detection test may identify only one virus (e.g., RSV). Second, isolation of infectious virus makes the agent available for further characterization, such as antiviral susceptibility testing and serotyping/subtyping for epidemiologic purposes. Third, viral isolation is a sensitive and specific standard with which more rapid methods are compared.

There are also several disadvantages to viral isolation. It requires the availability of a cell culture laboratory, with the need for specialized equipment and supplies and trained personnel. Second, isolation is slower than antigen detection, with results in days rather than hours. Finally, specimen collection and transport conditions are more critical for isolation than antigen tests.

Viral Antigen Detection

Viral antigen detection tests may be performed on cell cultures for early detection/confirmation of viral antigen, such as with the SVC/VAS technique previously mentioned, or on specimens directly from patients: nasal or nasopharyngeal secretions, BAL fluids, scrapings of vesicles or conjunctivae, swabs of the cervix or urethra, stool samples, or tissue biopsies. Because viral antigen is present in cells, it is important that specimens from patients contain a sufficient number of cells. Methods to detect viral antigen may be either direct or indirect. With direct methods, fluorescein, an enzyme, or a radiolabel (the indicator system) is conjugated to the antibody used to detect the virus (primary antibody). With indirect methods, the indicator system is conjugated to a secondary antibody (e.g., rabbit anti-mouse), which in turn is directed against the primary antibody (e.g., mouse MAB). The indirect method can be constructed to react with human IgG or IgM molecules for use in antibody assays. The major indicator systems include IFA, EIA, and radioimmunoassay (RIA).

In the EIA procedure, an enzyme (e.g., peroxidase) conjugated to the detector antibody results in the change of a colorless substrate to a colored product that can be read by the naked eye or quantitated in an automated spectrophotometer. The EIA procedure can be adapted to perform (a) an enzyme-linked immunosorbent assay (ELISA) in which an unlabeled antibody (the capture antibody) is bound to a solid phase (e.g., a latex bead or the bottom of a microtiter plate well) to capture the antigen and a second enzyme-labeled antibody is added to detect the captured antigen or (b) immunoperoxidase methods to demonstrate specific viral antigen by light microscopy in tissues from biopsy or autopsy specimens or cells from viral cell cultures. Many commercial ELISA and IFA kits are available to detect viral antigen in patient specimens or cell cultures or IgG or IgM antiviral antibody.

The major viral antigens that can be detected in direct patient specimens include (a) rotavirus and enteric adenovirus in stool specimens; (b) RSV, influenza A and B, the parainfluenza viruses, and the adenoviruses in respiratory specimens; (c) hepatitis B virus (HBV) surface antigen (HBsAg) and HIV p24 antigen in serum; (d) HSV and VZV in vesicle/ulcer swab specimens; and (e) CMV in BAL specimens. The major viruses detected by the SVC/VAS method include CMV, HSV, RSV, the influenza viruses, and adenoviruses.

There are several advantages to viral antigen detection. First, specimen collection and transport conditions are less critical than for viral isolation. Second, antigen detection test results are available sooner than viral isolation, usually within hours. Third, the antigen tests can detect viruses that will not grow in commercially available cell culture systems (e.g., rotavirus, enteric adenovirus, HBV, HIV). Fourth, the antigen detection tests do not require cell culture laboratory equipment and trained personnel for performance. Finally, there may be specimens in which viral infectivity has been lost (negative viral isolation results) but antigenicity has been preserved (true antigen-positive test).

There are also several disadvantages to viral antigen detection. First, there must be a good antiserum and test kit commercially available for the virus sought in the specimen. Examples of medically important viruses for which antigen detection systems are not yet available are Epstein-Barr virus (EBV), hepatitis A and C viruses, the enteroviruses, rubella, mumps, the arboviruses, and parvovirus B19. Second, a separate antigen detection test must be performed for each virus being sought. For example, with respiratory secretions, one test must be performed for RSV, another for influenza A, still another for influenza B, and so on. Finally, depending on the particular virus and antigen detection system available, the antigen test may be less sensitive and is always less specific than viral isolation.

Electron Microscopy

EM remains an important adjunct to other viral diagnostic methods, especially for the identification of agents of viral gastroenteritis. Antigen detection tests are available for two of the three most common causes of viral diarrhea: rotavirus (57,58) and enteric adenovirus (59). Aside from research laboratory serologic tests, alternative diagnostic methods are not yet commercially available for other enteric viral pathogens such as Norwalk virus, astrovirus, calicivirus, or small round viruses and small round structured viruses (60,61). Other uses for EM include detection of polyoma viruses in urine (62,63) and herpesvirus particles in vesicle fluid (HSV or VZV) (64) or in brain tissue (HSV, CMV, EBV), among others (65). Although EM allows detection of viral particles within hours and without the use of specific reagents, there are several disadvantages. A large enough concentration of particles must be present in the specimen to allow detection, and the procedure is expensive and not widely available. More recent methods to enhance EM such as concentrating virus by ultracentrifugation and adding specific antibody to facilitate aggregation of virus particles have been described (63,66). In general, EM is useful when no other viral detection method is available and/or in institutions where there are expertise and interest in EM viral diagnosis.

Nucleic Acid Hybridization and Amplification

Advances in molecular biology in the 1980s led to the development of probe technology using recombinant DNA techniques (67,68). Initial probes were double-stranded DNA containing large numbers of base pairs that led to problems such as nonspecific binding and prolonged incubation periods (7). Since that time, single-stranded nucleic acid probes that hybridize with DNA or RNA targets in clinical samples have been developed. Standardization of hybridization techniques including commercialization of some kits has eliminated the original problems.

After extraction of nucleic acid and denaturation, detection can occur by several hybridization formats: solid phase (slot/spot/dot-blot, microwell/bead capture, Southern/Northern blots), solution phase, and *in situ* hybridization (8,68,69,70 and 71). Solid phase is similar to standard antigen-antibody ELISA formats in which the viral target is immobilized on a membrane or filter and detected by a labeled probe. Initially probes were labeled with ^{32}P, ^{35}S, or ^{131}I. However, biotin and digoxigenin have replaced the radioactive labels. Bound probe is detected by an enzyme-labeled molecule specific for biotin and digoxigenin. In some assays, the substrates are chemiluminescent and emit light, which is detected photographically or is measured by a luminometer when hybridization occurs (72).

The hybridization protection assay (HPA) is an example of liquid-phase hybridization. An oligonucleotide probe labeled with a chemiluminescent acridinium ester is incubated with target nucleic acid. The reaction is subjected to alkaline hydrolysis. Bound probe is protected from hydrolysis, which degrades unbound probe causing it to lose its chemiluminescence. After addition of peroxides, chemiluminescence is detected by a luminometer (73). This method has been developed by GenProbe, Inc. (San Diego, CA) as a means of direct nucleic acid detection or detection of amplified DNA products (74).

The hybrid capture system is a U.S. Food and Drug Administration (FDA)–approved assay produced by Digene Diagnostics, Gaithersburg, MD, which is also based on liquid phase hybridization (75). In the case of human papilloma virus (HPV) detection, DNA is extracted from cells and denatured. Two groups of RNA probes, one containing four low-risk HPV types and the other containing nine high-risk types, are added to tubes coated with alkaline-phosphatase conjugated antibody that captures the RNA/DNA hybrids. Unbound probe is enzymatically degraded. Bound probe is detected with a chemiluminescent substrate (76). Assays for CMV (77) and HBV (78) are also available.

In situ hybridization is performed by hybridizing a labeled probe to fixed paraffin-embedded tissue. An advantage to this technique is the ability to determine the distribution and amount of viral DNA because cellular architecture is preserved. Limitations include cost and complexity of the procedure. Kits for detection of HPV DNA in tissues by *in situ* hybridization are available from several commercial sources.

Probe technology has most often been applied to detection of DNA viruses. However, there are some problems with DNA probe technology. In the absence of some form of amplification, such as PCR, the concentration of viral genomes in direct patient specimens is too low to allow detection with adequate sensitivity. For example, the commercially available probes for HSV and CMV detected only 70% to 90% of virus isolation–positive specimens (40,79).

The remarkable development of PCR technology (80,81,82 and 83), has allowed 10^5- to 10^6-fold amplification of a defined segment of a viral genome (the target). Nucleic acid amplification techniques have exploded in the past decade and are rapidly becoming the diagnostic tests of choice for many viral syndromes. A detailed discussion is beyond the scope of this chapter, and the reader is referred to other chapters in the text and to several reviews (68,69,84,85 and 86).

Amplification techniques can be categorized as (a) target amplification (PCR, transcription–mediated amplification, strand displacement, sequence based amplification); (b) probe amplification (ligase chain reaction, Qβ-replicase); and (c) signal amplification (branched-chain DNA). All techniques involve isolation and denaturation of viral nucleic acid, amplification step(s) and amplicon detection. Commercial assays are available for detection and quantification of hepatitis C virus (HCV) (84,87,88) and HIV-1 (89,90 and 91) and for the detection of nonviral diseases such as chlamydia, gonorrhea, and tuberculosis. For many viral illnesses, “home brew assays” are available in research and reference laboratory settings. Rigorous attention to contamination control is essential and there are evolving guidelines for standardization and quality control (92,93). Interlaboratory performance of these noncommercial assays, however, may vary substantially (94). In addition, clinicians should become aware of some inherent problems with nucleic acid detection, such as false-positive results related to contamination of reagents, samples, and carry-over of amplified product. False-negative results may be owing to the presence of inhibitors, inadequate or poor specimen quality, or poor nucleic acid extraction techniques. In addition, for some diseases, the assays are too sensitive because of indiscriminate detection of dead or live organisms and asymptomatic shedding of some latent viruses.

Despite the above, nucleic acid detection methods are superior to existing diagnostic methods and have emerged as the tests of choice for diagnosis of central nervous system (CNS) infections caused by the herpes viruses and enteroviruses (95,96). The tests are more sensitive and provide more rapid results. Detection of HCV and HIV before seroconversion is another important application (87,89). Finally, quantification of virus (viral load) has provided useful prognostic and therapeutic information in the management of patients with HCV (88), HBV (97), and HIV (90,91) as well as CMV in the susceptible immunocompromised host (98,99). Future technologies will provide improvements in nucleic acid extraction techniques, automation and ability to coamplify multiple targets in a single reaction (84).

SEROLOGIC METHODS IN VIRAL DIAGNOSIS

Part of "59 - Diagnostic Virology"

There are two major uses for serologic methods in viral diagnosis: (a) to diagnose a current or recent acute viral infection and (b) to determine susceptibility or immunity to a particular virus (e.g., VZV in a negative history health care worker exposed to a patient with chickenpox). Measurement of IgG antiviral antibodies is used to determine immunity, whereas quantitation of IgG or IgM antibodies can diagnose current or recent infection. Older serologic methods, such as neutralization, complement fixation (CF), or hemagglutination inhibition (HI), measure only IgG or total antibodies, whereas the newer techniques, such as IFA or ELISA, can be modified to detect either IgG or IgM.

From a clinical or virologic standpoint, there a several situations in which a serologic diagnosis is necessary or more useful than the virologic approach. First, the infectious virus or viral product (antigen, nucleic acid) is not readily available from the patient. A good example would be arbovirus infections of the CNS, in which viremia has cleared by the time the patient presents with encephalitis, and clinicians prefer not to perform a brain biopsy to define the etiologic agent. Second, specimens from the patient that contain virus are available, but the virus will not grow or is difficult to grow in cell culture and tests for viral antigen or nucleic acid are not readily available. Good examples include EBV, hepatitis A (HAV), rubella, and parvovirus B19. Finally, serologic tests are more useful when the incubation period is prolonged (e.g., 3 to 6 weeks) and antibody is already present in the circulation when the patient presents with illness, such as occurs with EBV and CMV mononucleosis and viral hepatitis.

Figure 59.1 shows a typical antibody response to acute measles. A similar response would be expected with virtually any acute, short incubation period (i.e., several days to 2 weeks) viral illness. At the onset of the rash or other symptoms, antibody is undetectable or in low titer. Within 10 days to 2 weeks, appreciable titers of antibody are detectable. With older serologic assays that measure IgG antibody, such as HI or CF, a fourfold or greater rise in titer between acute and convalescent sera (e.g., less than 1:8 to 1:256) enables a diagnosis of measles.

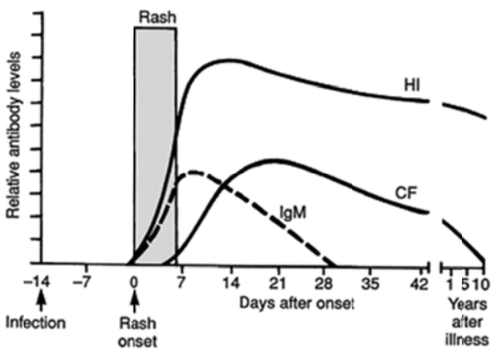

FIGURE 59.1. Antibody responses during acute measles. HI, hemagglutination inhibition antibody; CF, complement fixation antibody. (From Centers for Disease Control. Measles: United States. *MMWR Morb Mortal Wkly Rep* 1982;31:402.)

With IgG antibody assays, a fourfold fall in titer is presumptive evidence of a relatively recent infection, whereas unchanging low titers would be evidence against recent infection and indicate infection in the past (immunity). The presence of high titer antibody in a single convalescent phase serum specimen is not usually sufficient to enable a definitive diagnosis. Note that CF antibody titers rise later, reach lower levels, and may disappear several years after the acute illness. Alternatively, the presence of measles-specific IgM antibody in a single serum obtained 1 to 2 weeks after onset of illness also enables a diagnosis of measles. Typically, the IgM antibody disappears from the serum within a few weeks to a few months after the acute illness.

Many laboratories are now using ELISA kits to measure antibody titers. Results are reported in optical density units rather than dilutions of serum (e g., 1:8, 1:256). The OD units may vary, depending on the particular ELISA kit used and the given virus. To interpret results, therefore, reference range units must be provided by the performing laboratory: no detectable antibody or negative, low, mid, or high positive.

The traditional dogma about the IgM test is that a positive result on a single serum specimen obtained during convalescence is diagnostic of a current or recent infection. Importantly, however, there can be false-positive and false-negative results. False-positive results can occur when there is cross-reactivity, particularly among the herpesviruses (100). Another major factor causing false-positive results is the presence of rheumatoid factor (RF) in the serum (101,102). RF is an IgM antibody that binds to the Fc portion of IgG. So if RF and specific IgG antibody are present in the same serum sample, the IgG binds to the viral antigen and the IgM RF to the IgG, giving a positive test result. Because of the known false-positive IgM test results from RF, several of the commercially available kits either contain or offer reagents that will remove IgG from the serum. With some viruses (e.g., EBV), IgM antibody can persist in the serum of some patients for several months after the acute illness (103). Finally, with viruses known to cause latent infection (e.g., HSV and CMV), reactivation can result in the production of IgM antibody (104,105). So, in these latter two examples, the presence of IgM antibody can represent acute infection months earlier or reactivated latent infection, rather than an acute, recent, primary infection.

False-negative IgM tests can occur because of no or a low IgM response or a delay in the IgM response, particularly in the immunologically immature host (e.g., the neonate with congenital CMV or HIV infection) or in immunosuppressed patients (e.g., HIV-infected patients) (105,106 and 107). False-negative IgM tests can also occur when high-titer IgG antibody in the serum binds to all the viral antigen sites in the kit and prevents adsorption of IgM molecules (competitive inhibition) (101). In summary, although IgM tests may be very useful in the diagnosis of an acute viral infection, both positive and negative results must be interpreted with caution.

The major viruses for which serologic tests provide the most useful or only means for diagnosis of acute infection are listed in Table 59.3.

TABLE 59.3. MAJOR VIRUSES–SEROLOGIC DIAGNOSIS

Virus	Test	Comment
EBV	Monospot; VCA IgM	Nucleic acid detection in research labs
Hepatitis A, B, C, D	ELISA tests IgG, IgM; RIBA confirmation for C	Antigen tests for B, D; qualitative, quantitative nucleic acid detection assays for B, C
Measles, rubella mumps	ELISA tests IgG, IgM	Culture available
Arbovirus	IgG tests	Nucleic acid detection in research labs
Parvovirus B 19	IgG, IgM tests	Nucleic acid detection in research labs
Respiratory viruses	IgG tests	Useful when antigen and culture negative
HIV	ELISA tests; confirmatory Western blot assays	Antigen; Nucleic acid detection methods useful for newborns, acute seroconversion and monitoring viral load
Hantavirus	IgM, IgG tests	Nucleic acid detection in research labs

EBV, Epstein-Barr virus; VCA, viral capsid antigen; Ig, immunoglobulin; ELISA, enzyme-linked immunosorbent assay; HIV, human immunodeficiency virus.

When using IgG antibody tests to determine susceptibility or immunity to a particular virus, it is important to use the most sensitive method to detect antibody. As shown in Fig. 59.1, CF antibody titers are much lower than HI levels and may disappear after several years. Therefore, no detectable CF antibody may not indicate susceptibility. Studies on patients with VZV infections (108) demonstrated this finding.

Some major advantages of serologic diagnosis of viral infections are that the serum is easy to obtain, the serologic tests are widely available, and the specimen can be transported easily. Some major disadvantages are that tests for IgG antibody require acute and convalescent sera, tests for IgM antibody can have false-positive and false-negative results, and, most important, there is usually a delay of 2 to 3 weeks before a diagnosis can be made with short incubation period infections.

OPTIMAL TESTS FOR SPECIFIC VIRUSES

Part of "59 - Diagnostic Virology"

Table 59.4 lists the medically important viruses, together with the recommended tests for viral diagnosis, for (a) acute infection diagnosis—appropriate specimens, the optimal test for rapid and accurate results, and the usual turnaround time and (b) determination of immunity—the preferred antibody assay. The recommended test for diagnosis of acute infection takes into account the shortest turnaround time with acceptable sensitivity (greater than 90%) and specificity (greater than 95%). In general, tests for detection of viral antigen or viral isolation are preferred because of the shorter turnaround time. Serologic tests are used when isolation/antigen detection tests are not available.

TABLE 59.4. MOST RAPID, EXPEDIENT, SENSITIVE, AND SPECIFIC TEST FOR VIRAL DIAGNOSIS

	Diagnose Acute Infection				
Virus Group Virus	Specimen	Test	Time[a]	Determine Immunity[b]	Comments
Herpesviruses					
Herpes simplex virus	Vesicle/ulcer/eye/NP/mouth swab, WBCs, tissue biopsy	Culture in shell vial	16 hr	ELISA FA	Encephalitis-nucleic acid detection becoming standard
	CSF	Nucleic acid detection	6-8 hr		
Cytomegalovirus	Urine, BAL; NP aspirate, tissue biopsy	Culture in shell vial	24-48 hr to 10 d	ELISA FA	Asymptomatic shedding vs. infection
	WBCs	Antigenemia	4-5 hr		
	CSF	Nucleic acid detection	6-8 hr		
Epstein-Barr virus	Serum	Monospot, VCA IgM	1-2 d	VCA	May need to repeat test
Varicella-zoster virus	Vesicle/ulcer swab	Antigen detection by FA	2-4 hr	ELISA, FAMA	CF antibody low sensitivity to determine immunity
		Culture in shell vial	3 d		
Human herpes virus type 6 (HHV-6)	Serum	Anti-HHV-6 IgM	1-3 d	ELISA	
Human herpes virus type 7 (HHV-7)	Serum	Anti-HHV-7 IgM	1-3 d	ELISA	
Human herpes virus type-8 (HHV-8)	Tissue	Histopath			

Respiratory viruses					
Respiratory syncytial virus	NP aspirate Trach aspirate Throat swab	Antigen ELISA DFA Culture	4 hr 6 d	ELISA	Multiplex PCR assay available as RVO assay (Hexaplexi Prodesse, Inc., Wau Kesha, WI)
Influenza A, B	NP aspirate Trach aspirate Throat swab	Antigen DFA Culture	3 hr 7 d	ELISA HI	
Parainfluenza 1, 2, 3	NP aspirate Trach aspirate Throat swab	Antigen DFA Culture	3 hr 7 d	ELISA HI	
Adenovirus	NP aspirate Trach aspirate Throat/eye swab	Culture Antigen DFA, ELISA	7 d 3 hr	ELISA	
Hepatitis viruses					
Hepatitis A (HAV)	Serum	Anti-HAV	2 d	Anti-HAV IgG	Culture not available
Hepatitis B (HBV)	Serum	HBsAG, anti-HBc IgM	2 d	Anti-HBVs	
Hepatitis C (HCV)	Serum	Anti-HCV, ELISA, confirmatory immunoblot	2 d		Quantitative RT-PCR and genotyping useful in patient management
	Serum, EDTA-plasma	RT-PCR	2-5 d		
Hepatitis D (HDV)	Serum	HDV antigen Anti-HDV IgM	2 d		
Hepatitis E (HEV)	Serum	Anti-HEV IgM ELISA			No antibody tests licensed in U.S.
Gastroenteritis viruses					
Rotavirus	Stool	Antigen, ELISA latex	3 hr		Culture not available
Enteric adenovirus	Stool	Antigen, ELISA	3 hr		
Norwalk (SRSV)	Stool	EM	No fixed time period		EM, research ELISA available in some centers
Astroviruses	Stool	EM	No fixed time period		EM only available in some centers
Enteroviruses					
Coxsackie	NP/throat swab, stool	Culture	3-5 d	Neutral	
Echo	WBCs,			antibody	
Polio	CSF	RT-PCR	6-8 hr		
Measles	Serum	Anti-measles IgM, IgG	2 d	ELISA, IFA	Culture available but time consuming
Rubella	Serum	Anti-rubella IgM, IgG	2 d	ELISA, IFA	Culture difficult, time consuming
Mumps	Serum	Anti-mumps IgM, IgG	2 d	ELISA IFA	Culture available but time consuming
Human Immunodeficiency (HIV)	Serum	Anti-HIV ELISA Western immunoblot	2 d 2 d		PCR for proviral DNA, p24 antigen useful for acute disease and neonatal evaluation
	EDTA-plasma	RT-PCR quant (viral load)	2-3 d		
Arbovirus	Serum	Antibody CF	2-5 d	IFA CF	Paired acute and convalescent sera required; PCR available in some centers
Colorado tick fever	Blood clot	Culture:mouse inoculation IgG paired sera	2 wk 2-3 d	Research	Available in state labs; culture is most sensitive, serology, DFA on blood smears less sensitive
Parvovirus B 19	Serum Periph WBCs	Anti-parvo IgM PCR	2-3 d	ELISA, RIA	
Hantavirus	Serum	IgM, IgG	1-2 d		Available in most state labs

[a] Mean time from receipt of specimen in the lab to positive result.

[b] Serum specimen for IgG antibody, using the test method indicated.
NP, nasopharyngeal; WBCs, peripheral white blood cells; ELISA, enzyme-linked immunosorbent assay; FA, immunofluorescence assay (DFA direct FA; IFA, indirect FA); CSF, cerebrospinal fluid; BAL, bronchoalveolar lavage; VCA, viral capsid antigen; Ig, immunoglobulin; FAMA, immunofluorescence assay against membrane antigen; HI, hemagglutination inhibition; HBsAg, hepatitis B surface antigen; HBC, hepatitis B core; EDTA, ethylenediaminetetraacetic acid, anticoagulated peripheral blood for culture of white cells (buffy coat); RT-PCR, reverse transcriptase polymerase chain reaction; EM, electron microscopy; SRSV, small round structured viruses; CF, complement fixation.

With many viral infections, isolation in cell culture has been considered the gold standard. In many publications, therefore, sensitivity and specificity of antigen detection tests have been calculated based on the assumption that the viral isolation data are correct (100% sensitive and 100% specific). However, this may not always be the case because specimen collection, storage, and/or transport conditions may not have been optimal with resultant loss in viral infectivity but preservation of antigenicity. Assuming viral isolation results are the gold standard, therefore, would overestimate the sensitivity of isolation but underestimate the sensitivity of antigen detection. In the results summarized for individual viruses that follow, there has been an attempt (where the reporting of the data allows) to determine total true positive specimens: virus isolation positive plus virus isolation negative but two antigen detection tests positive (e.g., DFA and ELISA). True negative specimens would be the remainder of the samples. Sensitivity and specificity calculations are based on the true positive and true negative specimens.

Although few commercial amplification assays are FDA approved, data supporting their use are available as mentioned previously. Where appropriate, this information has been added to Table 59.4.

Herpes Simplex Virus

The major illnesses associated with HSV are herpes gingivostomatitis (primary oral), herpes labialis (recurrent oral), primary and recurrent genital herpes, primary and recurrent herpes conjunctivitis/keratitis, herpes encephalitis, and neonatal herpes. Most lesions can be sampled with a swab: vesicles or ulcers on the skin or mucous membranes, inflammation of the conjunctiva, cervix, or urethra. Other samples include buffy coat when viremia is suspected (e.g., neonatal herpes, disseminated disease in immunosuppressed hosts), CSF in meningitis complicating primary genital herpes and in neonatal herpes, and tissue biopsies in selected situations. With mucocutaneous vesicles or ulcers, it is important to sample lesions as early as possible in the course of the lesion (109). In our diagnostic virology laboratory, use of the SVC/VAS method with mink lung cell enables detection by the next day (16 to 24 hours) of 96% of the culture positives, with 100% specificity, compared with total cultures positive by CPE over 5 days (44; K. C. Carroll and J. C. Overall, Jr., unpublished observations). Other supportive cell lines include MRC-5, WI-38, rhabdomyosarcoma cells and primary rabbit kidney cells. Routine CPE in a sensitive cell line detects 50% of the positives in 24 hours; 80% in 48 hours; and 95% at 72 hours (110). A novel genetically engineered baby hamster kidney cell line, BHK21ICP6/LacZ (ELVIS, BioWhittaker, Inc., Walkersville, MD), which utilizes a histochemical ß-galactosidase assay, is reported to have a 100% sensitivity for HSV- 1 and -2 detection within 16 to 24 hours compared with detection of positive CPE (111). These cells are specific for HSV and are more costly than typical SVC. Regardless of the chosen culture method, it must be remembered that culture is not 100% sensitive. In a study of genital herpes lesions, culture was 80% sensitive, whereas DFA on cells scraped from the base of lesions was 79% sensitive (112). Both were 100% specific.

Antigen detection systems that can provide results within hours have been marketed. Sensitivity is approximately 80% and specificity 100% compared with culture (113,114). Unfortunately, results with asymptomatic shedding and resolving lesions that contain less virus are not as promising (60% to 75% sensitivity), so these kits would be less useful in situations in which there is a genuine need for rapid and accurate testing for HSV. For example, sampling vaginal secretions at the time of labor assists in decisions about cesarean section to prevent neonatal herpes.

HSV is the most common cause of acute sporadic encephalitis in the United States. In untreated patients, the mortality rate is greater than 70%, and severe neurologic sequelae occur in more than 95% of survivors (115,116 and 117). Intravenous acyclovir therapy has a reduced mortality rate of 30% with 50% of survivors recovering normally (115). Patients with herpes simplex encephalitis (HSVE) typically have focal neurologic clinical features or evidence of focal temporal lobe lesions on neurodiagnostic studies. However, approximately 50% of patients who present with focal disease have diagnoses other than HSVE (e.g., stroke, brain tumor, enteroviral meningoencephalitis, tuberculous meningitis) (118,119).

Diagnosis of HSVE in the past has been problematic. Routine virologic studies of CSF have not been rewarding. HSV has been isolated from only 4% of CSF specimens from patients with biopsy-proven disease (65). Studies examining altered CSF/serum anti-HSV antibody ratios (65,120,121,122 and 123), HSV-specific IgM in the CSF (122), antibody against HSV-1 glycoprotein B in CSF (124,125), and HSV-1 antigen in CSF (126) have yielded results diagnostic of HSV infection of the CNS, but CSF specimens obtained very early in the course of illness were unlikely to be positive. In general, CSF samples obtained 10 days to 2 weeks into the illness were required to have positive results in the majority of patients. Until recently, the most definitive means for establishing a diagnosis of HSVE has been brain biopsy of the involved site with isolation of infectious virus or demonstration of viral antigen (65). Most clinicians opted for empiric acyclovir therapy without a biopsy unless the clinical and neurodiagnostic studies were atypical or the patient worsened on therapy. PCR now provides a noninvasive, rapid, sensitive, and specific assay for diagnosis of HSVE (95,127,128,129,130,131,132,133,134 and 135). Oligonucleotide primers are employed that amplify gene segments from HSV-1 and -2. Although techniques vary among laboratories, amplification of viral DNA is emerging as the gold standard for diagnosis of this disease, as well as neonatal herpes and herpes keratitis. Overall sensitivity and specificity of numerous published studies are 96% and 99%, respectively (132). Quantification of virus may also have prognostic significance and may be useful to monitor response to therapy. In one study, patients with more than 100 copies of HSV DNA per microliter had more severe disease than patients with lower viral loads (133). In addition, mild or atypical cases of HSVE have been increasingly recognized as a result of amplification tests. In a study by Fodor et al. (134), 17% of HSVE patients had mild or atypical disease. Observations included absence of focal findings, subacute course, and initial normal CSF parameters or computed tomography scan. Patients with mild or atypical diseases were more likely to be immunocompromised or to have disease of the nondominant temporal lobe (134). A consensus report providing a strategy for optimal use of PCR in combination with intrathecal antibody measurement is provided in reference 135.

A recent study by Tebas et al. (132) evaluated the cost-effectiveness and patient outcomes of PCR versus empiric acyclovir therapy. When used in conjunction with careful clinical assessment, PCR can lead to good patient outcome and can help decrease costs associated with reduction in acyclovir usage (132).

Although HSV antibody can be demonstrated in the serum of patients who have recovered from primary infection, it has little relevance as a measure of immunity because of latency and reactivation in recurrent lesions of the lips, genitalia, eyes, and other skin sites (136). Conversely, studies of HSV-2 type-specific antibody (directed against glycoprotein G, a type-specific antigen) have provided important information about the frequency of and risk factors for infection with this virus, and the likely occurrence of asymptomatic primary infections (137). Importantly, commercially available IFA and ELISA antibody assays, even when tested against HSV-1 and HSV-2 antigens, do not discriminate cleanly among individuals infected with HSV-1 only, HSV-2 only, or both viruses (138,139). HSV-2 type-specific antibody assays could be used to screen at-risk pregnant women; those seropositive could be tested at the time of labor for shedding of HSV-2 in vaginal secretions (137).

Cytomegalovirus

Significant clinical disease with CMV usually occurs only in immunologically immature hosts (congenital CMV disease) or immunosuppressed patients (pneumonitis, chorioretinitis, colitis, hepatitis) (140,141). Because CMV can be shed asymptomatically for months to years after primary infection (140) and can be reactivated asymptomatically during periods of immunosuppression (142), it is important to be able to distinguish between such asymptomatic shedding and true CMV disease. The major sites for asymptomatic shedding are urine, cervical secretions, semen, and, to a lesser extent, saliva and respiratory secretions (143). Although higher titers of virus are generally present during disease than during asymptomatic shedding, there may be considerable overlap. Therefore, quantitation or semiquantitation of the amount of CMV present in clinical specimens can be helpful (but not absolute) in the diagnosis of CMV disease (144).

The only situation in which isolation of CMV from urine is of undisputed diagnostic value is specimens obtained from neonates during the first several days of life as evidence of congenital infection. In virtually all other situations, it is not possible to be certain whether CMV in urine represents primary infection, reactivation disease, or asymptomatic shedding. Hence, other types of clinical samples have been assessed to determine suitability for predicting CMV disease: BAL specimens, peripheral white blood cells (buffy coat), and plasma.

In immunosuppressed patients, such as organ transplant recipients or patients with the acquired immunodeficiency syndrome (AIDS), diffuse pneumonitis is a frequent opportunistic infection associated with appreciable mortality and morbidity (145,146). Etiologic agents include CMV, *Pneumocystis carinii*, HSV, the respiratory viruses, *Legionella pneumophila*, and a number of other bacterial and fungal agents. Because each agent requires different antimicrobial therapy, it is important to define the etiology. Ganciclovir (GCV) is indicated for treatment of CMV disease in immunosuppressed patients, and therapy of CMV pneumonitis with GCV in combination with CMV hyperimmune intravenous immune globulin (IVIG) has been successful in some centers (147,148,149 and 150). Because GCV has significant adverse effects (151), it is important to determine whether CMV in respiratory secretions represents lung disease or asymptomatic shedding.

Most medical centers perform BAL as the diagnostic procedure of first choice for defining the etiology of pneumonitis in immunosuppressed patients. Centrifugation culture of BAL has reported sensitivities of 70% to 95%, approximating that of culture of lung tissue (144,146,150,152). However, CMV may be isolated in the absence of disease in as many as one third of patients (150). PCR for detection of CMV in BAL samples is more sensitive than virus isolation (150,153). A negative result by PCR strongly supports another etiology for the pneumonia (153). However, the positive predictive value of PCR is low (153). A combination of PCR and immunostaining of alveolar cells may improve the specificity of PCR (150,153). Quantification

of virus in BAL holds promise in solid organ transplant recipients (150,154), but there was no correlation between virus load and pneumonia in bone marrow transplant recipients in one study (155).

As a practical matter, clinicians will administer GCV to severely immunosuppressed patients (such as bone marrow transplant recipients) with pneumonitis and positive CMV cultures from BAL specimens because the adverse consequences of withholding therapy in the presence of true CMV disease are unacceptable. Because mortality of CMV pneumonitis is so high despite GCV therapy, strategies to prevent infection have become the standard of care among bone marrow transplant and solid organ transplant programs (150). Antiviral prophylaxis in the form of either high-dose acyclovir or GCV is given in various regimens within the first 100 days posttransplantation (145,150). Such extensive prophylaxis regimens are costly and not without side effects. A preferred strategy by some programs is the use of early or preemptive therapy based on the detection of CMV infection and treating it before disease is apparent.

In several studies, isolation of CMV from buffy coat has been useful as a predictor of future CMV pneumonitis in organ transplant recipients (142,155). However, there may be both false-negative and false-positive results. For example, in renal transplant recipients, viremia was present in only 67% of patients with CMV disease and was found in 12% of subjects without disease (156,157). Certainly, the correlation of CMV isolation from blood with disease is much better than isolation from throat swabs or urine (142), and the association may be stronger in patients with more severe immunosuppression (e.g., bone marrow and cardiac transplant recipients, AIDS patients) (141,142). Because CMV is found mainly in neutrophils and, to a lesser extent, in monocytes (32), it is important to use leukocyte separation procedures that recover both neutrophils and mononuclear cells (34) in efforts to isolate CMV from the buffy coat. The drawback to using even rapid culture techniques (SVC/VAS) is that a proportion of patients develops disease simultaneously with the appearance of CMV in surveillance cultures.

More recently, investigators demonstrated the diagnostic value of antigenemia or the detection of CMV DNA by PCR as the prompt for beginning antiviral prophylaxis (98,99,158,159,160,161,162 and 163). These techniques are reviewed extensively by Boeckh and Boivin (158). The antigenemia test consists of direct staining of polymorphonuclear neutrophils from the peripheral blood of patients with monoclonal antibodies directed against the lower matrix protein pp65 (99,158,164). Results are reported as the number of antigen-positive cells compared with the number of cells used to make the slide. Quantitation of antigenemia provides an assessment of CMV viral load and seems to correlate well with the results obtained by quantitative PCR (158). Antigenemia has the advantages of a short processing time and some standardization compared with PCR assays and is amenable to testing in a routine clinical laboratory. The disadvantages include the need to process specimens in a timely manner because of loss of leukocyte viability (165), its time-consuming steps, and the difficulty in performing in the early transplant period when the patient is neutropenic. Commercial quantitative amplification assays are in development but none are yet FDA approved (99,158). Numerous studies demonstrate a correlation between high CMV viral load as detected by antigenemia or PCR and a greater risk of progression to disease, especially in HIV-infected patients and solid organ transplant recipients (98,99,161,166,167,168 and 169). However, the threshold for significance may vary depending on the type of transplant and other factors, such as graft versus host disease in the allogeneic bone marrow transplant patient, in whom any detectable level of CMV may be significant. CMV viral load detection may also be useful in monitoring response to therapy. More studies are needed to assess treatment strategies based on quantities of virus in different patient settings.

Testing for CMV IgG antibody has not been particularly useful in the diagnosis of acute or reactivation infection because of the delay in results: seroconversion takes several days to a few weeks after onset of illness (170). In immunologically immature hosts or immunosuppressed patients, the CMV IgM response during acute infection may also be delayed or may not occur at all. For example, CMV IgM antibody was present in the serum of only 70% of neonates proven to be congenitally infected by demonstration of viruria during the first few days of life (105).

The major uses of CMV serology in diagnostic virology laboratories, therefore, appear to be to (a) determine susceptibility or immunity in exposed or potentially exposed health care workers (170) or day care center personnel (171), (b) identify CMV seronegative blood donors for high risk patients (e.g., premature neonates, organ transplant recipients), and (c) to diagnose CMV infections in organ transplant recipients who were seronegative before transplant (172,173). Several of the commercially available ELISA or fluorescence-based IgG tests have acceptable sensitivity and specificity for this use (174,175,176 and 177).

Epstein-Barr Virus

The mainstay in the diagnosis of EBV infections is the Davidsohn modification (178) of the original Paul-Bunnell heterophile antibody test (179). During recovery from EBV infectious mononucleosis (IM), IgM antibodies are produced that react with sheep red cells and cause agglutination. The Davidsohn modification demonstrates differential absorption: IM-associated heterophile antibodies are adsorbed by beef red cells but not guinea pig kidney cells. More recent modifications of the heterophile antibody test employ horse or beef red blood cell antigens, which are more sensitive and specific (103) and are attached to latex or other particles and constructed in a slide or card test format (180,181).

Heterophile antibodies occur in approximately 85% of patients with the IM syndrome (182,183) and usually disappear in a few weeks to a few months. Responses may be delayed in some individuals (182), thus repeat testing may be required to confirm the diagnosis. Importantly, the heterophile test is negative in 70% to 80% of EBV infections in children younger than four years of age (184,185), therefore EBV-specific antibody tests are required for accurate diagnosis in this age group. Also important is the fact that sheep or horse red blood cell heterophile antibodies may persist for more than a year after acute illness in 20% to 70% of patients (103). This persistence of heterophile positivity can result in the erroneous diagnosis of recurrent or chronic IM. In cases of heterophile-negative mononucleosis, CMV is the cause in 70% and

EBV (proven by EBV-specific serology) in 16%, whereas rubella virus, *Toxoplasma gondii*, and adenovirus are rare causes (186).

In several situations, EBV-specific serologic tests may be necessary: (a) when heterophile antibody testing is negative in patients with clinical IM and EBV disease is strongly suspected, (b) in children younger than 5 years of age with IM in whom the heterophile test is insensitive, and (c) where the clinical picture of IM is atypical (182,187).

The following EBV-specific antibody tests are commercially available: IgG and IgM against viral capsid antigens (VCA), anti-EA, and anti-Epstein-Barr nuclear antigen (EBNA). The kinetics of the response to these antigens are shown in Fig. 59.2. The most useful test in the diagnosis of acute IM is VCA IgM; it appears soon after the onset of symptoms, disappears after a few weeks to months, and is 91% to 98% sensitive and 99% specific in the diagnosis (103,182). VCA IgG antibody titers are already elevated when patients become ill and persist for life and therefore are less useful for diagnosis of acute infection. Anti-EA antibodies rise early and disappear in a few months, whereas anti-EBNA appears late and persists for life in individuals who recover. Therefore, in the individual who recovers from IM and is several months post acute illness, there would be moderate antibody titers to VCA IgG and EBNA but low to absent titers against VCA IgM and EA (188).

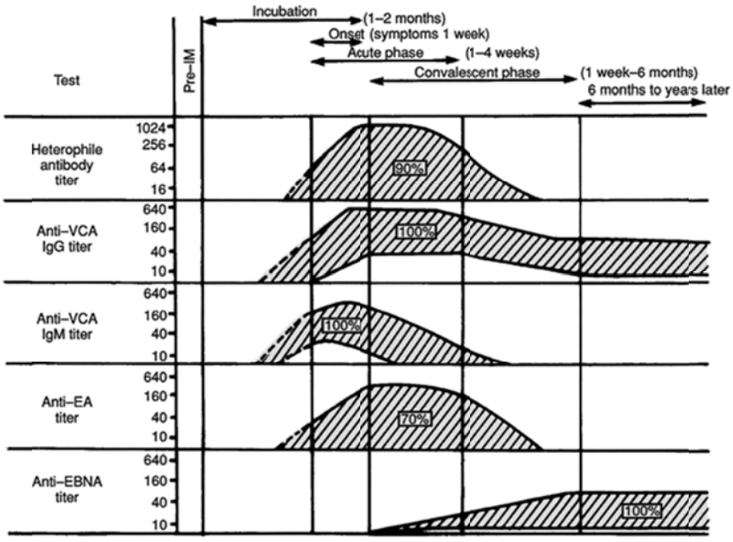

FIGURE 59.2. Antibody responses during EBV-induced infectious mononucleosis. (Modified from Sullivan JL. Epstein-Barr virus and the x-linked lymphoproliferative syndrome. *Adv Pediatr* 1983;30:365.)

In 1985, two papers described what was called the chronic mononucleosis syndrome (189,190). EBV was implicated as a cause based on (a) very high VCA IgG titers, (b) absent to low VCA IgM, (c) high anti-EA, and (d) absent to low anti-EBNA. Subsequent studies demonstrated that EBV plays little or no etiologic role in this chronic fatigue syndrome (CFS) (191,192,193,194 and 195). Many otherwise normal individuals have EBV antibody titers similar to those originally described in chronic mononucleosis (191), and most individuals with CFS do not have the classic chronic EBV titers (192). The cause(s) for the CFS remain(s) elusive (194,195).

Direct tests for EBV, such as cultivation in cord blood leukocytes (196) or detection of the genome by DNA probe (197), are performed in research laboratories but are not yet available in a commercial kit.

EBV may rarely cause or contribute to acute fulminant disease: the X-linked lymphoproliferative syndrome (198) and the virus-associated hemophagocytic syndrome (199). Heterophile and EBV antibodies may be absent, therefore diagnosis depends on demonstration of the virus by culture or DNA probe. *In situ* hybridization against EBV early RNA is the most sensitive method for detection of EBV in pathologic tissue (200).

Molecular techniques such as PCR are not widely available but may be useful in the diagnosis of EBV-associated encephalitis (201). Some investigators demonstrated an increase in EBV levels by quantitative PCR in immunocompromised patients weeks before the development of post-transplantation lymphoproliferative disorder (202).

Varicella-Zoster Virus

The diagnosis of chickenpox or herpes zoster can usually be made clinically. In the selected instances in which laboratory diagnosis is important, virus can be cultured from vesicle fluid and viral antigen can be demonstrated in cells scraped from the base of lesions (49). Infectious virus is quite labile. As much clear vesicle fluid should be aspirated as possible, mixed with a small volume of cell culture media (0.5 to 1.0 mL) and transported to the virology laboratory quickly. Isolation of the virus requires approximately 4 to 6 days. The DFA with MAB to VZV antigen is 92% sensitive (49).

VZV serologic tests are used usually to determine susceptibility or immunity, e.g., in a health care worker who has no history of varicella and is exposed to a patient with chickenpox or who wants to receive the varicella vaccine (203). Interestingly, 90% of such history-negative health care workers have VZV antibodies and are therefore immune (204,205). It is important to note that the CF test is an insensitive method for detecting VZV antibody, as false-negative results occur in an appreciable proportion of cases (108). Several other sensitive methods exist (206). The gold standard fluorescent antibody against membrane antigen test (108) is the most sensitive assay but is not widely available. Latex agglutination or ELISA tests are adequate substitutions (206,207), but at least one paper reports the failure of ELISA assays to detect antibody in patients immunized with the live attenuated vaccine (207). Therefore, an alternative method should be used in persons who have been immunized (207).

Human Herpesvirus Types 6 and 7

Human herpesvirus types 6 (HHV-6) and 7 (HHV-7) are considered emerging viral pathogens (208). Infections with HHV-6 occur in several clinical stages. Primary infection, roseola or exanthem subitum, a febrile illness with rash in infants and young children, was definitely linked to HHV-6 by Yamanishi et al. (209). The second stage of infection occurs in healthy children and adults who secrete virus in the salivary glands but are usually asymptomatic. Rarely, lymphadenopathy or a mononucleosis syndrome has been described (208). The most serious disease associated with HHV-6 occurs in the immunosuppressed patient, especially the transplant recipient (208,210). Reactivation has been associated with pneumonitis, hepatitis, encephalitis, and graft rejection. Synergistic infection with other viruses such as HHV-7 and CMV has resulted in increased severity of disease (208). The literature on the association between HHV-6 and CFS and multiple sclerosis is controversial (208). Like HHV-6, HHV-7 has also been associated with roseola and infections in immunocompromised patients (208,211).

HHV-6 infections can be diagnosed by viral isolation, serologic studies, and nucleic acid amplification techniques in research laboratories (210). Peripheral blood mononuclear cells appear to be the best specimens for virus isolation. Isolation using conventional cell culture is slow and labor intensive. A rapid shell vial assay using MRC-5 cells followed by staining with antiserum specific for the major immediate EA has been described (210).

Diagnosis of both HHV-6 and HHV-7 can also be made by the demonstration of IgG seroconversion or IgM antibody in serum (197,210,211,212 and 213). PCR assays are in development but must be capable of distinguishing actively infected cells from latent virus (210).

Human Herpesvirus Type 8

HHV-8 is the etiologic agent of endemic and AIDS-related Kaposi's sarcoma (214). HHV-8 has also been detected in body-cavity B-cell non-Hodgkin's lymphoma (215) and likely has a role in the pathogenesis of Castleman's disease (216). Diagnosis is typically made based on histopathologic evaluation of biopsied lesions. HHV-8 is difficult to cultivate. No commercial amplification or serologic assays are currently available.

Respiratory Syncytial Virus

RSV causes 50% to 90% of the episodes of bronchiolitis and 50% of the cases of pneumonitis in infants (217). Virtually all infants or toddlers are infected by two years of age, and approximately 1% of infants are hospitalized during the first year of life because of RSV-related disease (217). Infants with cyanotic congenital heart disease and infants with chronic lung disease such as bronchopulmonary dysplasia, particularly if they are oxygen dependent, are at much greater risk for mortality and serious morbidity from RSV bronchiolitis or pneumonitis (218). Diagnosis is usually made based on the characteristic epidemiology and clinical presentation (217,219). However, rapid viral diagnosis may be useful in facilitating appropriate isolation procedures and decisions regarding antiviral treatment and the need for additional laboratory studies, especially in the hospitalized patient (219).

Because culture for RSV requires a mean of 5 to 7 days to positive results, attention has focused on rapid detection of viral antigen in respiratory secretions obtained by NP aspirate or nasal-wash specimens. Two major approaches are available commercially: ELISA and DFA. For the most recently developed or modified ELISA kits, sensitivity is 71% to 98% and specificity 80% to 100%, whereas for DFA, the figures are 83% to 94% and 95% to 98%, respectively (28,50,51 and 52,220). There are membrane filter ELISA kits with individual tests for processing small numbers of specimens that have reported sensitivities of 83% to 100% and specificities of 74% to 96% (220,221). Although serologic tests are available, there is the problem of delay in diagnosis, and the antibody response may be poor or absent in very young infants, immunocompromised patients, and the elderly (219,222).

Influenza Viruses

Influenza is the most common cause for hospitalization for infectious lower respiratory tract disease in adults. It is the major contributor to pneumonia-related deaths in adults, particularly the elderly and individuals with underlying cardiopulmonary disease (19). However, more cases of influenza occur in children than in adults, and children are usually the first cases to occur in communities and families (223). Like RSV, influenza viruses can cause severe disease in children with congenital heart disease and chronic pulmonary disease (224). The availability of the antivirals

amantadine and rimantadine for influenza A and the new class of neuraminidase inhibitors with activity against influenza A and B (12) provide a strong stimulus for rapid viral diagnosis. Therapy must begin within 24 to 48 hours of the onset of symptoms to be maximally effective (22).

As with RSV, attention has turned toward antigen detection for rapid diagnosis of influenza because culture requires a mean time of 3 to 5 days for positive results. The SVC/VAS method has shortened the time for detection of influenza viruses to 48 hours. In early evaluations of this method, sensitivities ranged from 37% to 60% compared with culture (53,225). More recent reports evaluating SVC/VAS using Madin-Darby canine kidney cells demonstrated improved sensitivities of influenza A isolation approaching 100% (226,227).

Initial evaluation of a rapid membrane-bound ELISA for detection of influenza A indicated a sensitivity of 100% and a specificity of 92% compared with culture and DFA (228). More recent results indicated sensitivity of only 50% to 84% but similar specificity (228, 229). Most studies of DFA using commercial reagents for influenza antigen in respiratory secretion cells demonstrated low sensitivity (9% to 59%) but specificity of 95% or greater (54,225,227,230,231). New assays that detect both influenza A and B, the Zstat Flu (ZymeTX, Inc., Oklahoma City, OK) and the BioStar OIA Flu Test (BioStar, Inc., Boulder, CO) do not have appreciably improved sensitivity (60% to 76%) (232,233). Again, serology is available but results in a delay in diagnosis (19).

Other Respiratory Viruses

There are less urgent needs to make a rapid diagnosis of parainfluenza or adenovirus infections because of the lack of proven effective antiviral therapy. The time required for positive cell culture results is 4 to 6 days (55). DFA is available, but the sensitivity is low: 50% to 60% for the parainfluenza viruses and only 10% to 20% for the adenoviruses (54,0230).

A commercial multiplex reverse transcription PCR (RT-PCR)–enzyme hybridization assay (Hexaplex, Prodesse, Inc., Milwaukee, WI) that detects influenza A and B, RSV A and B, and parainfluenza virus types 1 to 3 is available for research use only (234). The cost and length of the assay (6 hours) likely preclude its routine use, but it may be helpful in the diagnosis of these pathogens in the immunocompromised patient with suspected viral pneumonia in whom rapid institution or ribavirin, for example, may be life saving.

Hepatitis Viruses

There are now six known hepatitis viruses—A, B, C, D, E, and G—a veritable alphabet soup of agents encompassing both DNA and RNA viruses. Only the first four are known to cause disease in the United States. Hepatitis viruses can be transmitted by the fecal-oral or percutaneous routes. HAV and hepatitis E virus (HEV) are transmitted primarily by the fecal-oral route. HBV, HCV, HDV, and HVG are blood-borne infections. The annual number of cases of hepatitis reported to the Centers for Disease Control and Prevention (CDC) in 1989 were HAV, 28,500; HBV, 23,200; and non-HAV, non-HBV (mostly C) hepatitis, 2,600 (235). The actual number of cases may be five- to 10-fold higher.

HAV is a member of the Picornaviridae family, genus *Hepatovirus* and is closely related to poliovirus and other enteroviruses (236). Transmission is typically by fecal-oral spread, and outbreaks associated with contaminated food or water (237) or closed settings such as day care centers (238) occur. Most infections occur in young children, but these are usually asymptomatic. HEV, also known as epidemic or enteric-transmitted non-HAV, non-HBV hepatitis, has been classified as a calicivirus (239). HEV is not endemic in the United States. Epidemics in developing countries are primarily related to contaminated water (240).

For HBV and HCV, the major risk factors are similar: intravenous drug abuse, homosexuality, sexual partner of a known chronic carrier, multiple sexual partners, recipient of blood or blood products, and health care workers exposed to blood (235). HBV may be transmitted perinatally (241), but the frequency of maternal fetal/neonatal transmission with HCV is not yet defined clearly (242). Before implementation of universal screening of blood donors for HCV, this virus was the cause of 80% of posttransfusion hepatitis cases (243). Because HDV is known to infect only individuals with acute or chronic HBV infection, the risk factors for infection with HDV are very similar to those for HBV (244).

Chronic hepatitis is known to occur with HBV, HCV, and HDV, but not HAV (235). Cirrhosis is a known sequela of chronic hepatitis with all three viruses (235), but so far only HBV and HCV have been associated with hepatocellular carcinoma (245,246). HGV was discovered in 1996 and is a member of the family Flaviviridae (247). It is acquired primarily by blood transfusions and does not seem to cause symptomatic hepatitis in most patients (247).

Table 59.4 lists the tests to diagnose acute hepatitis and to determine immunity for each of the four hepatitis viruses seen in the United States, as well as HEV because it may occur in returning travelers. Two serologic markers are most often used to diagnose HAV: IgM anti-HAV and total anti-HAV. IgM anti-HAV is a marker of acute disease, usually present just before the onset of symptoms and peaking 1 to 2 weeks later (248). Tests for total anti-HAV detect both IgG primarily, and IgM in both acute and convalescent sera. Samples that are IgM negative but total anti-HAV positive are indicative of past infection or recent vaccination. Total anti-HAV and IgM anti-HAV are usually performed by EIA (248). The reader is referred to reference 248 for a complete description of the various methods available. HEV can likewise be diagnosed by anti-HEV EIA; however, these commercial assays are not yet licensed in the United States (248).

Numerous tests exist for the diagnosis and evaluation of patients with HBV. These include HBsAg, antibody to surface antigen (anti-HBs), total antibody to core antigen (anti-HBc), IgM antibody to core antigen (anti-HBc IgM), HBV e antigen (HBeAg), and antibody to e antigen (anti-HBe). More recently, amplification assays, both qualitative and quantitative, have been introduced to characterize disease status further. In acute and chronic HBV, HBsAg and total anti-HBc are both present. Anti-HBc IgM is generally present in acute hepatitis but absent in chronic disease. Presence of HBeAg and absence of anti-HBe antibody

are markers of greater infectivity (increased likelihood of perinatal, sexual, and blood transfusion transmission) and a worse prognosis (greater risk of progression to chronic hepatitis, cirrhosis, and hepatocellular carcinoma) (249,250 and 251). A typical response when the patient recovers is loss of HBsAg, HBeAg, and HBV DNA and persistence of anti-HBs. With the advent of available molecular techniques, the best predictor of infectivity and viral replication is now detection of HBV DNA. Both molecular hybridization techniques and PCR assays are available (78,97). Quantitative assays are particularly valuable in assessing candidates appropriate for antiviral therapy and in monitoring response to treatment (97).

The remarkable effort to isolate and clone the gene of the major non-HAV, non-HBV (252) and to express the nonstructural protein c100-3 in a bacterial vector (253) led to the identification and characterization of HCV and to the demonstration that this virus was the causative agent in most cases of posttransfusion hepatitis (254). The c100-3 protein was used to develop a first-generation anti-HCV antibody assay. As this assay became more widely used, several limitations became apparent, including a delay in antibody detection for months and as long as a year after the initial infection (243) and false-positive results in individuals with active autoimmune chronic liver disease (255). A second-generation ELISA that incorporates HCV structural proteins appears to be more sensitive and specific, and antibody is detectable sooner after initial infection (256). Development of the confirmatory recombinant immunoblot assay for HCV antibody significantly reduced the problem of false-positive test results (255). Finally, RT-PCR for HCV RNA in serum appears to be the most sensitive and specific test, and several commercial assays are available and widely used in clinical practice (87,88,257). Most qualitative RT-PCR assays detect 100 to 1,000 viral genome copies per milliliter (257) and can be used to diagnose acute and chronic HCV. Quantitative tests are used to assist with predicting the likelihood of response to therapy (257). At least six different genotypes (1 to 6) and more than 90 subtypes of HCV exist. Seventy percent of cases in the United States are associated with genotype 1, with 1a occurring more frequently than 1b (257). Various non-FDA–approved genotyping methods are available in reference laboratories. Genotyping may be beneficial when stratifying treatment regimens because differences do exist with respect to response to therapy among the various genotypes (258).

Gastroenteritis Viruses

Viruses are a major cause of diarrheal disease worldwide. Four viral groups have been identified as established etiologic agents of gastroenteritis. In the United States, rotavirus causes disease primarily in the infant/toddler age group during the winter months (259,260) and accounts for 30% to 50% of pediatric cases of gastroenteritis that require hospitalization (61). Enteric noncultivatable adenoviruses (types 40 and 41) are responsible for 5% to 15% of hospitalized cases in the same age group year round (60,61,259,261). Human astroviruses are found worldwide and in the United States occur primarily in winter, associated with day care center outbreaks among young children (262). *Calicivirus*, Norwalk virus, and Norwalk-like viruses (small round structured viruses) are associated with food and water-borne, nonseasonal outbreaks of gastroenteritis among all age groups (61,63). In the United States, 30% to 50% of outbreaks are believed to be related to this group of viruses (61).

None of the gastroenteritis viruses grows in conventional cell cultures, but all can be detected by EM (60,61,63,66). Commercial ELISA tests with greater than 95% sensitivity and specificity (57,58,59,60 and 61) are available to detect both rotavirus and enteric adenovirus.

Enteroviruses

Nonpolio enteroviruses (Coxsackie A and B, echo) are the most common cause of hospitalization for febrile illness in infants younger than 2 months of age (264) and the most common cause of aseptic meningitis in older infants, children and adults (18,265). The ability to differentiate between bacterial sepsis/meningitis and enteroviral disease may allow the discontinuation of unnecessary diagnostic tests and antibiotic therapy and shortening of the duration of hospitalization (18,266). In addition, antiviral agents for enteroviral infections are currently undergoing clinical trials, increasing the urgency for rapid viral diagnosis (13).

Intensive efforts have been made to develop DNA probes to a conserved portion of the enteroviral genome (267). However, such methods for rapid diagnosis have not achieved sufficient sensitivity, specificity, and practicality for the usual diagnostic virology laboratory. The major means for laboratory diagnosis of enteroviral infections remains isolation of virus in cell culture by examining for viral CPE. Optimal specimens include throat swabs, CSF, and blood samples. There are two major problems with stool and rectal samples. First, enteroviruses may be shed asymptomatically in the stool for weeks after an illness. Second, live oral polio vaccine can be shed in the stool for days to weeks after vaccine administration resulting in a positive enterovirus culture. Therefore, stools should be avoided as clinical specimens for enterovirus culture in infants around the time of oral polio vaccine administration (268). By using four different cell lines for isolation, presumptive diagnosis of Coxsackie A versus Coxsackie B versus echovirus can be made more quickly (269,270 and 271). The Coxsackie B viruses grow best in buffalo green monkey cells and Coxsackie A and echo, in human rhabdomyosarcoma cells (271). The usual time for presumptive diagnosis by CPE is 4 to 7 days. SVC/VAS has shortened this to 72 hours for most cultures (272).

Serologic tests are not usually performed for the diagnosis of enteroviral disease unless there is a need to prove an etiologic role with an isolate from the stool of a patient. In this instance, one must demonstrate a fourfold or greater antibody titer rise in acute and convalescent sera that bracket the illness. At our diagnostic virology laboratory, however, we do offer two sets of neutralizing antibody titers against the enteroviruses: (a) the Coxsackie B group (1 to 6) for use when there are illnesses typically caused by these viruses (e.g., myocarditis, pericarditis, pleurodynia) and (b) the four to five most frequent echovirus serotypes currently causing disease in the community. Again, acute and convalescent sera bracketing the illness are necessary for optimal diagnosis.

RT-PCR is expected to become the diagnostic test of choice for the detection of enteroviruses in the CSF. The sensitivity and specificity of RT-PCR have been well demonstrated in the literature. In contrast to culture, which typically has a sensitivity of 65% to 70%, most amplification assays have sensitivities ranging from 92% to 100% (273,274 and 275). Investigators are applying this technology to blood samples to differentiate enteroviral sepsis from bacterial sepsis in febrile neonates, reducing the need for costly antibiotics and hospital stays in the case of viral disease (276).

Measles, Mumps, and Rubella

Although each of these viruses can be cultured in conventional cell lines, culture requires 7 to 10 days for measles and mumps and more than 3 weeks for rubella (277,278 and 279). With measles virus, the use of the SVC/VAS method with commercially available mouse MAB has resulted in a sensitivity compared with routine culture of 78% at 1 to 2 days and 100% at 5 days (280). Direct staining for measles virus antigen with this same MAB was 100% sensitive compared with culture for NP swab specimens but only 67% sensitive for throat swab and 85% for urine specimens (280).

The usual means for laboratory diagnosis of acute measles, mumps, and rubella is serologic: fourfold or greater rise in IgG antibody in sera bracketing the illness or presence of virus-specific IgM antibody in a single early convalescent serum. Although the traditional serologic test is HI for IgG antibody, several IFA and ELISA IgG and IgM kits are commercially available (281,282,283,284 and 285). Care must be used in interpreting positive IgM tests. The IgM antibody response may be delayed, so a negative test result does not rule out recent infection. If the diagnosis is strongly suspected, the test should be repeated 1 to 2 weeks later. False-positive results may also occur. Mumps IgM antibody has persisted for months after acute illness (284). IgM antibodies that cross-react with rubella have been found in patients with infectious mononucleosis (285), parvovirus B19 infection (286), and CMV infection (287). False-positive rubella IgM tests can be a particular concern in pregnant women (288). It may be wise, therefore, to confirm critical IgM positive results with (a) an IgM assay from another manufacturer or (b) a fourfold rise in IgG antibodies (287,288).

Human Immunodeficiency Virus

HIV is the cause of AIDS. HIV-1 is found worldwide and causes disease characterized by progressive decline in immune function resulting in death. HIV-2 is found primarily in West Africa and has a more benign clinical course. The major diagnostic tests for AIDS are both serologic and virologic: ELISA and Western immunoblot for HIV antibody, ELISA for p24 antigen, culture of peripheral blood mononuclear cells (PBMC) for infectious virus, use of PCR to detect HIV proviral DNA in PBMC, and qualitative and quantitative RT-PCR to detect viral RNA (89,90 and 91).

In most cases, infection is diagnosed by demonstrating HIV antibodies in serum. The adult or older child who presents with features of AIDS has been infected with HIV for weeks to months and already has antibody to the virus in serum. The traditional approach in this situation is to order a screening ELISA, with a repeat ELISA in those with positive results. Current generations of ELISA assays have sensitivities 99% or greater (289) and reported specificities of 99.6% to 100% (290,291 and 292). However, even a false-positive rate of 0.4% in a low prevalence population means that an unacceptable number of patients will be misdiagnosed. Therefore, all positive screening ELISA assays are confirmed by Western blot or IFA. The Western immunoblot measures the antibody response to nine HIV proteins or glycoproteins: gag proteins (p17, p24, p55), pol (p66, p51), and env (gp41, gp120, gp160). Various criteria have been proposed for interpretation of Western blot assays, but those defined by the CDC are the most widely accepted (293). The presence of any two of p24, gp 46, or gp120/160 is a positive test (293). If there is a response to some but not all the HIV antigen bands necessary to satisfy the CDC criteria, the result is said to be indeterminate, and repeat testing over the next 6 months is recommended. If a patient's Western blot results remain indeterminate over a 6-month period, he or she should be considered not infected with HIV-1 (293). In low-risk populations, patients with screening ELISA positive and indeterminate Western blot results are rarely, if ever, infected with HIV on follow-up serum testing (294).

If the results of serologic testing are not definitive for a suspected HIV-positive patient for whom it is important to make a diagnosis quickly (e.g., to institute anti-HIV therapy), there are several additional approaches. Tests may be undertaken for p24 antigen, culture of PBMC for the virus, and nucleic acid detection. Tests for p24 antigen are most useful in the period just before seroconversion in the acutely infected individual and in early diagnosis of the infected neonate (295,296). Culture of virus is available only in research or referral commercial laboratories and takes several days to a few weeks to perform, therefore, results are not readily available for patient management. Finally, nucleic acid amplification assays are available for both HIV-1 detection and quantitation. Proviral HIV DNA can be detected by PCR using primers within conserved sequences in the *gag* or *pol* genes (89,295,296). The reported sensitivity of HIV-1 DNA PCR is 96% to 99% (297).

HIV-1 DNA detection is most useful in early diagnosis in neonates (295,296,298). Several viral load assays that quantify HIV-1 RNA are commercially available. Quantification of HIV-1 RNA is most useful in assessing responses to antiretroviral therapy (90,91). Other applications include assessing prognosis and monitoring the course of disease (90,91).

In the infant with suspected AIDS whose mother is HIV seropositive, the presence of maternal transplacentally transmitted antibody confounds the interpretation of the screening ELISA or the Western immunoblot up to 18 months of age (299). In a child younger than 18 months of age, a definitive diagnosis of HIV disease can be made if the child meets clinical criteria for a diagnosis of AIDS or if the child is positive on two separate occasions utilizing one or more HIV-specific tests: culture, PCR, or p24 antigen (299).

Arbovirus Encephalitis

During 1996 to 1997, the major arboviruses causing encephalitis in the United States were LaCrosse virus, accounting for 88%

of total cases; St. Louis encephalitis virus, 5%; western equine encephalitis, less than 1%; and eastern equine encephalitis virus, 7% (300). Most cases of arbovirus encephalitis occur in the states with the largest mosquito populations: the coastal states, the Great Lakes regions, and the states bordering the Mississippi and Missouri Rivers (301). As the names of the viruses suggest, there is great regional variation in the number of cases and the particular viruses causing disease.

Because viremia has usually cleared by the time patients come for medical attention and because brain biopsy is rarely indicated or performed, the virus or viral product is not available for direct detection. The diagnosis is made by demonstrating seroconversion on acute and convalescent sera bracketing the illness. Available assays include traditional CF tests and ELISA kits (302,303).

Colorado Tick Fever Virus

Colorado tick fever is limited to the Rocky Mountain states and, as the name suggests, is transmitted by the wood tick *Dermacentor andersoni*. Typical features include a biphasic flulike illness without respiratory symptoms and an associated leukopenia. Viremia is prolonged and the virus is associated with red blood cells (304). The most sensitive diagnostic test is mouse inoculation of disrupted blood clot material (305). Demonstration of viral antigen by direct immunofluorescence staining of blood smears and detection of antibody in paired acute and convalescent sera are less sensitive alternatives to mouse inoculation (305).

Parvovirus B19

This virus causes erythema infectiosum (or fifth disease) (306), aplastic crisis in patients with hemolytic anemia syndromes (307), persistent anemia in immunosuppressed patients (308), and abortion and fetal hydrops in pregnant women (309). The virus is not cultivatable with routine methods. Diagnosis of acute infection in immunocompetent patients is best made by demonstration of IgG seroconversion or IgM antibody in serum (310,311). Past infection or immunity is determined by the presence of IgG antibody. Chronic infection in the immunocompromised host is made by detection of parvovirus DNA in serum or peripheral white blood cells (312,313).

Hantaviruses

Among the emerging viruses in the past decade are the new variant hantaviruses. Unlike the Old World or classic hantaviruses that cause primarily hemorrhagic fever with renal syndrome, these new variants are responsible for respiratory illness characterized by adult respiratory distress syndrome (ARDS) (314). The prototypic agent Sin Nombre virus was identified in 1993 after a cluster of unexplained deaths owing to severe respiratory illness in otherwise healthy young adults was described in the Four Corners area of the southwestern United States (315). Since then, several additional viral agents have evolved in the Western Hemisphere, and the associated disease is called hantavirus pulmonary syndrome. The source of infection is a rodent host, and the disease has four phases: (a) a prodrome indistinguishable from several other diseases, (b) pulmonary edema/shock (ARDS), (c) a spontaneous diuretic phase in survivors, and (d) the convalescent phase (316). Hallmarks of the disease during the ARDS phase include thrombocytopenia, hemoconcentration, and leukocytosis (316,317 and 318). Diagnosis is made clinically and usually confirmed by serology. Most state health laboratories have IgM and IgG assays available. Some university centers have RT-PCR available, and immunohistochemical staining can be performed on formalin fixed tissues (317,318).

Perinatal Viral Infections

The major viruses infecting the fetus and newborn infant are CMV, rubella, HSV, enteroviruses, HIV, and HBV. HIV was discussed previously, and HBV rarely results in acute disease in young infants. If we consider the four remaining viruses and the situations in which infection results in disease in the fetus or newborn, CMV and rubella are usually acquired congenitally by transplacental transmission with symptoms present at birth. HSV and enteroviruses are usually acquired during the birth process or postnatally with onset of symptoms several days to a few weeks after birth. Clinicians faced with a suspected perinatal viral infection in a neonate often request TORCH titers (*t*oxoplasma, *o*ther, *r*ubella, *C*MV, *H*SV) on the infant and mother. However, this is not an effective means to establish a rapid diagnosis. Routine TORCH titers measure IgG antibody that is passed transplacentally from mother to fetus. Because this is an active transport mechanism, the titer of virus-specific IgG antibody in the neonate may be twofold and occasionally fourfold higher than in the mother. Antibody present in neonatal serum, therefore, could represent an infection in the mother during this pregnancy or months to years earlier. Thus, the mere presence of antiviral IgG antibody in the serum of a neonate or the mother after birth does not prove current active infection. Only when IgG antiviral antibody persists beyond 4 to 6 months of age in the infant (the usual time for maternal transplacental antibody to disappear) can one assume active infection in the fetus or neonate. The IgG TORCH titer approach, therefore, cannot make a diagnosis for 4 to 6 months.

The virologic approach or culture of virus is the most direct and rapid method for CMV, HSV, and enteroviruses. Suggested specimens include (a) for CMV, urine and buffy coat obtained in the first several days of life; (b) for HSV, swabs of mucocutaneous vesicles or ulcers or conjunctival lesions, CSF, and buffy coat; and (c) for enteroviruses, throat swab, CSF, buffy coat, and stool. Although rubella can be recovered from throat swabs and occasionally CSF (319), the virus isolation process is tedious and can require 3 to 4 weeks for confirmation.

An alternative approach to the diagnosis of congenital viral infections is the demonstration of IgM antiviral antibody in neonatal serum. IgM is not normally passed transplacentally, and its presence indicates current or recent infection in the neonate. As mentioned previously, commercial tests for rubella, CMV, and HSV IgM are available. Because culture of rubella virus is delayed, the demonstration of rubella IgM in a neonate with features consistent with congenital rubella (e.g., small for

gestational age, hepatosplenomegaly, petechiae, jaundice, cataracts, abnormal heart sound) would confirm the diagnosis. However, the anti-CMV IgM is positive in only 50% to 70% of neonates with congenital infection proven by isolation of virus from urine obtained within the first few days of life (105,320). The use of IgM serology for rapid diagnosis of neonatal HSV infections is inappropriate because it may be 2 to 3 weeks after infection before a response is detected (321).

SUMMARY

Part of "59 - Diagnostic Virology"

Rapid diagnosis of infections with all the viruses listed in Table 59.4 requires the use of a variety of virologic and serologic techniques. In general, virologic methods are used when the clinical specimens readily available from the patient contain the virus. Serologic methods are used when virologic methods do not provide timely results or are not available and when the incubation period is long so that the patient already has antibody when presenting with illness. Among the virologic methods, antigen detection tests are preferred because results can be available within hours, but sensitivity and specificity must be sufficiently high to allow accurate conclusions. Finally, isolation of infectious virus is 100% specific and enables further biological characterization of the agent, and, if shell vial culture/viral antigen stain methods are available, can provide results within 1 to 3 days. Nucleic acid detection methods provide a sensitive, rapid, and in many cases cost-effective approach to viral diagnosis. At present, few FDA-approved assays are available except for detection and quantification of HBV, HCV, and HIV. An expanded menu of assays is likely to be available in the near future. It is also important for the clinician to understand the advantages and limitations of the methods used so that results can be properly interpreted.

Parasitology

Michael A. Pfaller

Medical parasitology is the study of invertebrate animals capable of causing disease in humans. In the context of this chapter, the term parasite refers to organisms belonging to three major subdivisions or taxonomic groups. These include the Protozoa (amebas, flagellates, ciliates, sporozoans, coccidia, microsporidians), the Platyhelminthes or flatworms (cestodes, trematodes), and the Nematodes or roundworms (Table 60.1). The Protozoa are rather simple microscopic unicellular eukaryotic organisms, whereas the Platyhelminthes and Nematoda are highly complex macroscopic multicellular worms possessing differentiated tissues and complex organ systems.

TABLE 60.1. CLASSIFICATION OF HUMAN PARASITES

Protozoa	**Nematodes**
Amebas	*Ascaris lumbricoides*
Entamoeba histolytica	*Enterobius vermicularis*
Entamoeba dispar	*Ancylostoma duodenale*
Entamoeba coli	*Necator americanus*
Entamoeba polecki	*Strongyloides stercoralis*
Entamoeba hartmanni	*Trichuris trichiura*
Endolimax nana	*Trichinella spiralis*
Blastocystis hominis	*Toxocara canis*
Iodamoeba bütschlii	*Ancylostoma braziliense*
Naegleria fowleri	*Wuchereria bancrofti*
Acanthamoeba culbertsoni	*Brugia malayi*
Flagellates	*Loa loa*
Giardia lamblia	*Onchocerca volvulus*
Chilomastix mesnili	*Mansonella ozzardi*
Dientamoeba fragilis	*Mansonella streptocerca*
Trichomonas hominis	*Mansonella perstans*
Trichomonas vaginalis	*Dirofilaria spp.*
Leishmania tropica	**Trematodes**
Leishmania mexicana	*Fasciolopsis buski*
Leishmania braziliensis	*Heterophyes heterophyes*
Leishmania donovani	*Metagonimus vokogawai*
Trypanosoma gambiense	*Opisthorchis sinensis*
Trypanosoma rhodesiense	*Opisthorchis viverrini*
Trypanosoma cruzi	*Fasciola hepatica*
Ciliates	*Paragonimus westermani*
Balantidium coli	*Schistosoma mansoni*
Sporozoa	*Schistosoma japonicum*
Plasmodium vivax	*Schistosoma haematobium*
Plasmodium malariae	**Cestodes**
Plasmodium ovale	*Diphyllobothrium latum*
Plasmodium falciparum	*Diphylidium caninum*
Babesia microti	*Hyrnenolepsis nana*
Coccidia	*Hymenolepsis diminuta*
Cryptosporidium spp.	*Taenia solium*
Cyclospora cayetanensis	*Taenia saginata*
Isospora belli	*Echinococcus granulosus*
Sarcocystis spp.	*Echinococcus multilocularis*
Toxoplasma gondii	*Multiceps multiceps*
Microsporidia	
Encephalitozoon	
Nosema	
Pleistophora	
Enterocytozoon	
Trachipleistophora	

TABLE 60.2. ESTIMATED WORLDWIDE PREVALENCE OF PARASITIC INFECTIONS

Infection	**Number Infected**	**Annual Deaths**
Amebiasis	10% of world population	40,000–110,000
Malaria	400–490 million	2.2–2.5 million
African trypanosomiasis	100,000 new cases/year	5,000
American trypanosomiasis	24 million	60,000
Leishmaniasis	1.2 million	
Schistosomiasis	>200 million	0.5–1 million
Opisthorchiasis	19 million	
Paragonimiasis	3.2 million	
Fasciolopsiasis	10 million	
Filariasis	85–100 million	
Onchocerciasis	>30 million	
Dracunculiasis	10 million	
Ascariasis	1 billion	1,550 (intestinal obstruction)
Hookworm	900 million	
Trichuriasis	500–800 million	
Strongyloidiasis	35 million	
Cestodiasis	65 million	

Although parasitic diseases are frequently considered tropical and thus of little relevance to physicians practicing in the more temperate, developed countries of the world, it is clear that the world has become a very small place and that it is essential for physicians to have knowledge of parasitic diseases. By any estimation, the numbers of parasitic infections and parasite-associated deaths are staggering and must be of concern to all health care workers (Table 60.2). Increasingly, tourists, missionaries, Peace Corps volunteers, and others are visiting and working for extended periods in exotic, remote parts of the world and thus are at risk for parasitic and other infections that are rare in the United States. Another source of infected patients is the ever-increasing population of refugees from developing countries. Finally, the profound immunosuppression accompanying advances in medical therapy as well as that associated with infection with the human immunodeficiency virus (HIV) places an increasing number of individuals at risk for developing infections attributable to particular parasites. Given these considerations, clinicians and laboratory workers should certainly be aware of the possibility of parasitic disease and should be trained in the ordering, performance, and interpretation of the appropriate laboratory tests to aid in diagnosis and therapy.

Although the mainstay of diagnostic clinical microbiology is the isolation of the causative pathogen in culture, diagnosis of parasitic diseases is most commonly accomplished by morphologic (usually microscopic) demonstration of parasites in clinical material. Occasionally, serodiagnosis is helpful in establishing the diagnosis. Increasingly, antigen detection and molecular diagnostic methods are proving useful in diagnosing parasitic infections (1, 2, 3, 4, 5 and 6). Proper diagnosis requires that (a) the physician consider the possibility of a parasitic infection, (b) appropriate specimens are obtained and transported to the laboratory in a timely fashion, (c) the laboratory competently performs the appropriate procedures for recovery and identification of the etiologic agent, (d) the laboratory results are effectively communicated to the physician, and (e) the results are correctly interpreted by the physician and applied to the care of the patient. For most parasitic diseases, appropriate test selection and interpretation are based on an understanding of the life cycle of the parasite as well as the pathogenesis of the disease process in humans. For example, although Ascaris is usually considered an intestinal nematode, early and profound clinical symptoms may be caused by larval migration through tissues weeks before eggs are present in feces.

This chapter provides an overview of the basic parasitology, epidemiology, clinical disease, and pathology of the major protozoan and helminthic parasites infecting humans. Individual organisms and disease processes are discussed under the major headings of blood and tissue protozoa, intestinal and urogenital protozoa, nematodes, trematodes, and cestodes. The reader is referred to several excellent reference texts for more detailed information (7, 8, 9 and 10).

BLOOD AND TISSUE PROTOZOA

Part of "60 - Parasitology"

The protozoa of blood and tissues include the sporozoan parasites *Plasmodium*, *Babesia microti*, and *Toxoplasma gondii*; the hemoflagellates include *Leishmania* and *Trypanosoma*; and the free-living amebae include *Naegleria*, *Acanthamoeba*, and *Balamuthia*. The major clinical manifestations of the protozoa causing bloodstream infection (malaria and babesiosis) are secondary to the destruction of red blood cells or sludging of infected red blood cells in the microvasculature of the brain and other organs. The protozoa causing tissue infection may cause significant damage to specific organs such as the eyes (toxoplasmosis, malaria, *Acanthamoeba* keratitis), the brain (toxoplasmosis, amebic meningoencephalitis, African sleeping sickness), the heart (toxoplasmosis, Chagas' disease), or the gastrointestinal tract (Chagas' disease) (Table 60.3).

TABLE 60.3. MAJOR BLOOD AND TISSUE PROTOZOA

Organism	Disease	Vector	Location	Laboratory Diagnosis
Plasmodium	Malaria	*Anopheles* mosquito	Blood	Giemsa-stained blood film
Babesia	Babesiosis	*Ixodes* tick	Blood	Giemsa-stained blood film
Toxoplasma gondii	Toxoplasmosis	None; food-borne, fecal-oral, transplacental	Reticuloendothelial system	Parasites in biopsy, serology
Leishmania	Leishmaniasis	*Phlebotomus* sandfly	Skin Mucosa Reticuloendothelial system	Parasites in Giemsastained smears, biopsy
Trypanosoma cruzi	Chagas' disease American trypanosomiasis	Reduviid bug	Blood Reticuloendothelial system	Trypanosomes in blood, biopsy
Trypanosoma brucei, gambiense or rhodesiense	Sleeping sickness African trypanosomiasis	Tsetse fly	Blood Lymphatics CNS	Trypanosomes in blood, CSF

CNS, central nervous system; CSF, cerebrospinal fluid.

Malaria

Malaria is the most important of all protozoan diseases; annually, it infects more than 250 million individuals and is a leading cause of illness and death in the developing world (Table 60.2). Efforts at eradication have failed because of the ability of both

the anopheline mosquito vector and the parasite to develop resistance to various eradication and treatment options. In the United States, malaria is well controlled, although it remains the most common acute febrile illness imported into the country.

Classification

Malaria is caused by blood-borne pathogens of the genus *Plasmodium*. There are four species that can infect humans and that are associated with somewhat different clinical presentations, laboratory characteristics, and geographic distribution (Table 60.4). These four species include *P. vivax*, *P. ovale*, *P. malariae*, and *P. falciparum*. *P. vivax* is the most common species worldwide, being found in India, Pakistan, Southeast Asia, South and Central America, and rarely in Africa. *P. ovale* is limited in distribution primarily to Africa. *P. malariae* is found in all countries with malaria, although it is much less prevalent than either *P. vivax* or *P. falciparum*. *P. falciparum* ranks second in prevalence to *P. vivax* and is primarily a tropical species. It is found most often in individuals from Africa, Haiti, and New Guinea but is also seen in Southeast Asia, South America, and the Pacific Islands. Clinically, *P. falciparum* infections are the most serious among the four species of plasmodia. Figure 60.1 depicts the distribution of malaria transmission, including that of drug-resistant strains.

TABLE 60.4. SELECTED CLINICAL CHARACTERISTICS OF FOUR TYPES OF MALARIA

Characteristic	*Plasmodium falciparum*	*Plasmodium vivax*	*Plasmodium ovale*	*Plasmodium malariae*
Usual incubation period (d)	8–11	10–17 or longer	10–17 or longer	18–40 or longer
Severity of primary attack	Severe in nonimmune	Mild to severe	Mild	Mild
Periodicity (h)	None	48	48	72
Duration of untreated primary attack (wk)	2–3	3–8	2–3	3–24
Duration of untreated infection	6–17 mo	5–7 yr	12 mo	20+ yr
Average parasitemia (per mm^2)	≥20,000	10,000	9,000	6,000
Anemia	Frequent and severe	Mild	Mild	Mild
CNS involvement	Yes, severe	Rare	Rare	Rare
Nephrotic syndrome	Rare	Rare	No	Frequent

CNS, central nervous system

FIGURE 60.1. World distribution of malaria. Black areas indicate distribution of chloroquine-susceptible *Plasmodium falciparum* malaria and gray areas indicate distribution of chloroquine-resistant *P. falciparum* malaria. (From Barat LM, Bloland PB. Drug resistance among malaria and other parasites. *Infect Dis Clin North Am* 1997;11:969–987.)

Clinical Manifestations

Malaria is characterized by acute cyclical periods (paroxysms) of high fever and shaking chills. After several replicative cycles of the parasite within the patient, a classic pattern of illness occurs. Patients develop a dull headache and generalized malaise followed by severe chills, peripheral vasoconstriction, and polyuria. Within a few hours, patients have high fever and flushing and, after 2 to 6 hours, a drenching sweat that resolves the episode but leaves the patient exhausted. Complete cycles occur in a tertian (48-hour) pattern in *P. vivax* and *P. ovale* and in a quartan (72-hour) pattern in *P. malariae* infections. A definite pattern frequently cannot be identified in *P. falciparum* infections; however, sometimes pronounced synchronization may be seen with a 36- to 48-hour periodicity. In addition to fever and chills, patients may also have flulike symptoms with myalgias, arthralgias, nausea, vomiting, abdominal pain, and headache. On physical examination, patients may have splenomegaly, hepatomegaly, or jaundice, although none of these is seen often. The most common laboratory abnormality associated with malaria is hemolytic anemia and hyperbilirubinemia. Elevated liver function tests, hyponatremia, and other nonspecific laboratory abnormalities may also occur.

The density of parasitemia may be extremely high in *P. falciparum* malaria, with as many as 50% of the red blood cells being parasitized. This degree of parasitemia can lead to severe hemolysis with hemoglobinuria and severe anemia. Sequestration of *P.*

falciparum infected erythrocytes in the microvasculature of the body may lead to occlusion of these vessels, causing symptoms related to capillary obstruction. With severe disease, virtually always caused by *P. falciparum*, evidence of cerebral infection with altered consciousness, encephalopathy, seizures, and focal neurologic deficits or intravascular hemolysis with renal failure (blackwater fever) may occur. This syndrome is considered a medical emergency and requires immediate and aggressive therapy.

There are several genetic factors that may alter the susceptibility to, and the clinical presentation of, malaria. The development of *P. falciparum* is suppressed by the presence of fetal hemoglobin, hemoglobin S, and perhaps other abnormal hemoglobins as well (11, 12). Persons with sickle cell trait have less severe infections with *P. falciparum* and do not have lethal sickle cell disease. The high frequency of hemoglobin S in certain parts of Africa is owing to the selective advantage of this balanced polymorphism. Likewise, persons with the Duffy-negative blood type (Fy^a and Fy^b negative) are resistant to infection with *P. vivax*. The Duffy blood group antigen is the specific receptor for invasion of red cells by *P. vivax* merozoites (11, 12). The low incidence of *P. vivax* in Africa is explained by the fact that most African blacks are Duffy negative.

The course of untreated malaria depends greatly on the infecting species. As noted previously, most fatal cases of malaria are caused by *P. falciparum*. In nonfatal cases of malaria, the febrile paroxysms become less severe over time and the disease gradually subsides. Clinical and parasitologic relapses may occur after months or years in individuals with *P. vivax* or *P. ovale* infection. These relapses are attributable to the emergence of latent exoerythrocytic forms present in the liver (hypnozoite; see Life Cycle section). *P. malariae* frequently causes an extremely low-grade parasitemia, and individuals with *P. malariae* infection may be asymptomatic with recrudescences occurring sporadically. It is thought that relapses or recrudescences may be associated with changes in the host's defense mechanisms or possibly with antigenic variation in the infecting organism.

Life Cycle

Malaria is transmitted to humans by the bite of the female Anopheles mosquito. Between 65 and 70 species of naturally infected *Anopheles* mosquitoes have been found in various parts of the world. Most malaria seen in the United States is acquired by visitors or residents from countries with endemic disease and is considered “imported” malaria. However, because the appropriate vector Anopheles mosquito is found in the United States, domestic transmission of the disease has been observed (introduced malaria) (11, 12). In addition to transmission by mosquitoes, malaria can be acquired by blood transfusions from an infected donor or by sharing of needles and syringes by intravenous drug users. Congenital transmission of malaria from an infected mother to the fetus is also described.

The four species of *Plasmodium* infecting humans share a common life cycle (Fig. 60.2) involving an asexual phase (schizogony) in humans and a sexual phase (sporogony) in the mosquito. The sexual phase requires a developmental period of

8 to 12 days in the mosquito and results in the production of infectious sporozoites.

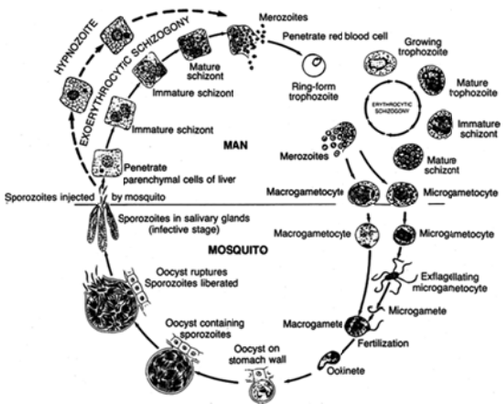

FIGURE 60.2. Life cycle of malaria. (From Strickland GT. *Tropical medicine*, 7th ed. Philadelphia: Saunders.)

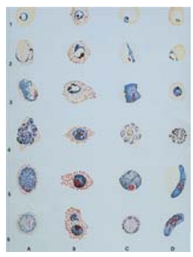

FIGURE 60.3. Developmental forms of four species causing human malaria. Columns: **A**, *Plasmodium vivax*; **B**, *P. ovale*; **C**, *P. malariae*; **D**, *P. falciparum*. Rows: 1, young trophozoites; 2, growing trophozoites; 3, mature trophozoites; 4, mature schizonts; 5, macrogametocytes; 6, microgametocytes. (From Wilcox A. *Manual for the microscopical diagnosis of malaria in man*. Bulletin no. 180. Bethesda, MD: National Institutes of Health, 1942.)

The infective sporozoites are injected into the subcutaneous capillaries of the vertebrate host as the mosquito feeds. The sporozoites penetrate the parenchymal cells of the liver, where they multiply asexually (exoerythrocytic schizogony) to produce thousands of uninucleate merozoites and form a tissue schizont. This growth of parasites in the liver is called the exoerythrocytic phase.

After a period of development (8 to 25 days depending on the species), the merozoites rupture from the hepatic cell and are released into the circulation, where they invade red blood cells. In infection caused by *P. falciparum* and *P. malariae*, the tissue schizonts all rupture simultaneously, and none persists in the liver. In contrast, *P. vivax* and *P. ovale* produce two types of exoerythrocytic forms: a primary type that develops and ruptures within 6 to 9 days and a secondary type called a hypnozoite that may remain dormant in the liver for weeks, months, or years. The hypnozoite form is responsible for relapses of erythrocytic infection observed with *P. vivax* and *P. ovale*.

Although relapses of *P. vivax* and *P. ovale* malaria may occur owing to the persistent exoerythrocytic (hypnozoite) phase, this is not the case with *P. falciparum* and *P. malariae*, which lack a dormant hepatic stage. Recurrent parasitemia with these species is caused by proliferation of persistent erythrocytic forms and is known as recrudescence. The prolonged delayed recrudescences occasionally seen with *P. malariae* are caused by erythrocytic parasites that have persisted in the tissue microcirculation.

The merozoites released from tissue schizonts invade circulating red blood cells and initiate the erythrocytic phase of infection. The erythrocytic phase is responsible for the clinical manifestations of malaria and on which laboratory diagnosis is based (Fig. 60.3). The different species of plasmodia selectively infect red blood cells of different ages. *P. vivax* and *P. ovale* preferentially infect young red blood cells, *P. malariae* infects only older circulating red cells, and *P. falciparum* can infect red cells of any age. The merozoites infecting red cells become small, rounded trophozoites or ring forms. Over time, the parasites develop into irregular ameboid trophozoites that utilize hemoglobin and produce an iron-containing pigment known as hematin or hemozoin. The mature trophozoite undergoes nuclear division and segmentation to form a mature schizont containing as many as 24 merozoites in a process known as erythrocytic schizogony. The erythrocytes containing the mature schizont rupture, liberating merozoites, which then go on to invade new red blood cells. This erythrocytic cycle is repeated with a periodicity that differs according to the species of *Plasmodium*.

Subpopulations of merozoites may also differentiate into sexual forms or gametocytes. The female form is called the macrogametocyte and the male form is called the microgametocyte. The gametocytes are ingested in the blood meal of a mosquito, sexual reproduction takes place, and the life cycle of the parasite is completed within the gastrointestinal tract of the mosquito with the production of new sporozoites.

Diagnosis

Malaria should be considered in any patient with an acute febrile illness and recent travel to or migration from an endemic area. The diagnosis is generally made by demonstration of the parasite within red blood cells. Organisms are easily seen in capillary blood obtained by fingerstick, although venous blood may also be used. Blood does not have to be obtained during the febrile period of infection; parasites may be present in blood even during the asymptomatic periods. The level of parasitemia may be low enough, however, that multiple attempts may be necessary to detect organisms within red cells.

Two types of blood films are prepared and examined for the laboratory diagnosis of malarial infections: thin films, with the blood spread over the slide in a thin layer, and thick films, with the blood concentrated in a small area. In the thick-film preparation, the red blood cells are lysed, and only white blood cells, platelets, and parasites (if present) are visible. The thick film is preferred for diagnosis because it permits the examination of a relatively large amount of blood and may be a more sensitive means of detecting low-grade parasitemias that may be missed with thin films. However, morphologic features of parasites are more distinct and typical in thin films, and thus both types of blood films should be prepared.

The preferred stain for malarial parasites in both thick and thin films is Giemsa buffered to pH 7.0. Although Wright's stain is commonly used to stain peripheral smears for hematologic examination, neither Wright's nor other Romanowsky stain produces the critical differentiation of morphologic features obtained with a Giemsa stain.

Identification of malarial parasites to the species level is critical. Patients with falciparum malaria are likely to have more severe disease, including severe hemolysis and cerebral involvement that can result in death in a matter of hours if not appropriately treated. Patients with infections caused by *P. vivax* or *P. ovale* require treatment for both erythrocytic and exoerythrocytic forms to avoid relapsing infection.

Identification to species level is accomplished by a combination of epidemiologic, clinical, and morphologic criteria (Table 60.4 and Table 60.5). As noted previously, some malarial species are seen more frequently in various geographic locations. The periodicity of clinical signs and symptoms is helpful, and patients with high levels of parasitemia or profound symptoms are more likely to have *P. falciparum* infection. When examining blood smears, there are three major factors to be considered (Table 60.5 and Fig. 60.3): appearance of erythrocytes, appearance of parasites, and developmental stages found. For falciparum malaria (Fig. 60.3, Fig. 60.4 and Fig. 60.5), infected red blood cells are normal in size, multiple parasites may be present per cell, the trophozoite stage is a small ring form with double chromatin dots sometimes peripherally located against the wall of the cell in an “appliqué” pattern, schizonts or other mature forms are seldom seen, and the gametocyte is banana shaped. In infections caused by *P. vivax* and *P. ovale* (Fig. 60.3 and Fig. 60.5, Fig. 60.6 and Fig. 60.7), infected red blood cells are usually enlarged and contain numerous pink granules or Schüffner's dots, the trophozoite is ring shaped but ameboid in appearance, more mature trophozoites and erythrocytic schizonts containing as many as 24 merozoites are present, and the gametocytes are round. The erythrocytes infected with *P. ovale* are often oval or fimbriated (more than 30% of infected red blood cells). Infections caused by *P. malariae* (Fig. 60.3, Fig. 60.5, Fig. 60.7, and Fig. 60.8) are characterized by parasitized red cells that are normal to small in size, trophozoites with dense cytoplasm and occasional band forms, schizonts with

six to 12 merozoites occasionally arranged in a rosette pattern around a pigment clump, and round gametocytes.

TABLE 60.5. COMPARATIVE MORPHOLOGIC FEATURES OF MALARIAL PARASITES IN STAINED THIN BLOOD FILMS

Characteristics	*Plasmodium falciparum*	*Plasmodium vivax*	*Plasmodium ovale*	*Plasmodium malariae*
Infected erythrocyte				
Enlarged[a]	–	+	±	–
Oval, fimbriated	±	±	+	-

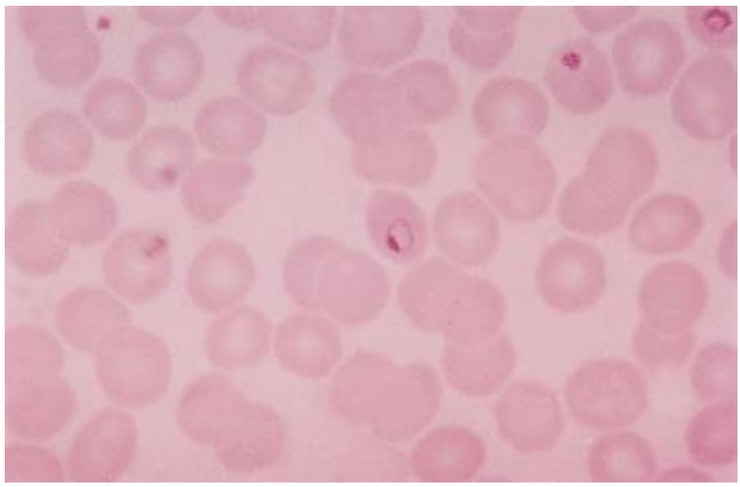

FIGURE 60.8. *Plasmodium malariae*: ring forms in thin film of peripheral blood. (From Smith JW, et al. *Diagnostic medical parasitology: blood and tissue parasites*. Chicago: American Society of Clinical Pathologists, 1976.)

Although mixed infections with more than one species of *Plasmodium* can occur, documentation is rare and caution should be used in making such a diagnosis unless there is definitive evidence of two species. The most common mixed infection is attributable to a combination of *P. falciparum* and *P. vivax*. The presence of characteristic *P. falciparum* gametocytes in a patient otherwise infected with *P. vivax* (enlarged red blood cells, multiple developmental forms present) is considered diagnostic. If only ring forms are present, the diagnosis of dual infection must be considered tentative at best.

Several serodiagnostic tests have been developed for malaria; however, they are primarily used for seroepidemiologic studies and are rarely necessary to diagnose clinical infections (3). Newer methods include microhematocrit centrifugation and staining with acridine orange, antigen detection by enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay, nucleic acid

detection by polymerase chain reaction (PCR), and detection of sporozoite- and merozoite-specific antibodies by ELISA or indirect immunofluorescence (5, 11, 13, 14, 15 and 16). None of these methods has yet supplemented routine microscopic diagnosis.

Treatment

Chloroquine is the drug of choice for both prophylaxis and treatment of infection owing to *P. ovale*, *P. malariae*, and susceptible strains of *P. falciparum* and *P. vivax* (11, 12, 17, 18, 19, 20, 21 and 22). Chloroquine-resistant strains of *P. falciparum* exist in virtually all malarious areas of the world except Central America northwest of the Panama Canal and limited parts of the Middle East, and their existence clearly complicates the prophylaxis and treatment of malaria. Updates on the prevalence of chloroquine-resistant *P. falciparum* and recommendations for antimalarial prophylaxis are published annually by the U.S. Centers for Disease Control and Prevention and by the World Health Organization. Resistance of *P. vivax* to chloroquine has been reported from Papua New Guinea, the Solomon Islands, Indonesia, and Brazil (17, 18, 19, 20, 21 and 22).

Patients infected with chloroquine-resistant *P. falciparum* (or *P. vivax*) may be treated with other agents, including mefloquine, quinine, quinidine, Fansidar (pyrimethamine-sulfadoxine), or doxycycline. Because quinine and Fansidar are potentially toxic, they are used more often for treatment rather than prophylaxis. Amodiaquine, an analogue of chloroquine, is effective against chloroquine-resistant *P. falciparum*; however, toxicity (agranulocytosis and hepatitis) limits its use. Newer agents with promising activity against multidrug-resistant strains of *P. falciparum* include halofantrine, a phenathrenenemethanol, and artemesinin, a sesquiterpene derivative of quinghaosu. They are not available in the United States.

Chloroquine and other blood schizonticides (quinine, quinidine, mefloquine, Fansidar, doxycycline) are not effective against the exoerythrocytic phase (hypnozoite) of *P. vivax* or *P. ovale*. To obtain a radical cure with these infections, primaquine is used to eradicate the hypnozoite and prevent its development to the tissue schizont stage and the subsequent release of infectious merozoites. Primaquine is not indicated for either *P. falciparum* or *P. malariae* infections because these parasites do not produce a hypnozoite stage in the liver. Use of primaquine may be dangerous in individuals with glucose-6-phosphate dehydrogenase deficiency and in whom the drug may cause hemolysis of older erythrocytes.

Prevention of malaria by vector control (insecticides, drainage of breeding sites) and personal protection measures against mosquito bites (mosquito netting, screening, insect repellents) are adjunctive measures to specific chemoprophylaxis and treatment regimens. The development of vaccines to protect individuals living in or traveling to endemic areas has been disappointing thus far.

Babesiosis

Babesiosis is a zoonosis infecting a variety of animals, including deer, cattle, and rodents. Humans are accidental hosts. Babesiosis is transmitted in nature by ixodid, or hard-bodied, ticks.

Classification

Babesiosis is caused by intraerythrocytic sporozoan parasites of the genus *Babesia*. Morphologically, *Babesia* resemble malaria parasites but can be distinguished from them by the absence of pigment within infected erythrocytes. More than 70 different species of *Babesia* have been described, including *B. bigemina*, *B. argentina*, and *B. divergens* in cattle; *B. caballi* and *B. equi* in horses; *B. canis* in dogs; and *B. microti* and *B. rodhaini* in rodents. Identification of the different species is based on morphology and the vertebrate host in which the parasite is found.

Babesiosis is a zoonotic disease occurring in Europe and the United States. The tick vector responsible for transmitting babesiosis, *Ixodes dammini*, is found throughout much of the United States. The natural reservoir hosts are field mice, voles, and other small rodents. Babesiosis is endemic in the United States, particularly on the East Coast. *B. microti*, the usual cause of babesiosis in the United States, generally causes a mild disease and is rarely fatal. *B. divergens*, which has been reported more frequently from Europe, causes severe, often fatal infections in individuals who have undergone splenectomies. Although most infections follow tick bites, transfusion-related infections have been reported.

Clinical Manifestations

Human babesiosis ranges in severity from asymptomatic to prolonged severe illness. For the most part, infection is self-limited and is characterized by general malaise, fever without periodicity, headache, chills, sweating, fatigue, and weakness (7, 23). The incubation period varies from 1 to 4 weeks. Mild to moderately severe hemolytic anemia and hepatosplenomegaly may develop secondary to red blood cell destruction by the parasite. In severe cases, renal failure and a picture of acute disseminated intravascular coagulation have been observed. The illness may last from a few weeks to several months. Low-grade parasitemia, with or without symptoms, may persist for as long as 4 months. Splenectomy or functional asplenia, as well as immunosuppression and advanced age, appear to increase individual susceptibility to infections, as well as more severe disease.

Life Cycle

Human babesiosis follows contact with an infected ixodid tick. The infectious forms are introduced into the bloodstream by the tick bite and infect erythrocytes. There is no evidence for an exoerythrocytic cycle such as that occurring in malaria. *Babesia* multiplies by budding within the red blood cell to form two to four daughter parasites. The red blood cells lyse, releasing merozoites, which can then infect other red blood cells and maintain the infection. The major clinical features of babesiosis, including hemolytic anemia, jaundice, and renal failure, are the result of multiplication within the red blood cells and their subsequent destruction.

The infected red blood cells can also be ingested by feeding ticks, in which additional replication can take place. Transovarial transmission from adult to larval tick also serves to maintain the infection within the tick population.

Diagnosis

As with malaria, the diagnosis of babesiosis requires the identification of characteristic intraerythrocytic parasites on Giemsa-stained thin or thick blood films (Fig. 60.9). Laboratory personnel must be experienced in differentiating *Babesia* and *Plasmodium* species. The morphologic characteristics of *Babesia* parasites are variable; however, *B. microti* usually appears as a small ring form indistinguishable from young trophozoites of *P. falciparum*. In contrast to *Plasmodium* species, no pigment is produced in erythrocytes infected with *Babesia*. Although characteristic, the tetrad form is rarely seen in human blood films. *Babesia* infections can also be diagnosed by animal (hamster) inoculation. Serologic tests are also available.

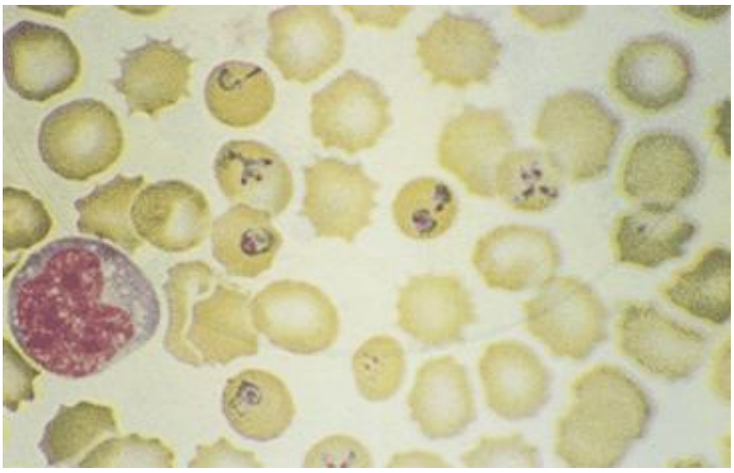

FIGURE 60.9. *Babesia* species ring and tetrad forms (Giemsa stain; original magnification, ×1,000). (From Garcia LS, Sulzer AJ, Healy GR, et al. Blood and tissue protozoa. In: Murray PR, Baron EJ, Pfaller MA, et al., eds. *Manual of clinical microbiology*, 6th ed. Washington, DC: American Society for Microbiology, 1995:1171–1195.)

Treatment

Human infections caused by *B. microti* are generally self-limited, and thus the effectiveness of treatment regimens has been difficult to evaluate. Symptomatic therapy is probably adequate for most patients. Various antiprotozoal regimens including chloroquine and pentamidine have been used with variable results. Severely ill (usually asplenic) patients have been treated successfully with quinine and clindamycin. Exchange blood transfusion has also been successful in splenectomized patients with severe infections caused by *B. microti* or *B. divergens* (7, 11, 23).

Preventive measures in endemic areas include wearing protective clothing and using insect repellents to minimize tick exposure. Because ticks must feed on humans for several hours before transmission occurs, prompt removal of ticks may also be protective.

Hemoflagellates

The blood and tissues of humans may be infected by one of several species of flagellate protozoa belonging to the family Trypanosomatidae. All belong to the *Leishmania* or *Trypanosoma* genus. All these organisms have developmental stages in blood-sucking arthropods (intermediate host) and in humans (definitive host), and many have a nonhuman mammalian reservoir host. *Leishmania* species are transmitted by sandflies (*Phlebotomus*, *Lutzomyia*), and the trypanosomes are transmitted by either the tsetse fly (*Glossina*) (African trypanosomes) or triatomid bugs (American trypanosomes).

The hemoflagellates may occur in a variety of stages in the human host and the insect vectors (Fig. 60.10). The amastigote form is an intracellular form that is small (2 to 5 μm) and round or oval in shape with a postcentral nucleus, anterior to which are the rodlike kinetoplast and an intracytoplasmic remnant of the

flagellum called the axoneme. The promastigote is an extracellular form present in culture and in the arthropod host. It is elongate and slender with a free flagellum. The kinetoplast is located at the anterior (flagellar) end of the parasite. The trypomastigote is the mature extracellular form that may be found in both the arthropod and the blood of the human host. It is long (17 to 30 mm) and slender with a centrally located nucleus and a subterminal kinetoplast. The axoneme forms the outer edge of the undulating membrane and extends anteriorly. The free flagellum projects from the anterior end of the parasite. The flagellum and the undulating membrane serve as a means of locomotion.

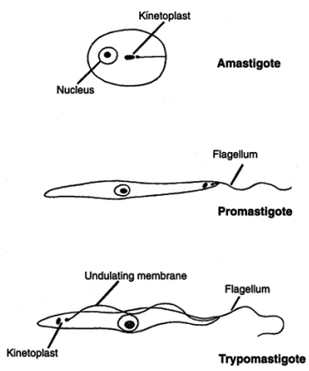

FIGURE 60.10. Morphologic types seen in various hemoflagellates of humans. (From Markell EK, Voge M, John DT. *Medical parasitology*, 7th ed. Philadelphia: Saunders, 1992.)

The number of stages present in the life cycle of the parasite varies with the genus and species. The amastigote form is present in the reticuloendothelial cells of individuals infected with *Leishmania* species and in cardiac muscle and other tissues of patients with American trypanosomiasis (Chagas' disease). The trypomastigote form occurs in the bloodstream, lymphatics, and cerebrospinal fluid in both Gambian and Rhodesian forms of African trypanosomiasis and in the bloodstream in Chagas' disease. Nonflagellate, cryptic forms have also been observed in the choroid plexus of individuals with African trypanosomiasis. The promastigote form is the developmental stage present in the midgut and pharynx of the arthropod vector of leishmaniasis. An epimastigote form (not shown), having a free flagellum and partial undulating membrane, is found in the salivary glands of the tsetse fly vector of African trypanosomiasis. Both promastigote and epimastigote forms may be present in the triatomid vector of Chagas' disease.

Leishmania

Classification

Leishmaniasis is caused by a group of protozoan parasites transmitted by species of sandflies (*Phlebotomus*, *Lutzomyia*). There are three general forms of leishmaniasis: cutaneous, mucocutaneous, and visceral. Individual members of this group have unique geographic distributions and propensities to cause disease. The *L. tropica* group causes cutaneous disease in the Old World (around the Mediterranean Sea, North and East Africa, the Near East, Southern Russia, the Middle East, Afghanistan, India, and China); the *L. mexicana* and *L. braziliensis* groups cause cutaneous and mucosal disease in the New World (from Mexico south through Central and South America, especially Colombia, Ecuador, Venezuela, Peru, and Brazil); and the *L. donovani* group causes visceral disease in both the Old and New World (24).

Leishmania live as amastigotes within the reticuloendothelial cells of the skin, mucous membranes, and viscera. Multiplication is by binary fission. The different species of *Leishmania* cannot be distinguished morphologically. Separation into species and subspecies has been based on unique clinical syndromes, geographic distribution, specific animal reservoirs, and species of sandfly associated with transmission. Recently, the application of newer taxonomic and genetic techniques such as restriction analysis of kinetoplast DNA, isoenzyme patterns, and serologic testing has led to some changes in classification and will likely lead to additional changes in the future.

Clinical Manifestations: Visceral Leishmaniasis

Visceral leishmaniasis or kala azar is caused by *L. donovani* and is endemic in some parts of South America, Africa, China, India, and the Mediterranean area. Infection ranges from asymptomatic in the majority of individuals to an overwhelming systemic illness with death in some. The disease may begin with a skin lesion but primarily is a disease involving the reticuloendothelial system of the visceral organs. The incubation period varies, but clinical manifestations generally occur 3 to 8 months after exposure. The disease tends to be most pronounced in small children.

Although clinical symptoms may arise quickly with an acute illness, most patients have the insidious development of fever, lassitude, abdominal discomfort, and distention secondary to massive hepatosplenomegaly, and progressive emaciation. Fever may be high and intermittent, similar to malaria, or may be continuous and low grade with night sweats. Symptoms are generally present for weeks to months before patients seek medical attention. These long delays are responsible for the high complication and fatality rates (as high as 75%) that have been reported in many studies.

On physical examination, the major findings include pallor, jaundice, and hepatosplenomegaly. Both liver and spleen can become massively enlarged but remain soft. The skin becomes thin and dry and may acquire an earthy-gray color. Laboratory abnormalities include anemia, leukopenia, and thrombocytopenia. A polyclonal hypergammaglobulinemia is common, and circulating immune complexes may lead to glomerulonephritis.

The pathogenesis of the disease is a mixture of the direct effects of the organism on infected cells and the host response to the infectious process. *L. donovani* disseminates throughout the reticuloendothelial system after ingestion by macrophages. Multiplication of the parasites within the liver, spleen, and bone marrow leads to the clinical syndrome of kala azar.

Although most infected patients mount an immune response based on production of antibody, T cells appear to be necessary for activation of macrophages to phagocytize and kill the organism. Patients with the most severe disease, usually the young or malnourished, have an inadequate T-cell response to infection.

Visceral leishmaniasis is usually a sporadic disease occurring in endemic areas. Outbreaks have also been described. For example, in the State of Bihar, India, in 1977, 70,000 to 100,000 cases with 4,000 deaths were reported (25).

Clinical Manifestations: Cutaneous and Mucocutaneous Leishmaniasis

Cutaneous leishmaniasis is caused by several species of *Leishmania* and occurs in both the Old and New World. Cutaneous leishmaniasis of the Old World is an infection characterized by nodular and ulcerative skin lesions caused by *L. tropica*, *L. major*, and *L. aethiopica*. It is also known as Oriental sore, Baghdad boil, and Delhi boil, among other names.

Cutaneous leishmaniasis of the Old World usually begins as a small papule that develops between 2 weeks and 6 months after the bite of an infected sandfly. This papule slowly enlarges and ulcerates. The ulcer remains shallow and has a well-defined, slightly raised margin. The lesion may be dry or moist and may

be single or develop multiple satellite lesions. Regional adenopathy may be present. The ulcer is usually painless and heals spontaneously after several months unless it is secondarily infected with bacteria. Alternative presentations include papules that do not ulcerate but that disseminate to distant sites and remain active for years, or leishmaniasis recidivans, a relapsing disease with lesions that heal in the center but continue to advance at the periphery and may spread to involve mucous membranes, leading to local destruction of nasal tissue.

Cutaneous leishmaniasis of the New World is also characterized by ulcerative skin lesions. The organism complex causing infection in Central America and southern Mexico is referred to as the *L. mexicana* complex. *L. mexicana* causes a lesion known as chiclero ulcer. The characteristic lesions of the ear occur in 40% of patients and are chronic, lasting many years. *L. braziliensis* causes cutaneous and mucocutaneous infections in humans occurring mainly in Brazil but also seen in other parts of South America. Simple cutaneous lesions caused by *L. braziliensis* generally heal spontaneously within 6 to 18 months but may persist much longer. Persons infected with *L. braziliensis* may develop metastatic spread of the disease to the nasal, pharyngeal, and buccal mucosa. This mucocutaneous form of infection is known as espundia. The mucosal lesions may develop months to years after the onset of cutaneous lesions. Lesions of mucous membranes are slow healing and progressive and may result in massive destruction of the nasal septum, palate, lips, pharynx, and larynx. If untreated, this form of the disease may result in death caused by aspiration, secondary bacterial infection, or progressive malnutrition.

Life Cycle and Transmission

The life cycle of *Leishmania* is relatively simple and is generally shared by all species (Fig. 60.11). Sandflies feeding on infected individuals ingest free amastigotes or parasitized macrophages. On reaching the midgut of the insect, the amastigotes transform into flagellated promastigotes that multiply in the gut and migrate to the proboscis, where they are introduced into the skin of a vertebrate host during a blood meal. Promastigotes injected into the host invade the reticuloendothelial cells, transform into amastigotes, multiply within the phagolysosome, and destroy the cell. The liberated amastigotes then invade other cells, continuing the cycle.

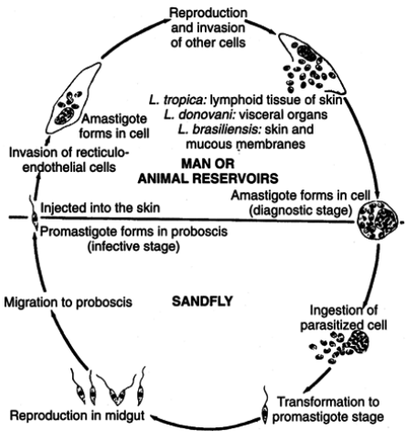

FIGURE 60.11. The life cycle of the *Leishmania*. (From Strickland GT. *Hunter's tropical medicine*, 7th ed. Philadelphia: Saunders, 1991.)

Leishmania live in a variety of canine and rodent reservoirs throughout the world. These reservoir hosts may have mild or asymptomatic disease, cutaneous lesions only, or severe visceral disease. Humans may also serve as the reservoir host, particularly in epidemic situations. Rare cases of transmission by blood transfusion or parenteral contact in laboratory settings has been described.

Because there is no animal reservoir of infection in North America, cases of leishmaniasis that occur in the United States occur in individuals who have traveled to endemic areas and who have exposure to the insect vector. Visceral leishmaniasis is most commonly seen in infants and small children in South America and the Mediterranean region and in older children and adults elsewhere. The immunologic mechanism for the predisposition of certain age groups to infection is poorly understood.

Diagnosis

The diagnosis of leishmaniasis is usually made by demonstration of amastigotes in reticuloendothelial cells. Cutaneous and mucocutaneous infection may be diagnosed by examination of material scraped or aspirated from the margin of the ulcer. The material is smeared on a slide and stained with Wright's or Giemsa stain. Biopsies from the edge of the lesion may also be obtained and stained by standard histologic methods. Visceral leishmaniasis may be diagnosed by microscopic examination of Giemsa-stained aspirates of bone marrow or spleen. The amastigote stage of the parasite may be found within macrophages or spread out from ruptured cells (Fig. 60.12). The kinetoplast of the organism stains well with Giemsa stain and provides a means of differentiating *Leishmania* from fungal pathogens such as *Histoplasma*. Although culture of promastigotes on artificial media may also establish the diagnosis, it is not widely available. A skin test, the Montenegro test, is frequently positive in cutaneous or mucocutaneous disease; however, it is usually negative in visceral infection. Several serologic tests are available and may be useful in diagnosis or epidemiologic studies. DNA probes and other nucleic acid–based test have been developed for direct examination of clinical material (5, 6, 24, 26). There are no commercially available products for these tests, and careful studies to determine the accuracy of testing procedures have not yet been performed.

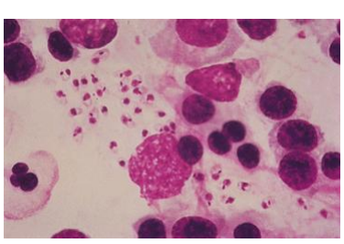

FIGURE 60.12. *Leishmania donovani*: Amastigote in human bone marrow smear (Giemsa stain; original magnification, ×1,280). (From Smith JW, et al. *Diagnostic medical parasitology: blood and tissue parasites*. Chicago: American Society of Clinical Pathologists, 1976.)

Treatment

Visceral leishmaniasis is treated with pentavalent antimonial compounds. Pentostam (stibogluconate sodium) is the agent most commonly employed and readily available. Therapy is not uniformly successful, and relapse rates of 2% to 8% are seen. Repeat

therapy with the same compound for extended periods may ultimately prove successful in difficult cases. Alternative approaches include the addition of allopurinol or treatment with pentamidine, amphotericin B, or one of several alternative oral agents (27,28). There is some toxicity associated with treatment with any of these compounds, and data on their effectiveness are limited.

Because simple cutaneous infection is usually self-limited, treatment is generally not administered. Treatment is considered for large lesions, for patients with potential or ongoing mucosal disfigurement, and occasionally for cosmetic reasons.

Trypanosoma

The trypanosomes infecting humans cause two distinctly different forms of disease: African trypanosomiasis (sleeping sickness) caused by *T. brucei gambiense* and *T. brucei rhodesiense* and American trypanosomiasis (Chagas' disease) caused by *T. cruzi*. All these species utilize blood-sucking arthropods as intermediate hosts and vectors for the transmission of infection.

African Trypanosomiasis

Classification. The African trypanosomes, *T. brucei gambiense* and *T. brucei rhodesiense*, are transmitted by species of *Glossina* (tsetse fly). Transmission is limited to the tsetse fly belt in central Africa. The two subspecies are indistinguishable morphologically but differ in the severity and rapidity of disease progression. In both *T. brucei gambiense* and *T. brucei rhodesiense*, the individual trypanosomes vary considerably in size and shape, ranging from delicate, spindle-shaped organisms with a free flagellum to broad, stumpy forms in which a free flagellum is not evident. Parasites may range from 14 to 22 μm in length and from 1.5 to 3.5 μm in breadth. The nucleus is usually centrally located or slightly posterior, and the posterior end of the organism is blunted rather than pointed.

Clinical Manifestations. Infection with the two subspecies results in different but overlapping clinical syndromes separated primarily by the rapidity with which the infection progresses. *T. brucei gambiense* is endemic in the Central African area, extending from the west coast through the central and equatorial zone as far east as Lake Victoria and Tanzania. It produces chronic disease, often ending fatally, with central nervous system involvement after several years duration. *T. brucei rhodesiense* is generally limited to the savanna areas of East Africa. Rhodesian sleeping sickness is characterized by a more fulminant course with the rapid onset of severe symptoms, frequently resulting in the death of the patient within a few months. Both varieties of African trypanosomiasis are associated with a mortality rate approaching 100% in untreated patients.

Infection with *T. brucei gambiense* and *T. brucei rhodesiense* occurs after a tsetse fly bite. At the site of the bite, a painless nodule develops known as the trypanosomal chancre. This lesion becomes firm and rubbery and resolves after approximately 2 weeks. Headache, fever, arthralgias, insomnia, edema, and lymphadenopathy accompany the early skin lesion as the parasite enters the bloodstream. Swelling of the posterior cervical lymph nodes is characteristic of Gambian disease and is called Winterbottom's sign. Eventually the organism enters the central nervous system, resulting in a variety of signs and symptoms, including irritability, tremors, ataxia, convulsions, meningoencephalitis, personality change, daytime somnolence, pronounced wasting, and eventually coma. Death is the result of central nervous system damage, combined with other infections such as malaria or pneumonia.

Infection with the more virulent *T. brucei rhodesiense* results in greater numbers of organisms in the blood and is generally without lymphadenopathy. Central nervous system invasion occurs early in the infection. The chronic stages of infection are not often seen with Rhodesian disease because, in addition to rapid central nervous system involvement, the organism produces kidney damage and myocarditis, leading to death. Persons with the Rhodesian form of sleeping sickness are usually dead within 9 to 12 months if untreated (24).

Life Cycle. The two African trypanosomes have similar life cycles (Fig. 60.13). Humans and other animals serve as hosts for the trypomastigote form, which lives and multiplies in the blood, lymph nodes, spleen, and cerebrospinal fluid. Tsetse flies become infected during meals on either humans or other infected animals, including several wild and domestic animals. Within the fly, the trypomastigotes multiply within the lumen of the gut, migrate to the salivary glands where they metamorphose into epimastigote forms, and eventually transform into metacyclic trypomastigotes that enter mammalian hosts during feeding. On entering the human host, the infective trypomastigotes remain in the tissues at the site of entry, often causing an interstitial inflammatory reaction. After several days, they gain entry into the bloodstream, where they multiply and then invade the lymphatics and central nervous system. Although they do not typically invade cells, they elicit an inflammatory response and hyperplasia of the vascular endothelium and produce injurious effects in every organ and tissue in the body.

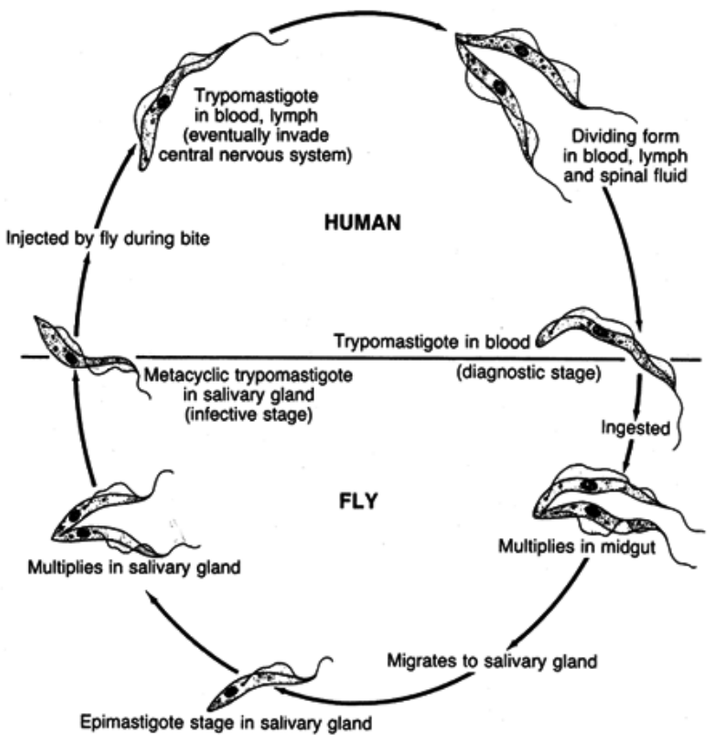

FIGURE 60.13. Life cycle of *Trypanosoma brucei gambiense* and *T. brucei rhodesiense*. (From Strickland GT. *Hunter's tropical medicine*, 7th ed. Philadelphia: Saunders, 1991.)

Diagnosis. Definitive diagnosis of African trypanosomiasis is made by demonstration of the parasite in Giemsa-stained blood films during febrile periods and in lymph node aspirates at other

times. Examination of cerebrospinal fluid may be useful in individuals infected with *T. brucei gambiense*; however, patients with *T. brucei rhodesiense* infection rarely survive long enough for the parasites to invade the central nervous system in large numbers. Parasites may be seen on wet preparations of blood and other fluids but are most easily detected in thick films of blood stained with Giemsa (24,29). Ideally, both thick and thin films should be examined because the characteristic morphology of the trypomastigote is best seen in thin smears (Fig. 60.14). Methods for concentrating parasites in blood may also be helpful. Approaches include centrifugation of heparinized samples or DEAE (*O*-diethylaminoethyl)-cellulose anion-exchange chromatography. Levels of parasitemia vary widely, and several attempts to detect the organism over several days may be necessary. Because trypomastigotes disintegrate rapidly on removal from tissues, preparations should be fixed and stained almost immediately. *In vitro* culture methods or inoculation of blood into suckling mice with subsequent detection of the parasite in tissue are available but not generally used in the diagnosis of African trypanosomiasis.

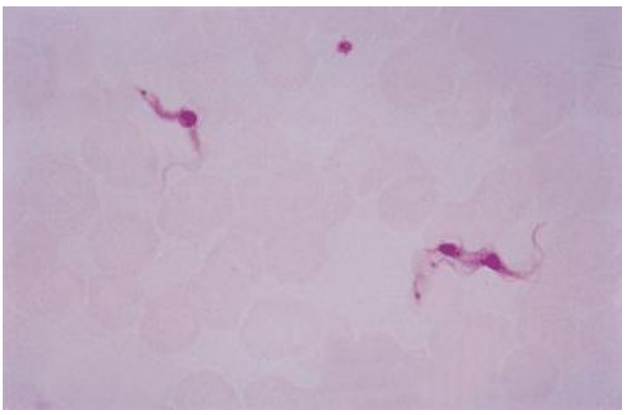

FIGURE 60.14. *Trypansoma rhodesiense*: trypomastigotes in thin blood film (Giemsa stain; original magnification, ×1,280). (From Smith JW, et al. *Diagnostic medical parasitology: blood and tissue parasites*. Chicago: American Society of Clinical Pathologists, 1976.)

Serologic tests are also useful diagnostic techniques. Immunofluorescence, ELISA, precipitin, and direct and indirect agglutination methods have been used. Most reagents for such tests are not available commercially. One difficulty in performing and applying serologic tests is the marked variability of the surface antigens of trypanosomes. Such antigens change over time for parasites infecting individual patients, thus antibody reactions may change over time unless antibody reagents identify more constant regions of the parasite surface.

Treatment. Therapy has generally been with suramin or pentamidine, although these drugs do not penetrate the central nervous system well. Arsenicals like melarsoprol have been used to treat more advanced central nervous system disease, although these agents are quite toxic. DL-α-Difluoromethylornithine (eflornithine) holds promise for treatment of all stages of disease, especially in Gambian trypanosomiasis. Alternative approaches to the control of trypanosomiasis have been to administer pentamidine as prophylaxis every 6 months in endemic areas or to attempt to eradicate fly vectors. Neither of these approaches has met with great success.

American Trypanosomiasis

Classification. American trypanosomiasis or Chagas' disease, although caused by a similar-appearing parasite, is different clinically and epidemiologically from African trypanosomiasis. Chagas' disease is caused by *T. cruzi*, an organism that differs from other trypanosomes infecting humans in that it has an intracellular amastigote stage in cardiac muscle and other tissues, as well as trypomastigote forms circulating in the blood. Unlike other trypanosomes, *T. cruzi* does not multiply in the blood. The amastigote stage replicates intracellularly within the tissues. *T. cruzi* is found in most of Central and South America and is transmitted to humans by the bite of reduviid bugs.

Clinical Manifestations. Chagas' disease may present clinically as an asymptomatic, acute, or chronic disease process. Some individuals may manifest all three stages of the disease. The disease is most severe in children younger than 5 years of age and frequently presents as an acute process with central nervous system involvement. The disease is usually more subacute or chronic in older children and adults. After the bite of the vector insect, the organisms proliferate locally in the tissues, producing an erythematous indurated area called a chagoma. These lesions frequently appear on the face and if present around the eye are known as Romaña's sign.

Acute infection is characterized by fever, chills, malaise, myalgia, and fatigue. Parasites may be present in the blood during the acute phase; however, they are sparse in patients older than 1

year. An acute attack may terminate in a few weeks in death or recovery, or the patient may enter the chronic stage of infection. Infected young children may develop central nervous system involvement and die within a few days or weeks.

In the chronic phase of disease, organisms proliferate as amastigotes in cardiac, skeletal, smooth muscle, and neurologic cells as well as the cells of the reticuloendothelial system. Damage to the autonomic nervous system of the heart and digestive tract as well as to the musculature of these organs produces the characteristic cardiac conduction and esophageal and colonic motility defects seen in chronic Chagas' disease. The chronic phase of disease commonly presents with myocarditis, megacardium, and electrocardiographic changes. Less commonly patients may have impaired esophageal and gastrointestinal motility and massive enlargement of the digestive tract, particularly the esophagus and colon (megaesophagus and megacolon). Hepatosplenomegaly is also apparent. Involvement of the central nervous system may produce a meningoencephalitis. Death from chronic Chagas' disease results from heart failure, cardiac arrhythmias, and other complications secondary to tissue destruction in the many areas invaded by the organisms.

Life Cycle. In the vertebrate host, *T. cruzi* occurs in the blood as a nondividing trypomastigote form. The life cycle of *T. cruzi* (Fig. 60.15) differs from that of the other *Trypanosoma* species with the development of an intracellular amastigote form within the tissues. The amastigote multiplies within the parasitized cells by binary fission, thus causing disruption of the cell. The released amastigotes then invade other cells and multiply within them. After a period of growth within the tissues, the amastigotes transform into trypomastigotes and are released into the circulating blood, where they may be ingested by new insect vectors. Within the reduviid bug, the organism transforms into the epimastigote stage and then back into the infective trypomastigote. The infective trypomastigotes pass out of the bug in its feces, are deposited on the skin during feeding, and then may be rubbed into the bite or a skin abrasion. The infective stages are almost immediately ingested by macrophages and transformed into amastigotes.

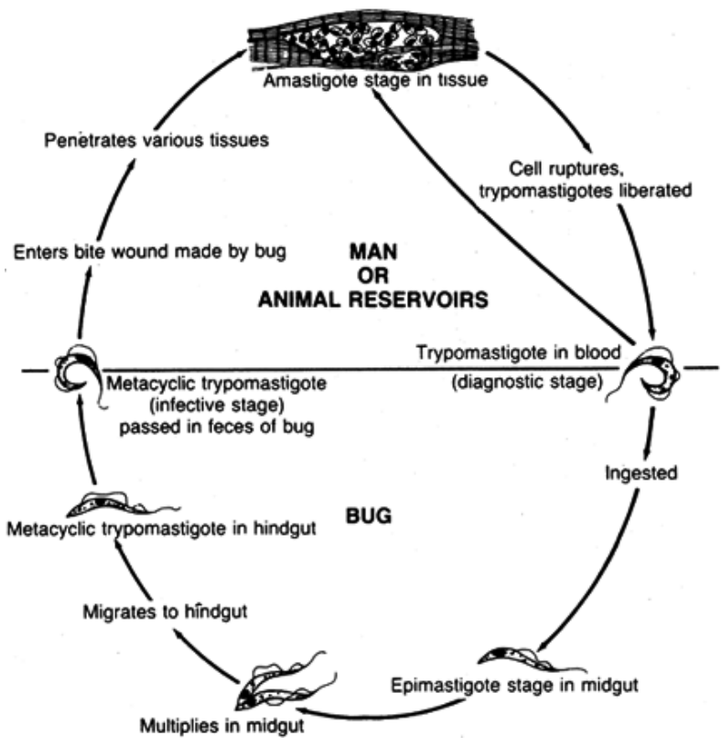

FIGURE 60.15. Life cycle of *Trypanosoma cruzi*. (From Strickland GT. *Hunter's tropical medicine*, 7th ed. Philadelphia: Saunders, 1991.)

Diagnosis. The diagnosis of Chagas' disease is based on the visualization of trypomastigotes in blood during the initial acute phase or during febrile periods in the chronic stage of the disease. The highest yield occurs during the early acute phase; latent or chronic disease is seldom associated with enough parasitemia to make direct detection possible. Amastigote forms may be found in biopsies of affected tissue (Fig. 60.16) or in aspirates from spleen, liver, lymph node, or bone marrow. Culture of blood or inoculation into laboratory animals may be useful when the parasitemia is low. In endemic areas, xenodiagnosis is widely used. Trypanosome-free reduviid bugs are allowed to feed on the patient suspected of having Chagas' disease, and the feces of the bug are examined for the appearance of parasites over a period of approximately 10 days. PCR amplification of nuclear or kinetoplast DNA has been shown to be very sensitive; however, it is not routinely available except in specialized centers (1, 5, 24).

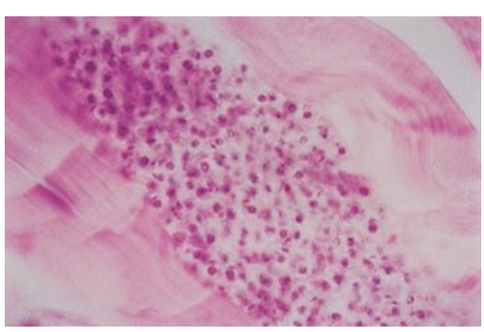

FIGURE 60.16. *Trypanosoma cruzi*: intracellular amastigotes in skeletal muscle (hematoxylin and eosin stain; original magnification ×1,280). (From Smith JW, et al. *Diagnostic medical parasitology: blood and tissue parasites*. Chicago: American Society of Clinical Pathologists, 1976.)

Diagnosis of chronic disease is largely based on serologic testing. Several serologic tests are available, including direct hemagglutination, complement fixation, immunofluorescence assays, and ELISA. No single method is thought to be adequate, and most patients are evaluated by multiple assays before making a final diagnosis (3, 4, 24).

Treatment. Treatment of Chagas' disease is limited by the lack of reliable agents. The current drug of choice is nifurtimox, a nitrofuran derivative. Although it has some activity against the acute phase of disease, it has little activity against tissue amastigotes and has several side effects. Alternative agents include allopurinol and benzimidazole, an imidazole compound. Another imidazole, the antifungal agent ketoconazole, has been shown to

inhibit the intracellular multiplication of *T. cruzi* amastigotes and to afford protection to mice infected with *T. cruzi* (30).

Prevention of infection is also important. Vector control through the use of insecticide treatment of reduviid bug infected dwellings, eradication of nests, and construction of homes to prevent nesting of bugs is essential. Screening of blood by serologic means or excluding blood donors from endemic areas prevents some infections that would otherwise be associated with transfusion therapy.

Toxoplasma gondii

Classification

Toxoplasma gondii is a typical coccidian parasite related to *Plasmodium*, *Babesia*, *Isospora*, and other members of the phylum Apicomplexa. *T. gondii* is an intracellular parasite and is found in a wide variety of animals, including birds and humans. There is only one species, and there appears to be little strain-to-strain variation. Human infection with *T. gondii* is ubiquitous; however, it is increasingly apparent that certain immunocompromised patients are more likely to have severe manifestations. The essential reservoir host of *T. gondii* is the common house cat and other felines.

Clinical Manifestations

Multiple clinical syndromes have been described for infection with *T. gondii*. Most common, however, is asymptomatic infection in normal hosts (31). When symptomatic disease occurs, the infection is characterized by intracellular replication of the organisms, cell destruction, and eventual cyst formation.

A small percentage of otherwise normal individuals on first exposure to the organism will develop an acute illness with cervical or generalized adenopathy. The adenopathy is typically nontender and nonfluctuant; however, occasionally the nodes can be quite tender. In some individuals, the acute infection may resemble infectious mononucleosis with fever, malaise, headache, night sweats, myalgias, sore throat, maculopapular rash, and hepatosplenomegaly (31). Atypical lymphocytes may be present on peripheral smear. A small percentage of these patients can have major complications, including retroperitoneal adenopathy with severe abdominal pain, chorioretinitis, myocarditis, pneumonia, or encephalitis. Most individuals with acute infection, however, have a benign course with spontaneous recovery in days to weeks.

Congenital infection with *T. gondii* also occurs in infants born to mothers who are infected during pregnancy. The likelihood of transmission of the organism from mother to infant increases during the course of gestation, with infection occurring in approximately 25% of infants exposed in the first trimester, 54% in the second, and 65% in the third. If infection occurs in the first trimester, the result is spontaneous abortion, stillbirth, or severe disease. Manifestations of infection in the infant infected after the first trimester include epilepsy, encephalitis, microcephaly, intracranial calcifications, hydrocephalus, psychomotor or mental retardation, chorioretinitis, strabismus, blindness, anemia, jaundice, rash, pneumonia, diarrhea, and hypothermia (31).

Infants may be asymptomatic at birth only to develop disease months to years later. Most often, these children develop chorioretinitis with or without blindness, or other neurologic problems, including retardation, seizures, microcephaly, and hearing loss.

In immunocompromised older patients, a different spectrum of acquired disease is seen. Reactivation of latent toxoplasmosis is a special problem in these individuals. The presenting symptoms of *Toxoplasma* infection in immunocompromised patients are usually neurologic, most frequently consistent with diffuse encephalopathy, meningoencephalitis, or cerebral mass lesions. Reactivation of cerebral toxoplasmosis has emerged as a major cause of encephalitis in patients with acquired immunodeficiency syndrome (AIDS) (32). The disease is usually multicentric, with more than one mass lesion appearing in the brain at the same time.

Symptoms are related to the location of the lesions and may include hemiparesis, seizures, visual impairment, confusion, and lethargy. Other sites of possible infection include the eye, lung, and testes (31, 33, 34). Although disease is seen predominantly in patients with AIDS, it may also occur with similar manifestations in other immunocompromised patients, in particular in those undergoing organ transplantation.

Life Cycle and Epidemiology

The life cycle of *T. gondii* is shown in Fig. 60.17. The complete life cycle (both asexual and sexual reproduction) occurs, as far as it is known, only in the cat. Humans and other animals are considered to be intermediate hosts in which only asexual reproduction, characterized by proliferative forms and cysts, has been observed. Felines ingest oocysts from the environment and cysts (bradyzoites) from tissues of other species. Organisms develop within the intestinal cells of the cat to form oocysts, which are passed in the feces. Oocysts shed in the feces are immature, becoming infective in 1 to 5 days. Intermediate hosts become infected by ingesting mature oocysts or by ingesting cyst-containing

meat from other infected animals. When ingested by the intermediate host, the organism develops into the rapidly multiplying tachyzoite form that is responsible for the initial spread of infection. The tachyzoites disseminate via the bloodstream to many organs and tissues, where they undergo intracellular replication. Multiplication of the parasites within an infected cell usually leads to death and rupture of the cell, releasing the tachyzoites to infect new cells, or it may lead to formation of a cyst within the infected tissue. The cyst form predominates in chronic or latent toxoplasmosis. Individual cysts contain the slowly developing bradyzoites and measure as much as 0.1 mm in diameter. Disease manifestations in chronic toxoplasmosis are primarily the result of the mechanical presence of the enlarging cyst.

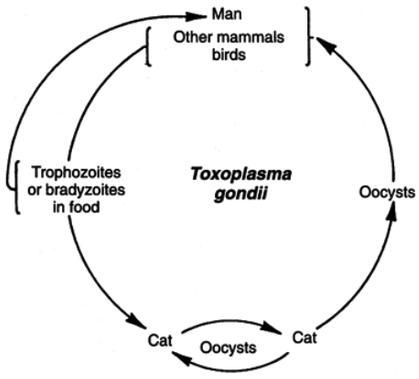

FIGURE 60.17. Life cycle of *Toxoplasma gondii*. (From Markell EK, Voge M, John DT. *Medical parasitology*, 7th ed. Philadelphia: Saunders, 1992.)

Human infection occurs after ingestion of viable cysts or trophozoites in undercooked meat or infective oocysts from cat fecal contamination. Because oocysts require several days outside the feline host to mature, infection will generally occur only if there is exposure to soil previously contaminated or to cat feces in a litter box that has not been cleaned for several days. Transmission of infection from contaminated beef, pork, lamb, and goat's milk has been described. Fresh fruit and vegetables may also be a source of infection if the soil they are grown in is contaminated with oocysts. Aside from congenital infection, transmission of infection from person to person has been described only rarely via blood transfusion or solid organ transplantation.

Seroprevalence rates vary from place to place for reasons that remain obscure; however, studies indicate that populations with greater consumption of rare or uncooked meat are more likely to be seropositive. For example, the highest recorded rate (93%) has been reported in Parisian women who prefer undercooked or raw meat (8, 32). Rates may also vary by climate because oocysts do not survive well in colder regions.

Although the rate of seroconversion is similar for individuals within a geographic location, that of severe infection is dramatically affected by the immune status of the individual. Patients with defects in cell-mediated immunity, especially those with HIV infection or after organ transplantation (or immunosuppressive therapy), are most likely to have disseminated or central nervous system disease. Illness in this setting is generally thought to be caused by reactivation of previously latent infection rather than new exposure to the organism.

Diagnosis

There are several possible approaches to the diagnosis of toxoplasmosis. The diagnosis may be established by laboratory tests, including direct visualization of the organism in tissue, growth in culture, detection by molecular methods, or more commonly by serologic methods. In immunocompromised individuals, the diagnosis is often presumptive based on typical findings and clinical impression.

Direct examination of tissue suspected of infection is the definitive method of diagnosis (Fig. 60.18). Biopsy specimens from lymph nodes, brain, liver, myocardium, or other suspected tissue or from body fluids including cerebrospinal fluid, amniotic fluid, bronchoalveolar lavage fluid, or peritoneal fluid can be examined directly for the organisms. The most useful stains appear to be direct fluorescent antibody stains and peroxidase-antiperoxidase stains using antibodies to *T. gondii*. The fluorescent antibody stains available to date have not been as sensitive and specific as the immunoperoxidase stain. Newer monoclonal antibody–based fluorescent stains may prove to be better than the older polyclonal versions. In addition, Wright-Giemsa stains of tissue specimens can be utilized to see the organism.

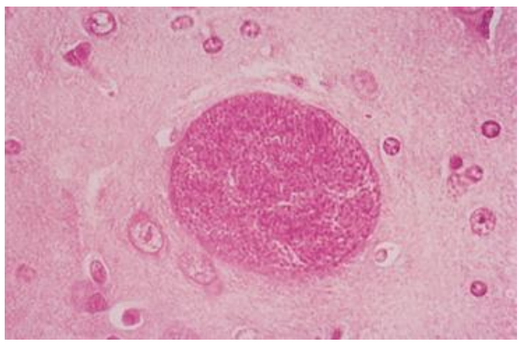

FIGURE 60.18. *Toxoplasma gondii*: cyst in brain section (hematoxylin and eosin stain; original magnification, ×560). (From Smith JW, et al. *Diagnostic medical parasitology: blood and tissue parasites*. Chicago: American Society of Clinical Pathologists, 1976.)

Culture methods for *T. gondii* are largely experimental and are not usually available in clinical laboratories. The two methods available are to inoculate potentially infected material into either mouse peritoneum or tissue culture. Tissue cultures are more readily available, may grow organisms more quickly, and are easier to process because identification simply requires microscopic examination of the culture vial. Mouse inoculation, however, may be more sensitive.

Application of molecular methods, such as PCR, has proven to be highly sensitive and specific for detecting *T. gondii* in cerebrospinal fluid, serum, and amniotic fluid (5, 31, 35). Unfortunately, commercial assays are not available, and these procedures are not widely available. Careful quality control is required to avoid false-positive and false-negative reactions.

Serologic testing is commonly employed for the diagnosis of toxoplasmosis. As with other infectious serologies, attention to increasing immunoglobulin (Ig) G titers in serially collected blood samples or a positive IgM titer is essential to differentiate acute, active infection from previous asymptomatic or chronic infection. Although the Sabin-Feldman dye test is considered the reference method for serologic testing, it is not widely employed in clinical laboratories because of the requirement for live organisms as the antigen source. Several alternative methods are available, including indirect fluorescent antibodies, indirect hemagglutination, complement fixation, and ELISA methods for both IgG and IgM antibodies (31, 36). Currently the ELISA tests for IgG and IgM are the most widely used because of their simplicity and rapidity in documenting acute infections. These tests are not generally satisfactory in immunocompromised individuals with latent or reactivated infections because these patients frequently fail to produce an IgM response or an increasing IgG titer.

Treatment

Therapy of toxoplasmosis depends on the nature of both the infectious process and the immunocompetence of the host. Most mononucleosis like infections in normal individuals resolve spontaneously without intervention. Conversely, disseminated or central nervous system infection in compromised patients must be treated. Before its association with HIV infection, immunocompromised patients with toxoplasmosis were treated for 4 to 6 weeks. In the setting of HIV infection, the rate of relapse when therapy is discontinued is approximately 25%. Such patients are now treated with an initial high-dose regimen of pyrimethamine and sulfadiazine and then continued on lower doses of both drugs indefinitely (37, 38). Although pyrimethamine and sulfadiazine are the agents of choice, side effects, in particular rash and bone marrow suppression, often require changes to alternative agents. Atovaquone and azithromycin (each alone or with pyrimethamine) also have some activity, although their efficacy and safety compared with those of clindamycin-pyrimethamine need to be assessed. Trimethoprim/sulfamethoxazole is not as acceptable as pyrimethamine-sulfadiazine for treatment of disseminated or central nervous system toxoplasmosis. Ocular infections generally respond well to pyrimethamine and sulfadiazine, with treatment periods lasting approximately 1 month.

Infection in the first trimester of pregnancy has been difficult to manage because pyrimethamine is teratogenic in laboratory animals. Both clindamycin and spiramycin have been substituted with apparent success. Spiramycin does not appear to be effective therapy for toxoplasmosis in immunocompromised individuals.

The use of corticosteroids in the treatment of toxoplasmosis remains controversial. It is definitely believed to be of benefit in ocular infections that involve or threaten the macula. The use of steroids for central nervous system infections, even when brain edema is evident on a computed tomographic scan, is not accepted as beneficial. Steroids are generally added in such cases only when progression of clinical symptoms continues despite appropriate antimicrobial therapy.

As more immunocompromised patients at risk for disseminated toxoplasmosis are identified, greater emphasis is being placed on preventive therapy. Routine serologic screening of patients is now being performed before organ transplantation and early in the course of HIV infection. Those with positive serologies are at much higher risk for development of disease and are now being considered for prophylaxis. Trimethoprim/sulfamethoxazole, which is also used as prophylaxis to prevent *Pneumocystis* infections, also appears to be effective at preventing or limiting infections with *Toxoplasma*. Additional preventive measures for pregnant women and immunocompromised hosts should include avoiding both consumption of raw or undercooked meat and exposure to cat feces.

Free-Living Amoebae

Classification

Free-living amebic infections are caused by organisms belonging to the genera *Naegleria*, *Acanthamoeba*, and *Balamuthia* (39, 40). These organisms are ubiquitous in nature and are free-living in soil or water. *Naegleria* species are classified as ameboflagellates and are able to exist temporarily in a flagellate form as well as in an aflagellar ameboid form. *Acanthamoeba* and *Balamuthia* organisms never produce flagella. All three organisms may undergo cyst formation outside the host, but only *Acanthamoeba* and *Balamuthia* form cysts in infected tissue (39).

Clinical Manifestations

Naegleria, *Acanthamoeba*, and *Balamuthia* organisms are opportunistic pathogens. Infections range from acute fulminating primary amebic meningoencephalitis to the more chronic granulomatous encephalitis and amebic keratitis. In most cases, it is thought that the infection was acquired from the environment either by swimming in contaminated water, inhalation of cysts in dust, or direct implantation on the surface of the cornea either by dust or contaminated contact lens material.

Acute primary amebic meningoencephalitis is most commonly caused by *N. fowleri* and occurs when amebae present in water invade the nasal mucosa and extend into the brain. Acute amebic meningoencephalitis may be indistinguishable from bacterial meningitis and is marked by fever, severe frontal headache, stiff neck, nausea, and vomiting. Abnormalities of taste and smell may be present and seizures are common. The process is rapid and may progress to coma within 48 hours. The cerebrospinal fluid is purulent and may contain many erythrocytes and motile amebae. Most cases are fatal.

In contrast to *Naegleria*, central nervous system involvement with *Acanthamoeba* and *Balamuthia* is generally a more subacute or chronic process with a granulomatous encephalitis and single or multiple brain abscesses. Headache and fever are present but are more insidious and low grade. A wide variety of neurologic signs eventually appears, depending on the area of the brain involved. The cerebrospinal fluid may contain both neutrophils and mononuclear cells, but amebae are rare. This form of amebic meningoencephalitis occurs more commonly in immunosuppressed individuals and is uniformly fatal.

Other forms of infection with free-living amebae are usually owing to *Acanthamoeba* and include ocular, cutaneous, pulmonary, and sinus involvement. The most common of these infections is amebic keratitis. The keratitis is usually associated with corneal trauma followed by contact with contaminated soil or water. In recent years, the most common form of amebic keratitis has been associated with improper use of contact lenses, particularly extended-wear lenses. Cases of apparent disseminated cutaneous and subcutaneous infection with *Acanthamoeba* and *Balamuthia* have been described in AIDS patients (39, 41, 42 and 43). These infections present with multiple soft-tissue nodules that on biopsy contain amebae. Central nervous system or deep-tissue involvement may also be present with this form of infection.

Life Cycle

The life cycle of the free-living amebae is relatively simple, involving both cyst and motile trophozoite forms. In addition, *Naegleria* has a flagellate stage that alternates with the ameboid trophozoite phase. Free-living forms of the amebae come into

contact with nasal or respiratory mucosa after exposure to contaminated water or dust. After multiplication locally, invasion of the central nervous system and other tissues occurs by hematogenous spread. In *Naegleria* infection, only the ameboid trophozoites are found within the tissue, whereas with *Acanthamoeba* and *Balamuthia* infection, both trophozoites and cysts are found in tissues. Amebic keratitis occurs by direct contact of the cornea with amebae, which may be introduced through mild corneal trauma or by exposure to contaminated water or contact lens material or solutions. Trophozoites and cysts of *Acanthamoeba* are found in infected corneal tissue.

Diagnosis

Diagnosis of free-living amebic infections is established by demonstrating the organisms in cerebrospinal fluid, nasal discharge, or tissue (corneal scraping, biopsy) by light or phase microscopy, culture, or animal inoculation (39). *Naegleria* and *Acanthamoeba* may be difficult to differentiate in tissue. Isolation in culture may be accomplished by growing the organism on plain agar plates seeded with gram-negative enteric bacilli. *Naegleria* measure 8 to 15 µm in diameter and have blunt pseudopodia, whereas *Acanthamoeba* are 10 to 15 µm and have spinelike pseudopodia. *Balamuthia* trophozoites are irregular in shape, produce broad pseudopodia, and measure from 12 to 60 µm in length. Additional differentiating features are the presence of a flagellate stage with *Naegleria* and the production of a cyst form in tissue with *Acanthamoeba* and *Balamuthia*. Morphologically, *Balamuthia* cannot be differentiated from *Acanthamoeba* by routine histology, although differences may be detected at the ultrastructural level. Immunofluorescent staining has been used to differentiate these organisms in tissue. *Balamuthia* do not grow on agar plates used for *Naegleria* or *Acanthamoeba* but have been recovered in tissue culture using mammalian cell lines.

Treatment

Treatment of free-living amebic infections is largely ineffective. Amebic meningoencephalitis caused by either *Naegleria*, *Balamuthia*, or *Acanthamoeba* is unresponsive to antibacterial and antiamebic drugs. Amphotericin B, a toxic antifungal agent, is the anti-*Naegleria* agent for which there is evidence of clinical effectiveness. Additional agents include miconazole, rifampin, and/or tetracycline, usually administered in combination with amphotericin B. *Acanthamoeba* and *Balamuthia* appear resistant to ketoconazole, miconazole, itraconazole, sulfadiazine, flucytosine, pentamidine, and polymyxin B. These agents may have some effect *in vitro* but have not been adequately tested in patients. Treatment of amebic keratitis may require repeated corneal transplantation. In some cases enucleation of the eye may be required.

INTESTINAL AND UROGENITAL PROTOZOA

Part of "60 - Parasitology"

Protozoa may colonize or infect the intestinal tract, oropharynx, and urogenital tract of humans. Most of these parasites belong to the amebae or flagellates; however, infection with ciliate, coccidian, or microsporidian parasites may also be encountered. In a review of stool specimens examined for intestinal parasites by the College of American Pathologists in the United States, the most common potential pathogen was *Giardia lamblia* followed in order by *Cryptosporidium* species, *Dientamoeba fragilis*, *Entamoeba histolytica*, *Isospora* species, and *Microsporidia* (44). These organisms are generally of worldwide distribution, and most are acquired by fecal-oral contamination.

Amoebae

The amoebae are simple, unicellular organisms. The amoebae that inhabit the intestinal tract of humans include members of four genera: *Entamoeba*, *Endolimax*, *Iodamoeba*, and *Blastocystis* (45). These organisms have a relatively simple life cycle involving an actively motile feeding trophozoite stage and a nonmotile, resistant, infective cyst stage. The cysts are ingested by the host and excyst in the small intestine. The motile trophozoites proliferate in the lumen of the colon. Motility of amebae is accomplished by the extrusion of cytoplasmic foot processes or pseudopods. The cyst form develops in response to environmental changes. Both trophozoites and cysts may be shed in the stool.

Of the amebae that occur in humans, most are considered nonpathogenic commensals, including *E. coli*, *E. hartmanni*, *E. dispar*, *E. gingivalis* (oral commensal), *I. bütschlii*, and *E. nana*. *E. histolytica*, the agent of amebiasis, is the major pathogen in this group. *E. polecki*, a parasite of pigs and monkeys, may occasionally cause diarrhea in humans. The pathogenicity of *B. hominis* is still controversial (45, 46 and 47). These organisms are differentiated one from other by morphologic characteristics as observed on microscopic examination of wet mounts and permanently stained preparations (45) (Table 60.6 and Fig. 60.19).

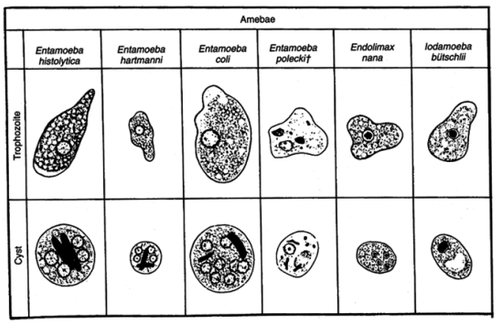

FIGURE 60.19. Amebae found in stool specimens of humans. *Entamoeba polecki* are rare, probably of animal origin. (From Smith JW, McQuay RM, Ash LR, et al. *Diagnostic medical parasitology: intestinal protozoa*. Chicago: American Society of Clinical Pathologists, 1976.)

Entamoeba histolytica

Classification

E. histolytica is characterized by an actively motile trophozoite form containing a single nucleus with evenly distributed peripheral chromatin granules and a small, centrally located karyosome. The trophozoite ranges in size from 10 to 60 µm in diameter and may contain phagocytized red blood cells (Fig. 60.20). The cyst stage may be as large as 20 µm in diameter and contains four nuclei in the mature form. The presence of rod-shaped chromatoid bodies with rounded ends in the immature cyst form may aid in distinguishing *E. histolytica* from other *Entamoeba* species (Fig. 60.21). It is now recognized that the ameba morphologically identified as *E. histolytica*, is actually two distinct species (45, 48). The pathogenic species is *E. histolytica* and the nonpathogenic species is *E. dispar*. *E. dispar* is differentiated from *E. histolytica* based on specific isoenzyme profiles (zymodemes). The zymodeme profiles represent stable genetic differences and do not interconvert (45, 48, 49 and 50). Additional biochemical, molecular, and immunologic evidence supports the existence of the two species (45,48–50).

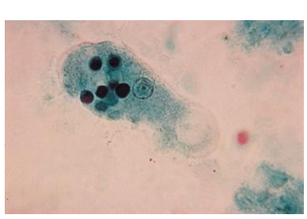

FIGURE 60.20. *Entamoeba histolytica* trophozoite with ingested erythrocytes in fecal smear (trichrome stain; original magnification, ×1,125). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal protozoa*. Chicago: American Society of Clinical Pathologists, 1976.)

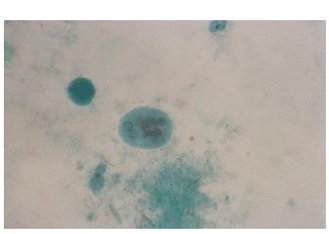

FIGURE 60.21. Mature cyst of *Entamoeba histolytica* containing chromatoidal bodies (trichrome stain of fecal smear; original magnification, ×1,200). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal protozoa*. Chicago: American Society of Clinical Pathologists, 1976.)

Clinical Manifestations

The clinical manifestations of amebiasis owing to *E. histolytica* are varied and depend in large measure on the extent of tissue invasion

TABLE 60.6. MORPHOLOGY OF AMEBAE TROPHOZOITES AND CYSTS

	Entamoeba histolytica/ E. dispar[a]	*Entamoeba hartmanni*	*Entamoeba coli*	*Iodamoeba butschlii*	*Endolimax nana*	*Blastocystis hominis*[b]
Trophozoites

and on whether the infection is confined to the intestinal tract or has spread to involve other organs. Intestinal amebiasis is the most common form of infection and is asymptomatic in most individuals (85% to 95% of cases). Asymptomatic individuals may continue to pass cysts in their stools for months and are an important epidemiologic link in the continued transmission of the organism. Although infections with *E. histolytica* may be asymptomatic (45, 51), based on zymodeme analysis, most asymptomatic individuals are infected with the noninvasive *E. dispar* (45, 48, 49 and 50). Between 5% and 15% of cases have definite signs and symptoms ranging from amebic colitis to severe amebic dysentery to extraintestinal complications (51). Amebic colitis has various symptoms related to localized tissue destruction in the large intestine. These intestinal lesions are characterized by small, pinpoint mucosal ulcerations that may expand into the submucosa to form typical flask-shaped ulcers. The more severe dysenteric form of the disease is characterized by severe abdominal cramping and bloody diarrhea. There is extensive invasion of

the mucosa with ulceration that may lead to intestinal perforation and peritonitis, hemorrhage, or secondary bacterial infection and abscess formation. Extraintestinal amebiasis most commonly involves the liver and is characterized by systemic signs of infection (fever, leukocytosis, weight loss) as well as localized tenderness and organomegaly. Rarely, amebic abscesses may appear in other organs, such as lung or brain, either by direct extension from a liver abscess (lung) or by hematogenous dissemination from an intestinal or hepatic focus.

Life Cycle and Epidemiology

The life cycle of *E. histolytica* is illustrated in Fig. 60.22. After ingestion of infective cysts in contaminated food or water, the cysts pass through the stomach, where exposure to gastric acid stimulates excystation and release of the pathogenic trophozoite in the duodenum. The number of trophozoites produced varies with the number of nuclei in the cyst stage. The trophozoites become established and proliferate by binary fission in the large intestine, where they produce extensive local necrosis. Under particular

conditions encystation occurs. The resulting cysts are passed in the feces, thus perpetuating the cycle.

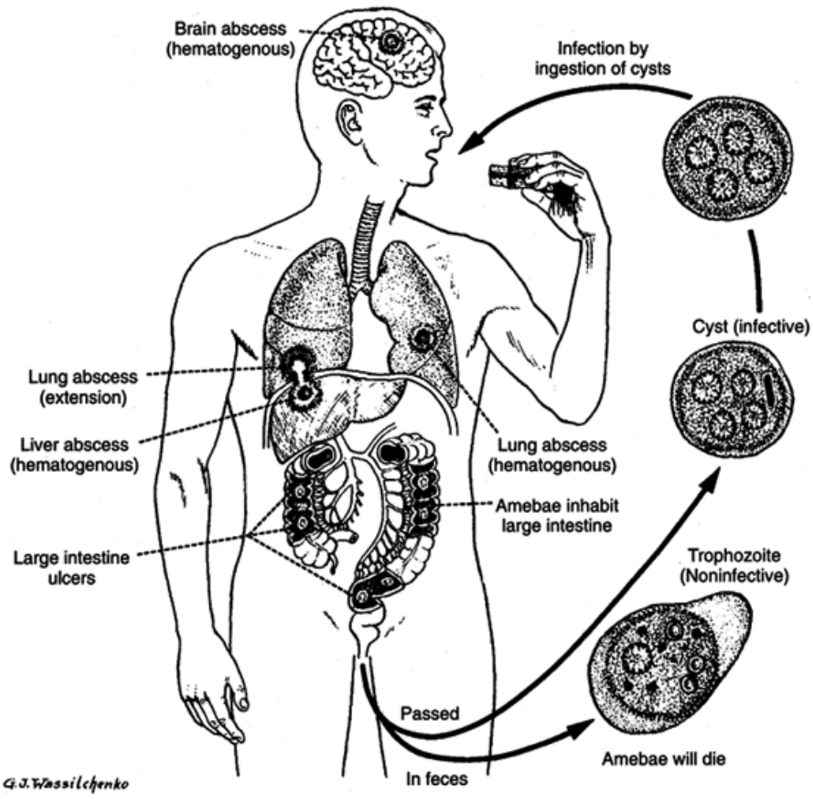

FIGURE 60.22. Life cycle of *Entamoeba histolytica*. (From Markell EK, Voge M, John DT. *Medical parasitology*, 7th ed. Philadelphia: Saunders, 1992.)

E. histolytica has a worldwide distribution; however, its highest incidence is in underdeveloped tropical and subtropical regions with poor sanitation and contaminated water. Many of the infected individuals are asymptomatic carriers and represent a reservoir for the spread of *E. histolytica* to others. Both symptomatic and asymptomatic individuals infected with *E. histolytica* may pass infectious cysts, as well as noninfectious trophozoites, in their stools. The trophozoites are unable to survive for prolonged periods in the environment and are destroyed by gastric acid if ingested. Contamination of food and water with infectious cysts is a particular problem in hospitals for the mentally ill, military and refugee camps, prisons, and crowded day care facilities. Sexual transmission of cysts by oral-anal sexual practices is an important means of transmission of amebiasis in homosexual populations.

Diagnosis

Examination of stool specimens will usually allow the diagnosis of intestinal amebiasis. The identification of *E. histolytica* trophozoites and cysts in stools and trophozoites in tissue is diagnostic of amebic infection. Microscopic examination of stool specimens is insensitive, and diagnosis may require collection and examination of multiple stool specimens or a purged series. False-negative stool examinations are attributable to the fact that the parasites are not usually distributed homogeneously in the specimen and are concentrated in the intestinal ulcers and at the margins of abscesses, rather than in the stool or the necrotic center of the abscess. False-positive microscopic examinations may be owing to failure to distinguish *E. histolytica* from other nonpathogenic amebae (Table 60.6 and Fig. 60.19), as well as polymorphonuclear leukocytes. Extraintestinal amebiasis may be diagnosed using radiographic scanning procedures for the liver, lung, or brain. Specific serologic tests are frequently positive in individuals with extraintestinal or symptomatic intestinal disease and are negative in asymptomatic carriers and uninfected individuals. In addition to conventional microscopic and serologic tests, investigators have developed immunologic tests for the detection of antigen in feces as well as PCR and nucleic acid probe assays for the detection of pathogenic strains of *E. histolytica* (45, 49, 50 and 51). Although promising, these newer diagnostic tests are not yet widely available.

Treatment

Treatment of amebiasis varies with the clinical stage of the infection. Asymptomatic carriage may be eradicated with

iodoquinol, diloxanide furoate, or paromomycin. Acute amebic colitis is treated with metronidazole plus iodoquinol. Amoebic dysentery may be treated with emetine, dehydroemetine, or metronidazole followed by iodoquinol. Metronidazole is generally considered the agent of choice in the treatment of extraintestinal amebiasis. Drainage of large amebic abscesses may occasionally be necessary.

Other Intestinal Amoebae

Other amoebae can parasitize the oral and gastrointestinal tract of humans. These include *E. coli*, *E. gingivalis*, *E. hartmanni*, *E. polecki*, *Endolimax nana*, *I. butschlii*, and *B. hominis*. All these amebae, with the possible exception of *E. polecki* and *B. hominis* are considered nonpathogenic commensals. *E. polecki* most commonly infects pigs and monkeys but may cause mild diarrhea in humans. Infections caused by *E. polecki* are confirmed microscopically and are treated in a manner similar to amebiasis caused by *E. histolytica*.

The role of *B. hominis* in human disease remains controversial (45, 46 and 47). When *B. hominis* is present in large numbers in the absence of other pathogens, it may be the cause of gastrointestinal disease (45, 46 and 47). The most common symptoms include recurrent diarrhea, vomiting, and abdominal pain. The diagnosis is made by detection of the organism using routine microscopic examination of stool. Metronidazole appears to be the most appropriate choice of therapy.

The nonpathogenic amebae must be differentiated microscopically from *E. histolytica*. This is particularly true for *E. coli*, which is similar in size to *E. histolytica* and is frequently found in stool specimens from patients exposed to contaminated food or water. Careful microscopic examination of trophozoite and cyst forms present in stained and unstained specimens is essential for the accurate identification of intestinal amebae (Table 60.6 and Fig. 60.21).

Flagellates

There are three clinically significant species of flagellates found in humans, *Giardia lamblia*, *Trichomonas vaginalis*, and *Dientamoeba fragilis* (45). Nonpathogenic commensal flagellates include *Chilomastix mesnili*, *T. hominis*, *T. tenax*, *Enteromonas hominis*, and *Retortamonas intestinalis*.

The trichomonads and *D. fragilis* have only trophozoite stages in their life cycle, whereas the other flagellates have both trophozoite and cyst stages (Fig. 60.23). The flagellates other than *D. fragilis* are easily recognized by their characteristic rapid motility. Additional characteristics include shape, number of nuclei, and the presence of fibrils and other structures, such as undulating membrane, sucking disk, and cytostome (Table 60.7).

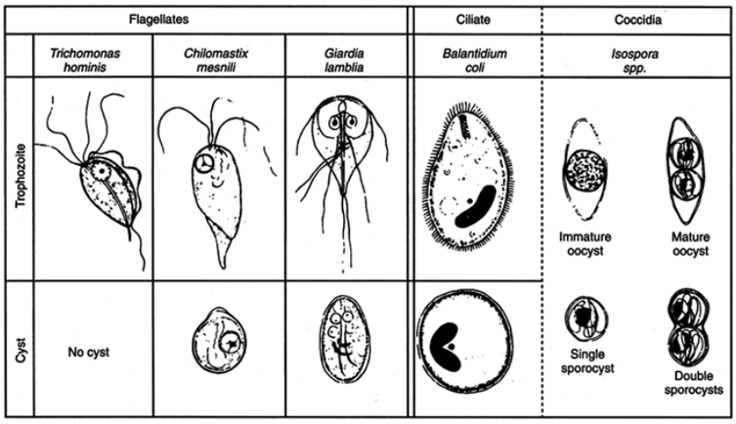

FIGURE 60.23. Protozoa found in human feces (flagellates, ciliate, coccidia). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal protozoa*. Chicago: American Society of Clinical Pathologists, 1976.)

TABLE 60.7. MORPHOLOGY OF INTESTINAL AND UROGENITAL FLAGELLATE TROPHOZOITES AND CYSTS

	Giardia lamblia	*Dientamoeba fragilis*	*Trichomonas vaginalis*
Trophozoites			
Size (μm)	10–20	5–15	5–30
Shape	Pear-shaped	Oval to round	Pear-shaped
Motility	"Falling leaf" motility in very diluted preps, otherwise motility is back-and-forth beating of flagella	Ameboid	Jerky, nondirectional
Nuclei	2	2, no chromatin, small karyosome divided into 4–6 distinct granules	1
Characteristic features	Sucking disk on ventral surface	Cytoplasm is finely granular, vacuolated with bacterial inclusions	Short undulating membrane, no free posterior flagellum; axostyle protruding posteriorly
Cysts			
Size (μm)	8–19	No cyst form exists	No cyst form exists
Shape	Oval or elliptical		
Nuclei	4, usually located on one end		
Characteristic features	Flagella and fibrils are positioned longitudinally in cysts; others lie laterally in cyst		
Clinical manifestations	Acute: irritation of mucosal lining, increased mucus secretion, dehydration, and epigastric pain, diarrhea, weight loss, flatulence	Diarrhea, abdominal pain, nausea, anorexia, malaise, fatigue	Vaginal irritation and discharge, urethritis, prostatitis
	Chronic: epigastric pain, flatulence, diarrhea, weight loss, malabsorption		
Diagnostic methods	O&P exam, DFA stain, ELISA, Entero-Test (String test)	O&P exam with permanent stain	Direct, wet mount, culture, DFA stain

O&P exam, ova and parasite examination; DFA, direct fluorescent antibody; ELISA, enzyme-linked immunosorbent assay.

Diseases produced by flagellates are primarily the result of mechanical irritation and inflammation of intestinal and/or urogenital mucosa. The tissue invasion and destruction seen with *E. histolytica* is rare with flagellates.

Giardia lamblia

Classification

G. lamblia (also known as *G. duodenalis*) is characterized by presence of both actively motile trophozoites and sessile cyst forms in

the same specimen. *Giardia* is one of the most easily recognized intestinal parasites. The pear-shaped trophozoite is bilaterally symmetrical containing two nuclei and eight flagella (Fig. 60.23 and Fig. 60.24). The trophozoite ranges from 10 to 20 μm in length and contains a large ventral sucking disk that occupies the anterior half to three fourths of the body. Division is by longitudinal binary fission. The mature cyst form ranges from 8 to 19 μm in length and contains four nuclei. The nuclei are concentrated toward the anterior end and are not distinct in unstained preparations. *Giardia* cysts are recognized by their oval shape, the fibrils present in the cytoplasm, and the anteriorly located nuclei (Fig. 60.23 and Fig. 60.25).

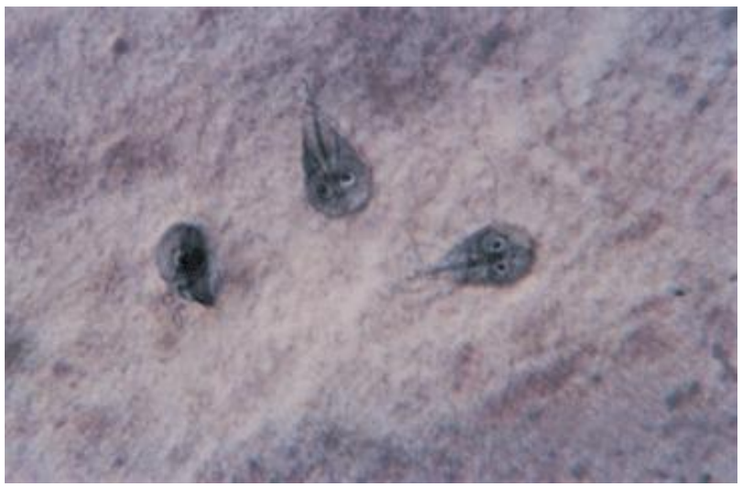

FIGURE 60.24. *Giardia lamblia* trophozoites in fecal smear (Kohn's chlorazol black E stain; original magnification, ×1,125). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal protozoa*. Chicago: American Society of Clinical Pathologists, 1976.)

FIGURE 60.25. *Giardia lamblia* cysts in fecal smear (trichrome stain; original magnification, ×1,600). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal protozoa*. Chicago: American Society of Clinical Pathologists, 1976.)

Clinical Manifestations

Giardia lamblia causes an infection of the small intestine (Fig. 60.26). Infection can be asymptomatic (in as many as 50% of individuals) or symptomatic. Symptomatic disease may range from mild diarrhea to a full malabsorption syndrome with diarrhea and steatorrhea. The disease may be accompanied by abdominal

bloating, cramps, and flatulence; however, blood and pus are rarely present in stools. The organisms appear to cause disease by both mechanical blockage of the absorptive surface of the small bowel and damage to the mucosal epithelium (45, 52). Frank tissue necrosis as seen in amebiasis does not occur, and spread beyond the gastrointestinal tract is rare. Although spontaneous recovery generally occurs after 10 to 14 days, a more chronic disease with multiple relapses may develop. Individuals with IgA deficiency are particularly prone to developing chronic giardiasis.

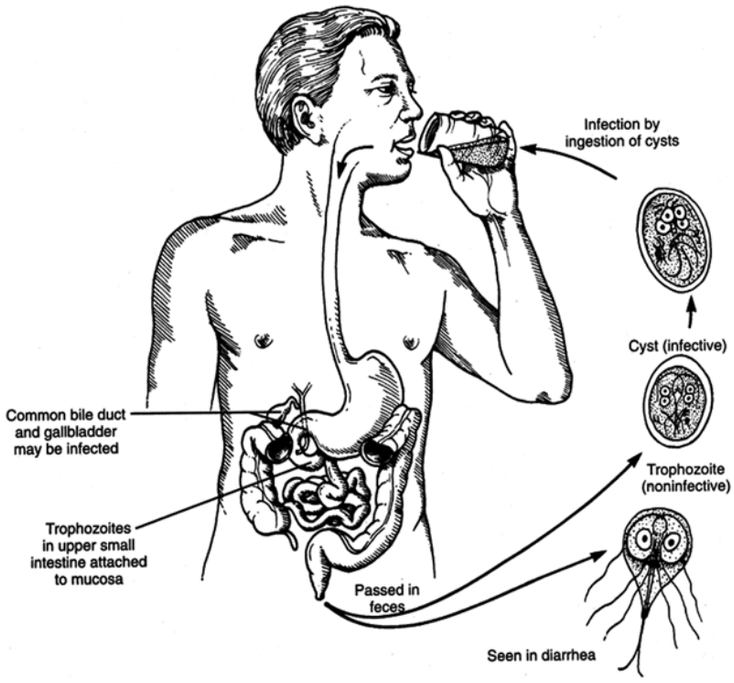

FIGURE 60.26. Life cycle of *Giardia lamblia*. (Modified from Markell EK, Voge M, John DT. *Medical parasitology*, 7th ed. Philadelphia: Saunders, 1992.)

Diagnosis

The predominant form seen on stool examination is the cyst form (Fig. 60.26). Trophozoites may be present in diarrheal stools or duodenal aspirates. Organisms may be visualized on a direct wet preparation with or without iodine staining. The use of stool concentration techniques and permanently stained (trichrome) fecal smears is necessary for complete stool workup (45, 52). In addition to conventional microscopy, several immunologic tests for detection of fecal antigen are available commercially. These tests include counterimmunoelectrophoresis, enzyme immunoassay, and indirect immunofluorescent staining. Reported sensitivities range from 88% to 98% and specificities from 87% to 100% (2, 7, 45, 52, 53).

Treatment

Treatment of both asymptomatic cyst passers as well as symptomatic individuals is necessary to interrupt the transmission of *G. lamblia*. The drug of choice is quinacrine hydrochloride (Atabrine). Metronidazole is also effective and may be less toxic. More than one course of therapy may be necessary in some individuals. Prevention and control of giardiasis involve avoidance of contaminated food and water.

Dientamoeba fragilis

Classification

D. fragilis, originally classified as an ameba, is now considered an amebalike flagellate more closely related to the genus *Trichomonas*. The organism lacks a cyst stage and is frequently binucleate. Electron microscopic studies have revealed internal structures typical of a flagellate.

Clinical Manifestations

Many individuals infected with *D. fragilis* are asymptomatic. In some individuals, the organism may cause mucosal irritation of the cecum and upper colon with accompanying symptoms of abdominal discomfort, flatulence, diarrhea, anorexia, and weight

loss (7, 45). The organism has been found in human bile ducts; however, its role in biliary tract disease is unknown.

Life Cycle and Epidemiology

D. fragilis resides in the mucosal crypts. The mode of transmission remains uncertain but most likely is fecal-oral in nature. It is postulated that the delicate trophozoite is transported from person to person inside the protective shell of helminth eggs such as the pinworm *Enterobius vermicularis*.

Diagnosis

Infection with *D. fragilis* is documented by detecting the labile trophozoites in appropriately preserved and stained stool specimens. The excretion of the parasite may fluctuate markedly from day to day, and thus collection of several stool samples may be necessary. Examination of a purged stool sample may also be useful.

Treatment

The antiamebic drugs iodoquinol and tetracycline are often stated to be the drugs of choice for *D. fragilis* infections; however, the cure rates are not high with these drugs. A more effective agent appears to be paromomycin. Metronidazole, furazolidone, and diloxanide furoate may also be effective against *D. fragilis* but require additional investigation.

Trichomonas vaginalis

Classification

T. vaginalis is a parasite of the urogenital system. *T. vaginalis* exists only as a trophozoite and is found in the urethras and vaginas of women and in the urethras and prostates of men. The organism is oval and 5 to 30 µg wide and possesses four flagella and a short undulating membrane that are responsible for motility (Fig. 60.27). There are a single large nucleus and an axostyle composed of microtubules that project from the posterior end. The organism is actively phagocytic and grows optimally under anaerobic conditions.

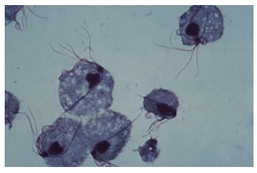

FIGURE 60.27. *Trichomonas vaginalis* trophozoites (Giemsa stain; original magnification, ×2,400). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal protozoa*. Chicago: American Society of Clinical Pathologists, 1976.)

Clinical Manifestations

Infection with *T. vaginalis* may be asymptomatic in both women and men. Symptomatic infection in women may range from a mild watery discharge to severe vaginitis with extensive inflammation and erosion of the epithelial lining, associated with burning, itching, and dysuria. Infection in men may involve the urethra, prostate, and/or seminal vesicles. A urethral discharge accompanied by dysuria, nocturia, and prostatic tenderness may be observed.

Life Cycle and Epidemiology

T. vaginalis is strictly a parasite of the urogenital system, where it exists as a motile trophozoite. Transmission is primarily by sexual contact or, less commonly, by contaminated fomites (toilet articles, clothing). Perinatal acquisition of disease is reported secondary to passage through the mother's infected birth canal.

Diagnosis

Diagnosis of infection with *T. vaginalis* is usually made by examining wet mounts of vaginal discharge or prostatic secretions or by examination of urine from both men and women. Stained or unstained smears may be examined (Fig. 60.27). The diagnostic yield may be improved by culturing the organism (93% sensitivity) or using monoclonal fluorescent antibody staining (85% sensitivity) (45). Serologic tests may be useful in epidemiologic surveillance.

Treatment

The treatment of choice is metronidazole; however, resistance has been reported, and retreatment with higher doses may be required. Both male and female sexual partners should be treated to avoid reinfection.

Ciliates

Balantidium coli is the only ciliate known to cause infection in humans (45). The organisms inhabit the large intestine, cecum, and terminal ileum where they may cause extensive ulceration.

Balantidium coli

Classification

B. coli is a large ciliated protozoa ranging in size from 40 to more than 200 µm in greatest dimension. The trophozoite is covered uniformly with rows of hairlike cilia that aid in motility. The organism is structurally more complex than an ameba, with both macronuclei and micronuclei, a cytostome, and numerous cytoplasmic contractile and food vacuoles (Fig. 60.28). The organism may exist in both trophozoite and cyst stage. Reproduction is by binary fission, although conjugation may occur.

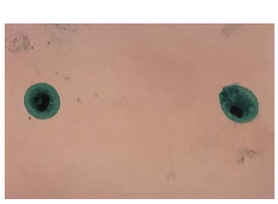

FIGURE 60.28. *Balantidium coli* cyst **(left)** and trophozoite **(right)** in fecal smear (trichrome stain; original magnification, ×180). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal protozoa*. Chicago: American Society of Clinical Pathologists, 1976.)

Clinical Manifestations

Infection with *B. coli* may be asymptomatic or present with a picture of severe intestinal involvement that can mimic the intestinal phase of amebiasis. Symptomatic disease is characterized by abdominal pain, cramping, and tenderness accompanied by nausea, tenesmus, and watery stools with blood and pus. Intestinal ulceration may be extensive, but metastatic (extraintestinal) spread is rare.

Life Cycle and Epidemiology

The life cycle of *B. coli* is simple, involving ingestion of cysts in contaminated food or water, excystation, and invasion of trophozoites into the mucosa of the large bowel. *B. coli* is distributed worldwide, but infection is rare. In the United States, epidemics have occurred in mental hospitals. Swine constitute an important reservoir in other parts of the world. Risk factors for human disease include contact with swine and substandard hygienic conditions.

Diagnosis

As in other intestinal infections caused by protozoa, the diagnosis of balantidiasis is confirmed by detection of the large cysts and trophozoites on microscopic examination of an appropriately collected stool specimen (Fig. 60.28). The organism is detected easily in fresh, wet microscopic preparations.

Treatment

The treatments of choice are tetracycline and iodoquinol. Metronidazole and paromomycin are alternative antimicrobials; however, mixed results have been reported with metronidazole. Preventive measures include appropriate personal hygiene and maintenance of sanitary conditions.

Coccidia

Coccidia are intracellular parasites that are part of a large group called Apicomplexa. This group includes intestinal parasites such as *Isospora*, *Cryptosporidium*, and *Cyclospora* as well as the blood and tissue parasites discussed earlier (*Plasmodium*, *Babesia*, *Toxoplasma*). All coccidia demonstrate both sexual (sporogonic) and asexual (schizogonic) reproductive cycles.

Isospora

Classification

Isosporiasis is caused by *I. belli*, a coccidian parasite of the intestinal epithelium. The organism is present in the stool in the form of oocysts, which average 30 µm in length by 12 µm in width. The mature oocyst contains two sporocysts, each with as many as four sausage-shaped sporozoites (Fig. 60.23).

Clinical Manifestations

Infections range from asymptomatic to significant gastrointestinal disease resembling giardiasis or cryptosporidiosis (54, 55). Symptoms include diarrhea, abdominal pain and cramping, flatulence, malaise, anorexia, weight loss, and low-grade fever. Symptomatic disease is usually self-limited; however, illness may persist for months or years, particularly in immunocompromised individuals such as those with AIDS.

Life Cycle and Epidemiology

Infection with *I. belli* is initiated with the ingestion of mature oocysts in contaminated food or water. After ingestion, excystation occurs in the small bowel releasing sporozoites, which in turn invade intestinal epithelial cells and become rounded trophozoites. The trophozoites undergo schizogony and produce merozoites, which ultimately rupture the host cell and are released to invade other epithelial cells. Some merozoites become sexual gametocytes. The product of sexual reproduction is the oocyst, which is released into the bowel lumen and eliminated in the feces. Fecal oocysts mature within 48 hours and are then infective.

Isospora is distributed worldwide but is rarely reported in humans. In recent years, *I. belli* has been recognized as an important opportunistic pathogen in individuals with AIDS (54, 55). Infection follows ingestion of contaminated food or water or oral-anal sexual contact. There is no evidence of an animal reservoir of *I. belli*.

Diagnosis

The presence of oocysts in stool may be difficult to detect without a concentration procedure. Zinc sulfate or sugar flotation is the most sensitive stool concentration technique. Stool concentrates may be stained with either iodine or a modified acid-fast procedure. Intestinal mucosal biopsy may be necessary to establish the diagnosis when stool specimens are negative.

Treatment

The treatment of choice is combined therapy with pyrimethamine and sulfadiazine or trimethoprim/sulfamethoxazole. Prevention and control are accomplished by adequate sanitation and avoidance of oral-anal sexual contact.

Cryptosporidium

Classification

Cryptosporidium species are coccidian parasites closely related to *I. belli* and *T. gondii*. *C. parvum* is the species associated with all well-documented cases of cryptosporidiosis in mammals (54, 55 and 56). *Cryptosporidium* has an apical complex but produces neither cilia nor flagella. The parasite is characterized by an oocyst without sporocysts and containing four sporozoites. Development of the oocyst takes place intracellularly just beneath the surface membrane of the intestinal epithelial cell and is thus extracytoplasmic.

Clinical Manifestations

Infection with *C. parvum* is usually asymptomatic or a mild, self-limited enterocolitis characterized by watery diarrhea without blood. Immunocompromised individuals may have severe diarrhea characterized by 50 or more stools per day with marked fluid loss, abdominal discomfort, nausea, anorexia, fever, and weight loss. Infection in these individuals may persist for months to years. In patients with AIDS, *Cryptosporidium* has been found in sputum, lung biopsy specimens, and the biliary tract (54, 55 and 56).

Life Cycle and Epidemiology

The life cycle of *Cryptosporidium* resembles that of other coccidian parasites (Fig. 60.29). Mature oocysts containing sporozoites are the infective stage. Infection is initiated with the ingestion of oocysts in contaminated food or water. After excysting from oocysts in the lumen of the intestine, sporozoites invade host cells within the brush border of the intestinal epithelium and develop into trophozoites. Both asexual and sexual reproduction occurs in the epithelial cells. Sporulated oocysts are released in the feces and serve to transmit the infection from one host to another.

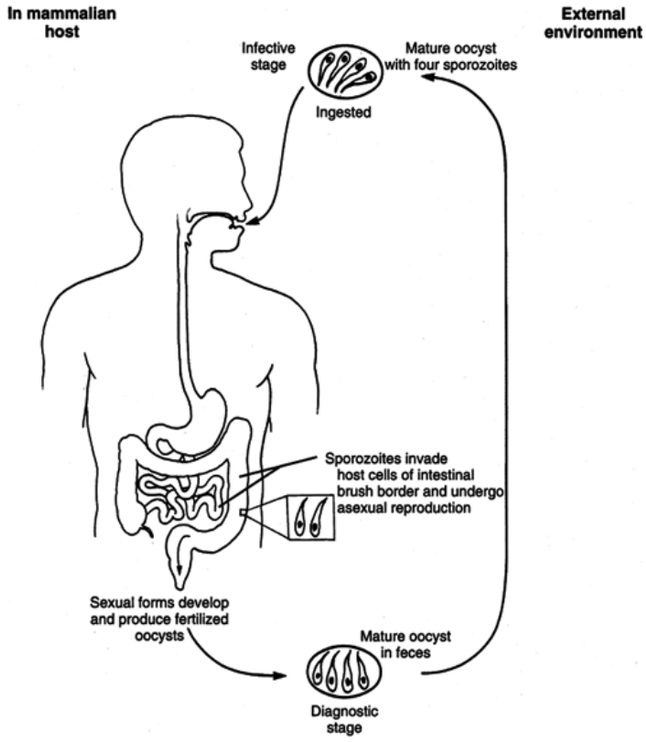

FIGURE 60.29. Life cycle of *Cryptosporidium* species.

Cryptosporidiosis is a zoonosis and can be spread from animal reservoirs to humans, as well as from person to person. The most common means of infection are the fecal-oral and oral-anal routes. Individuals at high risk include veterinarians, animal handlers, and homosexuals. Many outbreaks have now been described in day care centers where fecal-oral transmission is common.

Diagnosis

Cryptosporidium may be detected in large numbers in unconcentrated stool specimens obtained from immunocompromised individuals with diarrhea. Oocysts may be concentrated with the modified zinc sulfate centrifugal flotation technique or by Sheather's sugar flotation procedure (55, 56). Specimens may be stained using the modified acid-fast method or by an indirect immunofluorescence assay (2, 53, 55, 56). An enzyme immunoassay for detecting fecal antigen is also commercially available (2, 55, 56). The number of oocysts shed in stool may fluctuate; therefore, it is recommended that a minimum of three specimens be examined. Molecular (PCR) and serologic procedures for diagnosing

and monitoring infections are under investigation but are not widely available at present (55, 56 and 57).

Treatment

Treatment of symptomatic cryptosporidiosis in immunocompetent individuals is usually not undertaken because of the self-limited nature of the disease and the lack of a safe and effective therapy. Unfortunately, treatment of cryptosporidiosis in immunedeficient persons has been largely ineffective. No controlled studies have been published, and all therapeutic information is based on isolated reports and anecdotal information. Spiramycin, a macrolide antibiotic, may help to control the diarrhea in some patients with cryptosporidiosis during the early stages of AIDS but is ineffective in patients who have progressed to the later stages of AIDS (55, 56). Spiramycin was no more effective than placebo in treating cryptosporidial diarrhea in infants (55,56). Reports concerning the efficacy of azithromycin and paromomycin are promising but will require further confirmation. In the absence of an effective treatment, supportive measures to restore the fluid loss from watery diarrhea appears to be the only intervention available to most clinicians.

Cyclospora

Classification

Cyclospora is a coccidian parasite that is related taxonomically to *C. parvum*, *Isospora* species, and *T. gondii*. *C. cayetanensis* is the single species described thus far infecting humans (55, 58, 60). The oocysts of *Cyclospora* are spherical and, at 8 to 10 µm in diameter, are larger than those of *C. parvum* (4 to 6 µm). The oocysts of *Cyclospora* contain two sporocysts, each of which contain two sporozoites. The sporozoites contain a membrane bound nucleus and micronemes. As with *Cryptosporidium*, the development of the oocyst takes place intracellularly; however, *Cyclospora* develops within the cytoplasm of the host cell, whereas *Cryptosporidium* is extracytoplasmic.

Clinical Manifestations

Cyclosporiasis resembles cryptosporidiosis clinically and is marked by mild nausea, abdominal cramping, anorexia, and nonbloody, watery diarrhea. The diarrhea is generally self-limited in immunocompetent individuals but may be prolonged and last for weeks. Fatigue, malaise, flatulence, and bloating have also been reported to accompany the diarrhea. Clinical illness may be prolonged, severe, and marked by a high rate of recurrence in the immunocompromised host. In patients with AIDS, biliary tract infection has been reported (60).

Life Cycle and Epidemiology

The intermediary life cycle stages of *C. cayetanensis* occur in the cytoplasm of enterocytes located in the small intestine. The oocysts are excreted unsporulated and require 7 to 15 days outside of the host to become fully mature and infectious. Infection is initiated when the mature oocyst is ingested, usually via contaminated water or food (55, 59, 61). Within the lumen of the intestine, the sporozoites are released from the oocyst and invade the epithelial cells. The organism is found within vacuoles in the cytoplasm of jejunal epithelial cells, and its presence is associated with inflammatory changes, villous atrophy, and crypt hyperplasia.

Cyclospora is widely distributed in nature and infects a variety of birds, reptiles, and mammals. Direct animal-to-human or person-to-person spread has not been documented; however, it is now reasonably well established that *Cyclospora* infection is acquired via contaminated water (55, 58, 59, 61). The prevalence of infection ranges from 2% to 18% in endemic areas and from 0.1% to 0.5% in developed countries. In areas of endemicity, the peak incidence of cyclosporiasis coincides with the rainy season. Recent outbreaks in the United States occurred in the summer months and have been linked to contaminated fruit and water (55, 59, 61). *Cyclospora* oocysts are resistant to chlorination and remain viable and infectious when stored in potassium dichromate. Like *Cryptosporidium*, *Cyclospora* is not easily detected by methods used currently to ensure the safety of drinking water.

Diagnosis

The oocysts of *Cyclospora* may be detected in stool by light microscopy. In a wet mount preparation, the unstained oocysts appear as nonrefractile, spherical to oval, slightly wrinkled bodies measuring 8 to 10 µm in diameter with an internal cluster of membrane-bound globules. In fresh specimens, *C. cayetanensis* will fluoresce when examined with a fluorescence microscope fitted with a 365-nm excitation filter.

Cyclospora oocysts may be concentrated from stool with the modified zinc sulfate centrifugal flotation technique or by Sheather's sugar flotation technique. The organisms stain variably acid fast with the modified Ziehl-Nielsen stain or the Kinyoun acid-fast stain. The appearance on acid-fast staining ranges from unstained to mottled pink to deep red (Fig. 60.30).

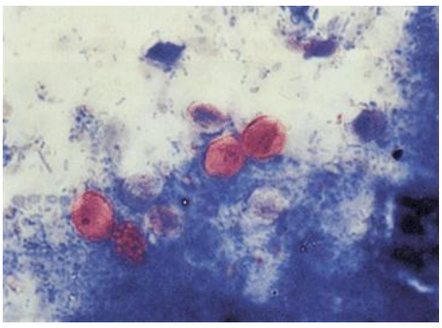

FIGURE 60.30. *Cyclospora* oocysts, acid-fast stain. (From Ortega YR. *Cryptosporidium*, *Cyclospora* and *Isospora*. In: Murray PR, Baron EJ, Pfaller MA, et al., eds. *Manual of clinical microbiology*, 7th ed. Washington, DC: American Society for Microbiology, 1999:1406–1412.)

The relative sensitivity and specificity of the available methods for diagnosing *Cyclospora* infection are unknown. Currently there are no commercially available immunodiagnostic methods to aid in the diagnosis and monitoring of these infections. A PCR assay has been described but has not been evaluated for use in a clinical laboratory (55, 60). The lack of understanding of the disease process coupled with rather poor diagnostic techniques all contribute to an underrecognition of *Cyclospora* infection.

Treatment

In HIV-infected individuals with cyclosporiasis, it appears that the high rate of recurrence may be attenuated with long-term suppressive therapy with trimethoprim/sulfamethoxazole (55, 59). The efficacy of trimethoprim/sulfamethoxazole therapy has been demonstrated in anecdotal reports, a large open-label study of HIV-positive individuals, and a placebo-controlled trial (55, 59, 60, 62). The effectiveness of numerous additional agents, including metronidazole, norfloxacin, quinacrine, nalidixic acid, tinidazole, and diloxanide furoate, has not been proven.

Prevention of *Cyclospora* infection is difficult and is compounded by the organism's resistance to chlorination. Regardless, treatment of water by chlorination and filtration remains a reasonable practice. Furthermore, the same methods of improved personal hygiene and sanitation used for other intestinal protozoa should be employed as preventive measures for this disease.

Microsporidia

Classification

Microsporidia are obligate intracellular pathogens belonging to the phylum Microspora. The parasites are characterized by the structure of their spores, which have a complex tubular extrusion mechanism used for injecting the infective material (sporoplasma) into cells. Microsporidia are considered to be primitive eukaryotic organisms because they lack mitochondria, peroxisomes, Golgi membranes, and other typically eukaryotic organelles.

Microsporidia have been detected in human tissues and have been implicated as participants in human disease (63, 64 and 65). To date, six genera (*Enterocytozoon*, *Encephalitozoon*, *Nosema*, *Pleistophora*, *Vittaforma*, and *Trachipleistophora*) and unclassified *Microsporidium* species have been reported in humans. *Enterocytozoon bieneusi* and *Encephalitozoon* (*Septata*) *intestinalis* have gained increasing attention as important causes of chronic diarrhea in patients with AIDS (66, 67); both *Encephalitozoon*-like and *Enterocytozoon*-like organisms have been reported in the tissues of AIDS patients with hepatitis and peritonitis (64, 65 and 66); *Pleistophora*, *Trachipleistophora*, and *Nosema* are known to cause myositis in immunocompromised patients (64, 66); *Nosema* has caused localized keratitis as well as disseminated infection in a child with severe combined immunodeficiency (64, 65 and 66); and *Microsporidium* species and *Encephalitozoon hellem* have caused infection of the human cornea (64, 66).

Clinical Manifestations

Clinical signs and symptoms of microsporidiosis are quite variable in the few human cases reported. Intestinal infection owing to *E. bieneusi* in AIDS patients resembles that which occurs in patients with cryptosporidiosis and cyclosporiasis. Patients experience chronic watery diarrhea without blood or mucus. The diarrhea is persistent and debilitating, leading to dehydration and extreme wasting. The clinical presentation of infection with other species of *Microspora* is dependent on the organ system involved and ranges from localized ocular pain and loss of vision (*Microsporidium* and *Nosema* species) to neurologic disturbances and hepatitis (*Encephalitozoon cuniculi*) to a more generalized picture of dissemination with fever, vomiting, diarrhea, and malabsorption (*Nosema*). In the latter, disseminated infection with *N. connori*, the organism was seen involving the muscles of the stomach, bowel, arteries, diaphragm, and heart and the parenchymal cells of the liver, lungs, and adrenals (64, 65).

Life Cycle

Microsporidia are obligate intracellular parasites with a wide host range among invertebrate and vertebrate animals. Transmission is by ingestion of spores that have been shed in the urine and feces of infected animals. After ingestion by a new host, pressure builds inside the spore, causing the polar filament to evert and injecting the sporoplasm with its nuclear material into an adjacent cell in the intestine, where it multiplies and is disseminated (64, 65). Although some species are highly selective in the cell type that they invade, collectively, the Microspora are capable of infecting every organ of the body.

Once inside a suitable host cell, the microsporidia multiply extensively, either within a parasitophorous vacuole or free within the cytoplasm of the host cell. The intracellular multiplication includes a phase of repeated divisions by binary fission (merogony) or multiple fission (schizogony) and a phase culminating in spore formation (sporogony). Parasites spread from cell to cell to continue merogony, which may overlap sporogony. During sporogony, sporonts divide into sporoblasts and sporoblasts mature into spores containing the infective sporoplasm. The mature spores are then excreted into the environment and the cycle continues.

Diagnosis

There are several techniques that have been useful for recognizing microsporidia in human material (63, 64 and 65, 68, 69). Diagnosis is frequently made by identification of the organisms in biopsy material and by light microscopic examination of cerebrospinal fluid and urine. Spores measuring between 1.0 and 2.0 µm may be visualized by Gram (gram-positive), acid-fast, periodic acid–Schiff, Calcofluor, and Giemsa staining techniques (Fig. 60.31). Giemsa-stained organisms are easier to see in histologic sections than those stained with hematoxylin and eosin. Immunohistochemical techniques may also be useful. Electron microscopy is considered the gold standard for diagnostic confirmation of microsporidiosis; however, its sensitivity is unknown. Species identification requires transmission electron microscopy.

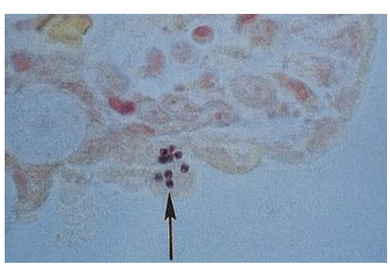

FIGURE 60.31. Gram-positive spores of microsporidia (*arrow*) in jejunal biopsy (Brown-Brenn stain; original magnification, ×1,750). (From Weber R, Bryan RT, Owen RL, et al. Improved light-microscopical detection of microsporidia spores in stool and duodenal aspirates. *N Engl J Med* 1992;326:161–166.)

Chromotrope-based staining techniques for light microscopic detection of microsporidial spores in stool or duodenal aspirates have proven useful (64, 65, 69, 70). The chromotrope-based techniques detect microsporidia spores on light microscopy of unconcentrated formalin-fixed fecal material. The spores show a characteristic pinkish-red staining pattern and can be distinguished

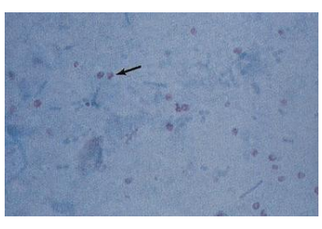

FIGURE 60.32. Smear of formalin-fixed stool specimen, showing pinkish red–stained microsporidia spores, some with a distinct pinkish beltlike stripe (*arrow*). Bacteria are stained faint green (chromotrope-based stain; original magnification, ×1.800). (From Weber R, Bryan RT, Owen RL, et al. Improved light-microscopical detection of microsporidia spores in stool and duodenal aspirates. *N Engl J Med* 1992;326:161–166.)

easily from bacteria, yeasts, and fecal debris (Fig. 60.32). This technique may serve as a practical noninvasive means of diagnosing microsporidiosis.

Additional diagnostic techniques, including culture and serologic testing, are currently under investigation (63, 64 and 65, 68). Nucleic acid-based methods, such as PCR, have been developed to detect or identify microsporidia but are largely relegated to research laboratories at the present time (63). The role of these techniques in the diagnosis of microsporidiosis has yet to be validated in clinical and epidemiologic studies (63, 64 and 65).

Treatment

There is no known effective treatment for microsporidial infections (63, 64 and 65, 71, 72, 73 and 74). Treatment with metronidazole has resulted in temporary improvement in patients with intestinal microsporidiosis. Likewise, some patients have been treated with sulfa drugs or albendazole and survived (63). *In vitro* studies have demonstrated activity of trimethoprim/sulfamethoxazole and the antibiotic fumagillin against Encephalitozoon (71, 72). Oral fumagillin has been shown to eradicate *E. bieneusi* from patients with HIV-associated diarrhea but was associated with unacceptable toxicity (74).

HELMINTHS

Part of "60 - Parasitology"

Helminths may assume both free-living and parasitic life forms and are classified into nematodes (roundworms) and platyhelminths (flatworms). The helminths are generally macroscopic, and the adult worms may vary tremendously in size from barely visible to 10 m in length.

Appropriate and timely diagnosis of a helminthic infection is dependent on a clear understanding of the life cycles of the parasites, the tissues likely to be involved, and the geographic distribution of the organisms (75, 76). The life cycles of helminths may be quite complex and include both direct and indirect cycles. The direct cycle requires only the definitive host, whereas indirect cycles require an intermediate host in which larval stages develop as well as definitive hosts, which harbor the adults.

The clinical signs and symptoms of helminthic infections depend on the location of the organisms and may be caused by adults, larvae, or eggs. The host response to the presence of organisms may be prominent and often includes eosinophilia, especially in the early stages of infection when the parasites are in tissue.

The final diagnosis is usually dependent on detection and identification of mature or developmental (larvae, embryo, egg) stages of the parasite. Occasionally, the diagnosis must be made clinically or serologically.

The majority of helminths produce characteristic eggs that are passed in the feces and serve as the chief means of diagnosing the infections. The identification of eggs should be approached in a systematic manner taking into account its size and shape, the thickness of the shell, and the presence or absence of specialized structures such as spines, knobs, or opercula (Fig. 60.33). The presence and characteristics of larvae present within the eggs may also be useful.

Nematodes

Nematodes are the helminths most frequently parasitizing humans and include intestinal nematodes as well as blood and tissue nematodes. The most common nematodes of medical importance are those inhabiting the intestinal tract (Table 60.8). Most of these organisms have a direct life cycle, and their presence may be confirmed by detecting the characteristic eggs in feces.

TABLE 60.8. MORPHOLOGY OF INTESTINAL NEMATODES

	Ascaris lumbricoides	*Enterobius vermicularis*	*Trichuris trichiura*	Hookworm (*Necator americanus* and Ancylostoma duodenale)	*Strongyloides stercoralis*
Method of infection	Ingestion of egg	Ingestion of egg	Ingestion of egg	Skin penetration by *Necator* and skin penetration and ingestion by *Ancylostoma*	Skin penetration
Location in host	Small intestine, migration in bile duct and lungs	Development in intestines, adults in cecum, appendix, colon, rectum	Cecum, appendix, colon, development in intestines	Migration into lungs, adults attached to mucosa of small intestine	Migration into lungs, females in mucosal epithelium of small intestine, autoinfection
Egg morphology	Fertilized egg, 45–75 × 35–50 µm; infertile eggs 85–95 × 43–47 µm	Smooth, thick-shelled eggs 50–60 × 20–32 µm, flattened on one side	Thick-shelled with bipolar plugs 50–54 × 20–23 µm	Thin-shelled 56–75 × 36–40 µm, unable to distinguish between species	Thin-shelled, rarely seen
Larva morphology				*Ancylostoma*: First-stage rhabditiform 250–350 × 17 µm, long buccal canal, genital primordium is small; infective third-stage filariform 625–675 µm long, pointed tail, sheath not striated. *Necator*: first-stage rhabditiform 250–300 × 17 µm, long buccal canal, genital primordium is small. Infective third-stage filariform 580–620 µm long, pointed tail, sheath striated	First-stage rhabditiform 180 × 14–20 µm wide, short buccal capsule, prominent genital primordium. Infective third-stage filariform 500 µm long, tail is notched, no sheath about infective larvae
Adult worm morphology	Females, 20–35 cm long × 3–6 mm wide with straight tail; males, 15–31 cm long × 2–4 mm wide with curved tail, 3 well-developed lips	Females, 8–13 mm long × 0.3–0.5 mm wide with pointed tail; males, 2–5 mm long × 0.1–0.2mm wide with curved tail	Females, 35–50 mm long with straight posterior ends; males, 30–45 mm long with 360˚coil at the caudal end	*Ancylostoma*: adult males 7–11 mm long × 0.4–0.5 mm wide; Females, 10–13 mm × 0.5–0.7 mm wide. Adults have a long buccal capsule containing 2 pairs of teeth. *Necator* adult males and females, 7–11 × 0.3 mm. Adults have a buccal capsule containing cutting plates rather than teeth	There is no parasitic male; females, 2.1–2.7 mm long × 30–40 µm wide
Clinical manifestations	Nutritional deficiencies, pneumonitis, eosinophilia, tissue reaction	Pruritus, perianal itching, nervousness, insomnia, nightmares	Abdominal cramps, severe rectal tenesmus, rectal prolapse	Iron-deficiency anemia, edema of the face and feet, listlessness; may cause hemoglobin levels of ≤ 5 g/dL pruritus, and erythema	Cutaneous: pruritus, erythema, lesions. Pulmonary: pneumonia, cough, shortness of breath, wheezing, fever, transient pulmonary infiltrates. Intestinal: peptic ulcer, abdominal pain; may mimic Crohn's disease, leukocytosis with peripheral eosinophilia
Diagnostic methods	O&P exam, ELISA, CF, HAI	Cellophane-tape prep	O&P exam	O&P exam	O&P exam, HAI
Specimen	Stool	Cellophane-tape slide	Stool	Stool	Stool, sputum
Common name	Large intestinal roundworm	Pinworm	Whipworm	*Necator*: New World hookworm *Ancylostoma*: Old World hookworm	Threadworm

O&P exam, ova and parasite examination; ELISA, enzyme-linked immunosorbent assay; HAI, hemagglutination inhibition; CF, complement fixation.

The filariae are among the most important of the blood and tissue nematodes. They are long, slender roundworms that parasitize the blood, lymph, and subcutaneous and connective tissues of humans. All filariae are transmitted by insect vectors, and most produce larvae called microfilariae that may be demonstrated in the blood, lymph, or connective tissue of the human host.

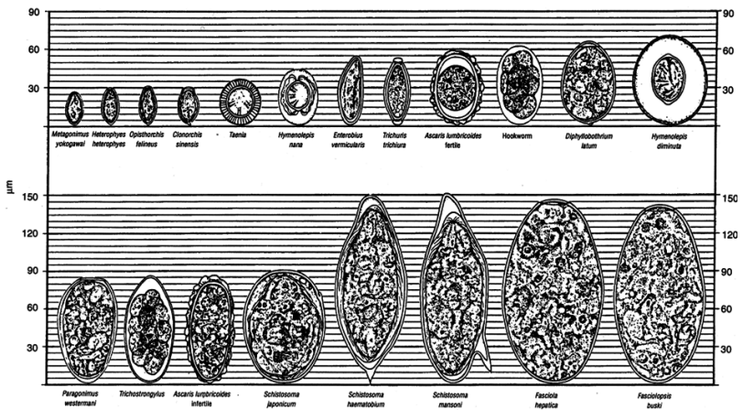

FIGURE 60.33. Helminths found in human specimens: relative sizes. (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

Enterobius vermicularis

Infection with *E. vermicularis*, the common pinworm, is the most common helminthic infection in North America. Both female and male worms inhabit the cecum and large bowel. The female worm measures as much as 13 mm in length and is cream colored with bilateral ridges or alae and a sharply pointed tail (Table 60.8 and Fig. 60.34). The male is smaller and rarely seen.

FIGURE 60.34. *Enterobius vermicularis*, adult female (whole mount). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

FIGURE 60.35. *Enterobius vermicularis*, embryonated eggs (low power). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

The gravid female migrates from the cecum to the perianal area, where as many as 20,000 eggs are deposited on the perianal skin. The eggs may be transmitted from hand to mouth or inhaled as fomites. The ingested eggs hatch in the small intestine and migrate to the cecum, where they mature into adults in 2 to 6 weeks, thus completing the cycle.

Clinical signs and symptoms of pinworm infection are generally mild. Intestinal pathology is rare; however, inflammation and granuloma formation around eggs has been reported. The role of the worm in appendicitis is questionable despite its occasional presence in the lumen of the resected appendix.

The most common clinical presentation is anal pruritus caused by the secretions of migrating worms. Scratching may lead to further irritation and excoriation, occasionally complicated by secondary bacterial infection. Migration of the worms into the vagina or urinary bladder may produce genitourinary problems and granulomas.

The diagnosis of enterobiasis is usually suggested by the clinical manifestations and confirmed by detection of the characteristic eggs (Fig. 60.35) on the anal mucosa. Detection of the eggs is accomplished by applying the sticky surface of a piece of cellophane tape to the mucocutaneous junction of the anus, applying the tape to the surface of a microscope slide and examining the slide under low power. Multiple samplings may be required to detect the eggs. Occasionally the female worm may be observed on the surface of the stool or on the perianal skin. Sampling should be obtained at night or in the morning before bathing. Systemic signs of infection such as eosinophilia are rare.

The treatment of choice is pyrantel pamoate with mebendazole as an alternative. Because of the potential for cross-infection in the family environment, treatment of all family members is recommended. Although cure rates are high, reinfection is common.

Trichuris trichiura

T. trichiura is the causative agent of whipworm infection. The worm is characterized by a long, thin, threadlike anterior portion and a bulbous posterior portion. The adult whipworm is 30 to 50 mm in length, and the female worm may produce 3,000 to 10,000 eggs per day. The adult worms reside in the cecum and large intestine for as long as 8 years. The whipworm is a cosmopolitan parasite and may infect as many as half a billion people worldwide.

Trichuris is a soil-transmitted helminth with a simple life cycle. The distinctive eggs (Fig. 60.36) are passed in the stool and deposited on soil, where they must mature for at least 10 days before they contain infective larvae. When ingested by the appropriate host, larvae are released in the small intestine and migrate to the cecum, where they penetrate the mucosa and mature to

adults. The adult worms remain attached to the mucosa by their slender anterior portions for the remainder of their lifetime.

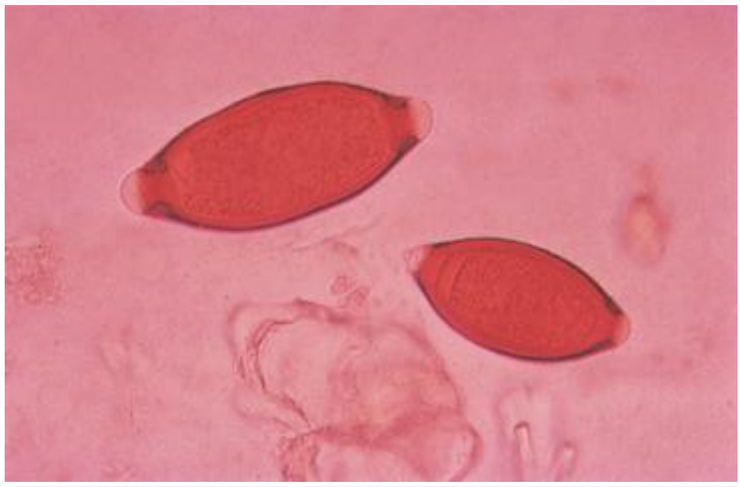

FIGURE 60.36. *Trichuris trichiura*, unembryonated fertile eggs (high power). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

The clinical manifestations of trichuriasis are generally related to the intensity of the worm burden. Most infections are with small numbers of *Trichuris* and are usually asymptomatic. Infections with larger numbers of organisms may result in abdominal pain, bloody diarrhea, weakness, and weight loss. Rectal prolapse may occur as a result of straining with defecation. Attachment of the adult worms to the intestinal mucosa may produce localized inflammation, ulceration, and hemorrhage with associated anemia and eosinophilia.

The diagnosis of trichuriasis is confirmed by detection of the characteristic bile-stained eggs with polar plugs (Fig. 60.36) on examination of stool. In light infections, a concentration step

may be required; however, this is not usually necessary in symptomatic infections because they usually produce more than 10,000 eggs per gram of feces.

The drug of choice for symptomatic infections is mebendazole. Asymptomatic infections generally do not require therapy. Prevention depends on adequate sanitation and avoidance of human feces as fertilizer.

Ascaris lumbricoides

A. lumbricoides is the most common and widely distributed of the soil-transmitted helminths. It is characterized by its large size, fusiform shape, and firm pink cuticle (Table 60.8). The adult Ascaris is 20 to 36 cm in length, and the female worm may produce as many as 200,000 eggs per day. The adult worms reside in the small intestine and have a relatively short life span of 6 to 18 months. It is estimated that as many as a billion people, including four million Americans, are infected with *Ascaris* worldwide.

Ascaris has a slightly more complex life cycle than *Trichuris* but is otherwise typical for a soil-transmitted roundworm. The large (35 to 55 µm) mammillated eggs (Fig. 60.33 and Fig. 60.37) are passed in the stool and deposited in soil, where they must mature for 2 to 3 weeks. The eggs are highly resistant to environmental stresses and may remain viable for as long as 6 years. When ingested by the host, the eggs hatch in the small intestine, releasing larvae, which penetrate the mucosa and enter the bloodstream. The larvae are carried to the lungs, where they develop for several days in the alveolar capillary bed. When they develop to the appropriate stage, the larvae rupture into the alveolar space, are coughed up and swallowed, and eventually reach the small intestine, where they grow to adulthood. The entire process from ingested egg to adult takes approximately 2 months.

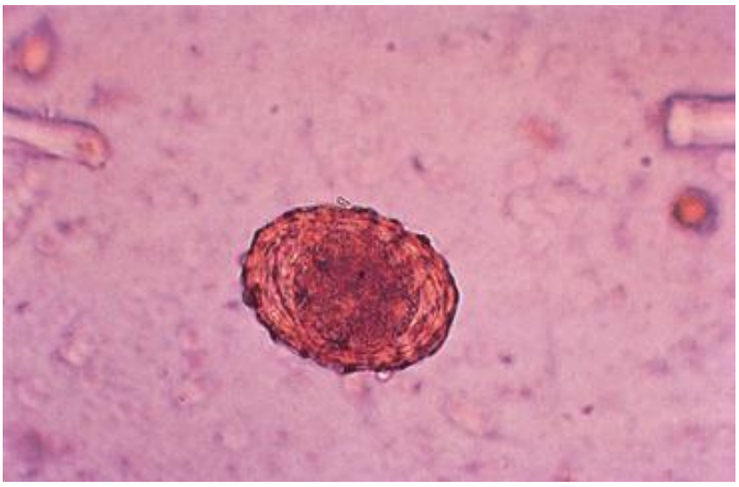

FIGURE 60.37. *Ascaris lumbricoides*, unembryonated fertile egg (low power). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

Ascariasis is a disease of warm climates and poor sanitation. It is prevalent in areas where human feces are used as fertilizer and may be maintained by small children who defecate outdoors, contaminating the soil, and pick up the infectious eggs on their hands during play. Both food and water may be contaminated with *Ascaris* eggs.

The clinical manifestations of ascariasis may result from either the migration of the larvae through the tissues or the presence of the adult worms in the intestinal lumen. Light infections are generally asymptomatic and may become apparent only when the adult worm is vomited up or passed in the stool. Pulmonary involvement owing to the migration of the larvae to the lungs is related to the degree of hypersensitivity induced by previous infections and the intensity of the current exposure. Pulmonary infiltrates and asthma like signs and symptoms are common and are accompanied by eosinophilia and oxygen desaturation (75). Death from respiratory failure may occur in massive infections.

In the intestinal phase of the infection, a large worm burden may produce nonspecific abdominal discomfort and diarrhea or may cause intestinal obstruction owing to a tangled bolus of worms. Migration of the adult worm to the appendix, bile duct, or pancreatic duct may cause obstruction, inflammation, and tissue damage of the organ. Intrahepatic abscesses may form if the organism reaches the liver. Direct perforation of the intestine resulting in peritonitis has also been reported (75).

Diagnosis of the infection is confirmed by detecting the characteristic eggs in feces or occasionally by examining an adult worm that has been passed in the feces or vomited. The eggs are oval with a thick shell and an irregular, bile-stained, mammillated external layer (Fig. 60.37). They may be fertilized or unfertilized and are usually quite numerous. Large worm burdens may be detected on roentgenographic examination of the small bowel. The pulmonary phase of the disease may be diagnosed by the finding of larvae and eosinophils in sputum.

Treatment of symptomatic infection is highly effective an may be accomplished with either pyrantel pamoate or mebendazole. Mebendazole is preferred if co-infection with *T. trichuris* is also present. Administration of mass therapy at 6-month intervals has been used as a means of community-wide control. Prevention depends on adequate sanitation and avoidance of human feces as fertilizer

Hookworms

The two principal species of hookworms causing disease in humans are *Ancylostoma duodenale*, the Old World hookworm, and *Necator americanus*, the New World hookworm. The adults of both species are pinkish-white, measure approximately 10 mm in length, and have mouthparts designed for sucking blood from injured intestinal mucosa. *A. duodenale* has a long buccal cavity containing two pairs of chitinous teeth, whereas the buccal cavity of *N. americanus* contains shearing chitinous plates rather than teeth (Table 60.8). Both male and female parasites attach to the mucosa of the small intestine. Males may be distinguished from females by the presence of a fan-shaped copulatory bursa at the posterior end. The female worm releases 10,000 to 20,000 thin-shelled eggs daily, which are passed in the feces.

Both *N. americanus* and *A. duodenale* are soil-transmitted helminths, and their life cycles are indistinguishable (Fig. 60.38). The eggs are passed in the feces and embryonate in the soil, where they hatch within 48 hours, releasing rhabditiform larvae. The first-stage larvae develop in the soil over the period of a week to become infective filariform larvae, which then may penetrate intact human skin and migrate via the lymphohematogenous system to the lungs. Similar to *Ascaris*, the larvae rupture into the alveoli, are coughed up, swallowed, and pass to the small intestine, where they mature in 1 to 2 months.

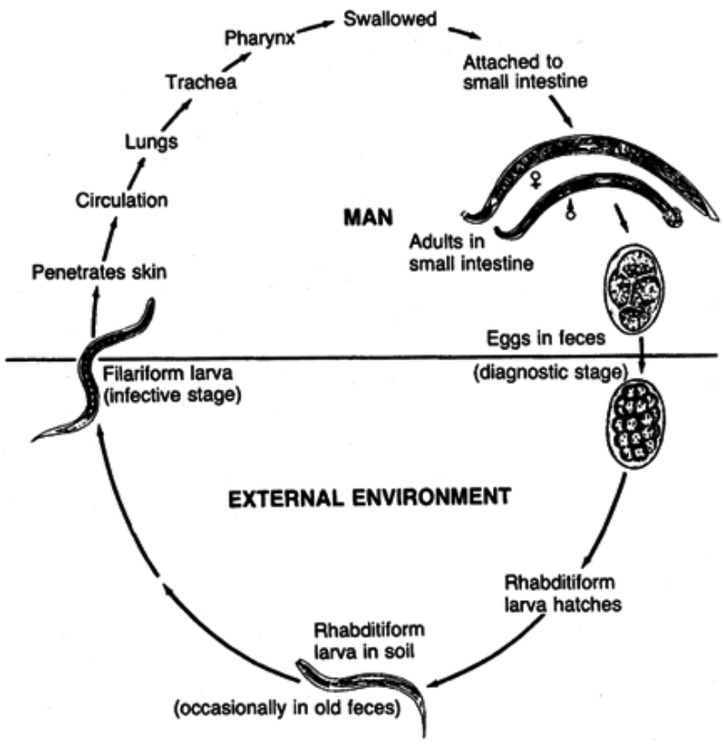

FIGURE 60.38. Life cycle of hookworm. (From Strickland GT. *Hunter's tropical medicine*, 7th ed. Philadelphia: Saunders, 1991.)

Transmission of hookworm infection requires deposition of egg-containing feces on shady, well-drained soil and is favored by tropical or subtropical conditions. It is estimated that approximately 900 million individuals worldwide are infected with hookworms, including 700,000 in the United States (75). Similar to infection with other intestinal helminths, most hookworm infections are asymptomatic because of the very low worm burden. Initial symptomatology may be related to the penetration of the skin by the filariform larvae (pruritic rash) or the migration of the larva through the lung (pneumonitis). The intestinal phase of infection may produce epigastric pain, nausea, vomiting, and diarrhea; however, the major consequences of hookworm infection are anemia and hypoalbuminemia secondary to chronic blood loss. The severity of the anemia is directly related to the worm burden and intake of dietary iron. Daily blood loss is estimated at 0.15 to 0.25 mL for each adult *A. duodenale* and 0.03 mL for each adult *N. americanus*. Severe anemia may develop over a period of months or years and may contribute to mental, sexual, and physical development retardation.

The diagnosis of hookworm infection is confirmed by detection of the distinctive eggs (Fig. 60.39) in direct or concentrated stool preparations. The oval eggs measure 56 to 75 µm long by 36 to 40 µm wide and have a thin shell. The eggs of *A. duodenale* and *N. americanus* are indistinguishable. Rhabditiform larvae may be present if the stool is allowed to stand too long at ambient temperature and must be differentiated from those of *Strongyloides stercoralis* (Table 60.8). Quantitative egg counts in direct wet mounts may be useful in estimating the worm burden:

fewer than five eggs per slide denotes light infections, whereas more than 25 denotes heavy infections.

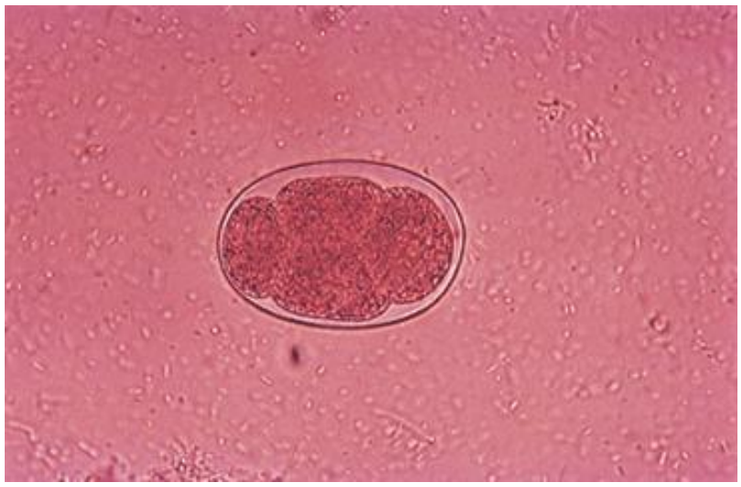

FIGURE 60.39. Hookworm, segmented egg (low power). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

Treatment of hookworm infection involves antihelminthic chemotherapy and correction of anemia when present. The drug of choice is mebendazole; pyrantel pamoate is an effective alternative. Anemia may be corrected by iron replacement or, if severe, by blood transfusion. Prevention may be accomplished by the wearing of shoes and by improved sanitation.

Strongyloides stercoralis

S. stercoralis, at 2 mm in length, is the smallest intestinal nematode infecting humans. Adult females burrow into the mucosa of the duodenum and reproduce parthenogenetically. The eggs are deposited within the mucosa, where they hatch, releasing rhabditiform larvae that are passed in the stool. Thus, eggs are almost never found in the stools. The rhabditiform larvae, which measure 180 × 16 µm in length, are distinguished from the larvae of hookworms by their short buccal capsule and large genital primordium (Table 60.8).

The life cycle of *S. stercoralis* may be either direct or indirect (Fig. 60.40). The direct cycle is similar to that observed with the hookworms, in which infective filariform larvae develop in soil for at least 1 week, and infection is acquired by the larvae penetrating the skin and migrating through the lungs to the intestine, where the female matures in approximately 1 month. Each female produces approximately a dozen eggs per day, which hatch within the mucosa and release rhabditiform larvae into the lumen of the bowel. The rhabditiform larvae are passed in the stool and may either continue the direct cycle by developing into infective filariform larvae or develop into free-living adult worms and initiate the indirect cycle. In the indirect cycle, free-living adult worms develop in the soil and produce eggs, which ultimately may give rise to infective third-stage filariform larvae. In humans, especially in debilitated individuals or in patients who are immunosuppressed, there may be a third cycle, that of internal autoinfection (75, 77, 78). This autoinfection occurs when the rhabditiform larva's passage through the intestine is delayed, allowing it to transform into an infective filariform larva while still in the body of the host. The larva may then invade the intestinal mucosa or the perianal skin without undergoing the external (soil) phase of the life cycle. This process may give rise to massive superinfection with larvae in many tissues and may lead to death (hyperinfection syndrome) (77, 78).

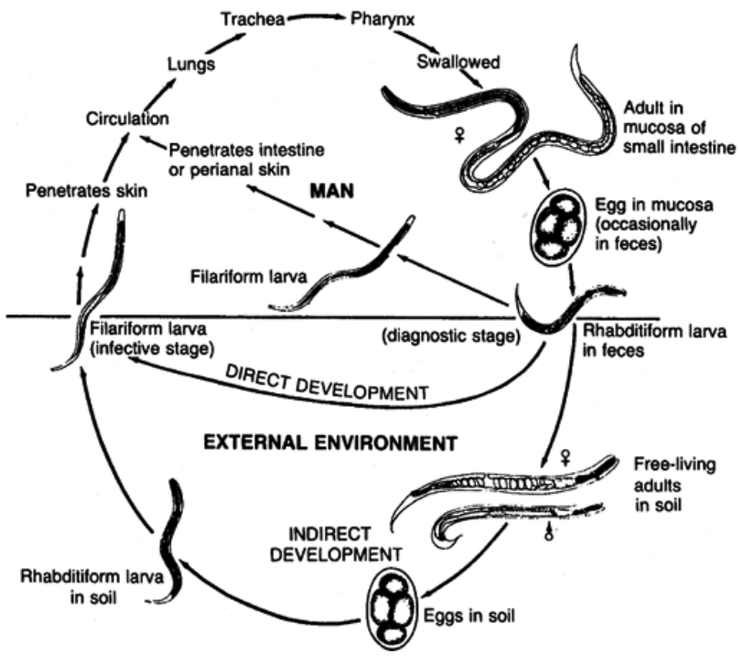

FIGURE 60.40. Life cycle of *Strongyloides stercoralis*. (From Strickland GT. *Hunter's tropical medicine*, 7th ed. Philadelphia: Saunders, 1991.)

S. stercoralis is similar to hookworm in its requirements for warm temperatures and moisture for the external development of larvae in soil. It infects approximately 35 million individuals throughout the tropical and subtropical areas of the world (75, 77).

Although individuals with strongyloidiasis do not manifest cutaneous symptoms (“ground itch”) secondary to the penetration of the infective larvae, they do present with pulmonary symptoms similar to those seen in both ascariasis and hookworm infection. The intestinal infection is usually asymptomatic; however, heavy worm loads may involve the biliary and pancreatic ducts, the entire small bowel, and the colon, causing inflammation and ulceration and leading to epigastric pain and tenderness, vomiting, diarrhea (occasionally bloody), and malabsorption. Symptoms mimicking peptic ulcer disease coupled with peripheral eosinophilia should strongly suggest the diagnosis of strongyloidiasis.

Diagnosis of strongyloidiasis may be difficult owing to intermittent passage of low numbers of first-stage larvae in the stool. In fresh stool specimens, the detection of rhabditiform larvae is indicative of *Strongyloides* infection. Differentiation of *Strongyloides* larvae from those of hookworm may be necessary when stool examination is delayed. First-stage rhabditiform *Strongyloides* larvae have a short buccal cavity and a prominent genital primordium compared to the long buccal cavity and inconspicuous genital primordium present in hookworm larvae. In contrast to hookworm infections, eggs are generally not present in the feces of patients with strongyloidiasis. When absent from the stool, larvae may be detected in duodenal aspirates or in sputum in cases of massive infection. Serologic tests are not generally available.

All infected patients should be treated to prevent autoinfection and potential dissemination (hyperinfection) of the parasite (77, 78). The drug of choice for both mild and severe infection is thiabendazole. Mebendazole is an alternative therapeutic agent. Stools should be checked after therapy to ensure adequate treatment. Patients in endemic areas should be examined thoroughly for the presence of this parasite both before and during steroid treatment or immunosuppressive therapy. Strict infection control measures should be enforced when caring for individuals with hyperinfection syndrome, as stool, saliva, vomitus, and body fluids may contain infectious filariform larvae. Similar to hookworm, *Strongyloides* control requires education, proper sanitation, and prompt treatment of existing infections.

Trichinella spiralis

T. spiralis causes the disease trichinosis. The adult form of *T. spiralis* lives in the duodenal and jejunal mucosa of flesh-eating mammals worldwide. The larval form is present in undercooked or contaminated meat. Among domestic animals, swine are most frequently involved. Humans become infected by ingestion of inadequately cooked meat that contains the encysted larval form of the organism. On ingestion, the encysted larvae are freed by gastric digestion, penetrate the mucosa of the intestine, and mature just above the lamina propria. The adult male and female worms mate in the intestinal mucosa, and the female produces new larvae, which enter the vascular system and are eventually deposited in skeletal muscle. A single female worm may produce larvae over a period of 4 to 16 weeks, generating as many as 1,500 larvae, each measuring 6 × 100 μm (76). Larvae penetrating striated muscle continue to grow and molt and are eventually enclosed in a fibrous capsule, which may calcify over a period of 6 to 18 months. The muscles invaded most frequently include the extraocular muscles of the eye; the tongue; the deltoid, pectoral, and intercostal muscles; the diaphragm; and the gastrocnemius. The encysted larvae remain viable for many years and would be infectious if ingested by a new animal host.

Trichinosis is one of the few tissue parasitic diseases still seen in the United States (76). As with other parasitic infections, most patients have minimal or no symptoms. The clinical presentation depends largely on the tissue burden of organisms and the location of the migrating larvae. Patients in whom 10 or fewer larvae per gram of tissue are deposited are usually asymptomatic, those with 100 or more generally have significant disease, and those with 1,000 to 5,000 have a very serious course that occasionally ends in death (76). The most common clinical manifestations of trichinosis are fever, myalgias, weakness, malaise, periorbital edema, and headache. Less frequent manifestations include skin rash, generalized edema, diarrhea, nausea, splinter hemorrhages, and subconjunctival bleeding. Symptoms generally appear approximately 2 weeks after initial infection and persist for several weeks. Diarrhea, if it occurs at all, tends to be early in infection when adult worms are still in the intestinal tract. Weakness occurs late as an end-stage manifestation of the presence of the calcifying larvae in the muscle tissue.

Trichinosis occurs throughout most of the world except Australia and the Pacific Islands. In the United States, infections are becoming less frequent owing to decreased consumption of pork and pork products, federal guidelines for the commercial preparation of pork products, and federal legislation regarding the preparation and composition of livestock feed to avoid inclusion of infected meat. Nevertheless, it is estimated that more than 1.5 million Americans carry live *Trichinella* cysts in their musculature and that 150,000 to 300,000 acquire new infection annually (76).

The diagnosis of trichinosis is confirmed by performing a muscle biopsy and visualizing the encysted larvae. Key to making the diagnosis is clinical suspicion of the disease and pursuit of the biopsy. The deltoid or gastrocnemius muscle will usually provide the best yield. Often several individuals are infected because of a common exposure to the same poorly prepared meat product. Along with the wide variety of clinical symptoms that are seen, patients usually have an eosinophilia ranging from 15% to 50% of the peripheral white cell count. Together, these epidemiologic, clinical, and laboratory features should lead to suspicion of the disease.

A serologic test using bentonite flocculation is a possible approach to confirming infection. Significant antibody titers are usually absent before the third week of illness but then may persist for years. ELISA tests are also under development, and one such test has been used as a screening method to detect infection in animals as part of the inspection process before the sale of meat products (76, 79).

Treatment of trichinosis is primarily symptomatic because there are no good antiparasitic agents for the tissue larvae. Patients with severe infections may be treated with corticosteroids plus either mebendazole or thiabendazole. Treatment of the adult worms in the intestine with mebendazole may halt the production of new larvae. Prevention is based on thorough cooking of pork and other meat.

Toxocara canis

T. canis, a large intestinal ascarid of canines, is the etiologic agent of toxocariasis or visceral larval migrans. The complete life cycle of this parasite occurs in dogs and is similar to that of the human *Ascaris*. Canines ingest *Toxocara* eggs, which hatch into larvae in the small intestine. These larvae migrate to liver, lung, and tracheae, are swallowed again, and mature into adult worms. Each female worm discharges approximately 200,000 eggs daily into the feces. Passage of larvae from pregnant females to fetuses can also occur and leads to ongoing infection when puppies are born. After reaching the soil, the eggs must embryonate for 2 to 3 weeks and thereafter are infectious for both canines and humans. The eggs may remain viable in soil for months to years.

Human infection occurs on ingestion of infectious eggs. The eggs hatch in the small intestine and the liberated larvae pass through the pulmonary capillaries and reach the systemic circulation. The larvae continue to grow, penetrate the vascular walls, and migrate through various tissues. Rarely, if ever, do the larvae reach the intestine and complete the maturation to adulthood in the human host.

The clinical manifestations of toxocariasis in humans are related to the migration of the larvae through tissues (76). The larvae may invade any tissue of the body, where they can induce necrosis, bleeding, and the formation of eosinophilic granulomas. Patients may be asymptomatic or have only eosinophilia but can also have serious disease that is directly related to the number and location of the lesions caused by the migrating larvae and the degree to which the host is sensitized to the larval antigens. The organs most frequently involved include the lungs, heart, kidney, liver, skeletal muscles, eye, and central nervous system. Signs and symptoms include cough, wheezing, fever, rash, anorexia, seizures, fatigue, and abdominal discomfort. On examination, patients may have hepatosplenomegaly as well as nodular, pruritic skin lesions. Death may result from respiratory failure, cardiac arrhythmia, or brain damage. Ocular disease can also occur with the movement of larvae through the eye and may be mistaken for malignant retinoblastoma. Prompt diagnosis is required to avoid an unnecessary enucleation.

T. canis is a cosmopolitan parasite. Wherever infected canines are present, the eggs are a threat to humans. The incidence of infection appears to be higher in the southeastern sections of the United States. Seroprevalence studies indicate that approximately 4% to 20% of the population has ingested *T. canis* eggs at some time. Children are particularly susceptible to infection, presumably owing to more frequent exposure to contaminated soil and the tendency to put objects in their mouth.

Diagnosis of visceral larval migrans is based on clinical findings, the presence of eosinophilia, known exposure to dogs, and serologic confirmation. ELISA assays are readily available and appear to offer the best serologic marker for disease. Examination of feces from infected patients is not useful because egg-laying adults are not present. Tissue examination for larvae may provide a definitive diagnosis but may be negative owing to sampling error.

Treatment is primarily symptomatic because antiparasitic agents are not of proven benefit. Agents including diethylcarbamazine, thiabendazole, and mebendazole have been tried. Corticosteroid therapy may be lifesaving if the patient has serious pulmonary, myocardial, or central nervous system involvement because a major component of the infection is an inflammatory response to the organism.

Ancylostoma braziliense

Cutaneous larva migrans is an infection of the skin caused by the dog and cat hookworm *A. braziliense*. This species of hookworm naturally infects dogs and cats and accidentally infects humans. Eggs discharged in the feces are deposited on warm, moist, sandy soil, where they develop into filariform larvae capable of penetrating skin on contact. The larvae can penetrate intact human skin but can develop no further in the human host. The larvae remain trapped in the skin and subcutaneous tissue for weeks to months, during which time they continue to migrate, creating serpentine tunnels and provoking a severe erythematous and vesicular reaction. Clinically, the patient notes pruritic, raised, red, linear lesions approximately 10 to 20 cm long (80). Scratching of the irritated skin may lead to secondary bacterial infection. Approximately half of the patients will develop transient pulmonary infiltrates with peripheral eosinophilia (Löffler's syndrome), presumably owing to pulmonary migration of the larvae. Larvae are rarely found in sputum or skin biopsies, and the diagnosis must be made on clinical grounds. The infection is treated adequately with thiabendazole. Antihistamines may be helpful in controlling the pruritus. Preventive measures include wearing shoes, deworming pets, and improvement of sanitation.

Filariae

The filariae are nematodes that are widely distributed in nature. The adults are long and slender, measuring many centimeters in length, and may inhabit virtually any tissue, including blood and lymphatic vessels, pleural and peritoneal cavities, subcutaneous tissue, heart, and brain. Some species migrate in tissues, and others remain localized and may become encased in a fibrous tissue reaction. The adults mate in the tissues, producing many progeny called microfilariae. The microfilariae are small (200 to 300 μm), slender, motile forms, which may be found in the circulating blood or migrating in the subcutaneous tissues, depending on the species.

Microfilariae are classified by morphologic characteristics, geographic location, and type of clinical infection seen (76). The major division of microfilariae is by the presence or absence of a sheath surrounding the parasite (Fig. 60.41). Unsheathed microfilariae include *Onchocerca volvulus*, *Mansonella ozzardi*, *M. perstans*, and *M. streptocerca*. The sheathed microfilariae include *Wuchereria bancrofti*, *Brugia malayi*, and *Loa loa*. Definitive identification to species is based on the presence and number of nuclei seen in the tail of the microfilaria. Alternatively, these parasites can be divided as causes of cutaneous, lymphatic, or body cavity infection. Species identification of blood microfilariae is particularly important because some may cause serious disease although others rarely do.

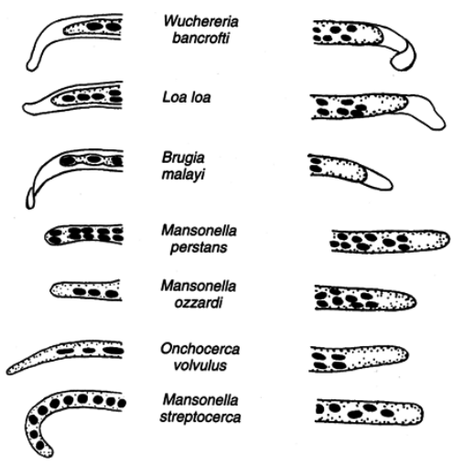

FIGURE 60.41. Differentiation of microfilariae, based on posterior ends **(left)** and anterior ends **(right)** of the microfilariae. Note the distribution of nuclei, their presence or absence in the extreme caudal portion, and the presence or absence of a sheath. (From Markell EK, Voge M, John DT. *Medical parasitology*, 7th ed. Philadelphia: Saunders, 1992.)

Onchocerca volvulus

Onchocerciasis, a major cause of blindness worldwide, is caused by the skin filaria *O. volvulus*. Humans become infected by the

bite of black flies of the genus *Simulium*. The filariform larvae of the parasite are injected by the bite of the fly into the skin and migrate to subcutaneous connective tissue, where they develop into adult worms. The 20- to 30-mm adults become encased in fibrous subcutaneous nodules within which they may remain viable for as long as 15 years. The female worm gives birth to as many as 2,000 microfilariae each day. These larval forms exit the capsule to migrate for as long as 2 years in the subcutaneous tissues, skin, and eye. The life cycle is completed by ingestion of the microfilariae by new black flies in which the microfilariae transform into infectious filariform larvae.

Clinical onchocerciasis is characterized by infection involving the skin, subcutaneous tissue, lymph nodes, and eyes. Patients present with pruritus, subcutaneous nodules, or visual impairment. The clinical manifestations of the infection are owing to the acute and chronic inflammatory reaction to antigens released by the microfilariae as they migrate through the tissues. Within the skin, this inflammatory process results in loss of elasticity and areas of depigmentation, thickening, and atrophy. Subcutaneous inflammation may produce fibrosing, obstructive lymphadenitis, which may result in elephantiasis. Firm, nontender, mobile nodules may develop, especially over bony prominences.

Onchocerciasis affects more than 50 million people in tropical Africa and Central and South America and causes blindness in approximately 5% of infected individuals. The mechanism for development of eye disease is thought to be a combination of both direct invasion by the microfilariae and antigen-antibody complex deposition within the ocular tissues (81). Patients progress from conjunctivitis with photophobia to punctate and sclerosing keratitis. Internal eye disease with anterior uveitis, chorioretinitis, and optic neuritis may also occur. The disease is one of the leading causes of blindness worldwide. In some communities in West Africa, as many as half of the adult male population is blind owing to this infection.

Diagnosis of onchocerciasis is made by demonstration of microfilariae in skin snip preparations from the infrascapular or gluteal region. A sample is obtained by raising the skin with a needle and shaving the epidermal layer with a razor. The specimen is incubated in saline for several hours, then inspected with a dissecting microscope for the presence of nonsheathed microfilariae (Fig. 60.42). In patients with ocular disease, the organism may also be seen in the anterior chamber with the aid of a slit lamp. Serologic and culture methods are not helpful, although efforts to develop serologic detection methods are ongoing.

FIGURE 60.42. *Onchocerca volvulus*: Microfilariae teased from skin snip (hematoxylin and eosin stain). (From Smith JW, et al. *Diagnostic medical parasitology: blood and tissue parasites*. Chicago: American Society of Clinical Pathologists, 1976.)

Treatment includes the use of ivermectin to eradicate the microfilariae and either surgical excision of nodules or administration of suramin for the adult worms. A single dose of ivermectin (150 µg/kg) greatly reduces the number of microfilariae in the skin and eyes, thus diminishing the likelihood of developing disabling onchocerciasis. Suppression of dermal microfilariae with ivermectin reduces the transmission of this vector-borne disease and may prove to be a successful preventive strategy (82).

Mansonella

Filarial infections caused by *Mansonella* species (*M. perstans*, *M. ozzardi*, and *M. streptocerca*) are generally asymptomatic but may cause dermatitis, lymphadenitis, hydrocele, and rarely lymphatic obstruction resulting in elephantiasis (76). All the *Mansonella* species produce nonsheathed microfilariae (Fig. 60.41) in blood and subcutaneous tissues, and all are transmitted by biting midges (*Culicoides*) or black flies (*Simulium*).

These filariae are found in South America and Central Africa. All are treatable with diethylcarbamazine. Species identification, if desired, can be accomplished with blood smears noting the structure of the microfilariae. Serologic tests are also available.

Wuchereria and Brugia

Lymphatic filariasis constitutes a group of diseases characterized by lymphatic obstruction that results in a condition known as

elephantiasis (76). The two species of filariae most commonly involved are *W. bancrofti* and *B. malayi*. The adult forms of these filariae parasitize the lymphatic vessels, primarily in the arms, legs, or groin, where they may exist for as long as 10 years. The female worms produce sheathed microfilariae (Fig. 60.41) that enter the bloodstream of the host and circulate with a nocturnal periodicity. The microfilariae may be found in greatest numbers in the peripheral circulation between 9:00 p.m. and 2:00 a.m., a time period that corresponds to the peak feeding time of the mosquito vectors (*Culex*, *Aedes*, *Anopheles*, or *Mansonia*). The microfilariae that are ingested by the mosquito vector transform first into rhabditiform and then into filariform larvae within the mosquito. The infective filariform larvae actively penetrate the feeding site when the mosquito takes its next meal and migrate to the lymphatic vessels, where they reach adulthood in 6 to 12 months.

Clinical manifestations of infection with *W. bancrofti* and *B. malayi* vary from asymptomatic infection with positive serology but no detectable microfilariae to lymphatic inflammation and chronic lymphatic obstruction with development of lymphoceles, lymphangitis, and elephantiasis. Acute symptoms may include fever, headache, and back pain in association with lymphangitis. The acute presentation is thought to be caused by the inflammatory response to the presence of molting adolescent worms and dead or dying adults within the lymphatic vessels. The acute response is followed by the formation of granulomas, fibrosis, and permanent lymphatic obstruction. With repeated exposure over many years, individuals develop heavy infections and massive lymphatic blockade. The resultant lymphedema and fibrosis may be complicated by recurrent bacterial infections, which contribute to the tissue damage. Continuation of this process over a period of decades results in elephantiasis, usually most severe in the lower extremities and genitalia (76). Occasionally ascites and pleural effusions secondary to rupture of enlarged lymphatics into the peritoneal or pleural cavities may be observed.

It is estimated that lymphatic filariasis currently infects between 80 and 100 million individuals in Africa, Latin America, the Pacific Islands, and Asia. *W. bancrofti* is distributed throughout these areas, whereas *B. malayi* is limited to Southeast Asia and Indonesia.

Eosinophilia is usually present during acute inflammatory episodes; however, demonstration of microfilariae in blood is required for definitive diagnosis. Microfilariae can be demonstrated in Giemsa-stained blood films as for malaria (Fig. 60.43 and Fig. 60.44). If the parasitemia is scant, the blood specimen may be concentrated before it is examined (76). Given the nocturnal periodicity of the microfilaremia, it is recommended that blood specimens be obtained between 9:00 p.m. and 2:00 a.m.

FIGURE 60.43. *Wuchereria bancrofti*: Microfilariae in thick film (Giemsa stain). (From Smith JW, et al. *Diagnostic medical parasitology: blood and tissue parasites*. Chicago: American Society of Clinical Pathologists, 1976.)

FIGURE 60.44. *Brugia malayi*: Microfilariae in thin film (Giemsa stain). (From Smith JW, et al. Diagnostic medical parasitology: blood and tissue parasites. Chicago: American Society of Clinical Pathologists, 1976.)

Both *W. bancrofti* and *B. malayi* produce sheathed microfilariae. Further identification is based on the study of head and tail structures (Fig. 60.41). Clinically, an exact species identification is not critical, as the treatment for all filarial infections is identical (diethylcarbamazine), with the possible exception of *O. volvulus* (ivermectin plus suramin).

Serologic testing is available but may lack sensitivity and specificity. Detection of circulating filarial antigens is promising but not widely available as a diagnostic test.

Treatment is of little benefit in most cases of lymphatic filariasis. Diethylcarbamazine has been used but has little apparent effect on adult worms. Ivermectin appears promising, although controlled studies have not yet been performed. Supportive and surgical therapy for lymphatic obstruction may be of some cosmetic help. Control programs combine mosquito control with mass treatment of the entire population.

Loa loa

Loiasis is a filarial disease found primarily in the rain forests of Africa, where *L. loa* is transmitted by biting flies of the genus *Chrysops*. The adult worms can persist in the human host for 17 years or more and migrate continuously through the subcutaneous tissues. During migration, the parasites elicit an intense eosinophilia and produce localized areas of allergic subcutaneous inflammation known as Calabar swellings. These swellings reach 10 to 20 cm in diameter, last 2 to 3 days, and may be accompanied by fever, pruritus, and pain. Occasionally, the adult worm may migrate across the eye subconjunctivally, producing tearing, pain, edema, and impaired vision.

The adult female produces sheathed microfilariae, which may be detected in the bloodstream during day time hours. The

sheath of the microfilariae does not stain with Giemsa, and the tail has nuclei extending to the rounded tip (Fig. 60.41).

The diagnosis of loiasis may be made by recovering the adult worm from the eye or by detecting microfilariae in the blood or aspirates of Calabar swellings. Eosinophilia is constant and may constitute 50% to 70% of the peripheral white count. Diethylcarbamazine is effective against both adults and microfilariae; however, destruction of the parasites may induce severe allergic reactions, which require treatment with corticosteroids. The role of ivermectin remains undefined for this infection.

Dirofilaria immitis

The canine heartworm *D. immitis* is endemic in the southeastern United States. It is transmitted by mosquitoes and has a typical filarial life cycle, with the dog serving as the definitive host. Accidental infections in humans may be acquired by the bite of the mosquito vector, resulting in one or more worms becoming lodged in the right heart or pulmonary artery. Because humans are unsuitable hosts for *Dirofilaria*, the parasite dies before maturing and is embolized to smaller branches of the pulmonary vasculature, where it may cause a small area of infarction that heals and may appear as a coin lesion on a chest radiograph. Throughout this process, most patients remain asymptomatic. The pulmonary coin lesion may pose a problem because it resembles a malignancy requiring surgical removal. A definitive diagnosis is made when a thoracotomy specimen is examined microscopically, revealing the typical cross-sections of the parasite (76, 83).

Unfortunately, no laboratory test currently available can provide an accurate diagnosis of dirofilariasis (76). Peripheral eosinophilia is rare, and the radiographic features are insufficient to allow one to distinguish pulmonary dirofilariasis from bronchogenic carcinoma. Serologic tests are not sufficiently sensitive or specific to be clinically useful (76).

Dracunculus medinensis

Dracunculiasis is a chronic subcutaneous infection caused by the tissue-invading nematode *D. medinensis*. *D. medinensis* has a simple life cycle depending on fresh water and a copepod of the genus *Cyclops*, which serves as the intermediate host. The infection in humans is initiated when a copepod infected with the larval stage of *D. medinensis* is ingested in drinking water. After ingestion, the larvae are released from the copepods in the stomach and small intestine, penetrate the wall of the digestive tract, and migrate to the retroperitoneal space, where they mature. Male and female worms mate in this location. The gravid female then migrates to the subcutaneous tissues, usually in the extremities, where a vesicle is formed in the host tissue. The vesicle ulcerates and the worm protrudes a loop of uterus through the ulcer. On contact with water, the larval worms are released. The larvae are then ingested by the *Cyclops* in fresh water, where they may in turn infect another mammalian host. When the female has discharged all the larvae, it may retreat into deeper tissue, where it is gradually absorbed, or it may simply be expelled from the site.

Dracunculiasis is generally asymptomatic until the gravid female creates the vesicle and the ulcer in the skin for the liberation of larvae. The time between initial exposure and ulceration is usually approximately 1 year. The site of the ulceration is painful and erythematous, and the adult worm may be visible in the center of the lesion. At the time of ulceration, the patient may develop local or generalized pruritus, nausea, diarrhea, and shortness of breath. Fluid present at the site of ulceration may contain many visible larvae. Patients with multiple adult worms may have several ulcerations occur simultaneously. Occasionally, the site may become secondarily infected with bacteria, leading to abscess formation and further tissue destruction.

D. medinensis occurs in many parts of Asia and equatorial Africa, infecting an estimated 10 million individuals. Reservoir hosts include dogs and other mammals. Humans perpetuate the cycle when infected individuals bathe or stand in the wells or ponds from which drinking water is obtained. Larvae are discharged from the lesions on the arms, legs, feet, and ankles to infect the copepods in the water, which are in turn collected with the drinking water.

Diagnosis of this infection is usually straightforward clinically, with the adult worm present in the ulcerated skin lesion. Larvae can also be detected under the microscope in samples of fluid from the ulcer site (76).

Treatment may be accomplished by administration of niridazole, metronidazole, or thiabendazole. Alternatively, the worm may be removed surgically. The ancient method of slowly wrapping the worm on a twig, thus extracting it from the ulcer, is still used in many endemic areas. This process may be complicated by infection and/or toxic reactions if the worm is broken during removal.

Prevention requires education concerning the life cycle of the parasite and avoidance of water contaminated with *Cyclops*. Ideally, adequate treatment of water supplies would result in elimination of this infection (84).

Trematodes

The trematodes or flukes are members of the Platyhelminthes and are generally flat, fleshy, leaf-shaped worms. They vary in length from a few millimeters to several centimeters and possess two muscular suckers: one oral, surrounding the opening to the primitive digestive tract, and one ventral for attachment. The digestive system consists of a muscular pharynx and esophagus and bilateral ceca that end blindly near the posterior aspect of the worm.

The flukes may be divided into two major categories based on their reproductive systems (75, 76). Most flukes are hermaphrodites. The adult hermaphrodite contains both male and female gonads and produces operculate eggs (Fig. 60.45). The schistosomes constitute the second major category and include organisms with separate sexes. The female schistosome deposits only nonoperculated eggs. Schistosomes also have more rounded bodies than do the hermaphroditic flukes. Both schistosomes and hermaphroditic flukes have similar life cycles that include one or more intermediate hosts. Mollusks (snails or clams) are essential, first intermediate hosts for all trematodes. The mollusks are infected by ciliated larvae or miracidia, which are released from eggs that have been deposited into fresh water. Within the first intermediate host, the miracidia undergo asexual reproduction to produce thousands of motile cercariae, which are released into the water where they actively swim about in search of their next host. In the case of schistosomes, the cercariae directly penetrate the skin of humans and produce infection.

The cercariae of the hermaphroditic flukes encyst in or on an aquatic plant or animal (crustacean or fish), where they develop into infective metacercariae. Their cycle is completed when the second intermediate host is ingested by a human.

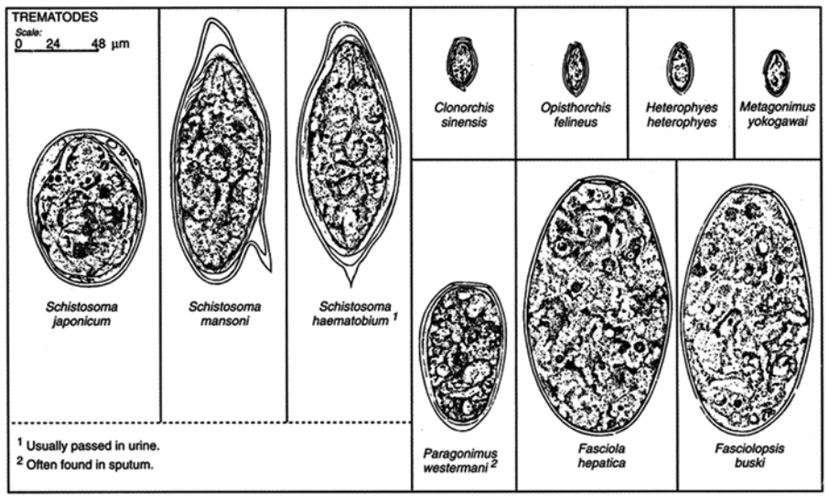

FIGURE 60.45. Trematode eggs found in human feces. (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

Another means of classifying the trematodes that cause human infection is by the anatomic location of the parasite in the human host (75, 76). Thus, we have the intestinal trematodes (Table 60.9), the liver and lung trematodes (Table 60.10), and the blood

TABLE 60.9. MORPHOLOGY OF INTESTINAL TREMATODES

	Fasciolopsis buski	*Heterophyes heterophyes*	*Metagonimus yokogawai*
Method of infection	Ingestion of water chestnut, bamboo shoots	Ingestion of freshwater fish	Ingestion of freshwater fish
Location in host	Attached to wall of the small intestine	Crypts and lumen of the small intestine	Crypts and lumen of the small intestine
Reservoir host	Dogs, pigs, rabbits	Fish-eating mammals	Fish-eating mammals
Intermediate host	*Segmentia* or *Hippeutis* snails	*Pironella* and *Cerithidea* snails	*Semisulcospira* snails
Adult worm	Large, up to 75 mm long × 20 mm wide	Small, pyriform-shaped, 1–2.5 mm long × 0.3–0.7 mm wide; single ovary is situated anterior to the posterior testes	Small, pyriform-shaped, 1–2.5 mm long × 0.3–0.7 mm wide; single ovary is situated anterior to the posterior testes

trematodes (Table 60.11). Of the many trematodes infecting humans, only seven representative agents will be discussed: the blood flukes, all of which are members of the genus *Schistosoma* (*S. mansoni*, *S. haematobium*, and *S. japonicum*), the liver flukes (*Fasciola hepatica* and *Opisthorchis sinensis*), the lung fluke (*Paragonimus westermani*), and the intestinal fluke (*Fasciolopsis buski*). The other flukes causing infection in humans are similar to these representative agents in terms of epidemiology, clinical syndromes, and therapy (75, 76). Basic details of additional intestinal and tissue flukes are provided in Table 60.9 and Table 60.10.

TABLE 60.10. MORPHOLOGY OF LIVER AND LUNG TREMATODES

	Opisthorchis sinensis	*Opisthorchis viverrini*	*Fasciola hepatica*	*Paragonimus westermani*
Method of infection	Ingestion of raw fish	Ingestion of raw fish	Ingestion of raw water plants	Ingestion of crabs, crawfish
Location in host	Bile ducts of the liver	Bile ducts of the liver	Bile ducts of the liver	Encapsulated in parenchyma of the lung
Reservoir host	Dogs, cats, fish-eating mammals	Dogs, cats, fish-eating mammals	Herbivores	Dogs, cats, tigers, lions
Intermediate host	1st: *Parafossarulus, Bulinus, Semisulcospira, Alocinma, Melanoides* snails	1st: *Bithynia* snail; 2nd: freshwater fish	1st: *Parafossarulus, Bulinus, Semisulcospira, Alocinma, Melanoides* snails	1st: *Semisulcospira* and *Brotia* snails; 2nd: Crabs, crawfish
Adult worm	Flattened, spatulate, 10–25 mm long × 3–5 mm wide, hermaphroditic with single round ovary anterior to testes	10–25 mm long, 2 testes lying one behind the other in posterior end, ovary anterior to testes	Large, fleshy, up to 30 mm long × 14 mm wide; anterior end is cone shaped, all internal organs are branched	Ovoid, 7.5–12 × 4–6 mm, hermaphroditic, lobed ovary located anterior to testes, testes lie side by side in posterior part of body
Egg morphology	Ovoid, thick-shelled, seated operculum; 27–35 × 12–19 µm; knob at abopercular end; prominent shoulders, contains miracidium	19–29 × 12–17 µm, operculated; prominent shoulders; contains miracidium	Large, ellipsoidal, unembryonated; operculated 130–150 × 63–90 µm; operculum is small	Ovoid, large, thick-shelled; unembryonated when passed in sputum or feces; 80–120 × 45–70 µm; thickened at abopercular end
Clinical manifestations	Biliary tract obstruction, bile retention, acute pancreatitis, cholecystitis, cholelithiasis, fever, chills, diarrhea, epigastric pain, enlarged tender liver, jaundice	Infection confined to biliary tract system, weakness, pain in right upper quadrant, elevated serum IgE levels (3 or 4 times)	Fever, right upper quadrant pain, eosinophilia associated with migratory phase, biliary obstruction, cholangitis, acute epigastric pain, fever, jaundice, enlarged liver, eosinophilia	Cough with increased production of blood tinged sputum, chest pain, dyspnea with chronic bronchitis, fever, headache, nausea, vomiting, visual disturbances, motor weakness, localized or general paralysis

Intestinal Trematodes

Several intestinal trematodes are recognized, including *F. buski*, *Heterophyes heterophyes*, and *Metagonimus yokogawai* (Table 60.9). *F. buski*, the largest, most prevalent, and important intestinal fluke, is a large (75 mm long by 20 mm wide) fleshy worm (Fig. 60.46) that is a common parasite of pigs and humans in China and Southeast Asia. An estimated 10 million individuals are infected with this intestinal parasite.

The life cycle of *F. buski* is typical of hermaphroditic trematodes. Metacercariae are encysted on aquatic plants, which serve as the second intermediate host. Ingestion of the metacercariae along with the freshwater vegetation results in establishment of the infection in the small intestine. The flukes live attached to the mucosa of the duodenum and jejunum by means of the ventral sucker. Self-fertilization occurs and egg production begins 3 months after the initial infection with the metacercariae. The eggs, which are broadly ellipsoidal (130 to 150 µm × 60 to 90 µm) and unembryonated with a small, indistinct operculum

FIGURE 60.46. *Fasciolopsis buski*, adult worm (carmine stain, whole mount). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

(Fig. 60.45 and Fig. 60.47), are passed in the feces and gain access to fresh water, where they require a prolonged maturation period. After maturation, the eggs release a ciliated, free-swimming larval stage (miracidium) that seeks a particular species of snail for further development.

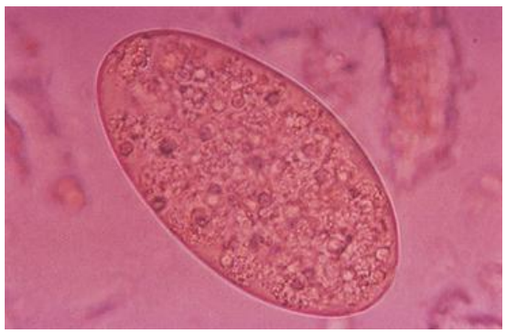

FIGURE 60.47. *Fasciolopsis buski*, egg (high power). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

Symptoms of *F. buski* infection are directly related to the worm burden in the small intestine. Ulceration of the superficial mucosa may occur, accompanied by inflammation and hemorrhage. Diarrhea and epigastric pain similar to that of a duodenal ulcer are the main presenting symptoms. Anorexia, nausea, and vomiting can occur, accompanied by eosinophilia. A malabsorption syndrome similar to giardiasis is common, and intestinal obstruction may occur if there are enough worms.

The diagnosis is made by finding the large, oval, bile-stained, operculate eggs in the stool (Fig. 60.47). The measurements and appearance of *F. buski* eggs are similar to those of the liver fluke *F. hepatica*, and differentiation of the eggs of these species alone is not usually possible (75). The large adult flukes can rarely be found in feces or specimens collected at surgery.

The treatment of choice is praziquantel. Alternatively,

niclosamide may be used. Prompt treatment of infected humans may minimize the spread of infection. Prevention may also include proper sanitation and elimination of the reservoir hosts through the use of molluscacides.

Liver Trematodes

There are several liver flukes in various geographic regions that parasitize the biliary passages of humans (76). These include *F. hepatica*, *Opisthorchis sinensis*, *O. viverrini*, *O. felineus*, and *Dicrocoelium dendriticum* (Table 60.10). The most important of these, *F. hepatica* and *O. sinensis*, are discussed in this chapter.

Fasciola hepatica

The largest liver fluke is *F. hepatica*, a common parasite of sheep and cattle with a worldwide distribution.

The large (30 × 13 mm), fleshy adult flukes live in the biliary tree, where they lay eggs that are passed in the feces. The eggs develop in water and follow a life cycle similar to that of *F. buski*, with human infection resulting from ingestion of fresh water vegetation that harbors the encysted metacercariae. When ingested, the infective larvae are released from their cysts and migrate through the duodenal wall, across the peritoneal cavity, and into the bile ducts (via the liver), where they become adult worms. As with *F. buski*, self-fertilization occurs and egg production begins approximately 3 to 4 months after the initial infection. The large (130 to 150 µm × 60 to 90 µm), operculated eggs (Fig. 60.45) are excreted in the stool.

Early clinical signs and symptoms are owing to the migration of the larvae through the liver. Right upper quadrant pain and tenderness, hepatomegaly, chills and fever, with marked eosinophilia may be observed. The presence of the adult worms in the biliary tree elicits an inflammatory response with resultant hyperplasia of the epithelium and eventual fibrosis. Biliary obstruction caused by bile duct fibrosis and stone formation may occur. Penetration of adult worms into the liver parenchyma occurs rarely but may result in necrotic foci and abscess formation known as “liver rot.”

The diagnosis is established by detecting the characteristic eggs in stools. The unembryonated, operculate eggs cannot be distinguished from those of *F. buski* (Fig. 60.45 and Fig. 60.47). Distinction between the two flukes is necessary for therapeutic purposes because *F. buski* responds favorably to praziquantel and *F. hepatica* does not. The two species may be distinguished by sampling the patient's bile to detect the eggs of *F. hepatica*. Care must be taken to differentiate true infection from the spurious presence of eggs resulting from the ingestion of infected liver. Several stool samples should be examined to rule out such spurious observations and ensure that there is a true infection.

F. hepatica responds poorly to praziquantel. Treatment with bithionol or triclabendazole has been effective. Control measures are similar to those for *F. buski*.

Opisthorchis sinensis

The Chinese liver fluke *O. sinensis* is the most common liver fluke that infects humans. *O. sinensis* infects approximately 19 million individuals in China, Japan, Korea, and Vietnam (76, 85). It is also seen among residents of the United States and can be traced to the consumption of raw, pickled, smoked, or dried freshwater fish harboring viable metacercariae. Cats and dogs serve as important reservoir hosts.

The adult fluke is small and delicate, measuring 10 to 25 mm long × 3 to 5 mm wide (Fig. 60.48). *O. sinensis* may survive in the biliary tract for as long as 50 years producing approximately 2,000 eggs per day. The tiny (15 × 30 µm), urn-shaped eggs enter the duodenum with the bile and are discharged in the feces. On reaching fresh water, the eggs are ingested by the molluscan first intermediate host, transformed into cercariae, and released to penetrate the tissues of freshwater fish, in which they encyst to become infective metacercariae. Infection is acquired by ingestion of uncooked fish. The ingested larvae excyst in the duodenum and migrate via the ampulla of Vater and the common bile duct into the bile ducts of the liver, where they mature and live.

FIGURE 60.48. *Opisthorchis sinensis*, adult worm (carmine stain, whole mount). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

Infection in humans is usually mild and asymptomatic. Severe infections involving large numbers of flukes may produce fever, diarrhea, epigastric pain, hepatomegaly, anorexia, and occasionally jaundice. Biliary obstruction may occur, and individuals with severe longstanding infection may develop bile duct carcinoma. Invasion of the gallbladder or pancreatic ducts may occur, causing cholecystitis and pancreatitis.

The diagnosis is made by detecting the distinctive eggs in stools. The eggs measure 27 to 35 µm × 12 to 19 µm and are characterized by a distinct operculum with prominent shoulders and a tiny knob at the posterior (abopercular) pole (Fig. 60.49). In mild infections, repeated examinations of stool or duodenal aspirates may be necessary. In acute symptomatic infection, there is usually an eosinophilia and elevation of serum alkaline phosphates levels. Radiographic imaging procedures may detect abnormalities of the biliary tract.

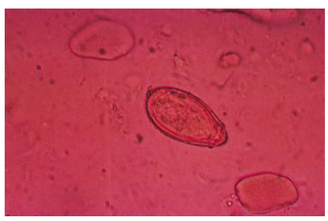

FIGURE 60.49. *Opisthorchis sinensis*, egg (oil immersion). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

Treatment is with praziquantel. Prevention requires avoidance of improperly cooked fish and the implementation of proper sanitation policies.

Lung Trematodes

The principal lung fluke of humans is *Paragonimus westermani*, which is found in the Orient; however, several additional species of *Paragonimus* parasitizing humans and other animals in Africa and South, Central, and North America have been described. *P. westermani* is a small (10 mm × 5 mm), reddish-brown worm that is a common parasite of shore-feeding animals (pigs, wild

boars, monkeys) as well as humans in China, Japan, and Southeast Asia. Its prevalence is directly related to the consumption of uncooked freshwater crabs and crayfish. It is estimated that approximately 3 million individuals are infected with this lung fluke. As many as 1% of all Indochinese immigrants to the United States are infected with *P. westermani* (76, 86).

The adult worms are usually found encysted in the pulmonary parenchyma of their definitive host. Infection is acquired by the ingestion of raw or partially cooked crabs or crayfish containing encysted metacercariae in their tissues. When ingested, the metacercariae excyst in the duodenum and migrate through the intestinal wall into the peritoneal cavity, through the diaphragm, and finally reach maturity in the lungs 5 to 6 weeks later. Occasionally organisms undergo aberrant migration and are retained in the intestinal wall and mesentery or migrate to other ectopic foci such as the liver, pancreas, skeletal muscle, subcutaneous tissue, or the central nervous system.

On reaching the pulmonary parenchyma, the flukes become encapsulated by the host's fibrous reaction. The adult worms deposit operculate, golden-brown eggs within the fibrous capsule. The capsule ultimately erodes into a bronchiole and discharges the eggs into the respiratory tree. The eggs may then be coughed up and spat out or swallowed and passed in the stool.

The clinical manifestations of paragonimiasis may be attributable to larvae migrating through tissues or to adults established in the lungs or other ectopic sites. The onset of the disease coincides with larval migration and is associated with fever, chills, and high eosinophilia. When established in the lungs, the adult worms stimulate an inflammatory reaction that results in fever and a chronic cough with increased sputum production and occasional hemoptysis. Evacuation of the capsule or cyst containing the adult worms and eggs produces a cavity, which may become secondarily infected with bacteria. The expectorated sputum is blood-tinged and contains numerous golden-brown eggs. Severe infections produce a chronic pneumonia with abscess formation and pulmonary fibrosis. Dyspnea, severe chest pain, and pleural effusion may be seen. Location of larvae, adults, and eggs in ectopic sites may produce severe clinical symptoms depending on the site involved. Cerebral paragonimiasis occurs in approximately 1% of Oriental cases and may produce a severe neurologic disease including seizures, paralysis, and visual disturbances.

The laboratory diagnosis of paragonimiasis depends on the detection of the golden-brown, operculated eggs in sputum and feces (Fig. 60.50). Pleural effusions, when present, should also be examined for eggs. Marked eosinophilia is common, and chest radiographs often show nodular shadows, calcifications, or patchy infiltrates. Serologic procedures are available through reference laboratories and may be useful, particularly in cases with extrapulmonary (e.g., central nervous system) involvement.

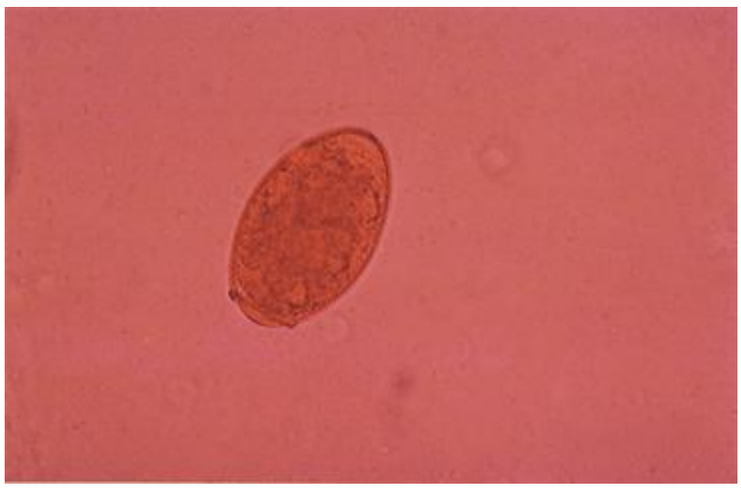

FIGURE 60.50. *Paragonimus westermani*, egg (high power). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

The disease responds adequately to treatment with either praziquantel or bithionol. Control requires adequate cooking of freshwater crustaceans before ingestion.

Blood Trematodes (Schistosomiasis)

Schistosomiasis is a major parasitic infection of tropical areas with some 200 million infections worldwide (76). The three schistosomes most frequently associated with human disease are *S. mansoni*, *S. japonicum*, and *S. haematobium*. As discussed previously, schistosomes differ from the hermaphroditic flukes in body structure and in having separate sexes, nonoperculated eggs, and a life cycle that includes only one intermediate host. They are also obligate intravascular parasites inhabiting the venules of the intestine (*S. mansoni* and *S. japonicum*) or the bladder (*S. haematobium*) rather than the cavities, ducts, and other tissues parasitized by the hermaphroditic flukes.

Infection with schistosomes is acquired by exposure to fresh water containing ciliated, free-swimming cercariae. The cercariae penetrate intact skin, causing intense pruritus, enter the circulation, and develop in the intrahepatic portal circulation. Adult male and female worms pair up early in development. The flat 1- to 2-cm male has a longitudinal (gynecophoral) canal resulting from folding the lateral aspects of the body toward the center. The long, slender, cylindrical female resides in the canal, and the two worms stay together in this fashion for the rest of their lives. After mating in the portal vein, the paired adult worms migrate to their final location in the small venules of the mesentery (*S. mansoni* and *S. japonicum*) or venous plexuses of the bladder (*S. haematobium*). In general, *S. japonicum* resides in the venous radicals of the small intestine, *S. mansoni* resides in the vicinity of the descending colon and rectum, and *S. haematobium* resides in the veins of the bladder and other pelvic organs. Once in the submucosal venules, the worms initiate oviposition, which may continue at the rate of 300

to 3,000 eggs daily for 4 to 35 years. Although the host inflammatory response to the adult worms, which are coated with host proteins, is minimal, the eggs elicit an intense inflammatory reaction with both mononuclear and polymorphonuclear cellular infiltrates and the formation of microabscesses. In addition, the larvae inside the eggs produce enzymes that aid in tissue destruction and allow the eggs to pass through the mucosa and into the lumen of the bladder and bowel, where they are passed to the external environment in the urine and feces, respectively.

The eggs are fully embryonated when they are passed to the environment and hatch quickly on reaching fresh water to release motile miracidia. The miracidia then invade the appropriate snail host, where they develop into thousands of infectious cercariae. The free-swimming cercariae are released into the water, where they are immediately infectious for humans and other mammals.

The infection is similar in all three species of human schistosomes in that disease results primarily from the host immune response to the eggs rather than from the adult worms. As noted above, the very earliest signs and symptoms of infection are owing to the penetration of the cercariae through the skin. Immediate and delayed hypersensitivity to parasite antigens results in an intensely pruritic papular skin rash.

The onset of oviposition, 1 to 2 months after primary exposure, results in the Katayama syndrome, characterized by fever, chills, cough, urticaria, arthralgias, lymphadenopathy, splenomegaly, and abdominal pain. Laboratory abnormalities include leukocytosis, eosinophilia, and a polyclonal gammopathy with elevated levels of IgG, IgM, and IgE. This symptom complex may persist for 3 months or more and is thought to be caused by the massive release of parasite antigens with subsequent immune complex formation.

The more chronic and significant phase of schistosomiasis is owing to the presence of the eggs in the various tissues and the resulting formation of granulomas and fibrosis (87). The retained eggs induce extensive inflammation and scarring, the clinical significance of which is directly related to the location and number of eggs. In *S. haematobium* infection, egg deposition in the walls of the bladder results in hematuria and dysuria and eventually may cause scarring and loss of bladder capacity, obstructive uropathy, and bladder carcinoma. Infections with *S. mansoni* and *S. japonicum* may produce hepatic and intestinal abnormalities. Deposition of eggs in the bowel mucosa results in inflammation and thickening of the bowel wall with associated abdominal pain, diarrhea, and blood in the stool. Importantly, eggs of *S. mansoni* and *S. japonicum* may be carried by the portal vein to the liver, where the resulting inflammation can lead to periportal fibrosis and eventually to portal hypertension with its associated manifestations. Although *S. mansoni* and *S. japonicum* eggs are primarily deposited in the intestine, eggs may appear in the brain, spinal cord, lungs, and other sites. Deposition of eggs in the central nervous system (brain and spinal cord) occurs more commonly with *S. japonicum* and may produce severe neurologic problems (87).

The geographic distribution of the various species of *Schistosoma* is dependent on the availability of a suitable snail host. *S. mansoni* is the most widespread of the blood flukes, occurring in Africa, the Middle East, South America, Puerto Rico, and several Caribbean islands. *S. haematobium* is largely confined to Africa and the Middle East where its distribution overlaps that of *S. mansoni*. *S. japonicum*, the Oriental blood fluke, is found only in Japan, China, the Philippines, and the Celebes. Schistosomiasis may be considered a disease of economic progress, as the development of massive land irrigation projects in desert and tropical areas has resulted in the dispersion of infected humans and snails to previously uninvolved areas.

The diagnosis of schistosomiasis is usually established by the demonstration of characteristic eggs in urine or feces. Concentration techniques may be necessary in light infections. Biopsy of bladder or rectal mucosa may be positive when repeated examination of urine and stool specimens are negative. In general, the three species of *Schistosoma* may be readily differentiated by their characteristic egg morphology (Table 60.11 and Fig. 60.45 and Fig. 60.51). The eggs of *S. mansoni* are oval, possess a sharp lateral spine, and measure 114 to 175 µm × 45 to 70 µm. Those of *S. haematobium* differ primarily in the terminal location of the spine. The eggs of *S. japonicum* are more nearly circular, possess a minute lateral spine, and measure 70 to 100 µm × 55 to 65 µm.

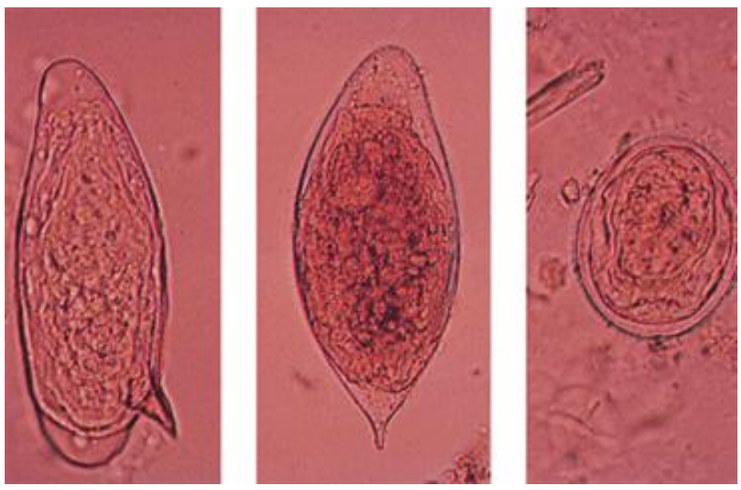

FIGURE 60.51. Eggs of *Schistosoma mansoni* **(left)**, *S. haematobium* **(center)**, and *S. japonicum* **(right)** (high power). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

Examination of the eggs for viability is necessary to confirm the presence of active infection (76). This is accomplished most easily by the detection of movement of flame cell cilia within the egg on microscopic examination. Alternatively, the eggs may be hatched in water. Quantitation of egg output in stool or urine is useful in estimating the severity of infection and the response to therapy.

Serologic testing is available but is largely of epidemiologic interest only. The development of newer tests using stage-specific antigens may allow the distinction of active from inactive disease and thus have greater clinical utility.

Specific therapy with praziquantel or oxamniquine may be indicated for individuals with moderate or severe active infections. Antihelmintic therapy may terminate oviposition but will not affect lesions caused by eggs already deposited in tissues. Schistosomal dermatitis and the Katayama syndrome may be treated with the administration of antihistamines and corticosteroids.

Prevention of schistosomiasis has been difficult (76). Proper sanitation and the use of molluscacides are necessary steps in interrupting the transmission of the parasite. Vaccine development is an area of intense research interest, but a candidate vaccine is not available for human use at this time.

Cestodes

The cestodes or tapeworms, members of the Platyhelminthes, are generally long, flat, segmented, ribbonlike intestinal parasites (75).

The adult worms vary in length; some species are barely visible to the naked eye, whereas others are 20 to 25 feet long. The adult tapeworms are divided into three distinct body parts: the anterior portion or scolex, a generative neck, and a long, segmented body, the strobila. The head or scolex is equipped with various structures for attachment to the intestinal mucosa. These attachment structures vary with species but usually include muscular suckers (*Taenia* species), long, lateral grooves or bothria (*Diphyllobothrium latum*), and a retractable rostellum armed with a crown of chitinous hooks (*T. solium*) (Fig. 60.52). Posterior to the scolex is the neck, which gives rise to the strobila, consisting of individual body segments or proglottids.

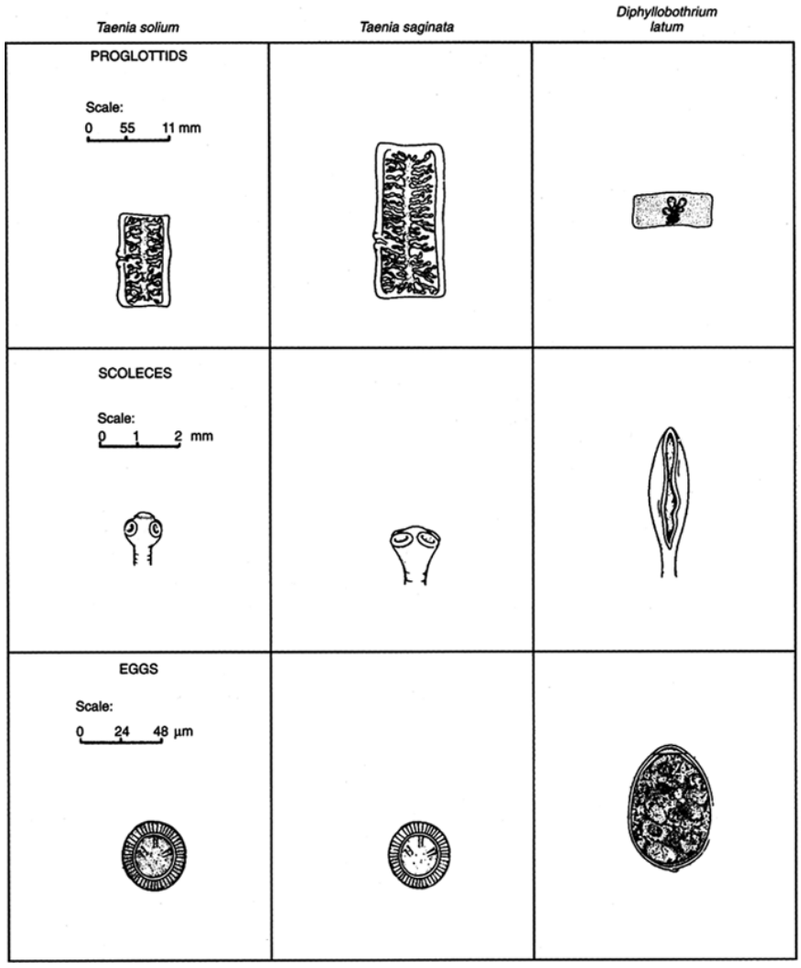

FIGURE 60.52. Diagnostic features of *Taenia solium*, *T. saginata*, and *Diphyllobothrium latum*. (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

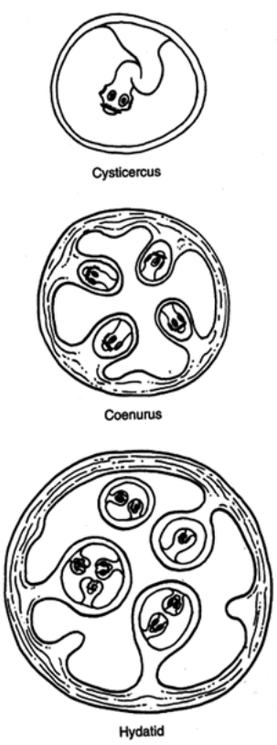

FIGURE 60.53. Tapeworm cysts. (Adapted from Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

All tapeworms are hermaphroditic, and each proglottid contains both male and female reproductive organs. Proglottids develop from immature to mature to egg producing, with the most developed segments located farthest from the neck. Each self-contained proglottid is joined to the rest of the worm by a common cuticle, nerve trunks, and excretory canals. Tapeworms have no digestive system, and nutrients are absorbed from the host intestine through the complex cuticle of the worm. Gravid proglottids release their eggs by rupturing, disintegrating, or passing the eggs through a uterine pore. In some species (*T. solium* and*T. saginata*), eggs are not released from intact proglottids; instead, gravid proglottids separate from the remainder of the worm and are passed intact in the feces. The eggs of most cestodes are nonoperculated and contain a fully developed, six-hooked (hexacanth) embryo. In contrast, the eggs of the fish tapeworm *D. latum* are immature at the time of deposition and possess an operculum, similar to fluke eggs, through which the embryo exits when fully developed (Fig. 60.52).

The life cycles of all cestodes are complex and, with the exception of *Hymenolepis nana*, require passage of the larvae through one or more intermediate hosts. For most cestodes, the eggs are ingested by the specific intermediate host and hatch within its gut. The released larvae then penetrate the intestinal mucosa and migrate to the tissues, where they encyst and develop to the infective stage. The life cycle is completed when infective larvae are ingested by the appropriate definitive host. *D. latum*, whose eggs are immature on release, requires two intermediate hosts to complete its larval development: aquatic invertebrates (copepods) and fish. The larval stages present in the tissues of intermediate hosts vary with the different species of cestode and include cysts with a single immature scolex or proscolex (cysticercus; *Taenia* species), cysts with multiple proscolices (coenurus; *Multiceps* species), and cysts containing multiple daughter cysts, each with multiple proscolices (hydatid cyst; *Echinococcus* species) (Fig. 60.53). In some instances, humans serve as an intermediate host that harbors larval stages. These extraintestinal larval infections are named according to the larval stage found in tissue (cysticercosis, coenurosis, hydatid disease) and are usually more serious than the presence of adult worms in the intestine.

Numerous cestodes infect humans, including *T. saginata*, *T. solium*, *D. latum*, *Echinococcus granulosus*, *E. multilocularis*, *Hymenolepis diminuta*, *H. nana*, *Dipylidium caninum*, and *Multiceps multiceps* (75). Together they infect approximately 65 million individuals, producing embarrassment, discomfort, anemia, and occasionally death. Of the many cestodes causing intestinal and tissue infections in humans, only four representative agents will be discussed: the pork tapeworm and cause of cysticercosis (*T. solium*), the beef tapeworm (*T. saginata*), the fish tapeworm (*D. latum*), and *E. granulosus*, the agent of hydatid disease. Basic details of the common intestinal cestodes of medical importance are provided in Table 60.12.

TABLE 60.12. MORPHOLOGY OF CESTODES

	Diphyllobothrium latum	*Taenia saginata*	*Taenia solium*	*Hymenolepis nana*	*Hymenolepis diminuta*
Method of infection	Ingestion of raw fish	Ingestion of undercooked beef	Ingestion of undercooked pork and ova	Ingestion of cysticercoid in infected arthropod, ingestion of egg, autoinfection	Ingestion of cysticercoid in infected arthropod
Location in host	Adult in small intestine	Adult in small intestine	Adult in small intestine;	Adult in small intestine; larvae in villi of small intestine	Adult in small intestine
Adult worm	4–10 m in length, gravid proglottids 3 × 11 mm, rosette-shaped central uterus, genital pore on mid-ventral surface	4–8 m in length, no rostellum or hooklets, mature proglottids, the ovary has 2 lobes and a vaginal sphincter muscle, gravid proglottids 18–20 mm × 5–7 mm, 15–30 lateral branches on each side of central uterine stem	3–5 m in length, mature proglottids, the ovary has 2 lobes and accessory lobe; vaginal sphincter muscle is absent; gravid proglottids 11 × 5 mm, 7–13 lateral branches on each side of central uterine stem	Small, 2.5–4 cm long, proglottids are wider than they are long	20–60 cm long, proglottids are wider than they are long
Scolex	Small, 3 × 1 mm, spatulate with 2 shallow grooves	Small, 1–2 mm in diameter with 4 suckers	Small, 1 mm in diameter, 4 suckers, rostellum with 2 rows of hooklets	Small, knoblike with 4 suckers, rostellum, and hooklets	Knoblike, 4 suckers, rostellum, no hooklets
Egg morphology	Ovoid, operculated, thick-shelled, 58–75 × 40–50 µm	Spherical, 31–43 µm, thick, radially striated; contains 6-hooked embryo (oncosphere)	Spherical, 31–43 µm thick, radially striated; contains 6-hooked embryo (oncosphere)	Spherical, thin, hyaline shell 30–47 µm in diameter, 6 hooked oncosphere, polar filaments	Spherical, thick-shelled, 70–85 × 60–80 µm, 6-hooked oncosphere, no polar filaments
Clinical manifestations	Intestinal obstruction, diarrhea, abdominal pain, or anemia, possible vitamin B_{12} deficiency	Obstruction, diarrhea, hunger pains, weight loss, appendicitis	Adult worm: hunger pains, indigestion, diarrhea, constipation, eosinophilia; cysticercus: epileptiform seizures, abnormal behavior, transient paresis, intermittent obstructive hydrocephalus, disequilibrium meningoencephalitis	Headache, dizziness, anorexia, abdominal pain, diarrhea	Infection is usually tolerated; very few symptoms
Diagnostic methods	O&P exam	O&P exam, HAI, ELISA	HAI, O&P exam, ELISA	O&P exam	O&P exam
Specimen	Feces	Feces, proglottids, scolex	Feces, proglottids, scolex	Feces	Feces
Common name	Broad fish tapeworm	Beef tapeworm	Pork tapeworm	Dwarf tapeworm	Rat tapeworm

O&P exam, ova and parasite examination; HAI, hemagglutination inhibition; ELISA, enzyme-linked immunosorbent assay.

Taenia solium

T. solium, the pork tapeworm, inhabits the human jejunum, where it may survive for decades and grow to a maximum length of 3 to 5 m. Its small scolex is armed with four sucking disks and a rostellum with a double row of hooklets (Fig. 60.52). Differentiation of *T. solium* from *T. saginata* may be accomplished by examination of the scolex and proglottids (Fig. 60.52). Gravid proglottids of *T. solium* are smaller than those of *T. saginata* and contain only seven to 13 lateral uterine branches versus 15 to 30 for the beef tapeworm. *T. solium* is widely distributed throughout much of the world and is particularly common in Eastern Europe, Asia, Africa, and Latin America. It is seen infrequently in the United States.

As indicated previously, the gravid proglottids of *Taenia* species become detached from the strobila and either rupture, releasing the characteristic eggs within the intestine, or are passed intact in the feces (Fig. 60.54). The eggs are spherical, 30 to 40 µm in diameter, and possess a thick, radially striated shell containing a six-hooked hexacanth embryo (Fig. 60.55). Both pigs and humans may become intermediate hosts when they ingest food contaminated with viable eggs. Autoinfection may occur when eggs are transferred from the perianal area to the mouth on contaminated fingers. When ingested, the eggs hatch in the

stomach of the intermediate host, releasing the hexacanth embryo or oncosphere. The oncosphere penetrates the intestinal wall and migrates in the circulation to the tissues, where it develops into a cysticercus over 3 to 4 months. The cysticerci may develop in muscle, connective tissue, brain, lung, and eyes and remain viable for as long as 5 years. Humans may become the definitive host for this parasite when they ingest inadequately cooked pork containing cysticerci. Digestion of the infected meat releases the cysticercus, which then everts, exposing the scolex, and attaches to the intestinal mucosa, where it develops into an adult worm, thereby completing the cycle.

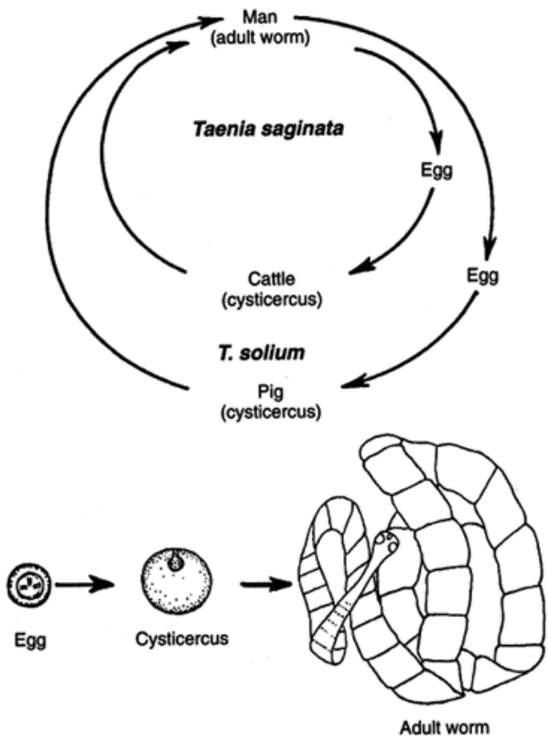

FIGURE 60.54. Life cycles of *Taenia saginata* and *T. solium*. (From Markell EK, Voge M, John DT. *Medical parasitology*, 7th ed. Philadelphia: Saunders, 1992.)

FIGURE 60.55. *Taenia* species, egg (high power). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

The symptoms produced by the presence of the adult *T. solium* in the intestine are minimal. Most patients are asymptomatic and become aware of the infection only when they see proglottids in their feces. Occasionally, individuals report abdominal discomfort, nausea, diarrhea, and weight loss.

An entirely different clinical picture may present when humans are the intermediate host. Cysticercosis may be of little consequence if the larvae lodge in the muscles or subcutaneous tissues; however, serious disease may follow as cysticerci develop in vital areas such as the brain or eyes (88, 89). In the brain, they may produce seizures, meningoencephalitis, hydrocephalus, and cranial nerve damage. In the eye, loss of visual acuity and visual field defects may occur. Tissue reaction to viable larvae may be only moderate, thus minimizing symptoms; however, the death of the larvae stimulates a marked inflammatory reaction with exacerbation of symptoms and resulting fever, muscle pains, and eosinophilia.

The laboratory diagnosis of intestinal infection is made by finding eggs or proglottids in the stool (75). As the eggs of *T. solium* and *T. saginata* are identical (Fig. 60.55), it is necessary to examine a proglottid to identify the species correctly (Fig. 60.52). The diagnosis of cysticercosis is usually established by detection and surgical removal of soft-tissue nodules, the appearance of calcified cysticerci in soft-tissue roentgenograms, and detection of cysts in the eye (87). Central nervous system lesions may be detected by computed tomography, radioisotope scanning, or ultrasonography (88, 89). Serologic studies may be useful, but false positives may occur in individuals with other helminthic infections.

The treatment of choice for intestinal infection is niclosamide, which acts directly on the worm. Praziquantel, paromomycin, and quinacrine are effective alternatives. The drug of choice for cysticercosis is praziquantel (89). Concomitant steroid administration may be useful in minimizing the inflammatory response to the dying larvae. Surgical removal of cerebral and ocular cysts may be necessary. Preventive measures include proper sanitation, adequate cooking of all pork products, and prompt treatment of all human cases of *T. solium* infection to minimize egg transmission.

Taenia saginata

T. saginata, the beef tapeworm, closely resembles *T. solium* and may parasitize the jejunum and small intestine of humans for as long as 25 years, attaining a length of 10 m. *T. saginata* bears a scolex armed with four muscular suckers but no hooklets, and its proglottids contain 15 to 30 uterine branches. *T. saginata* is rare in the United States but is highly prevalent in Africa, the Middle East, eastern Europe, and South America.

The life cycle of *T. saginata* is virtually identical to that described for *T. solium* (Fig. 60.54). A major difference is that humans rarely, if ever, act as intermediate hosts for *T. saginata* (76). As with *T. solium*, humans are infected when they ingest inadequately cooked meat containing cysticerci.

The clinical syndrome associated with *T. saginata* is similar to intestinal infection with *T. solium*. Patients are generally asymptomatic or may complain of vague abdominal pains, chronic epigastric discomfort, and weakness.

As with *T. solium*, the diagnosis is made by detection of eggs and proglottids in feces. Motile proglottids may be observed in freshly passed stool. Differentiation of *T. saginata* from *T. solium* is made by examination of mature proglottids or recovery of the entire worm with a scolex lacking hooklets.

Treatment is identical to that described for the intestinal phase of *T. solium*. A single dose of niclosamide is highly effective in elimination of the adult worm. Prevention depends on proper sanitation and adequate cooking of beef.

Diphyllobothrium latum

D. latum, the fish tapeworm, inhabits the human jejunum and ileum, where it may survive for many years and grow to a maximum

length of 4 to 20 m. Its elongated, fusiform scolex is armed with two lateral sucking grooves or bothria (Fig. 60.52). Unlike the *Taenia* species, the proglottids are uniformly wider than they are long and contain a centrally positioned, rosette-shaped uterus. The large (58 to 75 µm × 40 to 50 µm), ovoid, operculated eggs (Fig. 60.52 and Fig. 60.56) are discharged through the uterine pore of the proglottid. More than 1 million eggs are released per day into the fecal stream. *D. latum* is found worldwide, most prevalently wherever raw, pickled, or undercooked freshwater fish (including salmon) is eaten by humans (75). Human infections are found in central and northern Europe, Scandinavia, Siberia, China, and Japan. In North America, endemic foci have been described in Alaska, Canada, and the Great Lakes region of the United States.

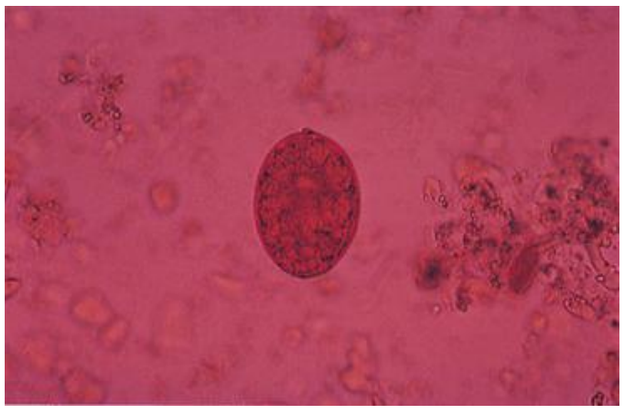

FIGURE 60.56. *Diphyllobothrium latum*, egg (low power). (From Smith JW, et al. *Diagnostic medical parasitology: intestinal helminths*. Chicago: American Society of Clinical Pathologists, 1976.)

The life cycle of *D. latum* differs from that of the *Taenia* species in that it requires two intermediate hosts (Fig. 60.57). The unembryonated, operculate eggs are shed in the feces and, on reaching fresh water, require a period of 2 to 4 weeks to develop a ciliated, free-swimming larval form called a coracidium. The fully developed coracidium leaves the egg via the operculum and is ingested by small freshwater crustaceans (e.g., *Cyclops* and *Diaptomus*), where it develops into a procercoid larval form. The crustacean is then eaten by a fish, and the infectious plerocercoid larvae develop in the musculature of the fish. Humans are infected when they eat raw or undercooked fish containing the plerocercoid larval forms.

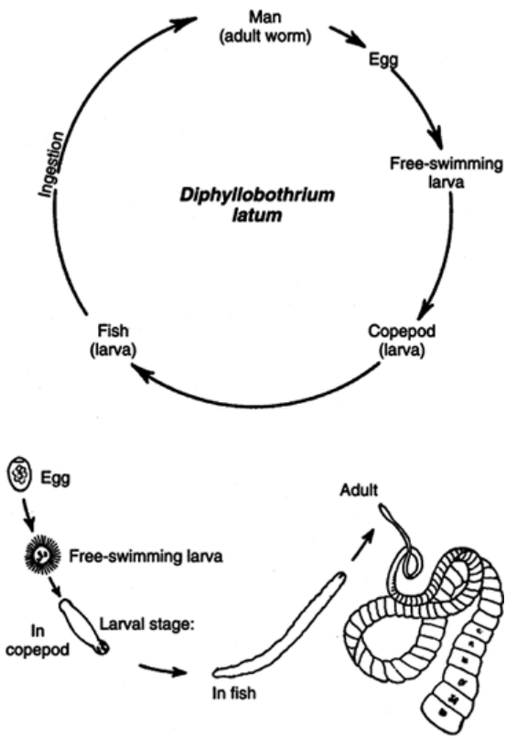

FIGURE 60.57. Life cycle of *Diphyllobothrium latum*. (From Markell EK, Voge M, John DT. *Medical parasitology*, 7th ed. Philadelphia: Saunders, 1992.).

Clinically, as is the case with most tapeworm infections, most *D. latum* infections are asymptomatic. Occasionally individuals complain of epigastric pain, abdominal cramping, nausea, vomiting, and weight loss. As many as 40% of persons infected with *D. latum* may have low serum vitamin B_{12} levels, presumably as a result of the competition between the host and the worm for dietary vitamin B_{12}, but only 0.1% to 2% develop clinical signs of vitamin B_{12} deficiency, including megaloblastic anemia and neurologic manifestations such as numbness, paresthesia, and loss of vibration sense.

The diagnosis of *D. latum* infection is made by detection of the bile-stained operculated egg (Fig. 60.56) or typical proglottids in stool. Concentration techniques are usually not necessary, as the worms produce large numbers of ova.

Treatment is similar to that described for *T. saginata* infections: single-dose therapy with niclosamide is highly effective. Vitamin B_{12} supplementation may be necessary in individuals with evidence of clinical vitamin B_{12} deficiency (e.g., anemia and neurologic symptoms). Thorough cooking of all salmon and freshwater fish and attention to proper sanitation are necessary preventive measures.

Echinococcus granulosus

Echinococcosis or hydatid disease is a tissue infection of humans caused by the larvae of the cestode *E. granulosus*. The adult *E. granulosus* is a small (5 mm) intestinal parasite of canines (e.g., dog, fox, wolf, coyote). The worm consists of a *Taenia*-like scolex with four sucking disks and a double row of hooklets and a strobila containing three proglottids: one immature, one mature, and one gravid. The eggs, which are identical in appearance to those of *Taenia* species (Fig. 60.55), are released from the terminal gravid proglottid and are shed in the feces, where they may be ingested by one of a number of mammalian intermediate hosts, including sheep, goats, deer, moose, and humans (Fig. 60.58). The ingested eggs hatch and the embryos penetrate the intestinal mucosa and are carried by the circulation to lodge in the liver, lungs, brain, heart, bone, and other tissues. Within the tissues, the larvae form hydatid cysts characterized by a laminated

germinative membrane from which daughter cysts or brood capsules arise, each containing multiple inverted proscolices (Fig. 60.53). The cysts expand slowly, accumulating fluid and hydatid sand composed of scoleces, hooks, and calcareous corpuscles from disintegrating brood capsules. Cysts generally reach a diameter of 1 cm over 6 months and ultimately may attain a size of 5 to 20 cm over a period of several years. Spillage of cyst contents may lead to the development of cysts in other sites, as the proscolices have the germinative potential to form new cysts. When hydatid-containing tissues of the intermediate hosts are ingested by a canine, thousands of scolices are released in the intestine to develop into adult worms. Humans and herbivores do not become infected with the adult worm.

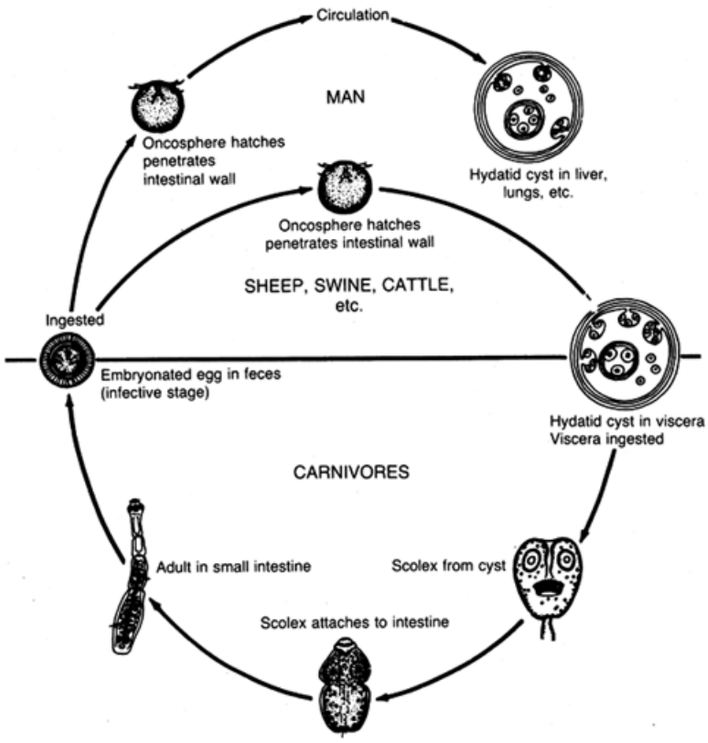

FIGURE 60.58. Life cycle of *Echinococcus granulosus*. (From Strickland GT. *Hunter's tropical medicine*, 7th ed. Philadelphia: Saunders, 1991.)

Human infection with *E. granulosus* most commonly occurs in countries where domestic herbivores such as sheep, cattle, and goats are raised in close contact with dogs (76). The highest incidence of hydatid disease is seen in Australia, New Zealand, South America, South and East Africa, Central Europe, and the Middle East. It also occurs in Alaska, Canada, and the sheep farming regions of the United States (Utah, New Mexico, Arizona, California). Humans become infected after ingestion of contaminated food and water, as well as from hand-to-mouth transmission of eggs as a result of handling dogs infected with the adult worm.

Human infection typically is asymptomatic for as long as 5 to 20 years after acquisition of the infection. The clinical manifestations of hydatid disease are owing to the space-occupying nature of the slowly expanding cyst and thus are directly related to the number, anatomic location, and rate of growth of the cysts. In the majority of cases, the cysts are in the lung or the liver, and symptoms include cough, hemoptysis and chest pain, or abdominal pain and tenderness. Rupture of the cysts occurs in 20% of cases, producing fever, urticaria, and occasionally anaphylactic shock and death owing to the release of antigenic cyst contents. Cyst rupture may also lead to dissemination of infection caused by the release of thousands of proscolices. Cysts in bone may cause pathologic fractures, whereas those in the brain present as tumorlike, space-occupying lesions with seizures, visual disturbances, and hydrocephalus. Over time, the cyst may die and become calcified (87).

Diagnosis of hydatid disease is difficult and depends primarily on clinical, radiographic, and serologic findings. Cysts may be observed on routine roentgenograms or by computed tomographic or ultrasonic scanning procedures (90). Although aspiration of cyst contents and demonstration of hydatid sand (e.g., scolices, hooks) may be diagnostic, it is contraindicated because of the risk of anaphylaxis and dissemination of infection. Serologic testing may be useful but is negative in 10% to 40% of infections.

Surgical excision of hydatid cysts is the therapy of choice for symptomatic patients. Aspiration of cyst contents and instillation of formalin, hypertonic saline, silver nitrate, or cetrimide to kill the proscolices and detoxify the remaining fluid may be indicated. If surgery is contraindicated, medical therapy with high-dose albendazole, mebendazole, or praziquantel may be considered. Preventive measures include attention to personal hygiene

and hand washing and deworming of infected dogs. Dogs should never be allowed to feed on the viscera of slain animals.

Section 10
Immunopathology

Immunopathology - Introduction

David F. Keren

Section Chief

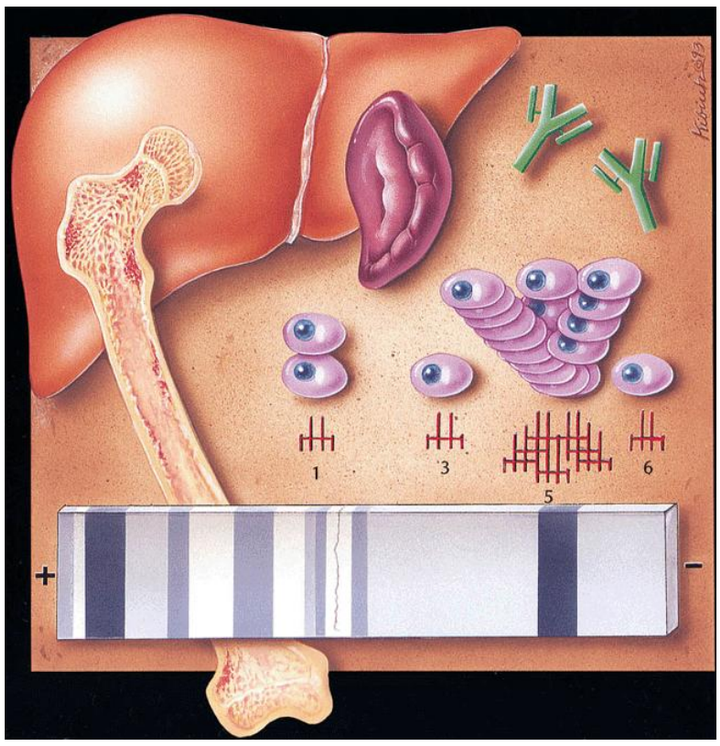

Figure.

The field of diagnostic immunology has become considerably broader in the past decade. The advent of flow cytometry, monoclonal reagents, and chemiluminescent probes, and the development of a clearer understanding of the immunopathology of autoimmune diseases have resulted in a tremendous increase in the number of types of diagnostic tests that are available. This section deals with the exploitation of immunologic techniques for clinical diagnosis.

Each chapter reviews features of diseases relevant to diagnostic immunology and discusses the techniques involved in the pathologic diagnosis. There is necessarily a modest degree of redundancy between some chapters within this section and those within other sections. For instance, some of the serology discussed here may also be relevant in the infectious disease sections. Some of the ligand assays discussed by Dr. England and Dr. Smart are complementary to information on radioimmunology in the chemistry section. Nonetheless, each chapter stands on its own with regard to the utility of the procedures discussed for making clinical diagnoses.

An attempt has been made to coordinate the chapters in this section to cover the field of diagnostic immunology as it relates to the diagnostic world today. Only minimal attention has been paid to the more historic aspects of the field. This is for the sake of readability and relevance to today's diagnostic procedures and is not meant to suggest that earlier techniques were not useful.

In each chapter, authors express their own opinions about particular procedures being discussed. This gives the reader important viewpoints from experts in the field.

61
Basic Principles of Immunodiagnosis

Roger S. Riley

F. Philip Anderson

The immune system is part of the body's defense against environmental agents (e.g., viruses, bacteria, fungi) and against our own cells that turn cancerous or learn to react against us. During the process of evolution, the immune system has acquired an impressive array of capabilities that are essential for its normal effective function. More than one trillion cells of various types constitute the immune system. Many of these cells are capable of differentiating “self” from “nonself,” rapidly destroying or disabling an invading organism, and “remembering” the encounter, so that an infectious organism is prevented from ever causing harm again. During the defense process, immune cells are constant and effective communicators through direct cell-to-cell contact or through the production of a wide variety of chemical intermediaries.

Scientists have applied an increasingly sophisticated array of tools and techniques to the investigation of the immune system. As a result, cells and cell products (antibodies, biological modifiers) with specific reactivity can be produced through laboratory manipulation of the immune response. These developments have greatly increased our understanding of the immune system and offer the promise of a natural, effective therapy for many immune and nonimmune diseases. In addition, immunologic products have been applied to medical diagnosis in a variety of imaginative ways and have become fundamental reagents in the clinical laboratory (1).

The term *immunoassay* refers to a biological test system that utilizes one or more immunological products or reagents. The basis for most immunoassays is the binding of an immunoglobulin molecule (antibody) to an antigen or hapten. However, other immunologic reagents, such as complement, are used in some immunoassays, and cell-to-cell interactions are the basis for others. In an immunoassay, the antigen may be another immunoglobulin molecule, a component of the cell membrane, or any other substance against which a specific antibody can be generated. The great specificity of the antigen-antibody reaction and the development of techniques that allow the large-scale production of antibodies have been the major factors in the clinical popularity of the immunoassay. To be useful in diagnosis, the product of an antigen-antibody interaction (immune complex) must be visualized or quantitatively measured by some means. Direct visualization with the naked eye is possible if the antigen is attached to cells or particles that clump together or agglutinate on interaction with the antibody. Although this simple interaction was the basis for early immunoassays and is still being used today, precise measurement of the antigen-antibody interaction requires that one or the other be labeled or tagged by some means.

BASIC IMMUNOLOGY

Part of "61 - Basic Principles of Immunodiagnosis"

The Immune Response

Animals respond to foreign substances (e.g., viruses or bacteria) by producing protein molecules in the blood called antibodies. Antibodies bind to the foreign substance as a part of the body's efforts to counteract it. Antibodies have the property of being highly specific, i.e., they will bind only to the foreign substance that caused them to be produced. Thus, the general term antigen designates any substance recognized by an animal as foreign and causing that animal to make antibodies.

The biological phenomenon of antibody production has been used in laboratory tests to identify substances found in human tissue. Because antibodies are highly specific for the antigen that caused them to be formed, they can be used to chemically locate that antigen in tissue. This is generally accomplished by the following method:

- A sample of the human substance (e.g., protein, enzyme, hormone) is injected into an animal (e.g., rabbit). Because the substance is of human origin, the animal recognizes it as foreign and makes antibodies against it. The human substance is the antigen causing the animal to produce antibodies. This process is known as immunization.
- A blood sample is then withdrawn from the animal and the anti-human antibodies are isolated and retrieved from the serum. These antibodies are highly specific for the human substance (antigen) that caused them to be formed and will not chemically bind with any other antigen in the tissue.
- In a laboratory, the antibodies can be applied to patient cell or tissue preparations. The antibody molecules will react with the type of human antigen that caused them to be made if it is present in the tissue. If the antigen is not present, no specific reaction will occur.

A *de novo* immune response begins with phagocytosis of the foreign invader, digestion and processing of the material, and presentation of some of the processed antigen on the cell surface (2,3,4 and 5). In conjunction with the self-HLA markers on the phagocyte and chemical mediators released from the phagocyte (monokines), the processed antigen is recognized by one kind of T lymphocyte (T-helper cell). These activated T-helper lymphocytes secrete a number of soluble substances (lymphokines, immune system hormones) that stimulate other immune cells, including suppressor T lymphocytes, which have a negative regulatory effect on the immune system. Another type of lymphocyte (B lymphocyte) produces soluble proteins termed antibodies (immunoglobulins). Each B cell is programmed to produce an antibody molecule that is highly specific for a single antigenic substance. When activated by lymphokines or by encounter with its antigen, a B cell rapidly reproduces. Each of these identical B cells differentiates into an antibody-producing factory (plasma cell) that can release thousands of antibody molecules per second (Fig. 61.1).

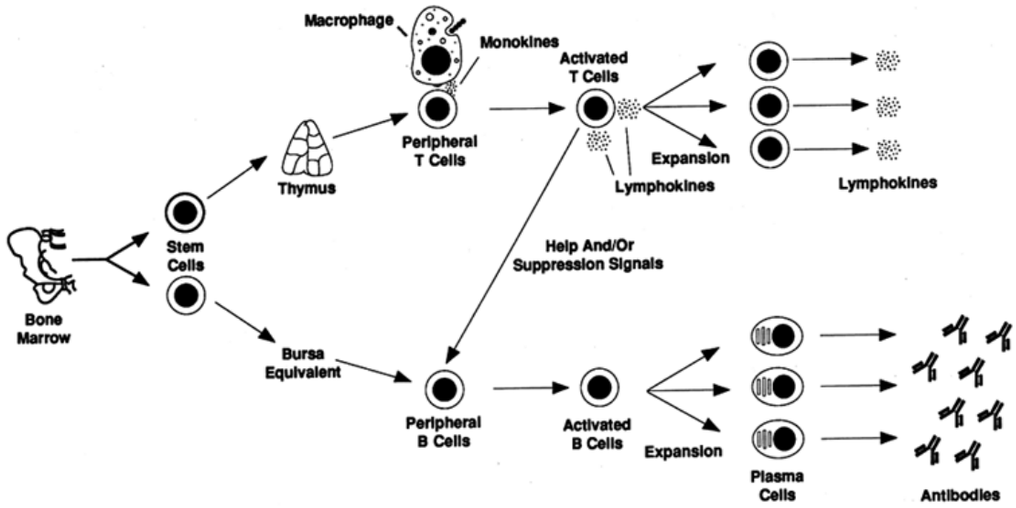

FIGURE 61.1. A schematic representation of the immune response.

Most T and B lymphocytes involved in an immune response die within several days. However, after each encounter, clones of memory cells persist in the body for life. If the offending antigen is ever encountered again, these cells are primed to quickly go into action without the delay faced during the first encounter.

A group of peptides termed cytokines is extremely important for immunoregulation and intracellular communication within the immune and inflammatory systems. These substances include the interleukins, interferons, tumor necrosis factors, and hemopoietic growth factors [colony-stimulating factors (CSF)] (6,7 and 8). Most of these substances were initially identified based on a single biological effect, but many have been subsequently found to have diverse local and even systemic effects. At the cellular level, cytokines interact through high-affinity surface receptors. The intracellular mechanism of action of many cytokines is currently unknown, although several cytokine receptors initiate the activation of adenylate cyclase, protein kinase C, tyrosine kinase, or other enzymes. The availability of immunoassays for the accurate measurement of cytokines in normal and diseased individuals and the discovery of recombinant DNA techniques to produce these substances in virtually unlimited quantity have led to a great interest in their potential diagnostic and therapeutic applications.

Polyclonal Antibodies

The natural immune response to an antigen is the generation of antibodies. Multiple clones of plasma cells respond to an antigenic challenge, and each produces antibodies that differ in antibody class, light-chain isotypes, idiotypic specificity, and combining ability (avidity). The number of antibody specificities generated depends on the complexity of the antigen. Although synthetic materials with repetitive epitopes may produce antibodies of a single specificity, hundreds to thousands of different antibodies are usually released in response to a large protein or cellular structure with multiple epitopes. Commercially, these polyclonal antibodies are usually obtained from animal sources. However, some antibodies, such as those with specificity for the HLA antigens, are commonly obtained from the serum of multiparous females or patients who have received multiple blood transfusions.

The commercial production of polyclonal antibodies from animals comprises a large industry that is closely protected by trade secrets. As a result, few details have been published in the literature (9,10). One exception is a review by Ritchie (11), who reported his experience gained from more than 10,000 animal bleedings.

The major considerations in the production of an antigen (immunogen) include:

- The size and chemical composition of the immunogen,
- The animal species used as the host,
- The age and general health of the animal host,
- The route of immunization,
- The dose of the immunogen,
- The immunization schedule,
- The site and method of protein conjugation (for haptens),
- The nature of the conjugate protein (for haptens).

Many animal species have been utilized for the preparation of polyclonal antibodies. The choice of animal depends on many factors, including the size of the animal, the cost and ease of maintenance, the phylogenetic similarity of the animal to the species from which the immunogen is recovered, and the absence of native materials antigenically similar to the immunogen (11). Goats are the best host for the production of large volumes of polyclonal antibodies because of the hardiness of the goat and the ease and relatively low cost of maintaining goat herds for long periods of time (11). Rabbits are an excellent source of quality antibodies, but their smaller size and higher maintenance cost are disadvantages compared with goats. Guinea pigs have been used for the production of antiinsulin antibodies because their native insulin is significantly different from human insulin, whereas fowl, fish, and reptiles produce antibodies that do not fix complement (11). The immunogen dosage and schedule of administration are important considerations in determining the quality and potency of antibody produced (11). The immunogen is commonly injected at 1- to 2-week intervals for periods of several weeks, followed by a challenge dose after a month's rest; however, each investigator uses a different schedule. If a good response is obtained, antibody titers may continue to rise with additional immunizing doses for 6 months or more. The animal is bled on a regular schedule until the antibody titer begins to drop; at that time, reimmunization is attempted. Some immunogens are given with an adjuvant (e.g., Freund's adjuvant, mineral oil) that enhances antibody production by producing an inflammatory response at the site of injection. The dose of the immunogen is the most difficult factor to control because a subliminal dose may cause tolerance, whereas an excessive dose can produce immune paralysis (11). Administration of the immunogen over a wide range (5 log or greater) may be required to produce immunization.

After immunization has taken place, the antibody concentration, reactivity, and other properties are measured (12). Undiluted serum can generally be stored at -20°C to -70°C for several years without loss of potency. However, in many cases, the immunoglobulin fraction of the serum is isolated and further purified. Purified antibody preparations can also be lyophilized and stored for years at room temperature. Immunoglobulin of the IgG class is usually preferred over IgM for immunoassays because it is more stable, easier to purify, and produced in the highest concentration (11). Antibody fragments such as Fab and $F(ab')_2$ are also gaining favor (13).

The major disadvantage of polyclonal antibodies for diagnostic testing is lot-to-lot variation in specificity and avidity, so that quality control becomes difficult. In addition, the antigen must exist in a highly purified state to generate a polyclonal antibody preparation that does not cross-react with other substances, and many antigens are poorly immunogenic or nonimmunogenic as well. Nevertheless, until recently, polyclonal antibody preparations were the only ones available, and they have been applied very successfully for diagnostic purposes, especially in radioimmunoassay (RIA) techniques and immunoperoxidase staining.

Monoclonal Antibodies

A clone of plasma cells derived from a single B lymphocyte produces immunoglobulin molecules that are specific for a certain antigen (monoclonal antibodies). Plasma cells represent the end stage of the B-cell maturation process and cannot be stimulated to divide further. Therefore, until the mid-1970s, the only source of monoclonal antibodies in large quantity was body fluids and effusions from patients with malignant plasma cell tumors. Monoclonal antibodies from this natural source were essential for the elucidation of antibody structure and function but were of no value for other research or clinical applications. However, in 1975 Kohler and Milstein (14) devised a practical method of immune manipulation that allowed the production of virtually unlimited quantities of monoclonal antibodies specific for any immunogenic substance. This discovery was one of the most important in the history of science because it has led to innumerable discoveries in the immunologic sciences, to numerous improvements in medical diagnosis, and to a large industry devoted to the commercial production of monoclonal antibodies.

Production of Monoclonal Antibodies

Kohler and Milstein (14) devised a technique to fuse nonimmortalized antibody-producing plasma cells from an immunized animal with immortalized myeloma tumor cells that produced either no antibody or antibody with an irrelevant specificity. The resulting hybridoma rapidly reproduced in culture while retaining the ability to synthesize immunoglobulin with the specificity of the original plasma cell. The hybridoma cells could be grown in culture or in the peritoneal cavity of an animal to obtain large quantities of monoclonal antibody.

Hybridoma production begins with the immunization of a mouse with a specific antigen (15). Plasma cells from the spleen of the mouse are then isolated and brought into contact with cells from a nonantibody-producing mutant murine malignant myeloma cell line that is deficient in the enzyme hypoxanthine guanine phosphoribosyl transferase (HPRT). Cellular interaction takes place in the presence of polyethylene glycol or another fusing (surface active) agent such as the Sendai virus. Under these conditions, fusion of the cell membranes of some of the cells occurs, and later the nuclear membranes fuse together as well. Many hybrid cells lose chromosomes in the process of fusion, but some retain most of the genetic information from both parents. The next step is to separate proliferating cells that produce antibody of the desired specificity from nonantibody-producing cells, from hybridomas producing specificity of undesired specificity, and from parental myeloma and plasma cells. A special culture medium containing hypoxanthine, aminopterin,

and thymidine (HAT medium) is used to separate hybridomas from the cell mixture. The plasma cells cannot divide, and the HAT medium prevents growth of the mutant myeloma cells because they are deficient in HPRT and cannot use the hypoxanthine and thymidine in the culture media. Therefore, only the hybridoma cells survive and grow in the culture. Each hybrid, antibody-producing cell is isolated and cultured, and the antibody produced is studied for its specificity. If a desired antibody is found, large quantities can be produced by growth of the hybrid cells in conventional tissue culture systems, in the peritoneal cavities of immunodeficient mice or nude rats, or in hollow fiber culture systems. The hybridoma cells continuously produce monoclonal antibody as long as they retain the necessary genes (Fig. 61.2). The recent application of genetic engineering techniques to monoclonal antibody technology has resulted in the production of recombinant antibodies, which are partly of human origin, for therapeutic purposes (16,17,18,19,20,21 and 22).

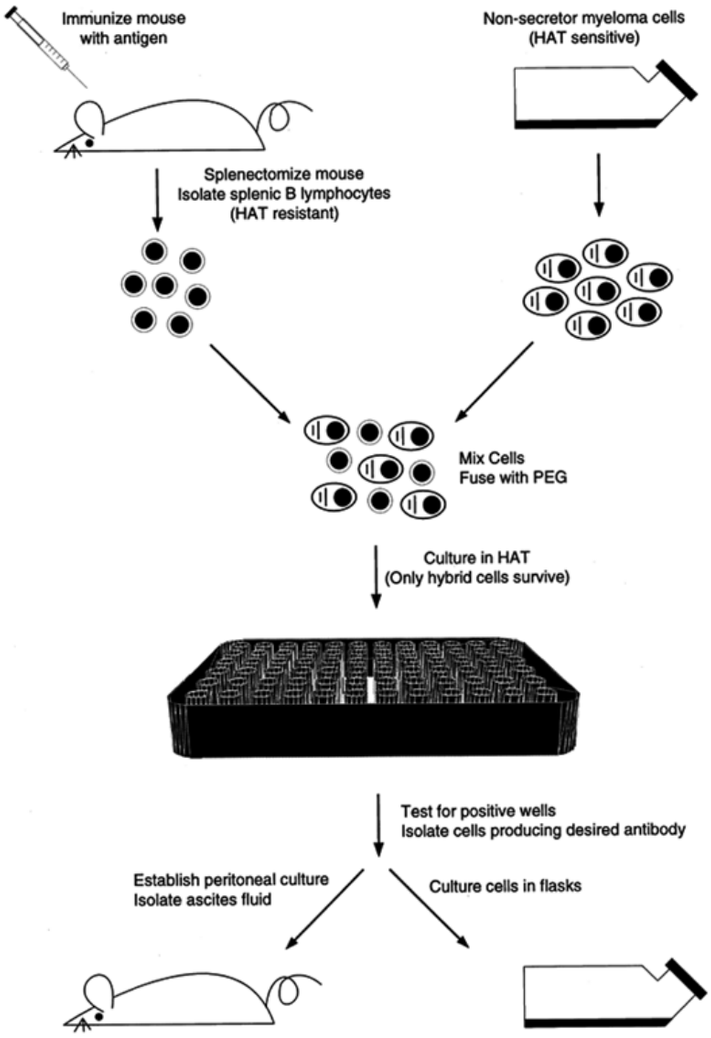

FIGURE 61.2. Production of a monoclonal antibody.

Clinical Applications of Monoclonal Antibodies

Monoclonal antibodies are highly specific for a desired antigen and can be produced in essentially unlimited quantities. In addition, monoclonal antibodies can be generated from relatively impure antigen preparation and show consistent sensitivity and specificity from lot to lot. For *in vivo* applications, even though relatively small amounts of monoclonal antibodies are utilized, they often lead to the development of heterophile (interspecies specific) antibodies in the host (23). This can lead to interferences

that are discussed later. However, the production of a monoclonal antibody with the desired specificity does not always lead to a useful product because the avidity (combining ability) of the antibody may be low, the antigen may be sparse on some cells and difficult to detect, or the monoclonal antibody may even be too specific, such as failing to detect variously glycosylated forms of human luteinizing hormone, even though they all have the same biological activity (24). For these and other reasons, polyclonal antibodies are still preferred over monoclonal antibodies for some applications.

Monoclonal antibodies have become essential reagents for many *in vivo* and *in vitro* diagnostic and therapeutic purposes (25,26,27 and 28). These applications can be classified as followed:

- *In vitro* diagnosis

  Monoclonal antibodies specific for leukocyte antigens

  Monoclonal antibodies specific for nonleukocyte antigens

- *In vivo* imaging

- Immunotherapy

  Organ transplantation

  Malignant neoplasms

Monoclonal Antibodies Specific for Leukocyte Antigens

Monoclonal antibodies specific for lymphoid antigens have been the most widely utilized of all monoclonal antibodies. Because the differentiation of T and B lymphocytes by rosetting and other techniques was tedious, time-consuming, and inaccurate, the development of a series of monoclonal antibodies specific for T-lymphocyte antigens in the late 1970s was a revolutionary event. These monoclonal antibodies (the OKT series) were rapidly applied in the diagnostic immunology laboratory for studying the phenotype of lymphoproliferative disorders and for the care of patients infected with the human immunodeficiency virus (HIV). Unfortunately, the rapid availability of numerous monoclonal antibodies, often with similar or identical reactivity, leads to much confusion among immunologists. Fortunately, the World Health Organization sponsored a series of workshops to compare and classify the reactivity of antileukocyte antibodies supplied from laboratories around the world. It was decided to group antileukocyte antibodies with similar reactivity into clusters. In addition, a cluster designation (CD) number was assigned to each of these groups.

Cellular identification and quantitation with a monoclonal antibody require that the antibody be labeled or tagged by some means so that the antibody-cell complex can be visualized. Fluorescent dyes such as fluorescein isothiocyanate (FITC) have been utilized most extensively for this purpose, and the labeled cells can be detected by flow cytometry or fluorescence microscopy. For the identification of cells in tissue sections, immunoperoxidase staining using horseradish peroxidase or another enzyme to produce a colored reaction product is used most.

The major diagnostic applications of the antileukocyte monoclonal antibodies include the diagnosis and monitoring of patients with congenital or acquired immunodeficiency disease (including HIV infection), the classification and monitoring of tumors of the hemopoietic system, and monitoring patients undergoing *in vivo* therapy with monoclonal antibodies (see below). In addition, antileukocyte monoclonal antibodies have been used as reagents for automated hematology counters and have great potential to assist in the diagnosis and monitoring of allograft rejection, graft-versus-host disease, autoimmune disease, and various infectious diseases. Therapeutically, monoclonal antibodies specific for leukocyte cell surface antigens are under evaluation for the treatment of hematologic malignancies, autoimmune disease, graft rejection, sickle cell disease, and even myocardial infarction (29,30,31,32,33,34,35,36,37,38 and 39).

Monoclonal Antibodies Specific for Nonleukocyte Antigens

The availability of monoclonal antibodies specific for a multitude of nonleukocyte antigens has changed both anatomic and clinical pathology. First, hybridoma technology has provided a means to detect substances that previously could not be evaluated. With the technique of immunoperoxidase staining and an armamentarium of monoclonal antibodies, the surgical pathologist can differentiate between lesions that were impossible to diagnose precisely only a decade ago. In addition, small numbers of human cancer cells can often be detected in body fluids and effusions with the use of monoclonal antibodies. Examples of some of the nonleukocyte monoclonal antibodies used in surgical pathology include those directed against epithelial cell antigens (epithelial membrane antigen), intermediate filaments (keratins, desmin, vimentin, neurofilament, glial fibrillary acidic protein), hormones (serotonin, synaptophysin), infectious agents (cytomegalovirus), and tumor-specific antigens (prostatic-specific antigen). The *in vivo* potential of some of these monoclonal antibody antibodies for cancer diagnosis and therapy is under evaluation (26,40,41,42 and 43).

In the clinical pathology laboratory, monoclonal antibodies have also provided a means to quantitate accurately many soluble biological products such as antibodies, hormones, enzymes, and drugs. In addition, monoclonal antibodies have improved the specificity of assays that were previously performed with polyclonal antibodies or colorimetric methods (27). Therefore, fewer false-positives occur due to inflammatory bowel disease or liver disease.

GENERAL PRINCIPLES OF IMMUNODIAGNOSIS

Part of "61 - Basic Principles of Immunodiagnosis"

Immunoglobulin Structure

Antibodies are protein molecules with a specific structure and function. Each molecule consists of two types of chains (heavy and light). The primary amino acid sequence of each chain is specified by the genetic code. Sequence analysis of the heavy and light chains from many immunoglobulin molecules revealed regions with similar (homologous) composition (constant domains), and other regions with little homology (variable domains). In addition, selective areas within the variable regions showed extreme variability (hypervariable regions) (44) (Fig. 61.3). Five immunoglobulin classes (IgA, IgG, IgM, IgE, and IgD) have been defined based on the sequence identities in the constant domains.

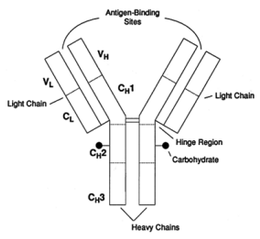

FIGURE 61.3. Basic structure of the immunoglobulin molecule.

The spatial conformation of the heavy and light chains of the immunoglobulin molecule is determined by hydrogen bonding between portions of the amino acid chains (secondary structure). Hydrogen and hydrophobic bonds between the polypeptide chains results in a complex globular configuration of the

molecule (tertiary structure), whereas associations between the heavy and light chains define the quaternary structure.

The specific biological function of each immunoglobulin class is determined by the tertiary structure of the constant domains (Fc region), whereas the antigen-combining regions (Fab regions) of the molecule are formed by spatial associations between the variable regions of the heavy and light chains. In each antigen-combining site, the hypervariable regions of one heavy chain and one light chain are brought in close proximity by tertiary folding to define an area complementary to the structure of an antigen. The number of antigen-combining sites determines the valence of the immunoglobulin molecule. IgG, IgD, and IgE exist as monomers, with a valence of 2, whereas the IgM molecule is a pentamer, with a valence of 10. Both monomeric and dimeric forms of IgA have been defined, with respective valences of 2 and 4. Binding sites for complement, the phagocyte and bacterial Fc receptor, staphylococcal protein A, and rheumatoid factor are present in the Fc receptor of the molecule (45).

Antigen-Antibody Interactions

Antigen-antibody interactions can be classified as primary, secondary, and tertiary. Primary reactions involve antigen binding and the formation of the antigen-antibody (immune) complex, secondary reactions involve interactions between antigen-antibody complexes (e.g., agglutination, precipitation, complement fixation), and tertiary reactions arise as *in vivo* consequence of the interaction of immune complexes with immune cells and other immune products (e.g., opsonization, chemotaxis).

The antigen-binding region is a shallow cleft (approximately 30Å× 14Å × 6Å) at the distal end of the Fab region. The binding of an antigen to an antibody is an event determined by the complementary geometric fit of the antigen in the binding groove, and by other factors, such as the temperature, pH, and ionic strength. The antigen-binding site accommodates approximately four to five peptides of a protein antigen or three to five residues of other types of antigens. Binding involves noncovalent forces, including hydrogen bonds, as well as electrostatic, hydrophobic, and Van der Waals forces. In chemical terms, the interaction of an antigen and antibody is a reversible reaction governed by the law of mass action, such that:

$$\text{Free Ag} + \text{Free Ab} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{Ag} \cdot \text{Ab Complex}$$

where k_1 and k_2 are the respective rates for the formation and dissociation of the antigen-antibody complex. At equilibrium, the formation of a stable immune complex determined by the ratio between the rate constants:

$$K = \frac{k_1}{k_2} = \frac{(\text{Ag} \cdot \text{Ab})}{(\text{Ag})(\text{Ab})}$$

where K is the equilibrium constant (affinity constant) of the reaction. The association constant of an antigen and antibody is also influenced by other factors, including the valence of the antibody and the valence and epitopic density of the antigen. The term avidity is used in reference to the overall stability of an antigen-antibody complex. Although the kinetics of the antigen-antibody reaction can be precisely defined for reactions involving monoclonal antibodies, polyclonal antibody preparations are more difficult to characterize because they consist of heterogeneous mixtures of antibodies of different class, valence, specificity, and affinity. In this circumstance, the average affinity (K_0) is defined by the reciprocal of the free antigen concentration when 50% of the binding sites are occupied:

$$K_0 = \frac{1}{(\text{Ag Free})}$$

Cross-reactivity occurs when antibodies react with heterologous antigens that are similar in structure but not identical to the original (homologous) antigen. Cross-reactivity is partly owing to the heterogeneous nature of the humoral immune response against an immunogenic substance and by the presence of multiple antigenic determinants on most complex natural antigens. In addition, an antibody will bind substances that are structurally similar to the homologous antigen, although usually with less affinity. The phenomenon of cross-reactivity is an important practical consideration in the design and clinical utilization of immunoassays because the sensitivity of the assay can be reduced, false interpretations can be made, and inappropriate therapy initiated.

Several different consequences can result from the interaction of antigen-antibody complexes with each other and with other immune substances such as complement. These secondary immune reactions are influenced by the nature, valence, and concentration of the antigen and by the valence, concentration, avidity, and immunoglobulin class of the antibody. Generally, multivalent antigens and antibodies are required for the induction of a secondary immune reaction. In the past, detection of the secondary immune reaction was the only means available for the detection and analysis of immune components. As a result, antisera were often classified by their ability to cause precipitation (precipitins), the hemolysis of red blood cells (RBCs) (hemolysins), the agglutination or precipitation of particulate antigens (agglutinins, precipitins), and other reactions. In addition,

the suffix *-ogen* was attached to an antigen that elicited a secondary immune response (e.g., agglutinogen, agglutinogen, precipitogen). The *in vivo* or tertiary consequences of the immune reaction are complex and generally involve the interaction of antigen-antibody complexes with cells and other immune products.

Clinical Utilization of the Antigen-Antibody Interaction

The humoral and cellular products of the immune system have achieved widespread utilization as reagents for medical diagnosis. In this regard, the unique specificity of the antibody has proven invaluable for the detection and quantitation of immune-related substances (other antibodies, immune products, and cells) as well as a wide variety of substances unrelated to the immune system (e.g., hormones, drugs, tumor antigens, RBC antigens). Therefore, antibodies and other immune products are standard reagents not only in the clinical immunology laboratory but also in surgical pathology, immunohematology, hematology, microbiology, clinical chemistry, and toxicology.

Classification of Immunoassays

Immunoassays are studies of the antigen-antibody reaction performed to detect the presence of an antigen, antibody, or immune complex (qualitative immunoassay) or to measure the concentration of one of the components of an antigen-antibody or hapten-antibody reaction (quantitative immunoassay).

Practical Considerations in Immunodiagnosis

The diagnostic relevancy of an immunoassay depends on the choice of the proper assay, adequate specimen collection and transportation, prompt and accurate laboratory analysis, and rapid reporting of the results of the assay in a format that is relevant to the clinician. For substances that are normally present in relatively large concentrations in the body (e.g., many serum proteins, some antibodies) or that undergo large changes in concentration in response to a disease process, relatively insensitive methods such as immunonephelometry or immunoturbidimetry may suffice for diagnosis. However, for the detection of small but diagnostically relevant changes in the concentration of an enzyme or to quantitate hormones, tumor markers, therapeutic drug levels, immunoregulatory substances, and other substances that are present in minute quantities, the most sensitive immunoassays available may be required.

In practice, an immunoassay is performed in a system of defined volume under controlled reaction conditions and with precisely measured volumes of test specimen and reagents. Under these conditions, the signal strength of the measured parameter is either directly (noncompetitive assay) or inversely (competitive assay) proportional to the concentration of the measured analyte. Dilutions of a purified preparation of the test substance are used to prepare a standard curve, and the concentration of the variable in an unknown specimen is determined from the standard curve. The results of these assays may be reported as quantitative, semiquantitative, or dichotomous (binary, positive/negative). In many immunoassay systems, especially for the presence of serum antibodies, serial dilutions of the specimen are tested, and the end result is taken as the highest specimen dilution that produces arbitrary defined signal strength (titer). In these circumstances, it is common to first assay a single fixed dilution of the specimen. If the signal strength of the screening assay is below a predefined limit, the assay is reported as negative and no additional testing is performed. However, if the signal strength of the screening assay is above the predefined limit (positive), additional dilutions are tested until the minimal signal strength is reached. The serum titer required to produce this result is reported as the end point.

Ultimately, immunoassay results are often used to determine whether an individual patient is diseased or nondiseased. Unfortunately, in any large population, there are diseased individuals with normal assay results (false-negative results), and nondiseased people with abnormal values (false-positive results). Causes of false-positive and false-negative immunoassays include cross-reactivity of the test reagents with an unrelated disease product, the presence of substances that interfere with the formation of the antigen-antibody complex, errors in test performance, and other factors. Under these circumstances, the correct clinical interpretation of the results of an immunoassay requires up-to-date information about the overall performance of the immunoassay procedure under consideration, such as that required by Clinical Laboratory Improvement Amendments 1988 (accuracy, precision, analytical sensitivity, analytical specificity, reportable range, reference interval, linear range) as well as knowledge of disease pathogenesis and the immune response to the disease process.

NONCELLULAR IMMUNOASSAYS

Part of "61 - Basic Principles of Immunodiagnosis"

Agglutination

Agglutination is a secondary immune phenomenon that occurs when insoluble or particulate antigens (cells or other particles) are cross-linked by an immune reaction (Fig. 61.4).

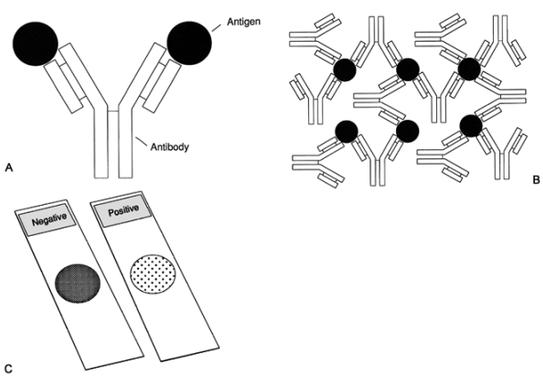

FIGURE 61.4. The agglutination reaction. Schematic illustration of the interaction of an antibody with an insoluble antigen, resulting in agglutination. **A:** The formation of antigen-antibody complexes. **B:** Cross-linking of the antigen-antibody complexes to form a lattice. **C:** Schematic illustration of the visual appearances of positive and negative agglutination reactions. The appearance of the reaction is greatly influenced by whether the assay is performed on a flat surface or in a vessel, such as a test tube or microtiter plate. The physical characteristics of the vessel (round bottom or V bottom) are also important.

Agglutination occurs because antibodies have two or more antigen recognition sites (bi- or multivalency). If multiple antigenic recognition sites are present on a particle, lattices can be formed that grow in size and eventually become a mass that is macroscopically visible. The major factors affecting the agglutination reaction include the class, affinity and avidity of the antibody, the proximity and number of binding sites on the particle, the relative concentrations of antibody and particles, electrostatic interactions (zeta potential), and the viscosity of the medium. Antibodies of the IgM class, with 10 antigen combining sites, are usually the best agglutinins and are more efficient than IgG in agglutination.

Agglutination assays are most often utilized for the detection of antibodies in serum or other body fluids but can also be used to detect soluble antigens. Agglutination assays are classified as direct or indirect, depending on whether the analyte is present in its native state or linked to a particle (carrier) to allow detection of the antigen-antibody reaction. Carriers vary in size from approximately 0.05 μ to 7 μ and may be RBCs, latex particles, liposomes, microcapsules, or other particles (46).

Because particles in suspension often possess negative charges and repel each other, it may be necessary to overcome the zeta potential by the addition of protein or inorganic salts to permit particle cross-linking. Antibody excess may prevent agglutination by coating all the binding sites, whereas inadequate antibody may not provide sufficient cross-linking for agglutination. In practice, this "prozone" phenomenon may require adjustment of particle or antibody concentration or performing an assay at a number of different concentrations. Interference with agglutination by any of these factors after a primary immune reaction is termed incomplete agglutination.

Direct Agglutination

Direct agglutination occurs when a suspension of particles is mixed with a specific antibody solution. If specific antibody with two or more antigen recognition sites is present, the particles may rapidly link together to form visible clumps (46) (Fig. 61.5). The classic example of the application of direct agglutination reaction is the Widal test for the diagnosis of typhoid fever. In this test, specific anti-*Salmonella* antibodies are detected by adding a constant amount of a *S. typhi* cell suspension to serum that has been serially diluted. After appropriate incubation, the tubes are examined for visible agglutination. The highest dilution of serum showing agglutination is the titer of the antibody.

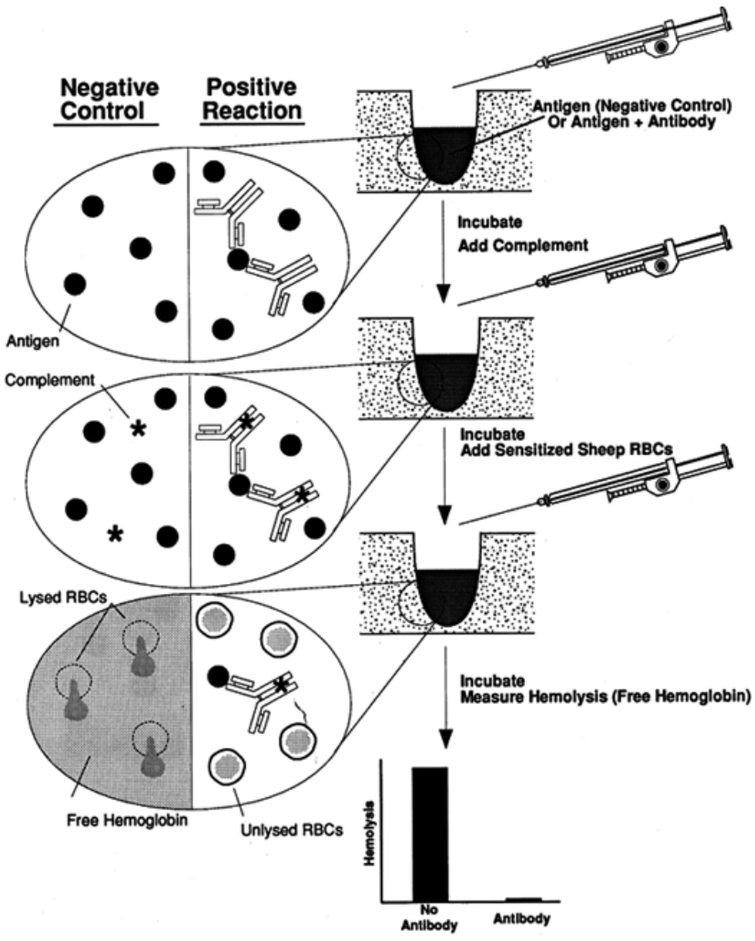

FIGURE 61.5. Principle of the complement-fixation assay. In this assay, antigen and antibody are permitted to interact in solution, and complement is then added. In the presence of an antigen-antibody complex, complement binds to the Fc portion of the antibody molecule. If there is no antigen-antibody complex, complement exists free and unbound in the reaction solution. Sensitized sheep red blood cells are added as an indicator for the presence of unbound complement. The sheep red blood cells are lysed only if there is free complement and an absence of antigen-antibody-complement complexes.

The agglutination of RBCs by antibodies directed against natural components of the cell surface is a type of direct agglutination termed hemagglutination. In immunohematology, direct hemagglutination is the principal method for the detection of antibodies specific for erythrocytic antigens.

Interspecies hemagglutinins (heterophile antibodies) can lead to false-positive results in agglutination tests that utilize nonhuman erythrocytes. Heterophile antibodies can be produced in the sera of some normal individuals as well as patients with serum sickness, autoimmune diseases, and some infectious diseases. However, in infectious mononucleosis the presence of sheep RBC (SRBC) agglutinins in high titer is highly characteristic of the disease.

Indirect Agglutination

Indirect agglutination techniques utilize particles as passive carriers of an antigen (direct passive agglutination) or antibody (reverse passive agglutination) (46). Although coated RBCs (passive hemagglutination) were initially utilized in the clinical applications of the indirect agglutination principle (47), inert particles (charcoal, bentonite clay, inorganic colloidal particles) have proven more versatile for many applications (Fig. 61.6). More recently, the use of coated latex microspheres, gelatin particles, colloidal gold, dye particles, and other substances has permitted the development of simple, cost-efficient assays for a wide range of clinically important substances. The sensitivity of these assays does not approach that of enzyme immunoassay (EIA), RIA, and other techniques but is adequate for many purposes. Particle inhibition

tests have also been described in which the presence of an antigen in the serum prevents the attachment of an antibody to an antigen on the surface of a particle. The term particle immunoassay has been applied to agglutination tests in which particles are used as a label for an antigen or antibody (48).

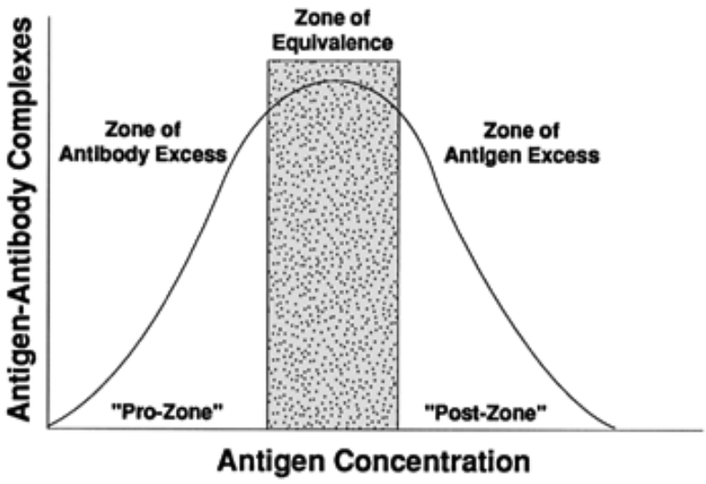

FIGURE 61.6. The precipitation curve and a schematic depiction of the phenomenon of immunoprecipitation.

The coating or sensitization of a particle for use in an immunoassay is accomplished by three techniques. Untreated erythrocytes spontaneously adsorb many proteins to their surface (thyroglobulin and other hormones, purified protein derivative, serum proteins, bacterial products). Other substances are adsorbed after treatment of the erythrocyte with tannic acid (“tanned” RBCs) or enzymes (49). Covalent attachment has been used for substances that cannot be adsorbed by these techniques. Sensitized erythrocytes are usually fixed with formaldehyde, glutaraldehyde, or another compound to increase the shelf life. The use of latex particles for immunoassay was first reported by Singer and Plotz (50) in 1956. Latex particles are usually coated by passive means, with the quantity of the adsorbed protein adjusted to provide agglutination of the analyte in its biological range. In addition, the use of latex particles avoids much of the variability encountered with RBCs. Even so, the prozone phenomenon can still be significant, and careful adherence to the manufacturer's instructions is necessary during the performance of clinical assays utilizing coated microspheres.

Examples of substances routinely detected by passive agglutination include rheumatoid factor, antinuclear antibodies, C-reactive protein, human chorionic gonadotrophin (hCG), parasitic, fungal, and bacterial antigens, and antibodies specific for

some infectious agents. Special variations of the passive agglutination technique include microhemagglutination, the Rose-Waaler test, the VDRL and rapid plasma reagin (RPR) test, and the Paul-Bunnell test.

Microhemagglutination techniques are used in a popular confirmatory test for syphilis [microhemagglutination assay—*Treponema pallidum* (MHA-TP)], and in the detection of antithyroid antibodies specific for microsomal and thyroglobulin antigens. These assays utilize small quantities of tanned, coated RBCs that are reacted with the test serum in a special plastic microtiter tray. The reaction is read with a magnifying mirror or microscope with a low-power objective. Agglutination results in the formation of a diffuse matrix coating the bottom of the tube, whereas nonagglutinated cells settle to form a compact button at the bottom of the tube. The Rose-Waaler test is an assay for rheumatoid factor that utilizes SRBCs sensitized with subagglutinating amounts of rabbit anti-sheep erythrocyte IgG. Agglutination results when these cells are mixed with serum containing anti-IgG (rheumatoid factor). The VDRL and RPR are tests for antisyphilitic antibodies that utilize the natural cross-reactivity of these antibodies with a lipid (cardiolipin) found in high concentrations in neural tissue and cardiac muscle. In the VDRL, particles of purified cardiolipin are mixed with a dilution of the test specimen [serum or cerebrospinal fluid (CSF)] under defined conditions and examined for macroscopically visible aggregates. The RPR test is an improved modification of the VDRL test that utilizes charcoal particles coated with a stabilized mixture of cholesterol and cardiolipin. Serum dilutions are used to titer positive specimens. However, all states have enacted laws requiring confirmation of a positive RPR or VDRL test by a confirmatory test utilizing antigens isolated from *T. pallidum* (MHA-TP or fluorescent treponemal antibody-absorption test).

Several techniques have been used to increase the sensitivity of agglutination assays. Immunoassay by particle counting has a sensitivity of 10 to 1,000 times that of slide-based latex agglutination assays (46). In this technique, a standard number of coated latex particles are incubated with the specimen and the reaction mixture is passed through an automated particle counter. Agglutinated and unagglutinated particles are differentiated based on light scatter and the number of unagglutinated particles is used to construct a dose-response curve. The concentration of an unknown specimen is determined from the dose-response curve. Although these assays are rapid and fully automated and do not require a separation step, they require expensive equipment and do not have the sensitivity of RIA or EIA. Latex agglutination on microtiter plates has also been described, with the quantification of agglutination by turbidimetric measurement (latex turbidimetric assay) (46,51).

Agglutination Inhibition

Agglutination inhibition reactions are based on the competition for antibody-binding sites between haptens (i.e., antigens) in solution and the same or similar haptens localized on sensitized indicator cells or particles. In the presence of a limiting amount of antibody, agglutination is inhibited by hapten present in the solution (46). Therefore, lack of agglutination is indicative of a positive test. These assays are normally performed by reacting the test solution with an antibody preparation, followed by reaction with the indicator cells or particles. Antigen in the test solution, if present, reacts with the antibody and subsequently prevents or decreases agglutination of the indicator. Agglutination inhibition assays are more sensitive than passive agglutination assays but are more difficult to develop and control.

Agglutination inhibition is widely utilized for the detection of hCG in the urine. In this assay, test urine is reacted with anti-hCG antibody and then with hCG-coated latex particles. Agglutination inhibition has also been used for the detection of drugs of abuse in the urine and antiplatelet glycophorin and antimicrobial antibodies in the serum (52,53,54,55,56 and 57). An adaptation of agglutination inhibition, turbidimetric latex agglutination inhibition, utilizes spectrophotometric measurement of the turbidity of the agglutination suspension as a detection method. This technique was recently adapted for automated therapeutic drug monitoring (58,59).

Cell Lysis

An antigen antibody reaction on a cell membrane can result in lysis of the cell if complement is present. If the cells are RBCs, hemolysis takes place. Cell lysis forms the base for the complement-fixation test, which is a sensitive method for the detection and quantitation of antigens or antibodies. The serum specimen is first heated to 56°C to inactivate native complement. Measured amounts of antigen and complements are then added. If antibody specific for the added antigen is present in the serum, antigen-antibody complexes will form, and these will bind or fix all the complement. The reaction mixture is the checked for the presence of free complement. The indicator system for complement consists of SRBCs plus an antibody specific for SRBCs. If all the complement has been fixed, none will be free to lyse the SRBCs and the test is positive. If no antibody was present in the patient's serum, then the complement is not fixed and is free to interact with the indicator system and lyse the red cells. In this case, the test is negative (Fig. 61.5). Properly conducted complement-fixation tests require the use of appropriate controls to ensure that the results will not be adversely affected by the presence of anticomplement compounds, such as denatured immunoglobulins,

heparin, chelating agents, or microbial contaminants. The complement-fixation test was widely used in the past to measure antibodies against viruses and other microbial agents but has recently been replaced by EIA to avoid anticomplement interference and other problems (60).

A different procedure using lytic reactions is the viral neutralization test. This method is based on the fact that some viruses, such as herpes simplex, produce effects (cytopathic effects) when added to target cells growing in tissue cultures. This phenomenon can be used to search for virus-neutralizing antibodies in a serum sample. This is done by adding the serum suspected of containing the antibody to a virus suspension and then adding this mixture to a susceptible cell culture. If the cells fail to show any change, then antibodies present in the serum sample neutralized the cytopathic effect of the virus. If cytopathologic effects develop, then neutralizing antibodies were not present.

Immunoprecipitation

Immunoprecipitation is a secondary immunologic phenomenon that results from the reaction of an antibody and soluble antigen in the proper proportions, with the formation of an insoluble immune complex. Immunoprecipitation has been used since the 1920s for the quantitation of antigens and antibodies.

Basic Principles of Immunoprecipitation

Heidelberger and Kendall first described immunoprecipitation as a manifestation of the antigen-antibody reaction, in 1935. Immunoprecipitation requires the presence of bi- or multivalent antibodies and an antigen with at least two antigenic determinants per molecule. Cross-linking of antigen molecules results in the formation of a lattice that gradually grows in size. Eventually, the lattice may become insoluble and precipitate from the solution. If immunoprecipitation is studied as a function of antigen concentration, with the same concentration of antibody, three phases can be delineated. During the initial phase of antibody excess (prozone), the number of antigenic determinants is small relative to the antibody concentration, and lattice formation is prohibited. As the amount of antigen is increased, the zone of equivalence is reached, where the reactants are at their optimal proportions and maximal precipitation occurs. At this point, a hydrophobic and ionic interaction between smaller complexes increases the size of the aggregates. The final phase is one of antigen excess (postzone), in which all the antibody-binding sites are saturated, cross-linking of antibody molecules cannot occur, and lattice formation is prohibited (Fig. 61.6).

The time course of an immunoprecipitation reaction can vary from hours to days, depending on the affinity, avidity, and valence of the antibody; the size and number of antigenic determinants of the antigen; the reaction temperature, ionic strength, and viscosity of the medium; the interactions between the medium and reactants; and other factors. The time course can be greatly accelerated by assisting the migration of the reactants through the use of an electric field. However, immunoprecipitation reactions generally lack the speed and sensitivity of many other immunoassay techniques, and the use of this type of analysis in the clinical laboratory is declining.

Immunoprecipitation reactions can be classified according to whether the interaction of the antigen and antibody is allowed to occur passively or actively (under the influence of an electric field) (61). Passive immunoprecipitation can be further classified according to the nature of the reaction medium (fluid or gel) (Table 61.1).

TABLE 61.1. CLASSIFICATION OF IMMUNOPRECIPITATION ASSAYS

Passive immunodiffusion assays
Ouchterlony double diffusion
Radial immunodiffusion
Active immunodiffusion assays
Countercurrent immunoelectrophoresis
Rocket immunoelectrophoresis
Combined immunodiffusion assays
Immunoelectrophoresis
Immunofixation electrophoresis

Support media composed of a substance extracted from seaweed (agarose) have been found to provide much better resolution than the gels used in the past. In passive immunodiffusion techniques utilizing gels, antigen and antibody solutions are usually placed in separate regions of the gel and the molecules diffuse radially outward through pores in the gel. When equilibrium is reached, a concentration gradient is formed for each reactant. The concentration is highest near the well and decreases geometrically with distance from the well. At the point in the region between the reactants where their concentrations fall into the zone of equivalence, an immunoprecipitate appears as a narrow band (precipitin band). Multiple precipitin lines are formed if more than a single antigen and/or antibody with different rates of diffusion is present. An alternative method of passive immunoprecipitation uses gels in which one of the reactants (antibody or antigen) is dissolved during the preparation of the gel. The rate of diffusion depends on the molecular weight and size of the antigen(s) and antibody(s); the pore size; degree of hydration and other properties of the support medium; the ionic strength and composition of buffer; and the interaction between the reactants and the support medium. In the preparation of a gel for passive immunoprecipitation, agarose (usually 1% wt/vol) is completely dissolved in distilled water or saline by heating with frequent stirring at temperatures of 100° to 110°C. If antisera are added, the solution is first cooled to approximately 50°C to prevent protein denaturation (61). Gels are cast in Petri dishes or on glass plates or Mylar sheets using gel-molding frames. Wells are added at the time the gel is cast, or at a later time, using a variety of templates. Precipitin lines may be directly visible if the concentration of antigen and antibody was high enough. Alternately, it may be necessary to stain the gel with dyes such as Coomassie brilliant blue R-250 or amido black to visualize the faint precipitin lines or clarify the pattern of precipitation. Gels may be stored in a preservative, or dried and stored.

Passive Immunodiffusion Immunoassays

Ouchterlony Double Diffusion

The two basic passive immunodiffusion techniques are double (Ouchterlony) immunodiffusion and single diffusion radial immunodiffusion

(RID). In the Ouchterlony procedure, antigen and antibody preparations are placed in separate wells cut in a thin layer of agar in a Petri dish. Typically, an antibody solution is placed in a center well, and antigen controls and test solutions are placed in wells around the outside of the gel. The reactants diffuse through the agar until they meet at optimal proportion, where bands of precipitation are formed. The antigenic relationships of the reactants are reflected in the precipitation pattern. The three basic patterns of reaction are identity, nonidentity, and partial identity. In reactions of identity, the two precipitation bands merge into a solid line. In reactions of nonidentity, the lines of precipitation cross. Partial identity is indicated by spur formation, indicating that one of the antigens is cross-reactive with, but not identical to, the other (Fig. 61.7).

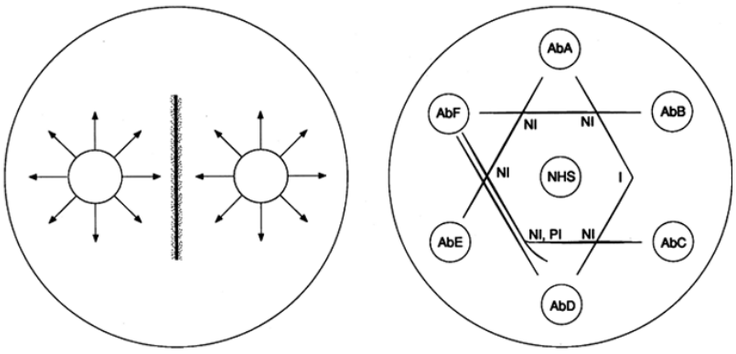

FIGURE 61.7. Principle of double (Ouchterlony) immunodiffusion. In this adaptation of the immunoprecipitation reaction, antigen and antibody are placed in wells punched in agarose gel. The reactants diffuse through the gel, and a visible line forms at the point of equilibrium where an antigen-antibody reaction occurs. In this example, normal human serum was placed in the center well, and various antibody solutions in the six surrounding wells. If an antigen-antibody reaction occurs, the identity (I), nonidentity (NI), or partial identity (PI) of the reactants can be ascertained by the characteristics of the precipitin line. For example, the cross-lines (NI) indicate that antibody A (AbA) and antibody B (AbB) react with different antigenic determinants, whereas antibody B and antibody C (AbC) react with the same antigenic determinant (reaction of identity). Antibodies D (AbD) and antibody E (AbE) react with the same antigenic determinant, but the spur indicates the presence of an additional antigenic determinant recognized by AbD but not AbE. The double precipitin line indicates the presence of an antigen recognized by AbE but not by AbD or AbF.

Immunodiffusion assays are simple and inexpensive to perform and do not require elaborate equipment. However, the precipitin reactions require a day or more for completion, the results are qualitative and not quantitative, and the reaction patterns may be time-consuming and difficult to interpret. For these reasons, more rapid, quantitative methods of immunochemical analysis have replaced double immunodiffusion for most high-volume clinical applications. One exception is in the identification of patients with some autoimmune antibodies, such as those directed against the Smith (Sm) antigen and ribonucleoprotein (RNP). Problems can arise from the presence of irregular wells, overfilling of the wells, or incubation on a nonlevel surface or at an improper temperature. False-negative results can theoretically result from antigen or antibody excess, and the gels and antigen or antibody reagents may have a limited shelf life. Other potential problems include bacterial or fungal contamination and drying of the gels during incubation (61). Other antibody detection methods, such as immunoblot and EIA, are replacing immunodiffusion in the diagnostic laboratory because they avoid these problems and show improved sensitivity and specificity (62).

Radial Immunodiffusion

RID is a gel-based quantitative immunoprecipitation method. In this procedure, a monospecific antibody with high affinity and excellent precipitating ability is added to an agarose solution before gels are cast. Wells are punched into the gel, antigen solution is added to the wells, and the gels are incubated. Under these circumstances, the antigen diffuses radially outward, resulting in a ring of precipitation around each well at the zone of equivalence (63). The diameter of the ring is proportional to the concentration of antigen in the well (Fig. 61.8).

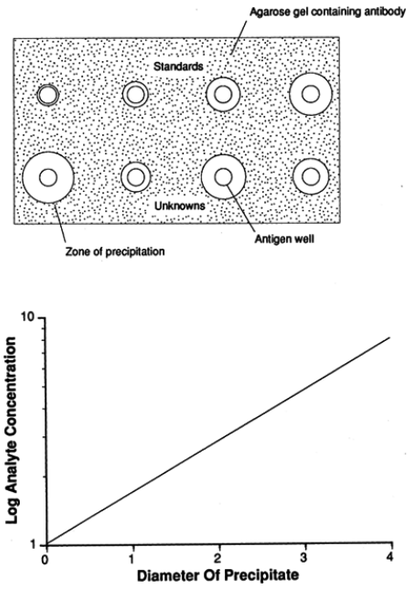

FIGURE 61.8. Radial immunodiffusion.

The molecular weight of the antigen is the major determinant of the time required for performance of a RID assay. Generally, this varies from 24 hours for small proteins like α_1-antitrypsin to as long as 72 hours for large molecular weight proteins such as IgM. In practice, at least three antigen solutions of known concentrations (standards) are included with each assay, and their ring diameter is used to construct a standard curve, from which the concentrations of unknown solutions are determined. Ring diameters can be measured using a ruler and magnifying glass, although more accurate measurements require a special reading device. To compensate for irregularities in the wells, it is customary to measure each ring diameter twice at right angles and to calculate the average of the measurement (44). Measurements

of ring diameter may be taken at the end point of the reaction (Mancini or end-point diffusion method), or at a fixed time before the end point (usually 18 hours) (Fahey or kinetic diffusion method). In the end-point diffusion method, the standard curve is prepared on linear graph paper by plotting the concentration of antigen on the *x* axis and the diameter squared of the precipitin ring diameter on the *y* axis. If the standard curve is nonlinear, a line of best fit is drawn. The antigen concentration of an unknown solution is usually determined directly from the standard curve, although mathematical interpolation can also be used. In the less precise kinetic diffusion method, precipitin ring diameter is plotted on the *x* axis of semilogarithmic graph paper and the concentration of the reference solutions is plotted on the *y* axis. Standard curves are not extended beyond the range of the standards. Specimens whose precipitin ring diameters exceed those of the reference solutions are diluted and reassayed, whereas specimens with precipitin rings smaller than the most dilute standard are reassayed with a more sensitive system or reported as being less than the value of the reference standard. Potential causes of inaccurate results include overfilling of the wells, damage to the wells during pipetting, inappropriate incubation time or temperature, and errors in reading precipitin diameters, preparing the standard cure, and determining unknown concentrations.

Active Immunodiffusion Immunoassays

The movement of a substance through a gel is greatly accelerated by an electric field. Active methods of immunodiffusion use this modification to decrease the time required for the formation of an immune complex. In addition to the properties of gels described previously, reverse buffer flow or electroendosmosis (EEO) is important in the consideration of gel electrophoresis. Gels with high reverse buffer flow are used in applications in which immunoglobulins move cathodically [i.e., countercurrent immunoelectrophoresis (CIEP)], whereas medium- or low-EEO gels are used for other applications (61).

Countercurrent Immunoelectrophoresis

In CIEP (electroimmunodiffusion), antigen and antibody solutions are located in parallel wells placed on opposite sides of an agarose gel. In the presence of an electric field at pH 8.6 (cathode on the side of antigen wells, anode on the side of antibody wells), the antibody molecules migrate toward the cathode, and the antigen toward the anode. After electrophoresis, precipitin lines will form between the wells at the zone of equivalence (61). The position of the precipitin line relative to the wells is dependent on the relative antigen and antibody concentrations, their ability to move through the pores of the gel, and the migration of these substances in an electric field. If the concentration of antibody is maintained constant, CIEP becomes semiquantitative because the migration distance of the precipitin line from the antigen well increases with the ratio of antigen/antibody concentration. In practice, serial dilutions of antigen are used as a reference for the concentration of an unknown solution. CIEP was first used clinically for the detection of hepatitis B antigen and has since been utilized for the detection of a variety of other microbial antigens, as well as autoantibodies and antibodies directed at infectious agents (i.e., influenza type A virus, adenovirus, cytomegalovirus, hydatid antigen, and *Haemophilus influenzae*). A recent study confirmed the diagnostic value of CIEP for the rapid diagnosis of typhoid fever (64).

Rocket IEP

Rocket IEP (electroimmunoassay) is a technique in which an electric force is used to drive an antigen into a gel containing an antibody. Immune complex formation results in the formation of a triangular or rocket-shaped precipitate (65). The total area, or even the height of the immunoprecipitate, is proportional to the concentration of antigen. Low-EEO agarose is utilized in rocket IEP, with the goal of minimizing migration of the antibody in the electric field. Because antigens may migrate either anodally or cathodally in the electric field, the wells must be placed to maximize use of the gel. Because the majority of plasma proteins migrate anodally in such a system, wells usually are placed near the cathode. Technical skill is required to perform rocket IEP because the samples must be applied to the gel rapidly to avoid lateral diffusion of the antigens, widening of the immunoprecipitin arcs, or even mixing of antigens in adjacent wells (61). A low-voltage field across the gel during sample application is used to minimize application artifacts. The voltage is then increased and maintained until the end of the reaction (usually several

hours). After electrophoresis, the gel is washed and stained, and the distance from the middle of each well to the top of the corresponding peak is measured with a precision of 0.1 mm. Standards spanning a wide range of concentrations are assayed with the test specimens, and a curve is plotted from the peak heights of the standard (*x* axis, peak height; *y* axis, concentration of standard). The concentration of the test specimens can be extrapolated from the standard curve, or calculated mathematically (Fig. 61.9). Rocket IEP is a cost-effective method of quantitative analysis that is frequently used in research and test development laboratories. In the clinical laboratory, its use is restricted to the analysis of substances in which high-volume methods of quantitation are not feasible, such as some clotting factors and α-fetoprotein.

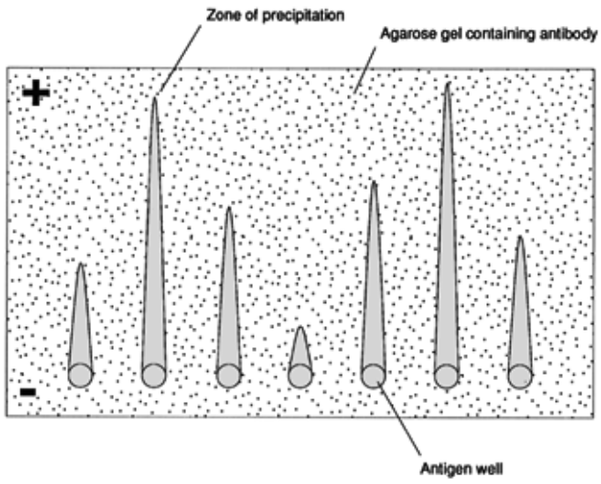

FIGURE 61.9. Principle of rocket immunoelectrophoresis.

Combined Immunodiffusion Techniques

Techniques in which active and passive immunodiffusion are combined [IEP, immunofixation electrophoresis (IFE)] are useful in resolving complex mixtures of antigens.

Immunoelectrophoresis

IEP is a technique for the separation and analysis of serum proteins that was first introduced by Grabber and Williams in 1953 and modified by Scheidegger in 1955. IEP is a two-stage procedure in which proteins are first separated electrophoretically and then identified by immunoprecipitation (66) (Fig. 61.10). IEP is performed as follows:

- The test solutions (e.g., serum, urine, CSF) are pipetted into cylindrical wells in a buffered agarose gel.
- Electrophoretic separation of the proteins is performed.
- Antisera are placed in troughs that run parallel to the path of electrophoretic migration and span most of the width of the gel.
- The gel is placed into a humidity chamber for 10 to 15 hours. During this time, proteins and antibodies diffuse into the gel and precipitin arcs form in the equivalence region between each well and trough.
- The gel is stained, dried, and then visually inspected and interpreted.

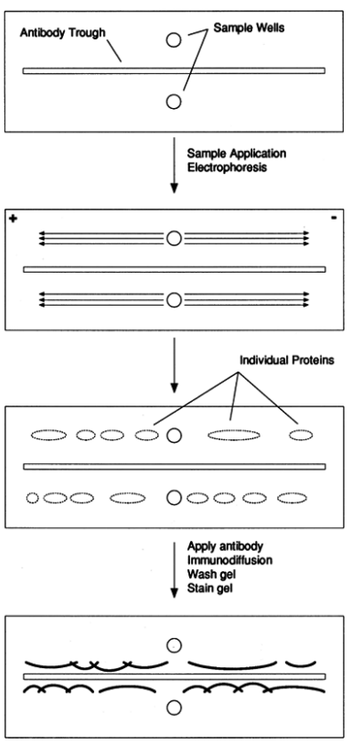

FIGURE 61.10. Theory and technique of immunoelectrophoresis. In immunoelectrophoresis, electrophoresis and immunodiffusion are sequentially applied to separate and identify protein antigens. The antigen is first applied to wells in an agarose or cellulose acetate gel, followed by electrophoresis. After electrophoretic separation of the proteins, an antibody solution is placed in the center trough and immunodiffusion is allowed to occur. Arcs of immunoprecipitation indicate an antigen-antibody reaction. The gel is then washed and stained with a protein-specific dye to clarify the reaction pattern. In clinical practice, antibodies against human immunoglobulin heavy- and light-chain immunoglobulins are commonly used with immunoelectrophoresis to identify abnormal proteins.

During IEP, a separate precipitin arc is formed for each antigenic component against which a corresponding antibody is present. Patterns of identity, nonidentity, and partial identity are formed that are identical to those formed during Ouchterlony

immunodiffusion and other immunodiffusion techniques. Although a complex pattern of arcs results if a polyspecific antiserum is utilized, monospecific antisera are usually employed for the identification of individual serum proteins.

The major advantages of IEP include small sample requirements, sensitivity, and specificity. However, the technique is time-consuming and labor-intense and requires skill and experience to perform and interpret. In addition, the results are only semiquantitative and are greatly affected by variations in the antigen/antibody ratio; antibody titer; and the specificity, avidity, and affinity of the antisera used. Problems of antigen or antibody excess are most frequently encountered. Under conditions of antigen excess, the precipitin arc moves closer to the antibody trough and becomes thickened and elongated. The precipitin arc often has a diffuse appearance on the trough side and can even disappear in situations of extreme antigen excess, in which the precipitin reaction is in the prozone. With antibody excess, the precipitin arc moves closer to the antigen well and assumes an increasingly diffuse appearance. A similar problem of indistinct precipitin arcs is encountered with a low antigen concentration and in the presence of a weak antigen-antibody reaction.

Immunofixation Electrophoresis

IFE was introduced by Alper and Johnson (67) for the identification of genetic variants of proteins, and was subsequently modified by Arnaud et al. (68) and Ritchie and Smith (69). However, because IFE has many advantages over IEP for the identification of monoclonal proteins, it has achieved increasing utilization in the clinical laboratory in recent years (71,72).

IFE, like IEP, is a two-step procedure requiring electrophoretic separation of proteins followed by immunoprecipitation. However, in IFE, the antibody is applied directly to the surface of the gel over the electrophoretically separated proteins rather than in a trough parallel to the axis of electrophoretic migration (Fig. 61.11). The technique is performed as follows:

- Samples are applied to agarose gel and separated electrophoretically, using conventional techniques. Protein solutions are diluted to a concentration of 50 to 100 mg/dL before application. During application, each specimen must be clearly separated from the adjoining specimens to avoid cross-contamination, and care must be taken in placing the electrodes so that the path of migration is parallel to the short axis of the gel. The gel must not be fixed after electrophoresis.
- Filter paper or cellulose acetate strips are cut to appropriate size, saturated with a dilute antibody solution, drained, blotted, and carefully applied over the gel. Separate strips are used for each sample. The strips must be applied without leaving air bubbles underneath and must be parallel to the path of electrophoretic migration.
- The gels are placed in a humidity chamber for approximately 1 hour. During this time, the antibody solution on each strip diffuses into the underlying gel, and immunoprecipitation occurs in the gel.
- The strips are removed, and the gel is pressed, washed, stained, and dried. Each immunoprecipitate appears as a band of varying width. Diffusion of antibody onto the application strips also occurs, so that the application strips can be stained.

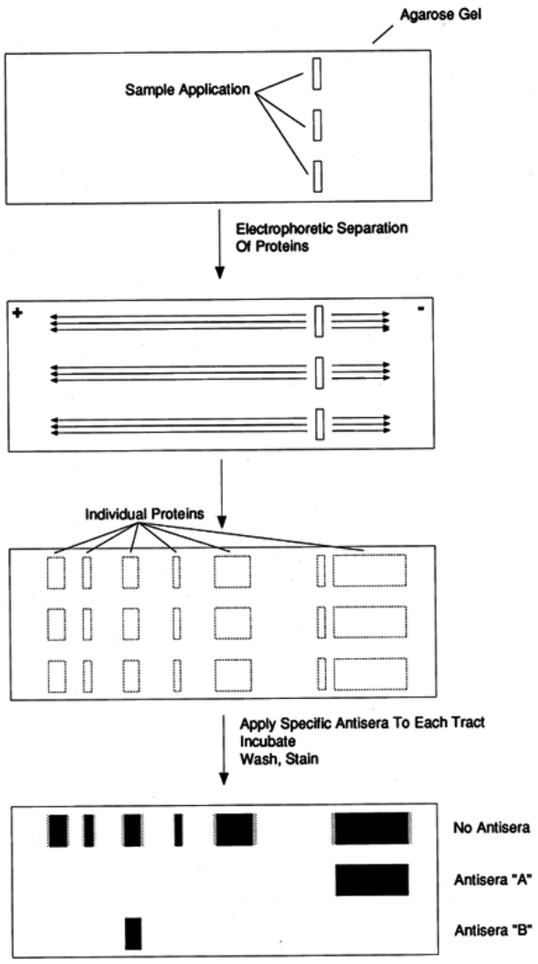

FIGURE 61.11. Technique of immunofixation electrophoresis. In this technique, strips of filter paper or cellulose acetate are soaked with antisera and placed on the surface of an agarose gel containing proteins first separated by electrophoresis. Immunodiffusion of the antisera into the agarose gel occurs, and a band of immunoprecipitation occurs at the site of each antigen-antibody reaction. The gel is washed and then stained with a protein-specific dye.

IFE has many advantages over IEP and is rapidly becoming the technique of choice for the identification of monoclonal proteins. The major advantages of IFE include its speed, high sensitivity, and relatively low cost. In conjunction with high-resolution electrophoresis and nephelometric analysis, IFE permits accurate, complete evaluation of protein abnormalities within hours instead of days. In addition, the precipitin bands obtained with IFE are directly comparable with high-resolution electrophoresis, which aids in the interpretation of electrophoretic patterns. The major disadvantage of IFE, in comparison with

IEP, is that the precipitin reaction is more dependent on the antigen/antibody ratio.

Turbidimetry and Nephelometry

Turbidimetry and nephelometry are techniques for the electrooptical quantitation of immune complex formation in solution. Because turbidimetry and nephelometry are precise, rapid, automated methods of immunoquantitation, they are extensively utilized in the clinical laboratory for the quantitation of a large number of medically important substances.

Light Scattering

The interaction of light with a particle can result in reflection, refraction, absorption, or scatter of the beam. When an immune complex is formed under carefully controlled conditions, measurement of these parameters can provide information regarding the quantity of analyte that is present (73). Turbidimetric techniques determine the reduction in the intensity of incident light from all interactions of an immune complex with a light beam, whereas nephelometric techniques measure light scattered at a specific angle to the incident beam. Although the ability of both systems to measure particles is highly dependent on the design and quality of the optical and electronic instrumentation utilized, nephelometry is more sensitive to small particles than turbidimetry, and turbidimetry more accurately quantitates large complexes (74).

Thus, for the interaction of light of wavelength λ and intensity I_0 with a particle of polarizability α, the intensity of emitted radiation ($I\theta$) at distance *r* from the particle is defined by the following relationship:

$$I_\theta = \frac{8\pi^4\alpha^2 I_0}{\lambda^4 r^2}$$

There are several consequences of this relationship (74). For example, because light scatter is proportional to $1/\lambda^4$, blue light (λ = 450 nm) is scattered more than red light (λ = 650 nm). In addition, white light scattered at an angle of 90 degrees appears blue, whereas transilluminated white light appears red because of removal of the blue wavelengths.

The formation of immunochemical aggregates, as depicted by the Heidelberger curve, involves the formation of small immune complexes through a primary immunochemical reaction, secondary interlinking of the complexes, and the tertiary formation of large aggregates through hydrophobic and charge-based interactions (75). Rayleigh scatter predominates during the primary and secondary immunochemical interactions, but large scatter complexes formed during the tertiary reaction may exceed the threshold for Rayleigh-Deybe scatter (Fig. 61.12).

Condition	In $Ag_x^{(m)}\ Ab_y^{(2)}$	Result
Extreme antibody excess	$\frac{y}{x} \geq m$	No steps (2), (3)
Antibody excess	$m > \frac{y}{x} > \frac{m}{2}$	Scatter↑ as $\frac{y}{x}$↓
Equivalence	$\frac{y}{x} = \frac{m}{2}$	Maximum scatter
Antigen excess	$\frac{m}{2} > \frac{y}{x} > \frac{1}{2}$	Scatter↓ as $\frac{y}{x}$↓
Extreme antigen excess	$\frac{y}{x} < \frac{1}{2}$	No steps (2), (3)

FIGURE 61.12. Light scatter during immunoprecipitation. The initial antigen concentration (x), antibody concentration (y), and antigen valency (m) are denoted as indices for various regions of the kinetic Heidelberger curve. The antibody concentration fixed, and the antibody is assumed to have a valence of 2. The regions of the kinetic Heidelberger curve include (1) primary immunochemical formation of antigen-antibody complexes, (2) secondary immunochemical linking of complexes, and (3) rapid build up of scattering centers owing to subsequent hydrophobic and charge-based interactions among complexes. (From Sternberg JC. Rate nephelometry. In: Rose NR, Friedman H, Fahey JL, eds. *Manual of clinical laboratory immunology*, 3rd ed. Washington, DC: American Society for Microbiology, 1986:34, with permission.)

In the region of antibody excess, light-scattering immune complexes form most rapidly during the first 20 seconds of the reaction (74). However, the formation of additional light scattering complexes continues for several minutes, reaches a plateau (equilibrium phase), and then decreases as intraparticle destructive interactions occur, and an insoluble immunoprecipitate is formed. In conditions of antibody excess, both the peak rate of the formation of light-scattering complexes and the amount of complexes that exist at the plateau region depend on the antigen concentration. End-point nephelometric or turbidimetric systems measure the curve at the plateau phase to determine antigen concentration, whereas rate or kinetic immunoprecipitation methods use the portion of the curve where the peak rate of reaction is maximal.

A problem faced by all quantitative immunoassay systems, but particularly by turbidimetric and nephelometric systems, is the symmetric shape of the Heidelberger curve. Thus, a given measured signal can represent two distinct concentrations of antigen, one in the antibody excess zone and one in the region of antigen excess (75). In turbidimetry and nephelometry, measuring immune complex formation in the region of antibody excess minimizes this problem. This permits the formation of complexes of a constant size and provides a reproducible, stoichiometric relationship between the number of complexes formed at a given antigen concentration (75).

In addition to antigen concentration, antibody avidity, ionic strength, pH, the presence of molecules with hydrophilic or hydrophobic properties, and the nature and concentration of anion (60) influence the formation of immune complexes. Antichaotropic ions with a high charge density (PO_4^{3-}, HPO_3^{-}, SO_4^{2-}) decrease solvation effects and promote immune complex formation, whereas chaotropic ions (SCN^{-}, ClO^{4-}, NO^{3-}) increase the availability of solvent ions and reduce immune complex formation. The use of polymers, such as dextran and the polyethylene glycols (PEG), to enhance immunoprecipitation was first reported by Hellsing and Laurent in 1964 (76) and is commonly used in both turbidimetry and nephelometry. The immunoenhancing effect of polymers is probably due to steric exclusion, which has the effect of decreasing the solubility of protein molecules, driving the antigen-antibody interaction toward immune complex formation, increasing the slope of the antibody excess part of the precipitin curve, and displacing equivalence towards higher antigen concentrations (74). PEG with a molecular weight of 6000 daltons (PEG 6000) is one of the most effective immunoenhancers, leading to a markedly decreased reaction time and marked increases in peak rate (74). PEG also precipitates

lipoproteins, leading to increased optical clarity and decreased background scattering.

Turbidimetric Immunoassays

Turbidimetry has been used since the early 1950s as a method of quantitative analysis. In this technique, the reduction in light intensity caused by interaction of a light beam with a suspension of particles is determined spectrophotometrically. The ratio of the incident and transmitted light is determined, and expressed in absorbance units (*A*):

$A = 2 - \log_{10} \cdot T$

where *T* is the percentage of transmittance. In the clinical laboratory, the major advantage of turbidimetry is that it can be performed with automated spectrophotometric instruments. The major disadvantage of turbidimetry is the requirement of a relatively high particle concentration and the relatively small change in light intensity caused by particle absorbance. Consequently, optical quality and alignment are extremely important for accurate turbidimetric quantitation, and the results can be affected by extraneous factors, such as the presence of dust or dirt particles. Light with a wavelength in the near-ultraviolet (290–410 nm) is usually utilized for illumination, whereas the photodetector must be aligned with the incidence source and detects light over narrow angle (77). The optical clarity of the reagents and the reaction cuvettes or cells is important, and the system must be able to mix reagents rapidly for analysis. The antisera must have high avidity and specificity and show optical clarity. The IgG fraction is generally the most suitable for turbidimetric analysis. An immunoenhancer, such as dextran or PEG, is frequently added to the reaction mixture to facilitate immune complex formation, and this must not cause turbidity when mixed with the antisera. The presence of turbid substances (e.g., chylomicrons and other lipoproteins, endogenous immune complexes, monoclonal proteins) in the samples is problematic and difficult to compensate with reagent blanks or by other means.

Nephelometric Immunoassays

Nephelometric techniques have been applied very successfully to the immunochemical measurement of specific proteins, drugs and other substances (74,78). In nephelometry, a known amount of specific antibody is added to a solution containing the antigen being measured. The intensity of light scattered from the large antigen-antibody complexes formed during the reaction is measured, and the rate signal is transmitted to a microcomputer, where concentration units are determined.

Techniques of rate nephelometry are used almost exclusively in commercial nephelometers for clinical laboratory applications. In rate nephelometry, a fixed antibody concentration is utilized, and measurements of light scatter are made under conditions of antibody excess, where antigen concentration can be determined from measurements of light scatter. The time course of a nephelometric reaction has the complex shape shown in Fig. 61.13. A small amount of Rayleigh scatter is initially present, and this increases slightly when the sample and then the antisera are added. Scatter intensity then undergoes a sigmoidal increase with the progression of primary and secondary immunochemical reactions and the formation of large scattering centers. There is no real end point, but the scatter intensity gradually reaches a maximum and then decreases as large complexes settle out. The reaction conditions are adjusted so that the maximal rate (scatter versus time) occurs during the first minute of the immunochemical reaction.

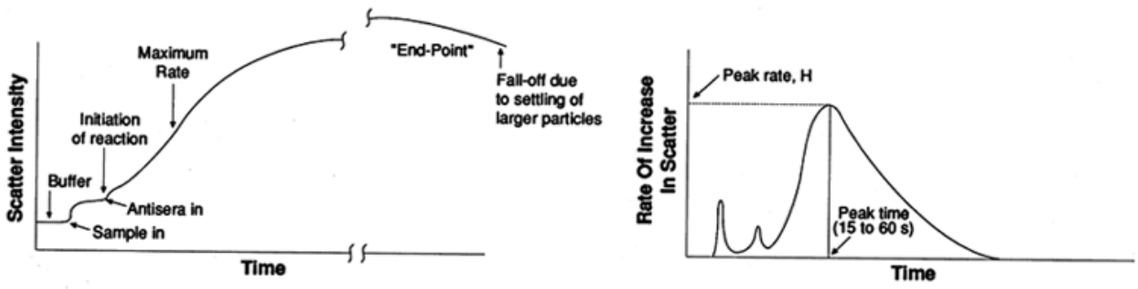

FIGURE 61.13. Time course of the nephelometric signal produced during an immunoprecipitation reaction. **A:** Variation in the t versus time. **B:** Rate of increase of scatter versus time. (From Sternberg JC. Rate nephelometry. In: Rose NR, Friedman H, Fahey JL, eds. *Manual of clinical laboratory immunology*, 3rd ed. Washington, DC: American Society for Microbiology, 1986:34, with permission.)

Commercial nephelometric systems monitor scatter and the rate of change of scatter at a forward angle of 70 degrees in a stirred reaction cell. The reaction is performed in a phosphate-buffered saline solution, and PEG is used as an immunoenhancer. Other nephelometric systems, including a particle-enhanced turbidimetric inhibition immunoassay (PETINIA), have been described. PETINIA is a competitive binding assay using hapten-coated latex particles. Agglutination, measured by a change in turbidity at 340 nm, is inhibited by binding of the unlabeled hapten to the antibody (79).

Ligand Immunoassays

General Principles of Ligand Assays

A ligand is a substance that will bind to or complex with another substance. In a ligand assay, one component of the reaction (e.g., label or tracer) is tagged in some manner so that the reaction can be measured. The substance to be measured (ligand, analyte, or hapten) can be an immunoglobulin, drug, tumor marker, hormone,

infectious agent, autoantigen, lipoprotein, oncoprotein, or other substance. The substance that binds the ligand (binding substrate) is usually an antibody (immunoassay) but can be a receptor (receptor assay), carrier protein (protein-binding assay), or any substance that specifically binds the ligand with a high affinity. The labeled reagent can exist in a solubilized form, or it can be immobilized (bound) to a solid surface such as a test tube, the sides of the wells of a microtitration plates, a latex particle, a plastic bead, or a solution of microparticles (80). In addition to the analysis of soluble substances in body fluids, the principle of ligand analysis is also utilized in tissue-based assays such as direct and indirect immunofluorescence, flow cytometry, and immunoperoxidase staining.

Kinetic Aspects of Ligand Analysis

The amount of ligand that binds to a substrate is defined by the number of binding sites and by the affinity of the binding substrate. The affinity is the sum of the strength of the hydrogen binding, van der Waals forces, ionic interactions, and other forces that influence the reaction. Thus, by the law of mass action,

$$\mathrm{Ag} + \mathrm{Ab} \underset{K_2}{\overset{K_1}{\rightleftharpoons}} \mathrm{Ag} \cdot \mathrm{Ab}$$

where K_1 and K_2 are the equilibrium constants for the reaction.

At equilibrium, the rates of the forward and reverse reactions are equal ($K_1 = K_2$) and the proportions of bound and unbound ligand become constant. The equilibrium constant (K_a) for this reaction is represented by the equation:

$$K = \frac{k_1}{k_2} = \frac{(\mathrm{Ag} \cdot \mathrm{Ab})}{(\mathrm{Ag})(\mathrm{Ab})}$$

When 50% of the binding sites are occupied, K_a is equal to the reciprocal of the free ligand concentration. K_a is expressed in L/mole or moles/L^{-1} and has a magnitude in the range of 10^7 to 10^{11} L/mole in most clinical laboratory assays.

Many ligand assays are used in the clinical laboratory for the quantitation of a wide variety of substances of medical importance. Basically, these assays differ in the labeling substance (e.g., radioisotope, enzyme, fluorescent dye, chemiluminescence precursor, bioluminescent substance, metal atom, bacteriophage, liposome, metal sols, latex particles), binding substrate (e.g., antibody, receptor, transport protein), reagent concentration (antibody excess, competitive binding), and the requirement for separation of the free and bound label (heterogeneous or homogeneous).

Unfortunately, the diversity of methodology has led to practical problems in the classification and nomenclature of the ligand assay systems (81). By convention, the type of label appears first in competitive assays (i.e., EIA, RIA), whereas the binding substrate appears first in the name of a reagent excess assay (i.e., immunoenzymetric assay). All reagent excess assays using an antibody-binding substrate can be referred to as immunometric assays. The acronym ELISA (enzyme-linked immunosorbent assay) is commonly, and incorrectly, used to refer to all types of EIAs and immunoenzymometric assays. The classification system utilized in the following (Table 61.2) is based on the classic differentiation of heterogeneous and homogeneous assays and a classification system proposed by Gosling (81).

Heterogeneous Ligand Assays

Heterogeneous ligand assays require physical separation of the free label from the label bound to the substrate. Techniques for this purpose rely on differences in the size or chemical composition of the bound and free label. The development of techniques that allow complete separation of the bound and free components has been one of the most challenging aspects of ligand assay techniques. In general, the relatively nonspecific separation methods used in the past (adsorption, chemical precipitation, immunoprecipitation) have been replaced by more specific separation methods, most notably solid phase techniques.

Adsorption is based on the difference in size between the free label and the label-substrate complex. Porous materials (e.g., charcoal, silica, ion exchange resins, Sephadex) adsorb small molecules (free label) but not larger particles (label-substrate complex). The adsorbent, with attached free label, can be removed from the reaction mixture by centrifugation or other techniques, leaving the substrate in the supernatant. In practice, a mixture of charcoal and cross-linked dextran was for a long time the most widely utilized adsorbent. Dextran prevents nonspecific adsorption of protein and determines the size of the free label that can be adsorbed. The properties of the adsorbing particles such as Sephadex can be also modified to maximize the specificity of the separation process. Chemical agents (e.g., ammonium sulfate, ethanol, sodium sulfate, PEG) alter the solubility of proteins in solution, causing precipitation. After centrifugation, the free label remains in the supernatant, where it can be measured. The action of these agents is nonspecific because both free and bound proteins are precipitated. Immunoprecipitation (second antibody, double antibody) methods use a precipitating antibody specific for the species in that the primary antibody is produced (e.g., anti-goat). Insoluble complexes are produced that can be removed by centrifugation, leaving the free label. These methods are similar to chemical precipitation in that all free and bound (labeled and unlabeled) substrate is removed from the reaction mixture.

In solid-phase separation, either the ligand or primary antibody is immobilized to an inert physical surface. Because the antigen-antibody reaction occurs on the surface, the free and bound ligand can easily be separated. Several imaginative solid-phase methods have been devised, first utilizing coated paper or

polystyrene (e.g., test tubes, beads, microtiter trays, paddles), followed by membranes (e.g., nitrocellulose, nylon, polymers) and more recently plastic and latex beads and microparticles, which may be magnetic. The major requirements for solid-phase immobilization is complete and uniform coating of the surface, linkage of the antigen or antibody to the solid phase by a technique that neither alters binding interactions nor permits spontaneous release during the reaction, and thorough washing to minimize nonspecific binding of the label. This analytical process has now been automated for a variety of analytes, such as therapeutic drugs, specific proteins, enzymes such as cardiac markers, hormones, antibodies to infectious agents, and drugs of abuse by many manufacturers. Automation has helped promote assay stability, reduced imprecision, speeded up the analytical process, and reduced labor requirements for performing these assays.

Heterogeneous ligand assays can be competitive or noncompetitive. In competitive assays, a constant amount of binding substrate and labeled ligand is used, and the amount of unlabeled ligand is the variable that is measured (Fig. 61.14). The labeled ligand is present in relatively large quantities, and a smaller amount of unlabeled ligand is allowed to compete for the available binding sites. The larger the quantity of unlabeled ligand present, the more labeled ligand will be displaced from the binding substrate. After separation, the amount of free or bound labeled ligand can be determined.

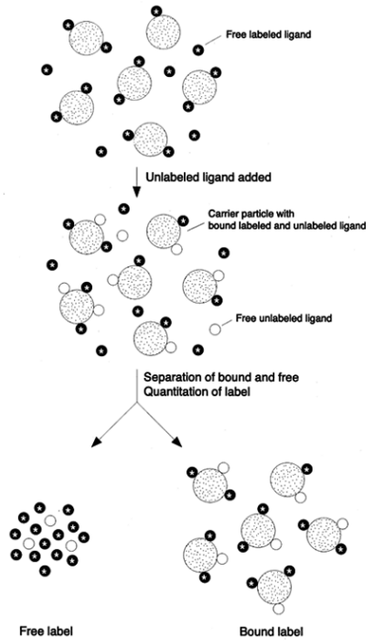

FIGURE 61.14. Principle of competitive binding immunoassays. An unlabeled ligand is added to a mixture containing measured amounts of free-labeled ligand and carrier particles with bound-labeled ligand. The label is usually a monoclonal antibody or a radioactive ligand. Displacement of some of the bound-labeled ligand by the unlabeled ligand results in a mixture of free-labeled ligand, free unlabeled ligand, and carrier particles with labeled and unlabeled ligand. The carrier particles are then separated from the mixture, and the amount of free or carrier-bound ligand is determined by the appropriate assay procedure. If standard curves are prepared using known amounts of unlabeled ligand, the amount of analyte in an unknown solution can be determined from the curves.

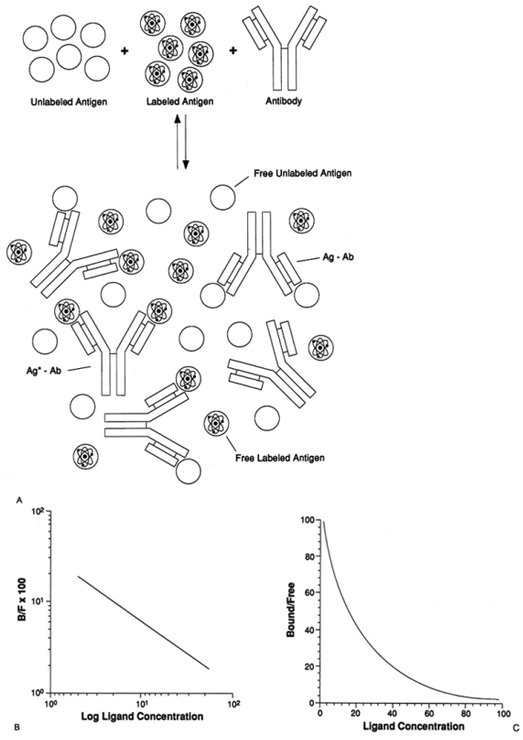

FIGURE 61.15. Radioimmunoassay by competitive binding. **A:** Schematic illustration of the theory of competitive binding. **B:** Graphic analysis by logit plot. **C:** Graphic analysis by a plot of bound/free versus ligand concentration.

The principle of competitive binding was first applied in an electrophoretic technique for the measurement of thyroxine in human plasma but quickly became the most widely used RIA technique (82). Competitive binding assays depend on the competition between radiolabeled and unlabeled antigen for the binding sites on a limited amount of antibody. In this procedure, the unlabeled analyte is allowed to compete with a highly purified radiolabeled antigen (radiolabeled ligand) for binding to a limited amount of antibody, under conditions of antigen excess. After incubation under appropriate conditions, the antibody-bound (B) and unbound (free, F) analytes are separated and the amount of radioactivity is determined in each. These values are used to calculate the ratio of bound to free analyte (B/F). The more unlabeled analyte present, the lower the B/F ratio because more labeled analyte will be displaced from the antibody. A sigmoidal curve results if the B/F ratio is plotted against the ligand concentration. These data are usually analyzed by a computer with a four-parameter logistic or spline function, avoiding the need to transform the data into some linearizing function such as logit/log of the ligand concentration, which was common when manual graphing of calibration curves was necessary. The logit is calculated by the following equation:

$$\frac{Y}{1-Y}$$

where,

$$Y = \frac{B/F}{B_0/F_0}$$

where B is the counts per minute of bound radioligand, F is the counts per minute of free radioligand, B_0 is the counts per minute of bound ligand determined in a system with no unlabeled ligand (zero value), and F_0 is the counts per minute of free radioligand in a system with no unlabeled ligand (Fig. 61.15).

In practice, the concentration of an unknown analyte is determined by reference to a standard curve prepared from the reaction of different concentration solutions of purified unlabeled antigen. It is necessary that the unknown specimen be analyzed under precisely the same conditions as the standard curve.

The labeled and unlabeled antigens are not required to be chemically or biologically identical but must follow the law of mass action.

A similar principle of competitive binding is also used in the radioreceptor assay. In the radioreceptor assay, the receptor is not an antibody but a purified preparation of a circulating binding protein (e.g., thyroid-binding globulin, cortisol-binding protein, intrinsic or for vitamin B_{12}), membrane receptor, or cytoplasmic receptor.

Noncompetitive (reagent excess) assays are usually of the "sandwich" type, in which a binding molecule is immobilized to an inert support. Antigen-capture assays require an immobilized antibody. The analyte or ligand control is added and binds to the available substrate sites. Labeled antibody is then added, and a sandwich is formed with the antigen in the middle. After a wash step to remove unbound labeled antibody, the bound antibody is measured and is directly proportional to the quantity of unlabeled antigen present. The antibody capture is similar but requires a ligand linked to the solid phase. After reaction with an antibody-containing specimen or control and a wash step to remove unbound antibody, the presence of bound antibody is detected by the use of labeled antihuman globulin. The amount of bound label is directly proportional to the quantity of specific antibody (Fig. 61.16). Note that these assays are generally applicable only to molecules that are large enough to have at least two distinct antibody-binding epitopes.

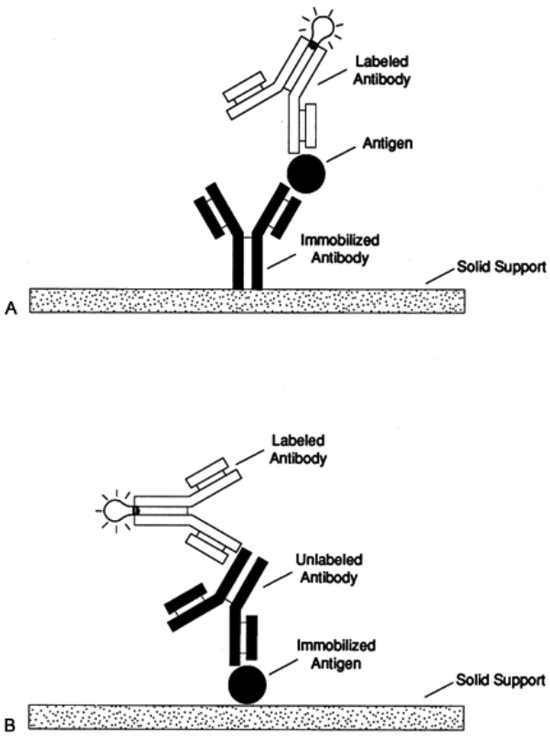

FIGURE 61.16. Principle of noncompetitive immunoassays. **A:** Antigen capture. **B:** Antibody capture. Antigen capture assays utilize an antibody immobilized to an inert support (usually a plastic test tube or plastic microtiter tray). Antigen (control ligand or analyte) is added, and an immune complex forms on the inert support. After incubation and washing, a labeled antibody specific for the antigen is added. The reaction mixture is incubated, washed, and the amount of bound antibody is measured. The concentration of analyte in an unknown solution can be determined from a standard curve prepared with known amounts of antigen. In antibody capture assays, a similar principle is used to measure the concentration of an antibody.

Homogeneous Ligand Assays

Homogeneous ligand assays do not require separation of the free and bound fractions. Many of these assays have grown in popularity in the clinical laboratory in recent years because of their speed, sensitivity, and overall technical simplicity. There are numerous types of homogeneous ligand assays using enzyme and fluorescent labels. Examples include the enzyme-multiplied immunoassay technique (EMIT, Syva Co., Palo Alto, CA, U.S.A.), enzyme immunochromatography, substrate-labeled fluorescent immunoassay, and fluorescent polarization immunoassay, and cloned enzyme donor immunoassay (CEDIA). These and other homogeneous ligand assays are described in the sections below.

Isotopic and Nonisotopic Labels

The choice of label is an important consideration in ligand assays. In this regard, the sensitivity of the assay largely depends on the specific activity (number of detectable events per label molecule per unit time) of the label and the completeness of the separation of bound label from unbound label. However, other factors, such as the ease and sensitivity of detection, freedom from background activity or environmental influences, ease of conjugation to a ligand, cost, and other factors are important.

Because the introduction of the RIA 40 years ago, iodine 125 (^{125}I) and other radioactive nuclides have been widely used as labels in immunoassay procedures. The popularity of radioisotopes as a label has been because of their sensitivity, measurement precision, lack of background, and freedom from environmental influences. However, these compounds are expensive, pose a slight health risk to the laboratory technologist, require special handling and disposal, and have a limited shelf life. In addition, specialized, expensive instrumentation is required for measurement of radioactivity, automation is difficult, licensing is required, and strict compliance with national, state, and local laws is required for their use (83). Fortunately, the sensitivity of the nonisotopic label immunoassays now exceeds that of RIA for many substances. With the recent emphasis on cost-effective laboratory diagnosis and the urgent need to decrease the use of radioisotopes and other substances that pose a health risk, the use of RIA techniques has decreased during the past two decades in clinical and research laboratories. By late 1999, the CAP Ligand survey (K/KN-C) indicated that less than 3% of laboratories used radiolabeled assays for prostate-specific antigen, 1% for thyroid-stimulating hormone (TSH), and approximately 2% for vitamin B_{12}. Because these represent assays for which radioactive labels had been thought necessary for sensitivity purposes, it is clear that this belief no longer holds. In contrast, in 1997, 35% of the articles in the journal *Clinical Chemistry* were devoted to some aspect of EIA (84).

The relative advantages and disadvantages of radioisotopes with nonisotopic labels (enzymes, fluorochromes, chemiluminescent substances) have received much consideration (85,86). For example, ^{125}I has a specific activity of one detectable event per second per 7.5×10^6 labeled molecules, whereas chemiluminescent

labels produce one detectable event per labeled molecule, and both enzymes and fluorescent labels can produce many detectable events per molecule. Thus, an enzyme label with a chemiluminescent or fluorescent substrate has in principle the lowest detection limit of commonly used labels. In practice, however, other issues such as nonspecific binding of labeled antibody to the solid phase clearly contribute to detection limit, as one commercially available immunoassay with a colorimetric substrate (in principle, several orders of magnitude less sensitive than chemiluminescence) has achieved a third-generation TSH assay. Moreover, various vendors' assays for TSH use a variety of label/separation/incubation combinations, often with very similar detection limit.

Radioimmunoassay

RIA techniques have been among the most sensitive laboratory procedures available. As a result, RIA was long the principal method for the detection of substances that are present in very low concentration in biological fluids (10^{-6} to 10^{-9} g/mL). In clinical medicine, the RIA was introduced in 1960 by Yalow and Berson (87) for the measurement of plasma insulin levels. It was quickly applied to the measurement of other peptide hormones and has subsequently been used for the determination of hundreds of substances, including drugs and toxins, infectious agents, tumor antigens, tissue peptides, and other substances.

The main requirements for a RIA are an antibody with a high specificity for the antigen being determined and a pure, radioactively labeled antigen of known concentration. In a RIA, one component of an immune complex reaction (antigen or antibody) is labeled with a radioactive isotope. After incubation, the immune complex that has formed is separated from the reaction mixture and the amount of bound (in the immune complex) and free radioactivity are determined. With appropriate standards, the amount of the substance under study (analyte) can be determined. A special type of RIA (radioallergosorbent technique) is used for the quantitation of antigens that are immunoglobulins. For nonimmunoglobulins, there are several RIA techniques, including the competitive binding assay and immunoradiometric assay.

RIA Techniques

Competitive binding assays and excess reagent (sandwich) [this is immunoradiometric assay (IRMA), discussed later] are the most common types of RIA. The sandwich technique requires a radiolabeled antibody that is utilized in excess. The amount of analyte is determined from the radioactivity in the immune complex. This type of RIA procedure is rarely used in the clinical laboratory. Competitive binding RIA techniques depend on the competition between radiolabeled and unlabeled antigen for a limited amount of antibody.

The excess reagent (two-site, double-antibody) RIA is a sandwich technique in that two antibodies are used in excess. One antibody, which is unlabeled, is attached to a solid phase (usually a polystyrene test tube) by electrostatic interaction. The test solution, containing unlabeled antigen (with two antibody-binding sites) is added to the tube, where an antigen-antibody complex forms. After excess antigen is removed by washing, the second (radiolabeled) antibody is added, and the formation of the sandwich is completed. After another wash step to remove unlabeled antibody, the amount of bound radioactivity is measured, and is proportional to the amount of antigen in the test solution (Fig. 61.17).

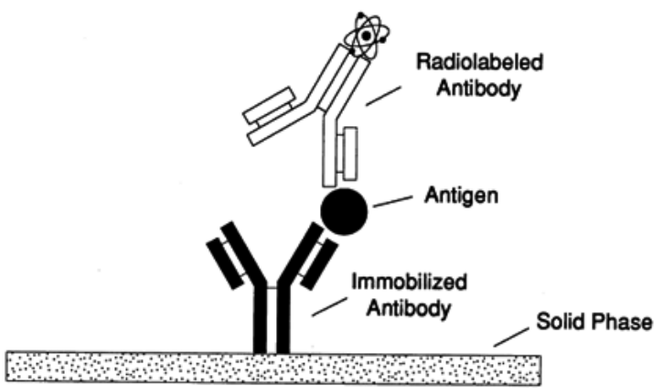

FIGURE 61.17. Principle of sandwich radioimmunoassay. This technique is an antigen capture immunoassay in that a radiolabeled antibody is used to measure the concentration of an antigen.

In the IRMA, the antigen is reacted with an excess of antibody, which is usually coupled to a solid phase. A wash step may or may not occur here, in two- and one-step assay designs, respectively. A second antibody, labeled with a radioactive tracer, is then added to the reaction mixture forming an Ab-Ag-Ab* sandwich. Finally, the solid phase is washed to remove nonbound radiolabeled antibody. The amount of antigen in the test solution is directly proportional to the radioactivity remaining.

The radioallergosorbent technique is a sensitive method for the detection of specific antibodies in biological fluids. It is a sandwich technique using a purified antigen bound to a solid support. The immobilized antigen is incubated with the test solution, resulting in the formation of an immune complex on the solid support. The formation of the sandwich is completed by the addition of radiolabeled antiglobulin, and the amount of bound radioactivity is determined after a final wash. Under these circumstances, the measured radioactivity is directly proportional to the amount of antibody present.

Practical Considerations in RIA Analysis

The major considerations in a RIA are an antibody with a high specificity for the analyte being determined, a highly purified, radioactively labeled preparation of the analyte, and an efficient method for separating antibody-bound and free components after the reaction. Other considerations include specimen adequacy, measurement of radioactivity, and the appropriate utilization of standards.

- Specimen
- Antibody
- Labeled analyte
- Separation of bound and free antibodies
- Measurement of radioactivity
- Standards

The specimen for analysis must be representative and obtained in the correct manner. In addition, care must be taken to

maintain the integrity of the analyte until the analysis is performed. Because labile protein substances are frequently analyzed, specimens for RIA are often centrifuged and maintained in the frozen state. Specimens sent to another laboratory for analysis are often kept frozen using dry ice.

Polyclonal and monoclonal antibodies have been successfully used in RIA procedures. The preparation of an antibody for an RIA procedure is performed by the standard techniques described above. Because many substances assayed by RIA have small molecular weights, carrier proteins are commonly employed during antibody production, and some antibodies recognize the analyte in addition to a portion of the carrier molecule. The specificity, avidity, and specificity of the antibody are critical factors in RIA. The avidity (affinity) of the antibody is a major determinant of the sensitivity of the assay and is determined using Scatchard or Wolf plots. Generally, antisera for RIA procedures must have K_a values between 10^{-2} and 10^{-9} mol/L (88). The sensitivity of the antibody is determined by binding studies utilizing the purified analyte and potential cross-reacting substances at a wide range of concentrations. The specificity of a polyclonal antibody preparation can usually be improved by the absorption of cross-reacting antibodies. In addition, steps can be taken to remove cross-reacting substances from the test solution before analysis. An antisera titer is chosen (usually $1:10^5$ to $1:10^6$) that will bind 30% to 50% of the labeled analyte (88).

The preparation of a labeled analyte involves the choice of a radioactive isotope, physical attachment of the isotope to the analyte, and isolation of the labeled analyte in a highly purified form. The choice of radiolabel depends on its ease of conjugation, specific activity, radioactive half-life, and emission characteristics, with gamma emission being preferred when possible because of the ease of counting compared with beta emission. The specific activity (activity per unit weight of isotope) determines the amount of radiolabeled ligand that must be present to produce a adequate sensitivity. The half-life of the radioisotope must be sufficient to provide adequate shelf life. Generally, ^{125}I is used as a label for proteins, peptides, and hormones because it has a relatively long half-life (60 days), emits a large number of disintegrations per minute, and emits gamma radiation of relatively low energy. Hydrogen 3 (^3H) is often used to label steroids, but its long half-life, beta emission, and relatively low number of disintegrations per minutes are disadvantages. Other radioisotopes used in RIA include carbon 14 and iodine 131. For the measurement of vitamin B_{12}, cobalt 57 or cobalt 60 are used to substitute for the cobalt that is naturally present. The characteristics of these radioisotopes are listed in Table 61.3.

From Holden NE, Walker FW. *Chart of the nuclides*, 10th ed. U.S. Atomic Energy Commission, 1968.

Chemical methods are used to attach the radiolabel to the analyte. It is essential that this be done in such a way as to achieve a uniformly labeled product with maximal utilization of the reactants and with minimal chemical damage to the analyte. For peptides and proteins containing tyrosine residues and labeled with ^{125}I, an iodination reaction catabolized by lactoperoxidase or chloramine-T is often used (88). Lactoperoxidase catalyzes the reaction of H_2O_2 and $Na^{125}I$ to form active iodine (I^+), which in turn reacts with the tyrosyl residue of proteins. Chloramine-T is a derivative of ρ-toluene sulfonamide that produces a similar incorporation of iodine into the aromatic ring of tyrosine. Enzymatic iodination with lactoperoxidase is preferable because it

causes fewer reactions with other amino acid residues than chloramine-T. A conjugation method using an iodinated ester is employed to label proteins lacking tyrosine residues.

When the labeling process has taken place, the labeled analyte is separated from free label and damaged analyte by chromatographic or electrophoretic procedures. The product is thoroughly evaluated for nonspecific binding and immunoreactivity under several conditions (88). In addition, a high specific activity (large amount of radioisotope per quantity of analyte) is desirable. The specific activity is commonly expressed as microcuries per microgram (μCi/μg) or disintegrations per micromole (dpm/μmol). For routine RIA procedures, an amount of label producing 10,000 to 25,000 dpm per assay tube (generally 0.01 μCi) is used, although maximal sensitivity is achieved with a high-affinity antibody and minimal quantities of label (often producing only 1,000 to 2,000 dpm/tube) (88).

Separation of the free and bound analyte is the least precise part of the RIA. Because the antigen-antibody complex is larger than the free antigen, this size difference is the basis of most separation methods. Although several separation methods have been employed, solid-phase separation, immunoprecipitation, and chemical precipitation have been most widely described. Adsorption with dextran-coated charcoal particles is a solid-phase separation technique that is employed in the RIA analysis of steroids and many other substances (89). In this technique, the smaller unbound antigen particles are bound to the charcoal, whereas the larger complexes remain in the supernatant. Unfortunately, it is difficult to prepare a uniform suspension of charcoal particles for pipetting, and ionic factors, protein concentrations, and many other factors can interfere with the adsorption process. Adsorption with silicates and chalk has also been used. Chemical substances such as saturated ammonium sulfate solution, ethanol, or PEG (Carbowax) precipitate the antigen-antibody complex, which can be removed from the reaction mixture by centrifugation (90). Immunoprecipitation (double-antibody precipitation) methods use an antibody (secondary antibody) from a different animal species, which is directed against epitopes of the antibody (primary antibody) binding the analyte. Under the proper reaction conditions and antibody concentrations, precipitates are formed that can be separated by centrifugation, electrophoresis, or chromatography (Sephadex, polyacrylamide, ion exchange, and paper). Although simple in theory, in practice, it is difficult to achieve precision with immunoprecipitation. A combination of immunoprecipitation and chemical separation with PEG has been used to shorten turnaround time in RIA testing. Recently, coated magnetized particles have been used successfully in some assays.

Enzyme Immunoassay

The EIA is a type of nonisotopic immunoassay in which enzymes, coenzymes, fluorigenic substrates, or enzyme inhibitors are used as labels (91).

Enzymes are utilized as labels in both heterogeneous and homogeneous assay systems and are used to assay both antigens and antibodies. The major prerequisite is that the antigen or antibody must be linked to an enzyme without destroying the immunologic or enzymatic activity of the antigen-antibody complex. In addition, in heterogeneous EIAs requiring a solid phase, the antigen or antibody under study must be attached to the solid-phase support in a manner that does not alter immunologic activity.

Enzymes used in immunoassay systems must be stable, available in a highly purified state, have a high turnover rate, undergo minimal interference by substances likely to be in the test solution, and be specific for the substrate. The final reaction product should be detected by a convenient means with a low detection limit. The most widely used enzyme in EIA is horseradish peroxidase (HRP). The substrate of HRP is hydrogen peroxide (H_2O_2) and the product is oxygen. This oxygen produced during the reaction is used to oxidize a reduced, colorless chromagen (usually reduced orthophenylenediamine). The final product, oxidized orthophenylenediame, has a brown color. Most EIAs utilize HRP or alkaline phosphatase as labels, although glucose oxidase, ß-D-galactosidase, and many other enzymes have also been used. Utilizing fluorometric techniques, the respective detection limits for HRP, ß galactosidase, and alkaline phosphatase are 5, 0.2, and 10 attomol (81). The practical detection limit of the EIA is approximately 0.01 to 0.02 attomol of ligand (92,93).

The coupling of an enzyme to an antibody or protein antigen must be performed in a manner that minimally alters immunoreactivity and enzyme activity. In addition, the coupling reaction must result in efficient incorporation of the label, and the conjugate should be stable with a long shelf life (94). Chemical reactions resulting in the activation of a carboxyl group are commonly utilized for the formation of hapten-enzyme conjugates. The mixed anhydride, carbodiimide, and *N*-hydroxysuccinimide ester coupling methods utilize this reaction. Other methods of hapten-enzyme coupling include periodate cleavage, or the use of heterobifunctional active esters such as m-maleimidobenzoic acid *N*-hydroxysuccinimide ester, or related compounds (95). Methods for protein-protein coupling include glutaraldehyde cross-linking, periodate coupling, dimaleimide coupling, the use of homobifunctional reagents such as 4,4′-difluoro-2,2′-dinitrophenyl sulfone, toluene-2,4-diisocyanate, or benzoquinone, and the use of m-maleimidobenzoic acid *N*-hydroxysuccinimide ester. Although coupling reactions that involve sites of antigen-antibody combination usually result in a reduction in avidity, coupling can result in an increased affinity and avidity in some circumstances. After the coupling reaction, the conjugate must be purified and then characterized in terms of the hapten-to-enzyme ratio, enzyme activity, and immunoreactivity (95).

Classification of EIAs

EIAs are usually classified based on the requirement of separation of the free and bound reactants (Table 61.4). In heterogeneous EIAs, enzyme activity is not affected by the interaction of antigen and antibody, and a separation step is required. The term ELISA is widely used as a general term for the heterogeneous EIA. In homogeneous EIA, there is no need for a separation step because enzyme activity is modulated by the antigen-antibody interaction.

Enzyme-enhancement immunoassay

The separation techniques that can be used in heterogeneous EIAs are limited by the large size of most enzyme molecules. As a result, solid-phase techniques (e.g., antigen- or antibody-coated

polystyrene test tubes or microtiter trays; polystyrene, latex, or agarose beads or particles, magnetized beads) have been principally utilized for separation of the bound and free enzyme conjugate. Immunoprecipitation with PEG, a second antibody, or a preprecipitated complex of two antibodies has also been utilized in some cases.

Competitive EIA techniques are similar to RIA, with the exception that they may be configured to be homogeneous as well as heterogeneous formats. One widely used adaptation of this technique, EMIT, uses a limited amount specific antibody that is reacted with unlabeled ligand (unknown sample, control, or standard) and a known amount of labeled antigen in addition to the enzyme substrate. In this case, binding of the ligand-enzyme conjugate to antibody greatly reduces the enzyme activity, so activity is proportional to ligand concentration. The end product is quantitated by spectrophotometry. The major disadvantages of this method include the need for relatively large amounts of pure antigen and the requirement that each different antigen be coupled to an enzyme.

EMIT was the first homogeneous EIA to be developed and has since been extensively been used for the quantitation of numerous chemotherapeutic substances (e.g., drugs of abuse, antiepileptic drugs, cardioactive drugs, antineoplastic drugs, antimicrobial drugs, antihistaminic drugs), hormones, and other substances. In the EMIT assay system, the ligand (usually a hapten) is covalently linked to an enzyme (usually nicotinamide adenine dinucleotide (NAD)–dependent glucose-6-phosphate dehydrogenase). In most EMIT assays, the binding of an anti-hapten antibody inhibits enzyme activity, probably by interfering with the molecular conformational changes that take place during the enzyme reaction or by direct steric exclusion of substrate binding (96). Because free hapten competes with the antibody for binding to the enzyme-immobilized hapten, the quantity of end product is directly proportional to the concentration of free hapten. In a few EMIT assays, the binding of antibody to the bound hapten increases enzyme activity. For example, in the EMIT assay for thyroxine, the enzyme-hapten (malate dehydrogenase-thyroxine) complex is inactive until antibody binding occurs. It is believed that the bound thyroxine occupies the active site of the enzyme but is removed from this area during the steric rearrangements that take place upon antibody binding (97). In the standard EMIT assay, 50 mL of the specimen is diluted with buffer, and the enzyme substrate is added, followed by the enzyme-hapten conjugate. The reaction mixture is aspirated into the flow cell of a spectrophotometer that is maintained at 30°C, and the change in absorbance is determined over a 30-second interval. The assay for some substances requires different specimen volumes, reading times, or pretreatment of the specimen to improve sensitivity. Although the basic equipment for an EMIT assay consists of a spectrophotometer and pipetter-diluter, numerous adaptations have been made for use in automated analyzers such as continuous flow systems, discrete analyzers, centrifugal analyzers, and the Du Pont ACA. The NAD-dependent reaction can be measured fluorometrically as well, and this detection method has been used to increase the sensitivity of the reaction.

Ligand-labeled enzyme cofactors have been effectively utilized in EIA systems (98,99 and 100). Most commonly, these systems are competitive in nature, with a specific antibody against the ligand, preventing the coenzyme-ligand conjugate from binding to the apo-enzyme and reducing enzyme activity. Because unlabeled ligand competes with the coenzyme-ligand conjugate for binding to the antibody, enzyme activity is directly proportional to the amount of unlabeled antigen. NAD is a cofactor for many enzymes (e.g., lactate dehydrogenase, malate dehydrogenase) and has been used as the cofactor in several of these assays. The major disadvantage of coenzyme-labeled immunoassays is their susceptibility to endogenous cofactors and other enzymes.

Immunoassays using ligand-labeled prosthetic groups are similar to those using enzyme cofactors. The ligand-prosthetic group (usually flavin adenine dinucleotide) competes with unlabeled ligand for a limited amount of specific antibody. The free, but not the antibody-bound, conjugate can interact with an apo-enzyme, such as apo-glucose oxidase, to generate the active enzyme (98). Similar assays with ligand-labeled modulators (e.g., antibody, inhibitor, receptor) have been reported (101).

The enzyme-enhancement immunoassay is a method in which enzyme-labeled antibodies are used (102). In this system, an enzyme-labeled antibody (E-AB1) and a succinylated antibody (AB2) are utilized. These antibodies form a complex with a polyvalent antigen in the reaction mixture to form a negatively charged microenvironment. Under these circumstances, the substrate is converted into a product (P2) that alters the light-scattering properties of the complex. The free-enzyme conjugate forms a product (P1) that remains soluble. The reaction is measured by turbidimetry.

Immunoenzymometric assays are noncompetitive (i.e., excess reagents are used). The antigen is first reacted with an excess of enzyme-labeled antibody, and a solid-phase antigen is then added in excess to remove unreacted enzyme-labeled antibody. After washing, the substrate is added. The amount of final product is inversely proportional to the concentration of free antigen. The major advantages of this technique include no need for a purified antigen and the ability to detect small haptens that are difficult to quantitate by other means.

Several sandwich modifications of the EIA to quantitate antigen have been described. The two-site immunoenzymometric assay utilizes a solid phase coated with specific antibody in excess. The test solution containing antigen is added to the solid phase and incubated, permitting the antigen to bind to the immobilized antibody. After washing to remove unreacted antigen,

the solid phase is incubated with an excess amount of enzyme-labeled antibody in the liquid phase. The enzyme substrate is added after a second wash, and the amount of end product is directly proportional to the amount of antigen in the test solution. Because the antigen must be able to bind to two different antibodies simultaneously, this procedure is best utilized to detect large, complex antigens with two or more antigenic sites. A competitive sandwich assay for antigen detection (double-antibody immunoenzymometric assay) uses solid-phase antigen. The solid phase is allowed to compete with free antigen for binding to a specific antibody in the liquid phase. After incubation and washing, an enzyme-labeled antibody against the first antibody is used to determine the amount of bound complex. This method is economical because a single enzyme-labeled antibody can be used in assays for many different antigens.

Recent Advances in EIA

Numerous innovative modifications of EIA techniques have been described utilizing microparticles, liposomes, recombinant enzyme fragments, biosensors, flow cytometry, and other materials and techniques. For example, Wilkins et al. (103) developed a highly sensitive homogeneous assay for thyrotropin using 800-nm particles and a new modular immunoassay system (Multipact). The assay was also the first to use fragmented monoclonal antibodies to avoid serum interference. The accuracy and precision of the assay were comparable with a commercial, highly sensitive IRMA for TSH. Two novel phase-separation immunoassays were described by Auditore et al. (104). In one system, the solid phase is generated *in situ*, after specific binding has occurred. This technique (*de novo* polymerization) to minimize nonspecific binding and enhance reaction kinetics. Thermal precipitation was used in the second system, which incorporated water-soluble polymers and temperature-dependent solubility.

The use of liposomes in immunoassay systems has also been described. For example, in the technique reported by Litchfield et al. (105), alkaline phosphatase was incorporated into liposomes. In a competitive assay, lysis of the liposomes and enzyme release by a hapten-cytolysin conjugate was prevented by conjugation with an anti-hapten antibody.

An EIA system using recombinant enzyme fragments has been described (106,107). In this system, termed CEDIA, two separate *Escherichia coli* genes for ß-galactosidase are engineered to produce separate, enzymatically inactive fragments that can spontaneously recombine to form an active ß-galactosidase enzyme. An anti-ligand antibody is attached to one fragment (enzyme acceptor), whereas the second fragment (enzyme donor) is labeled with ligand conjugate. The binding of antibody to the enzyme donor–ligand conjugate regulates the degree of recombination of the two fragments to form an active enzyme. In practice, a competitive system is used in which there is competition between the ligand in the specimen and the enzyme donor–ligand conjugate for a limited amount of antibody. Variations of the assay include a three-reagent system with enhanced sensitivity, and a single-reagent system suitable for on-site testing. The advantages of CEDIA compared with other homogeneous immunoassays include high sensitivity, linear standard curves, and low endogenous enzyme activity. The assay has been adapted for use in several commercial automated clinical laboratory analyzers.

Immunosensors have been utilized for a variety of *in vivo* and *in vitro* applications. Although most immunosensors are based on electrochemical detection, potentiometric, voltamperometric, thermometric, optoelectronics, acoustoelectronic and other methodologies have been described (108,109,110,111,112,113,114 and 115). Another immunoassay detection system monitors antigen or antibody binding on a surface by surface plasmon oscillations (116).

Several new membranes, fibers, and other materials are being used as solid phases in immunoassays. In radial partition immunoassays, antibodies are immobilized to glass-fiber paper, and enzyme activity is measured fluorometrically (117). In one assay for the detection of hCG, the capture antibody is immobilized to a nylon membrane in contact with an absorbent material (118). Both reference and test zones are included. Another popular assay for pregnancy detection uses the novel approach of microparticle-capture on glass-fiber membranes. This technique is based on the principle that coated polystyrene microparticles irreversibly adhere to the surface of glass fibers or glass-fiber membranes. Microparticles coated with anti-hCG antibodies are applied to a glass filter along a narrow line (test line), whereas hCG-coated microparticles are fixed along an intersecting horizontal line at right angles to the first (reference line). The sample is first passed through the filter, followed by the enzyme-antibody conjugate and substrate. If the reagents are functional, color is formed along the reference line to give a - sign. If hCG is present in the sample, the test line is also colored, giving a + sign.

Fluorescence and Chemiluminescence

Coon and associates were the first to use fluorescent dyes (fluorochromes) as a label for an antibody molecule. Since that time, they have proven to be sensitive and versatile labels for the detection and quantitation of antigens and antibodies in body fluids and tissues. Fluorochromes are easily conjugated to most substances of biological importance and are easily measured in the laboratory. In addition, some fluorescent probes can be coupled to other excited states or chemical species by energy transfer or chemical reactions.

Fluorescence and Phosphorescence

The emission of light is one possible outcome of the interaction of a molecule with light or other electromagnetic radiation. In response to the absorption of energy, fluorochromes enter an excited state, during which changes in electron configuration occur. However, the molecules are unstable in the excited state and undergo a rapid return to the stable or resting state. During this transition, most of the absorbed energy is dissipated in the form of heat, but some is released (emitted) as a photon of light (luminescence). There are two types of luminescence, depending on whether the time between excitation and emission is short (less than 10^{-8} seconds, fluorescence) or long (more than10^{-4} seconds, phosphorescence). Because some energy is lost as heat, the wavelength of the emitted energy is longer (lower energy) than that of the wavelength of the excitation source (higher energy) (Fig. 61.18).

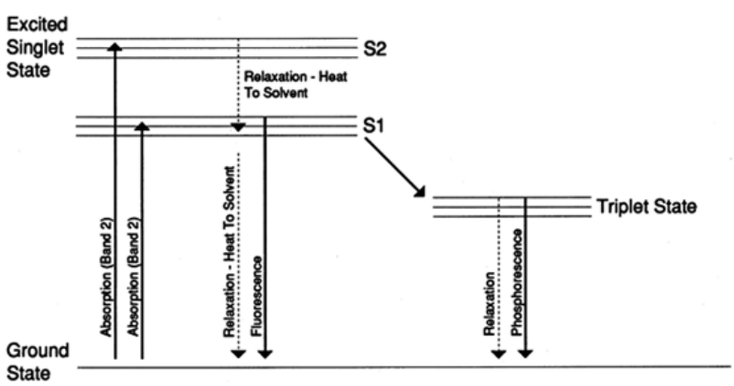

FIGURE 61.18. Energy transitions during fluorescence and phosphorescence. The absorption of light causes a transition of the molecule from its ground state singlet (S0) to one of a number of excited singlet states (e.g., S1, S2). The molecule is electronically unstable in the excited state, and the excess energy is dissipated by nonradiative means (heat) or radiative energy transfer (luminescence) during a return to the ground state. Fluorescence occurs if the molecule undergoes a direct radiative transition to the ground state, whereas phosphorescence results in cases in which the transition involves a series of semistable triplet states (e.g., T1, T2). Nonradiative transitions are indicated by straight arrows and radiative transitions by wavy arrows. (From Hemmila, I. Fluoroimmunoassays and immunofluorometric assays. *Clin Chem* 1985;31:360, with permission.)

Each fluorochrome is characterized by a number of parameters,

including the maximum wavelengths of maximal excitation (λ^{Abs}_{Max}) and emission (λ^{Fluor}_{Max}), the Stokes' shift, the extinction coefficient (ε) in the region of excitation, the quantum yield (Q), and the decay rate of the excited state (τ). The Stokes' shift is the difference between λ^{Abs}_{Max} and λ^{Fluor}_{Max}. It is usually 20 to 50 nm for most fluorescent compounds but may be as great as 200 nm for some phosphorescent compounds (Table 61.5). The maximal intensity of fluorescent emission occurs when a fluorochrome is excited with light at the wavelength of the excitation maximum. Decreases in fluorescent intensity occur at wavelengths above and below the maximum excitation wavelength. In practice, the excitation maximum cannot be utilized under two circumstances: (a) the light source does not provide an emission line of the proper wavelength and (b) two or more fluorochromes with different excitation maxima are simultaneously used with a single monochromatic excitation source. Under these circumstances, compromises can be made as long as the intensity of the signal emitted is adequate for particle detection. Fortunately, the intensity of the fluorescent emission is always proportional to the amount of fluorochrome present at a fixed wavelength. Optical

TABLE 61.5. PROPERTIES OF FLUOROCHROMES

Type of Probe	Name of Probe	Absorption Maximum (nm)	Emission Maximum (nm)	Extinction Maximum ($M^{-1}cm^{-1}$)	Quantum Yield
Covalent labels					
	FITC-NH-CH3	490	520	67	0.71

FITC, fluorescein isothiocyanate.

filters are utilized in laboratory instruments to maximize parameters for a particular fluorochrome or combination of fluorochromes.

The chemical and biological properties of a fluorochrome are influenced by the chemical composition of the substance, by the physical and chemical environment in which the substance is placed, and by a variety of other factors. In addition to a large extinction coefficient (ε) in the region of excitation, high quantum yield, an optimal excitation wavelength, and a proper excited state lifetime, fluorochromes must be photostable, biologically inert, and undergo minimal interference by other substances that may be present (quenching) (119). The compound must also possess functional groups for binding to an antigen or antibody. Isothiocyanates, chlorotriazine derivatives, or hydroxysuccinimido active esters covalently bind to the primary amino group of proteins, whereas iodoacetamido and maleimido groups attach to sulfhydryl groups (119). In conjugates of a fluorochrome with a protein antigen or antibody, the molar fluorescein-to-protein ratio (F/P ratio) is important. The F/P ratio is an indication of the relative number of fluorochrome molecules per protein molecule. Staining sensitivity is reduced if the F/P ratio is too small, whereas nonspecific fluorescence can be caused by an F/P ratio that is too high.

Although no single substance has all of the properties of an ideal fluorochrome, FITC, rhodamine, and phycoerythrin are employed for most applications at present. The properties of these and other fluorochromes of biological interest are summarized in Table 61.5.

FITC is the most widely used fluorochrome. FITC is excited at a wavelength of 492 nm and emits light at a wavelength of 510 nm (Fig. 61.19). This substance binds neutral amino acids and has been used as a tag for antibodies, hormones, lipids, lectins, and a wide variety of other biological molecules. The advantages of FITC are its solubility in water, high quantum efficiency, and large extinction coefficient, whereas its disadvantages include a pH dependence of fluorescent emission, moderate photoinstability, and an excitation wavelength less than 500 nm (119). Between two and five fluorescein molecules can usually be attached to most biological molecules before quenching limits fluorescent intensity. Covalent binding requires an alkaline pH (pH 8.5 to 9.0) at which the pH amino groups are in a reactive form.

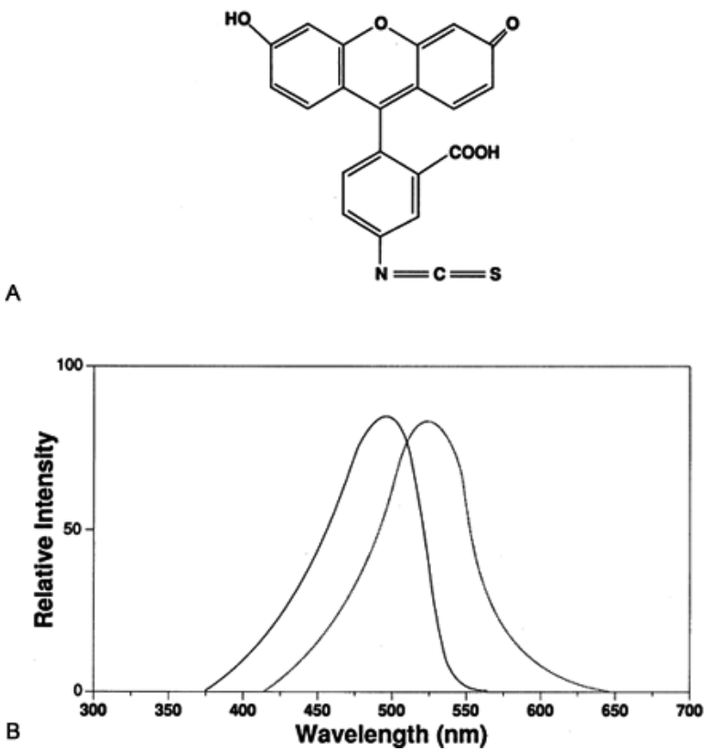

FIGURE 61.19. Molecular structure **(a)** and fluorescence spectra **(B)** of fluorescein isothiocyanate.

Rhodamine derivatives (e.g., rhodamine isothiocyanate, Texas red) have higher fluorescent excitation and emission wavelengths than FITC and are often used in conjunction with FITC for multiparametric analysis. Most of these compounds are less water soluble than FITC but are photostable and have fluorescent properties that are independent of pH (119).

Research in the early 1980s led to the development of a new class of fluorochromes that have been termed phycofluors (119,120,121,122 and 123). The major phycobiliproteins include the phycoerythrins (R-phycoerythrin, B-phycoerythrin), R-phycocyanin, and allophycocyanin. The advantages of these compounds include extremely high absorbance coefficients over a wide spectral range, very high quantum yields, constant fluorescence over a broad pH range, solubility in aqueous solution, and environmental stability. In addition, phycobiliproteins contain numerous lysyl side chains that permit easy conjugation to biological molecules that can confer binding specificity (immunoglobulins, lectins, protein A, avidin) (121,122).

Fluorescence Immunoassays

The use of fluorochromes for the identification and localization of antigen, antibodies, and immune complexes in histochemical, cytochemical, and cellular assays is described below. More recently, fluorochromes have been used in the clinical laboratory to quantitate antigens and antibodies in a manner analogous to RIA and EIA (124,125). Unfortunately, these assays have achieved limited application because of the need for specialized instrumentation, as well as extensively purified and well-characterized reagents. In addition, inherent limitations in the detection of fluorescent emissions limit the sensitivity of conventional fluorometric methods to the nanomolar range and above (83). These limitations include background fluorescence (particularly from autofluorescent substances normally present in serum), nonspecific binding of the reagents, fluorescence quenching, difficulties in differentiating the excitation and emission signals, and light scattering phenomenon. Fortunately, new fluorescent reagents and new techniques of applying these labels have alleviated many of these problems. Particularly important has been the use of some heavy metal compounds (i.e., lanthanide complexes) in conjunction with techniques such as time-resolved fluorescence immunoassay. In addition, the ability to chemically alter the properties of fluorochromes has resulted in great interest in the adaptation of fluorescent compounds for clinical laboratory diagnosis. Various biological dyes and even dyes utilized in the textile industry have been targets for these investigations as the parent compounds for synthesis of new fluorochromes. Because fluorochromes can act as substrates in biochemical reactions, these fluorogenic substrates have been extremely useful in

the study or quantitation of cellular properties (e.g., pH, membrane potential) or biological activity (e.g., enzyme activity, activation). The utilization of a compound as a fluorogenic substrate requires that it undergo a change in fluorescent properties (e.g., gain or loss of fluorescence, change in) with a change in the biological property or substance being studied.

Analytical fluorescence assays are most commonly classified as heterogeneous or homogeneous, based on the need for separation of the bound and free reagent. Other considerations include the type of reaction mechanism (competitive or noncompetitive), labeled component (ligand or antibody).

A solid phase is utilized in most heterogeneous fluorescent immunoassays for separation of the labeled and unlabeled reagents. Both competitive and noncompetitive reaction mechanisms have been described. Quantitation of the reaction mechanism is usually performed with a fluorometer.

Homogeneous immunoassays are rapid and easy to perform, although their sensitivity is limited compared with heterogeneous assays unless special instrumentation is utilized (typically 10^{-10} molar of analyte per liter) (126). In addition, these assays require highly purified, labeled antigen and specific antibody.

The quenching or enhancement of fluorescence of a ligand-labeled chromophobe caused by the binding of an antibody has been used to quantitate some substances. The enhancement fluoroimmunoassay for thyroxine described by Smith (127) utilizes a fluorescent derivative of thyroxine that undergoes an enhancement in fluorescent intensity on the binding of an antithyroxine antibody. In a competitive binding assay, unlabeled thyroxine in the reaction mixture competes for the antibody. With a sensitive fluorometer (Aminco Bowman SPF fluorometer), the assay has sensitivity equivalent to the standard RIA for thyroxine.

The phenomenon of energy transfer between fluorochromes has been incorporated into clinical analytical assays for multivalent antigens (128). Most commonly, fluorescein is used as the donor fluorochrome and rhodamine is the acceptor. Because the maximal fluorescence emission of fluorescein occurs at a wavelength of 525 nm, and tetraethyl- and tetramethyl-rhodamine have a strong absorption line at this wavelength, energy transfer can occur from fluorescein to rhodamine. Energy transfer occurs through dipole-dipole interaction at a rate that is inversely proportional to the sixth power of the distance between the molecules. Two types of fluorescence excitation transfer immunoassays have been described. The antibody is labeled with rhodamine in both types of assays. However, in one type, the antigen is directly labeled with fluorescein, whereas in the other type an indirect label (FITC-labeled antibody) is used. In the direct assay the fluorescein-labeled antigen and rhodamine-labeled antibodies are mixed together, causing a quenching of fluorescein fluorescence. When the unlabeled antigen is added to the reaction mixture, competition for binding sites on the antibody occurs, resulting in liberation of some of the fluorescein-labeled antigen, decreased quenching, and increased fluorescein fluorescence. The principle of the indirect assay is similar.

A fluorescent protection assay has been described for the analysis of protein antigens (e.g., immunoglobulin, hormones, serum proteins) or antibodies. In the assay for an antigen, the reactants include a fluorescein-labeled protein antigen, an antibody specific for the antigen, and a second antibody specific for fluorescein. The principle of the assay is that (a) binding of the anti-fluorescein antibody to the labeled protein results in the quenching of fluorescence, (b) the antigen-specific antibody sterically inhibits binding of the anti-fluorescein antibody, and (c) unlabeled antigen competes with the fluorescein-labeled antigen for antibody binding. Thus, fluorescence intensity is proportional to the quantity of unlabeled antigen.

The substrate-labeled fluorescent immunoassay has been used for the quantitation of haptens (including many therapeutic drugs), as well as immunoglobulins and other proteins. A complex of antigen and a fluorogenic substrate of an enzyme forms the basis of this assay. The principle is as follows: (a) the antigen is cleaved from the substrate complex by an appropriate enzyme, resulting in the formation of a fluorescent product, (b) the presence of an antibody to the antigen inhibits enzymatic cleavage, (c) free antigen inhibits antibody binding, (d) the rate of production of fluorescence is proportional to the free antigen concentration. In practice, umbelliferyl-ß-galactoside is usually utilized as the labeled enzyme substrate, and ß galactosidase is the enzyme. For many antigens, the sensitivity of this assay is comparable with that of RIA.

Particle concentration fluorescence immunoassays use small polystyrene beads as the solid phase. The reaction is performed in microtitration plates in which a 2-mm diameter porous membrane forms the bottom of each well. Specimens and reagents are removed from the wells by using suction. Total particle fluorescence is determined by front surface fluorescence. The utilization of this system for the quantitation of serum immunoglobulins and antibodies has been reported (129).

Fluorescence Polarization Immunoassays

Fluorescence polarization is a special property of fluorochromes that was first applied to an analytical assay by Dandliker et al. (130,131). Light is comprised of electric and magnetic fields (vectors), and polarization is defined by the orientation in time and space of the electric vector (132). If the electric vector can be considered to consist of two orthogonal components, the state of polarization of a light beam is defined by the relative amplitudes and phases of the orthogonal components. The orthogonal components are of equal magnitude and have no fixed relationship in the case of unpolarized (incoherent) light. In contrast, perfectly polarized light is coherent, and the orthogonal components are fixed in their relationship to each other (132).

Light produced from fluorescence emission is noncoherent because it arises from the summation of uncorrelated individual emission events (132). However, polarized light is absorbed by a chromophore in the same manner as nonpolarized light, provided that the absorption transition moment of the chromophore is in the same direction as the plane of polarization. The rate of depolarization can be determined by measuring the sample with detectors parallel and perpendicular to the plane of polarization (132,133).

The degree of polarization increases with restricted motion of a chromophore owing to increased viscosity of the medium or decreased fluidity of the membrane of other structural components. Therefore, small fluorochrome-labeled molecules in an aqueous solution have unrestricted motion and exhibit low polarization. However, when combined with an antibody, the

molecular motion of the fluorochrome is decreased, and the degree of fluorescence polarization increases.

Fluorescence polarization assays have been primarily utilized in the clinical laboratory for the analysis of small molecular weight substances, such as drugs and hormones. In one technique, polarization fluoroimmunoassay, the increased signal associated with binding of an antibody to a fluorophore-labeled antigen is measured (131). Assays for gentamicin, phenytoin, amphetamine, and other substances have been described (134,135,136 and 137). The recent advent of simpler, less expensive instrumentation for the laboratory may increase the use of fluorescence polarization.

The excited-state lifetime of a fluorescent compound has been applied in a type of fluorescent immunoassay termed time-resolved fluorescence immunoassay. These assays use fluorochromes with relatively long decay times, especially the rare earth metal chelates (10 to 10,000 milliseconds). In time-resolved fluorescence immunoassay, a rapidly pulsing excitation source is used, and fluorescence intensity is measured at a fixed interval after excitation. Because the decay time of substances that may cause background fluorescence is usually less than 10 nanoseconds, the inherent sensitivity of these methods is much greater than conventional fluorescent immunoassays (83,138). The rare earth metal europium has been most extensively used as a label in time-resolved immunoassays, although other trivalent lanthanide ions, such as terbium and samarium, have been used as well (138). Fluorometers for time-resolved fluorescence immunoassay are modified to measure only a portion of the emission cycle.

Particle-based flow cytometric fluorescence immunoassays have been described. For example, fluorescence quantitation by flow cytometry has been applied in an equilibrium-type competitive-binding fluorescence immunoassay (139). In this assay, relatively large (10 μm diameter) antibody-coated nonfluorescent particles were used with very small (0.10 μm diameter) antigen-coated fluorescent latex particles. During incubation with the sample, soluble unlabeled antigen competes with the small, antigen-labeled particles for binding to the larger spheres. The fluorescence distribution of 5,000 of the large spheres is determined by flow cytometry and read against a standard curve prepared with known concentrations of antigen. The sensitivity of this technique was 10^{-12} mol/L for quantitation of the antigen HRP, and the sensitivity was increased to 10^{-12} mol/L in a double-antibody sandwich assay. Lindmo et al. (140) described a different flow cytometric technique using two particle types coated with antibody of the same specificity but different affinity.

Chemiluminescent Immunoassays

Chemiluminescence is the emission of light after energy is transferred to the chemiluminescent molecule via a chemical reaction (141). Chemiluminescence and chemiluminescence energy transfer have been used for the detection of a variety of substances in the 10^{-18} to 10^{-21} mol/L range (108,142,143,144,145,146 and 147). Most of these assays utilize synthetic chemiluminescent compounds such as luminol (3-amino-phthalhydrazine), luminol derivatives such as isoluminol, or acridinium ester derivatives as labels for antigens or antibodies. Photon emission is measured in a luminometer or liquid scintillation counter after the addition of an oxidizing agent (e.g., H_2O_2) and a catalyst (e.g., hemin, lactoperoxidase, copper or cobalt ions). Although the low efficiency (less than 1%) of photon emission limits the sensitivity of assays based on chemiluminescence, the stability of the reagents and the low background activity are advantages. Chemiluminescence energy transfer has been used to increase the sensitivity of the assay (145).

Interferences in Immunoassays

Several molecules can cause false-positive or false-negative reactions in immunoassays (23,148,149). Commonly considered is the phenomenon known as cross-reactivity, in which an epitope or epitopes on one molecule have enough similarity with the analyte that they are recognized by the antibody or antibodies used in the assay. Early assays for TSH, for example, had significant cross-reactivity with similar hormones with identical α and similar β chains, such as luteinizing hormone, follicle-stimulating hormone, and hCG. More specific antibodies utilizing two-site principles have largely eliminated this problem for these hormones, but for some drugs and steroid hormones this is still an important consideration.

High-Dose Hook Effect

For immunometric assays, when an analyte is present in extraordinarily high concentration, it is possible to exceed the binding capacity of the immobilized capture antibodies. When this occurs in a one-step assay, the analyte can then react with the labeled antibody, preventing the formation of some of the sandwich complexes that would usually form, thus decreasing the signal measured and the apparent analyte concentration. A signal versus concentration plot reaching such high analyte levels actually begins to trail off or “hook” when high enough concentrations are reached (150). The high-dose hook effect is named for this characteristic curve. Manufacturers of diagnostic kits typically generate this graph, then make a claim in the package insert that samples with analyte concentrations up to X will not have the high-dose hook effect (Fig. 61.20). There is usually an error code generated by the instrument when a value is above the upper limit of reportability but below the level at which the hook effect will not interfere with the assay, alerting the operator that the sample needs to be diluted and rerun. Note that in a two-step assay, the signal reaches a maximal level but never decreases with increasing concentration. Thus, this type of assay format does not exhibit this hook effect.

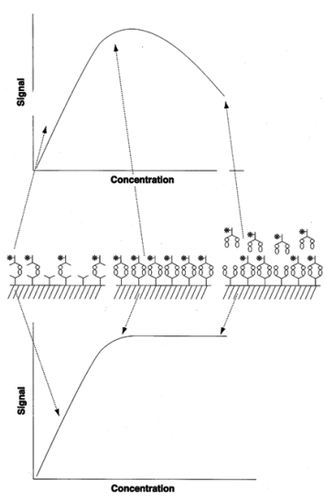

FIGURE 61.20. Principle of high-dose hook effect.

Heterophile Interference

This topic has been very well presented by several authors in great detail. The basic issue is that antibodies can be formed by humans, for a variety of reasons, that interact with the antibodies that are used as reagents in various assays. The most commonly described variant of this is referred to as HAMA or human anti-mouse antibodies. These HAMA can react with mouse monoclonals used in many assays and, depending on the assay configuration, can cause a false-positive or a false-negative result. Although HAMA is generally illustrated and thought of as a positive interference, an interesting report describing the development of a HAMA-resistant carcinoembryonic antigen assay found that both positive and negative interferences could be found in different patient specimens in the same assay (151).

Automation of Immunoassays

The most significant advance in immunoassay progress during the past decade has undoubtedly been in the area of automation, specifically random access automation. Before the 1990s, instrumentation had been available to perform assays in a batch mode, i.e., the instrument could analyze samples for only one analyte at a time and did not allow samples to be added after the run had begun. Random access automation, however, allows the analysis of multiple analytes on multiple consecutive samples without the need to pause between analytes or samples. This has allowed a tremendous increase in productivity for technologists, greatly reduced turnaround times for many analytes, and improved stability as well. Calibration and on-board reagent stability of greater than 1 month are now commonly achieved. Assays adapted to such platforms include drugs, hormones, specific proteins, tumor markers, and antibodies to infectious agents. The emphasis on random access immunoassay systems is owing to manufacturers' solving the problem of automating an effective wash step and configuring the assays on their instruments in such a way that incubation times were either constant for most assays or that variable incubation times did not interfere with throughput.

This emphasis on automation has been accompanied by the emphasis on enzymes as labels for immunoassays. Although fluorescent or colorimetric substrates were often used in early systems, chemiluminescent substrates are commonly employed with new instruments today.

CELLULAR IMMUNOASSAYS

Part of "61 - Basic Principles of Immunodiagnosis"

The development of assays for the identification and enumeration of immune cells and for the assessment of cell function has been essential for the understanding of the immune system. In addition to applications in organ transplantation, these assays have been useful in the diagnosis and treatment of patients with malignant neoplasms, autoimmune diseases, and infectious diseases. The major technical developments in cellular immunology have included:

- *In vitro* cytotoxicity assays
- The discovery and utilization of anti-HLA antisera from multiparous women in histocompatibility testing
- Cryopreservation and thawing of lymphocytes
- Assays of cell-mediated immune function (mixed lymphocyte culture, antibody-dependent cell-mediated cytotoxicity)
- Cellular typing using cell-mediated lympholysis (CML), homozygous typing cells, and primed lymphocyte typing
- Miniaturization, automation, standardization, and improved quality control
- Monoclonal antibody technology, flow cytometry, and immunochemical analysis
- Gene cloning, DNA sequence analysis, and recombinant DNA technology

Basic Techniques in Cellular Immunoassay

Specimen Collection and Cell Preparation

Specimen Collection and Transportation

A successful cellular assay begins with the procurement of the proper specimen in the correct manner with prompt transportation of the specimen to the clinical laboratory. Care must be taken that the person obtaining the specimen is correctly informed about specimen requirements for the assay that has been ordered and that any special instructions for obtaining the specimen are followed. For most cellular immunoassays, 5 to 20 mL of anticoagulated venous blood is required, although cellular immunoassays may require serum or plasma, other body fluids, or lymphoid tissue. Because immune cells and many immune substances are labile, the specimen should be received within the laboratory and processed within 24 hours. Most specimens are maintained at room temperature during transportation.

Cell Separation and Purification

The peripheral blood, lymph nodes, spleen, and other components of the immune system consist of a heterogeneous mixture of cell types (lymphocytes, monocytes, granulocytes, macrophages, RBCs, and platelets). However, most cellular assays assess the properties or function of one particular cell type and cannot be performed in the presence of large numbers of contaminating cells. Purified lymphocyte preparations are preferred

in many cellular assays because they strongly express HLA class I and II antigens, whereas monocyte cell preparations are utilized for many cellular assays, but other assays require isolated granulocytes, platelets, or even a purified subset of a particular cell type. Some techniques for the isolation and purification of cells are based on differences in basic physical properties (e.g., size, density, granularity), and others rely on functional differences (e.g., adherence, phagocytosis), or the presence of a particular cell surface antigen (152).

Whole blood leukocyte preparations are adequate for many purposes, including the enumeration of lymphocyte subsets by flow cytometric immunophenotypic analysis. The direct removal of RBCs from peripheral blood by ammonium chloride lysis is being increasingly utilized for routine lymphocyte enumeration studies. This technique is efficient, rapidly performed, and minimizes specimen handling. In addition, the selective loss of some lymphocyte subsets associated with density gradient centrifugation is avoided.

Cell density is the conventional property used for the separation of mononuclear cells (lymphocytes and monocytes) from other cell types. In cell isolation procedures using differences in cell density, the unpurified cell suspension is centrifuged in a solution containing a single or multilayer density gradient. After centrifugation, cells are distributed in the solution in layers based on differences in their density. A Ficoll-Hypaque gradient is most commonly used for this purpose (152,153,154,155,156,157 and 158). Ficoll-Hypaque is comprised of sodium diatrizoate (3,5-bis acetylamino-2,4,6 tri-iodo benzoic acid, hypo-opaque, iso-opaque) and Ficoll. Ficoll is a high molecular weight sucrose polymer (specific gravity, 1.076 to 1.078), whereas Hypaque is a dense iodinated organic compound also used as a radiographic contrast medium. Ficoll contributes viscosity to the solution and promotes rouleaux formation of the RBCs, whereas Hypaque increases the viscosity of the solution. When properly prepared, a Ficoll-Hypaque solution has a specific gravity of 1.077 at room temperature and is more dense than lymphocytes, monocytes, and platelets but less dense than granulocytes and RBCs.

In practice, blood for mononuclear cell isolation is collected aseptically into a heparinized container, a buffy coat is prepared and layered over or under Ficoll-Hypaque. Mononuclear cell preparations are prepared from tissue specimens by mincing the tissue into a tissue culture media [usually Roswell Park Memorial Institute (RPMI) medium containing 5% fetal calf serum, RPMI/5% fetal calf serum] or by gently forcing the tissue through nylon mesh. Wire or nylon mesh of various grades is also useful in removing cell aggregates and removing stroma and extraneous pieces of tissue from a cell preparation. Cell suspensions prepared from lymphoid tissue usually contains few erythrocytes and can be directly placed on Ficoll-Hypaque. After a one-step centrifugation with Ficoll-Hypaque, platelets (specific gravity, 1.040) and plasma (specific gravity, 1.025 to 1.029) are located above the Ficoll-Hypaque, lymphocytes (specific gravity, 1.070) and some platelets are found at the plasma-Ficoll-Hypaque interface, and granulocytes (specific gravity, 1.087 to 1.092) and RBCs (specific gravity, 1.093 to 1.096) form a pellet at the bottom of the tube (Fig. 61.21). Residual platelets are removed by washing and a low-speed spin. Incubation of the buffy coat preparation at 37°C with carbonyl iron can also increase the purity of the final cell preparation because neutrophils and monocytes phagocytize the carbonyl iron, thus increasing their density and allowing better gradient separation. Isolated lymphocyte preparations prepared from fresh peripheral blood by Ficoll-Hypaque isolation should provide 1×10^6 lymphocytes per milliliter that are 90% to 100% viable and contain fewer than 5% granulocytes and monocytes. Granulocytes can also be obtained from a Ficoll-Hypaque separation by removing the supernatant, suspending the pelleted cells, and removing RBCs by the addition of an ammonium chloride solution.

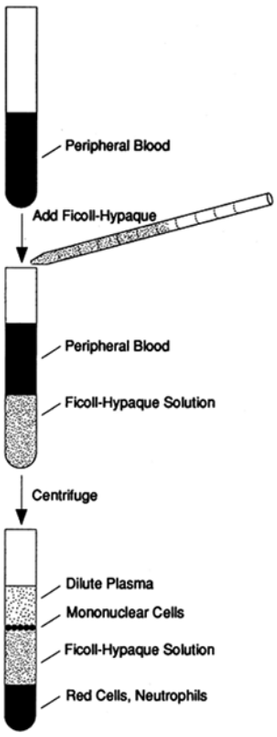

FIGURE 61.21. Technique of Ficoll-Hypaque density isolation of mononuclear cells. Whole blood is layered unto a Ficoll-Hypaque mixture with a specific gravity of 1.007, and the test tube is centrifuged. During centrifugation, the lymphocytes are separated from the other formed elements of the blood and form a discrete layer at the plasma-Ficoll-Hypaque interface, which can easily be removed with a pipette. (From from Riley RS, Mahin EJ, Ross W. *Clinical applications of flow cytometry*. New York: Igaku-Shoin Medical Publishers, 1993, with permission.)

Rosetting with SRBCs is an older method for the separation of T lymphocytes from other mononuclear cells (159,160). In this procedure, a monocyte-depleted peripheral blood mononuclear cell preparation is prepared by Ficoll-Hypaque or another technique. After incubation with SRBCs, the rosetted T cells are

separated from the B lymphocyte–enriched medium by density gradient separation. T cells can be isolated from the rosettes by ammonium chloride lysis of the RBCs. Pretreatment of the SRBCs with neuraminidase, 2-S-aminoethyl-isothiouromium bromide, or papain can be used to increase the purity of the final cell preparations. B lymphocytes can be rosetted with anti-human Fab-coated SRBC or ox erythrocytes coated with anti-B cell monoclonal antibodies (160).

The anti-$F(ab')_2$ monolayer technique for the isolation of B lymphocytes utilizes polystyrene flasks absorbed with affinity-purified anti-human $F(ab')_2$. Surface immunoglobulin-positive B lymphocytes in a monocyte-depleted peripheral blood mononuclear cell preparation adhere to the surface of the flask. Nonadherent T lymphocytes are washed away, whereas the adherent B lymphocytes are eluted through the use of immunoglobulin-rich serum (161,162). This technique results in highly purified T and B lymphocyte preparations but requires more technical expertise to establish and quality control.

Immunomagnetic separation techniques are increasingly replacing older cell separation techniques, particularly when a cell population with a selectively enriched cell subpopulation is needed (163,164). This technique utilizes detachable immunomagnetic microspheres labeled with monoclonal antibody(s). The initial cell suspension is first incubated with the microspheres, then a magnetic field is applied to separate the microspheres with attached cells. The cells are removed from the microspheres by washing.

Assessment of Cell Purity and Viability

Adequate cell purity and viability are essential for most cellular assays. In this regard, dead cells can cause false-negative reactions by nonspecifically absorbing antibodies and lowering antibody titer. In addition, false-positive reactions may also occur in assays using cell death as the end point (i.e., microlymphocytotoxicity) because dead cells previously present in the assay cannot be differentiated from cells killed during a microlymphocytotoxicity assay. For histocompatibility assays, 80% or more of the cells must be viable for accurate results (165). Assays using purified cell preparations require fewer than 20% contaminating cells.

Generally, cell preparations of adequate viability can be obtained from peripheral blood specimens if they are processed within 8 to 10 hours after drawing. Bone marrow, body fluids and effusions, and tissue specimens must be processed as soon as possible. Cryopreservation or storage at reduced temperature in culture media is best if the specimen cannot be processed immediately. Enzymatic treatment can also be utilized to remove nonviable cells. DNase is commonly used for this purpose because it enzymatically digests dead cells but is harmless to living cells at the concentration used.

Cell viability is usually determined by light microscopy and the use of a vital dye, such as trypan blue or eosin, which is incorporated into dead cells but excluded from living cells (165,166). In this technique, an aliquot of the cell suspension is mixed with the dye solution and placed onto a hemocytometer. After settling, the nonstained viable cells are rounded and refractile, whereas dead cells are round and flattened. A minimum of 100 cells is examined and the proportion of viable cells is determined and expressed as the percentage of viability. Cell concentration can be adjusted at the same time. The use of fluorescent dyes provides a more accurate alternative to vital dyes. In the most recent variation of the fluorescent dye technique, dual-color fluorescence is measured by flow cytometry, using the dyes fluorescein diacetate and propidium iodide. Fluorescein diacetate is a nonpolar, nonfluorescent compound that readily permeates the cell membrane. However, in viable cells, it is rapidly converted to a polar, highly fluorescent (green emission) substance that is trapped within the cell. Propidium iodide is a highly polar compound that emits light in the red region of the spectrum and can only permeate cells with damaged cell membranes. In practice, the cell suspension is stained with solutions of both dyes, and the proportion of cells with high green fluorescence and low red fluorescence (viable cells) or low green fluorescence and high red fluorescence (nonviable cells) is determined by flow cytometry (167,168).

Purity assessment can be performed by morphologic examination with light microscopy or phase contrast microscopy or by immunophenotypic analysis with flow cytometry or fluorescent microscopy (165).

Cryopreservation and Thawing

Long-term storage of cells (months to years) is required for histocompatibility analysis and may be desirable for the storage of functionally intact cells from patients with malignant tumors or immunologic diseases. Controlled-rate freezing and preservation in the vapor phase of liquid nitrogen are most commonly used for long-term cell preservation (166,168,169,170,171,172 and 173). Dimethyl sulfoxide is usually used to prevent damage during the process. If carefully frozen and thawed, cells remain viable for indefinite periods of time (174).

Immunofluorescent Staining

Monoclonal antibodies specific for cell surface antigens are commonly utilized for the enumeration of mononuclear cell populations and subpopulations. FITC is the most popular fluorescent probe for labeling monoclonal antibodies, although rhodamine, phycoerythrin, Texas red, and other fluorochromes are also used. Of the five classes of immunoglobulin (IgG, IgM, IgA, IgD, IgE), monoclonal antibodies of the IgG class are most often used in clinical flow cytometric studies. In addition, the Fc portion of the antibody molecule is usually removed by pepsin treatment to reduce binding to Fc receptors, which are present in great numbers on many types of cells. Removal of the Fc portion of the molecule leaves the F(ab)2 fragment, which consists of the two F(ab) antigen-binding sites. Two different immunofluorescent staining techniques (direct and indirect) are utilized, depending on the monoclonal antibodies available and the goal of the analysis.

Direct immunofluorescent staining is used when large quantities of a monoclonal antibody can be obtained and easily labeled with a fluorochrome. In this technique, the labeled monoclonal antibody is applied to the cell in a one-step staining process requiring the following steps (Fig. 61.22).

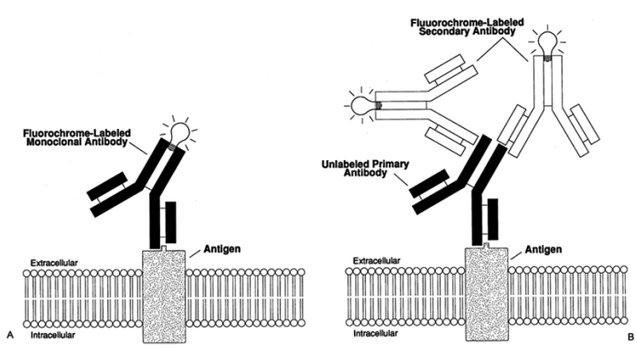

FIGURE 61.22. Principle of direct and indirect immunofluorescent staining. (From Riley RS, Mahin EJ, Ross W. *Clinical applications of flow cytometry*. New York: Igaku-Shoin Medical Publishers, 1993, with permission.)

- Mix cell suspension with FITC-labeled antibody solution
- Incubate
- Wash cells
- Analyze by flow cytometry

Nonspecific binding is not a problem if monospecific antibodies are used in a direct staining procedure. In addition, direct staining is rapid and easily performed and permits simultaneous staining with two or more labeled monoclonal antibodies (multiparametric analysis). Multiparametric analysis is more economical than analysis using a single labeled marker per cell (single color immunofluorescent analysis) and has the additional advantage of providing a means to assess the interrelationship between cell populations and analyze subpopulations of cells. Most commonly, two monoclonal antibodies, one labeled with FITC and the second with rhodamine or phycoerythrin, are applied to the cell suspension at the same time (two-color or dual-color immunofluorescent analysis). More recently, the simultaneous use of three monoclonal antibodies has become popular, in part because of the development of a fluorochrome consisting of a tandem conjugate of R-phycoerythrin plus Texas red. The excitation of this compound results in energy transfer from phycoerythrin to Texas red and the emission of light at a wavelength distinct from that of phycoerythrin. Specifically, the phycoerythrin component of the conjugate excites at 488 nm and emits light with a maximum of 575 nm. The phycoerythrin emission in turn excites adjacent Texas-red molecules, which emit red light with a maximum of 618 nm. In three-color analysis, one monoclonal antibody is labeled with FITC, a second with phycoerythrin, and the third with the tandem conjugate of Texas red and phycoerythrin. Unfortunately, the sensitivity of direct immunofluorescent staining is limited in circumstances in which a small number of surface markers are present. In addition, cell autofluorescence can interfere with the detection of the fluorescence emission from the fluorochrome, and labeled monoclonal antibodies are not yet available for every substance of biological interest. In systems in which two or more fluorochromes are simultaneously analyzed, differentiation of the separate emission signals requires more complex optical and electronic systems and the need for additional quality control.

In indirect immunofluorescent staining procedures, an unlabeled antibody (primary antibody) is first attached to the cell and then developed in a second step, utilizing a fluorochrome-labeled monoclonal antibody directed against the first monoclonal antibody (secondary antibody). Polyclonal FITC-labeled goat anti-mouse antibody is often used as the secondary antibody (Fig. 61.22). The following steps are required.

- Mix cell suspension with unlabeled monoclonal antibody
- Incubate
- Wash
- Apply FITC-labeled anti-mouse antibody
- Incubate
- Wash
- Analyze by flow cytometry

Indirect immunofluorescent staining is economical because a single FITC-labeled secondary antibody can be used with many primary monoclonal antibodies. However, it is technically more complex and time-consuming than direct staining and produces a relatively higher degree of background staining. Indirect staining is primarily used when a limited quantity of a monoclonal antibodies is available to avoid the loss of antibody associated with purification and conjugation and for the detection of cell surface antigens present at a low density. Multiparametric analysis using indirect immunofluorescent staining is impractical because

it requires the use of antibodies obtained from different species.

Removal of Autoantibodies

Autoreactive antibodies are commonly present in patients with connective tissue diseases, chronic liver disease, some renal diseases, chronic viral infections, and other diseases. In histocompatibility testing, the presence of autoantibodies (especially those directed against HLA class I and II antigens) may interfere with the detection and analysis of alloreactive antibodies. Autoreactive antibodies are detected by the inclusion of an autocontrol (patient's serum with patient's lymphocytes) in every histocompatibility assay. If the autocontrol is positive, attempted removal of the autoreactive antibodies by absorption with lymphocytes from the same individual is attempted and the assay is repeated. Another technique [dithiothreitol (DTT) treatment] is utilized when autoreactive antibodies cannot be removed by absorption.

Autoantibodies and the circulating pan–T-cell antibodies found in lupus patients are usually of the IgM class and are inactivated during treatment with DTT. The anti-HLA antibodies resulting from previous transplantation and/or multiple blood transfusions are usually of the IgG class and are not affected by DTT. DTT reduces the IgM molecule to its constituent units, leaving the IgG molecule intact. The finding of a positive HLA cross-match with both untreated and DTT-treated serum is consistent with the presence of anti-HLA antibodies. A positive cross-match with untreated serum, but not with DTT-treated serum, suggests the presence of autoreactive antibodies and is presumptive evidence for the absence of anti-HLA antibodies.

Cell Identification and Enumeration

Lymphocytes can be subdivided into stages of differentiation and into functionally active subsets, based on the cell surface antigens that are present. A revolution in immunology was brought about by the subclassification of lymphocytes into T and B cells based on the cell surface antigens and has now expanded to the analysis of other cells, such as monocytes, macrophages, myeloid stem cells, tumor cells. Clinically, cell surface analysis has been useful both in the detection of abnormal cells and in the analysis of normal cells that vary in different diseases. Specific clinical applications of cell surface marker analysis (immunophenotypic analysis) include:

- Determining the origin and stage of differentiation of lymphomas and leukemias
- Detecting early recurrence of hematologic malignancies
- Diagnosing and monitoring inherited and congenitally immunodeficient patients
- Chemotherapeutic monitoring
- Pre- and posttransplantation monitoring and evaluation

Rosetting

Rosetting techniques were originally used in the differentiation of T and B lymphocytes (159,160). Because T lymphocytes have a cell surface receptor (CD2) that binds SRBCs, aggregates of T lymphocytes and SRBC (E rosettes) are formed when the two cell types are incubated together. The presence of three or more SRBCs adhering to a lymphocyte is considered a rosette and evidence for identifying the cell as a T lymphocyte. Rosettes are visualized and counted under the light microscope, with the percentage of rosetting lymphocytes taken as the percentage of T cells. B lymphocytes can be enumerated with rosetting with antibody-coated SRBCs (EA rosette) or complement-coated SRBCs (EAC rosette). Unfortunately, these techniques are subjective, labor intensive, and inaccurate. In addition, the immature lymphocytes found in many types of acute leukemia and other hematologic malignancies may not possess the SRBC receptor or Fc receptors. Because of these problems, flow cytometry has become the method of choice for the quantitation of cell populations.

Assays of Cell Function

Lymphocyte Transformation Immunoassays

Lymphocyte transformation assays directly measure the ability of lymphocytes to respond to a stimulus. Because lymphocyte functional abnormalities can occur in the absence of changes in morphology or relative or absolute cell numbers, these assays are important in the evaluation of patients with congenital immunodeficiency or acquired immune defects as a result of viral infections or immunosuppressive therapy. In addition, the principle of lymphocyte transformation is used in different ways, including identifying lymphokines, detecting antigen sensitization, and detecting transplantation antigens.

Principles of Lymphocyte Transformation

The basis of all lymphocyte transformation assays is the detection of metabolic changes that occur in the lymphocyte during activation. In this regard, virgin or resting lymphocytes that encounter their specific foreign antigen or a specific chemical signal are triggered to proliferate and differentiate into an activated form that can carry out the predestined effector or regulatory functions of the cell. During this transformation process, T cells synthesize DNA, RNA, and protein, express HLA class II antigens, and synthesize and release lymphokines and other products. Morphologically, these changes are reflected by an increase in cell size, the acquisition of abundant basophilic cytoplasm, the appearance of multiple nucleoli, and changes in chromatin characteristics (lymphoblasts). Repeated mitotic divisions of the transformed cell occur, the progeny become progressively smaller, and the cell eventually resumes the size and appearance of the original unactivated lymphocyte.

The incorporation of tritiated thymidine (^{3}H-thymidine) has been the standard method for the quantitation of cellular proliferation (175). However, techniques utilizing fluorescent dyes have been found to provide equivalent sensitivity without the requirement of radioisotopes. In addition, flow cytometric analysis permits multiparametric quantitation of the cell populations under study and is more rapidly performed than radioisotopic determination. In one type of flow cytometric analysis, the mitogenic response of lymphoid cells, cellular activity in mixed lymphocyte cultures, and related parameters have been performed by measuring cell cycle progression with a DNA-specific

fluorochrome, such as propidium iodide (176). The use of a fluorescent-labeled monoclonal antibody against Ki67, a nuclear antigen that appears in proliferating cells, has been used for measuring lymphocyte proliferation (177), together with measuring the incorporation of an analog of uridine [bromodeoxyuridine (BrdUrd)] (178) and PKH26 dye, a fluorescent dye directly incorporated into the cell membranes of living cells (179).

Mitogen-Induced Blastogenesis

Mitogens or interleukin-2 are used to induce lymphocyte transformation. Of the mitogens, phytohemagglutinin and concanavalin A induce T blastogenesis, whereas pokeweed mitogen and staphylococcal protein A trigger B cell activation. In the past, the incorporation of tritiated thymidine has been the standard method for determining lymphocyte transformation. In this procedure, lymphocytes are isolated with Ficoll-Hypaque density gradient centrifugation and cultured for 2 to 4 days with a mitogen (or 5 to 7 days with an antigen or mixed allogeneic lymphocyte preparation) in a media enriched with human AB serum. Tritiated thymidine is added to the culture medium, and the plates are incubated for an additional 18 hours. Cells are isolated (harvested) from the plates using a special device (cell harvester) and transferred to disks of filter paper (Fig. 61.23). The disks are placed in scintillation fluid and counted for tritium in a liquid scintillation counter.

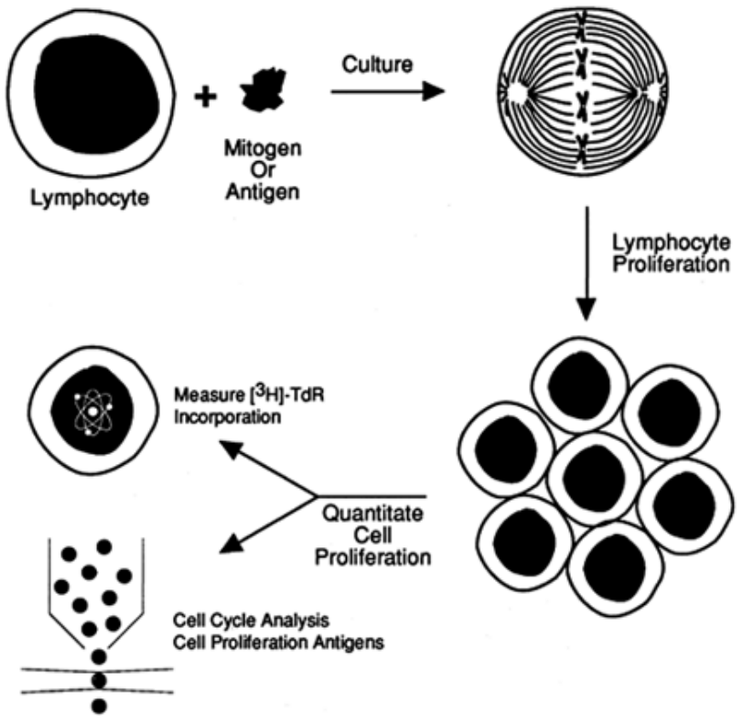

FIGURE 61.23. Principle of lymphocyte stimulation assay. Lymphocytes are cultured with antigen or mitogen. If stimulation occurs, a proliferative reaction takes place, with the formation of daughter cells. The amount of proliferation can be determined from tritiated thymidine (^{3}H-TdR) incorporation, by flow cytometric cell cycle kinetic analysis, or by measuring a cell proliferation antigen such as Ki67. (From Riley RS, Mahin EJ, Ross W. *Clinical applications of flow cytometry*. New York: Igaku-Shoin Medical Publishers, 1993, with permission.)

Several controls are necessary for lymphocyte proliferation assays because the assay may be influenced by the number of cultured cells, incubation time and temperature, mitogen concentration, and various inhibitory factors that may be present. The results are usually expressed as a stimulation index, that is, the ratio of radioisotope incorporation into the test and control cells. Alternatively, the relative proliferation index (RPI) can be calculated (175,180). The RPI is the ratio of the Dcpm (counts per minute of stimulated cells minus counts per minute of unstimulated control cells) of the test subject to the Dcpm of a panel of normal individuals that are tested simultaneously. The RPI is theoretically more accurate because it corrects for the large individual variations in blastogenic response. Specific soluble antigens may be used in place of a mitogen. Flow cytometric assays of blastogenesis have also been reported (177,181).

Mixed lymphocyte Culture

The mixed lymphocyte culture assay (MLC) is a special type of lymphocyte stimulation assay based on the ability of histoincompatible lymphocytes from one individual to stimulate the lymphocytes of another individual (mixed lymphocyte reaction) (182,183,184 and 185). Although complex in etiology, the MLC phenomenon is determined by the D locus of the HLA system. When two cells share common D loci, they are not able to stimulate each other, but when the D loci are different, the cells are stimulated. The MLC is unilateral (one way) when one group of cells is made incapable of responding (by treatment with radiation or mithramycin) or bidirectional (two way) when no radiation or mithramycin is utilized. The one-way MLC is almost exclusively used in clinical immunology. In the one-way MLC, the untreated cells are termed the responder population, and the treated cells are the stimulator population.

In the MLC, purified lymphocyte suspensions are prepared from the individuals to be tested as well as from controls. Responder cells are distributed into the wells of round-bottom microtiter plates. Stimulator cells are first irradiated with 3,000 rad using a cesium irradiator or other appropriate source of radiation and then added to appropriate wells of the microtiter tray. After an incubation period of 4 to 6 days in a humidified atmosphere of 5% CO_2 in air, ^{3}H-thymidine (usually 1 μCi) is added to each well, and the trays are incubated for an additional 18 hours. The

cells are then harvested onto glass or paper fiber filters, using a cell harvester with distilled water. After drying, the radioactivity present on each filter is counted (cpm or dpm) in a scintillation counter (Fig. 61.24).

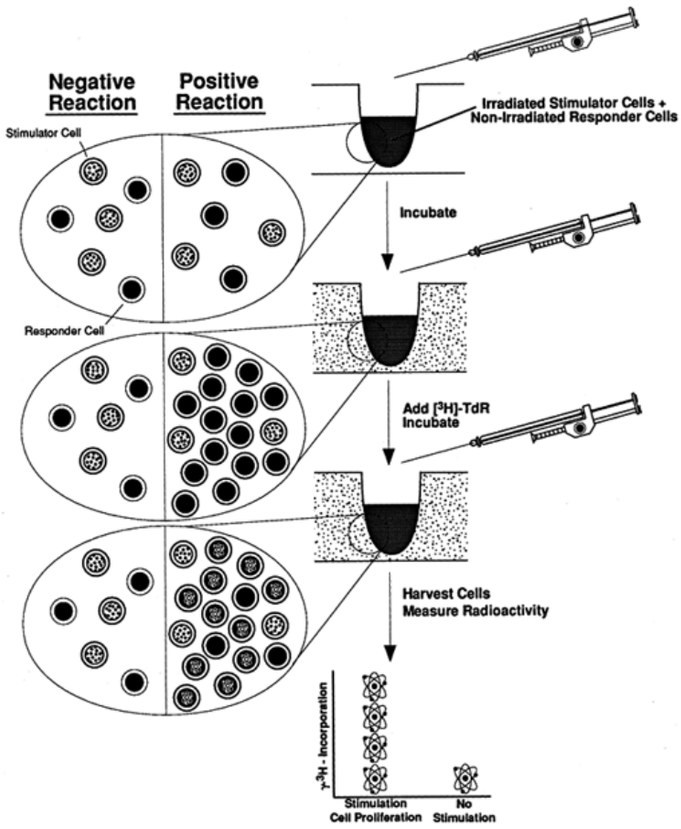

FIGURE 61.24. The one-way mixed lymphocyte culture assay. Irradiated stimulator cells, which are incapable of cell division, are mixed with nonirradiated responder cells, which can proliferate and divide. After incubation under cell culture conditions for approximately 1 week, the responder cells proliferate in the presence of a disparity in the HLA-D locus **(right)**, whereas no proliferation occurs if the responder and stimulator cells are HLA-D compatible **(left)**. Tritiated thymidine is added to the reaction mixture, and the degree of proliferation is determined by liquid scintillation counting. (From Riley RS, Mahin EJ, Ross W. *Clinical applications of flow cytometry*. New York: Igaku-Shoin Medical Publishers, 1993, with permission.)

Numerous factors must be considered in the performance and interpretation of the MLC. Because the reaction is complex, a lack of stimulation between two cell types cannot be considered conclusive evidence of histocompatibility at the HLA-D locus. Other minor histocompatibility loci may also be involved as well as some non-HLA loci. In addition, specific and nonspecific serum factors can inhibit the assay, and lymphocytes from diseased individuals may not perform well. Numerous controls (including autologous controls) must be included and must performed as expected for the results to be accepted as valid.

The primary use of the MLC assay in patient care is to assist in the selection of a compatible donor for a kidney or bone marrow transplant. The MLC assay is a predictor of host response to a transplanted organ. To prevent graft rejection or graft-versus-host disease, the donor and recipient cells must be mutually nonstimulatory. Practically, the use of the MLC is restricted to the selection of living related donors because the performance time of the assay is far longer than the organ preservation time limit. Another use of the MLC is to determine the HLA-D type. For this purpose, irradiated stimulator cells that are homozygous at

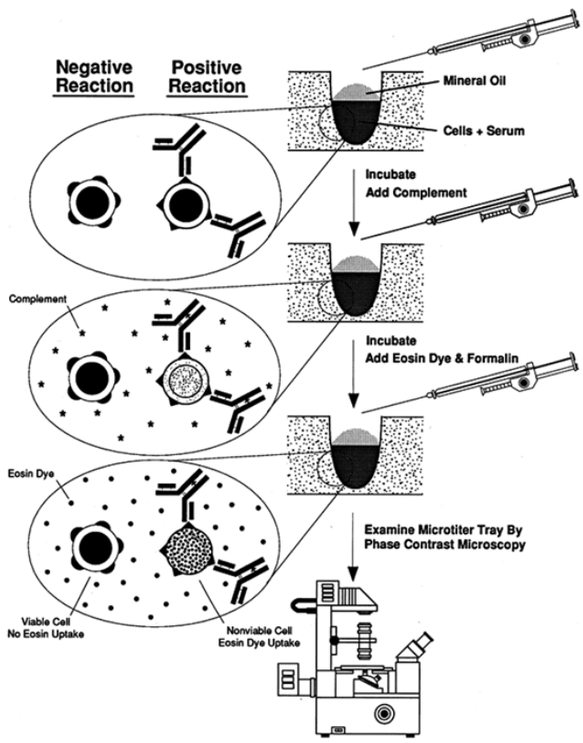

FIGURE 61.25. Principle of microlymphocytotoxicity by dye exclusion. Cells and serum are incubated together in the wells of a microtiter tray. Mineral oil at the top of the wells prevents fluid evaporation. Complement is added, and a second incubation is performed. The cells are washed, eosin is added, and the cells are fixed with formalin. Cells that fixed antibody and were killed through the action of complement take up of eosin and appear dark and nonrefractive under a phase-contrast microscope. In contrast, living cells are refractive and easily identified by phase contrast microscopy. Variation of the microlymphocytotoxicity assay are used for HLA typing, the HLA cross-match, and detection of anti-HLA antibodies. (From Riley RS, Mahin EJ, Ross W. *Clinical applications of flow cytometry*. New York: Igaku-Shoin Medical Publishers, 1993, with permission.)

the HLA-D locus are used in a one-way MLC. Stimulation suggests nonidentity of the HLA-D antigens.

Flow cytometric quantitation of the mixed lymphocyte reaction has been reported. In the method reported by Cram et al. (181) and by Kanda et al. (186), nuclear DNA content during lymphocyte blastogenesis was determined with a DNA-specific fluorochrome (propidium iodide). In this technique, the proliferative index (percentage of cells in the S phase and G_2M phase of the cell cycle) is a direct measurement of *de novo* DNA synthesis. A good correlation (r = 0.9493) was observed between the flow cytometric measurement of the MLR and the results using a traditional MLC with ^{3}H-thymidine incorporation. Although the flow cytometric determination is potentially more accurate than the MLC and avoids the use of radioisotopes, the flow cytometric technique has not achieved routine use in histocompatibility testing at present. Bontadini et al. (178) measured BrdUrd incorporation by flow cytometry to measure the mixed lymphocyte reaction. BrdUrd is an analog of thymidine against which a monoclonal antibody is available. BrdUrd incorporation is an extremely sensitive method for the detection of cycling cells because the incorporation of a few molecules of BrdUrd can be detected. This sensitivity permitted the detection of cell proliferation 24 to 48 hours before tritiated thymidine (^{3}H-TdR) incorporation.

Spontaneous Blastogenesis

Spontaneous blastogenesis assays determine the ability of cultured, unstimulated lymphocytes to undergo activation. The assay is usually performed by measuring the rate of ^{3}H-thymidine incorporation. Increased spontaneous blastogenesis in transplant recipients has been associated with allograft rejection.

Cytotoxicity Assays

Assays with cell death (cytotoxicity) as the end point are commonly used in cellular immunology. These assays are used in various ways to measure cell function activity and to detect cell surface antigens. In these assays, cytotoxicity may occur as the result of complement activity (complement-mediated cytotoxicity) or the direct effect of one cell on another (cell-mediated cytotoxicity). Until recently, target cell lysis was determined either by the release of a substance such as chromium 51 (^{51}Cr) from the cell on death or by the incorporation of a vital dye such as eosin or trypan blue. However, the accuracy and reproducibility of these assays have been compromised by problems such as poor uptake or nonspecific release of the marker, the length and technical complexity of the assays, or the need for the subjective interpretation of the results. The advent of new markers, in combination with the quantitative and multiparametric abilities of the flow cytometer, may make cellular assays much more practical for routine use in patient care. One example of these new markers is PKH-1, a fluorochrome that emits light in the green region of the spectrum, binds avidly to the cytoplasmic membrane, and is not transferred to other cells. In one application, PKH-1 is used to label the target cells, and a second fluorochrome with a red emission signal (propidium iodide) is used to detect nonviable cells (187). This combination of markers allows statistically valid quantitation of both dead and live effectors and targets, permitting the simultaneous determination of the percentage of target lysis, effector-to-target ratio, viability of the effector cells at the termination of the assay, and viable effector-to-target cell ratios. The use of the fluorescent dyes carboxyfluorescein diacetate and/or propidium iodide for the determination of lymphocytotoxicity has been described (187,188 and 189).

Microlymphocytotoxicity Assay

One type of cytotoxicity assay, the dye exclusion lymphocytotoxicity assay, is a commonly used procedure for the detection of an antibody-antigen interaction on a cell surface. The lymphocytotoxicity assay was introduced by Terasaki and McClelland in 1964 and was later accepted as the National Institutes of Health (NIH) standard procedure for histocompatibility testing. In the histocompatibility laboratory, variations of the lymphocytotoxicity assay are used for HLA typing, the detection of anti-HLA antibodies, and cross-match testing.

In the lymphocytotoxicity procedure, viable cells (usually lymphocytes) are incubated with serum containing antisera. If a cell surface antigen is present that antibodies in the sera recognize, an antigen-antibody complex will form on the surface. These complexes are detected by the sequential addition of rabbit complement and a vital dye, such as eosin, to the reaction mixture. The occurrence of complement fixation on the cell membrane leads to activation of the terminal complement components and eventually to cell lysis and death. Dead cells are detected and counted by phase microscopy after differential uptake of the eosin dye and fixation with formalin. Antibody-bound lymphocytes will die, take up the eosin dye, and give a positive reaction, whereas unbound lymphocytes will remain viable, exclude the eosin dye, and give a negative reaction (dye exclusion) (Fig. 61.25).

Microtiter trays are read under a properly adjusted inverted phase contrast microscope in a serpentine fashion, beginning at well 1A through 1F, continuing with 2F through 2A, 3A through 3F,…, 12F through 12A for a 72-well tray. Cells that are not injured appear small, bright, and refractile, whereas injured cells that have taken up the eosin dye are larger, darker, and nonrefractive and have a slightly granular surface. The result of the analysis is expressed as an estimated percentage of cells killed, taking background killing into consideration. To facilitate and standardize the evaluation process, a standardized system approved by the NIH is used. With this system, each well is assigned a score based on the number of cells killed (Table 61.6).

TABLE 61.6. SCORING SYSTEM FOR HISTOCOMPATIBILITY TESTING

Cell Death	Interpretation	Score
Unreadable well	—	0
0–10%	Negative	1
11–20%	Weak negative	2
21–50%	Weak positive	4
51–80%	Positive	6
81–100%	Strong positive	8

HLA typing is utilized to define the HLA-A, B, C, DR, and DQ locus antigens present on human T lymphocytes. In addition to selecting donors for organ transplantation, HLA typing is important in disease association, parentage testing, and the selection of donors for platelet or leukocyte transfusions. HLA typing is performed by lymphocytotoxicity using viable cells from the patient, and serum containing antisera of known specificity. Whole lymphocyte preparations or purified T-lymphocytes are commonly used for HLA class I antigen (HLA-A, B, C) determinations, whereas enriched B-lymphocyte suspensions are required for the determination of HLA-DR and HLA-DQ alleles. Currently, clinical laboratories do not routinely perform typing

for HLA-DP antigens because anti–HLA-DP antibodies are not generally available for microlymphocytotoxicity assays. The antisera used in HLA typing are commonly obtained from multiparous women and are commercially available on preplated trays. Antisera are also obtained through exchanges with other laboratories, regional sharing programs, and the NIH serum bank. Because some antisera are monospecific and others are polyspecific, it is necessary that each HLA antigen be defined by at least two monospecific antisera or by three antisera that are operationally polyspecific. Fluorescent procedures for HLA-DR

typing are preferred in some laboratories because of their reproducibility and technical simplicity. In the two-color fluorescent technique, mononuclear cells from an unseparated Ficoll-Hypaque purified mononuclear cell preparation are mixed with FITC-labeled anti-immunoglobulin antibody. After incubation for 5 minutes at 37°C, T lymphocytes are unstained, monocytes show speckled fluorescence, and B lymphocytes develop a fluorescent cap at one end of cell. After incubation of the labeled cells with anti-HLA serum and complement, the number of viable and nonviable cells in each population can be counted under an inverted phase fluorescent microscope (190,191). A simplified single-color version of this technique has been described that greatly reduces the time required to perform the assay (192).

The microlymphocytotoxicity assay is also used for the detection of anti-HLA antibodies and HLA cross-matching. The development of antibodies against HLA class I and II antigens is common in patients awaiting transplantation, who can be immunized by blood transfusions, previous organ transplantation, pregnancy, or a combination of these factors. Antibody screening is helpful in determining the cause of a positive cross-match and avoiding a similar incompatibility in the future. It is also helpful in identifying highly sensitized patients who are difficult candidates for transplantation. Sensitization against the HLA antigens also occurs in patients receiving multiple transfusions of blood products. The detection of anti-HLA antibodies (antibody screening) is performed with a panel of lymphocytes of known HLA type. Serum is added, and the lymphocytotoxicity assay is performed. Each antigen must be represented on at least two or three different panel lymphocytes because a technical problem with one cell could result in antiserum specificity being missed or misinterpreted. The results of the assay are expressed as the percentage of cells in the panel that give a positive reaction (percent panel reactive antibody, PRA). If anti-HLA antibodies are present, their specificity can usually be determined from the pattern of reactivity with the panel lymphocytes.

The third application of the microlymphocytotoxicity assay in the histocompatibility laboratory is in the HLA cross-match.

Lymphocyte-Mediated Cytotoxicity

The detection of cytotoxic effector killer cells generated *in vivo* is commonly performed by lymphocyte-mediated cytotoxicity (LMC). In this assay, ^{51}Cr-labeled target cells are incubated with a purified mononuclear cell preparation from the test subject. Killing of the target cells occurs by a direct, complement-independent mechanism, which results in the release of the ^{51}Cr into the medium (193).

The LMC has been utilized in histocompatibility testing and research studies of third-population cells. In organ transplantation, the LMC is used to detect the presence of preformed recipient killer cells specific for the potential donor. In this application, target cells are obtained from the peripheral blood of a potential living-related donor or from the lymph node and/or spleen cells of a cadaveric donor (194). Four-, 12-, and 16-hour LMC assays have been described.

Cell-Mediated Lympholysis

The LMC assay detects the *in vitro* generation of cytotoxic T lymphocytes against a histoincompatible-immunizing cell. In CML, isolated peripheral blood lymphocytes are incubated with stimulator cells in a 5- to 8-day mixed lymphocyte culture. The effector cells are then isolated and incubated with phytohemagglutinin-activated, nonirradiated stimulator cells that have been labeled with ^{51}Cr. Target cell lysis and ^{51}Cr release is proportional to the number of cytotoxic T lymphocytes (195,196). Appropriate controls must be utilized, and the data must be corrected for spontaneous ^{51}Cr release. Generally, different dilutions of effector cells are used to yield effector/target cell ratios of 100, 50, 25, 12.5, and 6.25. In addition, triplicate determinations of each effector-target cell combination are used. The results are expressed as the percentage of cytotoxicity or in lytic units (LU). The LU is the number of effector cells required to kill a given number of target cells and is usually expressed as LU/107 cells. Because the CML assay duplicates the *in vivo* process of tissue destruction through cellular interactions, it has been of great value in studies of allograft rejection (194).

Spontaneous Cell-Mediated Cytotoxicity

Natural killer (NK) cells are defined by their capability to lyse target cells without prior sensitization.

The release of ^{51}Cr from labeled target cells is the standard method for the characterization of NK cells. The chronic myeloid leukemia cell line K562 has been used as the standard target for these assays. Various cell separation techniques have been studied for isolation of a purified fraction of effector cells, and a whole blood assay has also been described (197). However, the ^{51}Cr-release technique has many disadvantages, including the use of radioisotopes, low sensitivity, and the spontaneous release of ^{51}Cr. Several other techniques have been developed for the assessment of NK cell function, but none has achieved widespread utilization. These methods include the incorporation of radioactive nucleotides during cell proliferation (198) dye exclusion (199,200), the measurement of target cell enzyme release (201), and flow cytometry (202,203). Although determinations of single-cell cytotoxicity by dye exclusion has some advantages over ^{51}Cr release for the measurement of NK-cell function, this technique requires laborious, subjective evaluation by microscopy. Therefore, flow cytometric techniques have received considerable attention. In this regard, McGinnes et al. (202) labeled the target cells with carboxyfluorescein diacetate (CFDA) and measured the decrease in fluorescence during lysis, whereas Zarcone et al. (189) quantitated nonviable cells by the use of propidium iodide dye exclusion, and Vitale et al. (204) utilized light scattering parameters. Shi et al. (203) used two-parameter analysis with fluorescein diacetate and propidium iodide and were able to study the interaction between live effector and live target cells, in addition to quantitating lysis of target cells.

Antibody-Dependent Cell-Mediated Cytotoxicity

Antibody-dependent cytotoxicity (ADCC) is mediated largely by a subpopulation of large granular lymphocytes (K cells), although certain other cell types with Fc receptors, including macrophages and granulocytes, also have this ability. ADCC involves fixation of IgG to the surface of a target cell, followed by binding of the Fc receptors of the effector cells to the IgG, and lysis of the target cells (Fig. 61.26). The reaction is usually measured by the use of ^{51}C-labeled target cells (205).

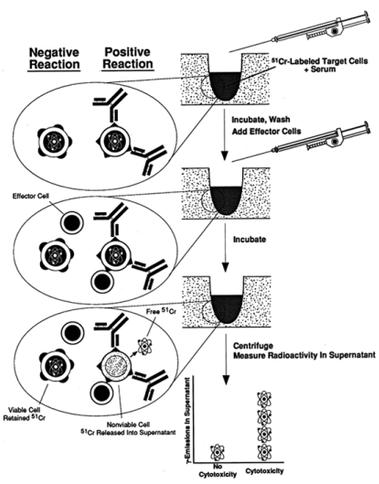

FIGURE 61.26. Principle of the antibody-dependent cell-mediated cytotoxicity assay. This assay is performed with mononuclear cells from a kidney organ donor or from several unrelated individuals (panel cells) that are stimulated with phytohemagglutinin (PHA) and labeled with ^{51}Cr. After incubation with eluate from another nephrectomy specimen or normal human serum, the labeled cells are washed and incubated with effector cells from a normal unrelated individual. Radioactivity (γ emissions) in the cells at the end of the experiment represents unlysed cells. The results are expressed as the percentage of cytotoxicity. (From Riley RS, Mahin EJ, Ross W. *Clinical applications of flow cytometry*. New York: Igaku-Shoin Medical Publishers, 1993, with permission.)

Clinically, this assay has been used to determine the functional activity of cells capable of mediating ADCC and to detect specific antibodies against target cell antigens. It is believed that *in vivo* ADCC is an important mechanism for the destruction of virally infected cells and tumor cells. In addition, antibodies capable of initiating ADCC have been reported to be responsible for some cases of hyperacute allograft rejection.

Assays of Nonspecific Immunity

The activity of neutrophils and macrophages is complex and involves the movement of the cell toward an inflammatory stimulus (chemotaxis), adhesion, opsonization, phagocytosis of foreign particles, and intracellular killing of microorganisms. Some patients with immune function defects have abnormalities of cell movement, phagocytosis, or intracellular killing. The laboratory analysis of these nonspecific immune parameters have been difficult to measure, and many of the assays now in use are subjective and lack standardized methodology and quality control. However, several flow cytometric assays of phagocytic function measure the phagocytosis of microorganisms by cells. In contrast to the subjective assays, flow cytometric studies are rapid, reproducible, and statistically valid. In addition, the multiparametric capability of the flow cytometer allows the simultaneous determination

of several cell functions and an assessment of the interrelationship between cell functions. Flow cytometric assays are currently used for the measurement of phagocytosis of microorganisms, degranulation and enzymatic activity, intracellular killing and degradation of microorganisms, exocytosis, opsonization, oxidative metabolism, membrane potential, phagosomal pH, intracellular calcium, cell volume, and other parameters (206,207,208,209 and 210).

Assays of Cell Movement

Unstimulated neutrophils exhibit random motility. However, in the presence of some substances (chemotaxins), movement becomes nonrandom and unidirectional in the direction of the chemotaxin. Chemotaxis is induced by certain complement activation fragments (C5a and Ba), some coagulation factors (kallekrein and plasminogen activator) substances produced by leukocytes, some byproducts of arachidonic acid metabolism (prostaglandins and leukotrienes), some substances produced by microorganisms, and some synthetic peptides.

The random locomotion of neutrophils can be demonstrated by the capillary tube method. In this procedure, a thin layer of cells from a buffy coat preparation is carefully layered in a capillary tube and observed on an hourly basis. Movement of the cell layer occurs, and the distance from the starting point is recorded after several hours.

The micropore filter technique is the most sensitive means of evaluating chemotaxis and cell migration. Several types of chemotactic chambers are available for this purpose. These consist of two chambers separated by a micropore filter with holes large enough to permit active locomotion but not passive transit (5-mm porosity). A solution containing a chemotactic substance is placed in the lower chamber and a cell suspension in the upper chamber. The chemotactic factors commonly used in the assay include supernatant from a culture of *E. coli*, serum containing activated C5 components, or a synthetic chemotactic peptide (*N*-formylmethionylleucylphenylanaline) (211). After incubation of the chamber, the filter paper is removed and stained. The presence of neutrophils on the underside of the filter is indicative of migration through the paper. However, more accurate assessments of cell migration can be obtained by determination of the average distance migrated per cell (microsectioning method). This leukotactic index is measured by counting the number of cells at 10-mm intervals from the proximal surface of the filter to the distal surface. The number of cells at each interval is multiplied by the distance from the proximal surface and the sum of the products is divided by the total number of cells counted (211). The micropore filter technique has been used to determine the chemotactic ability of different substances, in addition to the evaluation of patients with suspected congenital or acquired disorders of neutrophil migration.

An alternative method for assessing cell migration is the agarose technique, in which the cells under study are placed into a central well punched in a layer of agarose and are allowed to migrate under the agarose toward peripheral wells containing controls or chemoattractant (212,213). Although simple to perform, the agarose method is many times less sensitive than the micropore technique (211).

Ficoll-Hypaque density gradient separation and counterflow centrifugal elutriation have been found to provide the best cell suspensions of studies of neutrophil function (214). In addition, it is essential to maintain cells for studies of random locomotion and chemotaxis at room temperature because even short exposures to cold temperatures can impair these parameters.

Assays of Phagocytosis

Phagocytosis is determined by the use of a particle that is visible within the cell and can be counted after ingestion or an ingestible substance that can be extracted from the cell and measured. Live or heat-killed *Candida albicans* fulfills the first criterion and permits a convenient means of measuring phagocytosis. Neutrophils are incubated with the yeast particles in the fresh serum, Giemsa-stained cell preparations are made, and 200 neutrophils are examined and counted for the presence of ingested yeast (215,216). The results are expressed as the percentage of neutrophils showing phagocytosis and the number of particles per phagocytic neutrophil. Living staphylococci have also been used, with the number of bacteria remaining after phagocytosis determined by culture (217). Another means is to use oil droplets containing dissolved oil red O stain and coated with *E. coli*, liposaccharide, and C3 complement. After incubation, the cells are separated, the oil red O is extracted, and the results are measured spectrophotometrically (218).

Several flow cytometric assays of phagocytosis have been described that are quantitative and more accurate than subjective studies using visual counting of phagocytosed microorganisms. Most investigators (219,220,221,222,223,224,225,226 and 227) use fluorescent microspheres coated with opsonins. However, Wilson et al. (228) and Rothe and Valet (229) reported an increase in red fluorescence in cells stained with acridine orange during phagocytosis. In this, intracellular pH and cell esterase activity during phagocytosis was determined with 1,4-diacetoxy-2,3-dicyanobenzene. A commercial kit for the whole blood flow cytometric assessment of phagocytosis is available (Orpegen, Heidelberg, Germany) that can differentiate between surface-bound and internalized *E. coli* particles (210,230).

Assays of Enzymatic Activity and Intracellular Killing

The intracellular killing of microorganisms is mediated by complex enzymatic mechanisms. In this regard, oxygen-dependent mechanisms of cell killing are the most important, although oxygen-independent have been described. The increase in oxidative metabolism during phagocytosis has been referred to as the oxidative burst. During this process, the key event is the activation of a membrane-bound pyridine nucleotide-dependent oxidase (NADPH oxidase), which reduces oxygen to O_2^- (superoxide anion) and oxidizes NAD(P)H to NAD(P)$^+$. Subsequently, hydrogen peroxide (H_2O_2), hydroxyl radical (OH), and singlet oxygen, are generated. All these compounds are directly toxic to the cell, but the H_2O_2-halide-myeloperoxidase system is the most important mechanism of bacterial killing. In the presence of H_2O_2 and halide ions (I^-, Cl^-), myeloperoxidase catalyzes a direct halogenation of the bacterial cell wall and also produces damage to the cell wall by converting amino acids into aldehydes.

In the clinical laboratory, the Nitroblue tetrazolium dye (NBT) reduction assay has been the standard method for the determination of the oxidative capacity of the neutrophil (209,231,232).

NBT is a yellow dye in its oxidized state. However, when reduced, NBT forms formazan, a crystalline substance that has a deep blue color. NBT is attached to latex particles or microorganisms to permit phagocytosis, or it can be ingested in the soluble form by neutrophils that have been stimulated by endotoxin or other means. If the normal oxidizing environment in the phagolysosome is present, the resultant blue particles can be detected microscopically, or the formazan can be extracted and measured spectrophotometrically (Fig. 61.27). Approximately 10% of normal unstimulated neutrophils ingest and reduce NBT, but this increases to 80% with stimulated neutrophils.

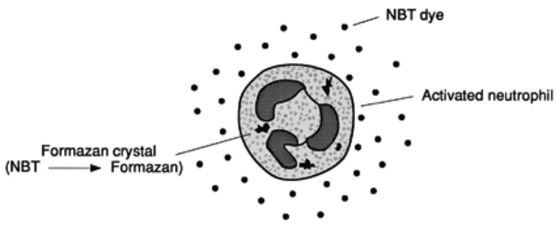

FIGURE 61.27. Principle of the nitroblue tetrazolium (NBT) reduction assay. Neutrophils are incubated with NBT. Enzymatic activity in the activated neutrophil converts NBT into an insoluble brownish-black precipitate (formazan) that is visible under the microscope. The proportion of neutrophils with intracytoplasmic precipitated material is determined.

Bactericidal activity by tritiated thymidine incorporation and autoradiography has been described by Cline (233). In this assay, leukocytes are incubated at 37°C with *Staphylococcus aureus*, ^{3}H-thymidine is added to the reaction mixture, and further incubation is carried out. Autoradiography is performed, and the total number of intracellular bacteria and the number of grains associated with the bacteria are determined in 50 phagocytic neutrophils. The incorporation of ^{3}H-thymidine is observed only in living bacteria.

Several different flow cytometric techniques have been reported for analysis of oxidative metabolism and the oxidative burst. Thorell quantitated NAD(P)H oxidation by measuring the loss of ultraviolet-excited fluorescence associated with NAD(P)H (234,235 and 236). By this technique, the respiratory burst induced by PMA was found to be an all-or-none phenomenon, probably reflecting a narrow threshold between $NAD(P)^{+}$ reduction and complete NAD(P)H oxidation. Bass et al. (237) described a flow cytometric technique for the quantitation of H_2O_2 production. In this technique, the fluorogenic substrate dichlorofluorescein-diacetate (DCFH-DA) is actively taken up by the cell and diacetylated by intracellular esterases into a nonfluorescent compound (2′,7′-dichlorofluorescein, DCFH), which is trapped within the cell. In the presence of H_2O_2 and peroxidase, DCFH is oxidized into dichlorofluorescein (DCF), which is highly fluorescent in the green region of the spectrum (Fig. 61.28).

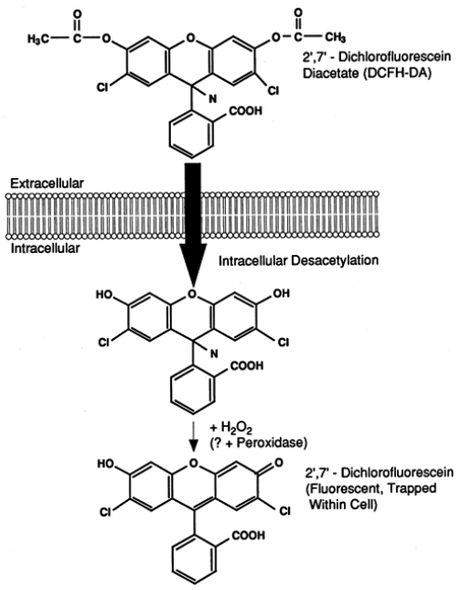

FIGURE 61.28. Flow cytometric analysis of the oxidative burst of polymorphonuclear leukocytes. In this assay, dichlorofluorescein-diacetate (DCFH-DA) is taken up by the cell and is trapped by deacetylation, with the formation of 2′, 7′-dichlorofluorescein. During the oxidative burst, the nonfluorescent 2′, 7′-dichlorofluorescein is converted into the fluorescent product dichlorofluorescein. The fluorescent intensity in the green region of the spectrum is proportional to the oxidative capacity of the cell. (From Bass DA, Parce JW, Dechatelet LR, et al. Flow cytometric studies of oxidative product formation by neutrophils: a graded response to membrane stimulation. *J Immunol* 1983;130:1910–1917, with permission.)

Bass et al. (237) and other investigators utilized this technique to study neutrophilic oxidative metabolism in normal individuals and in patients with infectious diseases and immunodeficiency diseases such as chronic granulomatous disease. Hydroethidine and DCFH were used by Rothe and Valet (238) to simultaneously quantitate both H_2O_2/peroxidase and KO_2. Hydroethidine is oxidized by KO_2 to ethidium bromide. Flow cytometric techniques for the simultaneous measurement of phagocytosis and intracellular killing have been reported (224,239,240).

Recent discoveries have revealed specific functional roles for the cellular receptors for complement components (CD11b, C3bi receptor), the Fc region of IgG (CD16, FcR III; CD32, FcR II; CD64, FcR I) and cell surface adhesion molecules (CD18) on phagocytes. In addition, an intrinsic deficiency of these receptors has been found in some patients with immune deficiency disease (241,242,243,244,245,246 and 247). Flow cytometric evaluation of peripheral blood mononuclear cells for the presence of these receptors and their regulation in the presence of various stimuli is routinely available (209).

Assays of Opsonization

The phagocytosis of microorganisms and other foreign bodies greatly enhanced by the presence of particular chemical substances (opsonins) on the surface of the foreign body. Opsonization is an important function of some antibodies and is demonstrated by some complement breakdown products (C3b, C4b). In patients with some immunoglobulin and complement deficiencies, an increased susceptibility to infection results in part because of decreased opsonization. Opsonins in the serum can be detected by incubating the serum with normal neutrophils and yeast particles and visually quantitating phagocytosis of the yeast particles by normal neutrophils. In addition, flow cytometric methods have been used for the measurement of serum opsonin function (248,249 and 250). In these studies, live FITC-labeled *Neisseria meningitidis* was used to study the opsonic response in patients with serogroup B meningococcal disease. In this assay, the labeled bacteria were preopsonized by incubation with serum for 7.5 minutes, and then incubated with human polymorphonuclear neutrophilic leukocytes (PMNs) for 5 minutes at a bacteria-to-PMNs ratio of 20:1. The results were expressed in the number of bacteria incubated per phagocyte. The opsonic response was markedly increased in acute compared with convalescent serum and remained elevated during the 3-year period examined. ELISA quantitation showed parallel increases in IgG1, IgG3, IgA, and IgM antibodies against type specific group B meningococcal outer membrane proteins (249,251).

Complement Assays

Complement is essential for the defense of the body against disease. In this regard, the complement system can eliminate target

cells or organisms by direct lysis. In addition, individual complement components and fragments produced during complement activation promote immune adherence, opsonization, and chemotaxis, release histamine, and increase vascular perme-ability.

Complement System

The complement system consists of a series of more than 20 proteins that interact in a specific, cascadelike manner (252,253,254,255 and 256) (Table 61.7). The system is regulated by the naturally short life of the activated components and by a number of specific inhibitory compounds. There are two pathways of complement activation (classic and alternative) that are initiated by different mechanisms and may function independently or in concert. Because quantitative and functional abnormalities of the complement system have been associated with autoimmune disease and increased susceptibility to infectious disease, laboratory studies of the complement system can be of diagnostic significance (255,257,258 and 259). Laboratory assays for the assessment of the complement system include immunochemical quantitation of individual complement components, determinations of the functional activity of complement, and tests of complement activation. The detection of complement in tissue can be performed by immunofluorescent or immunoenzymetric staining.

Functional Complement Assays

The functional integrity of the complement system is determined by RBC lysis. The principle of this assay is that the complement components, acting in concert, can lyse RBCs coated with subagglutinating amounts of an anti-RBC antibody. Because lysis occurs only when all the complement components are functional and present in adequate amounts, a deficiency or

functional defect of a single component can prevent lysis. Therefore, the presence of complement dysfunction can be detected by this technique, but the specific nature of the defect must be determined by other methods. For this reason, these assays are usually referred to as total hemolytic complement assays.

Hemolytic techniques for functional complement can be performed in either a liquid suspension or an agarose gel matrix. The animal source of the RBCs used in the assay determines which pathway is measured. Because the classic pathway is activated by antigen-antibody complexes, SRBCs sensitized with a subhemolyzing dose of rabbit antibodies to SRBCs are utilized in its evaluation. In the alternative pathway hemolytic assay, rabbit RBCs are used because they selectively activate complement via the alternative pathway.

The conventional hemolytic tube technique for functional complement utilizes a standardized suspension of RBCs mixed with a series of dilutions of fresh serum. After an incubation period, the reaction tubes are centrifuged, and the supernatants are analyzed spectrophotometrically to determine the amount of free hemoglobin present and the percentage of RBCs lysed. The measurement of hemolysis is most sensitive in the region where 50% of the RBCs are lysed (Fig. 61.29). Therefore, a unit of total serum hemolytic complement is the dilution of serum required to lyse 50% of a standardized amount of RBCs coated with a standard amount of antibody. The tube titration assay is usually performed in the 50% lysis area, and results are expressed in CH50 (classic pathway) or AP50 units (alternative pathway). Standards can be determined by each manufacturer or purchased by commercial sources.

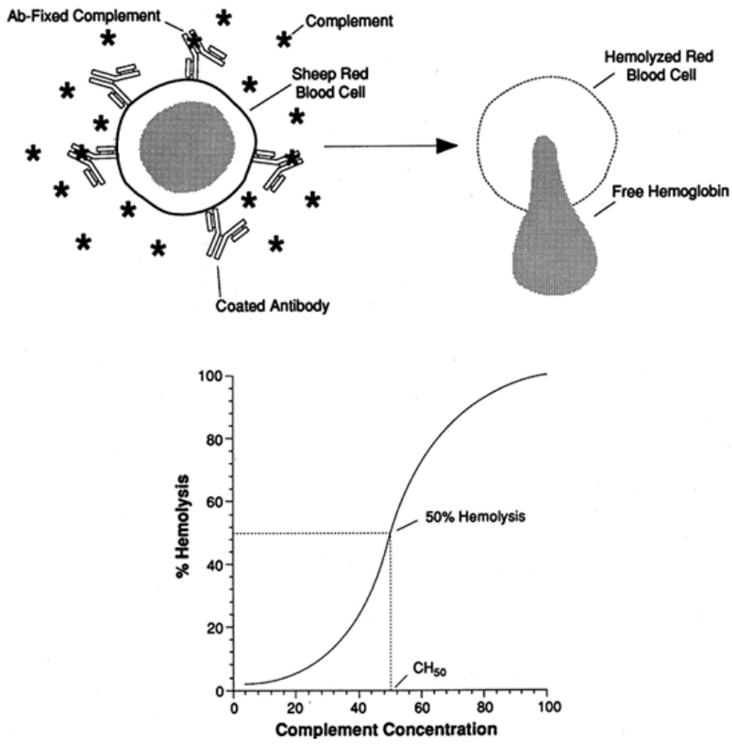

FIGURE 61.29. The hemolytic tube assay for functional complement activity. Sensitized sheep or rabbit red blood cells are the target cells in this assay. Lysis of sheep red blood cells occurs from complement activation on the surface of the red blood cell, resulting in hemolysis and the release of free hemoglobin. The assay can be performed in a liquid medium (hemolytic tube assay) or in agarose gel (gel matrix or radial diffusion method). Sheep red blood cells are used to detect activation of the classic complement pathway, whereas rabbit red blood cells are used for the alternative pathway.

In the gel matrix or radial diffusion method for the determination of functional complement, RBCs are suspended in a buffered agarose mixture that is poured into radial diffusion plates and allowed to solidify. Wells are punched into the agarose. Complement reference sera containing known units of functional complement activity are added to the wells, together with the unknown patient's sera. After an incubation period, a

cleared zone of lysed RBCs appears around each well where hemolysis has occurred. The diameter of the hemolytic zone is proportional to the functional activity of the complement in the well. Therefore, the diameter of each well is measured, and a reference graph is prepared from the known specimens. Unknowns are determined by reading from the graph.

The unit of measurement in the radial diffusion method is the dilution of serum necessary to cause 100% lysis of a standardized preparation of RBCs after activation via the classic or alternative pathways. The results are usually expressed in CH100 or AP100 units (259).

The results obtained by hemolytic tube titration are not directly comparable with those of hemolytic radial diffusion because the analytic techniques are different, and the end points of the assays are measured at different points on the complement response curve. Although the 50% hemolytic units generated by tube titration assays may be considered more sensitive and quantitative than 100% hemolytic units, tube titrations are also more complicated and labor intensive. Radial diffusion requires less elaborate laboratory equipment and is not as sensitive as tube titration to minor changes in reaction conditions. Both assays should be considered as qualitative screening tests for levels of functional complement activity and used in conjunction with quantitative tests. EIA techniques are under evaluation for complement activity (260,261).

Quantitation of Individual Complement Components

The quantitation of the complement components C3 and C4 is routinely performed in the laboratory by nephelometric and other immunoassay techniques. These components are present in the highest concentration in the serum and serve as monitors for the activation of complement. Depressed levels of C4 are usually indicative of classic pathway activation, whereas decreased serum C3 can result from activation of either the classic or alternative pathway. However, normal or elevated C3 and or C4 levels do not rule out complement activation because these substances are acute phase reactants, and their increased synthesis during acute inflammation or infection can more than compensate for consumption. Serum C1q, C2, C5, factor B, and other complement components can be quantitated by radial diffusion in gels or by other techniques if needed in the evaluation of selected patients (262,263).

Tests of Complement Activation

Quantitative assessment of a patient sample for *in vivo* complement activation may be necessary when complement activation is suspected but undetected by immunochemical or functional assays. One reason for this is the wide normal range of complement components, especially C3 and C4. If a patient's C3 or C4 level is normally near the upper range of normal, it may decrease into the lower range of normal during an illness but still be reported as normal.

In vivo activation could also go undetected because most complement components are acute-phase reactants that undergo increased synthesis during states of illness. This compensatory effect may cause normal *in vitro* complement levels or function, even in the presence of complement breakdown.

Testing for activation fractions can also be useful in studies of decreased complement levels because low values may be caused by increased consumption or decreased synthesis. If activation fragments are not found in the presence of low quantitative and functional levels, the cause is decreased synthesis.

The methods utilized for the laboratory detection of complement activation fragments include (a) IEP, (b) IFE, (c) crossed IEP, (d) electroimmunodiffusion, (e) RIA, and (f) ELISA (264). Using these techniques, it is possible to detect the smaller breakdown products of C3a, C3c, C3d, C4d, Ba, and Bb.

Immunohistochemical Staining

A new era of pathologic diagnosis evolved with the introduction of immunochemical techniques into the histology laboratory. These techniques utilize the natural specificity of the antibody to identify and localize a variety of antigens, including immunoglobulins, cell surface markers, hormones, enzymes, oncodevelopmental antigens, viral/bacterial substances, many of which were previously undetectable by cytochemical staining. Polyclonal or monoclonal antibodies labeled with a fluorescent dye were first used as immunohistochemical stains. Unfortunately, immunofluorescent staining is of limited sensitivity and requires frozen tissue sections. In addition, a fluorescent microscope is required for reading the slides. Immunoperoxidase techniques, utilizing monoclonal or polyclonal antibodies, are many times more sensitive than immunofluorescent methods and can usually be performed on fixed, paraffin-embedded tissue. Immunoperoxidase-stained sections can be examined with the ordinary light microscope and are able to withstand long storage.

Coons et al. first used antibodies conjugated with a fluorescent dye for the localization of antigens in tissue in 1941. FITC has been the most widely used fluorescent label because the human eye is very sensitive to its yellow-green fluorescence and because green autofluorescence is less common in nature than red autofluorescence (126). The direct and indirect methods of tissue immunofluorescence have been used, although inhibition and complement-staining techniques have been described.

Direct immunofluorescent staining is used to detect the presence of antigen in a tissue. In this procedure, the fluorochrome-labeled antibody is directly applied to the tissue section at its optimal dilution and incubated for a short period of time. After washing to remove unbound dye, the section is mounted in a water-soluble medium (usually buffered glycerol) and visualized by light microscopy. The sensitivity of direct immunofluorescent staining depends on the avidity of the antibody, the density of the antigen in the tissue, and the sensitivity of the eye.

Indirect immunofluorescent staining is primarily used to detect the presence of an antibody in body fluids, although the same procedure can also be applied for the identification of an unknown antigen in a tissue. In indirect staining, unlabeled antibody is first reacted with the antigen in the tissue. After incubation and washing to remove unlabeled antibody, a fluorochrome-labeled secondary antibody specific for the primary antibody is used. The tissue is visualized by fluorescent microscopy after a second incubation and washing. The indirect method is more sensitive than the direct technique because the second antibody amplifies the staining intensity. In addition, this technique is economical because the same-labeled antibody

can be used with multiple primary antibodies. However, nonspecific staining can be increased relative to direct staining.

There are numerous quality control considerations in immunofluorescent staining. First, the specificity of an antibody used in immunofluorescent staining must be extensively documented and the antibody must be used at its proper dilution. For the identification of antigens in tissue, controls with and without the antigen must be available. If possible, demonstration of the specificity of binding of the antibody should be documented by inhibition or blocking of fluorescent staining on known positive tissue by unlabeled antigen. In addition, loss of staining should be observed in the positive control after the antiserum is adsorbed with purified antigen. The dye:protein ratio is another consideration. The negative charge of a conjugate with a high dye:protein ratio can lead to increased nonspecific staining. Conversely, the sensitivity of detection of the staining reaction is reduced by the use of a conjugate with a dye:protein ratio that is excessively low. Electrophoresis with densitometric scanning of the gel can be used to detect the presence of unlabeled fluorescein and/or protein. The total protein concentration of a conjugate is measured by the biuret reaction of similar procedure. Unlabeled dye can be removed by dialysis, whereas highly negatively charged conjugates can be separated by DEAE-cellulose chromatography. The presence of nonspecific, extraneous antibodies in antisera is best detected by IEP or precipitin reactions in gels (126). Documentation of the sensitivity of a conjugate is performed by gel diffusion precipitation, using serially diluted preparations of the conjugate against a solution of the antigen at a concentration of 1 mg/mL. The highest dilution of the conjugate that gives a visible line of precipitation is the unitage. Conjugates for immunofluorescent staining should have at least 4 units per 1% protein (126). Although F:P ratios can be expressed as a weight ratio (micrograms of bound FITC per milligram of protein), they are usually expressed as molar ratios by multiplying the weight ratios by a factor of 0.411.

Commercial antisera and conjugates are supplied with information regarding the F:P ratio, protein concentration, and the results of assays for immunologic sensitivity and specificity. However, because the optimal working dilution will vary in each laboratory, it must be individually determined before using the reagent. For direct immunofluorescent staining, serial dilutions of the conjugate are used with a positive control to determine the optimal combination of bright fluorescence and low background staining. In indirect staining, where two antibodies are used, chessboard (or checkerboard) titrations are performed. In this technique, serial dilutions of a primary antibody are incubated with a well-characterized positive control, and each dilution is in turn developed with serial dilutions of the fluorochrome-labeled secondary antibody. The fluorescence intensity of each combination is recorded in tabular format. For each dilution of primary antibody, the fluorescent intensity will be constant for several dilutions of conjugate (plateau titer). In general, the highest conjugate dilution (plateau end point) can be diluted twofold to obtain a working dilution. For fluoresceinated antibodies with an F:P ratio of 3:5, a plateau end point between 1/6 and 1/64 is expected against a high-titered primary antibody, and a working dilution of approximately 1/4 unit/mL is generally used. For conjugates employed in direct immunofluorescent staining, dilutions of 1 unit per milliliter to 1/4 unit per milliliter provide satisfactory results in most circumstances (126). Because antibody conjugates are labile, storage conditions are critical. Generally, fresh conjugates should be ultracentrifuged, divided into small aliquots, and stored in a protein-rich medium (2 mg/mL or greater) at ultra-cold temperatures (-80°C or the vapor phase of liquid nitrogen) for long-term storage. Conjugates should be thawed only once before use and should be given a high-speed centrifugation before use (126). Stabilized, undiluted conjugates can usually be stored at 4°C for several weeks.

Proper preservation and sectioning of tissue is essential for the retention of immunologic reactivity and morphologic detail. Needle biopsies or small pieces of tissue (approximately 3 to 5 mm) are obtained in the fresh state and placed on pieces of moistened (not soaked) gauze for transport. The tissue is then placed on a piece of a wooden tongue blade, sponge, or cork, embedded in OCT compound (Ames Co., Elkhart, IN, U.S.A.), and snap or flash frozen by complete immersion in liquid nitrogen, isopentane cooled to the temperature of liquid nitrogen, or a dry ice-acetone mixture. The frozen tissue is then wrapped in aluminum foil, placed in a precooled, airtight storage container, and stored at a temperature of -70° or -80°C until sectioning and staining. Sections of 4 to 6 μ are cut under reduced temperature with a standard cryostat. Brief fixation of the tissue sections in acetone or absolute ethyl alcohol is sometimes employed to prevent the loss of soluble antigens or antibodies.

The fluorescent microscope provides a means of illuminating stained tissue with light of a proper wavelength under dark-field conditions, separating the excitation and emission wavelengths and visualizing the stained tissue. Fluorescent microscopes can be classified into two types based on optical configuration. The bright-field incident (epi-illumination) system described by Ploem in 1967 has been the most widely utilized. The heart of the epi-illumination fluorescent microscope is a dichroic (beam-splitting) mirror. In this system, excitation light from a high-intensity light source is passed through a primary filter, strikes a dichroic mirror placed at a 45 degree angle, and is deflected through the objective of the microscope unto the slide where a dark field is created. The light emitted from the specimen returns through the objective and passes through the dichroic filter and secondary filter to the oculars. The primary (excitation) filter is used to select light of the proper wavelength for excitation, whereas the secondary (barrier) filter transmits light at the emission wavelength of the fluorochrome under study, while removing excitation wavelengths. The dichroic filter is essential to reflect excitation light to the slide and transmit emitted light to the observer. One advantage of this system is that a condenser, with its associated light loss, is not required because the objective acts as a condenser. In addition, filter systems can be easily exchanged for viewing tissue sections labeled with multiple conjugated dyes, and fluorescence can be performed in conjunction with phase contrast and other types of microscopy. Fluorescent microscopes with transmitted illumination usually employ dark-field (oil-immersion) condensers. Excitation light passes through a primary filter and the dark-field condenser onto the glass slide. Emitted light passes through the microscope objective and secondary filter to the ocular lens (Fig. 61.30). This design is less efficient than epi-illumination systems because some light is diffused

in passing through the condenser and barrier filter. In addition, filter configurations are more difficult to change. In all microscopes, the objectives must be nonfluorescent and collect and transmit light with high efficiency (i.e., have high numerical aperture).

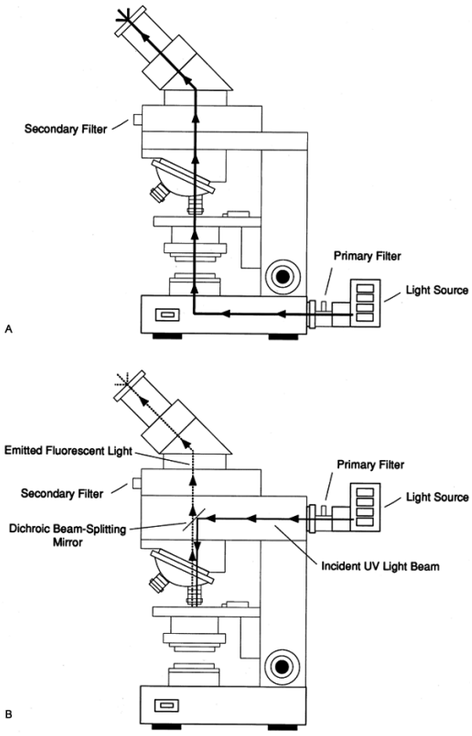

FIGURE 61.30. Schematic illustrations of epi-illumination **(a)** and transmitted illumination **(B)** fluorescent microscopes.

High-pressure arc (mercury, xenon) and halogen (quartz-iodine or tungsten-halogen) lamps have traditionally been the excitation sources for fluorescent microscopes. High-pressure arc lamps are the most widely used excitation sources because they produce light of very high intensity and have relatively long life spans (approximately 200 hours). However, light intensity decreases with age, and these lamps require a protective housing because they operate at high temperature and pressure. In the near future, the small, inexpensive lasers that have recently become

available in flow cytometers may be incorporated into the fluorescent microscope. These have very long life spans and produce monochromatic light of very high intensity.

If an assay for the detection of identification of antibodies is conducted, appropriate positive and negative sera must be used for controls. For antibody identification, serial dilutions of the specimen are tested, and the dilution (titer) that produces a minimal degree of fluorescence is reported as positive.

Flow Cytometry

J. Philip McCoy Jr.

Flow cytometry has evolved from a research tool to an integral component of contemporary laboratory medicine. Flow cytometry, which offers the ability to examine multiple features of individual cells in rapid succession, has become useful, if not required, in the evaluation and diagnosis of many diseases. Key to the evolution of flow cytometry has been the development of instrumentation which simplified maintenance and quality control procedures. Additional factors that have spurred the transition into the clinical laboratory include the development of new and better fluorochromes and a broad array of monoclonal antibodies. These have permitted more multiparameter analyses of specimens and thus a more precise dissection of disease processes.

This chapter reviews the current status of flow cytometry in laboratory medicine. Only cursory mention is made of instrument design and theory of operation; several excellent texts thoroughly cover these topics (1, 2). While numerous assays are discussed in terms of methodology and interpretation, a goal of this chapter also is to convey, in a broader sense, an appreciation for the abilities, potential abilities, and limitations of flow cytometry. It is essential to bear in mind that flow cytometric analyses frequently are adjunctive laboratory assays: clinical diagnoses must integrate the flow cytometric findings with other laboratory findings and the clinical presentation. Interpretation of data derived from flow cytometric analysis is nearly impossible without appropriate correlation of morphological and clinical parameters. Finally, flow cytometry is a single technology for which many applications have been found. The clinical applications described in this text are by no means complete; rather, they reflect those that are most commonly performed. For a more in-depth discussion of these applications, a variety of excellent texts are available (3,4,5 and 6).

DISEASE STATES

Part of "62 - Flow Cytometry"

Flow cytometric assays are used in the evaluation of a multitude of disease states to examine a wide variety of cellular features. The features examined include cell surface proteins and carbohydrates, intracellular antigens, cellular enzymes, and nucleic acids. Of these, the most common flow cytometric assays involve the detection of cell surface antigens. This is most often accomplished through the use of fluorochrome-conjugated monoclonal antibodies directed against lineage-specific (or -associated) antigens and/or antigens associated with maturation or clonality.

The plethora of these reagents has led to a series of workshops designed to better classify the distribution of the antigens on hematopoietic cells. The result of these workshops is a series of cluster designations (CD), which describe the distribution of a number of antigens defined by monoclonal antibodies from a variety of sources. Representative cluster designations, their distribution, and commonly available antibodies for each CD are given in Table 62.1 (7). Armed with these tools for the understanding of hematopoiesis, one can utilize flow cytometric immunophenotyping to characterize disease processes.

As mentioned above, flow cytometric assays used in the clinical laboratory are by no means limited to cell surface immunophenotyping. Assays have been described for the quantitation of cellular DNA (for ploidy and proliferation studies), RNA (for reticulocyte maturation), cell surface receptors (e.g., estrogen), carbohydrates (by lectin binding), intracellular antigens (e.g., cytoplasmic mu and Tdt), ion fluxes (such as calcium fluxes in triggering target cells), and phagocytosis, to name a few. In many instances, these parameters may be examined concomitantly with cell surface markers. This section will illustrate the application of some of these flow cytometric assays in the study of selected disease in the clinical laboratory.

Leukemia

Acute

The diagnosis of acute leukemia is dependent upon clinical presentation of the patient as well as the examination of a number of laboratory parameters such as morphology and cytochemistry. A detailed description of the complete laboratory evaluation of acute leukemia is found in Chapter 43, Acute Leukemias and Myelodysplastic Syndromes. Immunophenotypic analyses of abnormal cells in peripheral blood and bone marrow by flow cytometry complements other laboratory studies and has substantially enhanced our ability to classify leukemias (8,9,10,11,12 and 13). These phenotypic analyses are primarily focused upon delineating cell lineage and stage of maturation of the cells in question, thus helping to delineate lymphoid from myeloid acute leukemias, and to subclassify leukemias within each lineage. A schema for surface marker expression as a function of lineage and maturation can be constructed as illustrated in Fig. 62.1. Immunophenotyping data is particularly useful to establish a diagnosis when standard morphology or cytochemistry provides ambiguous, conflicting, or incomplete results.

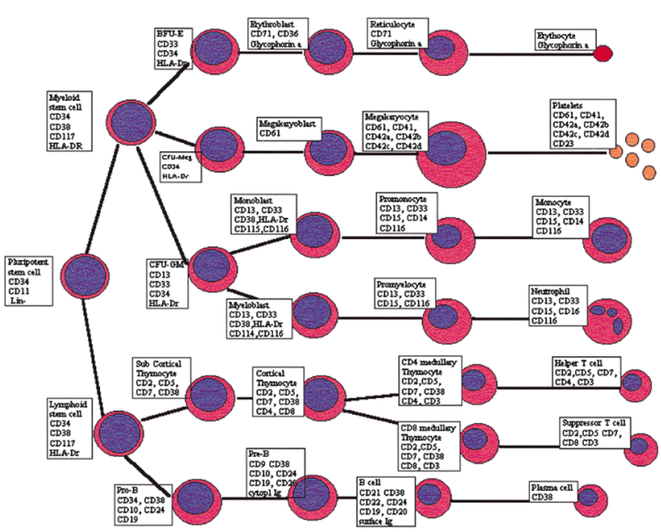

FIGURE 62.1. A maturation schema for hematopoiesis in relationship to marker expression.

TABLE 62.1. CD ANTIGENS AND CELLULAR DISTRIBUTION

Antigen	Cellular Distribution	Name/Membrane Component
CD1a	thymocytes, Langerhans dendritic dermal cells, B lymphocyte subset	gp49
CD1b	thymocytes, dendritic dermal cells, B lymphocyte subset	gp45
CD1c	thymocytes, dendritic dermal cells, B lymphocyte subset	gp43
CD2	all T lymphocytes, 95% thymocytes, natural killer cells	CD58 (LFA-3) receptor, gp50
CD2R	activated T lymphocytes	CD2 epitopes restricted to activated T cells
CD3	mature T lymphocytes	CD3 receptor complex (5 chains), gp/p26,20,16
CD4	T lymphocyte subset, helper/inducer T lymphocytes, monocytes	MHC Class II/HIV receptor, gp59
CD5	all T lymphocytes, some B lymphocyte subsets	gp67
CD6	mature T lymphocytes, B lymphocyte subset	gp 100
CD7	all T lymphocytes	gp40
CD8	T lymphocyte subset, cytotoxic/suppressor T lymphocytes, Natural killer cells	MHC Class 1 receptor gp72 heterodimer (gp30,32)
CD9	monocytes, B lymphocytes, platelets, B progenitors	p24
CD10	B lymphocytes, common acute lymphoblastic leukemia, progenitors, granulocytes, germinal center B cells	neutral endopeptidaseB gp100, CALLA
CD11a	leukocytes	LFA-1, gp 180/95
CD11b	monocytes, granulocytes, natural killer cells, macrophages	C3bi receptor (CR3), gp 155/95
CD11c	monocytes, granulocytes, macrophages, B lymphocyte subset natural killer cells,	gp 150/95 heterodimer
CDw12	monocytes, granulocytes, platelets	p90–120
CD13	granulocytes, monocytes	aminopeptidase N, gp 150
CD14	monocytes, granulocytes, follicular dendritic reticulum cells, epidermal Langerhans cells	gp55
CD15	granulocytes, monocytes	Hapten X on 3-FAL
CD15s	granulocytes, monocytes	Sialyl-Lewis X
CD16	granulocyte, natural killer cells, macrophages	lgGFcRIII (low affinity), gp50–65
CDw17	granulocytes, platelets, monocytes	lactosylceramide
CD18	leukocytes, broad	ß-chain to CD11a,b,c
CD19	all B lymphocytes, some myeloid progenitors	gp95
CD20	B lymphocytes, follicular dendritic reticulum cells, all peripheral B lymphocytes, some late B progenitors, some Reed-Sternberg cells	gp35, p37/32, ion channel?
CD21	B lymphocytes, B lymphocyte subset, follicular dendritic reticulum cells	C3d Epstein-Barr virus receptor, gp 140, CR2 for C3d fragment
CD22	B lymphocytes, B progenitors, and most peripheral B lymphocytes to myelin	gp 135, homology weak on germinal center B, assoc.gp (MAG) cytoplasmic B/surface B lymphocyte subset
CD23	B lymphocyte subset, activated monocytes, follicular dendritic reticulum cells, eosinophil	IgE FcRil receptor (low affinity), gp45–50
CD24	B lymphocytes, granulocytes, all B lymphocytes including progenitors, polymorphs	gp45,55,65 heterotrimer
CD25	activated T lymphocytes, B lymphocytes, monocytes	II-2 receptor ß-chain, gp55
CD26	activated T lymphocytes	dipeptidylpeptidas e IV, gp110
CD27	T lymphocytes	p55(dimer)
CD28	T lymphocyte subset	gp44
CD29	T lymphocyte subset (others)	VLA ß, Integrin ß-chain, platelet GPIIa, p135
CD30	activated T lymphocytes, activated B lymphocytes, activated Hodgkin's and Reed-Sternberg cells	gp120, K1-1 prototype
CD31	monocytes, granulocytes, platelets, T lymphocytes, bone marrow cells, epithelium, B lymphocytes	gp 140, platelet GPIIa
CD32	monocytes, granulocytes, platelets, B lymphocytes	FcRII receptor, gp40
CD33	myeloid leukemia, myeloid progenitors, monocytes	gp67
CD34	myeloid and lymphoblastic leukemia, some bone marrow cells, endothelium, lymphocyte progenitor cells	gp 115
CD35	granulocytes, monocytes, B lymphocytes, red blood cells, follicular dendritic reticulum cells	CRI for C3b fragment of C3,p220
CD36	monocytes, macrophages, platelets, early erythroid	GP90, platelet GPIV
CD37	B lymphocytes, all peripheral B lymphocytes, some late B progenitors, some leukocytes, some T lymphocytes, monocytes	GP40–52
CD38	early B lymphocytes, T lymphocyte, T blasts, plasma cells, leukocyte progenitors	p45/12 heterodimer
CD39	B lymphocytes, endothelial cells, activated T cells and NK cells	gp78
CD40	B lymphocytes, interdigitating reticulum cells, dendritic cells, carcinomas	gp50, homology to NGF receptor
CD41	platelets, megakaryocytes	CPIIb/IIIa complex (receptor for fibrinogen)
CD42a	platelets, megakaryocytes	GPIX, gp22
CD42b	platelets, megakaryocytes	GPIb receptor for factor VIII antigen, gp135/25
CD42c	platelets, megakaryocytes	gp22, GPIb receptor for factor VIII antigen
CD42d	platelets, megakaryocytes	gp85, GPV
CD43	T lymphocytes, most leukocytes except B cells	leukosialin, sialoopherin, gp95
CD44	most leukocytes, red blood cells	Pgp-1, pg80–95
CD44R	erythrocytes, monocytes, epithelial cells	Gp130,160,190
CD45	leukocytes	leukocyte common antigen, T200

CD45RA	T lymphocyte subset, B lymphocytes, granulocytes, monocytes, myeloid cells	restricted T200, gp220
CD45RB	T lymphocyte subset, B lymphocytes, granulocytes, monocytes, macrophage	restricted T200, gp220
CD45RO	T lymphocyte subset, B lymphocytes, granulocytes, monocytes	restricted T200, gp 180
CD46	broad	membrane cofactor protein (MCP), gp66/56
CD47	broad	Integrin associated protein (IAP)
CD48	leukocytes	gp43, GPI-linked, BLAST-1
CD49a	activated T and B cells, monocytes	Integrinα1, VLAα1, gp210
CD49b	activated T and B cells, platelets, monocytes	Integrinα2, VLAα2, GP1a, gp160
CD49c	broad, non-hematopoietic cells	Integrinα3, VLAα3, gp150
CD49d	broad	Integrinα4, VLAα4, gp150
CD49e	platelets, monocytes, neutrophils	Integrinα5, VLAα5, gp150
CD49f	platelets, T lymphocyte subset, monocytes, megakaryocytes	Integrinα6, VLAα6, gp140, platelet GPIc
CD50	leukocytes, broad	ICAM-3, gp120, PI-linked
CD51	platelets, some B lymphocytes, monocytes, endothelial cells	VNR-α-chain
CD52	leukocytes	Campath-1, gp21-28
CD53	leukocytes	gp32-40, PI-linked
CD54	broad, activated, endothelial cells	ICAM-1
CD55	broad	decay accelerating factor (DAF)
CD56	natural killer cells, some T lymphocytes	Gp180, N-CAM
CD57	subset of natural killer cells, T lymphocyte subset	gp110, HNK1
CD58	leukocytes, epithelial cells, endothelial cells	LFA-3, gp55-65
CD59	broad	gp18-20
CDw60	T lymphocyte subset, platelets	9-0-acetyl GD3
CD61	platelets, megakaryocytes, B lymphocytes	integrin ß3-, VNR ß-chain, platelet GPIIIa
CD62E	endothelial cells	ELAM-1, E- selectin
CD62L	NK cells, some T and B cells, monocytes	L-selectin
CD62P	activated platelets	GMP-140 (PADGEM), gp140 P-selectin
CD63	activated platelets, monocytes, granulocytes,	gp53 T lymphocytes, B lymphocytes
CD64	monocytes	FcγRI, gp75
CD65	granulocytes, monocytes	poly-n- acetylactosamine
CD65s	granulocytes, monocytes	poly-sialyl-n- acetylactosamine
CD66a	granulocytes	Biliary glycoprotein (BGP) gp 180-200
CD66b	granulocytes	CGM-6, gp95-100
CD66c	granulocytes	NCA, gp90-95
CD66d	granulocytes	CGM-1, gp30
CD66e	granulocytes	CEA, gp 180-200
CD66f	granulocytes	Pregnancy-specific antigen (PSG)
CD67	now CD66b	
CD68	macrophages, activated platelets, monocytes	gp 110
CD69	activated B and T lymphocytes	gp32/38, AIM
CD70	activated B lymphocytes, T lymphocytes, Reed-Sternberg cells	Ki-24, CD27 ligand
CD71	proliferating cells, erythroid cells	transferrin receptor
CD72	B lymphocytes	gp42
CD73	B lymphocyte subset, T lymphocyte subset	ecto-5'-nucleotidase, gp69
CD74	B lymphocytes, monocytes	Class II assoc. invariant chain, gp41/35/33
Cdw75	mature B lymphocytes, T lymphocyte subset	p53
Cdw76	mature B lymphocytes, T lymphocyte subset	gp85/67
CD77	restricted B lymphocytes, Burkitt's lymphoma	globotriasylceramide (Gb3)
Cdw78	B lymphocytes, macrophages	unknown
CD79a	B lymphocytes	Igα, mb-1 gene product, gp33
CD79b	B lymphocytes	Igß, gp40
CD80	B cell subset	B7, BBI, gp60
CD81	broad on hematopoietic cells	TAPA-1, p26
CD82	broad on hematopoietic cells	R2, gp50-53
CD83	dendritic cells, Langerhans cells	gp43
Cdw84	monocytes, macrophages, platelets, some B and T cells	p73
CD85	plasma cells, monocytes, B cell subset	P120
CD86	activated B cells, monocytes	gp80
CD87	activated T cell, monocytes, NK cells	UPAR, gp50-65
CD88	granulocytes, monocytes, macrophages	C5a-R, gp40
CD89	granulocytes, monocytes, macrophages, lymphoid subsets	Fcα-R, gp55-70
CD90	hematopoietic stem cell subset	Thy-1, gp18
CD91	monocytes, macrophages, erythroblasts	α2MR, p600
Cdw92	granulocytes, monocytes	p70
Cdw93	granulocytes, monocytes	p120
CD94	NK cells, T cell subsets	Kp43, gp43
CD95	activated lymphocytes, broad	FAS, APO-1, gp42
CD96	activated T and NK cells	TACTILE, gp160
CD97	activated lymphocytes, monocytes	p74,80,89
CD98	broad, activated lymphocytes	4F2, gp80/40
CD99	broad on all hematologic cells	E2/MIC2, gp32
CD99R	broad on all hematologic cells	gp32
CD100	broad on hematopoietic cells	gp150

CD101	activated T cells, monocytes, granulocytes, macrophages	p140
CD102	lymphocytes, monocytes, platelets, endothelial cells	ICAM-2, gp55-65
CD103	mucosal associated lymphocytes	integrin αE, HML-1, gp150/25
CD104	thymocytes, epithelial cells, endothelial cells, monocytes	integrin ß4, gp205
CD105	activated monocytes, endothelial cells	endoglin, gp95
CD106	endothelial cells	VCAM-1, INCAMI 10, gp100
CD107a	platelets	LAMP-1, gp110
CD107b	platelets	LAMP-2, gp110
Cdw108	activated T cells	JMH, gp80
CD109	activated T cells, endothelial cells, platelets	gp170/150
CD110	reserved	
CD111	reserved	
CD112	reserved

CD166	endothelial cells, activated T cells, monocytes	ALCAM, gp100

Table 62.2 and Table 62.3 illustrate common immunophenotypes associated with lymphoid and myeloid leukemias, respectively. Acute leukemias are not limited to these immunophenotypes, rather these point to typical findings within each subtype. Some variation occurs even within subtype. It also is fairly common in acute leukemias to have aberrant expression of a marker associated with another lineage (14,15,16 and 17). Caution must be taken in attempting to interpret immunophenotyping data in the absence of clinical information and other laboratory findings. An example of this is the similarity in immunophenotypes of precursor B-ALL and chronic myelogenous leukemia in acute lymphoid blast crisis.

TABLE 62.2. COMMON IMMUNOPHENOTYPES ASSOCIATED WITH VARIOUS TYPES OF ACUTE LYMPHOBLASTIC LEUKEMIA (ALL)

* MPO negative by cytochemistry, but frequently positive by flow cytometry

Flow cytometric immunophenotyping is useful to identify both biphenotypic and biclonal leukemias (18,19,20,21,22 and 23). The former form of leukemia displays cell surface markers, or other characteristics, of two lineages or types of leukemias on the same cell whereas the latter form of leukemia involves the identification of two separate leukemic clones within the same patient. There is not a sharp delineation between what is considered lineage-aberrant marker expression and biphenotypic leukemia (8). While there is no universally agreed upon standard for distinguishing between these two entities, one widely accepted criterion is the biphenotypic leukemia must have at least two lineage-specific markers from each lineage present. Aberrant marker expression on the other hand, would have only one lineage-specific marker. Biclonal leukemias, by contrast, display two distinct populations of cells each bearing a separate and clearly defined array of surface markers. Biclonal leukemias may have different clones from the same or differing lineages (21,22 and 23).

In addition to immunophenotyping of cell surface markers, flow cytometry may also be used to examine intracellular components of leukemic cells. Flow cytometric assays have been described for intracellular enzymes such as myeloperoxidase (MPO) and terminal deoxynucleotidyl transferase (TdT), and cytoplasmic immunoglobulin and cytoplasmic CD3 (24). Terminal deoxynucleotidyl transferase (TdT), a template-independent DNA polymerase, is useful as a marker for ALLs. While present in the majority of ALLs, TdT is not found in the majority of AMLs and mature non-Hodgkin's lymphomas. As part of a panel including immunophenotyping, morphological examination, and cytochemistries, TdT is a useful tool in diagnosis and in the detection of recurrent disease. MPO, an enzyme marker found in myeloid, but not lymphoid, leukemias is another useful intracellular marker in leukemia to distinguish lineage. Detection of MPO has historically been performed by cytochemical methods, however antibody-based cytometric methods for this are now available and appear to offer greater sensitivity as well as ease of testing (25).

Measurement of cellular DNA content is often of use in the study of acute leukemias either alone or in conjunction with surface marker analysis. Measurement of DNA content serves to identify aneuploid populations of tumor (although minor DNA alterations and chromosome translocations cannot be detected) and to estimate proliferation rates. Aneuploidy is a strong indi-

cator of malignancy and, as such, can aid in diagnosis when immunophenotypic and morphological examinations are not conclusive (26, 27). Aneuploidy also can be used as a means to detect recurrent disease (26), and prognosis has been associated with ploidy in selected diseases. For example, Look and colleagues (28) demonstrated a better prognosis in childhood acute leukemia associated with a hyperdiploid (DI >1.16) DNA content. The observations by Look and colleagues in childhood ALL do not apply in adult ALL. Thus, it should be noted that ploidy-prognosis relationships are by no means universal; each type of lesion and group of patients must be independently assessed to determine the validity of ploidy evaluation in prognosis.

Minimal Residual Disease

Flow cytometry is one of several technologies that is being applied to detect residual disease in patients with acute leukemia prior to overt relapse (29,30,31 and 32). Flow cytometric assays to detect minimal residual disease (MRD) have relied on aberrant marker expression to distinguish leukemic blasts from normal marrow precursors. Here aberrant marker expression is considered any one of the following: expression of lineage aberrant markers, unusual intensity of marker expression, failure of cells to express expected lineage markers, and asynchronous marker combinations. In order to detect surface marker combinations which are aberrant or which are somewhat unique to the leukemic cells, a rather large panel of antibodies must be analyzed at diagnosis. This serves to “fingerprint” the leukemic cells in sufficient detail that they may be distinguished in small numbers from normal hematologic precursor cells. CD45/log side scatter gating (33), described below, is particularly useful in this endeavor. Arguably, in some patients, a unique “fingerprint” may not be identifiable due to the leukemic blasts close immunophenotypic appearance to normal cells. In those patients where a “fingerprint” is identified, sequential analyses of remission marrows will provide the best identification of residual disease.

Chronic

Chronic lymphoproliferative disorders (CLPD) are a group of diseases characterized by atypical proliferations of small, mature lymphoid cells. A number of diseases fall within this category and there is a varying degree to which immunophenotyping is used in the diagnosis of each disorder. Chronic lymphocytic leukemia (CLL) is the most common CLPD in Europe and North America and thus represents the most frequent of these diseases encountered in the clinical flow cytometry laboratory.

CLL are monoclonal proliferations of B cells with cell surface immunoglobulins (34,35 and 36). CLLs are mature B-cell lesions, typically identified by the expression of CD19, CD20, HLA-DR, cytoplasmic immunoglobulin heavy chain, and the weak, but monoclonal, expression of heavy and light immunoglobulin chains on the cell surface (seldom seen in B-ALLs). In contrast to B-ALLs, CLLs do not express the CALLA antigen; however, most are positive for CD5. Thus, CD19+, CD20+, CD5+ cells with dim, clonal, light chain expression is highly characteristic of CLL. Additionally, the presence of CD23 helps to distinguish CLL from mantle cell lymphoma, which expresses a similar immunophenotype (37). By contrast, prolymphocytic leukemia is generally CD5 negative with stronger expression of clonal surface light chain (38, 39) (Table 62.4).

TABLE 62.4. IMMUNOPHENOTYPES ILLUSTRATIVE OF CHRONIC LYMPHOPROLIFERATIVE DISORDERS

CLL, chronic lymphocytic leukemia; PLL, prolymphocytic leukemia; HCL, hairy cell leukemia; PCD, plasma cell dyscrasia; T-LGLD, T lineage large granular lymphocyte disorder; NK-LGLD, natural killer large granular lymphocyte disorder

Myelodysplasia and Chronic Myelogenous Leukemia

The role of flow cytometry and immunophenotyping in the evaluation of myelodysplasia is somewhat uncertain (40, 41). CMLs

are classically described by the presence of a consistent chromosomal abnormality, the Philadelphia chromosome (Ph1). Surface marker analysis is of limited utility during the chronic phase of this disease, as many immature and mature myeloid elements are present, but it is of substantial value during the acute phase (blast crisis) (42, 43). The acute phase is similar to an acute leukemia, and here the cells may bear either lymphoid or myeloid characteristics. Delineation of these two forms of blast crisis is critical because each responds differently to chemotherapeutic regimens. Lymphoid variants generally bear the CD10, CD19, and HLA-DR surface markers, and the myeloid variants express CD13, CD33, and HLA-DR. Additionally, blasts can display erythroid or megakaryocytic features and thus can be identified through the use of glycophorin A or Plt-1, respectively.

Lymphoma

The lack of a specific antigen, or combination of antigens, which can identify Hodgkin's lymphoma has severely limited the use of flow cytometry in the diagnosis of these lymphomas, however, flow cytometric immunophenotyping is quite useful in the diagnosis and staging of non-Hodgkin's lymphomas (NHL) (8, 44,45,46,47 and 48). The majority of NHL are of the B cell lineage, flow cytometric identification of a light chain restriction is important in establishing a diagnosis of lymphoma in many cases. In addition to identifying clonality, immunophenotyping also is useful in subclassifying B-NHL, as illustrated in Table 62.5. In addition to studying the lymph nodes themselves, examination of the bone marrow by immunophenotyping permits a more precise and sensitive method for detection of marrow involvement, and thus staging, than possible by morphologic studies alone.

TABLE 62.5. IMMUNOPHENOTYPES REPRESENTATIVE OF LYMPHOMAS

Follicular	Mantle Cell	MALT	Burkitt's
CD19+	CD19+	CD19+	CD19+
CD20+	CD20+	CD20+	CD20+

CD10+	CD10-	CD10-	CD10+
light chain+	CD23-	light chain+	light chain+
	CD43+		
	cyclin D1+		
	light chain+		

T lineage lymphomas may be immunophenotyped by flow cytometry, but clonality is much more difficult to establish (44). As with all lymphoma immunophenotyping, flow cytometric analysis of putative T cell lesions must be conducted only in the context of appropriate morphologic studies. Within a morphologic diagnosis of lymphoma, surface markers may be used to delineate B lineage from T lineage. T lineage lymphomas generally display aberrant immunophenotypes, particularly characterized by the absence of an expected pan T-cell antigen, and this may be used as additional. In mature forms with aßT cell receptor complexes (TCR), antibodies to variable ß the TCR regions of may be used as indicators of clonality (49). Because of the large number of antibodies required for these studies, this task is generally not feasible in the clinical laboratory.

Analysis of the cellular DNA content of lymphomas may be of use when one is presented with a difficult differential diagnosis such as a reactive node, although, in general, molecular studies to assess clonality are preferable. As with leukemias, aneuploidy in lymphomas is very strongly correlated with malignancy. High proliferation rates in lymphomas are closely associated with high-grade disease and a high frequency of an initial complete remission of short duration (50,51 and 52). Recent surveys reveal that, despite the increased utilization of molecular techniques in the diagnosis of malignant lymphoma, flow cytometric assessment of DNA content remains a widely performed test (53, 54).

Immunodeficiencies

Human Immundeficiency Virus (HIV) and Acquired Immunodeficiency Syndrome

Perhaps the most common application of immunophenotyping is in the diagnosis and therapy of HIV disease and acquired immunodeficiency syndrome (AIDS) (54). The HIV virus has been shown to infect and destroy helper T (CD4+) lymphocytes (55, 56). Thus laboratory findings in support of a diagnosis of AIDS include a decrease in the absolute number of the CD4+ cells and thus a low ratio of CD4+ to CD8+ T lymphocytes (57,58 and 59). Normal individuals generally have a CD4/CD8 ratio of approximately 2.0; AIDS patients quite often have ratios less than 0.5. Enumeration of CD4+ cells provides a direct indicator of disease progression in HIV-infected individuals and of survival in patients with AIDS (58, 59). CD4 enumeration and HIV viral load

testing usually is performed in parallel to assess both the quantity of virus detectable in the patient and the effect of the virus on the immune system. In addition to diagnostic testing, both assays are extremely important in monitoring of therapy, particularly therapy including protease inhibitors where declining viral loads and increasing CD4 counts may be observed (60, 61).

Immunophenotyping also may be used to examine subsets of both CD4 T cells and CD8 T cells in HIV infection which may be important in disease progression. CD45RA, CD45RO, CD28, and CXCR4 have, among other antigens, been examined on helper or suppressor subsets during HIV infection (62,63 and 64). While these additional markers to subset helper and suppressor T cells have provided interesting information regarding the nature of HIV disease and are being used in various clinical studies, none have become a universal standard of practice thus far.

Historically, a CD4 percentage from a flow cytometer and an absolute lymphocyte count obtained from a hematology analyzer, or by manual methods, had to be used to calculate an absolute CD4 count (a “dual-platform” method). Recently, though the use of bead standards placed in the blood to be analyzed, absolute CD4 counts as well as percentages can be obtained directly from a flow cytometer (a single-platform method) (65). Data has been published demonstrating less variability in CD4 counts obtained using single platform methods in comparison to a dual platform technique (66, 67).

Congenital Immunodeficiencies

Surface marker analysis is used in conjunction with other laboratory tests, such as those for serum immunoglobulins, cell function, and enzyme deficiencies, to examine a variety of primary immunodeficiency syndromes such as severe combined immunodeficiency (SCID), DiGeorge syndrome, and common variable immunodeficiency (CVID) (68,69,70,71 and 72). Immunophenotyping in patients with suspected immunodeficiencies may be performed to: (i) assess the lineages and subsets of leukocytes present; (ii) detect the absence of normal cell surface antigens; and (iii) to evaluate the presence of inducible antigens.

Determination of the lineages and subsets of cells present on the peripheral blood is of value in immunodeficiencies characterized by an absence, or diminution in numbers, such as DiGeorge's syndrome (thymic hypoplasia). This is a disease of T cell deficiency and immunophenotyping can be used to pinpoint the paucity of T lymphocytes in the peripheral blood (72). It is important to note, however, that a diagnosis of DiGeorge's syndrome cannot be made solely on the basis of immunophenotyping data.

The absence of normal cell surface antigens is observed in immunodeficiencies such as leukocyte adhesion deficiency (LAD) (68, 73, 74). LAD-type 1 patients, who suffer from recurrent bacterial infections, have a defect in leukocyte integrins including CD11a, CD11b, and CD11c in conjunction with CD18. In most cases, leukocytes from LAD-1 patients display decreased expression of these antigens as well as decreased function. Cell surface immunophenotyping is quite useful in the overall evaluation of the patients.

The detection of inducible antigens may be used in the overall evaluation of some immunodeficiency diseases such as DiGeorge's syndrome and SCID. An example of this is the expression of CD69 in response to mitogen stimulation (75, 76). Increases in CD69 expression, an early activation marker, occur on lymphocytes as early as 4 to 6 hours of culture with mitogens and thus may be used as a measure of cellular activation. In addition to providing quicker data than classical methods, such as thymidine incorporation, CD69 staining for lymphocyte activation also readily permits multiparameter studies in which cellular activation can be examined on various lymphoid subsets. Caution must be exercised in using this approach, as CD69 expression may be induced under conditions other than mitogenesis and might be less sensitive than thymidine incorporation (77).

Various immunodeficiencies are associated with specific enzymatic defects in various cell types. Chronic granulomatous disease (CGD), for example, is classically associated with a defect in the oxidative metabolism of neutrophils, resulting in a lack of hydrogen peroxide production. This defect is classically detected using nitroblue tetrazolium tests (NBT), but also may be assayed by flow cytometry using dichlorofluorescein diacetate (DCF-DA)-a nonfluorogenic substrate capable of entering live cells (78). Production of hydrogen peroxide within the cell converts DCF-DA into an insoluble, fluorogenic compound, dichlorofluorescein. Alternative, dihydrorhodamine can be used for the same purpose (79). Phagocytosis, which should be comparable in CGD and normal individuals, also may be examined through the use of beads or opsonized fluorochrome labeled bacteria. It is possible to assay both oxidative burst and phagocytosis simultaneously in a single flow cytometric assay, screening for both possible defects in individual cells (80).

Transplantation

Solid Organ

Flow cytometry can be used either pretransplantation or posttransplantation in support of solid organ transplantation. Flow cytometric assays for the detection of alloantibodies are widely used in the pretransplantation setting. These assays involve the incubation of donor cells with recipient serum followed by a fluorochrome-conjugated antihuman reagent. Compared to complement dependent-cytotoxicity crossmatching, flow cytometric assays are more sensitive, objective, rapid and permit concomitant examination of multiple types of cells (81, 82).

Flow cytometric assays for post-transplantation are directed at monitoring therapy and predicting or detecting rejection. Flow cytometric analysis of cell surface markers has been used to assist in delineating graft rejection *vis á vis* viral [cytomegalovirus (CMV)] infection, to monitor the efficacy of cytoreductive/immunosuppressive therapy, and to detect antibodies to murine immunoglobulin during OKT3 therapy. In the study of graft rejection versus CMV infection, several studies have demonstrated an association between an increase in interleukin 2 (IL-2) receptor-positive, CD3+ T lymphocytes and graft rejection (83, 84). There is controversy concerning the value of total T-cell enumeration, CD4/CD8 ratios, and the expression of HLA-DR (Ia) on T cells in discriminating rejection from CMV infection (85, 86). The monoclonal antibody OKT3 is often used as antirejection therapy to block the activity of cytotoxic T lymphocytes (87).

This therapy relies on the establishment of sufficient plasma levels of OKT3 to bind the T cells and remove them from the circulation (at least temporarily) without the development of antimurine antibodies. Flow cytometric assays are available to monitor CD3+ cells and plasma (or serum) levels of OKT3 and, therefore, to provide an overall assessment of the likelihood of successful OKT3 therapy (88, 89). Similarly, through the use of blocking assays (90,91 and 92), it is possible to use flow cytometry to detect the presence of anti-OKT3 antibodies that may develop in response to therapy with this murine antibody.

Flow cytometry also can be used to detect intracellular cytokines, such as IL-2 and interferon-gamma (93, 94). These cytokines are produced in activated T lymphocytes, and their production is impaired by many antirejection agents. Multiparametric flow cytometry assays are capable of detecting alterations in the levels of intracellular cytokines in lymphoid subsets, permitting such parameters to be used in monitoring the efficacy of immunosuppressive agents.

Hematopoietic Stem Cell

Transplantation of pluripotent hematopoietic stem cells has become an accepted form of therapy for a myriad of diseases (95,96 and 97). Common to this therapy is the eradication of the patient's existing immune system with subsequent introduction of new immune cells from either an autologous or allogeneic source. Keys to successful engraftment of the new immune system include transplantation of adequate numbers of stem cells to the host and transplantation of stem cells of appropriate purity. Both of these tasks are well-suited to monitoring by flow cytometric immunophenotyping.

Enumeration of hematopoietic stem cells is now generally accomplished through the use of CD34 monoclonal antibodies (98,99,100,101,102,103,104 and 105). Although the precise immunophenotype of the true pluripotent stem cells remains controversial, CD34 is the most universally accepted marker for identifying these cells, or at least cells which are capable of engraftment and reconstituting the immune system. Simplistically, enumeration of CD34+ cells is cell surface immunophenotyping similar to that performed for CD4 enumeration or a number of other assays. Unfortunately, accurate CD34 determination is more complex due a variety of factors such as the low percentage of stem cells in most specimens, the intensity of CD34 staining, and the recognition of different epitopes by various CD34 antibodies. CD34 monoclonal antibodies have been assigned three classes (I, II, and III) based on the sensitivity of the epitopes recognized to enzyme digestion (102). To promote inter-institutional consistency of therapy and design of cooperative studies, attempts have been made to design “consensus” protocols for the enumeration of CD34+ stem cells, and commercial products have become available for stem cell enumeration (Table 62.6). While there is no agreement concerning which of these protocols is optimal, there is increasing acceptance that stem cell enumeration is best performed with class III antibodies with phycoerythrin as the fluorochrome. Fig. 62.2 illustrates the data analysis strategy for CD34+ stem cells enumeration proposed by the International Society for Hematotherapy and Graft Engineering (ISHAGE).

TABLE 62.6. STEM CELL ENUMERATION PROTOCOL COMPARISON

Protocol (ref)	Mabs and Fluorochromes Used	Number of Events Collected
ISHAGE (100)	CD34 (class II or III for PE, class III for FITC), CD45	75,000 CD45+
SIHON (103)	CD34, CD14, CD66e, LDS-751	50,000 nucleated
Milan (98)	CD34	50,000 gated
Procount* (104)	CD34 (class III), CD45, nucleic acid dye	Variable
Stem-kit** (105)	CD34, CD45 (modified ISHAGE)	75,000 CD45+

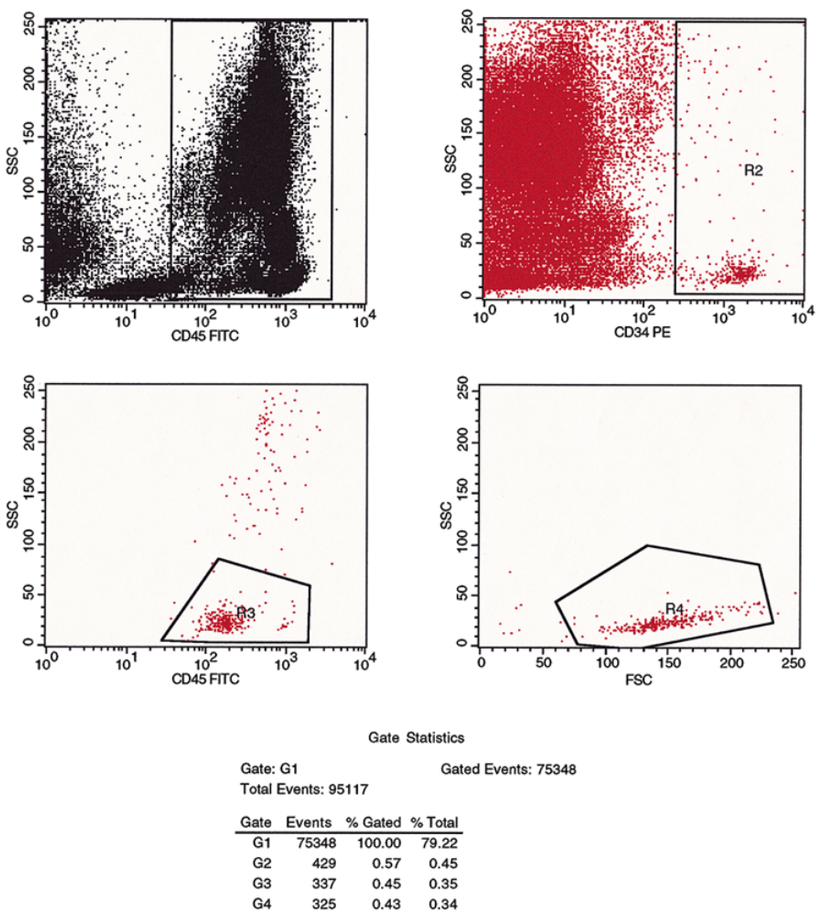
ISHAGE, International Society for Hematotherapy and Graft Engineering; SIHON, Foundation for Immunophenotyping in Hemato-Oncology of the Netherlands

Key clinical issues associated with poststem cell transplantation management include assessing the engraftment of the marrow, preventing, detecting, and managing graft versus host disease, and in certain instances, detecting minimal residual disease. Engraftment is often assessed by bone marrow biopsies and differential counts on smears or peripheral blood. Immunophenotyping may be used as an ancillary assay to provide a more comprehensive picture of the reconstituted immune system in these patients. Flow cytometric quantitation of reticulocyte RNA also has been proposed as a method of predicting successful engraftment of bone marrow (43). Here thiazole orange is used to stain the RNA in reticulocytes, providing an index of maturity in these cells, which is thought to be an early indicator of generally functioning marrow.

Graft versus host (GVH) disease in allogeneic marrow transplants is a major concern with grave consequences. Here the transplanted immune system recognizes the host as foreign. Reduction of mature T cells in the donor stem cells reduces the incidence of GVH, and immunophenotyping is often of use in monitoring T-cell depletion of these preparations before transplantation (107). A variety of studies have presented immunophenotypic correlates or predictors of GVH, but none of these has yielded an assay that has become a widespread and standardized practice in the monitoring of these patients (108).

Antibody-Mediated Diseases

There are autoimmune diseases characterized by the production of antibodies that react with, and destroy, specific cells or tissue. Included among these diseases are several forms of thrombocytopenia and neutropenia. Examples of the former are neonatal alloimmune thrombocytopenia, transfusion-induced thrombocytopenia, and autoimmune thrombocytopenia purpura; examples of the latter include transfusion-induced neutropenia and neonatal isoimmune neutropenia. In the evaluation of these diseases, it is important to establish whether the paucity of cells is because of immune-mediated destruction or lack of production or maturation.



Gate Statistics

Gate: G1 Gated Events: 75348
Total Events: 95117

Gate	Events	% Gated	% Total
G1	75348	100.00	79.22
G2	429	0.57	0.45
G3	337	0.45	0.35
G4	325	0.43	0.34

FIGURE 62.2. An example of one method for CD34+ stem cell enumeration, the ISHAGE protocol. Specimens are stained with CD45 to identify leukocytes and CD34 to identify stem cells. Stem cells are identified and quantitated using a series of gates. Gating parameters include forward light scatter, side light scatter, CD45 staining, and ultimately CD34 staining.

Flow cytometry is well suited for assaying peripheral blood specimens for the presence of circulating antibody in the serum or plasma or antibody bound *in vivo* to the cell surfaces, using indirect and direct immunofluorescence techniques, respectively (109,110,111,112,113 and 114).

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH), a rare, chronic hemolytic disease, is from a deficiency of cell surface glycoproteins that are glycosylphosphatidylinositol-anchored. Classic laboratory tests for PNH include the sucrose hemolysis test and the acid hemolysis test (Ham's test). CD55 (decay accelerating factor) and CD59 (membrane inhibitor of reactive lysis, protectin) are two glycosylphosphatidylinositol-anchored membrane glycoprotein whose expressions are diminished in PNH. In addition to being expressed on erythrocytes in normal individuals, these two markers also are present on granulocytes. The defect in PNH patients that diminishes the expression of CD55 and CD59 on erythrocytes, and contributes to their lysis, also diminishes the expression of these glycoproteins on granulocytes, but without resulting lysis. A flow cytometric assay has been developed to quantitate CD55 and CD59 expression on granulocytes for the diagnosis of PNH (115, 116). The specificity of

these antibodies together with the quantitative aspects of flow cytometry permit a rapid, accurate diagnosis and identification of partially (PNH II) or completely (PNH III) deficient cells.

Abnormal Hematopoiesis

The laboratory evaluation of anemia frequently includes reticulocyte enumeration as a measure of hematopoiesis. The normal response of bone marrow to anemia is the increased production of erythrocytes, although this is not observed when the anemia is the result of abnormal marrow function, which is often because of vitamin or iron deficiencies (hypoproliferative states). Thus, reticulocyte enumeration is often of use in determining the cause of anemia and monitoring the effect of therapy. Reticulocyte enumeration also has been proposed as a method of assessing the function of engrafted bone marrow. Reticulocytes are immature red blood cells that, although lacking nuclei, retain RNA in higher amounts than is found in more mature red blood cells. This residual RNA can be measured rapidly and quantitatively on a per-cell basis by flow cytometry using dyes such as thiazole orange (117,118,119 and 120). In addition to their use for the enumeration of reticulocytes, the quantitative aspects of the flow cytometric assay have been used to devise a reticulocyte maturity index (RMI) based upon the quantity of RNA in these cells (118).

Platelet Disorders

Platelet activation is associated with a variety of diseases, including adult respiratory distress syndrome (121), renal failure requiring dialysis (122), heparin-induced thrombocytopenia-thrombosis (123) and a number of cardiovascular ailments (124,125 and 126). Activation of platelets is generally assessed by flow cytometry using monoclonal antibodies directed against activation-related antigens, such as CD62P directed against P-selectin, a granule membrane protein GMP-140, and CD61 directed against the activated form of the platelet membrane glycoprotein IIb-IIIa complex (126,127 and 128). Flow cytometric assays of this type have several advantages over other approaches: subpopulations of platelets can be analyzed; multiple parameters may be examined simultaneously (129,130 and 131).

Non-Neoplastic Diseases of Erythroid Cells — Sickle Cell, ß-Thalessemia, Feto-Maternal Hemorrhage

While most flow cytometric assays are performed on nonerythroid components of hematologic specimens, recent advances have made certain studies of erythroid cells by flow cytometry practical and useful tests in the clinical laboratory. The development of monoclonal antibodies direct against fetal hemoglobin (HbF) has been the most prominent advance in this area and have permitted the development of flow cytometric assays for the detection of fetal hemoglobin (132,133,134 and 135). With the use of appropriate agents to permeabilize the cell, specific staining can be achieved with fluorochrome conjugated anti-HbF. This can be used as a replacement for the (acid elution) Kleihauer-Betke test, which has been the classical method of detecting HbF. The detection of cells containing fetal hemoglobin is of importance in monitoring therapy of sickle cells disease with butyrate and hydroxyurea, in detection of feto-maternal hemorrhage, and in the evaluation of various ß-thalessemias.

Ankylosing Spondylitis and Other Arthropathies

A strong genetic association exists between the presence of the HLA-B27 antigen and certain arthritic diseases including ankylosing spondylitis, a chronic, progressive form of arthritis affecting the spine. HLA-B27 typing has become a valuable component in the diagnosis of these diseases. The classical method of typing for HLA-B27 is through complement-mediated lymphocytotoxicity. This assay, while reliable, is time consuming and somewhat laborious. Several groups have described flow cytometric methods for HLA-B27 determination using fluorochrome-labeled anti-HLA-B27 monoclonal antibodies (136,137,138 and 139). The use of CD3 gating in multiparameter flow cytometry studies for HLA-B27 may improve the reliability and sensitivity of this method (137), as will the use of multiple monoclonal antibodies (139, 139).

Solid Tumors

DNA Analysis

The analysis of cellular DNA by flow cytometry is limited by the fact that only gross alterations in the DNA can be measured: translocations and small alterations in total DNA content escape detection. Furthermore, the need to dissociate solid tissue into monodispersed suspensions also places restrictions on this endeavor. The total G0/G1 nuclear DNA content (ploidy) and the rate of proliferation as determined by calculating the percentage of cells in each phase of the cell cycle are the two most common applications of flow cytometry in the clinical laboratory. Abnormal DNA content (i.e., aneuploidy) is perhaps the single cellular feature demonstrating the strongest correlation with neoplasia (140). While many neoplastic lesions are not aneuploid, the presence of aneuploidy is closely associated with neoplastic or preneoplastic lesions. Thus, in specimens where morphologic or phenotypic studies are ambiguous or not available, the detection of aneuploidy can assist in arriving at a diagnosis. This use may be extended to exfoliative cytology or body cavity effusions from suspected neoplasms in which the assessment of tissue architecture is not possible and sample preparation for flow cytometry is enhanced by the more dispersed nature of the cells. DNA studies also may be conducted on paraffin-embedded tissue as well as fresh tissue, thus allowing for retrospective studies or the ploidy assessment of a specimen at a later time without the necessity of procuring extra tissue. Studied of paraffin-embedded tissue, however, is fraught with technical difficulties and great care must be directed at obtaining reliable data (141,142,143 and 144).

Great controversy exists concerning the use of DNA content/cell cycle analysis as a prognostic marker for various types of solid tumors. Numerous studies have been published examining these parameters in a wide assortment of solid tumors, largely using paraffin-embedded tissue (reviewed in 145,146,147,148 and 149). Quite likely the technical artifacts associated with the study of paraffin-embedded material resulted in much of the conflicting data and conclusions. The American Society of Clinical Oncology concluded that insufficient data exists to warrant use of DNA content/cell cycle analysis as a prognostic marker in breast and colorectal cancer (150).

Despite this report and the controversy over the merits of DNA analysis, a recent survey indicated that DNA/cell cycle analysis remains to be a widely performed test (54).

Methodologies

Flow cytometry relies upon the intersection of a stream of cells or particles with a stable light beam of known wavelength and the subsequent detection of fluorescence or light scattering from cells. Before any specimens are analyzed on a flow cytometer, there must be assurance that the stream of cells and the light beam are intersecting at a point where the cells are optimally illuminated and the resulting signals are capable of being collected by the appropriate detectors. The process of bringing the sample stream and light beam into proper orientation is termed alignment. Improper alignment of an instrument can lead to weak, unusual, or even missing signals from cells. In most recently manufactured clinical instruments alignment is optimized by service engineers and does not need to be adjusted on a daily basis. Alignment should be checked daily by analyzing specimens (beads or cells) with known light scatter and fluorescence characteristics to ensure that these are detected in a consistent manner. In addition to alignment, calibration of flow cytometers must be performed prior to the analysis of any clinical specimens to determine how sensitive the detection of standardized signals is from day to day. Again, this is normally accomplished by analyzing standard beads or chicken erythrocytes. Fluctuations in the signal obtained with predetermined instrument settings and laser power generally are indicative of misalignment, a dirty optical path, or a failing light source, detector, or circuitry, among other causes. Reproducible calibration thus ensures standard sensitivity of a cytometer, which is particularly important in DNA studies or when studying markers that result in dim fluorescence. A third general procedure in preparing to analyze samples by flow cytometry is setting proper compensation for specimens stained with multiple fluorochromes. Because fluorochromes generally have wide emission spectra, they will overlap to various extent into the band of emission being collected for other fluorochromes. By using a set of standard beads with commonly used fluorochromes, this overlap can be minimized using an electronic compensation to subtract contaminating signals. These procedures are more thoroughly examined elsewhere (1,2,3,4 and 5, 151).

Gating

Flow cytometers are incapable of distinguishing cells of interest from other particles that may be present in specimens submitted for analysis unless procedures are implemented to uniquely distinguish these cells. Cytometers are capable of measuring (in addition to fluorescence signals) the forward and orthogonal light scatter signals emanating from cells, which are roughly indicative of particle size and granularity, respectively. Empirically, and through the use of staining with monoclonal antibodies, the light scatter patterns of normal peripheral blood have been determined and correlated with cell type (152). Armed with this knowledge, it is possible to examine only cells of interest for immunophenotyping, excluding the extraneous cells, debris, or particles through a process referred to as light scatter gating. Here the cytometer is directed to ignore events (particles) whose light scatter characteristics do not fall within a predefined set of parameters. In routine lymphocyte subset analysis of peripheral blood, erythrocytes can be lysed from the whole blood to reduce the number of particles flowing through the cytometer. The lymphocytes can then be analyzed separately from the monocytes and granulocytes, which also remain through the use of gating (Fig. 62.3). Failure to exclude cells of extraneous lineages from analysis can, and usually does, lead to misinterpretation of marker expression.

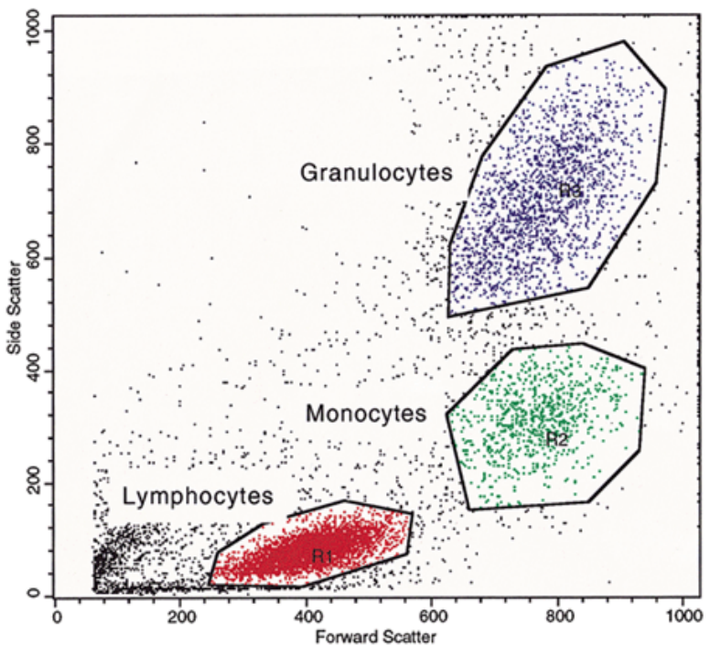


FIGURE 62.3. A dot density, two-parameter histogram illustrating the forward light scatter (FSC) on the x-axis and side (90°) light scatter (SSC) on the y-axis of human peripheral blood after lysis of the red blood cells. The red area surrounded by the box represents the gated lymphoid cells; monocytes are indicated by the green cells; the granulocytes are indicated in blue. Debris and small particles are to the left of the lymphoid cells.

While gating using forward versus side scatter signals has been the standard methodology for a decade, gating also may be performed using features other than, or in addition to, light scatter signals. For example, the identification of leukocytes in heterogeneous samples can be accomplished by gating on cells that stain with CD45. Leukocyte subsets and their precursors can be distinguished with high sensitivity in bone marrow using a combination of CD45 staining and side light scatter collected in a logarithmic mode rather than the more common linear mode (Fig. 62.4) (33).

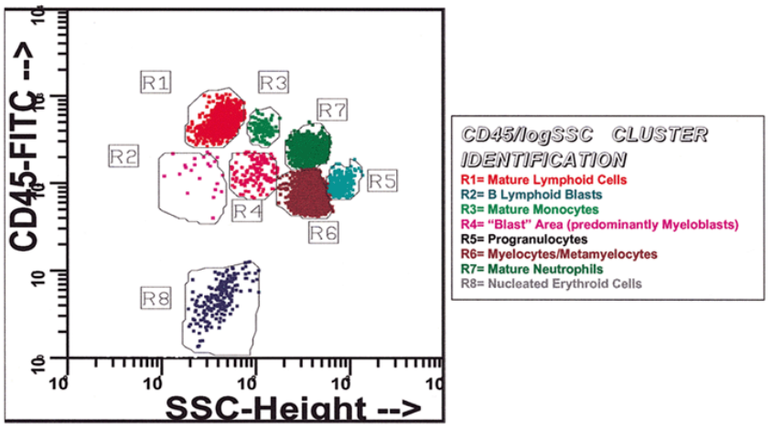

FIGURE 62.4. CD45 versus log SSC gating of human bone marrow. By using the pan-leukocyte reagent (CD45) and log side scatter, a better resolution of leukocyte subsets is obtained than with the FSC versus SSC gating demonstrated in Fig. 62.3.

Surface Marker Staining of Lymphocyte Subsets

The most common clinical applications of flow cytometry involve the analysis of cell surface markers on leukocytes. The key advantage to this technology is the examination of multiple cellular features in a rapid, quantitative manner on individual cells. In contrast to manual immunofluorescence techniques, flow cytometric immunophenotyping often examines multiple antigenic markers simultaneously to more precisely determine lineage, maturity, and/or state of activation of each cell type. This is possible through the use of multiple fluorochromes that have distinct emission wavelengths. Quantitation of the emissions at prespecified wavelengths will yield a value proportional to the amount of fluorochrome-conjugated antibody bound to the cells and, ultimately, to the amount of antigen present. Examples of commonly used fluorochromes are given in Table 62.7. Staining of cells with multiple antibodies is best accomplished using a direct immunofluorescence technique, i.e., having fluorochrome-conjugated antibodies rather than using a sandwich (indirect) technique to avoid cross-reactivity. Currently, three- and four-"colors" (fluorochromes) normally are examined together with light scatter signals, yielding five or six parameter studies (153,154 and 155).

TABLE 62.7. COMMONLY USED FLUOROCHROMES FOR IMMUNOPHENOTYPIC STUDIES

Fluorochrome	Excitation* (nm)	Emission* (nm)	Comments
Fluorescein isothiocyanate (FITC)	488	525	Low molecular weight, stable
Phycoerythrin (PE)	488	580	High quantum yield
Cy3	488	575	
Peridin chlorophyll protein (PerCP)	488	672	Bleached by high laser power
Tandem conjugate (ECD, Red613)	488	613	Tandem conjugate of PE and Tx Red
Tandem conjugate (Red670)	488	670	Tandem conjugate of PE and Cy5
Cy7	743	785	
Allophycocyanin	633	660	Requires He, Ne, krypton, or dye laser
Texas red	600	620	Requires dye laser
Cy5	633	667	Binds monocytes, requires He, Ne, krypton, or dye laser

* The values listed for excitation and emission wavelengths are not necessarily the maximum, but rather those that are commonly used in the laboratory.

Care must be taken in sample procurement and handling to avoid the introduction of artifacts into the analysis of surface markers. A wide variety of factors such as the anticoagulant used for the collection of the peripheral blood specimen and the collection time of day have been demonstrated to influence the enumeration of various lymphocyte subsets (151, 156,157 and 158). Further more, maintenance of the specimens at room temperature has been demonstrated to be a strict requirement; storage at 4°C for even short periods of time will induce capping of the antigens and alter the detection of lymphocyte subsets (151, 158,159 and 160).

Peripheral blood specimens are prepared for staining either by density-gradient separation of lymphocytes or by the lysis of red blood cells with agents such as ammonium chloride. Removal of erythrocytes from peripheral blood specimens is generally thought to be necessary because it allows the flow cytometer to analyze other cellular populations more quickly. The latter technique, commonly referred to as the "whole blood lysis" technique, generally is used because it is quicker, it may be performed before or after staining, and it permits the examination of monocytic and granulocytic components concomitant to the analysis of lymphocytes. The major questions regarding this approach are whether the specific antigen is altered by the lysing agent and whether there is a need for the cells of interest to be further concentrated. Phenotyping data from both methods of sample preparation are generally similar, although density-gradient procedures may produce loss of certain populations of cells (151, 161, 162). Recently, a consensus conference on the immunophenotyping of leukemias and lymphomas recommended the density gradient

separation **not** be used on these specimens (163). Nonetheless, approximately one fourth of laboratories performing lymphocyte immunophenotyping continue to use density gradient separation as a preparative technique (54). One approach to the flow cytometric analysis of lymphocyte subsets, not commonly in use, would preclude the need for removal of erythrocytes. This approach involves the use of a monoclonal antibody to the CD45 (common leukocyte) antigen as well as nucleic acid dyes to distinguish leukocytes from erythrocytes and adjusting the cytometer to "recognize" only the cells staining for this antigen (164). Subsetting is then accomplished through the use of additional monoclonal antibodies conjugated to other fluorochromes.

Staining of peripheral blood and bone marrow with monoclonal antibodies may be performed either prior to or after lysis of red blood cells. Most laboratories use the stain-then-lyse method (54). The amount of antibody used is variable, but in most instances should be of sufficient quantity to saturate all of the antigen sites on the cells. The time of incubation with these antibodies may also vary, but for most commonly examined cell surface markers, incubation time between 15 and 30 minutes are sufficient. After this incubation, the cells are washed with an isotonic solution and, in most clinical laboratories, fixed with paraformaldehyde. Besides preserving the cells better for later analysis, this fixation also has been demonstrated to inactivate the human immunodeficiency virus (151, 155, 165). Cells prepared in this manner, if stored at 4°C and protected from light, may be stored approximately 10 to 12 days without substantial loss of staining or light scatter properties.

Surface Marker Staining of Cells Other Than Lymphocytes

A myriad of cells other than lymphocytes can be analyzed for cell surface marker expression in the clinical flow cytometry laboratory. Each cell type will have unique specimen handling or staining requirements. Certain specimens, such as platelets, require that special care be taken in procurement, transport, and staining to reduce artifacts such as aggregation. Analysis of platelet activation is highly influenced by the type of anticoagulant used, the length of time prior to analysis, and the use of aspirin or similar products by the patient. In these assays (in contrast to lymphocyte immunophenotyping), it is often desirable to fix the specimen with paraformaldehyde prior to staining to minimize the artifacts introduced after procurement of the specimen (54, 60). Other nonlymphoid hematologic cells also present unique requirements. Monocytes, for example, bind the fluorochrome Cy5 independent of monoclonal antibodies against monocytoid antigens (166), therefore the use of Cy5-labeled monoclonal antibodies to study monocytes is not recommended. Granulocytes survive for much shorter periods of times *ex vivo* than do most lymphoid cells, thus studies of these cells must be performed in a more rapid manner.

The staining of platelets, neutrophils, and lymphocytes for autoantibodies against each of these cell types may be performed by using either direct or indirect immunofluorescence techniques. Direct staining, using a xenogenic antihuman immunoglobulin antibody, is used to detect autoantibody bound *in vivo* to the cells. To control for the specificity of the staining, an antibody directed against an irrelevant antigen that is derived from the same species as the anti-Ig antibody and matched for isotype and F/P ratio is used. An indirect staining method is used to detect autoantibodies in the circulation. In this approach, relevant donor cells are incubated with the serum (usually heat inactivated) from the patient with the suspected autoimmunity. After an appropriate length of incubation, the cells are washed and incubated with a fluorochrome-conjugated antihuman immunoglobulin reagent. Controls in this instance normally include identical staining with serum obtained from a normal donor. The isotype of the autoantibodies can be identified through the use of isotype-specific antihuman reagents.

Staining of Intracellular Antigens

A wealth of clinically relevant information is present within cells as well as on their cell surfaces. Flow cytometry may be used to detect intracellular antigens in addition to, or instead of, cell surface antigens. Examples of these include cytoplasmic immunoglobulin, cytoplasmic CD3, terminal deoxynucleotidyl transferase (Tdt), and myeloperoxidase (167,168 and 169). To stain intracellular components it is necessary to permeabilize the cell membrane for appropriate penetration of the monoclonal antibodies into the cell. If distinct cell surface antigen expression is to be examined at the same time as intracellular antigens, cell surface staining must precede permeabilization of the cells. Cells

may be permeabilized using a number of different reagents, including a number of proprietary formulations. Perhaps the most common nonproprietary permeabilization reagents are a combination of paraformaldehyde and Tween 20 (169, 170). Key concerns in selection of permeabilization reagents is not only assuring adequate accessibility of the monoclonal antibodies to the target antigens, but also ensuring that the target antigen is not destroyed or altered by the permeabilization reagent.

DNA Staining

The staining of hematological material for DNA content is easily accomplished because the cells to be examined are predominantly in single-particle suspension. This is not the case, however, for the DNA analysis of tissue derived from solid tumors. Here the specimen must be disaggregated to obtain a monodisperse suspension. This is accomplished by mechanical dissociation and/or enzyme (protease or collagenase) digestion, generally followed by filtration through a 50- to 70-mm mesh (171). The yields from dissociation procedures vary because of the procedure itself and the nature of tumor being dissociated. Therefore each laboratory needs to assess the merits of each procedure on each type of tumor to be routinely analyzed. Cellular losses should be, at worst, random, or at best, exclusive of the cells of interest. Dissociation procedures must be performed appropriately for the type of analysis to be conducted, e.g., enucleation procedures may be used if only DNA is to be studied, however if both surface markers and DNA are to be examined, then care must be taken to ensure an intact cell membrane.

DNA analyses are not limited to specimens freshly obtained from the patient or *in vitro* cultivation. Cryopreserved specimens generally yield coefficients of variation (CVs) approximating those obtained from fresh tissue. As mentioned previously, DNA assays also may be performed on formalin-fixed, paraffin-embedded tissue (172, 173). Here sample preparation and data interpretation are more rigorous than required in DNA analysis of fresh tissue. Sample preparation concerns begin at the time of original tissue fixation and embedding. The type of fixative has a profound effect on the resulting DNA histograms, and neutral-buffered formalin has been demonstrated to be the fixative of choice (174). However, even this fixative introduces some DNA artifacts, by reducing the accessibility of the DNA to the fluorescent dye (175). Sections usually are processed from paraffin blocks rather than the entire tissue. This generally is because of a desire to retain some tissue for any future medical or legal issues. Section thickness has a substantial effect on the resulting DNA histograms, and it generally is agreed that 50-mm sections provide the optimal results (176). The sections are deparaffinized using xylene or the equivalent and subsequently rehydrated using a series of decreasing ethanol solutions. The rehydrated tissue is now disassociated with enzymes (pepsin or trypsin) and filtered to obtain single cell suspensions. To reverse the effects of the formalin fixation, the cells should be subjected to heat treatment prior to staining (141). These cell suspensions are then stained with propidium iodide as described for fresh tissue.

A number of fluorescent dyes that may be used to stain cellular DNA are available; however, the dye most commonly used for this purpose in the clinical laboratory is propidium iodide (PI). PI intercalates into cellular DNA and yields fluorescence signals in the orange/red region proportional to the amount of DNA. It is readily excitable at 488 nm and is stable in solution, and these factors contribute to its widespread use. The staining achieved with propidium iodide is uniform and reproducible, yielding very small CVs. CVs reflect the “tightness” of a histogram peak; therefore, the tighter the CV of a G0/G1 DNA peak, the easier one can detect slight aneuploidy in a specimen (e.g., the sensitivity of an aneuploidy detection increases). A number of methods have been described for staining cellular DNA with propidium iodide (92, 93). The classic procedures (177, 178) rely upon lysis of the surface membrane of the cell, digestion of the RNA, and staining of the residual intact nuclei. Using this approach, a one-step method has been developed for DNA staining. Using a filtered solution of 10 mM Trizma base, 10 mM NaCl, 0.7 U/mL RNAse, 7′ 10 5 M PI, and 0.1% NP-40, cells can be lysed, enzyme-digested, and stained with PI concomitantly. This solution is added to the cells while vortexing, and the cells are then incubated at 4′C for 30 minutes. The stained nuclei can be analyzed immediately by flow cytometry or fixed with paraformaldehyde and stored for as long as a week until analysis. As DNA standards (discussed later), chicken or trout erythrocytes may be added to the specimen prior to staining.

Specimens stained with propidium iodide may be analyzed to determine the ploidy of the specimen and, in most instances, to assess proliferation. This is possible because cellular DNA is increased as cells progress through S-phase and enter G2/M. In G2/M, cells have 4N DNA and yield PI fluorescence twice that observed in G0/G1 nuclei (Fig. 62.5). Proliferation may be assessed in freshly-obtained specimens to determine the *in vivo* proliferative rate (particularly for anaplastic specimens), or specimens may be stimulated *in vitro*, then stained with PI to assess their proliferative response. The latter is performed in the evaluation of immunodeficiencies in which the response of peripheral blood lymphocytes to mitogen stimulation is important in pinpointing the immune defect. Patients' lymphocytes are cocultured with mitogen (e.g., phytohemagglutinin) for 72 hours, harvested, and stained with PI as described above. The percentage of cells in S-phase and G2/M is determined and compared to patient cells cultured without mitogen or to normal, resting lymphocytes stained in the same manner. This assay also may have a positive control consisting of normal lymphocytes cocultured with mitogen and responding in the predicted manner.

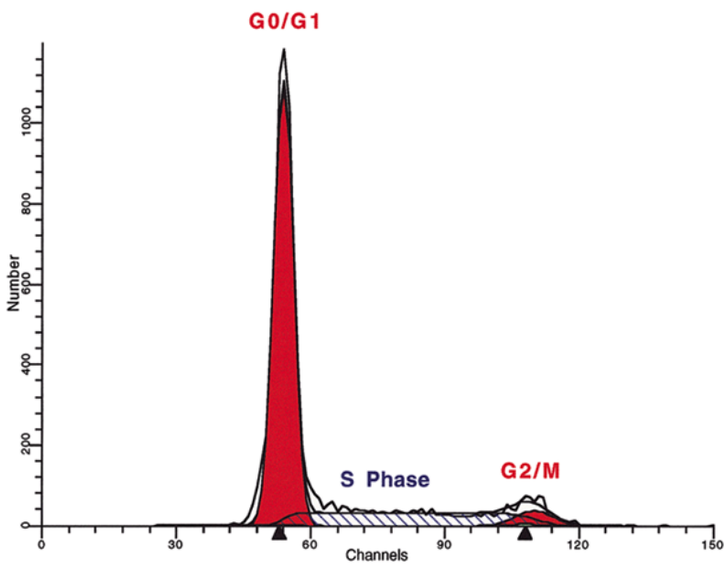

FIGURE 62.5. A representative one-parameter histogram of cell nuclei stained with propidium iodide. Phases of the cell cycle are as indicated. (Note the broad, irregular S phase.) Ploidy determinations among specimens are made by comparing the position of the G0/G1 peaks.

Combined Surface Marker/DNA Staining

There are obvious advantages to being able to concomitantly examine the surface markers and DNA content of the same cells. The proliferation of neoplastic cells can be assessed much more accurately if one can gate on the relevant cells through the use of a surface marker. The detection of aneuploidy in minimal residual disease becomes more sensitive if only cells of the pertinent lineage are examined. The assessment of proliferation can be examined by cell lineage and subset through the use of concomitant cell surface marker/DNA staining. A technique for the dual staining of cells for surface markers and DNA was introduced by Braylan et al. (179) and remains in use with varying degrees of modification. Cells from fresh tissue are incubated with the

fluorochrome (usually FITC)-conjugated antibody against the surface marker in sodium azide at 4°C for an appropriate length of time, then are washed thoroughly. The cells, suspended in PBS or medium, are vortexed while an equal volume of 100% ethanol is added. The cells are incubated in the ethanol for 1 hour at 4°C, washed, treated with RNAse, and finally stained with propidium iodide. A major disadvantage of this procedure is the loss of resolution in the light scatter patterns. Cell surface/DNA staining has also been achieved through the use of sequential paraformaldehyde/detergent treatment of cells or detergent treatment alone (180, 181).

Methods also have been introduced that permit the concomitant analysis of surface markers, cytoplasmic antigens, and DNA content while retaining most light scatter characteristics of the fresh cells (182, 183). In these methods, cells are stained for a specific surface marker, washed, then briefly fixed with a low concentration of paraformaldehyde and washed again. The cells are then permeabilized with 70% methanol and again washed. The cells may now be stained for the expression of intracellular antigens. If FITC was used to mark the surface antigen, a distinct fluorochrome such as allophycocyanin or Duochrome is used to stain the intracellular antigen. The cells are again washed and finally incubated with an RNAse/propidium iodide solution to stain the DNA. This method has been demonstrated to reliably stain all parameters, with a fair preservation of light scatter signals, and only minor diminution of the propidium iodide fluorescence because of the paraformaldehyde. A single-step proprietary reagent has also been reported which maintains light scatter properties while permitting staining of both surface markers and intracellular components (184).

Reticulocyte Staining

Reticulocyte staining is dependent on the staining of residual RNA in immature erythrocytes. A number of RNA-binding dyes have been used for this purpose, including pyronin Y, acridine orange, thioflavin T, and thiazole orange. Thiazole orange (117) is a membrane-permeable dye, excited at 488 nm, that intercalates into nucleic acids and fluoresces at 533 nm. Staining of reticulocytes with this dye is easily accomplished: 5 mL of whole blood is incubated for 1 hour at room temperature with 1 mL of 0.1 mg/mL thiazole orange in PBS containing EDTA and sodium azide.

Interpretation

Surface Marker Staining

Flow cytometric data are customarily displayed as histograms, or plots, of the digitized data. With digitized data, the light scatter and/or fluorescence signals emanating from individual cells are assigned to a channel proportional to the strength of the signal. The number of channels varies from instrument to instrument

but is normally 64, 256, or 1024. The stronger the signal from the cell (e.g., the more fluorescent the cell), the higher the channel number to which that cell is assigned. Various numbers of parameters may be displayed on a histogram, the most basic being a one-parameter display. Here the histogram consists of the intensity of signal (channel number) on the x-axis (on either a log or linear scale) versus the number of particles (cells) in each channel on the y-axis. Most contemporary flow cytometry examines more than one parameter of a cell, and therefore one parameter histograms are rarely used. Two-parameter histograms display the intensity of two separate signals on the x- and y-axes, with the number of events being displayed either by dot density (Fig. 62.4) or contours or in isometric form. Three-parameter histograms are occasionally used to display multiparameter data and rely on three-dimensional (cubic) displays. The display of the number of events often requires color density graphics; therefore, the use of three-parameter histograms has been somewhat limited. Probably the most common display used in the clinical laboratory is the two-parameter histogram dot-plot. Here correlated data from individual cells may be visualized in a readily understandable manner. For three- and four-color (or more) studies, data are displayed in multiple two-parameter histograms.

Virtually all cells will display some degree of autofluorescence if stimulated with sufficient light. This would result in nonstained cells being placed at various positions in the histogram displays. This usually is not desirable because fluorescence intensity is typically displayed on a log scale and the ability to delineate small shifts in fluorescence decreases on the upper portion of the scale. Therefore, using an unstained control, the laser power and/or voltages to the photomultiplier tubes are adjusted to bring the unstained samples near the origin of the histogram display. This defines where “negative” cells will appear on future histograms.

Historically, the interpretation of “positive” staining relied on the “background” staining observed with isotypic controls (monoclonal antibodies of the same isotype as the test antibody but directed against irrelevant antigens) (151, 185). The isotype control defined negative staining. Recently, the use of isotype controls has been proposed to be superfluous, and potentially misleading at times (163, 186,187 and 188). Isotype controls ultimately have use in certain in clinical situations, however total, blind reliance on isotype controls is not appropriate (189).

The interpretation of immunophenotyping in the clinical laboratory is highly reliant on the immunophenotyping of normal control specimens. This serves two purposes: first, immunophenotyping normal controls on a daily basis, or with each assay, ensures that the assay is being properly conducted and the reagents are performing as expected; second, maintaining a historical database of normal control values allows better determination if a specific patient's phenotype falls within the range considered to be normal. Specimens used as normal controls should be as similar to the patient specimen as possible. For example, both should be collected in the same anticoagulant, if possible, and both should be prepared in the same manner (density gradient or whole blood lysis). Age, race, sex, and time of collection have all been shown to influence immunophenotyping, although the variations are generally regarded as insufficient to warrant separate controls.

The results of immunophenotyping assays are often reported in terms of percentages of cells (i.e., lymphocytes) positive for a specific marker. While this is sufficient in most instances, there are disease states that require the determination of absolute numbers of a given cell population, particularly if the patient is lymphopenic. In AIDS, for example, the absolute number of CD4+ cells is usually desired (155). The absolute number is readily obtained by multiplying the percentage of positive cells (for CD4 in this instance) by the absolute lymphocyte concentration. Alternatively, absolute numbers of CD4+ cells can be determined using bead standards (65). In the immunophenotyping of leukemia and lymphomas, reporting the percentage of cells positive for a given marker is considered of less value than describing the markers present on an abnormal population of cells (188, 190).

Quantitative Flow Cytometric Immunophenotyping

Flow cytometry is often used to determine if cells express a particular antigen, however, it also may be used to quantitate the amount of fluorescence resulting from antibody binding to a cell (191,192,193 and 194). As with manual immunofluorescence studies, staining evaluated by flow cytometry often has been reported as “bright” or “dim.” Through the use of a variety of standard beads, flow cytometric immunophenotyping may be reported in quantitative units such as molecules of equivalent soluble fluorochrome MESF) or antibody-binding capacity (ABC) (191,192 and 193). This quantitative approach to reporting flow cytometric immunophenotyping data offers a much more rigorous interlaboratory standardization for interpreting intensity of marker staining, as intensity of surface marker staining is often of potential value in the study of hematologic neoplasia and in HIV disease (163, 195, 196). A recent survey indicated that, in the analysis of leukemias and lymphomas, less than 4% of respondents used MESF units, although more than 70% routinely commented on intensity of marker staining (54).

DNA Analysis

One of the major reasons for undertaking DNA studies is to determine the ploidy of a specimen. Flow cytometry is a convenient method for this purpose, given the limitations of sensitivity discussed previously, and the interpretation of these data generally is straightforward (for more detail see 197, 198). The inclusion of a known diploid control, such as normal peripheral blood, is crucial to this interpretation. This control may be run in a separate tube or admixed with the patient specimen as an internal control. Preferably, the analysis is performed with the following array of samples: (a) diploid control, (b) patient specimen, and (c) diploid control and patient specimen. The third sample reduces the possibility that any shift in the G0/G1 peak from control to patient is because of fluctuations in the instrument. It remains desirable, however, to retain a separate diploid control. This serves to confirm that a single peak in a patient specimen reflects a diploid population rather than a technical error (e.g., failure to mix the control and specimen at the proper ratio). In simplest terms, the ploidy, or DNA index (DI), is determined by dividing the peak channel number of the G0/G1 peak of the specimen by the peak channel number of the G0/G1 peak of the diploid control. A

diploid specimen will have a DI equal to 1.00. A hyperdiploid specimen will have a DI greater than 1.00, and a hypodiploid specimen will have a DI less than 1.00.

The interpretation of DNA histograms is occasionally more complex than the proceeding would suggest. This primarily relates to the CV of the G0/G1 peaks. As mentioned previously, the lower the CV, the better and more precise the detection of aneuploidy. A specimen that is only slightly aneuploid may not yield a distinct G0/G1 peak, even with low CVs. Rather, one would observe a “shoulder” on the diploid G0/G1 peak because of the slightly aneuploid population. Discriminating a true an-euploid shoulder from an uneven diploid G0/G1 peak may be quite difficult. Experience, the “three tube” approach to analysis, and repeated analysis of the specimen in question are the means of addressing this question. Caution also must be taken in the interpretation of the case in which no distinct aneuploid peak appears in a patient specimen. This does not necessarily imply a true diploid genome; the deletion of some chromosomes, accompanied by the overreplication of others, could yield a net DNA content resembling normal diploidy. Therefore, the failure to detect an aneuploid G0/G1 peak should not be reported as diploidy, but rather as “no aneuploid peak detected.”

The interpretation of tetraploidy also must be approached cautiously because this peak will fall in the same channels as the normal G2/M peak and as doublets of diploid G0/G1 cells. The latter artifacts (doublets) may be detected using pulse processing, a technique by which the shape of the pulse signal may be used to delineate tetraploid cells from doublets. In lieu of pulse processing, or in addition to it, the manual microscopic examination of specimens concomitant to their analysis by flow cytometry will reveal whether or not doublets are present in the specimen. Tetraploidy should never be reported without at least one of these quality assurances. In specimens in which doublets are not present, a question may remain whether a tetraploid peak reflects a true aneuploid population or the G2/M population of the diploid cells. In some cases, this may never be ultimately resolved, although the following guidelines are helpful: (i) in most instances, an increase will be observed in S-phase if the tetraploid cells are G2/M cells; and (ii) if the tetraploid cells represent a true aneuploid population, the presence of an octoploid (8N) population might be expected, which would represent the G2/M population of the tetraploid cells.

A second reason for undertaking studies of cellular DNA is to assess proliferation. Here the DNA histograms must be analyzed in a manner that most accurately determines the percentage of cells in each phase (G0/G1, S, and G2/M) of the cell cycle. In the commonly used one-parameter DNA analysis, it is not possible to distinguish between G0 and G1 or G2 and M; therefore, these are considered collectively as G0/G1 and G2/M, respectively. For the comparison of proliferation rates among cell populations, the S-phase or combined S plus G2/M phases are computed. Because these phases represent periods of DNA synthesis, the higher the percentage of cells in these phases, the more rapidly a population is proliferating.

S-phase is best determined in cultured cells by the incorporation of bromodeoxyuridine, followed by two-color flow cytometric analysis (199). Most clinical specimens are not cultured *in vitro*, thus, clinical specimens usually are stained only with nucleic acid dyes such as propidium iodide. A number of computer programs have been written to determine the percentage of cells in G0/G1, S, and G2/M in one-color DNA analysis, and have been elegantly described elsewhere (200,201,202 and 203). In general, the more normal appearing the DNA histograms and the tighter the CVs, the more accurate are the data derived from these programs. The determination of cell cycle compartments may be complicated by the presence of debris and multiploid specimens. In these instances, cell cycle compartments, particularly the S-phase, may be contaminated by extraneous events. The debris or cells from other clones in a multiploid specimen may erroneously become a component of the cell cycle determination. New software that considers debris and aneuploid G0/G1 peaks in the estimation of cellular proliferation are available and are particularly helpful in the analysis of solid tumors (201, 202).

Data Collection

There are several methods to collect and store data from flow cytometers. Data may be collected and stored as histogram representations of the specimen analysis, or they may be collected and stored in “list mode” fashion (204). The essence of list mode data collection and storage is the fact that each piece of information regarding each cell is stored and may be recalled and reanalyzed in a large number of methods. By contrast, data stored in a histogram form may only be reanalyzed in the same manner in which it was stored. Storage of list mode data versus histogram storage is somewhat comparable to a histopathologist's storage of tissue embedded in paraffin blocks rather than a single stained tissue section. The list mode data can be used to generate a histogram, as a paraffin block may be used to generate a stained tissue section. Yet, list mode data, like paraffin blocks, contain information not necessarily evident in the processed histogram or slide. For example, list mode storage allows regating of the data, whereas histogram storage would not. With the increasing complexity of flow cytometric analyses and the availability of large, low-cost data storage devices on computers, list mode data collection has become the standard in the clinical laboratory.

Cytometer Reliability and Performance

Flow cytometers are complex arrays of optic, pneumatic, hydraulic, and computer systems integrated in such a way as to allow interrogation of multiple cellular features. Failures in any of these systems can lead to an overall malfunction of the instrument. Total failure is less of a concern than a partial failure in which the instrument appears to remain functional, yet the resulting data are flawed. For example, a partially obscured orifice will alter light scatter patterns, and fluctuations in either the laser output or the sample pressure will alter apparent fluorescence intensity of a specimen. Experienced cytometer operators will generally detect abrupt shifts in these patterns and cease performing clinical analyses until the problem is identified and corrected. Subtle changes, which occur over a long period of time, are more difficult to detect; however, they may equally affect the quality of the flow cytometric data. Requirements to assure proper instrument performance and maintenance are outlined by Clinical Laboratory Improvement Amendments (CLIA) and are enforced

by routine inspection of flow cytometry laboratories by an agency endorsed by CLIA (205). The daily alignment (if required) and calibration of the cytometer, together with the analysis of normal controls on a daily or per-run basis, serve as methods to detect gradual deterioration in instrument performance (151, 155, 185, 206). An additional and most important quality assurance measure is the participation in interlaboratory proficiency testing programs (207,208 and 209). In these programs (e.g., College of American Pathologists), aliquots of specimens are routinely distributed among participating laboratories for analysis. The data from the different institutions are compared, and institutions reporting data significantly different from the mean are recommended to check their instrumentation and procedures. Clearly, these programs are necessary to ensure a certain level of consistency in data analysis and interpretation among clinical flow cytometry laboratories.

Standardization and Consensus

With the firm entrenchment of flow cytometry on the clinical laboratory, much effort has been directed in recent years toward standardizing the practice of clinical flow cytometry. One component of standardization comes from the regulatory requirements discussed above. As in all other areas of clinical pathology, interlaboratory standardization of flow cytometric techniques and interpretation will benefit the clinician and patient alike. To achieve standardization of practice, a number of consensus conferences have been held on a range of pertinent topics. These topics include DNA analysis (52, 145,146,147,148 and 149, 210), immunophenotyping of hematologic neoplasms (48, 163, 188, 190, 211), and stem cell enumeration (100, 101). Additionally, the National Committee for Clinical Laboratory Standards (NCCLS) has put forward guidelines for immunophenotyping of peripheral blood lymphocytes (151), immunophenotyping of leukemia and lymphoma (212), flow cytometric reticulocyte enumeration (213), as well as numerous general laboratory procedures. Guidelines for performing CD4+ T-cell enumeration in HIV disease have been published by the Centers for Disease Control (155). These published guidelines and consensus recommendations are crucial for standardization of flow cytometry practices and should be strongly considered when implementing and performing pertinent procedures.

SUMMARY

Part of "62 - Flow Cytometry"

Flow cytometric assays are now commonplace in the clinical laboratory. The techniques used for these assays are highly varied, and it is increasingly difficult for any one laboratory to maintain expertise in all applications. The field of clinical flow cytometry continues to be a dynamic realm. Improved, yet easier-to-use instrumentation is becoming increasingly available; new reagents are making it possible to examine more cellular features simultaneously on a given cell; and the benefits of research to date provide an impetus for further study and the implementation of new clinical assays. Perhaps the most exciting prospect lies in the merger of flow cytometric analysis with molecular genetics to provide a study of disease processes of a cellular basis, from the level of the gene through the surface proteins. Clearly, flow cytometry does not, and will not, stand as a separate diagnostic procedure. Rather, it is one of many approaches used to ascertain the status of a patient's health.

PROTECTIVE DETERRENTS TO INFLAMMATION

Part of "63 - Cellular and Humoral Mediators of Inflammation"

External Barriers

The skin and mucous membrane linings of the respiratory, urinary, and gastrointestinal tracts constitute the body's first line of defense as an intact barrier of epithelial cells. The epithelial barrier cells and the biochemical defense mechanisms in the secretions serve to protect from infections. Lysozyme (muramidase) decreases the viability of susceptible bacteria by cleaving the cell wall proteoglycan between the residues of N-acetylglucosamine and N-acetylmuramic acid. Stomach gastric acids inhibit infections with *Salmonella* spp., *Vibrio cholera*, and enveloped viruses. Secretory immunoglobulins can neutralize viruses and bacterial endotoxins and prevent bacterial attachment to mucosal cells.

Cell Adhesion Molecules (CAMs)

Cell Adhesion Molecules (CAMs) regulate cell-cell and cell-matrix adhesion, processes that are involved in host defense against infections, antigen recognition, and immune surveillance. There are at least six families of CAMs (1) (Fig. 63.1), based on their structural profiles or specific adhesion-promoting domains: (i) cadherins, (ii) immunoglobulinlike proteins, (iii) integrins, (iv) selectins, (v) cell surface mucins, and (vi) cell surface proteoglycans.

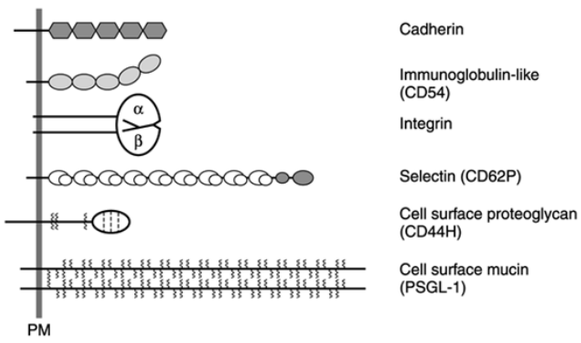

FIGURE 63.1. Schematic diagram of representative members of the cell adhesion molecule (CAM) families. The extracellular region of cadherins consists of five repeats. CD54 is shown here as a representative of the immunoglobulin (Ig)-like protein family. The characteristic structure of the Ig family is depicted here as ellipsoid. Integrins are drawn to accommodate the head and tail morphology revealed by electron microscopic studies. Human P-selectin consists of a globular lectin domain, an epidermal growth factor (EGF) domain, and nine short consensus repeats assembled as rod-shaped structure. Hema-topoietic CD44 has an N-terminal proteo-glycan tandem repeat stabilized by three pairs of cysteine residues, followed by a region containing multiple O-linked and chondroitin sulfate ||| attachment sites. P-selectin glycoprotein ligand (PSGL-1), a dimeric transmembrane glycoprotein with a large mucin ectodomain depicted as a rodlike structure, with arbitrary-based carbohydrate branches. Adapted with permission from Arnaout MA. Structural diversity of cell adhesion molecules and their role in inflammation. *Textbook of Rheumatology*, Kelley WN, Ruddy S, Harris ED, et al., eds., St. Louis, MO: W.B. Saunders, 1997:303–321.

Cadherins are crucial in embryonic stages of development to maintain initial intercellular adhesion and stability essential for morphogenesis. In adult tissues, cadherins maintain tight gap junctions and intercellular spacing. Cadherins bind homophilically to other cadherins in a temperature and calcium (Ca^{2+})-dependent binding reaction described as a “linear zipper” of cell adhesion.

The immunoglobulin (Ig) supergene family of CAMs, so called because all contain 60–100 amino-acid sequences common to immunoglobulins, mediate cell recognition events during morphogenesis, inflammation, homeostasis, and immunity. Many of the Ig supergene family proteins serve as receptors for parasitic or viral infections [e.g., CD4 is the major receptor for the human immunodeficiency virus (HIV)]. Another Ig member is $ß_2$-microglobulin, which disulfide bonded to an integral membrane protein.

Integrins are surface-membrane receptors consisting of one α-subunit noncovalently associated with a ß-subunit that spans the membrance and has a C-terminus binding site for cytoskeletal proteins. The ß-2 Leu-CAMs, first identified by monoclonal antibodies as the cluster designation (CD) 11 series: CD11a, CD11b, CD11c, and CD11d, are found on leukocytes and involved in chemotaxis, phagocytosis, adhesion, and migration across endothelial cells, lymphocyte proliferation, and natural killer (NK) cell and cell-mediated killing of target cells. Other ß-subgroup integrins (ß1, ß3, ß4, ß5, ß6, ß8) are found on other cell types and are involved in intracellular signaling events. Integrin-mediated signaling results in cell responses such as migration, proliferation, and gene induction. Leukocyte adhesion deficiency (LAD-1), a rare autosomal-recessive disorder where leukocytes are unable to migrate to tissue sites, is caused by a defect in ß2 integrins. LADs will be fully described in Chapter 65, Primary Immunodeficiency Disease.

Selectins bind directly to sialylated fucosylated lactose amines on proteins and glycosphingolipids. Three subgroups have been identified: L-selection, P-selectin, and E-selectin. L-selectin is expressed on prothymocytes, immature thymocytes, naïve T and B cells, monocytes and granulocytes where it appears to be responsible for leukocyte trafficking to peripheral lymph nodes and extravasation at inflammatory sites in nonlymphoid tissues. L-selectin is lost from the cell surface during activation and significant levels of the functional protein can be found in serum during active inflammation. P-selectin binding events are responsible for extravasation of leukocytes into inflamed tissues, phagocytic cell recruitment to sites of platelet activation, and phagocytosis of activated platelets. E-selectin is inducible on activated endothelial cells where it promotes binding of granulocytes and monocytes to activated endothelial cells. The synovial fluid of rheumatoid arthritis (RA) patients contains soluble adhesion receptors. Soluble (s)E-selectin levels are elevated in the peripheral blood as well as the synovial fluid of RA patients, associated with increases in erythrocyte sedimentation rate (ESR) and neutrophil infiltration into the synovium (2). Conventional therapy for RA may modify synovial inflammation by altering leukocyte adhesion.

Mucin segments on glycoproteins are responsible for cell-cell recognition and also modulate cell-cell adhesion, either promoting or impeding adhesion. N-acetyl galactosamine-containing O-linked oligosaccharides are found in cell surface mucins. Epithelial

mucins with specific repeats are present in carcinoma. Although many mucins are antiadhesive, when certain specific receptors (e.g., selectins) are present, mucins can promote rather than inhibit adhesion.

Proteoglycans are found in several forms: secreted, intracellular, and membrane-associated, and provide functions such as simple mechanical support, cell adhesion and migration, and cell differentiation and proliferation. CD44 proteoglycan, a major leukocyte hyaluronate receptor, is involved in lymphocyte homing to lymph nodes. Syndecans are a subfamily of heparin and chondroitin sulfate on cell surface proteoglycans expressed on epithelial cells where they serve as matrix receptors and coreceptors for certain growth factors. Sydecans also stabilize epithelial cell growth factors.

NONSPECIFIC CELLULAR RESPONSE TO INFLAMMATION

Part of "63 - Cellular and Humoral Mediators of Inflammation"

Granulocytes

Polymorphonuclear neutrophils (PMNs) are the largest population of leukocytes in the peripheral blood. These phagocytic cells contain distinct primary granules composed of proteases (cathepsin G, elastase, and proteinase 3); antibiotic proteins (myeloperoxidase, lysozyme, defensins, asurocidin, and bactericidal permeability-increasing protein [BPI]); and secondary granules that include lactoferrin, lysozyme, and human neutrophil lipocalin (HNL) (3). Cathepsin G is a proteolytic enzyme that can cleave complement factors, coagulation factors, and other proteins resulting in biologically active compounds and also can induce platelet aggregation. The proteolytic activity of Cathepsin G is neutralized by α-1 antichymotrypsin. Elastase and proteinase 3 are serine proteases with elasteolytic activities that contribute to tissue injury and may be involved with the glomerular injury in glomerulonephritis. Elastase and proteinase 3 activity can be inhibited by α-1 antitrypsin and α-2 macroglobulin. Antibiotic proteins in primary granules have microbicidal activities as well as other biologic functions. BPI/cationic antimicrobial protein (CAP57) is an effective killer of gram-negative bacteria and can bind to lipopolysaccharide (LPS) and neutralize some of the endotoxin effects on neutrophils. Lactoferrin, an iron-binding protein, is believed to interfere with the iron metabolism of microbes. Lysozyme is found in both primary and secondary granules, has bactericidal activities, and can be quantitated in plasma to measure monocyte/macrophage turnover in monocytic leukemia. HNL binds hydrophobic molecules (e.g., lipids and vitamins), and is measurable in serum and other body fluids as a specific marker of neutrophil activation to distinguish between bacterial and viral infections.

The mechanisms by which PMNs are involved in the nonspecific immune response include: (i) attachment to the damaged epithelium, (ii) amoeboid movement, (iii) emigration through the blood vessels, (iv) directed movement toward the particles to be engulfed, (v) ingestion of the bacteria, (vi) degranulation, (vii) oxidative metabolism (respiratory burst), and (viii) digestion of the foreign material.

Adherence of PMNs to the vascular endothelial cells occurs relative to membrane changes after exposure to chemoattractants that facilitate adherence through events associated with CAMs. Locomotion or ameboid movement, in conjunction with adherence to the walls of the capillaries, both are necessary for diapedesis to occur. During diapedesis (emigration), the pseudopods of the PMN are inserted between the junctions of endothelial cells. This enables the leukocyte to move from the inside of the blood vessel, through the capillary walls, between the endothelial cells, into surrounding tissues.

Chemotaxis is the directed migration of phagocytic cells mediated primarily by fluid-phase components of the complement system, particularly C5a. Other molecules known to be chemotactic include by-products of the coagulation or fibrinolytic pathways such as arachidonic acid metabolites and platelet activating factor (PAF), certain cytokines (interleukin [IL]-8), and various bacterial products. Chemoattractants form a gradient whereby PMNs move toward the increasing concentration of the substance.

Phagocytosis, the ingestion of particles, occurs when the external cell wall of the PMN adheres to and completely surrounds the offending bacteria or other particle. The foreign substance becomes encapsulated with a layer of inside-out membrane, a phagosome. Complement-activation products (C3b/iC3b) and immunoglobulins (IgG and IgA) can function as opsonins because PMNs and other phagocytic cells have receptors on their surface (Table 63.1) that specifically recognize those molecules coating bacteria or other particles. Neutrophils and eosinophils express two kinds of complement receptors (CR): CR1 (CD35) that interact with C3b and C4b, and CR3 (CD11b/CD18) that bind iC3b (cleaved and inactivated C3b). Three types of FcγR (IgG Fc receptors) are found on neutrophils: FcγRI (CD64), FcγRII (CD32), and FcγRIII (CD16). FcγRI are induced by the cytokine, interferon (IFN)-γ to mediate phagocytosis of monomeric IgG. FcγRII requires two or more molecules of IgG to induce phagocytosis, the respiratory burst, and degranulation. FcγRIII interacts with dimeric IgG to induce granule secretion without phagocytosis or respiratory burst. FcαR (IgA Fc receptor) are found in a low-affinity state on neutrophils and eosinophils, but can be upregulated to high-affinity receptors by the colony stimulating factors (CSF), GM-CSF (granulocyte/monocyte) and G-CSF (granulocyte). The FcR and CR selectively increase the type, rate, and quantity of particle uptake. During phagocytosis, O_2 and glucose are consumed, primarily through the hexose monophosphate shunt.

TABLE 63.1. MONONUCLEAR PHAGOCYTE CELL SURFACE RECEPTORS AND MARKERS

CD Designation	Molecule Function/Characteristic	Monocyte	Macrophage	PMN
	Immunoglobulin Receptors			
CD64	FcγRI, High affinity IgG receptor	++	++	+
CD32	FcγRII, Low-affinity IgG receptor	++	++	++
CD16	FcγRIII, Low-affinity IgG receptor	++	++	++
CD23	FcεRIIa,b, Low-affinity IgE receptor	--	--	++
	Complement Receptors			
CD11b	CR3. Binds C3bi	++	--	++
CD35	CR1. Binds C3b, C3bi, C3c, C4b	++	--	++
	Cell Adhesion Molecules (CAM)			
CD11a	LFA-1 α chain; p180	++	+	++
CD11c	CR4. P150,95 α chain	++	+	++
CD18	95 kD glycoprotein, linked to CD 11a,b,c	++	++	++
CD49f	Laminin receptor; VLA-α6 chain	++	??	--
CD29	VLA-ß chain	++	++	++
CD44	LECAM-III, hyaluronic acid receptor	++	++	++
CD58	LFA-3; binds CD2 molecule on T cells	++	++	++
CD36	Thrombospondin receptor; 85 kD glycoprotein	--	++	--
CD54	ICAM-1	+	++	+
CD102	ICAM-2	+	++	--
CD31	PECAM	++	+	++

CD, cluster of designation; LFA, leukocyte-function associated antigen; kD, kilodalton; VLA, very-late antigen; VCAM, vascular cellular adhesion molecule; LECAM, leukocyte endothelial cellular adhesion molecule; ICAM, intercellular adhesion molecule; CR, complement receptor; Ig, immunoglobulin; PECAM, platelet endothelial cell adhesion molecule.
Adapted from Thomas R, Wong R, Lipsky PR. *Textbook of Rheumatology*. W.B. Saunders (pub), Kelley WN, Ruddy S, Harris ED, et al. eds. St Louis, MO: W.B. Saunders, 1997:135.

Degranulation, the extracellular release of granule contents, can occur before (during chemotactic migration), during ("regurgitation while feeding"), or after phagocytosis (at cell death). The contents of the primary granules are released mainly into the phagocytic vacuoles, but the constituents of the secondary granules are often mobilized to the plasma membrane and released to the external environment. The granule contents are responsible for much of the tissue damage of inflammation.

During the respiratory burst that occurs as the phagocytosed particle is digested, the O_2-radicals formed are dismutated to H_2O_2. The mechanism by which many types of bacteria are killed following ingestion by phagocytes requires H_2O_2 and myeloperoxidase. Defects in these killing mechanisms result in a heterogeneous group of inherited disorders, chronic granulomatous disease, that will be discussed thoroughly in Chapter 65, Chronic Granulomatous Disease (and Related Disorders). Bystander tissues also can be damaged by the reactive oxygen species that might contribute to neutrophil-induced tissue damage at vascular sites of immune complex deposition, lung injury, or Crohn's disease, for example. See Venge, Bergstrand, and Hakansson, 1997 (3) for a more thorough review of the pathologic effects attributable to oxidative metabolism.

Eosinophils arise from a common progenitor with PMNs, are found in small quantities (1% to 4%) in peripheral blood, and are primarily found in tissues. Eosinophils are less efficient than PMNs at phagocytosis. Eosinophil granules are rich in acid phosphatase and peroxidase, but do not contain lysozyme. Eosinophil granules contain eosinophilic cationic protein (ECP), eosinophil protein X (EPX), and major basic protein (MBP), which are bactericidal and toxic to helminthic parasites (3). Eosinophils also produce leukotrienes and PAF. Functions attributed to eosinophils include clearance of parasites, ingestion of immune complexes, and antagonizing the effects of mediators released from basophils, mast cells, and platelets during inflammatory

reactions. Eosinophilia is associated with parasitic infections and allergic reactions.

Basophils and mast cells (MCs) originate from hematopoietic stem cells, but basophils complete their differentiation in the bone marrow while mast cells differentiate in peripheral tissues. Both release biochemical substances (mediators) that increase both vascular permeability and smooth muscle contraction to augment the inflammatory response. Basophil granules contain biogenic amines (histamine), proteoglycans (heparin and chondroitin sulfate E), neutral proteases (tryptase, chymase, cathepsin G, carboxypeptidase) and several sulfidopeptide leukotrienes (4). Histamine causes vascular dilatation and leakage by stimulating the H_1 receptor on vascular smooth muscle and endothelium. Basophils respond to IgE-containing immune complexes that bind to their IgE receptors to stimulate degranulation. The primary function of the basophil is to amplify and disseminate the reactions that begin with mast cells at the site of the entry of antigen. No specific diseases have been associated with basophilia.

Two distinct types of MCs have been described with different protease compositions of their granules. MC_T, containing only tryptase, is predominant in lung alveoli and small intestinal mucosa. MC_{TC} contains chymase, carboxypeptidase, cathepsin G, and tryptase, and are found in the skin, gastrointestinal submucosa, and synovium. Immunologic reactions, involving IgG or IgE binding to their respective receptors on the surface of mast cells or basophils, trigger degranulation and mediator release. Nonimmunologic mechanisms such as infections of the skin and mucous membranes, mechanical trauma (e.g.,surgical incisions), C5a, ECP, certain bacterial products, various chemokines, and other agents (e.g., opiates), also can stimulate mast cells to degranulate. The pharmacologic responsiveness of mast cells is dependent upon the tissue source (e.g., disodium cromoglycate inhibits the secretory response of lung-derived mast cells, but not skin or intestinal mast cells).

Platelets

Platelets play a critical role in coagulation, but also are involved in inflammation. Platelet *dense* granules contain mediators such as serotonin and adenine nucleotides that are released during platelet aggregation. Platelet *alpha* granules contain coagulation factors (fibrinogen, plasminogen, factor V), adhesion molecules (fibronectin, von Willebrand factor), plasma proteins (albumin and IgG), platelet-specific proteins [platelet factor 4 (PF-4)], ß-thromboglobulin and mitogenic proteins [platelet-derived growth factor (PDGF) and transforming growth factor-ß (TGF-ß)] (5). Platelets interact with PMNs and mutually enhance their activation. TGF-ß is a major product of platelets during the inflammatory process, augmenting the adhesion of leukocytes by inducing CAM receptors. TGF-ß also induces FcγRIII receptors on monocytes to promote phagocytosis, and stimulates the production of certain cytokines [IL-1, tumor necrosis factor (TNF), PDGF, and others]. TGF-ß also functions as an immunosuppressant for T and B lymphocyte growth and effector functions.

Mononuclear Phagocytes

Blood and bone marrow monocytes and tissue macrophages are mononuclear phagocytes that reside in every tissue and organ, known as the mononuclear phagocyte system. Their functions include removing debris such as old or injured erythrocytes, leukocytes, platelets, bacteria, antigen-antibody complexes, and degenerated or damaged cell membranes. Tissue macrophages include Küpffer cells of the liver; alveolar macrophages; splenic macrophages; histiocytes of the lymph nodes, peritoneum, and other areas; bone osteoclasts, nervous system microglial cells, and synovial A and C cells (6).

Mononuclear phagocytes express a wide variety of surface markers (Table 63.1). The primary role of FcR is to facilitate phagocytosis, but FcR also are involved in cell-mediated cytotoxicity, tumor immunity, and macrophage-T cell antigen presentation. Complement receptors (CR) bind different portions of C3 and C4 molecules to facilitate phagocytosis in synergy with FcR. CAMs mediate adhesion of leukocytes to endothelial cells and are involved in migration of macrophages to sites of tissue inflammation. Mononuclear phagocytes also have receptors for most of the cytokines (to be discussed later in this chapter), and for certain hormones.

Although mononuclear phagocytes can respond to chemoattractants, they primarily respond to soluble factors released from T lymphocytes (cytokines). Monocytes found in peripheral blood are not as efficient at phagocytosis and killing of bacteria as are PMNs, and their mechanisms of killing are not as well understood. Monocytes and macrophages secrete a wide variety of biologically active factors including peptide hormones (cytokines) that influence the activities of lymphocytes and other cells, complement components, coagulation factors, proteolytic and other enzymes (e.g., lysozyme), enzyme and cytokine inhibitors, CAMs and other binding proteins, bioactive lipids and other low-molecular-weight substances (6).

Phagocytic functions described previously for PMNs also occur with mononuclear phagocytes. Surface receptors enable the phagocytic cells to distinguish between normal cells and damaged cells or foreign bodies. Pinocytosis is another function of mononuclear phagocytes whereby soluble or fluid phase compounds are interiorized and concentrated. Phagocytosed and pinocytosed substances are digested intracellularly via an enzymatic process using lysosomal hydrolases to degrade internalized microorganisms or other ingested materials.

The functions of phagocytosis, pinocytosis, and intracellular digestion facilitate the antimicrobial and antiviral functions of mononuclear phagocytes. Reactive oxygen intermediates (antioxidants) are an important antimicrobial function for oxygen-dependent microorganisms. Oxygen-independent mechanisms include removal of iron by iron-binding proteins, direct actions of cationic proteins, and digestion by lysozyme and lysosomal hydrolases. Although certain cytokines produced by macrophages (IL-4, TGF-ß, IFN) suppress viral replication, ironically, macrophages also can provide a reservoir of protection for internalized viruses (e.g., HIV). Macrophages also play a role in tumor immunity in a non-phagocytic manner, by lysing neoplastic cells by a contact-dependent mechanism, i.e., antibody-coated tumor cells bind to Fc receptors on activated macrophages initiating killing mechanisms.

Although PMNs are end-stage cells that die after phagocytosis and degranulation, mononuclear phagocytes are stimulated (activated) by the phagocytic processes to become microbicidal

or tumoricidal, primarily by IFNγ secreted by T cells, but also by IL-2, IL-4, IL-13, and GM-CSF. Following phagocytosis, monocytes and macrophages become activated secretory cells that can proliferate locally within tissues.

Antigen presentation is one form of immunoregulation, an important function of a subset of macrophages called antigen-presenting cells (APC), that are regulated by the expression of class II MHC molecules on their surface. Class II MHC molecules can be upregulated by IFNγ, IL-4, IL-13, and GM-CSF and downregulated by IFNα, E series prostaglandins, TGF-ß, IL-6, IL-10, α-2 macroglobulins, TNF-α, and other molecules. APCs present antigens to T cells, which serve to stimulate the specific immune response.

Natural Killer Cells

Natural killer (NK) cell-mediated cytotoxicity, although not MHC-restricted, now is known to be regulated by the expression of class I MHC molecules expressed on target cells. Different subsets of NK cells express receptors that recognize MHC molecules, delivering inhibitory signals to NK cells to avoid eliminating normal self cells (7). Other receptors on NK cells trigger NK cells to eliminate allogeneic or autologous cells expressing "abnormal" MHC-molecules. Since NK cells also kill MHC-negative target cells, certain receptors might recognize non-MHC ligands. These unique NK receptors are summarized in Table 63.2.

TABLE 63.2. UNIQUE HUMAN NATURAL KILLER CELL RECEPTORS AND LIGANDS

CD Designation	Common Name	Ligand	Molecular Wt.	Receptor-Ligand Interaction Characteristic
		Inhibitory Receptors		
Killer inhibitory receptors – Ig superfamily				
CD158	NKIR	HLA-Cw3,4	58 kD	Inhibition of NK cell cytotoxicity
undesignated	NKB1	HLA-Bw4	70kD	Influence recognition mediated by NK cells
undesignated	undefined	HLA-A3,11	140 kD	Inhibition of NK cell cytotoxicity
Lectin superfamily				
CD161	NKR-P1	undefined	undefined	Inhibit or activate NK cell clones cytotoxicity
CD94	NKG2A-E	HLA-A,B,C	39/43 kD	Affect recognition HLA-A,B,C transfected targets
CD94	NKG2C	HLA-G	undefined	Protects trophoblast from maternal NK activity
		Activating Receptors		
CD158 a,b	KARAPS	HLA-C	50 kD	Activation of NK cell cytotoxicity
CD11/CD18	ß-2 integrins	ICAM-1,-2	150/95 kD	Tumor cell destruction by NK cells

CD, cluster of designation; KIR, killer inhibitory receptor; HLA, human leukocyte antigen; kD, kilodaltons; KARAPS, killer-activating receptor-associated proteins; ICAM, intracellular adhesion molecules.
Adapted from Thomas R, Wong R, Lipsky PE. Monocytes and macrophages. In: Kelley WN, Ruddy S, Harris ED, et al. eds. *Textbook of Rheumatology*, St Louis MO: W.B. Saunders, 1997:128–145 and Moretta A, Parolini S, Castriconi R, et al. Function and specificity of human natural killer all receptors. *Eur Immunogen* 1997;24:455–468.

NK cells are large granular lymphocytes (LGL), most of which express the surface antigen phenotype $CD3^-$ (T cell receptor), $CD2^+$ (E rosette receptor), $CD56^+$, $CD8^{+/-}$, $CD16^+$ (IgG FcR), $CD45^+$ (leukocyte common antigen), CD11a/$CD18^+$ [lymphokine function-associated antigen-1 (LFA-1)], CD11b/$CD18^+$ (Mac-1), and CD11c/$CD18^+$ (p150,95). NK cells do not recirculate between blood and lymph, but are found in the spleen, liver, and lungs (8). Subsets of LGL include NK cells, killer (K) cells, and lymphokine-activated killer (LAK) cells. Morphologically, these cells resemble lymphocytes, but function more like activated macrophages. These cells are termed LGL because they have azurophilic granules in their cytoplasm and have a high cytoplasm:nucleus ratio. The stages of effector function for LGL include: (i) target cell binding, when physical contact is made between the effector cells and the target cells; (ii) programming for lysis, during which the cytoskeletal components and Golgi apparatus of the effector cell move within the cytoplasm to the area of physical contact with the target cell; (iii) secretion of factors by the effector cell (e.g., NK cytotoxic factor, IL-1, and granule cytolysin); (iv) the cell-independent phase of the lytic event where soluble factors complete the killing process.

NK cells recognize and kill tumor cells *in vitro*. Similar to the activation of macrophages, NK cells can be activated by cytokines released by T helper cells when they encounter foreign antigens: all three classes of interferons (IFN α, ß, γ) and the interleukins (IL-2, IL-7, IL-12). Morphologic changes induced by these activators include a significant increase in the number of cytoplasmic granules. Unlike T and B lymphocytes, activation of NK cells does not induce immunologic memory. NK activity is suppressed by corticosteroids, hepatitis B surface antigen, and ligand-binding to the IgM Fc receptor site. NK cells rapidly and efficiently secrete several cytokines when activated: IFNγ, TNF-α, IL-1, IL-3, and GM-CSF.

Killer (K) cells cannot be distinguished from NK cells by their morphologic appearance or by their surface markers. K cells are characterized by their ability to bind antibody-coated target cells (via their IgG Fc receptors) and subsequently lyse those cells. These target cells can be erythrocytes, bacteria, parasites, or tumor cells. K cells appear to represent a particular stage of NK cell development or activation.

LAK cells can be generated *in vitro* using purified or recombinant IL-2. LAK cells have many of the same cell surface markers as NK cells and apparently are previously unstimulated NK cells. The LAK activity reflects the potent ability of IL-2 both to stimulate cytotoxic activity and to expand the population(s) of LGL effector cells. *In vitro* generated LAK cells are used in treatment of some forms of cancer.

Endothelial Cells

Endothelial cells line the cavities of the heart, the blood vessels, and the lymphatic system, forming an interface between blood and tissues. By responding to vasodilatory mediators, endothelial cells contract and relax, forming intercellular gaps that allow for passage of fluids between the tissues and blood vessels. Vasoactive amines such as histamine, serotonin, bradykinin, C3a, C5a, PAF, and leukotrienes can cause increased permeability of the endothelial cells resulting in vascular leakage. Endothelial retraction also can be induced by certain cytokines. Leukocyte-endothelial interactions may injure endothelial cells and cause increased vascular permeability. Immune-complex mediated injury to endothelial cells accompanied by complement activation allows the exudation of leukocytes as well as plasma proteins. Activation of endothelial cells results in synthesis and secretion of CAMs including E-selectin, ICAM-1, and VCAM-1 as well as a variety of cytokines, e.g., IL-1, IL-6, IL-8, PDGF, and TGF-ß(9). Lymphocyte homing to peripheral lymph nodes is controlled by CAMs on lymphocytes and endothelial cells. Angiogenesis is governed by endothelial cells and their extracellular matrix. Endothelial cells also contribute to T cell activation.

Recent evidence suggests that endothelial cell dysfunction is involved in atherosclerosis. Factors possibly involved in endothelial cell dysfunction in atherosclerosis include elevated low density lipoproteins (LDL); hypertension; diabetes mellitus; elevated homocysteine levels; certain infectious diseases; free radicals resulting from cigarette smoking; and combinations of these and other causes (10). The inflammatory response to these factors results in adhesiveness of the endothelium, deposition and activation of platelets and phagocytic cells, leading to the release of hydrolytic enzymes, cytokines, chemokines, and growth factors that induce further damage. When the artery can no longer dilate to compensate for the lesion formed, the flow of blood is altered leading to myocardial infarction (10).

NONSPECIFIC HUMORAL RESPONSE TO INFLAMMATION

Part of "63 - Cellular and Humoral Mediators of Inflammation"

Acute-Phase Response

When the body is injured, it responds by increasing the hepatic synthesis of a number of plasma proteins. The systemic acute-phase response helps to ensure survival during the period immediately following injury. The systemic response must help to achieve the same goals as the localized inflammatory response, i.e., to contain or destroy infectious agents, to remove damaged tissue, and to repair the affected organ.

Fever was one of the first acute-phase responses recognized. Fever may occur following many types of inflammatory stimuli including non-infectious states. Fever reflects the effects of endogenous pyrogens (IL-1, IL-6, TNFα, IFNγ), which elevate the set point of the hypothalmic center for body temperature. Another long recognized, but variable, acute-phase response is an increase in the granulocyte count in the blood. This initially reflects release from the storage pool and later reflects increased production by the bone marrow. A principle reason for the leukomoid response to inflammation is to provide a source of lysosomal enzymes.

Lysosomal Enzymes

During phagocytosis and following the death of phagocytes, lysosomal contents of granules are released to enhance inflammation and provide microbicidal activity. Much of the tissue damage of inflammation is from destruction of “innocent bystander” cells by lysosomal enzymes released during the inflammatory process.

C-Reactive Protein

C-reactive protein (CRP) was recognized in 1930 because of its ability to precipitate with the C-polysaccharide extract of pneumococcus (11). Although CRP is distinct from antibody, many parallels between the two molecules exist. CRP will react with its substrate to cause lattice formation and precipitation. CRP can promote passive agglutination of red blood cells coated with binding substrate. An example of the similarity between CRP and immunoglobulins is the initiation of the complement cascade through C1 activation by complexed CRP (analogous to antibody-antigen complexes). Opsonization for ingestion by phagocytes can result from complement activation by CRP.

Unlike antibody, CRP is produced by hepatocytes. CRP is a pentamer with five identical, noncovalently linked subunits. The binding of CRP to C-polysaccharide or other phosphocholine-containing compounds is calcium-dependent. Approximately one phosphate is bound to each of the 5 CRP subunits, requiring two Ca^{2+} ions per phosphate binding site.

CRP may be considered a primitive form of an antibody molecule, with specificity for components found in cell membranes of microorganisms (bacteria, fungi) and for damaged membranes of cells. When complexed to a binding specificity, CRP activates complement via the classical pathway to opsonize and clear microorganisms and serves as a regulatory protein in alternative pathway activation (12). Complexed CRP binds to LGL and to macrophages and can activate these cells to be tumoricidal (13, 14).

Although CRP has many similarities to antibodies, deficiency states of CRP have not been found. CRP is present in microgram per liter quantities in normal humans, but elevates dramatically and rapidly in the presence of bacterial infections where levels >100 mg/L are common. With resolution of those infections, the CRP levels decrease within a few days, reflecting the half-life measured in hours (Fig. 63.2). Moderate CRP levels of 10 to 100 mg/L are found in chronic inflammatory conditions such as systemic lupus erythematosus (SLE), malignancies, congestive heart failure, and pregnancy. Viral infections, by contrast, do not manifest a CRP response unless there is superimposed bacterial infection.

CRP is an especially useful marker of inflammation to monitor patients after surgery. In uncomplicated cases, the CRP levels peak between 48 and 72 hours and return to normal by day 7. If the postoperative course is complicated by inflammation or sepsis, the CRP levels remain elevated or increase (15). For CRP to be a valuable tool in assessing inflammatory complications, the test must be available 24 hours/day, 7 days/week. Recently, CRP has been proposed as predictor of coronary heart disease (CHD) (16, 17). For CRP to be used effectively to predict CHD, the test must be able to detect the protein at low levels (1 to 10 mg/L) as well as the high

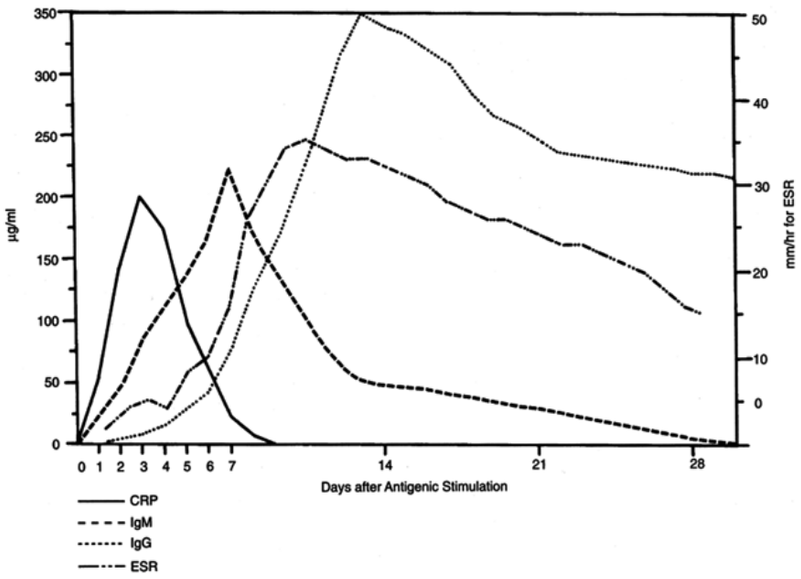

FIGURE 63.2. Kinetics of CRP and ESR responsiveness. (From James K. Immunoserology of infectious diseases. *Clin Microbiol Rev* 1990;3:135–152.)

levels more commonly seen in acute infectious process (100 to 400 mg/L). The technology is available to perform CRP as a random access assay and to detect low levels, but to-date, has not yet been routinely established in clinical laboratories to meet the clinical needs.

Erythrocyte Sedimentation Rate

Measuring the erythrocyte sedimentation rate (ESR) has become a commonly used index of inflammation, most useful in assessing chronic inflammation because the ESR elevates much more slowly than does CRP. The ESR measurement is directly proportional to the plasma level of fibrinogen, haptoglobin, or other acute phase reactants (18). Immunoglobulin elevations (e.g., macroglobulinemia, myeloma) also affect *rouleaux* formation and cause the ESR to rise. Alterations in erythrocyte size or shape (e.g., macrocytes, microcytes, sickle cells) also influence the ESR.

In contrast to CRP, the ESR elevation is slower and much more prolonged (Fig. 63.2), reflecting the significantly slower indirect stimulus of fibrinogen synthesis by hepatocytes. The magnitude of increase of fibrinogen (two to fourfold) also is significantly different from that of CRP (elevates several hundredfold). Certain chronic inflammatory diseases such as SLE have very elevated ESRs, but normal to only slightly elevated CRP levels. Rheumatoid arthritis, in contrast, demonstrates elevations in both ESR and CRP. Although the ESR has certain applications as an indicator of inflammation, the test cannot be performed STAT and should be replaced by random access quantitation of CRP by immunoassay for most of the current uses of the test.

Complement

The complement system consists of 16 components involved in three separate pathways of activation. Five proteins unique to the classical pathway include the trimolecular complex of C1 (C1q, C1r, C1s), C4 and C2. Three proteins unique to the alternative pathway include factor B, factor D and P (properdin). Two components are unique to the lectin pathway: mannose-binding lectin (MBL) and MBL-associated serine protease (MASP). Six components participate in all three pathways: C3, C5, C6, C7, C8 and C9. Because the components were named in the order discovered, the sequence of activation is not in numerical order, but the components interact in a specific cascading sequence (Fig. 63.3). All three pathways can be divided into three units (recognition, activation, and membrane attack) to simplify the understanding of complement activation (19).

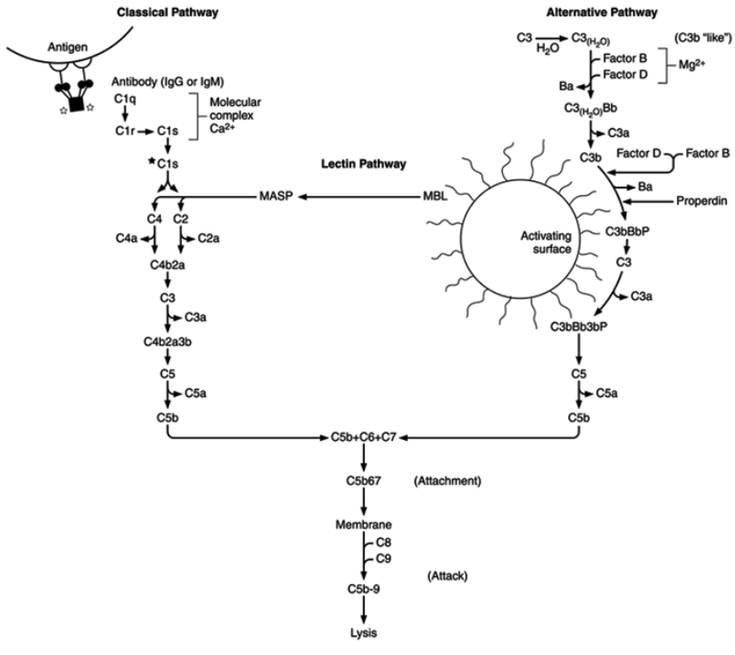

FIGURE 63.3. Complement pathways.

Classical Pathway Recognition Unit

The C1q molecule contains a collagenous region with six globular head groups. When specific antibody interacts with its corresponding

antigen, binding sites are exposed on the Fc region of the antibody molecule for the globular head groups of C1q. Two molecules of IgG or CRP, or one molecule of IgM, are required for the binding of C1q. In circulation and in the presence of calcium, the collagen portion of C1q is surrounded by two molecules each of C1r and C1s. When C1q binds to the Fc region of antibody or CRP, a conformational change occurs in C1q. This change in C1q causes the proenzyme C1r to become the enzymatically active C1r. The substrate for the enzyme C1r is C1s, which then is cleaved to become the serine esterase, C1s.

Classical Pathway Activation Unit

The active enzyme of C1s cleaves C4 and C2 in a magnesium-dependent reaction. C4b and C2a combine to form an active enzyme C4b2a, the classical pathway C3 convertase, with C4a and C2b as by-products. The enzymatically active C4b2a complex can cleave many molecules of C3 into C3a and C3b. The C3b can then either form a covalent bond with the antigen or with bystander surfaces (e.g., erythrocytes) in immune adherence, or can bind to C4b2a to form C4b2a3b, an enzyme with specificity for C5. The final enzymatic step of the classical complement pathway is the cleavage of C5 into C5a and C5b by the C5 convertase, C4b2a3b. At this point, the classical pathway and the alternative pathway converge.

All Pathways Membrane Attack Unit

C5b binds to one molecule of C6 to form a stable bimolecular complex, C5b6. If C7 is present, the trimolecular complex C5b67 is formed, which binds hydrophobically to a membrane. Once C5b67 is bound, C8 can attach to form a functional transmembrane channel. Up to 6 molecules of C9 then surround the

lesion to prevent the channel from being resealed. C9 accelerates lysis, but is not essential for the lytic event.

Lectin Pathway Recognition and Activation Unit (20)

MBL binds to specific carbohydrates at the surface of microorganisms and triggers activation via the mannose residues on bacterial surfaces. MASP then cleaves C4 and C2 enzymatically to form the active enzyme C4b2a.

Alternative Pathway Recognition Unit

Activation of the alternative pathway requires an activating surface not protected by sialic acid. Substances known to provide an activation surface are bacterial cell walls, bacterial lipopolysaccharide (LPS), fungal cell walls, certain virus-infected cells, and rabbit erythrocytes. The “activating surface” actually is a protective surface, protecting spontaneously hydrolyzed C3 (nonenzymatically cleaved into C3a and C3b) from being inactivated by the control proteins (21). Hydrolyzed C3 becomes C3b-like. In the presence of Factor D and Mg^{2+}, this C3b-like molecule can cleave Factor B into Ba and Bb. Ba becomes a by-product while Bb binds to the C3b to form an alternative pathway C3 convertase, C3bBb. By itself, C3bBb is a very unstable molecule and is quickly inactivated by control proteins unless it binds to an activating surface.

Alternative Pathway Activation Unit

When protected by an activating surface and stabilized by P (properdin), the C3bBbP enzymatic complex can cleave additional molecules of C3. If a second C3b molecule is inserted into the C3 convertase to become C3bBb3bP, this becomes a C5 convertase, which can cleave C5 into C5a and C5b.

Membrane-Associated Complement Proteins (Receptors and Regulators) (22)

Complement Receptor Type 1

CR1 binds C3b and C4b. These receptors are present on erythrocytes, PMNs, monocytes, B cells, NK cells, some T cells, eosinophils, mast cells, renal podocytes, and follicular dendritic cells. CR1 is involved in the clearance of immune complexes and also accelerates the decay of C3 and C5 convertases. CR1 has the cluster designation CD35.

Complement Receptor Type 2

CR2 binds C3d; C3d,g; and iC3b. They are present on B cells, NK cells, and follicular dendritic cells. CR2 is involved in regulation of B cell functions such as retention of memory and induction of antibody. CR2 is the receptor for Epstein-Barr virus. CR2 has the cluster designation CD21.

Complement Receptor Type 3

CR3 binds iC3b and has the cluster designation CD11b/CD18. CR3 is found on PMNs, monocytes, macrophages, NK cells, and cytotoxic T cells. CR3 is the specific receptor for phagocytosis.

Complement Receptor Type 4

CR4 also binds iC3b, but has the cluster designation CD11c/CD18. It is found on the same cells as CR3.

Membrane Cofactor Protein

MCP is involved in the breakdown of C3b and C4b on cell surfaces as a cofactor, but does not have decay accelerating activity. MCP is present on most cell types except erythrocytes and has the cluster designation CD46.

Decay Accelerating Factor

DAF accelerates the decay of C3 and C5 convertases, but does not have cofactor activity. It is present on most cell types, including erythrocytes. DAF has the cluster designation CD55.

Homologous Restriction Factor

HRF binds C8 and C9 to prevent insertion of the membrane attack complex into the cell membrane. It is found on erythrocytes and is restricted to homologous species.

Membrane Inhibitor of Reactive Lysis

MIRL binds C5b-8 and prevents formation of the membrane attack complex by preventing polymerization of C9. MIRL is found on erythrocytes, renal cells, and most other cell types and has the cluster designation CD59.

Biologic Consequences of Complement Activation

Amplification

C3b can be generated by C3 convertase from either the classical or lectin pathway (C4b2a) or the alternative pathway (C3bBbP). This provides a feedback loop that uses the alternative pathway components (B, D, P) to amplify the activation of the C3 through C9 components of activation and membrane attack.

Anaphylatoxin

The cleavage of C4, C3, and C5 results in the release of the biologically active peptides C4a, C3a, and C5a. These anaphylatoxins mediate inflammation by inducing the release of histamine from basophils and mast cells, by causing smooth muscle to contract, and by increasing vascular permeability.

Immune Adherence

Immune adherence is the covalent bonding between the cleaved form of C3 (C3b) and nearby soluble immune complexes or particulate surfaces. The portion of the C3b that does not adhere is exposed and available for binding to the CR1 for C3b or C4b on human erythrocytes, B cells, NK cells, monocytes, renal podocytes, eosinophils, or mast cells. B cells and macrophages also have CR2s for C3d, which is formed by cleaving C3b into C3c and C3d (Fig. 63.4). One biologic purpose for immune adherence

would be to facilitate removal of soluble circulating immune complexes (CIC) by first binding to erythrocyte CR1, then interacting with CR3, stimulating phagocytosis of the erythrocyte-bound CIC.

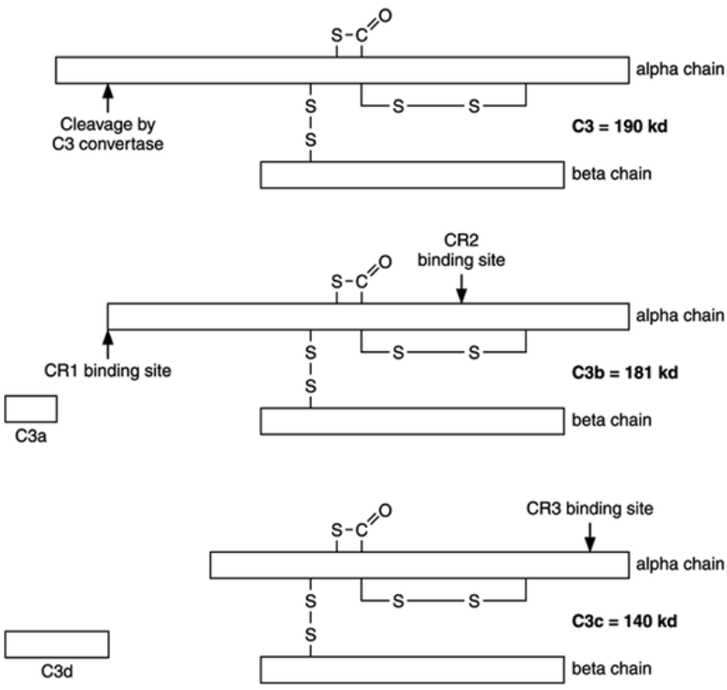

FIGURE 63.4. C3 Molecular structure.

Opsonization and Phagocytosis

Deposition of C3b opsonizes a surface, for more effective phagocytosis by PMNs and/or monocytes. The CR3s on these phagocytic cells bind to the exposed C3b on the surface of the particle. The membrane of the phagocytic cell surrounds the opsonized particle, the cell membrane fuses together thereby phagocytosing the particle. The cross-linking of CR1 on phagocytic cells stimulates the secretion of lysosomal enzymes, involved in killing of microorganisms and contributing to tissue damage at inflammatory sites.

Chemotaxis

The by-product resulting from the cleavage of C5 is C5a, a potent chemoattractant as well as an anaphylotoxin. C5a induces the directed migration of neutrophils and monocytes into the area of inflammation.

Kinin Activation

The fragment of C2 (C2b), which is released during cleavage by C1s, interacts with plasmin to produce kininlike activity. The biologic activity of C2b results in smooth muscle contraction, mucous gland secretion, increased vascular permeability, and pain.

Lysis or Direct Killing

In the laboratory, the activity of complement is studied by measuring the degree of lysis of sheep erythrocytes (ShE) that occurs. Lysis, however, plays a relatively minor biologic role. One example of lysis as the biologic consequence of complement activation would be an antibody-mediated transfusion reaction. The lytic function of complement also appears to be necessary for host defense against *Neisseria* spp.

Control Mechanisms of Complement Activation

If any or all of the biologic consequences of complement activation were to go uncontrolled, the effects of even minor inflammatory processes involving activation of either complement pathway would be potentially devastating. The body, however, does not leave a reaction uncontrolled. The first means of control is the extreme lability of activated complement components. If an activated enzyme does not combine with its substrate within milliseconds, the activity is lost or markedly decayed. “Innocent bystander” cells in the vicinity of activated complement would be rapidly destroyed if the activated components were not so highly labile. Additionally, there also are several inhibitors or inactivators of specific reactions or products involved in the complement cascade.

C1 Inhibitor (C1Inh)

C1Inh forms an irreversible complex with both C1r and C1s, which blocks their enzymatic activities and dissociates them from C1q. The hereditary or acquired deficiency of this protein results in uncontrolled activation of the classical pathway. Control proteins that exercise their activity at the level of C3 or later are still functioning, retarding the amplification loop and other biologic consequences of C3-C9 activation. C1s, in the absence of C1Inh, continues to cleave C4 and C2 unchecked, resulting in release of C2b kininlike activity and C4a anaphylatoxin activity.

ß1H (H) and C3b Inactivator (I)

The most important biologic consequence of complement activation is the feedback loop amplification mediated by C3b. Proteins H and I serve to tightly control the enzymes that cleave C3 and C5. H accelerates the decay of the alternative pathway C3 convertase by dissociating Bb from the enzyme, while I inactivates C3b and C4b. H and I are both involved in cleaving C3b into its hemolytically inactive form, C3bi, which is further cleaved into C3c and C3d. Fluid phase C3b is rapidly inactivated by H and I. Consequently, activation of the alternative pathway is dependent upon the presence of a protective (activating) surface which shelters C3b from these two control proteins.

C4 Binding Protein (C4BP)

C3b inactivator (I) can also cleave and inactivate C4, but requires an accessory protein, C4BP.

Anaphylatoxin Inactivator

Carboxypeptidase controls the effects of C4a, C3a, and C5a by removing a single amino acid, a carboxyterminal arginine. Cleavage of this amino acid destroys the anaphylatoxin activity of these peptides.

Properdin (P)

The above control mechanisms are all inhibitors. Properdin is an enhancer. While not required for the activation sequence of the alternative pathway, P stabilizes the C3 and C5 convertases to prolong their activity.

C3 Nephritic Factor (NF)

NF is a pathological enhancing protein. NF is an IgG antibody with specificity for the alternative pathway C3 convertase (23). NF binds to the C3 convertase in such a way that it prevents inactivation by the control proteins H and I. When NF is present, C3 activation proceeds uncontrolled, thereby markedly depleting C3.

Measuring Complement in the Clinical Laboratory

The complement components usually quantitated are C3 and C4; C3 because of its pivotal location and role in both the classical and alternative pathway, and C4 to distinguish classical from alternative pathway activation. All complement components can be quantitated, however, components other than C3 and C4 rarely are required and are best performed by research laboratories. The only reason to measure any component other than C3 and C4 would be if a component deficiency is suspected. The screening method of choice for a component deficiency is the hemolytic assays.

Hemolytic complement assays are measured as CH_{50} (hemolytic complement 50% lysis point), which is a fluid phase assay, or CH_{100} (hemolytic complement 100% lysis), which is performed in agar. In both systems, either the classical pathway or the alternative pathway can be measured by varying the indicator cells. For the classical pathway hemolytic assays, sheep erythrocytes (ShE) are sensitized with antibody (ShEA). For the alternative pathway hemolytic assays, rabbit erythrocytes (RaE) are used without antibody. In the fluid phase assay, the ShEA (or RaE) are suspended in buffer containing the appropriate divalent cations (Ca^{2+} for the classical pathway or Mg^{2+} for the alternative pathway). Because complement components are normally present in excess levels from what is needed for lysis of either pathway, the CH_{100} would be less sensitive to half levels (heterozygous deficiencies) of certain components than the fluid phase assay would be. Because complement deficiencies are relatively rare, and half-levels are only relevant in complicated disease processes, CH_{100} can replace CH_{50} in most situations. The solid phase assay is much easier to perform, detects consumption of components in disease states, and does detect homozygous component deficiencies.

Neither CH_{50} nor CH_{100} are useful to monitor disease activity because their endpoint (lysis) is very insensitive to changes in component levels and can occur even with significant depletion of most components. It takes very few C2 and C4 molecules to cause lysis and yield a “normal” CH_{50} level. Quantitation of C3 and C4 are much more sensitive measures of complement consumption *in vivo* than are the hemolytic assays. The patterns of complement consumption in various disease states are shown in Table 63.3.

TABLE 63.3. INTERPRETATION OF LABORATORY TESTS FOR COMPLEMENT ACTIVATION

↓ CH_{50}, ↓ C3, ↓ C4	↓ CH_{50}, ↓ C3, Normal C4
Classical Pathway Activation	*Alternative Pathway Activation*
Active SLE	Acute post-strep GN
Serum sickness	Membranoproliferative GN
Immune complex disease	Severe bacteremia
Chronic active hepatitis	C3 nephritic factor
Subacute bacterial endocarditis	C3, H, or I deficiency
↓ to Normal CH_{50}, Normal C3, ↓ C4	↓ CH_{50}, Normal C3, Normal C4
Mild Classical Pathway Activation	*Defective Hemolytic Function*
Cryoglobulinemia	Improperly handled sera
Vasculitis	Coagulation-associated depletion
C1Inh deficiency	
C4 deficiency	Component deficiency (e.g., C2, C5-C8)

Complement components are acute-phase reactants and increase in concentration during inflammation. Consequently, the acute-phase increases can offset any consumption *in vivo* and result in normal hemolytic and normal quantitative levels in the presence of subclinical disease. C4 is the most sensitive indicator of *in vivo* complement consumption. Because C3 levels are 10-fold

greater than C4 levels, it takes significantly more consumption of C3 to offset an acute phase response than it does for C4.

Unfortunately, some of the rheumatology literature still considers CH_{50} as the assay of choice to monitor complement activation in disease. This is attributable to a lack of understanding by commercial companies and their users of the need to use monospecific antisera to C3c or another unique domain on the C3 molecule (Fig. 63.4). Some commercially available C3 assays use antisera that react with multiple domains on the C3 molecule and therefore detect breakdown products of C3 as well as the intact molecule, resulting in falsely elevated (or falsely normal) levels in active stages of disease. Falsely elevated levels are not as pronounced with C4 because the concentration is lower.

Specimen handling is critical for accurate measurement of complement components, and especially for the functional assays. Complement components (many of which are enzymes) are extremely labile and are easily activated in the test tube or inactivated due to adverse storage conditions. Although not considered a "standard of practice," specimens for quantitation of C3 and C4 AND for functional assays should be collected as plasma with EDTA as the anticoagulant. EDTA chelates the available Ca^{2+} and Mg^{2+}, preventing activation of either pathway *in vitro*. The plasma should be frozen until tested to prevent breakdown by proteolytic enzymes as well as preserve the labile complement components. The buffer systems used to test for functional activity in either the CH_{50} or the CH_{100} assay contain an excess of Ca^{2+} and Mg^{2+}, more than enough to support either the classical or alternative pathway without these divalent cations from serum. The amount of EDTA present in the plasma is insufficient to chelate the excess divalent cations provided by the buffer systems. Collection of complement specimens as EDTA plasma prevents the artificial activation of complement *in vitro* associated with the coagulation pathway in certain patient sera (24).

Disease resulting from deficiencies of complement components and control proteins are thoroughly discussed in Chapter 65, Primary Immunodeficiency Diseases.

Cytokines and Cytokine Receptors (CR) (25,26,27,28,29,30,31,32,33,34,35,36,37,38 and 39)

Cytokines are small polypeptide or glycopeptide molecules (mol. wt. 5 to 70,000 daltons) whose primary functions are to mediate infectious and inflammatory processes. Cytokines act at very low concentrations as pleiotropic hormones, overlapping suppressive functions and stimulatory events. The inflammatory cytokines (IL-1α, IL-1ß, TNF-α, IFN-α, -ß, -γ) are involved in the pathogenesis of many infectious and autoimmune diseases. The antiinflammatory cytokine (IL-10) profoundly suppresses macrophages, inhibiting the synthesis of proinflammatory cytokines. Cytokines can be categorized loosely as interleukins, interferons, cytotoxins, chemokines, and growth and stimulatory factors. Fig. 63.5 illustrates some of the functions and interactions

of cytokines. Table 63.4 is a partial list of cytokines, the cells producing them, their target cells, and their primary functions.

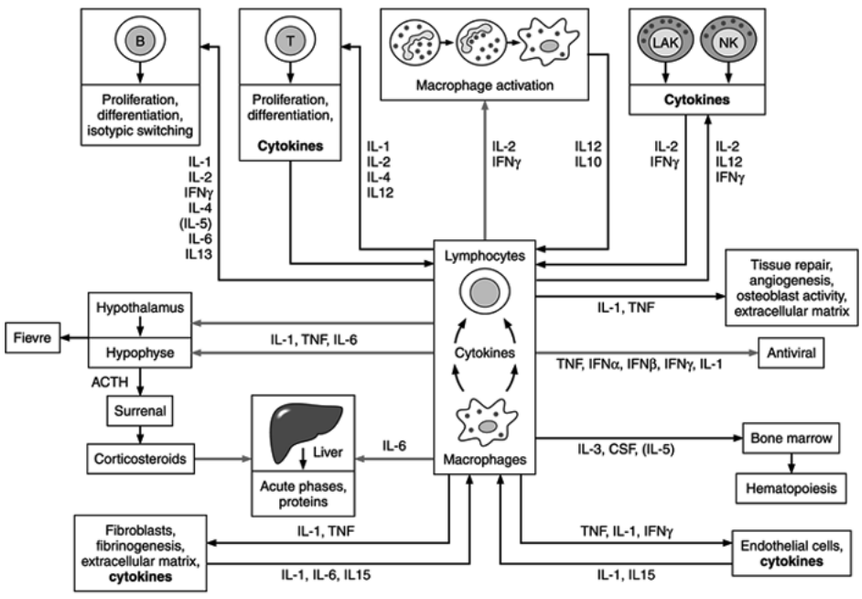

FIGURE 63.5. Selected functions of cytokines. Reproduced with permission from Fridman WH, Tartour E. Cytokines and cell regulation. *Mol Aspects Med* 1997;18:3–90.

Cytokine receptors (CyR) are noncovalently associated with intracellular tyrosine kinases. CyRs can be classified based on their subunit composition (25) (i) homodimers where two receptor molecules bind one molecule of ligand (e.g., hGH-R, EPO-R, G-CSF-R); (ii) two different subunits (α and ß) where the α subunit functions primarily in ligand binding while the ß subunit functions as a signaling subunit (e.g., IL-6R, GM-CSF-R, IL-3R, IL-5R); and (iii) three different subunits (α and ß and γ) where one of these subunits is common to several different receptors (e.g., IL-2R, IL-4R, IL-7R, IL-9R, IL-13R, and IL-15R).

Certain of the CyRs are found in the peripheral circulation as soluble cytokine receptors (sCyR). They are synthesized either by proteolytic cleavage or shedding (sIL-1R, sIL-6R, sTNF-R) or by differential splicing leading to the production of an altered receptor lacking the transmembranous and cytoplasmic regions (sIL-4R, sIL-5R, sIL-6R, sIL-7R, sIL-9R) (26). sCyR may modulate the host response to the cytokine by binding to the cytokine to block interaction with cell-bound CyR, either reversibly when low affinity or irreversibly whereby the cytokine-sCyR complex is rapidly removed from circulation (Fig. 63.6).

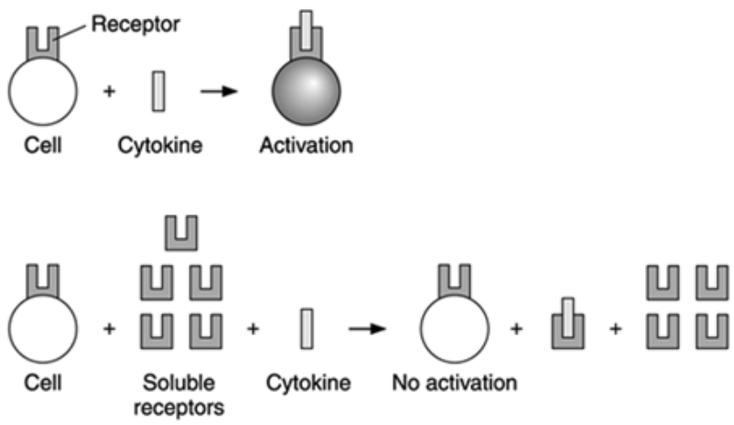

FIGURE 63.6. Cytokine receptors and soluble cytokine receptors. Reproduced with permission from Remick DG. Applied molecular biology of sepsis. *J Critical Care* 1995;198–212.

Interleukins and Interleukin Receptors

Most interleukins are synthesized by activated T-lymphocytes, however IL-1 and several other interleukins are also secreted by

TABLE 63.4. A PARTIAL LIST OF HUMAN CYTOKINES[27,28]

Cytokine	Cells Producing	Target Cells	Primary Functions
IL-1α	Macrophages, B cells, NK	T, B, NK cells, eosinophils, hepatocytes, synovial cells, many other cell types	Induces fever, acute phase protein synthesis by hepatocytes, hypotension, anorexia, phagocytosis, hematopoiesis, hormones (insulin, ACTH, cortisol)
IL-1ß	cells neutrophils, synovial cells, many other cell types		
IL-1ra	Hepatic cells, monocytes/ macrophages, PMNs, endothelial cells, fibroblasts, many other cell types	Cells expressing IL-1R	Inhibits the effects of IL-1α and IL- 1ß by specifically blocking the IL-1 receptor on target effector cells.
IL-2	T cells	T, B, NK cells	Growth factor for target cells
IL-3	T cells	Stem cells, mast cells	Hematopoietic growth factor
IL-4	T cells, B cells, stromal cells	T cells, B cells, hematopoietic precursors	T & B cells growth factor, induces isotype shift in B cells (IgE and IgG_4), regulates antibody production
IL-5	T cells, mast cells	Eosinophils, B cells, hematopoietic Precursors	Eosinophil growth factor, bone- marrow cells maturation and differentiation
IL-6	Macrophages, T cells, hepatocytes, endothelial cells, fibroblasts, many other cell types including neoplastic cells	Hepatocytes, megakaryocytes, bone marrow precursors, and many other cell types	Stimulates production of acute-phase proteins by hepatocytes, promotes immunoglobulin secretion by activated B cells, induces maturation of megakaryocytes and other bone marrow precursors
IL-7	Bone marrow and thymic stromal cells	Pre-T and pre-B cells	Promotes the maturation of T & B cells, enhances NK cell function
IL-8	Monocytes, T cells, many other cell types	PMNs, T cells	Activates PMNs, chemotactic for PMNs, T cells, basophils
IL-9	T cells	T cells, erythroid progenitors, mast cells, megakaryocytes	Hematopoietic growth factor
IL-10	T cells, B cells, macrophages	T cells, B cells, mast cells, monocytes	Regulates T cell and macrophage function, coactivates B cells for secretion of IgA, IgG_1, and IgG_3; induces IL-1ra
IL-11	Stromal cells	Hematopoietic stem cells, megakaryocytes	Supports proliferation of hematopoietic precursors
IL-12 (NKCF)	Monocytes, B cells	T cells, NK cells	Activates the cytolytic potential of T cells and NK cells
IL-13	T cells	B cells, NK cells, monocytes	Similar to IL-4, promotes B cell growth and differentiation for production of IgE and IgG_4
IL-14	T cells	Hematopoietic stem cells	Hematopoietic growth factor
IL-15	Monocytes, fibroblasts, endothelial cells, almost all nucleated cell types	T cells, NK cells	Similar to IL-2, growth factor for target cells
IFN-α1/α2	T cells, B cells, monocytes/macrophages	Macrophages, NK cells, B cells, many other cell types	Activating factor, MHC I and II modulcation, antiviral activity
IFN-ß	Fibroblasts, many virus infected cells	Macrophages, NK cells, many other cell types	Similar to IFN-α, activating factor
IFN-γ	T cells, NK cells, endothelial cells	Monocytes/macrophages, fibroblasts, smooth muscle cells, many other cell types	Stimulates vasoconstriction of smooth muscle cells, modulates MHC I & II expression, inhibits cell growth
TNF-α	Macrophages, PMNs, T cells, NK cells	Lymphocytes, PMNs, eosinophils, endothelial cells, fibroblasts, other cells types, virus-infected cells	Cytotoxic to virus-infected cells, induces IL-1 and IL-6 in many cells, activates lymphocytes, granulocytes, endothelial cells
TNF-ß	T cells	Similar to TNF-α	Similar to TNF-α, lymphotoxin, cytotoxic to virus-infected cells
Lymphotoxin	T cells	Similar to TNF-α	Similar to TNF-α
MCP	Monocytes/macrophages, fibroblasts, endothelial cells, B cells, smooth muscle cells	Monocytes/macrophages	Chemokine for monocytes; regulates expression of adhesion molecules on the surface of macrophages
RANTES	T cells, platelets, renal epithelium, mesangial cells	Monocytes, T cells, eosinophils, basophils	Chemokine for monocytes and eosinophils; enhances basophil histamine release
MIP-1 α,ß	T cells, B cells, monocytes, mast cells, fibroblasts	Monocytes, T cells, PMNs, eosinophils (MIP-α)	Chemokine for target cells; activates monocytes
GM-CSF	T cells, fibroblasts, endothelial cells, macrophages, mast cells, eosinophils	Stem cells, T cells, monocytes, granulocytes	Activation and differentiation
G-CSF	Monocytes/macrophages, fibroblasts, endothelial cells, T cells, PMNs	PMNs and precursors	Activation and differentiation of granulocytes
M-CSF	Monocytes/macrophages, fibroblasts, endothelial cells	Monocytes and precursors	Activation and differentiation of monocytes
TGF-α	Macrophages, keratinocytes, pituitary cells, brain cells	Fibroblasts, epithelial cells	Activates fibroblasts, angiogenic
TGF-ß	Megakaryocytes/platelets, monocytes/macrophages, lymphocytes, fibroblasts, many other cell types	B cells, osteoblasts, fibroblasts, endothelial cells, NK cells, others	Induces isotype shift in B cells, activates osteoblasts, inhibits endothelial cell proliferation, inhibits growth of NK cells, T and B cells
PDGF	Platelets, endothelial cells, and other cell types	Fibroblasts, smooth muscle cells, NK cells, endothelial cells, epithelial cells	Activates fibroblasts to synthesize collagen, vasoconstrictor for smooth muscle cells, inhibits NK cells, stimulates granule release from PMNs and monocytes
MCAF	Monocytes/macrophage, fibroblasts, neoplastic cells and other cell types	Monocytes/macrophages	Regulates expression of adhesion molecules on macrophages, chemotactic for monocytes
SCF	Bone marrow stromal cells, endothelial cells, fibroblasts	Multipotential progenitor cells	Activation and differentiation of target
MIF	T cells	Monocytes/macrophages	Activates targets, inhibits migration

IL, interleukin; NK, natural killer; PMN, polymorphonuclear neutrophils; NKCF, natural killer cytotoxic factor; IFN, interferon; MHC, major histocompatibility complex; TNF, tumor necrosis factor; RANTES, regulated on activation, normal T expressed and secreted; MIP, macrophage inflammatory protein; CSF, colony stimulating factor; TGF, transforming growth factor, PDGF, platelet-derived growth factor, MCAF, monocyte chemotactic and activating factor (also called MCP, monocyte chemotactic protein); SCF, stem cell factor; MIF, migration inhibitory factor.

monocytes/macrophages. Many other cell types produce interleukins including fibroblasts, endothelial cells, PMNs, NK cells, B cells, hepatocytes, and others. To date, 17 biologically potent signaling molecules have been designated as interleukins (27, 28): IL-1α, IL-1ß, IL-1ra, IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-8, IL-9, IL-10, IL-11, IL-12 (NKCF), IL-13, IL-14, IL-15. Several of these molecules share biologic activities.

The IL-1 family of cytokines includes IL-1α, IL-1ß, and IL-1 receptor antagonist (IL-1ra). Although IL-1α and IL-1ß have distinct amino-acid sequences, the two molecules are structurally related, interact with the same receptors, are not distinguishable based on their biologic properties, and are collectively referred to as IL-1. IL-1 induces fever, neutrophilia, anorexia, increased levels of hormones (insulin, ACTH, cortisol), and synthesis of acute phase proteins by hepatocytes. The changes in endothelial cells induced by IL-1 are directly related to the pathologic lesions in vascular tissues that occur during inflammation. These changes include increasing the adhesiveness of the endothelial cells promoting leukocyte adherence to endothelial cells by inducing the expression of the cell adhesion molecules, ICAM-1, VCAM-1 and E-selectin. IL-1 is the proliferation-induction factor for many cells. IL-1ra binds to IL-1 receptors (IL-1R), but does not induce an intracellular response. Instead, it blocks the binding of IL-1α and IL-1ß, thereby inhibiting their proinflammatory effects.

There are two types of IL-1R, type I (CDw121a) that mediate most of the activities, and type II (CDw121b) that binds and inactivates IL-1 (effectively functioning as a decoy), decreasing the concentration of IL-1 available for activating type I receptors. IL-1R cannot distinguish between IL-1α and IL-1ß, but does not recognize other cytokines. Both type I and type II IL-1R are found on T cells and many other cell types. Soluble IL-1R (sIL-1R), types I and II, are found in relatively high levels (50 to 200 pM) in healthy individuals, with 2- to 3-fold increases in severe disease (29). The inhibitory effects of IL-1ra are decreased by sIL-1R, type I, but enhanced by sIL-1R, type II.

IL-2 is a growth factor for lymphocytes and NK cells. It is synthesized and secreted by T cells (Th0, Th1) that have been activated in the presence of antigen-presenting cells (macrophages) and an appropriate antigen. Once activated and producing IL-2, these T cells then develop IL-2 receptors (IL-2R) for the feedback loop which promotes proliferation of the T cells. IL-2 stimulates the proliferation of T, B, and NK cells, also activating NK cells to achieve their cytotoxic potential. IL-2 induces the synthesis by T cells of IFN, IL-4, IL-5, IL-6, and GM-CSF.

IL-2R exist as three classes of receptors distinguished by their ligand-binding affinities: IL-2Rα (CD25) a low affinity 55-kDa polypeptide chain; IL-2Rß (CD122) an intermediate affinity 75-kDa (p75) receptor; and γc, a high affinity receptor which is common to several other cytokine receptors (to date: IL-4, IL-7, IL-9, and IL-15) (30). Binding of IL-2 by all three receptor moieties is required to induce a proliferative signal in T cells. Activated T cells can release their IL-2R into solution, however, sIL-2R has low affinity for IL-2 and the presence of sIL-2R does not inhibit IL-2 reactions (31). The primary reason for measuring sIL-2R is as a marker for T-cell activation.

IL-3 is a potent hematopoietic growth factor, secreted by activated T cells. This cytokine promotes the development of granulocytes, macrophages, megakaryocytes, mast cells, erythroid cells, T cells, and B cells. It is not required for normal hemopoiesis, but sustains or amplifies the hemopoietic response during immune reactions. The principle action of IL-3 appears to be cellular ontogenesis before differentiation has taken place. IL-3R (CD123) is a heterodimer composed of an α-chain specific for IL-3R and a $ß_c$-chain common to GM-CSFR and IL-5R. IL-3R is expressed on a subset of T cells. To date, sIL-3R has not been reported.

IL-4 induces isotype shifts in B cells involved in IgE and IgG_4 production and inhibits the synthesis of IL-1α, IL-1ß and IFNγ by IL-2 activated NK cells. IL-4R is a member of the IL-2 receptor family, all of which share the γ_c chain. Two forms of IL-4R (CDw124) exist, classical and alternative. Both are heterodimers. The classical form consists of an IL-4R α-chain and the γ_c chain, predominantly found on hematopoietic cells, while the alternative form includes an IL-4R α-chain and an IL-13R α-chain is expressed on nonhematopoietic cells. sIL-4R has been found in biological fluids.

IL-5 promotes eosinophil differentiation and function. It also is involved in B cell responses and in bone marrow cell maturation and differentiation. IL-5R (CD125) is a heterodimer composed of an α-chain specific for IL-5R (predominantly expressed on eosinophils) and a $ß_c$-chain, common to GM-CSFR and IL-3R (more widely expressed). The α-subunit is required for ligand binding specificity while the ß-chain is responsible for the binding affinity. To date, sIL-5R has not been reported.

IL-6 is produced by many cell types including neoplastic cells. It stimulates hepatocytes to secrete acute phase proteins and also promotes the secretion of Ig by activated B cells. It induces the maturation of megakaryocytes and shortens the resting phase in hematopoietic progenitor cells. Plasmacytomas and plasma cells from patients with multiple myeloma produce and respond to IL-6; thus IL-6 may be an autocrine growth factor for malignant plasma cells. IL-6R (CD126), is a heterodimer with a ligand-specific α-chain, that shares the gp130 molecule as a common ß-chain transducing signal with IL-11R and several other molecules not discussed in this chapter (28). Circulating sIL-6R not only can bind IL-6 while in soluble form, but also can activate cells that express gp130 (but are devoid of IL-6R) that normally would not respond to IL-6 (28).

IL-7 promotes the growth of mature, activated T cells. IL-7R (CDw127) is a member of the IL-2 receptor family. In *in vitro* studies, bacterial invasion induced IL-7R expression in a colonic epithelia cell line, a process that was inhibited by cytochalasin D, a specific inhibitor of actin polymerization (32). IL-7/IL-7R interactions appear to be critical during early thymocyte development. To date, sIL-7R has not been reported.

IL-8, a chemokine (described further below) activates PMNs and is chemotactic for neutrophils, T cells, and basophils where it also stimulates release of histamine. IL-8R (CDw128) is α-chemokine receptors (CXCR). There are two IL-8R, IL-8RA (CXCR-1) and IL-8RB (CXCR-2) on the surface of PMNs. These IL-8R are decreased in several types of infections. To date, sIL-8R has not been reported.

IL-9 is an hematopoietic growth factor. IL-9R (CD not designated) is a member of the IL-2 receptor family. Three functions have been attributed to IL-9/IL-9R interaction: growth stimulation, protection against dexamethasone-induced apoptosis,

and cell proliferation of target cells. To date, sIL-9R has not been reported.

IL-10 regulates T cell and macrophage function and coactivates B cells for secretion of IgA, IgG_1, and IgG_3 and inhibits the production of IFN-γ by T cells, monocytes/macrophages, and NK cells. It suppresses NK cell functions and inhibits tumor cytotoxicity by human monocytes and alveolar macrophages. The IL-10 gene coding sequence is highly homologous to the Epstein-Barr virus (EBV) BCRF1 open reading frame, which might provide insight into viral tumorigenesis (28). IL-10R (CD not designated) is a member of the interferon receptor family (includes IFNα, IFNß, IFNγ, and IL-10). Ligand binding and activation of IL-10R results in the phosphorylation of signal transducer and activator of transcription 1 (STAT1) and STAT3 proteins. To date, sIL-10R has not been reported.

IL-11 supports the proliferation of hematopoietic cells much the same as IL-6. IL-11R (CD130) is a member of the IL-6R family, which shares the gp130 molecule as the common ß chain transducing signal. Soluble IL-11R/IL-11 complexes are capable of mediating an IL-6-type signal in cells that are devoid of IL-6R.

IL-12 (NKCF) is a cytotoxin. IL-12R (CD not designated) is composed of two subunits, designated ß1 and ß2. Mutations in the ß1 subunit have been associated with recurrent infections with intracellular bacteria. To date, sIL-12R has not been reported.

IL-13 functions similarly to IL-4. IL-13R (CD not designated) is a member of the IL-2R family with similar functions to IL-4R. Blockade of IL-13 activities by sIL-13R resulted in the complete reversal of allergen-induced airway hyperresponsiveness to a variety of stimuli and may have other effects on the immunopathogenesis of allergic asthma.

IL-14 is a hematopoietic growth factor. IL-14R (CD not designated) has not been characterized, to date.

IL-15 has similar functions to IL-2. IL-15R (CD not designated) is a heterotrimeric complex composed of IL-2Rß and γ chains in combination with a unique α-chain. IL-15 can bind to components of the IL-2R even though it has no sequence homology with IL-2, however, IL-15 can substitute for IL-2 under most conditions. To date, sIL-15R has not been reported.

Interferons and Interferon Receptors

Interferons originally were described as antiviral substances, but are now known to be important regulators of the immune response in general (33, 34). IFN-γ (type II IFN), in conjunction with TNF and in the presence of bacteria or virus, activates macrophages stimulating the production of IL-12 and IFN-α and -ß (type I IFNs). Type I IFNs, by increasing the expression of MHC class I antigens, enhance NK cell activity to virus-infected cells.

IFN-R have been identified for the two types of IFN; type I (α, ß, ω) and type II γ. Type I IFN-R consists of two chains, IFN-αR1, a full chain, and IFN-αR2 exists in soluble, short and long forms. Type II IFN-R consists of two transmembrane chains, IFN-γR1 that binds the IFN-γ ligand and IFN-γR2 that is required for signal transduction. In both type I and type II IFN-R, ligand binding activates the Janus family kinases (Jak1 and Jak2), which phosphorylate the R1 chain to serve as the recruitment site for STAT (signal transducers and activators of transcription) (35). Soluble type II IFN-R has been described.

Cytotoxins and Receptors

TNF activity was first described as a monokine that could cause tumor cell death (necrosis). Subsequently, TNF was shown to be homologous to cachectin, the mediator of cachexia accompanying parasitic infections (36). Some biologic properties of TNF are quite similar to those of IL-1; i.e., pyrogenic, induces shock, stimulates hepatocytes to synthesize acute phase proteins, induces prostaglandin E2 and collagen synthesis. Despite the similarities, TNF and IL-1 are distinct and receptor binding to each ligand is only displaced by the specific cytokine. The beneficial effects of TNF are most relevant as protective functions in parasitic, certain fungal and viral infections. The detrimental effects of TNF/cachectin include induction of cachexia, a state of anorexia and wasting, which occurs over a period of months.

TNF is known to be a major cytokine involved in inflammatory reactions. IL-1 and TNF are induced during inflammatory reactions where they, in turn, increase the expression of adhesion molecules on endothelial cells. Vascular permeability is increased, facilitating cell and plasma protein extravasation. IL-1 and TNF then are directly involved in tissue damage, degrading cartilage, facilitating proteolysis of muscle cells, destroying bone at the site of the local inflammatory reaction (27). TNF-α and IL-1 exhibit synergistic effects when used together. TNF works in conjunction with IFN to promote antiviral activity.

Natural killer cytotoxic factor (NKCF) has now been designated as IL-12. This cytotoxin activates NK cells and LAK cells to enhance their lytic capacity. It is released from LGL after LGL bind to their susceptible target cells. NKCF then binds to the target cell, leading to target cell death.

Lymphotoxin is 27% to 32% homologous to TNF-ß, the two substances compete for the same cellular receptor, and are functionally indistinguishable (37). Lymphotoxin, TNF-ß, and IL-1 all can stimulate bone resorption. Lymphotoxin can be released from myeloma cells and may be involved in the hypercalcemia and osteolytic lesions associated with multiple myeloma.

There are many members of the TNF-R family, including TNF-R1, TNF-R2, CD27, CD30, CD40, Fas, and others. These receptors all have cysteine rich pseudorepeats, each containing about six cysteines and 40 amino acids. Two distinct TNF receptors, TNF-R1 (the primary TNF receptor on most cells) and R2 are representative of the TNF-R family. TNF-R1 is responsible for signaling cytotoxicity and induction of several genes, while TNF-R2 is capable of signaling proliferation of primary thymocytes, significantly reducing the TNF concentration required for cell killing by regulating the rate of TNF association with TNF-R1. TNF receptor triggering results in three types of biological responses: necrosis, apoptosis (to be discussed later in this chapter), or proliferation. The TNF receptor family contains death receptors (TNF-R1, Fas, DR3, DR4, DR5) and a cytoplasmic death domain, capable of inducing apoptosis. Various biologic fluids (e.g., urine, serum from normal humans, septic, cancer and autoimmune patients) contain sTNF-R, particularly during active phases of the diseases. The effects of sTNF-R appear to be modulatory rather than inhibitory (31).

Chemokines and Receptors

Chemokines are very small (8 to 10 kd) chemoattractant proteins with 20% to 70% amino-acid sequence homology. There are at least four families of chemokines, only two of which have been extensively studied to date: α-chemokines that have one amino acid separating the first two cysteine residues (CXC), and ß-chemokines where the two cysteine molecules are adjacent (CC) (38). IL-8 is an α-chemokine. Monocyte chemoattractant protein (MCP), RANTES (regulated on activation, normal T expressed and secreted), and macrophage inflammatory protein-1 (α and ß) are ß-chemokines. For a complete discussion of chemokines, see Reference 38.

Four human CXC chemokine receptors (CXCR1 – CXCR4), eight human CC chemokine receptors (CCR1 – CCR8) have been identified. CCR1 and CCR2 are constitutively expressed on monocytes, but CCR2 can be downregulated by lipopolysaccharide, making the cells unresponsive to MCP-1 (38). The chemokine receptor, DARC (Duffy antigen receptor for chemokines) found on erythrocytes and endothelial cells, can bind both CXC and CC chemokines and may function as a sink for chemokines, clearing them from circulation.

Growth and Stimulatory Factors and Receptors

Granulocyte/monocyte colony stimulating factor (GM-CSF) and IL-3 stimulate progenitor cells to produce hematopoietic cells of multiple lineages. Once IL-3 and GM-CSF stimulate the microenvironment, stroma cells and macrophages produce the other two CSFs (G-CSF and M-CSF) to support self-renewal and survival of stem cells. GM-CSF-R (CDw116) is a member of the IL-3, IL-5, GM-CSF receptor family. G-CSF-R is a member of the IL-6 receptor family.

Transforming growth factor (TGF-ß) induces an isotype shift in B cells in conjunction with IL-10. It also inhibits the growth of NK cells, T cells, and B cells. Platelet-derived growth factor (PDGF) is mitogenic for many cell types; i.e., it stimulates fibroblast collagen synthesis, causes smooth muscle cells to vasoconstrict. It also stimulates the release of granules from PMNs and monocytes. Monocyte chemotactic and activating factor (MCAF) regulates the expression of CAMs on macrophages. Stem cell factor (SCF) activates and differentiates multipotential stem cells.

TGF-ß transduces signals through two different serine/threonine kinase receptors, TB-R1 and TB-R2. TB-R2 is a primary binding protein for the ligands and TB-R1 is an effector protein that determines the specificity of the signals (39). TBR have been found to act as tumor suppressor genes in various tumors.

Cytokine Antibodies

Natural antibodies to cytokines in human sera have been reported to date against TNF-α, IL-1α, IL-1ß, IL-2, IL-6, IL-8, IL-10, IFN-α, IFN-ß, IFN-γ, GM-CSF, chemokines, and nerve growth factor (NGF). These autoantibodies have been shown to bind to naturally occurring cytokines as well as recombinant cytokines. High avidity antibodies might interfere with the functions of their corresponding cytokines. The following cautions have been identified: (i) cytokine autoantibodies can interfere with the quantitation of cytokines in biologic fluids, (ii) existing autoantibodies could neutralize cytokine therapy, (iii) monitoring of certain immunoinflammatory diseases by quantitation of specific cytokines might be efficacious, and (iv) some pooled human IgG preparations contain high avidity cytokine autoantibodies (40). No differences in the levels of cytokine autoantibodies were detectable in studies comparing healthy individuals and RA patients (41).

Cytokines in Disease

Although mouse models (where knockout or transgenic mice can be used to delete specific cytokine gene or cytokine receptor genes), and *in vitro* studies have been useful in identifying the role of cytokines in immune regulation and pathologic states, the role of cytokines in human disease is much more complicated. Inflammatory diseases (infections, sepsis, autoimmune diseases, allergic respiratory disease [ARD]) have been the target of most studies regarding the effects of cytokines in humans. IFN-α2 and -ω have been shown *in vitro* to inhibit HIV replication. *In vivo* high serum levels of IFN appear to decrease viral burden during the acute stage of HIV infection, but late in the infection, these cytokines and sTNF-R are associated with disease progression. TNF, IL-1, IL-6, and IFN levels have been quantitated in HIV infections and inconsistently shown to be elevated (42).

Sepsis results from excessive systemic host inflammatory response to infection, largely mediated by cytokines. Cytokines that are elevated in human sepsis are TNF-α, IL-1ß, IL-6, and IL-8. Human trials of cytokines in sepsis (using anti-TNF-α or IL-1ra to block the effects of their respective cytokines) have been disappointing (43). The timing of administration and dose may be critical and once the cytokine cascade has been activated, attempts to intervene may be insufficient to improve outcomes. There is always the danger that blocking cytokine production may inhibit other critical host defense mechanisms.

Inflammation, associated with abnormal cytokine production, is a prominent feature of several autoimmune diseases, e.g., joint disease in patients with RA, destruction of pancreatic islet cells in insulin-dependent diabetes, altered intestinal mucosa in inflammatory bowel disease, and myelin sheath destruction in multiple sclerosis. IL-1 and TNF-α induce cartilage degeneration promoting synovial inflammation in RA (44). Neutralizing the effects of TNF-α with monoclonal antibodies has shown some therapeutic promise, but the deleterious effects of an antibody response to the mouse protein complicates the process. Neutralizing the effects of TNF-α with sTNF-α-R, a natural inhibitor of the cytokine, has reduced inflammation or prolonged survival. Use of IL-1ra to block IL-1 activities in several disease states (sepsis and graft vs. host disease) showed a dose-dependent decrease in IL-6 and decreased mortality (29). When IL-1ra was given to RA patients, there was a dose-dependent reduction in the number of swollen joints and new bone erosions and a decrease in CRP and ESR. Corresponding studies using sIL-1R did not show beneficial effects. IL-4, IL-10, and IL-13 function as antiinflammatory molecules. Administration of IL-10, in RA is in process (44). IL-4 and IL-13 are other candidates for treatment in RA to downregulate the synthesis of proinflammatory cytokines, however, the safety and efficacy has not yet been determined.

ARD has increased in prevelance and severity in recent years. In the mouse model, IL-13 plays a critical role in the development of both allergic and nonallergic asthma. Blocking IL-13 effects with recombinant IL-13 reversed AHD in mice and resulting in a decrease in total serum IgE (45). These findings suggest a possible therapeutic approach for treating asthma in humans.

There is increasing evidence that at least some of the beneficial effects of administering intravenous immunoglobulin (IVIG) to patients with immunoinflammatory conditions might be from naturally occurring cytokine antibodies (27, 41). Cytokine antibodies do not appear to be pathogenic since they are frequently present in healthy humans. They are IgG molecules, and as such, may be responsible for IgG FcR-mediated activation of killer cells and potentiate tumor cell destruction (41).

It is likely that chemokines play a role in inflammatory diseases, causing the accumulation and activation of leukocytes in tissues. Chemokine receptors are thought to play a role in HIV infection because high-risk individuals who have a polymorphic variant of CCR5, when exposed to HIV-1, remain uninfected (38). Additionally, cells from individuals who are homozygous for this variant cannot be infected with HIV-1 *in vitro*, while cells from individuals heterozygous for the variant have a much slower rate of progression of HIV-1 infection than other individuals. Several herpesviruses express chemokine-receptor homologues, thought to be involved in infectious processes (38).

It is possible that normal cytokine balances are disrupted in some human inflammatory diseases, but the circumstances have not been definitively proven. Likewise, the use of cytokines as therapeutic agents is an area currently under intense exploration. Cytokines and cytokine receptors still hold promise of therapeutic potential.

Lipid Mediators

Arachidonic acid (AA), the precursor of eicosanoids, is liberated from membrane phospholipids (phospholipases A_2 [PLA_2]) during inflammatory reactions. AA is metabolized to prostaglandins (PG) and thromboxanes (TXA) by the cyclooxygenase (COX) pathway and leukotrienes (LT) by the 5-lipoxygenase pathway (Fig. 63.7) (46). PGE_2 and PGI_2 are responsible for edema and vasodilation that contribute to the pain experienced at the site of inflammation. LTs increase local permeability and are chemoattractants for PMNs, which contributes to the phagocytic cell infiltration at the site of inflammation. TXA_2 and $PGF_{2\alpha}$ function as vaso- and bronchoconstricting agents. Platelet activating factor (PAF) contributes to this inflammatory activity by aggregating platelets, activating leukocytes, promoting AA metabolism, increasing microvascular permeability and decreasing blood pressure. PAF is also a potent mediator of shock.

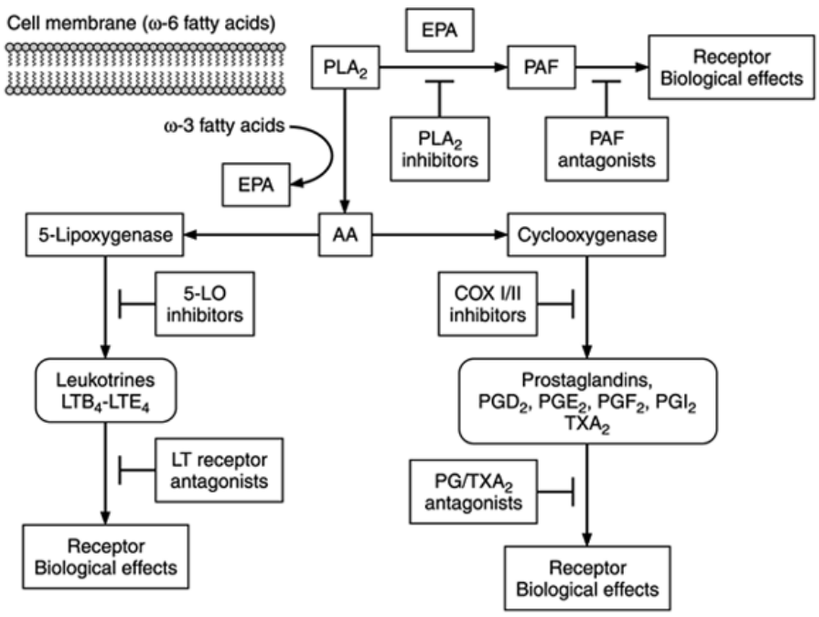

FIGURE 63.7. Lipid mediator pathways. Reproduced with permission from Heller A, Koch T, Schmeck J, et al. Lipid mediators in inflammatory disorders. *Drugs* 1998;55:487–496.

Lipid Mediator Inhibitors

Two forms of COX pathways have been elucidated: the constitutive COX-1, and the cytokine-induced COX-2. Substances that inhibit the COX-1 or -2 pathways include nonsteroidal antiinflammatory drugs (NSAIDs) that inhibit the conversion of AA to prostaglandins and thromboxanes (Fig. 63.7). COX inhibitors are very effective systemic antiinflammatory agents, but COX-1 inhibitors tend to have more gastrointestinal toxicity than do COX-2 inhibitors (46). COX-2 inhibitors also have

been shown to suppress the growth of colorectal cancer. In ARD, supplementing COX-2 inhibitors with the aerosolized vasodilator PGI_2 controls inflammation and the symptoms of ARD.

LT receptor antagonists or 5-lipoxygenase pathway inhibitors have been effective in controlling inflammation and obstructive airway disease in asthma. Synthetic PAF receptor antagonists have been used in septic shock, rheumatoid arthritis, and asthma without significant benefit. Interestingly, dietary supplementation with ω-3 fatty acids has shown beneficial effects in a variety of inflammatory diseases. It is thought that the eicosapentaenoic acid (EPA) released from ω-3 fatty acids competes with AA resulting in decreased production of lipid mediators of inflammation (46).

Immune Complexes

Immune complexes are formed whenever antigen and antibody combine. In normal individuals, immune complexes are effectively and efficiently removed by PMNs and phagocytic mononuclear cells. The dynamics of immune complex formation are continuously modified relative to the concentration of antigen or antibody present. The size of the immune complexes in circulation is determined by the relative ratio of antigen to antibody and the valence of the antigen (large antigens have more antigenic determinants) and the antibody (IgG has two combining sites, IgM has 10). Antigen excess produces very small circulating immune complexes. Antibody excess produces very large immune complexes that are efficiently removed by the phagocytic system. When antigen and antibody are present in more balanced ratios (equivalence), they localize in vessels and mesangial areas. Complement is activated while the immune complexes are in circulation, depositing C3b on their surface, which facilitates localization or deposition in blood vessels and renal glomeruli. C3b deposited on basement membranes provides the “activating surface” necessary to initiate the activation loop of the alternative complement pathway. Complement activation releases chemotactic factors that attract PMNs. During phagocytosis, the PMNs extrude the contents of their granules, which are cytotoxic for endothelial cells. Thus immune complexes initiate as well as perpetuate the inflammatory process. Immune complex diseases will be discussed in Chapter 65.

INFLAMMATION

The “cardinal signs” of inflammation include redness, swelling, heat, pain, and loss of function. Inflammation represents an orderly series of events which protect the host by destroying foreign invaders, eliminating the debris, and repairing any damage to host tissue. Cytokines, cytokine receptors, and lipid mediators are all involved in the inflammatory process. IL-1 and TNF function synergistically as proinflammatory molecules involved in the initiation and progression of inflammation, locally and systemically. Locally, at the site of production, IL-1 and TNF activation stimulates hydrolysis of phosphatidylchone, ultimately releasing AA precursors of lipid-derived mediators. IL-1 and TNF also induce chemokines (IL-8). COX inhibitors reduce the IL-1 and TNF-induced production of PGE_2. Corticosteroids inhibit the transcription of IL-1, TNF, and most cytokines.

The inflammatory response is generally self-limiting, primarily because of a negative feedback biological process via antiinflammatory cytokines. IL-4, IL-10, IL-13, and TGFß suppress the synthesis of IL-1, TNF, and other cytokines and increase the production of IL-1ra that competes with IL-1 for IL-1R.

The four stages of inflammation are: increased vascular permeability, emigration of neutrophils, emigration of mononuclear cells, and cellular proliferation.

Vascular Permeability

The microcirculation (capillaries, arterioles, and venules) is involved in the vascular phase of the inflammatory response. When an injury occurs, blood rushes to the affected area (hyperemia), facilitated by localized dilatation of capillaries. The dilatation is a direct result of the effects of histamine released from mast cells in the skin that has been damaged. Histamine and kinins also increase vascular permeability by causing the smooth muscle of the endothelial cells to contract, creating gaps between the cells through which fluids (transudates) and cells (diapedetic PMNs) can pass. As transudation continues, the blood flow slows or stops completely (stasis) caused by hemoconcentration when fluids are lost through transudation, leaving red blood cells clumped. In contrast to thrombosis, stasis is reversible; when blood flow is restored, the clumps of red cells disperse. If the inflammation is severe, microthrombi form and irreversible platelet aggregation occurs.

Emigration of Granulocytes

PMN migration from the peripheral blood to inflamed tissues involves three steps: (i) selectin-mediated interactions with endothelial cells, (ii) integrin-dependent adhesion to endothelial cell surfaces expressing CAMs, and (iii) chemokine-regulated migration of leukocytes across the vessel wall (47). Damage to the endothelial cells causes changes in the surface membranes that facilitate adherence of granulocytes, primarily PMNs. Chemokines and C5a attract additional PMNs until the entire area becomes pavemented by leukocytes. Emigration of PMNs into the area of inflammation results in active phagocytosis of microorganisms and any other foreign material. With phagocytosis, degranulation occurs. The contents of these granules are directly toxic to surrounding tissues.

Emigration of Mononuclear Phagocytes

The third stage of the inflammatory response is migration of mononuclear phagocytes into the affected area. These activated macrophages begin to synthesize cytokines, particularly IL-1 and IL-6, which are responsible for further inflammatory reactions such as fever, synthesis of acute phase proteins, and attraction of T and B lymphocytes to the area of inflammation.

Cellular Proliferation and Repair

IL-1 stimulates IL-2 synthesis and IL-2R generation. Interaction of IL-2 with IL-2R results in proliferation of lymphocytes and fibroblasts, which begins within 18 hours and peaks by 72 hours. During proliferation, fibroblasts produce acidic mucopolysaccharides

to neutralize the effects of chemical mediators released by damaged mast cells and basophils. Resolution and repair are the final stages of the normal inflammatory process.

Apoptosis And The Immune System

The term apoptosis is derived from the Greek word that means “a falling off” such as leaves fall off of trees (48). This derivation is applied to the first definition “fragmentation of a cell into membrane-bound particles that are then eliminated by phagocytosis.” The second definition “programmed cell death,” a tightly regulated event in normal development and homeostatis, is the more common medical usage of the term. Apoptosis is a physiologic process in all multicellular organisms, and in animals is involved in the development, regulation, and functioning of the immune system. When the process of programmed cell death malfunctions, immunodeficiency disease, autoimmune diseases, or lymphoid malignancies can result.

Stages of Apoptosis

Programmed, physiologic cell death has been described in four stages: (i) the stimulus that provokes the apoptotic event, (ii) detection and transduction of the signal that activates the processes involved in apoptosis, (iii) the effector phase that involves activation of specific proteases, and (iv) the postmortem stage where the cellular chromatin condenses and its DNA is degraded (49, 50). The signaling process may be initiated through surface receptors (various members of the TNF-R family, (e.g., CD95), TNF-R1, TNF-R2, CD30, CD40) or may originate intracellularly as a result of action of a drug, toxin, or radiation damage. Once the signal is detected, the mechanisms are activated and this message is sent to the apoptotic effector machinery. The key components of the effector phase are the cysteine proteases (IL-1ß converting enzyme or ICE, CPP32, and others) that are activated during apoptosis. There are also regulatory mechanisms for the apoptotic process, the most studied of which is bcl-2. The expression of bcl-2 inhibits apoptosis in many cell types by inhibiting activation of the cysteine proteases. In the final postmortem stage, the apoptotic cells are efficiently phagocytosed by macrophages and other inflammatory cells.

Developmental Apoptosis

During development, the majority of T and B lymphocytes (90% to 95%) in the thymus and the bone marrow die because they fail to receive signals to survive, the apoptotic pathway is activated, and the cells die by neglect (50). In the thymus, cells that bear the T-cell receptors (TCR) and recognize self major histocompatability (MHC) antigens are positively selected while a subset of cells that express high-affinity MHC are negatively selected (Fig. 63.8) (51). Less currently is known about the development of B cells in the bone marrow, but it is thought that surface immunoglobulin (sIgM and sIgD) functions similarly to the TCR on T cells, whereby self-reactive B cells are clonally deleted by apoptosis. Current theory proposes that certain autoimmune diseases are the result of failure in programmed cell death of self-reactive T and/or B cells.

Homeostasis of Peripheral Lymphocytes

Lymphocytes that develop in the primary lymphoid organs traffic to the secondary lymphoid organs where they encounter a multitude of antigens and accessory signals (e.g., cytokines) and become activated. The activated lymphocytes proliferate and differentiate, producing antibodies (B cells) or secreting cytokines or killing target cells (T cells). Cells that are no longer needed are removed by activation-induced cell death (ACID) (50, 51). ACID appears to be mediated by binding of its associated ligand to receptors that are members of the TNF-R family, especially CD95 (Fas/APO-1). It is thought that cells that generate low affinity antibodies or antibody directed to self-antigens are removed by apoptosis in normal humans. Cytotoxic T lymphocytes (CTL) induce apoptosis in target cells by two distinct pathways:

primarily through the action of granzyme B and perforin, or secondarily through a CD95/CD95L (receptor-ligand interaction) pathway.

Role of Apoptosis in Diseases of the Immune System

Certain body sites that are protected from immune interaction (immune privilege), e.g., the eye and the testis, have been shown to express high levels of CD95L, believed to contribute to preventing inflammation in these delicate tissues (51). Experiments of nature illustrate the effects of defective apoptosis: the rare autoimmune lymphoproliferative disease where mutations in CD95 inhibit apoptosis, X-linked severe combined immune deficiency (SCID) where a defect in IL-2R results in increased apoptosis of the lymphocyte population, and Chediak-Higashi syndrome where CTLs are unable to degranulate and destroy target cells.

Apoptosis is a defense mechanism against viral-infected cells. When a cell detects a virus and activates the intrinsic apoptotic mechanisms or when a CTL recognizes a virally infected cell, the cytopathic effects are defensive apoptosis. The death of CD4+ T cells in HIV is known to occur by apoptosis. Uninfected, bystander cells also can be eliminated by apoptotic mechanisms. Fulminant hepatic necrosis following infection with hepatitis B or hepatitis C is an example of apoptosis gone awry. It is hoped that apoptotic protease inhibitors might one day combat graft rejection by blocking CTL killing, prevent CD4 cell death in AIDS, or minimize hepatic cell damage in viral hepatitis. Bcl-2 antagonists might be used to treat follicular lymphoma or eliminate lymphocytes mediating autoimmune diseases. Radiation, certain chemotherapeutic agents, and steroids currently used for immunosuppression and/or tumor depletion, exert their effects by activating apoptosis.

Monoclonal Gammopathies

David F. Keren

A monoclonal gammopathy is the protein product of a single clone of plasma cells. Although the term “monoclonal gammopathy” often has been used to designate the proteins produced by the malignant cells in multiple myeloma and other B-cell lymphoproliferative lesions, such as Waldenström's macroglobulinemia, a monoclonal gammopathy also may be the product of a “regulated” cell. Patients with profound infections or considerable polyclonal autoimmune stimulation often have marked expansion of one or a few (oligo-) clones. When one clone predominates, a picture resembling a monoclonal gammopathy from a B-cell lymphoproliferative lesion may result. Thus, the presence of a monoclonal protein (M-protein) alone does not indicate that a neoplastic process is present. Factors to consider when evaluating an M-protein include the quantity of the M-protein, the fluid in which it is found (serum versus urine), and the chemical type of the M-protein (light chains will more likely be found in the urine than in the serum). The term M-protein is used in the literature to describe the monoclonal gammopathy. Although it has been variously used for “monoclonal component, myeloma protein, and macroglobulin protein,” the recently published guidelines for evaluating monoclonal gammopathies recommend the use of the term “M-protein” (1,2 and 3).

The clinical investigator must be able to detect even small M-proteins. Formerly, small M-proteins were not thought to be of clinical significance. Indeed, as discussed below, most M-proteins less than 1,000 mgidl, are part of the monoclonal gammopathy of undetermined significance (MGUS) category. However, some of them represent the products of B-cell lymphoproliferative lesions such as chronic lymphocytic leukemia and well-differentiated lymphocytic lymphoma. Conditions often overlooked when a quantitatively small M-protein is detected include amyloidosis, peripheral neuropathies, and nonsecreting, or, more typically, hyposecreting myeloma.

This chapter reviews the new monoclonal gammopathy guidelines, and the major disease states that result in the production of a monoclonal gammopathy. The methodologies for detecting them are evaluated and a strategy for assessing M-proteins is given.

GUIDELINES FOR EVALUATING MONOCLONAL GAMMOPATHIES

Part of "64 - Monoclonal Gammopathies"

In May 1998, new National Consensus Guidelines for the Clinical and Laboratory Evaluation of Patients with Monoclonal Gammopathies were adopted (1). The Guidelines conference was cosponsored by The Clinical Center of the National Institutes of Health, The American Society of Hematology, The American College of Rheumatology, and The College of American Pathologists.

The conference focused on three questions:

1. Which patients should be evaluated for the presence of a monoclonal (M) protein?
2. What types of specimens should be studied, and how often should they be used to follow patients with M-proteins?
3. Which laboratory methods should be used to detect, identify, and follow M-proteins?

Which Patients Should be Evaluated for the Presence of an M-Protein?

M-proteins are found in the serum and/or urine of patients with a wide variety of clinical conditions. The occurrence and clinical symptoms of these conditions vary widely (Table 64.1). For instance, approximately 13,000 new cases of multiple myeloma are reported annually in the United States, whereas, the estimated occurrence of MGUS has been as high as 750,000. Patients with multiple myeloma have an average survival of 3 years, while individuals with MGUS have the average life expectancy for their age group (about 10 years). Clearly, the significance of M-proteins varies widely and the mere presence of an M-protein must be evaluated in the clinical context of that patient (2).

TABLE 64.1. CONDITIONS ASSOCIATED WITH THE PRESENCE OF AN M-PROTEIN

Condition	Clinical Features
Multiple myeloma	Back pain, osteolytic lesions, fatigue, elevated sedimentation rate, nephrotic syndrome, infections, anemia, elevated calcium
Waldenström's macroglobulinemia	Fatigue, elevated sedimentation rate, dizziness, anemia, hyperviscosity
B-Lymphoproliferative disorders	Fatigue, anemia, lymphadenopathy, lymphocytosis
Amyloid (AL), light chain deposition disease	Nephrotic syndrome, congestive heart failure, carpal tunnel syndrome
Neuropathy and M-protein	Peripheral sensory and/or motor neuropathy
Monoclonal gammopathy of undetermined significance (MGUS)	No symptoms related to the M-protein

TABLE 64.2. CONDITIONS WITH RELATIVELY SMALL QUANTITIES OF M-PROTEIN IN SERUM

Condition	Associated Feature
Light chain disease	15% of cases of multiple myeloma are light chain disease
Amyloid (AL)	20% have multiple myeloma or Waldenström's macroglobulinemia
Heavy chain disease	Alpha chain disease is rare in United States
	Gamma chain disease is associated with B-lymphoproliferative disorders
M-protein associated neuropathy	Must do Immunofixation of serum to rule out
Cryoglobulin type II	Associated with Hepatitis C
Solitary plasmacytoma	Tiny or no M-protein in serum
B-Lymphoproliferative disorder	Often with overall gamma suppression
MGUS	The most common cause of serum M-proteins

Traditionally, the size of the M-protein has been helpful in determining the significance for the patient. Typically, a large quantity of M-protein (greater than 2 G/dL) is more likely to be associated with myeloma, whereas, a small quantity of M-protein may be associated with MGUS. Yet, several important conditions associated with small quantities of M-proteins may be overlooked if these M-proteins are not recognized (Table 64.2). This is why it is important to use a logical sequence of testing and high quality laboratory methods to detect M-proteins.

Because of the high prevalence of MGUS, it is not useful to screen patients who do not have signs or symptoms consistent with the other conditions listed in Table 64.1 and Table 64.2 with serum and urine protein electrophoresis. In order for a positive result to have a significant predictive value for the individual patient, serum and urine protein evaluations must be performed selectively. The degree of clinical suspicion is also useful in determining how far to proceed with the testing process.

What Types of Specimens Should be Studied, and How Often Should They be Used to Follow Patients with M-Proteins?

The initial evaluation of a patient with clinical features suggesting the presence of an M-protein should include a serum and urine electrophoresis using high-resolution methods (Fig. 64.1). It is important to include both urine and serum in this initial evaluation, because in some patients the M-protein will only be located in one or the other fluid. Alternatively, in some cases, only a small amount of M-protein will be found in the serum while a massive amount of monoclonal free light chain (Bence Jones protein) will be present in the urine.

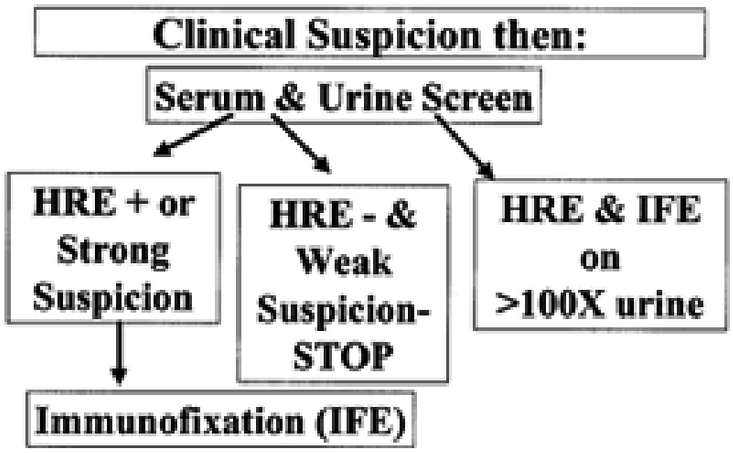

FIGURE 64.1. Specimens and evaluation for detecting monoclonal gammopathies.

If the serum protein electrophoresis is negative, and there is a low index of suspicion, one may wish to look for other causes of the symptoms before performing an immunofixation (IFE). However, if the clinical suspicion is high, an IFE should be performed even when no M-protein is seen on the screening electrophoresis. If an M-protein is found on the screening electrophoresis, an IFE must be performed to identify the M-protein. This identification serves several purposes. First, it rules out a false positive due to some other protein that may mimic an M-protein on serum protein electrophoresis (Table 64.3). Second, because IFE is more sensitive than screening electrophoresis, it may identify a second M-protein (often a monoclonal free light chain that accompanies the intact molecule in the serum). Third, it identifies the M-protein for comparison with subsequent samples from the patient. If there is no change in the migration of the identified M-protein on subsequent samples, there is no need to perform further IFE studies. Repeat IFE studies are only needed when the electrophoretic migration changes on subsequent samples because this may indicate the development of a second clone, or the appearance of monoclonal free light chains in addition to the intact M-protein.

TABLE 64.3. PROTEINS THAT MAY MIMIC AN M-PROTEIN

Although one may detect monoclonal free light chains (Bence Jones proteins) in the serum, they mainly are found in the urine. Urine for evaluating the presence of monoclonal free light chain should be a 24-hour sample. False negatives are most likely to occur on spot samples of urine. Therefore, a negative result on a spot urine sample cannot be used to rule out the presence of monoclonal free light chains.

All urine samples suspected of containing an M-protein must be concentrated at least 100X by the laboratory and must be tested by *both* electrophoresis and IFE. False negatives may occur with dipsticks, sulfosalicylic acid tests and the old heat-acid precipitation test. There is an *incorrect* general belief that the sulfosalicylic acid test is an adequate screen. The monoclonal gammopathy panel of experts was unanimous that it is not. All panel members reported seeing several cases of monoclonal free light chain missed by the sulfosalicylic acid method.

Once an M-protein has been identified, how should one follow it? This depends upon the clinical situation. Depending on the population of patients selected for M-protein evaluation, most cases will be MGUS. However, one must rule out all of the relevant conditions listed in Table 64.1 and Table 64.2 before classifying a patient as MGUS. For instance, congestive heart failure from

amyloid (AL) may be suspected because of a small quantity of lambda M-protein in the serum or urine. Once those conditions are ruled out, patients classified as MGUS need have serum and urine quantifications of the M-protein only annually, assuming no change in the clinical or laboratory features. Kyle has found that about 20% to 25% of patients with MGUS followed for 20 to 35 years will develop clinically significant B-lymphoproliferative disorders including myeloma, Waldenström's macroglobulinemia, B-cell leukemia, and B-cell lymphoma (3, 4).

Patients with multiple myeloma and Waldenström's macroglobulinemia who are receiving therapy need to be followed every 1 to 2 months with serum and urine electrophoresis. The laboratory needs to report the quantity of the M-protein as a guide to the effectiveness of ongoing therapy. It is wasteful to repeat the IFE on samples with no change in the migration of the M-protein by serum protein electrophoresis. A repeat IFE does not provide useful information. Indeed, repeating IFE on a serum with a previously characterized M-protein and no change in migration pattern is an unfortunate waste of time and money. The panel was unanimous that the clinician needs to know what has happened to the quantity of the M-protein since the last evaluation, not to reidentify a known molecule.

For serum, the best measurement of the M-protein is achieved by performing high-resolution electrophoresis and measuring the amount of protein below the spike (Fig. 64.2). Sometimes, when the M-protein migrates in the beta region, this may be a problem if the quantity of the M-protein is small and it comigrates with either transferrin or C3. In practice, however, most clinically significant M-proteins either migrate in the gamma region, or are large enough in quantity that the interference in measurement by transferrin or C3 is relatively trivial. For those few cases, however, quantification of the M-protein (usually IgA or IgM) will provide adequate follow-up (5).

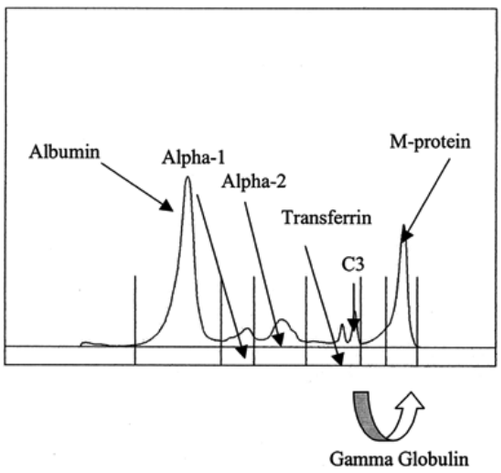

FIGURE 64.2. Capillary zone electropherogram with M-protein. M-proteins should be measured by integrating the area under the peak.

For the urine, it is important to follow the monoclonal free light chains and not the intact M-protein immunoglobulin that may be found in the urine. The prognosis and threat to the kidney is mainly due to the amount of monoclonal free light chain and not due to the intact M-protein.

The panel agreed that the term “Bence Jones protein” has been somewhat confusing in this regard. Bence Jones protein only refers to the monoclonal free light chains, not to the intact monoclonal immunoglobulins. Because of this, the consensus panel recommends use of the more specific term “monoclonal free light chain” instead of the older term “Bence Jones protein.” The panel recognized that because of the long use of the term “Bence Jones” protein, it would be a slow process to remove it. However, the confusion caused by mistaking intact M-proteins with monoclonal free light chains is of enough significance to warrant this effort.

Monoclonal free light chains may damage renal tubules, and are associated with amyloid (AL), as well as light-chain deposition disease. To follow the quantity of monoclonal free light chain in the urine, obtain a 24-hour sample of urine. The laboratory needs to perform electrophoresis and determine the amount of protein associated with the monoclonal free light chain peak. If there has been any change in migration of the monoclonal free light chain, the laboratory needs to perform IFE to determine if a new peak is another form of monoclonal free light chain (dimer, tetramer) or a new intact M-protein peak. Results are expressed as grams of monoclonal free light chain/24 hours.

Which Laboratory Methods should be used to Detect, Identify, and Follow M-Proteins?

The panel was unanimous that the laboratory should use a high-resolution electrophoretic method in the initial evaluation of serum and urine. A high-resolution method is one that permits a crisp separation of transferrin and C3 in the beta region (Fig. 64.3). This gives the interpreter the best view of subtle, but potentially clinically significant M-proteins (6, 7).

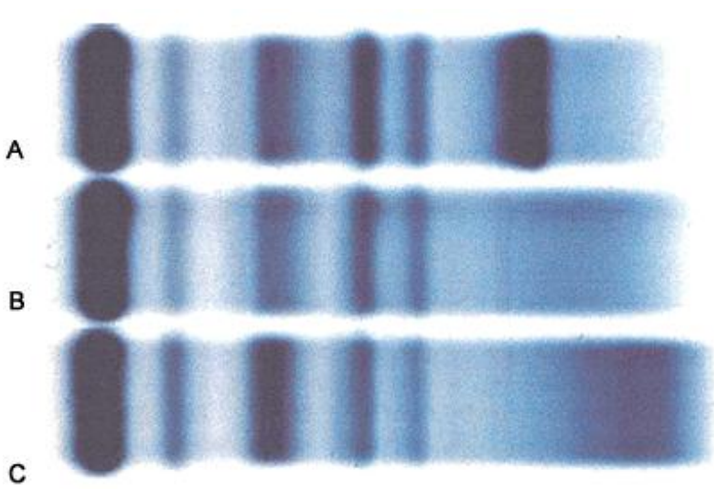

FIGURE 64.3. High-resolution electrophoresis with M-protein (top), normal (middle), and polyclonal patterns. The gel or CZE pattern should provide crisp separation of the beta-1 (transferrin) band from the beta-2 (C3) band.

There is a wide variation in the quality of electrophoretic gels available. The importance of using high-resolution electrophoresis methods was demonstrated on a national level in a College of American Pathologists (CAP) Survey Sample (8). Less than one third of laboratories using a low-resolution electrophoretic system could detect a subtle, but potentially clinically significant M-protein in the CAP Survey, while over 95% of laboratories using high-resolution methods were able to detect this M-protein.

In addition to gel-based methods, capillary zone electrophoresis also is available in a high-resolution format. The crisp separation of the beta region components by high-resolution capillary zone electrophoresis is evident in the examples shown in Fig. 64.2 and Fig. 64.3.

All urine must be evaluated by both high-resolution electrophoresis and by IFE on the initial evaluation for the presence of an M-protein. The urine must be concentrated at least 100X prior to study. It is important to do both tests initially to be certain that an obvious M-protein seen on the high-resolution electrophoresis of the urine is not missed because of a technical error, or to an antigen excess effect. IFE must be able to detect the presence of kappa and lambda monoclonal free light chains. When monoclonal free light chains are identified, they must be quantified on 24-hour samples to follow the patients.

The presence of a monoclonal free light chain in the urine is more ominous and uncommon than the presence of a small M-protein in the serum. This is because the tubules are capable of reabsorbing up to 1 gram of protein in 24 hours. Therefore, before the monoclonal free light chains are detected in the urine, they must be present in a relatively large amount to exceed the tubular reabsorptive capacity. Therefore, when one detects a monoclonal free light chain in the urine, one must be particularly mindful of the more subtle conditions such as amyloid (AL) and light chain deposition disease that may be associated with those M-proteins.

DISEASE STATES

Part of "64 - Monoclonal Gammopathies"

Myeloma

Multiple myeloma is the most common malignant cause for the presence of an M-protein in serum or urine. This disease is because of a malignant proliferation of a clone of B lymphocytes that manifests predominantly as plasma cells. Note that multiple myeloma often is considered to be a condition of malignant plasma cells. In fact, the malignancy involves the entire B-cell lineage but manifests mainly as malignant plasma cells. When one examines the bone marrow from individuals with multiple myeloma, pre-B cells with the same idiotype as the monoclonal protein can be found. Usually, patients with multiple myeloma present with involvement of the bone marrow. The plasma cells synthesize and secrete large quantities of the monoclonal whole immunoglobulin. These plasma cells are like inefficient factories because they often produce excessive numbers of monoclonal free light chains (Bence Jones protein). Patients with multiple myeloma present with a wide variety of clinical symptoms. Bone pain often is a presenting feature because the bone marrow involvement creates lytic lesions in the ribs, vertebrae, skull, and long bones. The plasma cells produce an osteoclast-activating factor that results in recruitment of osteoclasts that dissolve the bone in these locations. As a result of the destruction of the bony elements, these individuals may present with a so-called pathological fracture. These are fractures of bones resulting from relatively trivial trauma. Because the lytic lesions weaken the cortex, it is more susceptible to breakage (9,10 and 11).

Patients with multiple myeloma also present with infectious diseases. This results from a marked suppression of the production of polyclonal immunoglobulins in these individuals. When one examines the serum protein electrophoresis, one usually finds a large M-protein in the gamma or the beta region.

Note, however, that a spike may occur anywhere from the a region through the y region in monoclonal gammopathy. In multiple myeloma, the normal production of y-globulin is suppressed so that the background of normal antibodies is markedly decreased. As a result, many patients with multiple myeloma suffer from pyogenic bacterial infections that are normally defended by opsonizing immunoglobulins.

Other myeloma patients present with weakness resulting from anemia. The anemia tends to develop later in the course of the disease and is relatively nonspecific. However, examination of the peripheral blood from patients with multiple myeloma may show a blue hazy background due to the excessive amount of protein present in the serum. Other key laboratory parameters in these individuals include Rouleaux formation, an increase in the serum alkaline phosphatase, and calcium from the destruction of bone. Note that the elevated calcium usually appears relatively late in the course of this disease. Early on, one usually will not find evidence of hypercalcemia.

The excessive production of free light chains (Bence Jones protein) in these patients appears mainly in the urine. Where they occur depends on their structure. The light chains may be present as monomers, dimers, or tetramers. The monomers are small molecular weight (22,000 daltons) and readily pass through the glomerular basement membrane into the urine. Dimers weigh approximately 44,000 daltons and pass into the glomerular filtrate less readily than monomers. Therefore, patients with dimers may have a small spike in the serum and most of the Bence Jones protein in the urine. Lastly, patients with tetramers will have virtually no Bence Jones protein in the urine, while a spike is seen in the serum. This is because the weight of the tetramer is too great to pass through a normal glomerular basement membrane. The finding of Bence Jones proteins is clinically significant for the patient. Individuals with large amounts of Bence Jones proteins tend to do worse clinically than individuals who lack Bence Jones proteins. The main reason for this is that the Bence Jones proteins are reabsorbed by the proximal convoluted tubules in the kidneys. There, depending on their immunochemical makeup, they may damage the proximal tubules. Significant damage may occur and produce myeloma kidney. In this, the proximal tubule cells form syncytia, and casts consisting of monoclonal protein are found within the tubule lumen. Renal failure is an uncommon but real cause of demise in some patients with multiple myeloma (12,13,14,15,16,17,18 and 19).

The classification of multiple myeloma is not merely based on finding a monoclonal protein in serum. Indeed, some investigators worry that they may not be able to detect every possible case of monoclonal gammopathy no matter how extensive a screening

program they set up. Clearly, there are cases of nonsecreting or hyposecreting myelomas that will be missed. There are other unusual cases of myeloma in which a relatively small amount of the monoclonal protein is produced and hides under a normal beta region component such as transferrin (simulating an iron-deficiency anemia pattern) or under C3 (simulating a subacute inflammatory response pattern). The laboratorian must be aware that serum protein electrophoresis, though an excellent screening method, is not the only criterion used for the diagnosis of multiple myeloma. These individuals need to be assessed by virtue of their clinical symptoms (bone pain, anemia, infectious disease problems, renal disease, neuropathies, etc.) (11, 20). Some unusual variants of multiple myeloma may be more difficult to diagnose. One of these is POEMS syndrome. This stands for the 5 to 7% of cases of multiple myeloma that present mainly with a peripheral neuropathy, organomegaly (mainly the liver and spleen), endocrinopathy (often thyroid dysfunction or diabetes mellitus), M-protein, and skin lesions (usually increased skin pigmentation). These individuals have the interesting skeletal findings of osteosclerotic lesions rather than the usual osteolytic lesions. Note that both osteosclerotic and osteolytic lesions may be present simultaneously. Sometimes, multiple myeloma may be present with amyloidosis (amyloid AL) (21,22 and 23).

Immunoglobulin Isotypes in Multiple Myeloma

The isotypes of immunoglobulins seen in multiple myeloma largely reflect their prevalence in normal serum. IgG myeloma proteins predominate. They are almost always monomers weighing 160,000 daltons. It is rare that IgG myeloma proteins produce significant problems with hyperviscosity (see Waldenström's Macroglobulinemia, below). IgE myeloma is extremely rare and can occur as monomers or as polymers with variable molecular weight. Because IgE molecules tend to self-aggregate, they, like IgM, may cause problems with hyperviscosity symptoms. IgA myeloma may be difficult to diagnose on occasion because IgA tends to migrate in the P region. Therefore, early in its course, the other beta region bands may mask the IgA myeloma. C3, transferrin, or fibrinogen from an inadequately clotted sample of blood or an inadvertently examined sample of plasma may obscure the presence of an IgA myeloma M-protein. Also, IgA myeloma bands tend to be more diffuse because of the heavy glycosylation of IgA myeloma proteins. IgD myelomas are quite uncommon, representing about 1% of the total cases of multiple myeloma. The light chain types usually reflect the percentage of kappa and lambda present in the serum. Two thirds of IgG and IgA myelomas are of the kappa light chain type and one third are of the lambda type. However, an exception occurs with IgD myeloma, for which the ratio of kappa to lambda light chains is 1:9.

Although some anecdotal reports have illustrated minor differences in clinical course if one has kappa as opposed to lambda light chains, no significant difference has been documented in more extensive studies. Therefore, the typing of light chains is merely useful for classifying the patients but does not alter the prognosis.

IgD myelomas also may be missed because the amount of M-protein may be relatively small (24). If one is using the older five-band electrophoresis techniques, a normal alpha 2 or beta region band may hide the small IgD component. Also, as discussed later, when radial immunodiffusion plates perform quantification, at least two dilutions of the patient's serum must be performed to avoid antigen excess. In antigen excess, the ring of precipitation may be so small that it would go unnoticed or be washed away. Indeed, this is one of the reasons why the recently released monoclonal gammopathy guidelines recommends not using radial immunodiffusion to quantify the immunoglobulins.

It is uncommon for multiple myeloma to occur with IgM. That is not to say that it does not occur.

Sometimes one can reach that incorrect conclusion from the literature. However, only a handful of cases of multiple myeloma with IgM have been reported. This is because patients with IgM M-proteins usually have a different clinical disease called Waldenström's macroglobulinemia. This author has seen only rare examples of multiple myeloma with IgM. One of them was a defective IgM product that contained only the CH1 and variable portion of the IgM chain together with a single light chain. It appeared mainly in the patient's urine. It is important to anticipate such unusual events, but overall, IgM myeloma is about as rare as IgE myeloma (25).

Alpha heavy-chain disease is extremely uncommon in the western world. In the Middle East and Mediterranean regions, an unusual disease called a heavy-chain disease occurs. The tissue distribution of the plasma cells in this lesion roughly parallels that for the normal distribution of IgA along the gastrointestinal tract and other mucosal surfaces. This disease is different from IgA multiple myeloma. In alpha heavy-chain disease, the individuals usually have a slow progression of their disease during the early phase. Cures have been reported with antibiotic treatment at this stage. Also, the disease is particularly difficult to diagnose in the clinical laboratory. Often, serum samples do not show obvious abnormal bands on serum protein electrophoresis, although one may find a rather broad band in the beta region. Because no reaction is seen with the light-chain antisera, the assumption is made often that a monoclonal gammopathy is not present. Note that with IgA myeloma, light chains are often difficult to demonstrate. A technique termed immunoselection has been used to assist in this diagnosis. In this technique, antibodies against light chains are mixed into the agarose (similar to setting up a radial immunodiffusion). Then, a standard immunoelectrophoresis is carried out. Since intact immunoglobulin molecules contain either kappa or lambda light chains, they must precipitate with the anti-kappa and anti-lambda in the sample well. The only molecules to migrate from the well will be those that lack light chains (hence the alpha chain disease molecule). The distance migrated from the well correlates with this concentration. Another way to determine alpha-chain disease is always to quantify IgG, IgA, IgM, and light chains by nephelometry or turbidimetry and to perform serum protein electrophoresis simultaneously. Patients with alpha chain disease will have increased concentrations of IgA. By subtracting the sum of the light chain-containing immunoglobulins from the IgG +IgA +IgM, a relatively large positive number would, be obtained (normally the number should be near zero). This is because the excess alpha chains do not have detectable light chains. Therefore, one would suspect the possibility of heavy-chain disease from this calculation and perform an immunoselection. The diagnosis

of alpha-chain disease may be missed in the western world because these cases are so rare that immunoselection technique is not a standard procedure in clinical laboratories in this country (25).

The more common form of heavy-chain disease seen in the Western world is Franklin's disease (gamma heavy-chain disease). Most of these patients have a form of B-cell lymphoma or leukemia. The patients may present with a generalized lymphadenopathy, hepatosplenomegaly, pleural effusions, and ascites. Similar to alpha chain disease, an immunoselection method may be optimal to confirm this diagnosis (25). We prefer to use the Sun technique, a modified immunoselection procedure (26).

Biclonal gammopathies can be somewhat confusing. These conditions have expansion of two B lymphocyte clones rather than one. Actually, there is no special significance to this finding. Individuals who clinically have multiple myeloma have no different disease process if they have one clone or two clones. To confirm a true biclonal gammopathy, one must either demonstrate two different light chain types, which are by definition two distinct clones, or perform DNA rearrangement studies to document this distinction. If one has two clones with the same light chain, DNA studies would be the only way to determine if they were from one clone or two. Because there is no clinical significance to making this determination, it is not cost-effective. About 5% of patients with monoclonal gammopathies have a biclonal gammopathy pattern. Note that the presence of two different heavy chain types with the same light chain type does not imply necessarily a biclonal gammopathy. During maturation of B-lymphocytes, there is often a stage at which a switch occurs from one heavy-chain isotype to another. That is why some B lymphocytes will have both a mu chain and an alpha or gamma chain simultaneously on their surface membrane. Therefore, the finding of two different heavy chain types with the same light chain isotype does not establish the existence of a biclonal gammopathy. As mentioned earlier, however, making the distinction is of no clinical significance (25).

Lastly, some patients with multiple myeloma present with profound hypogammaglobulinemia. Although there have been several theories as to why this profound hypogammaglobulinemia often occurs in multiple myeloma, the pathogenesis is still uncertain. Further, not all individuals with multiple myeloma will present with a hypogammaglobulinemia. Some studies have shown that peripheral blood lymphocytes from patients with multiple myeloma have a poor response to B-cell mitogens. In other studies, a marked decrease has been found in the number of normal peripheral blood B lymphocytes in patients with multiple myeloma. This implies the existence of some sort of suppressive influence on B lymphocyte maturation. However, it has not been clearly demonstrated that suppressor T lymphocytes are the cause of this change. An increase in the number of circulating T helper cells with the suppressor-inducer phenotype (CD4+, CD45R+) has been described. Patients with multiple myeloma also have an increase in the T helper cells that have the immunoglobulin-secreting helper capacity phenotype (CD4+, CD45R-). Clearly, the two helper and suppressor cells can function to effect the immunoglobulin containing cells in these patients. Patients with T helper lymphomas, for instance, will often have a polyclonal increase in gamma globulins. However, one must be careful to avoid oversimplification with these functions. For example, in individuals with acquired immunodeficiency syndrome (AIDS) the T helper (CD4+) lymphocytes have been destroyed by infection with human immunodeficiency virus (HIV). Yet, a polyclonal immunoglobulin increase is consistently found in the serum of these patients. Further, transient M-proteins may be found in patients with other infectious processes such as subacute bacterial endocarditis (25, 27,28 and 29).

Waldenström's Macroglobulinemia

Patients with Waldenström's macroglobulinemia suffer from complications of hyperviscosity from the presence of large amounts of circulating IgM. IgM almost always circulates as a pentamer (19S). Therefore, when one develops a monoclonal proliferation of cells producing IgM, the increased concentration of large proteins in the blood disturbs the normal circulation hemodynamics, resulting in the hyperviscosity syndrome. This causes a variety of neurologic complaints, cardiac insufficiency, and vascular insufficiency throughout the body. In addition to the hyperviscosity syndrome, Waldenström's macroglobulinemia differs from multiple myeloma in other respects. These patients do not develop the lytic skeletal lesions seen in multiple myeloma. They do tend to present with symptoms of weakness and fatigue because of the combination of hyperviscosity and anemia. Clinically, these patients have a more protracted course than individuals with multiple myeloma. Usually, an IgM level of greater than 20 g/L is needed to produce the hyperviscosity syndrome. Keep in mind that IgM is not the only immunoglobulin that will produce the hyperviscosity syndrome. On occasion, IgA also will produce a hyperviscosity syndrome when secreted in large amounts. This is because IgA tends to self-aggregate and IgA can occur in serum as a multimer. IgG rarely has been reported to cause a hyperviscosity syndrome, and this author has seen one case of hyperviscosity syndrome from K light-chain disease (25, 30).

The clinical laboratory can provide several supportive bits of information for this clinical diagnosis. On examination of the peripheral smear, Rouleaux formation is characteristic of this disease. It is not pathognomonic for this condition, as it also may be seen in multiple myeloma. The bone marrow shows an infiltration by lymphoplasmacytoid cells. If one performs immunohistochemical examination, the cells would contain the monoclonal IgM component. Obviously, the serum viscosity usually is increased in these patients. Serum protein electrophoresis is an excellent screening test for this condition. The usual case of Waldenström's macroglobulinemia will show a monoclonal spike that is located close to the origin. Although this is not requisite, the bulky nature of the molecule together with the relative lack of charge at the pH 8.6 normally used for serum protein electrophoresis causes the IgM gammopathy to linger near the origin. Quantification of immunoglobulins discloses large amounts of IgM, usually greater than 20 g/L, and normal amounts of IgG and IgA. Performing immunofixation or immunoselection following serum protein electrophoresis best identifies the gammopathy. Although can identify large M-proteins by measuring IgG, IgA, IgM, kappa and lambda together

with high-resolution electrophoresis, small M-proteins are not readily identified by this technique. Immunoelectrophoresis will identify most M-proteins, but is slower than immunofixation and often more difficult to interpret. Therefore, the recent guidelines recommend replacement of immunoelectrophoresis with immunofixation (1, 5, 31,32,33 and 34).

Monoclonal Gammopathy Of Undetermined Significance

In older textbooks, the term for this section would have been “benign monoclonal gammopathies.”

That name is incorrect. The term benign implies that we can predict the biological behavior of the neoplasm. In pathology this means that a benign lesion will not invade further nor metastasize with potentially lethal consequences. We cannot make such a confident statement about a monoclonal gammopathy that we identify in the serum. Kyle correctly coined the term MGUS to categorize these individuals until we have a better understanding of the significance of the lesions that we detect. A restricted band on serum protein electrophoresis in the gamma region that is identified as a monoclonal gammopathy implies that it has been the product of a single clone or plasma cells. This is correct. However, the nature (benign versus malignant) of those plasma cells and their B-lymphocyte precursors cannot be inferred from the presence of the gammopathy. Even relatively large gammopathies, up to 3,000 mg/dL, may represent a product of a benign lymphoplasmacytic lesion, while some cases of multiple myeloma will produce tiny or undetectable amounts of monoclonal component (3).

In his series, Kyle found that 70% of patients with monoclonal gammopathy had MGUS as their working diagnosis. By this term, he referred to individuals who have a monoclonal component demonstrated in the serum, but who lack other key features for diagnosing a malignant monoclonal gammopathy. These patients are not anemic, they do not have lytic lesions, and they do not have elevated serum calcium or serum enzymes. They do not have a prominent plasmacytosis in the bone marrow, although they may have as many as 10% plasma cells in the bone marrow. About 20% of patients with MGUS over a 10-year period will progress to develop a malignant B-cell lymphoproliferative lesion, usually multiple myeloma. Some of the other cases will develop into chronic lymphocytic leukemia, well-differentiated lymphocytic lymphoma, amyloidosis, and rarely other forms of B-cell proliferative lesions. The vast majority of patients with MGUS do not develop any other overt clinical process (4).

The majority of patients with MGUS do not have a distinctive pathological process that can be detected.

Obviously, somewhere in their bodies they harbor a clone producing this gammopathy. Some may merely represent a response to a particular infection. Others may be part of an autoimmune process in which one clone against the autoantigen predominates. In many other cases, however, we have no idea if some antigen is driving the clone or whether it is a self-driven, neoplastic clone. MGUS patients have quantities of M-protein that range from as little as 300 mg/dL to greater than 3,000 mg/dL. Some of these patients have suppression of their normal immunoglobulin synthesis as shown by decrease in the normal gamma-globulin component by serum protein electrophoresis. This feature alone, however, does not portend a negative prognosis. Usually, these patients do not have significant amounts of Bence Jones protein, although small amounts may be detected. Therefore, in any patients having a monoclonal gammopathy detected in serum in our laboratory, we routinely recommend that a urine sample be obtained to detect Bence Jones protein. We believe that currently, the most sensitive technique for this determination is a combination of serum protein electrophoresis and immunofixation. We also recommend that the clinician follow this patient with a serum protein electrophoresis every 6 to 12 months to determine if the process is evolving or regressing. Of course, routine hematologic and chemical analysis should be performed. If these are in the normal range, and there are no clinical symptoms of bone pain, further studies such as bone marrow examination are probably useless (2).

B-Cell Neoplasms

A variety of B-cell neoplasms have been associated with monoclonal gammopathies. These neoplasms are discussed in detail elsewhere in this text. However, it is useful to note their association with monoclonal gammopathies, as they may provide the clinician with further evidence to do more aggressive, invasive diagnostic procedures. It used to be thought that monoclonal gammopathies were rare in cases of chronic lymphocytic leukemia or well-differentiated lymphocytic lymphoma. In fact, the majority of these patients have a monoclonal gammopathy in either their serum or their urine when high-resolution electrophoresis and immunofixation are combined to study these samples. Monoclonal gammopathies also have been demonstrated in patients with Burkitt's lymphoma and B-cell ALL. Clearly, serum protein electrophoresis is not the ideal way to diagnose these conditions. Nevertheless, the finding of a monoclonal band in the serum or urine of a patient with malaise and lymphadenopathy with splenomegaly, for example, might prompt the clinician to perform a lymph node biopsy (24, 35, 36).

Amyloidosis

About 4% patients with plasma cell proliferation will have amyloid deposition in their tissues. There are two major biochemical types of amyloid. One consists of an immunoglobulin light chain and is termed AL. The second is composed of protein A and is termed AA. AA is probably a breakdown product of the much larger normal serum molecule amyloid A-related protein. When either type of amyloid deposits in tissues, a dysfunction of the involved organs occurs, depending on the location of the amyloid deposits. For instance, in patients with AL amyloid, there is frequently deposition in the heart, gastrointestinal tract, tongue, blood vessels, tendon, skin, and peripheral nerves. The clinical picture that these individuals present with depends on which site is involved. For example, patients with amyloid deposition primarily in the tongue will present with macroglossia. Those who have deposition within the heart will present with symptoms of congestive heart failure.

Patients with amyloidosis and monoclonal gammopathy usually

do not have bone pain or osteolytic lesions. It may be appropriate to biopsy the rectum, or involved sites to determine the presence of amyloid. Tissues with extensive involvement of amyloid stain dark blue with iodine, hence the term amyloid (meaning starchlike). The definitive diagnosis of amyloidosis requires positive staining with Congo red, giving a characteristic blue-green birefringence when polarized light is used. These tinctorial qualities relate to the structural beta-pleated sheet formation that occurs with either AL or AA. Monoclonal gammopathies may be found in both the serum and urine of patients with amyloidosis (23, 25).

Methodologies

Immunologic Reaction in Gel Diffusion

The classic precipitation reaction is the basis for immunofixation and immunoelectrophoresis. As discussed earlier in this section, antibody-antigen interactions are highly concentration dependent. Therefore, when an antibody is placed in one well and diffuses toward the antigen placed in another well, a precipitation reaction occurs somewhere between the two wells. The distance from the well where the band forms depends upon the concentration and the size of the reactants. When the antigen and antibody are of approximately equal size and concentration, the band will occur midway between the two wells. These reactions are highly specific and are therefore, useful to identify the specific immunoglobulin involved in a monoclonal gammopathy (25).

Serum Protein Electrophoresis

The older five-band electrophoretic patterns have been replaced in recent years by high-resolution agarose or acetate electrophoresis patterns. These are vastly superior for evaluating serum for the presence of a monoclonal gammopathy. They permit distinction of subtle monoclonal bands that are present in the alpha 2 and beta regions, as well as the easy-to-see bands that are present in the y region. The older five-band gel methods did not permit facile discrimination of bands in the alpha 2 and beta regions. Several versions of high-resolution electrophoresis are commercially available in both agarose and acetate form. Any of the systems is preferred over the older acetate form. The older acetate gels would be adequate screens if one were to perform immunofixation along with them. However, this is expensive, time-consuming, and redundant in most cases (25, 37). The current monoclonal guidelines recommend that a technique that provides crisp resolution of the beta-1 and beta-2 region bands (transferrin and C3) (1).

Most, but not all clinically significant monoclonal gammopathies are readily detected electrophoresis that provide crisp definition of the beta and gamma regions. They contain either a band in the alpha-2, beta, or gamma region, a distorted band from binding of a normal component by the monoclonal gammopathy, or hypogammaglobulinemia (the latter must always be evaluated with immunofixation and urine examination for Bence Jones protein) (24, 25).

When a sample is sent for monoclonal gammopathy evaluation, a high quality electrophoresis is performed together with either immunofixation, immunosubtraction, or immunoglobulin quantification if an M-protein is seen. The presence of any abnormal band or hypogammaglobulinemia on the electrophoresis gel results in the performance of an immunofixation on that sample. If the electrophoresis demonstrates even minor distortions in the beta region an immunofixation study will be performed. This reflects the fact that IgA and IgM M-proteins may be present in the beta region and the presence of transferrin, C3, and beta-1 lipoprotein in this region may obscure a small M-protein (25, 5). Although the identification of the M-protein in most cases can be evaluated without resorting to immunofixation if high-resolution electrophoresis is performed with quantification of IgG, IgA, IgM and kappa and lambda, most laboratories perform immunofixation to identify the M-protein. The newer immunofixation procedures are quick, efficient and some have features of automation that dramatically decrease the workload (5).

Urine electrophoresis and immunofixation should be performed on all patients who are suspected of having myeloma, Waldenström's macroglobulinemia or amyloid AL. Light-chain disease may have a normal or mildly hypogammaglobulinemic pattern on serum protein electrophoresis. This is why urine must be examined along with serum in all of these cases as recommended by the new guidelines (1, 5).

Immunofixation

In evaluating patients for a monoclonal gammopathy, one must put the entire clinical picture together: the history that is provided, and other laboratory parameters (hematocrit, total protein, evidence of lytic lesions, serum calcium) to make the correct diagnosis (38,39,40,41,42,43 and 44). Immunofixation is performed by repeating the serum protein electrophoresis with the patient sample run in several tracts. After the electrophoretic step, each tract is overlaid with a specific antiserum against IgG, IgA, IgM, kappa or lambda (Fig. 64.4). The patient sample applied to each tract is diluted to achieve a concentration of approximately 100 mg/dL prior to electrophoresis. This optimizes the immunoprecipitation reaction. If too large a quantity of patient serum is used, an antigen excess effect will be seen. If too small a concentration is used, rarely, an antibody excess effect will be seen or the resulting reaction may be too small to be seen. Therefore, one must know the concentration of specific immunoglobulins prior to performing immunofixation in order to use the correct concentration of serum. Following electrophoresis, the specific antiserum is overlaid onto the tract and allowed to incubate for 30 minutes. After this step, the sample is washed so that unprecipitated proteins will be removed. Thereafter, the sample is stained with a sensitive dye. Coomassie blue or Crystal violet serves well in this regard. After the sample is dried, a permanent record is formed. We use immunofixation to detect subtle gammopathies where there is not an obvious band by serum protein electrophoresis, but where there is a lingering clinical suspicion of the patient's harboring an M-protein (45,46,47,48,49 and 50).

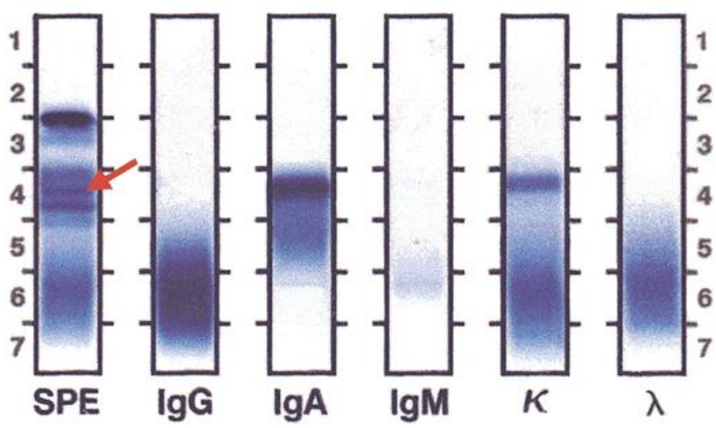

FIGURE 64.4. Immunofixation with an IgA kappa M-protein. Note the small M-protein band (arrow) in the SPE lane. The IgA and kappa restrictions are obvious.

Capillary Zone Electrophoresis

In capillary zone electrophoresis (CE), serum is aspirated into narrow (50 μ) capillary tubes that have a strong net negative

charge. This negative charge provides a strong endosmotic flow, which propels the serum proteins to the cathode. At the cathodal end, protein fractions are estimated by measuring the optical density at 215 nm (peptide bond absorbance) and an electropherogram is produced (Fig. 64.2). This is a highly automated version of electrophoresis because there is no staining and destaining. The technologist puts reagents on the instrument, reviews the electropherograms, and performs maintenance on the instrument. About 40 samples can be processed in an hour. The instrument allows the operator to convert the electropherograms into virtual gel images that resemble the high-resolution gel patterns with crisp separation of the beta-1 and beta-2 regions. However, one of the drawbacks of this methodology is the relatively short gamma region compared to the high-resolution gel-based systems. Artifacts also have been reported in this system because of non-M-protein molecules that absorb at 215 nm. For instance, radiocontrast dyes may produce a restriction that resembles an M-protein. This is another reason why all putative M-protein spikes must be characterized (whether seen on CE or traditional gel-based methods). CE is relatively new for general application, but has been gaining application in larger laboratories that wish to have an automated, high-resolution system (51).

Immunosubtraction

Immunofixation may not be performed on a CE system. However, advantage may be taken of a technique called immunosubtraction (ISUB) that was described several years before CE was even used. With ISUB one mixes the serum with beads coated with specific antibody. After, an incubation is performed for each major heavy-chain isotype and kappa and lambda. Identification of the M-protein is accomplished by its removal using the appropriate antibody-coated beads. For example, a serum containing an IgG kappa M-protein will have the spike removed by beads coated with anti-kappa, but not by those coated with anti-lambda. Similarly, the spike will be removed by beads coated with anti-IgG (or Staph protein A), but not by beads coated with anti-IgM or IgA. Although the process sounds laborious, commercially available coated beads are packaged for complete performance of IgG, IgA, IgM, kappa and lambda identification on the automated CE instrument. Unfortunately, anti-IgD and anti-IgE beads were not readily available at the time of this writing. The other drawback of ISUB is its inherent insensitivity. With IFE, there is an enhancement of the sensitivity of electrophoresis that allows detection of small M-proteins that are not seen on even high-quality systems. With ISUB, if you do not see the spike on the electrophoresis step, it obviously cannot be immunosubtracted. Nonetheless, this is a practical technique for quickly identifying most M-protein spikes (26).

Primary Immunodeficiency Diseases

Jeffrey S. Warren

Our understanding of primary immunodeficiency diseases has advanced rapidly. There is perhaps no better example than that of X-linked agammaglobulinemia (XLA). In 1952, a pediatrician named Colonel Ogden Bruton described an 8-year-old boy who, beginning at approximately 2 years of age, had begun to suffer from recurrent bacterial pneumonia and septicemia. Recognition of the association between recurrent infections with high-grade bacterial pathogens and very low concentrations of serum gammaglobulins had been made possible by the recent development of serum protein electrophoresis. The cause-and-effect nature of this association was confirmed when the infections ceased following high-dose intramuscular gammaglobulin injections. Examination of similar patients, uniformly boys, coupled with the observations that infections were caused by encapsulated bacteria such as *Streptococcus pneumoniae*, *Hemophilus influenzae*, *Streptococcus pyogenes*, etc., but not by intracellular pathogens such as mycobacteria, viruses, and fungi, and that lymph nodes from XLA patients were devoid of germinal centers but not lymphocytes in the deep paracortical regions, led to the conclusion that Bruton's agammaglobulinemia is an X-linked defect in B lymphocyte maturation. In 1993 it was determined that XLA is caused by a variety of mutations in the X-linked gene, *BTK* (B-cell–specific or Bruton's tyrosine kinase).

From a clinical, immunologic, and “pathogenesis of disease” standpoint, it remains useful to group immunodeficiency disorders into broad categories based upon whether the defect is congenital or acquired and according to which system (or systems) of host defense is defective. These host defense systems have traditionally included the complement system, the phagocytes, the humoral immune system (immunoglobulins), the cellular immune system, and combined systems. The latter grouping reflects disorders that result from defects in more than one system (e.g., severe combined immunodeficiency). It must be emphasized that even in the case of nosologically distinctive entities there are features that extend beyond a single “simple” system. For example, optimal antibody production by B lymphocytes (humoral immunity) requires intact T helper lymphocytes. Likewise, efficient phagocytosis of some microorganisms requires opsonization of the foreign particles with C3b and/or iC3b (complement system) and immunoglobulin (humoral immune system). In many diseases, seemingly unrelated immune defects are observed in the same patient. It was stated in the first edition of this textbook that “causative defects have been identified in only a few immunodeficiency disorders.” In the short time since publication of the first edition of *Clinical Laboratory Medicine*, this statement has become outdated. Literally dozens of primary immunodeficiency diseases now have been defined at the genetic level. For each disease, many questions remain. These entail such issues as: why are there variations in disease expression? How are genetic defects translated into functional defects? How can knowledge of genetic defects be exploited diagnostically and therapeutically?

Primary immunodeficiency diseases frequently present as failure to thrive, chronic or recurrent infections, unusual infections (e.g., uncommon microorganisms or atypical manifestations), and allergic disorders. Immunodeficiency patients may exhibit nonspecific manifestations such as skin rashes or eczema, chronic diarrhea, evidence of exaggerated autoimmunity, lymphadenopathy, hepatosplenomegaly, and growth failure. Some primary immunodeficiency disorders are associated with features that appear to be unrelated to the host defense system. For example, patients with the Chedick-Higashi syndrome typically express partial oculocutaneous albinism, patients with the DiGeorge syndrome may exhibit structural defects related to the development of the third and fourth branchial pouches (e.g., structural abnormalities of the great vessels and absent parathyroid glands), and patients with ataxia-telangiectasia exhibit characteristic neurological and cutaneous anomalies. In general, the frequency and severity of infections observed in a patient with an immunodeficiency disease parallel the magnitude of the immunologic defect. For example, in the absence of definitive therapy, patients with severe combined immunodeficiency (SCID) typically survive less than 1 year and suffer from frequent, often overwhelming bacterial, viral, and fungal infections. In contrast, patients who harbor IgA and/or isolated IgG subclass deficiencies may be asymptomatic, suffer from only a slightly increased frequency of upper respiratory infections, or may suffer from moderately severe lower-respiratory-tract infections that lead to complications such as bronchiectasis. The types of infection that occur may provide insight into the type of immunodeficiency. Recurrent pyogenic infections such as bacterial pneumonia and otitis media are typical of hypogammaglobulinemic patients while those with cellular immune defects commonly suffer from viral, fungal, mycobacterial, and protozoal infections. Patients who harbor deficiencies of the distal complement system (C5-C8) may suffer from recurrent neisserial sepsis.

Many primary immunodeficiency disorders can be classified based on clinical findings and the results of widely available laboratory

tests. Specialized evaluations of the immune system are often labor intensive and expensive. Clinical presentation, a detailed family history, and course of illness, provide important diagnostic clues and must be carefully considered in order to carry out an efficient laboratory evaluation. Leukopenias are relatively common given to prevalence of immunosuppressed oncology and transplantation patients. In most cases of iatrogenic immunodeficiency the cause is readily apparent. Disorders that are not primary to the “classic” immune system, per se, also may be accompanied by increased susceptibility to infections. For example, patients with cystic fibrosis often suffer from persistent, recalcitrant lower-respiratory infections secondary to *Pseudomonas* and *Staphylococcus aureus*. Among cystic fibrosis patients mucous secretions may be poorly cleared because of their high viscosity. Sickle cell anemia often leads to splenic microinfarctions and autosplenectomy, which in turn is associated with an increased risk of bacterial sepsis. There are a variety of dysfunctional cilia syndromes in which impaired ciliary clearance of respiratory secretions results in an increase in susceptibility to bronchopulmonary infections. Finally, the importance of the acquired immunodeficiency syndrome (AIDS) cannot be overemphasized. While these disorders will not be discussed further here, they serve to emphasize that a thorough general medical evaluation is required to arrive at a correct diagnosis in a patient in whom an immunodeficiency disorder is a consideration.

This chapter will provide a necessarily brief overview of the most common and/or prototypic primary immunodeficiency diseases. Brief discussions of laboratory studies that have relevance to the diagnosis and management of immunodeficiency disorders will be incorporated into each corresponding section. Excellent, comprehensive texts that review the clinical, epidemiologic, genetic, and diagnostic features of primary immunodeficiency diseases are available.

DISEASE STATES

Part of "65 - Primary Immunodeficiency Diseases"

Disorders of the Complement System

Since the initial characterization of a patient with a genetically determined complement deficiency in 1960, defects and/or deficiencies of nearly all of the complement components and their soluble and cell surface-linked regulatory proteins have been described (Table 65.1). Despite the existence of approximately 24 such proteins, primary complement component deficiencies account for fewer than 1% of all patients with recognized immunodeficiency disorders. Most of the inherited disorders of complement result in either recurrent infections, systemic lupus erythematosus (SLE), lupuslike disorders, other autoimmune disorders, or glomerulonephritis. Characteristically atypical clinical features may provide clues that suggest an inherited disorder of the complement system. The biology of the complement system is detailed elsewhere, but a number of less familiar or only recently recognized biological consequences of complement activation provide insight into how complement system defects lead to disease.

TABLE 65.1. COMPLEMENT COMPONENT DEFICIENCIES[a]

Complement	Gene(s)	Inheritance[b]
C1q	*C1QA, C1QB, C1QG*	AR
C1r/C1s	*C1R/C1S*	AR
C4	*C4A/C4B*	AR
C2	*C2*	AR
C3	*C3*	AR
C5	*C5*	AR
C6	*C6*	AR
C7	*C7*	AR
C8α/β	*C8A/C8B*	AR
C8γ	*C8G*	AR
C9	*C9*	AR
Factor I	*IF*	AR
Factor B	*BF*	AR
Factor D	*?*	?
Factor H	*HF1*	AR
Properdin	*PFC*	X-linked R
Mannose binding lectin	*MBL*	AR and AD
C1 esterase inhibitor	*C1NH*	AD
C4 binding protein	*C4BPA, C4BPB*	?
Decay accelerating factor (CD55)	*DAF*	AR
CD59 (Homologous restriction factor 20; membrane inhibitor of reactive lysis)	*CD59*	AR

[a] Table adapted from Ross SC, Denson P. Complement deficiency states and infection: epidemiology pathogenesis and consequences of neisserial and other infections in an immune deficiency. *Medicine* 1984; 63: 243–273 and Sullivan KE, Winklestein JA. In: HD Ochs, CI Edvard Smith, JM Tuck, eds. *Primary Immunodeficiency Diseases*, 1st ed. New York and Oxford: Oxford University Press, 1999: 397–416.

Activation of the classical complement pathway usually is triggered by fixation of C1q,r,s by stoichiometrically sufficient densities of surface-bound IgM or IgG (subclasses 1, 2, 3). While C1q binding to appropriately spaced Fc domains of either IgM or IgG results in sequential activation of C1r and C1s and C4 cleavage, C4 also can be cleaved via the lectin activation pathway in which mannose binding lectin (MBL) is bound to microbial oligosaccharide moieties. In addition to its well-recognized role as an opsonin (along with iC3b), C3b appears to play an important role in immune complex solubilization and clearance. Primate red blood cells express CR1 receptors that bind to circulating immune complexes that are coated with covalently bound C3b. CR1-bearing red cells function as a “buffering system” to clear C3b-opsonized immune complexes. The immune complex-coated red blood cells pass through the liver and spleen where mononuclear phagocytes remove the complexes from red cells, which then return to the circulation. Finally, there is accumulating evidence that peptide fragments of early complement components (e.g., C3b, C3d), via CR1 and CR2 (CD21) on B lymphocytes (and perhaps often cell types), amplify the humoral immune response and facilitate follicular dendritic cell antigen trapping. In addition to causing clinically important, albeit rare, predispositions to infections and autoimmune disease, characterization of the various defects in the complement system has led to a more detailed understanding of the biology of complement.

Complement Cascade Protein Defects

The clinical consequences of genetically determined deficiencies of individual complement components are varied. The most common

manifestations include increased susceptibility to infection and rheumatologic or autoimmune disorders. Some clinical associations are distinctive [e.g., neisserial infections among patients with late complement component (C5, C6, C7, or C8) deficiencies] or unusual (angioedema in patients with C1 esterase inhibitor deficiency). Affected individuals are frequently asymptomatic. With the debated exception that heterozygous carriers of C2, C3, or C4 deficiency may suffer from an increase in prevalence of autoimmune disorders (e.g., SLE), only patients with homozygous complement component deficiencies suffer from overt clinical illness.

C1q consists of six sets of three polypeptides, C1qA, C1qB, and C1qC. These polypeptides are encoded by three corresponding highly homologous genes (*C1QA*, *C1QB*, *C1QG*) located on chromosome 1. A variety of nonsense and missense mutations in each of the three genes has been described. Some patients produce no detectable C1q while others produce dysfunctional C1q. It appears that C1qA is required for assembly of intact C1q. C1q-deficient patients from a variety of ethnic backgrounds have been described. As would be predicted, these patients exhibit very low CH_{50} values (<5% of normal) and C1 functional activity is typically <1% of normal. Almost all C1q-deficient patients have SLE and many suffer from recurrent pyogenic infections.

C1r and C1s are homologous serine esterases. C1r and/or C1s deficiency are exceedingly rare and detailed knowledge of the specific mutations is lacking. These patients also exhibit low CH_{50} values and suffer from either SLE, glomerulonephritis, and/or bacterial infections.

C4 is synthesized as a single polypeptide which is then cleaved to form the 3-chain disulfide-linked mature C4. C4 exists as two isotypes, C4A and C4B, which differ with respect to their efficiency in transacylation reactions. Complete C4 deficiency, marked by a CH_{50} of <1% of normal, is very rare. A variety of isoform and heterozygous C4 deficiencies have been described. These patients are relatively common and typically suffer from SLE, glomerulonephritis, and/or recurrent infections. C4-deficient SLE patients, like C2-deficient SLE patients, may have prominent cutaneous features and are more frequently ANA and anti-dsDNA negative than their complement-sufficient counterparts.

C2 is closely linked to factor B. C2 deficiency is the most common complete complement component deficiency. More than 90% of completely C2-deficient individuals are homozygous for a 28-base pair deletion, which leads to a splicing abnormality and transcription defect. These patients exhibit very low CH_{50} values and nearly half develop SLE, cutaneous lupus, and/or recurrent infections.

C3 is encoded by a gene on chromosome 19 and is synthesized as a single polypeptide precursor that is processed into two disulfide-linked chains. An array of mutations that lead to C3 deficiency have been described. C3 deficiency, either through a primary genetic defect or through absence of the regulatory protein, factor I (C3b inactivator), leads to reduced serum opsonizing capacity and an increased incidence of severe infections attributable to encapsulated pyogenic bacteria, such as *S. pneumoniae*, *Haemophilus influenzae*, and nonpneumococcal streptococci, as well as others, including Gram-negative enterobacteriaceae and *S. aureus*. Patients with C3 deficiency also suffer from an increased incidence of SLE, glomerulonephritis, and vasculitis. Complete absence of C3 is inherited in an autosomal-recessive pattern while clinically normal heterozygotes possess serum C3 concentrations that approximate one half of normal levels. Because C3b is important in both the propagation of the complement activation sequence and as an opsonin, it is difficult to know how these functional defects affect the risk of pyogenic infections. Because C3-deficient patients tend to suffer from a spectrum of infections similar to that seen in a splenectomized person, C3b may be particularly important as an opsonin in the clearance of bacteria from the circulation. Patients with C3 deficiency exhibit decreased CH_{50} and C3 values.

Deficiencies of components in the lytic pathway result in impaired bacteriolysis without impairment of opsonization. Patients with C5, C6, C7, or C8 deficiencies suffer from frequent disseminated neisserial infections (*Neisseria meningitides* and *Neisseria gonorrhoeae*), but interestingly, the clinical illness in such patients is less severe and epidemiologically distinct from that observed in disseminated neisserial infections seen in complement-sufficient individuals. C5-deficient patients exhibit decreased total hemolytic complement activity. There is a diversity of C5 gene mutations that lead to the clinical disorder. The C6, C7, and C9 genes (see below) are linked on chromosome 5. Again, a variety of clinically significant mutations have been identified. C6 deficiency has been subclassified into 3 forms: the most common marked by undetectable C6 and at least two other forms of so-called subtotal C6 deficiency (C6SD). One form of C6SD is characterized by a truncated, but partially functional, C6 molecule. These individuals do not suffer from recurrent infections. Several types of C7 deficiency have been characterized. C8 is composed of three polypeptide chains (α, ß, and γ), which are encoded by three genes, *C8A*, *C8B*, and *C8G*. C8-deficient patients are rare. Defects that lead to deficiencies of the C8 α-γ chain and C8ß chain have been described. It appears that C8ß deficiency occurs primarily in whites while C8 α-γ deficiency is more common in blacks. Patients with deficiencies in the distal complement system exhibit markedly reduced CH_{50} valves.

A few C9-deficient patients have been described, primarily in Japan. C9-deficient serum contains partially reduced hemolytic complement activity. Epidemiologic studies have revealed an increase in incidence of systemic meningococcal infections but this complication is less common in C9-deficient individuals than in individuals deficient of either C5, C6, C7, or C8.

Complement Regulatory Protein Defects

C1 esterase inhibitor (C1-INH) is an autosomal codominantly expressed member of the serine proteinase inhibitor (SERPIN) family. Patients with C1-INH deficiency (because of either a silent C1-INH allele or an allele encoding a dysfunctional molecule) possess less than 50% of normal levels of functional protein. While some patients manifest SLE or lupuslike syndromes, virtually all C1-INH deficient patients manifest hereditary angioedema (HAE). Hereditary angioedema is an autosomal-dominant disorder characterized by episodic, localized, acute attacks of painless edema typically involving the extremities, face, or upper respiratory tract. Some patients manifest with abdominal pain from localized involvement of gastrointestinal mucosa. It is often unclear what triggers an angioedema attack. Type I HAE (85% of cases) is characterized by low plasma levels of antigenic

and functional C1-INH, normal or depressed C1 levels, depressed C4 levels, and normal C3 levels. Because intact C1-INH is catabolized more rapidly than normal, levels of intact C1-INH are often only 5% to 30% of reference concentrations. Type II HAE is less common. Type II HAE is associated with normal or elevated levels of dysfunctional mutant protein together with low levels of normal C1-INH. These patients typically have normal to elevated antigenic C1-INH levels and reduced functional levels.

There are several acquired forms of C1-INH deficiency. These disorders usually are associated with increased C1-INH consumption related to B-cell lymphoproliferative disorders or autoimmune disorders accompanied by autoantibodies directed against C1-INH. Acquired C1-INH deficiency patients typically exhibit depressed C1 and C4 levels, normal or increased antigenic C1-INH, and decreased functional C1-INH levels. Patients with acquired C1-INH deficiency almost always exhibit profoundly depressed C1q levels, while patients with HAE (type I or type II) may have depressed C1q levels, but often do not. Attenuated androgens reduce the frequency and severity of “edema attacks” in the hereditary forms and acquired forms of angioedema, but higher doses are typically required in the latter group.

Defects in nearly all of the other complement regulatory patients have been described but are exceedingly rare (Table 65.1). Special comment is in order regarding genetic deficiencies of decay accelerating factor (DAF) and CD59 and low serum concentrations of mannose binding lectin (MBL).

Genetic defects in DAF and *CD59* are isolated and result in clinical features that are distinct from the more generalized GPI linkage defect seen in paroxysmal nocturnal hemoglobinuria, an acquired clonal disorder. Decay accelerating factor is GPI-linked and plays a role in disassembly of the classical and alternative pathway C3 convertases. Isolated genetic DAF deficiency is associated with the Inab phenotype (absence of the Cromer complex of blood group antigens). DAF deficiency is not associated with clinical hemolysis even though red cells are somewhat more sensitive to *in vitro* complement-mediated lysis. A few DAF-deficient patients have had protein-losing enteropathy but it is unknown what relationship this has with the genetic lesion. CD59 is a GPI-linked protein that inhibits C8 and C9-mediated cell lysis. The only described isolated (primary genetic) CD59-deficient patient identified to date had hemolytic anemia and recurrent CNS infarctions.

Mannose-binding lectin functions somewhat like C1q but can activate the classical and alternative complement pathways. Serum levels are influenced by several polymorphic amino acids. MBL deficiency is believed to increase the risk of both recurrent infections and SLE.

Phagocytic Function Disorders

The importance of phagocyte function in host defense is perhaps best exemplified by the frequent occurrence of severe life-threatening infections in patients rendered granulocytopenic by chemotherapy. Severely granulocytopenic patients (e.g., absolute neutrophil count less than 0.5×10^9/L) frequently suffer from episodes of bacterial sepsis. In many cases, organisms of low intrinsic pathogenicity are responsible. Understanding the mechanisms involved in the individual steps that characterize neutrophil function in the acute inflammatory response (adhesion, chemotaxis, phagocytosis, respiratory burst, and degranulation) is helpful when classifying phagocytic cell defects. With the development of more facile clinical techniques (e.g., flow cytometry and molecular biology), it has become easier to routinely identify specific phagocytic cell defects.

Chronic Granulomatous Disease (and Related Disorders)

Chronic granulomatous disease (CGD) encompasses a genetically heterogenous group of lesions that result in a complete or near-complete absence of the respiratory burst that normally occurs upon phagocyte activation. Activation of the cytoplasmic membrane-associated NADPH oxidase in phagocytes results in the generation of O_2^- (superoxide anion), which in turn gives rise to a variety of reactive oxygen intermediates. Because of the importance of oxidants in phagocyte-mediated microbial killing, individuals who cannot generate NADPH oxidase-derived O_2^- are susceptible to recurrent bacterial and fungal infections.

The clinical, genetic, and molecular heterogeneity of CGD is well understood in terms of NADPH oxidase (Table 65.2). The NADPH oxidase complex consists of four subunits: $gp91^{phox}$, $p22^{phox}$, $p47^{phox}$, and $p67^{phox}$, and a number of associated regulatory proteins ($p40^{phox}$, rap1A, rac1, rac2). Mutations within each of the genes that encode the four major subunits have been described. Mutations in *CYBB* on chromosome Xp21.1 gives rise to the X-linked form of CGD (approximately 65% of all cases). Mutations in the genes which encode $p22^{phox}$ (*CYBA*), $p47^{phox}$ (NCF1), and $p67^{phox}$ (*NCF2*) are located on different autosomes and account for the remaining 35% of CGD cases. $Gp91^{phox}$ and $p22^{phox}$ are membrane-associated in resting phagocytes and contain a cytochrome (b_{-245} or b_{558}) while $p47^{phox}$ and $p67^{phox}$ are located in the cytosol of quiescent cells. Phagocyte activation results in the translocation of the cytosolic component to the membrane component. Patients are classified according to the component of the NADPH oxidase which is affected: $gp91^{phox}$, $p22^{phox}$, $p47^{phox}$, and $p67^{phox}$. Other than a small number of patients in whom mutations in the promotor region of CYBB has been identified, nearly all CGD mutations involve one of the genes which encode these four subunits.

TABLE 65.2. CHRONIC GRANULOMATOUS DISEASE

NADPH Component	Gene Locus/Gene	Inheritance	% of Cases
$Gp91^{phox}$	Xp21.1/*CYBB*	X	65%
$P22^{phox}$	16p24/*CYBA*	AR	6%
$P47^{phox}$	7q11.23/*NFC1*	AR	23%
$P67^{phox}$	1q25/*NFC2*	AR	6%

AR, autosomal recessive; X, X-linked

CGD patients suffer from a variety of recurrent bacterial and fungal infections. These include pneumonia, lymphadenitis, skin infections, hepatic and perirectal abscesses, osteomyelitis, otitis media, conjunctivitis, gastrointestinal infections, and septicemia. CGD patients also may exhibit failure to thrive, anemia of chronic disease, chronic diarrhea, and hepatosplenomegaly. The bacteria and fungi that infect CGD patients have in common

the ability to produce catalase. It is believed that microbial catalase degrades H_2O_2 produced by the infecting microorganisms thus allowing for the elimination of nearly all oxidant accumulation within phagolysosomes. Common microbial isolates include *S. aureus*, Gram-negative enterics, *Aspergillus* sp., *Candida albicans*, *Burkholderia cepacia* (formerly *Pseudomonas*), *Serratia marcescens*, *Streptococcus* sp., and *Nocardia* sp.

Diagnosis requires recognition of both typical and atypical clinical features and demonstration of a defective phagocyte respiratory burst. Several assays that detect the ability of neutrophils to produce O_2- via NADPH oxidase have been developed. CGD subgroup classification is carried out commonly by analysis of immunoblot assays (all four NADPH oxidase subunits can be identified), cell-free NADPH oxidase functional assays, and by molecular assays (PCR, RFLP, and DNA sequencing).

Several hundred of polymorphic variants of glucose-6-phosphate dehydrogenase (G6PD) have been described. G6PD deficiency is the most common cause of hemolytic anemia caused by a red blood cell enzyme deficiency. Hemolytic episodes often are triggered by exposure to a drug that produces oxidative stress (e.g., antimalarials, sulfa drugs, etc.), ingestion of fava beans, or an infection. Severe G6PD deficiency in which patients present with a CGD-like syndrome have been described. G6PD, part of the hexose monophosphate shunt, is an X-linked heterodimer that catalyzes the generation of NADPH from glucose-6-phosphate and NADP+. The G6PD expressed in leukocytes is encoded by the same gene as the enzyme expressed in red cells, but is normally expressed at high enough concentrations that leukocyte dysfunction does not occur. Patients who suffer from recurrent infections possess very low concentrations of leukocyte NADPH and exhibit leukocyte enzyme activity levels that are usually less than 5% of normal. Male patients have been reported more often than females.

As in patients with “typical” CGD, patients with severe leukocyte G6PD deficiency suffer from recurrent coagulase-positive *S. aureus* infections, infections with *Escherichia coli*, and infections with *Serratia marcescens*. Sites of infection commonly include the lungs, skin, mucous membranes, and lymph nodes. These patients also suffer from hemolytic anemia attributable to red cell G6PD deficiency. As in the case of CGD, leukocytes from profoundly G6PD-deficient patients fail to generate O_2- or its metabolites.

Leukocyte Adhesion Deficiency

During the mid-1980s, several groups of investigators identified a small number of patients who suffered from recurrent bacterial infections and in whom neutrophils exhibited reduced spreading on surfaces, impaired aggregation, impaired iC3b-mediated cell function, and reduced antibody-dependent cellular cytotoxicity. This disorder, which can manifest as the so-called “moderate” and “severe” phenotypes initially, was named leukocyte adhesion deficiency. Following the later elucidation of another type of LAD (see below), the original disorder was renamed LAD1. It was soon recognized that leukocytes from LAD patients lack or are partially deficient of three surface molecules that are now known to be members of the ß2 or leukocyte integrin family. The integrins represent a superfamily of adhesion molecules each consisting of noncovalently associated α and ß chains. The leukocyte integrins possess distinct α chains and a common ß chain. This family includes CD11a/CD18, also known as lymphocyte function-associated antigen (LFA-1), CD11b/CD18 (Mac-1), and CD11c/CD18 (p150,95). CD11b/CD18 now is known to be complement receptor 3 (CR3). CD11b/CD18 and CD11c/CD18 are expressed on the lining surfaces of specific and tertiary neutrophil granules and are thus detected as an increase in cell surface density when these lysosomes fuse with the cytoplasmic membrane following cell activation. In contrast, CD11a/CD18 is expressed only on the surface of neutrophils and is therefore not “up-regulated” upon degranulation. CD11a/CD18 (LFA-1) is found in highest density on the surfaces of T, B, and NK cells, while CD11b/CD18 (Mac-1) is found in highest density on neutrophils, eosinophils, monocytes, macrophages, and NK cells. Patients with LAD1 possess mutations in the ß chain gene resulting in variable decreases in surface $ß_2$ integrin expression. Several different ß chain mutations have been described. LAD1 is inherited in an autosomal-recessive manner. The clinical result is a heterogeneous group of patients who exhibit different degrees of adhesion defect and variable severity of problems.

Patients with LAD typically suffer from recurrent bacterial infections without much pus, and with periodontitis, delayed wound healing, elevated circulating leukocyte counts, and a history of delayed shedding of the umbilical cord stump. Peripheral blood neutrophil counts typically range between 15×10^9/L and 60×10^9/L between infections and can reach 100×10^9/L or more during infections. Soft-tissue infections are particularly common and are often quite severe. *S. aureus*, *Pseudomonas* sp., and members of the enterobacteriaceae are the most common isolates. Diagnosis is made based on clinical data, demonstration of impaired adhesiveness and aggregation, and flow cytometric analysis.

LAD2 (Rambon-Hasharon syndrome) is an exceedingly rare cellular adhesion defect that results from abnormal fucosylation reactions.

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is an autosomal-recessive disorder characterized by the presence of giant cytoplasmic granules in neutrophils, monocytes, and lymphocytes, as well as in some nonhematologic cell types. The genetic defect has not been completely characterized but appears to result from mutations in the recently discovered *CHS1*gene. *CHS1* encodes a protein that may be involved in organellar protein trafficking. The basic defect in this disorder is unknown, but involves multiple organ systems as evidenced by the occurrence of oculocutaneous albinism, defective platelets, and in some patients either sensory or motor neuropathies. Patients with Chédiak-Higashi syndrome typically have very light skin, photophobia, and characteristic silver-colored hair. The defects in pigmentation are the result of abnormal melanosome aggregation. Giant neutrophil granules can be seen in myeloid precursor cells. Because many myeloid series cells die before completion of maturation, Chédiak-Higashi patients typically are leukopenic ($2–3 \times 10^9$WBC/L). Because of the neutropenia and a host of neutrophil, monocyte, and lymphocyte functional defects, patients suffer from recurrent bacterial and fungal infections. The most common infections are of the skin, mucous membranes, and respiratory tract. The platelet defect is associated with decreased storage pools of ADP and serotonin, resulting in prolonged

bleeding times. Patients with Chédiak-Higashi syndrome can enter a so-called “accelerated phase” which is marked by local lymphocytic proliferations within the liver, spleen and bone marrow as well as a progressive pancytopenia. The pancytopenia of accelerated Chédiak-Higashi syndrome is accompanied by hemorrhage and infection. Among a variety of defects described in leukocytes from Chédiak-Higashi patients are abnormally fluid cell membranes, high resting rates of cellular respiration, impaired adherence to surfaces, and reduced chemotactic responsiveness. It is thought that altered membrane fusion relates to the formation of giant cytoplasmic granules, which in the case of neutrophils, contain reduced quantities of dilute lytic enzymes.

Other Phagocyte Function Disorders

The molecular basis of specific granule deficiency appears to be the result of a regulatory defect in hematopoietic gene expression. Neutrophils are either completely or nearly completely devoid of specific granules and their contents. Specific granules contain a variety of host defense proteins. These include lysozyme, lactoferrin, and Mac-1. Deficiency of Mac-1 results in defective adhesion to endothelium. In addition to its role in leukocyte-endothelial adhesion, Mac-1 also functions as the iC3b complement receptor. Neutrophils deficient of specific granules exhibit defective chemotaxis, adhesion, and microbicidal activities. Patients with specific granule deficiency suffer from recurrent and severe bacterial (*S. aureus*, *Pseudomonas aeruginosa*, Gram-negative enterics) and fungal (*Candida* sp.) infections of the mucous membranes, skin, and lower respiratory tract. The diagnosis, suggested by the history, patient examination, and abnormal neutrophil morphology, is confirmed by data from leukocyte functional assays (e.g., specific granule release assay) and flow cytometry [reduced or absent CD11b/CD18 (Mac-1) expression].

Myeloperoxidase (MPO) deficiency is a relatively common disorder (1 in 2,500 to 4,000 people) in which granulocytes produce O_2- and H_2O_2 but cannot generate normal levels of MPO-dependent hypohalite (HOC1) or HOC1-derived chloramines. Patients with complete MPO deficiency, with partial MPO deficiency, and with acquired MPO deficiency have been described. A variety of mutations that result in defective posttranslational processing of MPO have been described. Acquired partial MPO deficiency occurs in patients with acute myelogenous leukemia (M2, M3, and M4), in patients with chronic myelogenous leukemia, and in patients with myelodysplastic syndromes. *In vitro* leukocyte function assays reveal that affected cells exhibit delayed neutrophil-mediated microbial killing. Clinically affected patients, usually diabetics, suffer primarily from recurrent candidal infections. This disorder appears to involve other undefined factors because most MPO-deficient individuals are asymptomatic. Flow cytometric analysis may reveal an augmented respiratory burst, but diagnosis usually is made by cytochemical staining procedures.

Finally, several other exceedingly rare phagocyte function defects have been described. These include cyclic neutropenia, congenital neutropenias that include the Kostmann and Shwachman syndromes, and several less well-characterized defects.

Disorders of “Humoral” Immunity (B-Lymphocyte Defects)

As mentioned above, the first well-documented description of an immunodeficiency disorder was made in reference to a boy with agammaglobulinemia. Disorders of the “humoral” immune system are relatively common, considering that this group of disorders includes patients with common variable immunodeficiency (CVID) and selective IgA deficiency. This classification scheme is imperfect when one considers that there are pivotal interactions between antibody-producing cells (B lymphocytes and plasma cells) and T lymphocytes, as well as between the effector molecules of the humoral system (antibodies) and phagocytes (e.g., antibody-dependent cellular cytotoxicity) or complement components (e.g., C1q binding to IgG or IgM molecules). It should be emphasized that most deficiencies of γ-globulins are not primary and that they occur in the context of many disease states (e.g., protein-losing enteropathy, nephrotic syndrome, multiple myeloma, light chain disease, and secondary to immunosuppressive therapy). While the basic defect remains unknown in some humoral immunodeficiency disorders, specific genetic defects have been defined in an increasing proportion of these entities (Table 65.3). While many patients with immunoglobulin deficiencies are recognized because they suffer

from recurrent infections, individuals with some disorders experience infections no more frequently than normal (e.g., some patients with selective IgA deficiency).

Agammaglobulinemia

Bruton's or X-linked agammaglobulinemia is the first human primary immunodeficiency disease in which the genetic defect was definitively identified. In 1993 it was determined that mutations in a cytoplasmic tyrosine kinase, *Bruton's tyrosine kinase (BTK)*, lead to this clinical entity. *BTK* mutations result in a maturation arrest in B lymphocyte development. It should be noted that different *BTK* mutations give rise to disease phenotypes of varying clinical severity. A few male patients with agammaglobulinemia plus growth hormone deficiency have been described. Some of these patients have had normal *BTK* while others have possessed *BTK* mutations. Finally, a few females with the XLA phenotype have been described, but no *BTK* mutations have been defined in these patients.

Males with X-linked agammaglobulinemia are usually well until 6 to 9 months of age, the time by which maternal antibodies acquired *in utero* have been largely catabolized. Patients typically suffer from recurrent respiratory tract, joint, CNS, and systemic infections with high-grade encapsulated pyogenic bacteria. The spectrum of infections is broad, including pneumonia, sinusitis, otitis, meningitis, and sepsis. The most common bacterial isolates include *S. pneumoniae*, *H. influenzae*, and *Streptococcus* sp. Patients are particularly susceptible to viral hepatitis, and a number of patients have developed paralysis after exposure to live attenuated polio vaccine. A significant number of XLA patients also have died as the result of chronic echovirus infections of the central nervous system. This disorder typically is accompanied by a dermatomyositislike syndrome. A small percentage of patients with XLA develop neutropenia, which may be transient, cyclic, or persistent. *Pneumocystis carinii* pneumonia has been reported in neutropenic agammaglobulinemic patients. In contrast to patients with defective cellular immunity, growth retardation is uncommon as are fungal or other opportunistic infections.

Patients with XLA typically possess very low serum concentrations of γ-globulin (less than 100 mg/dL) and very low to undetectable concentrations of immunoglobulin in secretions. Analysis of peripheral blood typically reveals normal concentrations of total lymphocytes but very low numbers of B lymphocytes. While pre-B lymphoid series cells can be identified in the bone marrow of these patients, biopsies of lymphoid tissues reveal hypoplasia, the absence of germinal centers, and markedly diminished numbers of plasma cells. Patients with XLA are supported by assiduous attention to signs of infection, antibiotics, and immunoglobulin replacement therapy. The major long-term problem in patients who avoid complications like chronic viral CNS infections is the development of chronic and recurrent respiratory tract infections, which can lead to the development of bronchiectasis and pulmonary insufficiency.

Common Variable Immunodeficiency

Common variable immunodeficiency (CVID) is a heterogeneous group of diseases characterized by a deficiency of γ-globulins. Nearly all patients exhibit marked reductions in serum IgG and IgA levels and approximately 50% of patients also exhibit a marked reduction in IgM. This group of disorders manifests in a manner that is somewhat similar clinically to X-linked agammaglobulinemia except that it occurs with equal frequency in both males and females and it can present at different ages. While many patients present in infancy or early childhood, most common variable immunodeficiency patients present during later childhood or adulthood. In general the γ-globulin deficiency is less severe than that seen in X-linked agammaglobulinemia, typically on the order of 200 to 300 mg/dL of total immunoglobulins. In addition to pyogenic infections, CVID has been associated with a variety of autoimmune and neoplastic disorders. Patients with CVID suffer from a markedly increased incidence of giardiasis and bronchiectasis. In addition to autoimmune and infectious complications, these patients suffer from an increased incidence of gastric carcinoma, lymphomas, and amyloidosis.

The defects responsible for common variability immunodeficiency appear to be heterogeneous. Patients with CVID typically have normal numbers of circulating B cells but they don't differentiate normally *in vivo* or become immunoglobulin-producing plasma cells *in vitro*. Indeed, there are defects in terminal B lymphocyte maturation, a process that is now better understood in the context of interleukins. Interestingly, first-degree relatives of CVID patients have an increased incidence of selective IgA deficiency, and vice versa, suggesting the possibility that these disorders have a related pathogenetic origin. In fact, some patients with selective IgA deficiency eventually develop CVID.

Patients with common variable immunodeficiency are treated with antibiotics and immunoglobulin replacement therapy.

IgA Deficiency

Selective IgA deficiency is marked by the presence of very low serum concentrations of IgA accompanied by diminished IgA concentrations in mucosal secretions. Selective IgA deficiency is the most common primary immunodeficiency, with a prevalence of between 1:350 and 1:3000. IgA deficiency generally is associated with an increased incidence and severity of respiratory, genitourinary, and gastrointestinal tract infections as well as an increased likelihood of autoimmune and lupuslike syndromes. Patients with this immunodeficiency may also develop a spruelike malabsorption syndrome, which often responds favorably to a gluten-free diet. Interestingly, not all IgA-deficient individuals manifest such problems. It appears that many, but not all, clinically ill IgA-deficient patients suffer from concomitant deficiencies of IgG subclasses, most commonly subclasses IgG2 and IgG4. The most common offending organisms are pyogenic bacteria. Some IgA-deficient patients go on to develop CVID, and some IgA deficient patients have spontaneously remitted.

The basic defect responsible for selective IgA deficiency is unknown but appears to be a regulatory defect since α1 and/or α2 heavy-chain gene deletions have been identified in only a few patients. A number of drugs also have been implicated in the induction of selective IgA deficiency. Cell surface analysis of circulating lymphocytes reveals that IgA-bearing B lymphocytes also

express IgM and IgD, an abnormal finding that suggests that such cells are maturation-arrested. Treatment of IgA-deficient patients is based on the severity of clinical illness. Antibiotics are the mainstay of therapy. Great care to avoid sensitization of IgA deficient patients with IgA-bearing blood products should be practiced because such patients can experience anaphylactic reactions following exposure to IgA-containing blood products. Unfortunately, the presence of IgE antibodies directed against IgA does not absolutely predict a predisposition to an untoward reaction following receipt of blood products. If blood products are absolutely required, IgA-poor preparations should be used. Each patient must be considered at risk and observed closely when receiving blood products.

Selective Antibody Class and Subclass Deficiencies

Many individuals harbor IgG subclass (IgG1, IgG2, IgG3, IgG4) deficiencies. The total serum IgG concentration may be normal or abnormal depending on which subclass is deficient and on the severity of the defect. For example, because nearly 70% of the total serum IgG is IgG1, a marked IgG1 subclass deficiency would be reflected in a decreased total IgG concentration. In contrast, because IgG4 accounts for only a small percentage (less than 1% to 2%) of the total IgG, a complete absence of IgG4 would not be reflected by measurements of total IgG concentration. Serum IgA and IgM leads usually are normal, although perhaps one fifth of IgA-deficient patients have a concomitant IgG subclass deficiency. Some patients mount normal antibody responses following immunization while others do not. Clinically, IgG subclass-deficient patients fall within a spectrum ranging from no symptoms to recurrent pyogenic infections, typically involving the paranasal sinuses or the lower respiratory tract. The most common isolates include *S. pneumoniae*, *H. influenzae*, and *S. aureus*. The diagnosis for IgG subclass deficiency sometimes is not made for years. The primary defects(s) are not well understood. Therapy includes appropriate antibiotics and γ-globulin replacement therapy.

Other Deficiencies of Antibody Production

Specific antibody deficiency, also known as “antibody deficiency with near-normal immunoglobulins,” is rare. These patients have defective antibody responses to certain antigens despite normal serum immunoglobulin concentrations and normal T lymphocyte function in available laboratory assays. Patients exhibit selectively subnormal antibody responses to various antigens, including pneumococcal polysaccharide vaccines, bacteriophage φX174, tetanus toxoid, and diphtheria toxoid. Most patients also are devoid of blood group antibody titers. The primary defect in selective antibody deficiency is unknown. Current therapy includes γ-globulin replacement and antibiotics.

Only a few cases of selective IgM deficiency have been reported. A variety of serious infectious, including meningococcemia, disseminated enterobacteriaceae infections, pneumococcal meningitis, staphylococcal soft-tissue infections, and respiratory tract infections have been associated with IgM deficiency. The specific defect responsible for selective IgM deficiency is unknown. Treatment includes antibiotic therapy.

Transient hypogammaglobulinemia of infancy is relatively rare and, as its name suggests, manifests with recurrent infections and hypogammaglobulinemia. In contrasts to patients with common variable immunodeficiency or X-linked agammaglobulinemia, infants with this disorder possess isohemagglutinins and can respond to administered antigens such as diphtheria and tetanus toxoid. Such specific antibody responses usually can be detected before serum immunoglobulin concentrations reach normal levels. Because of the transient nature of this disorder and the potential for suppression of endogenous antibody production, replacement γ-globulin is not recommended.

Combined Humoral and Cellular Immune Dysfunction

The combined humoral and cellular immunodeficiency disorders include syndromes that vary greatly in severity and in the spectrum of defects that give rise to individual diseases (Table 65.4). For instance, patients with adenosine deaminase (ADA) deficiency suffer from a profound humoral and cellular immunodeficiency as well as skeletal abnormalities while patients with X-linked hyper-IgM syndrome suffer from recurrent pyogenic bacterial infections and exhibit pronounced lymphadenopathy. As noted for humoral immunodeficiency disorders, classification of combined disorders can be problematic. Leukocyte adhesion deficiency (see earlier discussion) affects both lymphocyte and neutrophil-mediated host defense processes and could be considered either a disorder of phagocyte function or a combined cellular and humoral defect. In an increasing number of disorders, the specific defect(s) responsible for combined humoral and cellular disorders has been defined (Table 65.4). Clinically, patients with combined humoral and cellular defects may present with bacterial infections reminiscent of pure humoral deficiencies, opportunistic infections typically associated with cellular immune dysfunction, or features unique to given disorders. Examples of the latter include skeletal (costochondral) abnormalities in ADA deficiency, the characteristically extensive erythematous scaly rash in Omenn syndrome, and dwarfism in cartilage-hair hypoplasia.

TABLE 65.4. COMBINED HUMORAL AND CELLULAR IMMUNODEFICIENCIES

AR, autosomal recessive; X, X-linked

Severe Combined Immunodeficiency

While SCID vary in agenetic etiology, mode of inheritance, lymphoreticular histopathology, mechanism of cellular dysfunction, and to some extent, clinical characteristics, they have in common the near complete absence of cellular and humoral immune function. As a result, affected patients are profoundly ill and die within a short period of time, unless they can be isolated from the environment, their immune systems can be replaced by bone marrow transplantation, or in appropriate instances, specific enzyme replacement therapy can be instituted. The SCID disorders present within the first months of life and are marked by recurrent episodes of upper respiratory, lower respiratory, and cutaneous bacterial infections. Persistent opportunistic infections caused by *Candida*, measles, varicella, cytomegalovirus, and *Pneumocystis* also are prevalent. Patients with SCID suffer extreme wasting and are at risk of developing graft-versus-host (GVH) disease.

Clinical and laboratory evaluation of immune function reveal profound abnormalities. There is a virtual absence of cellular immune function manifested by lymphopenia, cutaneous anergy, and the absence of *in vitro* lymphocyte proliferative responses to antigens, mitogens, or allogeneic cells. Serum immunoglobulin concentrations usually are markedly depressed, and antibody responses to immunization are difficult to detect. A small number of autosomal recessive SCID patients in whom nearly all circulating lymphocytes appear to be natural killer (NK) cells have been reported.

As shown in Table 65.4, SCID can be subclassified into T^-B^- and T^-B^+ categories based on immunophenotypic data. While many fundamental questions remain, a great deal has been learned about the regulation of T lymphocytes and B lymphocytes antigen receptor gene recombination and expression [including V(d)J recombination]. It has become clear that defects in the recombination mechanism can lead to SCID. Defects in *RAG1* and *RAG2*, which encode "recombination activating genes 1 and 2", respectively, have been specifically linked to SCID. Patients with RAG1 and RAG2 SCID do not possess their own circulating T or B lymphocytes. Omenn syndrome is a T^-B^- severe combined immunodeficiency that, in addition to the combined system immunodeficiency is characterized by generalized erythroderma, eosinophilia, elevated serum IgE, and hepatosplenomegaly. These patients also harbor *RAG* mutations. Reticular dysgenesis (RD) is not well understood but reflects failure of bone marrow stem cell production. Patients with RD are profoundly lymphopenic and granulocytopenic.

Autosomal-recessive and X-linked recessive SCID patients present with recurrent or persistent bacterial, fungal, protozoal, and viral infections accompanied by wasting. It has become clear in recent years that X-linked SCID is caused by mutations in the gene that encodes the common γ chain of the IL-2, IL-4, IL-7, IL-9, and IL-15 receptors. Autosomal-recessive SCID patients are indistinguishable clinically and immunophenotypically from X-linked SCID patients. Autosomal-recessive T^-B^+ SCID patients harbor mutations in the gene that encodes JAK3, a tyrosine kinase that transduces the interleukin γ chain receptors noted above. Care must be taken not to subject these patients to GVH disease. GVH disease may develop following receipt of blood products contaminated with variable lymphocytes and can even occur as the result of maternal-fetal hemorrhage *in utero*. Replacement γ-globulin has not been effective in preventing the demise of SCID patients. Some patients have been immunologically reconstituted with HLA-identical or D locus-compatible bone marrow transplantation. Recent progress also has been achieved by reconstituting SCID patients with haploidentical allogeneic bone marrow purged of postthymic T lymphocytes.

Immunodeficiencies Associated with Abnormal Purine Metabolism

Adenosine deaminase (ADA) and purine nucleoside phosphorylase (PNP) are sequential enzymes in the purine salvage pathway. Dysfunction of in either of these enzymes can lead to accumulation of toxic intermediates that cause the loss of lymphocytes and can result in SCID. ADA deficiency accounts for approximately 40% of all autosomal recessive SCID cases and 20% of all SCID cases. PNP deficiency is less common. ADA-deficient SCID patients suffer from the same infections as other SCID patients but also may exhibit skeletal abnormalities. Deficiency of ADA results in the accumulation of adenosine, 2′-deoxyadenosine, and 2′-O-methyladenosine, which are toxic to lymphocytes. It appears the adenosine and deoxyadenosine inactivate the enzyme,

S-adenosylhomocysteine (SAH) hydrolase, which in turn is an inhibitor of most intracellular methylation reactions. Reduction of SAH hydrolase activity leads to excessive methylation and lymphocytotoxicity. Patients with ADA-deficient SCID typically become lymphopenic within the first year of life. ADA-deficient SCID patients have been treated successfully with bone marrow from HLA-matched siblings and allogeneic haploidentical T-lymphocyte-purged bone marrow. An approach that has also been successful in some patients is ADA enzyme replacement either through infusion of irradiated adenosine deaminase-containing red blood cells or infusion of polyethylene glycol-linked bovine ADA. Autosomal-recessive SCID with ADA deficiency also is a prime candidate for gene-replacement therapy. PNP deficiency results in a profound T lymphocyte defect and a variable B lymphocyte defect. These SCID patients also suffer frequently from neurologic abnormalities and autoimmune disorders.

Hyper-IgM Syndrome

Immunodeficiency with hyper-IgM is a heterogeneous group of disorders in which patients suffer from recurrent bacterial and opportunistic infections and exhibit low serum concentrations of IgG, IgA, and IgE. Lymph nodes from hyper-IgM patients display abnormal architecture that includes a lack of germinal centers. In most cases hyper-IgM is X-linked, but autosomal recessive, autosomal dominant, and acquired forms have been described. During the 1990s it has become clear that most hyper-IgM cases are raised by a mutation in the CD40L gene which encodes CD40 ligand, a transiently expressed T lymphocyte surface molecule that, in the presence of appropriate cytokines, induces immunoglobulin production in B lymphocytes via cell surface CD40. Defective signaling via B lymphocyte CD40 also can result in a hyper-IgM syndrome.

Patients with this disorder typically present in infancy with recurrent pyogenic infections including pneumonia, sinusitis, otitis media, and tonsillitis. In contrast to patients with X-linked agammaglobulinemia, these patients have pronounced lymphadenopathy. Serum IgA and IgG concentrations are markedly depressed, and there is typically a polyclonal increase in serum IgM. Patients with immunodeficiency with elevated IgM occasionally have concomitant neutropenia and may manifest autoimmune hemolytic anemia and/or thrombocytopenia.

Major Histocompatibility Complex Deficiencies

Only a few cases of HLA class I deficiency (type 1 bare lymphocyte syndrome) have been described. In these cases, very low levels of HLA class I molecules can be detected. (Complete HLA class I deficiency has not been described and may be presumed to be lethal.) HLA class I molecule deficiency is not associated uniformly with an increase in susceptibility to infections. Clinically affected patients have typically suffered from chronic bacterial infections of the respiratory tract and in a couple of cases, vasculitis. Several HLA class I-deficient individuals without disease have been reported. Several lesions can give rise to HLA class I molecule deficiency. Studies to date have revealed constitutive decreases in class I HLA gene expression in lymphocytes and mutations in TAP2, a gene that encodes a subunit of TAP (a transporter associated with antigen processing), a protein involved in the transportation into the endoplasmic reticulum of peptide antigen fragments that have been endogenously degraded.

Major histocompatibility complex class II (MHC II) deficiency results in a profound combined immunodeficiency fungal and protozoal infection, which primarily involves the respiratory and gastrointestinal tracts. As in the case of HLA class I deficiency, this syndrome also is referred to as the “bare lymphocyte syndrome” (BLS). One classification scheme utilizes the designations BLS type I, BLS type II, and BLS type III (for classes I and II). MHCII deficiency is an autosomal-recessive disease that is caused by mutations in at least three different transcription factors (*RFX5, RFXAP*, and *MHC2TA*), which regulate HLA class II molecule expression.

Other Combined B- And T-Cell Immunodeficiencies

Additional combined immunodeficiencies include mutations in *CD3E* and *CD3G*, genes that encode CD3ε and CD3γ, respectively. CD3ε and CD3γ are proteins that are required for T lymphocyte receptor (TCR) function. Some CD3-deficient individuals have been healthy while others have suffered from recurrent lower respiratory tract infections, intractable diarrhea, and failure to thrive.

IL-2 receptor α-chain deficiency and ZAP-70 deficiency, the latter the result of a mutation in the T cell receptor zeta-chain associated protein kinase gene (*ZAP70*), are exceedingly rare immunodeficiency syndromes.

Miscellaneous Well-Defined Immunodeficiency Disorders

Wiscott-Aldrich Syndrome (and X-Linked Thrombocytopenia)

Wiskott-Aldrich syndrome (WAS), also known as immunodeficiency with thrombocytopenia and eczema, is an X-linked disorder marked by cellular and humoral immunodeficiency, thrombocytopenia, eczema, and an increased risk of hematopoietic malignancies. Mutations responsible for both WAS and X-linked thrombocytopenia (XLT) (see below) have been mapped to Xp11.22. The *WAS* gene encodes the WAS protein (WASP), which is expressed in all hematopoietic stem-cell–derived lines. It is believed to be important in signal transduction and the regulation of cytoskeletal function. Boys with WAS sometimes present with a thrombocytopenic bleeding diathesis heralded by prolonged bleeding following circumcision. Skin lesions and recurrent infections typically occur during the first year. Early in the course of the disease patients exhibit impaired humoral responses to encapsulated high-grade bacterial pathogens resulting in otitis media, pneumonia, meningitis, and sepsis. Later, patients suffer from herpes infections and *Pneumocystis* infections. WAS carries a grave prognosis and most patients die during childhood. There is an increased incidence of lymphoreticular malignancy.

Thrombocytopenia is accompanied by normal numbers of

megakaryocytes in the bone marrow. Immunologic abnormalities reflect the clinical course of the disorder. Patients typically have borderline or low immunoglobulin levels with depressed serum IgM levels, low or low-normal IgG levels, and elevated serum IgA and IgE levels. Defective humoral immune responses to carbohydrate antigens and depressed isohemagglutinin levels are apparent early. Later, poor humoral responses to protein antigens become apparent. Cutaneous anergy and decreased concentrations of peripheral blood T lymphocytes are also present.

Treatment, including platelet transfusions, splenectomy, and γ-globulin therapy, generally has been supportive. Some recent successes have been achieved with stem cell transplantation.

Hereditary XLT, a less severe phenotypic variant of WAS, is characterized by thrombocytopenia, mild or no eczema, and moderate or no immunologic abnormalities. It appears that XLT is caused by different mutations in the WAS gene.

DiGeorge Syndrome

The DiGeorge syndrome is the result of defective embryogenesis involving the 3rd and 4th pharyngeal pouches. The recognition of partial forms of DiGeorge syndrome and the discovery that approximately 90% of cases are caused by a deletion of chromosomal region 22q11 have led to the recognition that this disorder is relatively common (1:3000 to 1:4000 live births) among primary immunodeficiency disorders. It appears that there is a common genetic abnormality and phenotypic overlap with velocardiofacial syndromes and conotruncal anomaly face syndrome. It is believed that the DiGeorge syndrome reflects a defect in neural crest cell migration into the third and fourth pharyngeal pouches. The result is hypoplasia or aplasia of the thymus and defective T-lymphocyte-dependent immunity. Patients with DiGeorge's syndrome usually suffer from defects involving other structures derived from the third and fourth branchial arches including the parathyroid glands, the great vessels, esophagus, cardiac septa, and several facial structures. The clinical results of these defects include neonatal hypocalcemic tetany secondary to agenesis of the parathyroid glands, persistent right-sided aortic arch, esophageal atresia, atrial and ventricular septal defects, and facial defects such as hypertelorism, short philtrum, low-set ears, and mandibular hypoplasia.

The degree of thymic hypoplasia is variable. Some patients manifest only limited defects in cellular immunity and thus suffer from few infectious complications. At the other end of the spectrum are patients with thymic aplasia who may present like patients with severe combined immunodeficiency. These patients suffer from recurrent life-threatening viral, fungal, and protozoal infections, and may develop GVH disease after receipt of blood products.

Patients with DiGeorge's typically have decreased numbers of circulating T lymphocytes with normal immunoglobulin concentrations. Some patients have decreased serum IgA and may have increased serum IgE concentrations. *In vitro*, the response of peripheral blood lymphocytes to T-lymphocyte mitogens usually is depressed. Thymic tissue is generally atrophic, although in some cases small tissue rests containing Hassall's corpuscles and thymocytes can be identified. Lymph nodes and splenic tissue typically show depleted T-cell-dependent areas. Therapy is supportive. Some groups have reported benefit from fetal and more recently, postfetal, thymus transplantation.

HYPER-IgE SYNDROME (JOB'S SYNDROME)

Hyper-IgE syndrome is an autosomal-dominant disorder of unknown cause. Patients typically suffer from recurrent staphylococcal abscesses involving the skin, lungs, joints, and soft tissues. Some patients with hyperimmunoglobulinemia E syndrome also suffer from a generalized dermatitis. The so-called Job's syndrome is considered to be related. The Job syndrome is characterized by recurrent skin abscesses in association with a poorly characterized neutrophil motility defect.

Patients with hyperimmunoglobulinemia E typically exhibit normal serum immunoglobulin concentrations except for IgE, which is typically markedly increased to concentrations in excess of 2000 IU/mL and as high as 20,000 to 50,000 IU/mL. In addition, peripheral blood eosinophilia is characteristic. Some patients have neutrophil and/or monocyte chemotactic defects. The mainstay of therapy is antibiotic treatment.

Chronic Mucocutaneous Candidiasis

Chronic mucocutaneous candidiasis (CMC) is a syndrome marked by chronic candidal infections of the skin and mucous membranes. In contrast to the other cellular immune disorders, CMC is rarely fatal. The cause of this disorder is unknown. In some cases, no immunodeficiency cause can be identified. Some patients have accompanying endocrinopathies involving the parathyroid, thyroid, adrenal glands or pancreas. Ketoconazole is the most efficacious therapy reported to date.

X-Linked Lymphoproliferative Syndrome (Duncan Disease)

X-linked lymphoproliferative disease (XLP) was initially described in a group of patients from a single kindred, the Duncan family. Recent studies have linked the syndrome to defects in the XLP (*LYP*) gene located at Xq25. Manifestations (see below) have been reported in individuals who harbor an abnormal XLP (*LYP*) gene but have never been exposed to the Epstein-Barr virus (EBV). This observation indicates that the disease is not a specific sequel to EBV infection (except in cases of fatal EBV-induced infectious mononucleosis). The syndrome is varied in its clinical manifestations but has in common an abnormal response to EBV infections. Patients with X-linked lymphoproliferative disease are well until they first suffer from an EBV infection. Nearly 70% of patients die as the result of an intense lymphocyte proliferation that occurs during mononucleosis. Most survivors develop hypogammaglobulinemia, B-cell lymphoma or a combination of both. Most patients who survive mononucleosis do not mount a normal antibody response to EBV nuclear antigen, whereas titers to the viral capsid antigen may range from zero to markedly elevated. There is often an accompanying depression in T-cell immunity to EBV. Nonspecific immunologic defects also have been associated with Duncan's disease. Such patients may have normal numbers of circulating B and T lymphocytes

with an elevated percentage of CD8+ (T-suppressor) cells. Finally, *in vitro* lymphocyte immunoglobulin synthesis to B-cell mitogens is also often blunted. There is currently no specific effective therapy for this disorder.

Cartilage — Hair Hypoplasia

Cartilage-hair hypoplasia is an autosomal-recessive disorder with variable penetrance. It has been linked to mutations in the *CHH* located at chromosome 9p13. This disorder is prevalent particularly among the Amish and is characterized by short-limbed dwarfism accompanied by frequent, often life-threatening infections. Patients with this disorder possess fine light hair and eyebrows, hyperextensible joints of the hands and feet, and a characteristic short-limbed dwarfism that is particularly pronounced in the hands. While defective antibody mediated immunity is demonstrable in most patients, there also is defective cellular immunity and a markedly increased propensity for life-threatening infections. Progressive vaccinia and vaccine-associated poliomyelitis have been observed in some patients.

DNA Breakage-Associated Syndromes

Ataxia-telangiectasia (A-T) is an autosomal-recessive disorder that was first recognized in 1926. This entity is characterized by progressive neurological abnormalities (most commonly cerebellar ataxia, choreoathetosis, and oculomotor abnormalities), ocular and cutaneous telangiectasias, immunodeficiency, growth retardation, and sensitivity to ionizing irradiation. A-T was mapped to chromosome 11q22-23 in 1988 and the ATM (ataxia-telangiectasia mutated) gene identified and cloned in 1995. *ATM* is a phosphatidylinositol -3-kinase which is involved in cell cycle control, cellular response to DNA damage, and intracellular protein transport.

Typical patients manifest progressive cerebellar ataxia within the first 12 to 18 months of life, and most patients suffer from recurrent bacterial sinopulmonary infections. Telangiectasias typically become apparent on the conjunctiva and skin early in childhood. In addition to disordered immune function, ataxia, and telangiectasias, patients with ataxia-telangiectasia are at risk of developing malignancies involving the hematopoietic system.

Both patients and heterozygotic carriers of this disorder exhibit defective DNA repair accompanied by inordinate sensitivity to ionizing irradiation. *In vitro*, B lymphocytes often exhibit an intrinsic inability to synthesize IgA.

The immunologic profile in ataxia-telangiectasia patients is variable. Most patients exhibit decreased serum IgA and IgE concentrations accompanied by variable decreases in serum IgG. Cellular immune function usually is depressed but not to the degree observed in severe combined immunodeficiency disorders or complete cases of the DiGeorge syndrome.

Chromosomal instability syndromes other than ataxia-telangiectasia include Fanconi anemia, Bloom syndrome, and ataxia-telangiectasia variants (AT-V). The latter classification was proposed in the late 1980s, for the group of patients who exhibit cytogenetic abnormalities identical to those seen in A-T patients but who display different clinical features. AT-V patients suffer from microcephaly and do not develop ataxia (which occurs in 100% of A-T patients). Some investigators have subclassified AT-V into two groups; AT-V1 (Nijmegen breakage syndrome) and AT-V2 (Berlin breakage syndrome). This rationale for this subdivision has come into recent question and is thus controversial.

Interferon-γ-Associated and Interleukin-12-Associated Immunodeficiencies

Mutations that result in interferon-γ receptor defects, an interleukin-12 (IL-12) deficiency, and an IL-12 receptor defect have been defined recently. These include mutations in the *IFNGR1*, *IFNGR2*, *IL12B*, and *IL12RB1* genes, which encode subunits of the IFNγ1-receptor, the IFNγ2-receptor, IL-12(p40 subunit), and the IL-12 receptor ß1, respectively. All of these patients exhibit a marked increase in susceptibility to disseminated mycobacteriosis. This is a particular issue in locales where live *Bacillus Calmette-Guerin* is administered as a vaccine.

The great advances that have occurred in understanding of the genetic and molecular bases for primary immunodeficiency disorders have important implications in the classification, diagnosis, and management of such patients. From a practical standpoint it remains important to recognize the typical as well as unusual clinical features of immunodeficiency diseases and to judiciously apply appropriate testing approaches to their diagnosis. The impact that these advances have had in deepening our understanding of the biology of the immune system cannot be overstated.

66
Allergic Conditions

Eric Brestel

Donald R. Hoffman

TYPES OF IMMUNOPATHOLOGICAL HYPERSENSITIVITY

Part of "66 - Allergic Conditions"

There are several mechanisms by which the immune response can initiate a pathological process (Table 66.1). Coombs and Gell were the first to propose this classification scheme, and it has been updated by Snyderman (1). The type I response is initiated by the reaction of allergen with IgE bound to tissue mast cells via the Fc epsilon receptor. This antigen recognition by IgE results in a transmembrane signal that initiates the release of mediators from the mast cell. These include histamine, leukotrienes, platelet-activating factor, prostaglandin D2, and a variety of intracellular enzymes, including a specific tryptase. These mediators can result in an immediate (within 5 to 30 minutes) response depending on the route of allergen exposure: a wheal-and-flare in the skin, rhinitis, asthma, vomiting and diarrhea, or systemic anaphylaxis. IgE-mediated responses also can cause systemic anaphylaxis and gastrointestinal allergic reactions manifested by vomiting, crampy abdominal pain, and diarrhea. The IgE-mediated response occurs within several minutes following exposure to an allergen and may gradually subside over 60 minutes. A secondary exacerbation of this response, however, may occur several hours after the initial mast cell degranulation and has been called the late response. This late response is felt to be a key component of chronic rhinitis and asthma and also can be seen in the skin following insect sting reactions and after the injection of allergens to which the patient is sensitive. The late response is caused by mediators released by eosinophils and lymphocytes, which are recruited to the site by upregulating vascular endothelial adhesion proteins and chemoattractants.

TABLE 66.1. TYPES OF IMMUNOPATHOLOGICAL HYPERSENSITIVITY

Type	Cell Types Involved	Mediators	Examples
Immediate (I)	Mast cells with cooperation from basophils, eosinophils, mononuclear cells, and possibly platelets for the late response	Histamine, leukotrienes, platelet activating factor	Allergic rhinitis and asthma, insect venom hypersensitivity, penicillin hypersensitivity
Cytotoxic (II)	Macrophages and neutrophils	Complement and phagocyte-derived mediators (enzymes, oxidants, eicosanoids, etc.)	Goodpasture syndrome, ABO incompatability, thrombocytopenic purpura, myasthenia gravis
Immune complex (III)	Same as type II	Same as type II	Serum sickness, glomerulonephritis
Cell mediated (IV)	Lymphocytes, macrophages, and occasionally basophils	Cytokines	Allergic contact dermatitis, the tuberculin reaction, graft-versus-host disease, chronic allograft rejection, possibly multiple sclerosis

The type II response involves antibodies, usually of the IgG or IgM class, binding with a protein that is present on a-cell membranes or other biological tissues. Examples of this form of immunopathology include Goodpasture disease, immune thrombocytopenic purpura, myasthenia gravis, and ABO and Rh incompatibilities.

The type III response involves the reaction of antibodies, usually of the IgG class, with a soluble antigen to form immune complexes. Immune complexes react with complement, deposit on subendothelial surfaces, and recruited leukocytes activate vasculitis.

In the type IV responses, lymphocytes recognize antigen via the T-cell receptor (CD3). Lymphocytes specific for the antigen release cytokines, which recruit more lymphocytes to the area and further recruit monocytes and macrophages. These cells aid in antigen processing, but they also contribute to the inflammatory response. An example of the type IV response is the intracutaneous reaction to purified protein derivative of *Mycoplasma tuberculosis*. The type IV response also is involved in the host defense against *M. tuberculosis*. Another example is allergic-contact dermatitis, which, more specifically, is cutaneous basophil hypersensitivity because of the intense basophilic infiltrate. This is the mechanism for the inflammatory response seen in poison ivy (Rhus dermatitis).

In this chapter, we will primarily concentrate on type I and type IV hypersensitivities, which are IgE- and lymphocyte-mediated, respectively.

DEFINITION OF ALLERGY

Part of "66 - Allergic Conditions"

Clinicians usually reserve the term allergy to apply to acquired hypersensitivities that have an immune basis. More specifically, allergy usually is reserved for conditions mediated by immunoglobulin E (IgE) and lymphocytes. At present, no single laboratory test or other diagnostic procedure can define a patient as being an allergic individual. Rather, the diagnosis usually is based on the accumulated evidence of the patient's history and *in vivo* and *in vitro* diagnostic procedures. Many investigators define the IgE-mediated allergic state as positivity on skin testing to one or more common aeroallergens, foods, insect venoms, some drugs, and perhaps an elevation of the total serum IgE concentration. This method of defining allergy presumes the allergic individual is capable of producing exaggerated levels of specific IgE to foreign proteins or drugs. It is not uncommon for persons to have positive skin tests to allergens without exhibiting clinical sensitivity on contact with the allergen. Studies with college students, however, have indicated that individuals with positive skin tests are very likely to develop clinical symptomatology within the next 3 years. The term allergy also includes the lymphocyte-mediated allergic contact dermatoses.

REALM OF CLINICAL ALLERGY

Part of "66 - Allergic Conditions"

IgE-mediated hypersensitivity usually results in the clinical conditions of allergic rhinitis, asthma, insect-sting hypersensitivity,

food hypersensitivity of an immediate nature, and occasionally, urticaria and angioedema. The clinical allergist also may be asked to evaluate responses to drugs and foods that do not have a known immunopathological basis, including hypersensitivity to the nonsteroidal antiinflammatory drugs, radiocontrast media, sulfite, and benzoate. There are nonallergic forms of rhinitis in asthma, and the amount of the IgE-mediated component of atopic dermatitis may vary among patients. Likewise, occupational lung diseases may have an immune component or may have an idiopathic etiology. Occasionally, the allergist is asked to evaluate a patient suspected of having a hypersensitivity pneumonitis. This is a group of conditions that often is thought to have an immunopathological basis and precipitated by encounters in the workplace. With the exception of penicillin hypersensitivity, the evaluation of adverse drug reactions is probably the most enigmatic problem facing the clinical allergist. It is rare to find a specific immunopathological mechanism for most adverse drug reactions, and clinical testing is not usually available.

Allergic contact dermatitis results when a sensitizing material is recognized as foreign by the lymphocyte. Unlike the more complex proteins that can induce IgE-mediated allergic processes, small organic compounds and inorganic ions are the usual allergens that induce allergic contact dermatitis. Some time is required for the recruitment of the cells required to mediate type IV hypersensitivity, and reactions usually are not noted for 24 to 72 hours after initial contact with the allergen. Common examples of this form of hypersensitivity include poison ivy dermatitis, dermatitis to nickel contained in jewelry and other apparel items, and the dermatitis resulting from hypersensitivity to the hair-coloring material p-phenylenediamine.

DISEASE STATES

Part of "66 - Allergic Conditions"

Rhinitis

Allergic Rhinitis

Allergic rhinitis is one of the most prevalent disease states in western civilization. Approximately 15% to 20% of the general population is allergic as defined by positive skin tests to inhaled aeroallergen(s) and clinical symptomatology that results from exposure to them. The symptomatology may be seasonal, corresponding to the pollination of plants whose pollen is airborne (grasses, trees, and weeds) and the spores of molds. It also may be perennial, as in the case of house dust mite and animal dander hypersensitivity, where the allergens are in the home or workplace. Some patients have perennial allergic rhinitis from house dust mite hypersensitivity with exacerbations during the pollination seasons. Clinical symptomatology of seasonal allergic rhinitis includes sneezing, watery nasal discharge, postnasal drainage of mucus, and nasal airway obstruction. Itching and swelling of the conjunctival surfaces of the lids of the eyes with increased tearing is a common accompaniment. Allergic rhinitis can be complicated by serous or infectious otitis media or sinusitis resulting from edema of the nasal airway with the occlusion of the Eustachian tubes or sinus ostia, respectively.

Nonallergic Rhinitis

In some subjects who present with a history of nasal congestion and increased nasal mucus production, no evidence of an IgE-mediated disease process can be determined. This condition often has been referred to as vasomotor rhinitis. It is likely that nonallergic rhinitis is actually a group of disorders with different etiologies presenting as nasal congestion with increased mucus production. The patient with vasomotor rhinitis often has the symptomatology of congestion with exacerbation of nasal symptoms on exposure to irritating vapors, bright sunlight, or the inhalation of cold, dry air. Subjects with nonallergic rhinitis with eosinophilia often have symptomatology typical of allergic rhinitis, with marked congestion, sneezing, and rhinorrhea. However, the symptoms often occur outside of the typical pollination seasons. This should alert the physician to look for eosinophils in the nasal mucus. It is presumed that the eosinophils are playing a role in this disorder, but the reason for their appearance in the nasal mucosa and secretions has not been determined.

Patients with disorders of immune function, such as immunoglobulin deficiency states and ciliary dyskinesia, also may present with symptoms of rhinitis. A clue to these conditions is a history of recurrent pyogenic infections of the sinuses, middle ear, and lungs.

Asthma

Asthma may be defined as a condition of reversible obstructive airways disease in which there is a high degree of airway hyperirritability to agents such as methacholine and histamine. While many asthmatics may have their obstruction completely reversed with bronchodilator (beta agonist) therapy, there is growing evidence that poorly controlled chronic asthma may result in a condition of poorly reversible airway obstruction. Asthma is best diagnosed by performing spirometry and determining the patient's reversibility with inhaled bronchodilators. Patients suspected of having asthma but having a normal spirometry can be challenged with methacholine, which can induce airways obstruction in asthmatics at a much lower concentration than normal subjects.

The prevalence of asthma in the general population is increasing in western societies, and death rates from asthma have been increasing in all age groups (2). The reason for these increases has not yet been determined, but it may have its basis in the nature of the life-style of western civilization.

Allergic Asthma

For many years, it was estimated that approximately 20% to 25% of all asthmatics had an allergic component to their disease. More recent data suggest that allergy may play a role in a more significant percentage of asthmatics (3). These estimates, however, are based on skin testing to common aeroallergens and elevations of total serum IgE. It remains to be determined if either of these criteria specifically indicates that a given aeroallergen, or that allergy in general, is contributing to the disease process. It generally is accepted that allergy is a common feature of the childhood asthmatic, and the severity of childhood asthma usually is proportional to the number of positive skin tests and the severity of the reaction to those skin tests (4). Allergy seems to be less frequently diagnosed in older asthmatics, especially if the onset of the asthma occurs late in life. Specific treatment of the allergic condition with allergen immunotherapy has been demonstrated to benefit allergic asthmatics and to diminish the airway's response to allergen (5).

Occupational Asthma

Asthma can result from exposure to specific agents unique to the workplace. Occupational asthma may have an allergic or nonallergic component. Allergic asthma has been noted in seafood processors, bakers sensitive to flour, animal handlers, grain workers sensitive to storage mites, egg processors, and workers exposed to molds, wood dusts, and insect products (6).

Occupational asthma also can occur in response to low-molecular-weight chemicals on an allergic or a nonallergic basis (7). Diisocyanates are used in the production of polyurethane, adhesives, and plastics. It is possible that a small percentage of workers in these industrials have an IgE-mediated disease, but the mechanism in the majority of individuals has not been determined. Isocyanate sensitivity can be disabling and can result in asthmatic symptoms recurring hours after the initial exposure. Airway hyperreactivity can persist for years after removal from isocyanate exposure. Workers exposed to a variety of wood dusts can develop asthmatic symptoms. Plicatic acid is a material derived from western cedar that can cause asthma in some individuals. It is possible that some of the responses to plicatic acid are mediated by IgE. Occupational asthma also has been described in persons exposed to acid anhydrides used in the production of epoxy resins, platinum salts, and to colophony present in solder fluxes. Many other occupational asthmas can result from exposure to organic compounds capable of eliciting IgE responses.

Asthma Exacerbated by Nonsteroidal Antiinflammatory Drugs and Food Additives

Approximately 10% of all chronic asthmatics can have an exacerbation of their asthma within 30 to 60 minutes of the ingestion of a nonsteroidal antiinflammatory drug (NSAID) (8). The mechanism of this disorder is pharmacologic, and there is no evidence of its being immune-mediated.

These drugs inhibit the enzyme cyclooxygenase, the enzyme responsible for prostaglandin synthesis. It is presumably by this mechanism that they induce the exacerbation of asthma. There have been several proposed mechanisms, and they include the suppression of the production of prostaglandin E2, which is a natural inhibitor of the 5-lipoxygenase, or the shunting of arachidonic acid through the 5-lipoxygenase pathway to produce bronchospastic leukotrienes. A heightened responsiveness to leukotriene E4 also has been proposed. Asthmatics sensitive to NSAIDs often have chronic asthma that may require oral or inhaled corticosteroids for control, and they often have nasal polyposis and chronic sinusitis. Subjects identified as being sensitive to NSAIDs must avoid them because life-threatening asthmatic reactions can occur.

Chronic asthmatics also appear potentially sensitive to sulfite, which often is used as a preservative for foods, beverages, and medications (9). The mechanism of sulfite sensitivity has not been determined, but it appears the response is triggered by the inhalation of sulfur dioxide gas that is in equilibrium with sulfite and not by the gastrointestinal absorption of sulfite. Foods and beverages that commonly contain sulfite include beer, wine, dried fruits, sauerkraut, cider, fresh red meat, and processed potatoes. The use of sulfite in restaurant salads has been outlawed, but sulfite may still be applied to grapes. The flavor enhancer monosodium glutamate also has been associated with rare cases of exacerbation of asthma.

Urticaria and Angioedema

Idiopathic Urticaria and Angioedema

The specific cause of recurrent or chronic urticaria and angioedema usually cannot be determined (10). Acute urticaria (urticaria persisting for less than 6 weeks) has been associated with a variety of infectious disorders, including streptococcal pharyngitis, infectious mononucleosis, sinusitis, cholecystitis, and during the prodrome of hepatitis B infection. It is possible that the acute phase response lowers the threshold for mast-cell degranulation. It is certainly possible that urticaria can be associated with an IgE-mediated response, as in the case of some forms

of food and insect sting hypersensitivity. Most cases of angioedema are from mast-cell degranulation occurring in deeper dermal tissues; therefore, individual urticarial wheals are not visible. Many subjects with angioedema give a history of having urticaria concomitantly or on separate occasions.

In addition to IgE-mediated and idiopathic urticaria/angioedema, a number of physical factors can precipitate the disorder. Cold urticaria can occur on exposure to cold air or contact with cold objects. Cholinergic urticaria is triggered by the initiation of sweating. Delayed pressure urticaria is delayed dermal swelling (angioedema) occurring several hours after some form of pressure to a given area. Dermatographism is triggered by scratching of the skin and can be caused by the rubbing of clothing. It presents as linear streaks of urticaria and can be readily diagnosed by stroking the skin and noting the characteristic wheal-and-flare response. Urticaria pigmentosa and systemic mastocytosis can present with generalized urticaria as well as anaphylaxis.

Hereditary Angioedema

Hereditary angioedema (HAE) is a rare condition resulting from the functional absence of the C1 esterase inhibitor molecule (11). The clinical state presents with recurrent orofacial and peripheral angioedema or with acute abdominal crises of pain and diarrhea. Trauma, including surgical procedures, can trigger an attack. The absence of this inhibitor allows for the uninhibited activation of complement by the action of the C1 esterase on C4 and C2. Plasmin, whose formation is triggered by the activation of the fibrinolytic system after thrombosis, is also inhibited by the C1 esterase inhibitor, and plasmin can activate the formation of bradykinin. It is possibly through this mechanism that trauma initiates the angioedematous process.

Acquired C1 Esterase Inhibitor Deficiency

A syndrome similar to HAE can be acquired in patients with disorders associated with large levels of circulating neoantigens (12). Disorders such as autoimmune hemolytic anemia and lymphosarcoma can be associated with the presence of antigens recognized as foreign and to which large amounts of antibodies can be produced. This large burden of immune complexes actually consumes C1 and the C1 esterase inhibitor molecule, resulting in low circulating levels. The angioedema results from the same mechanism as in patients with the hereditary form. Patients with the onset of angioedema after the second decade should have an evaluation for a possible coexisting disorder that is causing the process. Angioedema may precede by many months the other signs of the process causing the decline of the C1 esterase inhibitor levels. If angioedema occurs in the setting of low serum C4 and C1 esterase inhibitor levels in a patient in the third decade or later, a careful physical examination and further laboratory screening tests should be ordered, including a complete blood count, antinuclear antibody determination, hepatocellular enzymes, and testing for lymphoma.

Insect Venom Hypersensitivity

Hymenoptera venoms from bees, wasps, and ants are capable of stimulating the production of specific IgE. Reexposure to these venoms then can initiate an IgE-mediated response that can result in allergic symptoms including generalized urticaria, oropharyngeal angioedema, asthma, and anaphylactic shock. Persons with severe prior systemic adverse reactions are prone to potentially life-threatening reactions after future stings. One exception to this rule appears to be children who have only had dermatologic responses to venom exposure; these children do not appear to be prone to life-threatening events on subsequent stings any more so than the general population (13).

Adverse Reactions to Foods and Food Additives

The most common manifestations of IgE-mediated hypersensitivity to food proteins are nausea, vomiting, diarrhea, and urticaria and angioedema occurring within minutes after ingestion. Anaphylaxis and asthma also may occur. There are delayed reactions to some food substances, and food hypersensitivity has been implicated in the pathogenesis of some cases of atopic dermatitis. In this particular case, ingestion of an offending food allergen can cause an exacerbation of the eczematous dermatitis. Food hypersensitivity has been suggested as the etiologic basis for many other conditions, including hyperactivity, migraine headache, chronic fatigue, depression, and a variety of other somatic complaints not typically associated with mast cell-mediated events. Definitive evidence for the involvement of IgE in these conditions is lacking.

Food protein intolerance has been associated with several other disorders for which definitive evidence of an immune-mediated mechanism is lacking. Food protein-mediated gastroenteropathy occurs in infants and young children and has been associated with intolerance to a variety of foods. The process usually is transient, but it may be associated with vomiting, diarrhea, occult or gross bleeding, and growth retardation. An immunoglobulin E-mediated hypersensitivity to cow milk has been identified in a subset of these individuals. Eosinophilic gastroenteritis can present with vomiting, diarrhea, weight loss, and abdominal pain in either adults or children. Intolerance to milk protein has been documented in some cases even though an immune-mediated hypersensitivity is often lacking. Peripheral eosinophilia and an eosinophilic infiltration in the bowel wall are characteristic features of the disorder.

Gluten-sensitive enteropathy is associated with an intolerance to the wheat protein gliadin. An immune response to gliadin has been demonstrated. The disease usually begins within the first year of life, and symptoms are episodic diarrhea and abdominal pain. Growth retardation with malabsorption of a variety of nutrients may be seen. Immunoglobulin A deficiency exists in these patients at a frequency higher than that of the general population. Dermatitis herpetiformis is a papulovesicular skin disease often associated with gluten-sensitive enteropathy.

Atopic Dermatitis

Atopic dermatitis is a rather common disorder occurring in up to 4% of the population. As its name implies, it is often associated with the presence of IgE-mediated hypersensitivity and is frequently associated with other IgE-mediated disease states such as allergic rhinitis and asthma. This disorder often appears in infancy,

but it can have its onset at any age of life. It is associated with an eczematous dermatitis that can at times be generalized but tends to concentrate in the flexures of the neck and inguinal regions and in the popliteal and antecubital fossae. Xerosis often is found in areas of the skin that are not frankly eczematous, and skin biopsies of these areas show an infiltration of lymphocytes in the dermis. The reason that the skin is the particular shock organ in this atopic diathesis is unknown, but the frequent colonization of the skin with *Staphylococcus aureus* and the frequent improvement of the symptomatology with antistaphylococcal antibiotics suggests that this organism may contribute to the inflammatory response. Patients with head and neck involvement usually show colonization with and antibody responses against the dermatophyte fungus, *Malassezia furfur*. Food hypersensitivity has been associated with exacerbations of the disease; proteins from cow milk, peanut, and egg are common offenders. Double-blind, placebo-controlled food challenges have documented that such foods can exacerbate the dermatitis in patients in whom there is immediate (IgE-mediated) skin test reactivity to the food extracts (14).

Allergic Contact Dermatitis

The term contact dermatitis refers to any dermatologic condition that is triggered by contact with a substance. This does not necessarily imply an immune-mediated etiology. To refer to such a syndrome as allergic is to imply that an immune-mediated response is the cause of the inflammatory state. Allergic contact dermatitis is from a hypersensitivity triggered by a lymphocyte recognizing the offending material as foreign (a type IV response). Because only a small percentage of circulating lymphocytes have specificity for the antigen, a considerable period of time is required for the inflammatory response to become manifest. This is because the immediate reaction of the lymphocyte with the antigen results in the release of cytokines that recruit and stimulate nonspecific lymphocytes and also recruit Langerhans' cells and monocytes to the area to participate in the inflammatory response. It takes approximately 48 hours for a significant response to appear, although reactions may appear as early as 24 hours or as late as 72 hours. The urushiols, which are the contact sensitizers derived from plants of the *Rhus* genus (poison ivy, poison oak, and poison sumac) can trigger this type of response. Nickel sensitivity, as demonstrated by an intolerance to nickel-contaminated metals found in jewelry and clothing apparel, is also very common, and its sensitivity occurs in approximately 10% of the female population in western societies. Other common contact sensitizers include chromates, the hair dye p-phenylenediamine, and chemicals used in the production of rubber. The eczematous dermatitis that results from allergic-contact hypersensitivity may be localized to the site of initial contact, but the antigen may be spread by the fingers to other areas of the body; this is frequently the case in nickel and Rhus dermatitis. When allergic contact dermatitis involves the hands, a particularly severe hand eczema can result and may be recalcitrant to medical therapy.

Drug Hypersensitivity

In the case of drug hypersensitivity, the term hypersensitivity is used to refer to an adverse reaction to a pharmacologic agent that is not a manifestation of the drug's normal pharmacologic action or interaction with other drugs. Drug hypersensitivities may or may not have an immune etiology. Certainly, the most common cause of drug hypersensitivity is the IgE-mediated hypersensitivity to penicillin and its semisynthetic derivatives such as ampicillin and dicloxacillin. Penicillin hypersensitivity also is associated with occasional cross-reactivity to the cephalosporins.

Drug hypersensitivity also may be manifested by erythema multiforme, which is a skin rash with lesions resembling targets and may involve the mucosal surfaces with bulla formation, erythema, and desquamation. Extreme cases may result in the desquamation of the skin as well. There is no firm evidence for an immune-mediated cause for this disorder, and it may result in some cases from an idiopathic toxic response to the drug. Other cutaneous manifestations of drug hypersensitivity include urticaria/angioedema, allergic contact sensitivity, fixed drug eruptions, and a variety of nonspecific, papular or macular eruptions.

Drugs may fix to certain elements in the blood, such as erythrocytes, platelets, and neutrophils, and act as haptens to which antibodies are made. Immunoglobulins responding to the drug on the cellular surfaces can facilitate the removal of these cells, resulting in anemia, thrombocytopenia, and granulocytopenia. A number of drugs have resulted in lupuslike illnesses. They include quinidine, hydralazine, anticonvulsants, isoniazid, and procainamide. An interesting drug-induced syndrome can occur in patients with the acquired immunodeficiency syndrome. Nearly 50% of these individuals will have adverse reactions to sulfonamides. The underlying mechanism for these reactions is unknown.

IgE-mediated hypersensitivity is a common mechanism for adverse reactions to drugs that are proteins, such as insulin, protamine, chymopapain, and heterologous antisera. If immunoglobulin G is the primary antibody produced by the host, serum sickness can occur.

The iodinated radiocontrast media (RCM) can produce acute anaphylactoid reactions that do not appear to have an immune basis. The hyperosmolar nature of many of these preparations may contribute to their ability to initiate reactions. Persons with a history of previous RCM adverse reactions possess a greater susceptibility than the general population to react to these agents on subsequent exposure. The most common manifestations of adverse reactions to RCM are flushing, generalized urticaria, hypotension, and respiratory distress.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis refers to a group of lung disorders having an immune etiology that are often caused by the occupational exposure to a sensitizing protein. Primary sensitization to proteins can occur through the pulmonary route, and repeated exposure to these proteins can result in an inflammatory state. There has been considerable controversy over the years as to the mechanism of the inflammatory response. Early work suggested that complement-fixing immunoglobulins were responsible for the syndrome (i.e., type III hypersensitivity), but more recent evidence suggests that antigenic stimulation of lymphocytes may be responsible for the chronic inflammatory response seen in this group of conditions. Nevertheless, the presence of precipitating (IgG) antibodies in the serum of affected individuals may assist

in the diagnosis and will be discussed later in this chapter. Further evidence that delayed (type IV) hypersensitivity is instrumental in the disease process is given by the pathological finding of noncaseating granulomata containing epithelioid and giant cells.

Farmer's lung is a disorder triggered by the inhalation of spores of *Micropolyspora faeni* or thermophilic actinomycetes, which often contaminates hay used for the feeding of livestock. Pigeon breeder's disease, or bird fancier's disease, is caused by the inhalation of proteins contained in bird droppings when hobbyists or laboratory personnel enter the animal's living facilities. Similar respiratory disorders are seen in maple bark stripper's disease, mushroom worker's lung, and many other pneumonitides resulting from the inhalation of protein antigens (15) (Table 66.2).

TABLE 66.2. EXAMPLES OF HYPERSENSITIVITY PNEUMONITIS

Disorder	Antigen Source
Farmer's lung	Thermophilic *actinomycetes* in grains and hay
Bird fancier's disease	Proteins in bird droppings
Bagassosis	Thermophilic *actinomycetes* in moldy sugar cane
Malt worker's lung	*Aspergillus* species in moldy barley
Maple bark disease	Mold in maple bark
Woodworker's lung	Wood dusts or molds in wood

Clinical symptomatology often presents as fever, malaise, myalgias, and respiratory symptoms such as cough or dyspnea, occurring several hours after exposure to the offending protein. Repeated exposures over many years may result in a chronic pulmonary condition finally ending in fibrosis and irreversible pulmonary disease. Suspecting the disease process and making the diagnosis is essential so that counseling can be instituted to reduce exposure to the offending proteins and thus to prevent the end-stage lung disease that may result.

Allergic Bronchopulmonary Mycosis

Allergic bronchopulmonary mycosis (ABPM) is a complication that can occur in allergic asthmatics. It is believed that patients with IgE-mediated hypersensitivity to *Aspergillus* and other species may inhale spores of the organism, resulting in an acute asthmatic response associated with the increased production of tracheobronchial mucus characteristic of allergic asthma. The organism then can reside in mucus creating chronic inflammation resulting in a chronic and progressive asthmatic state. Because of this heavy allergen exposure in the lung, the patient develops precipitating IgG antibodies to offending fungal antigens as well as very high titers of specific and nonspecific IgE. Like hypersensitivity pneumonitis, ABPM was originally thought to be caused by complement-fixing, (IgG) antibodies initiating the inflammatory response, but more recent evidence suggests that this condition, too, may be associated with a significant type IV hypersensitivity component. It also is possible that a chronic late-phase response (see beginning of chapter) exists in these individuals. If unrecognized, the condition may proceed to bronchiectasis and finally fibrosis. ABPM may also be a complication of cystic fibrosis.

METHODOLOGIES

Part of "66 - Allergic Conditions"

IgE-mediated Disease

Skin Testing

In patients suspected of having IgE-mediated disorders, skin testing remains the most accurate and cost-effective method of diagnosis (Table 66.3). Skin testing relies on the specific IgE-mediated release of mediators from tissue mast cells that cause a wheal-and-flare response. Skin testing should be performed by personnel trained in its application with supervision by physicians experienced in the diagnosis of IgE-mediated diseases. Extracts must be purchased from reliable suppliers, and there is a growing emphasis on the need for allergen extract standardization.

TABLE 66.3. METHODS FOR EVALUATING HYPERSENSITIVITY

Disorder	Diagnostic Test(s)
IgE-mediated diseases:	Skin testing
Allergic rhinitis	RAST and other *in vitro* methods for determining allergen-specific IgE
Allergic asthma	
Atopic dermatitis	
Insect venom allergy	
Food allergy	
Penicillin and protein drug allergy	
Hypersensitivity pneumonitis	Precipitating antibody to antigen by double immunodiffusion
	Chest radiograph
Hypersensitivity to NSAID and sulfite	Oral challenge with monitoring spirometry
Allergic bronchopulmonary aspergillosis	Skin testing to *Aspergillus*
	Total serum IgE (RIST)
	Precipitating antibody to *Aspergillus* by double immunodiffusion
	Chest radiograph
Allergic contact dermatitis	Patch testing

In persons suspected of having IgE-mediated hypersensitivity to inhalants or foods, the percutaneous or epicutaneous skin tests should be applied first. A 1:10 or 1:20 weight/volume (w/v) aqueous extract containing 50% glycerol is applied as a drop to the volar aspect of the forearm or to the back. The allergen then is introduced into the epidermis with a sharp device by passing the point of the device through the drop and into the epidermis. Reproducible application has been demonstrated with the Wyeth bifurcated needle (resembling the old vaccinia scarification device), the Pharmacia Lancet, and the Staller point (a variation of the Morrow Brown needle) (16, 17). In performing percutaneous tests, hypodermic needles, the standard Morrow Brown needle, and the Staller kit give slightly less reproducible skin tests than the devices previously mentioned. After the allergenic extract has been introduced into the epidermis, the extract is wiped from the skin, and the wheal-and-flare is measured 15 to 20 minutes later.

When epicutaneous tests are negative, intracutaneous testing may be required as a more sensitive test to identify aeroallergen hypersensitivity. The intracutaneous test is less specific than the epicutaneous test but can still be interpreted with confidence providing the proper concentrations of materials are used. A 1:1000 w/v concentration of allergen extract is injected at a very shallow angle so that material is introduced into the dermis just beneath the epidermis. Approximately 0.02 mL of material is injected. This volume is critical because wheal size is directly proportional to the volume of the material injected. The intracutaneous test result also is interpreted 15 to 20 minutes after its application.

Total Serum IgE, Specific IgE, and Other in vitro Methods (18)

Total serum IgE can be determined by a variety of methods. The most commonly used methods include solid-phase immunoassay with fluorescence detection, radiolabeled immunoprecipitation, immunoplate enzyme-linked immunosorbent assay (ELISA), microparticle-enhanced immunoassay, and solid-phase immunoassay with luminescence detection. IgE is measured in international units that are equal to 2.2 ng. The method chosen should have a minimum operating range from 5 to 1,000 IU/mL. The method should be tested to assure that it does not exhibit a large “hook effect”, giving falsely low values for specimens with elevated levels. Occasionally, specimens will be encountered with total IgE levels at least 100-fold out of range. Typical coefficients of variation are 15% for better commercial assays, except for specimens that are substantially out of operating range. A typical standard curve has 7 points, because the assays do not exhibit linear performance. Semiquantitative and screening IgE assays are of very limited value.

The radioallergosorbent test (RAST) was developed in the late 1960s and early 1970s following the discovery of IgE as the antibody causing type I hypersensitivity reactions. RAST is the classic method for determining specific IgE antibody. While originally developed as a research laboratory method, it was rapidly translated into a commercial diagnostic procedure. Allergen is usually covalently linked to a cellulose disk, but other insoluble support systems such as agarose may be used. The patient's serum is added to the allergen. The solid phase is washed and then incubated with a radiolabeled antibody specific for IgE. The solid phase is rinsed again, and the amount of bound radioactivity is quantitated to determine the amount of specific IgE directed toward the allergen in the original serum sample. This method generally has been replaced by the Immuno-CAP procedure, which uses an expanded cellulose matrix with high ligand binding capacity and enzyme based fluorescence detection. This method is significantly more sensitive and slightly less specific than most other methods in current use.

Other methods have been developed to quantitate specific IgE *in vitro*. The antibody binding to the allergen-affixed IgE can be labeled with an enzyme that uses a substrate that is converted to a colored product (ELISA) or produces a fluorescent product (the fluorescent allergosorbent test or FAST). One method utilizes luminescence generated by radiographs released in the radioactive decay of 125I-labeled anti-IgE (the multi-thread allergosorbent test or MAST). Others use chemiluminescence, colorimetry, or particle counting methods. In various methodologies, allergen is bound to cyanogen bromide activated paper disks, microtiter plates, activated fibers, microparticles or is labeled with biotin. Each of these methodologies is available through a commercial vendor. Basically, these methods are all similar in principle to the RAST and share similar advantages and disadvantages of RAST. There are significant differences in the performance of each commercial method, and for some allergens performance of many methods is poor. Manufacturers should provide information on the sources and characterization of allergens used in their systems. Fungal allergens and many fresh fruits and vegetables are particular problems in most methods. The performance characteristics of assays used for diagnosis of life-threatening conditions, such as venom anaphylaxis, and occupational conditions, such as latex allergy, need to be carefully evaluated before relying on negative results.

In vitro methods with multiple allergens coupled to the support are available and can be used for screening for atopy. These methods are slightly less sensitive than using individual allergen tests, but can be used in a cost effective manner.

Although most specific IgE tests can be reported in quantitative units, these methods are not truly quantitative because of the unknown composition of most allergen extracts. Results are not comparable between different allergens and among different methods.

Clinical States Where Skin Testing, Specific IgE Antibody and Total IgE Are Useful (19)

Perhaps the greatest utility for skin testing and specific IgE antibody lies in their ability to aid in the diagnosis of aeroallergen hypersensitivity and the resulting conditions of allergic rhinitis and asthma. Skin testing and, to a more limited extent, specific IgE antibody can be used to confirm IgE-mediated hypersensitivity to hymenoptera, including imported fire ant venoms. True IgE-mediated reactions to foods can be confirmed with skin testing to food extracts, but many adverse reactions to foods have no known immunopathological basis. Furthermore, skin tests to fruits and vegetables are unreliable and false-negative reactions are common. Epicutaneous testing by pricking a fresh fruit or vegetable and then pricking the skin may be necessary when testing with a commercial extract is negative and true IgE-mediated hypersensitivity is suspected. The avoidance of foods to which there is skin test positivity can also benefit patients with atopic dermatitis.

Skin testing for drug hypersensitivity is much more limited in usefulness. Skin testing to drugs that are proteins, such as insulin or protamine, can be informative, but testing to nonprotein drugs is greatly limited. There may be several reasons for this. First, mast-cell degranulation and the positive skin test depend on the reaction of at least two IgE molecules with an antigen. Most drugs are haptens, and without a “carrier” molecule with multiple drug-binding sites, IgE bridging cannot occur. Second, drug metabolites may be the sensitizing antigens. Finally, it may be that many adverse reactions to drugs do not have an IgE-dependent basis. Penicillin and anesthetics are exceptions. Penicillin sensitivity can be determined with a polyhaptenic synthetic

penicilloyl polylysine (PrePen). Skin test positivity to this so-called major determinant will predict an urticarial reaction to penicillin administration. Unfortunately, this skin test reagent will not predict all hypersensitivity (especially anaphylactic) reactions to penicillin, and one also should test with a fresh penicillin preparation as well as with minor determinants for which a commercial test preparation is in development. Specific IgE testing is useful in evaluation of latex sensitivity and standardized skin test reagent is in development. Total serum IgE usually is not useful in determining whether or not a condition has an IgE-mediated basis. The test is helpful in making the diagnosis of allergic bronchopulmonary aspergillosis and can be used to monitor disease activity. Total IgE also can be used to aid in the diagnosis of the hyper-IgE syndrome, a condition manifested by eczema, recurrent cutaneous and visceral staphylococcal abscesses, and mucocutaneous candidiasis.

In Vitro Activation of Basophils and Measurements of Mediator Release (18)

Circulating basophils possess a high-affinity receptor for IgE and contain histamine that is released when an allergen crosslinks IgE on the surface of the cell. The test is performed either on whole blood or on various preparations of partially purified basophils. Cells from some donors are poor releasers and are not suitable for testing. The testing may be carried out using either cells from the subject or by passive sensitization of donor cells. Methods are available to detect histamine release by either coupling to o-phthalaldehyde with fluorescence detection, labeling by enzymatic addition of radioactive methyl group, or immunoassay. Autoanalyzer-based methods and microplate assays are commercially available. Leukotriene production can be measured by immunoassay. Alternatively, degranulation can be monitored by flow cytometry. These methods are useful in pharmacologic studies of IgE mediated reactions as well as for diagnosis of IgE mediated reactions.

Tryptase, an enzyme mediator preformed in mast cells, is released upon mast-cell activation. It can be measured by immunoassay and is useful for the evaluation of anaphylactic and anaphylactoid reactions and systemic mastocytosis. Tryptase has a plasma half-life of about 90 minutes.

Recently there has been interest in the measurement of eosinophil-derived mediators in tissues and body fluids. Research studies have examined the distribution of eosinophil major basic protein and eosinophil-derived neurotoxin by immunostaining procedures. There is a commercial method available for eosinophil cationic protein measurement, which can be measured in serum, urine, nasal secretions, bronchial secretions, and specimens derived from the gastrointestinal tract. This may provide a useful adjunct method for evaluation of inflammatory aspects of the IgE mediated response. There also are studies of nitric oxide production in sputum and nasal secretions to evaluate inflammatory responses.

Experimentally, a number of other mediators have been studied including prostaglandins, thromboxanes, platelet activating factor, adenosine, chymase, eosinophil major basic protein, reactive oxygen species, kinins, and anaphylatoxins. Presently, none of these tests is utilized clinically.

Cytology

Cytologic examination of nasal secretions and lower respiratory mucus can be helpful in the diagnosis of certain pathological conditions. Nasal mucus may be obtained by scraping the inferior turbinate or by collecting nasal mucus by having the patient blow onto a waxed paper. The latter method will reveal inflammatory cells that have migrated into the mucus and will have fewer contaminating epithelial cells that are obtained when the nasal mucosa is scraped. The mucus is spread thinly on a glass slide, allowed to dry in air, fixed with methanol, and then stained with a solution that is sensitive in detecting eosinophils. Hansel's stain is popular for this purpose, but stains used for making peripheral blood smears may be adequate. The absence of eosinophils does not rule out an allergic condition because neutrophils also migrate into the nasal passages in allergic rhinitis. Furthermore, a secondary sinus infection may result in a greater percentage of neutrophils in the mucus of the allergic subject. Nasal cytology may be most helpful in confirming the diagnosis of nonallergic rhinitis with eosinophilia (NARES) and in differentiating acute viral rhinitis from allergic rhinitis. When a large percentage of the nasal inflammatory cells are eosinophils (usually greater than 50%) and all of the skin tests to common aeroallergens are negative, one should feel comfortable in making the presumptive diagnosis of NARES. It may be difficult clinically to determine the cause of acute coryza in a patient presenting during a pollination season. In such cases, nasal cytology often reveals a high percentage of eosinophils in allergic subjects, but primarily epithelial cells are seen in patients with acute viral coryza.

Lower respiratory mucus can be more difficult than nasal mucus to examine for inflammatory cells. These cells do not stain as well, and it is difficult to differentiate them. Lower respiratory mucus, however, can be examined as a wet mount preparation pressed snuggly between a cover slip and a glass slide. With a little practice, one can recognize lymphocytes, neutrophils, eosinophils, ciliated epithelial cells, erythrocytes, and alveolar macrophages at 400X magnification without the use of staining materials (Fig. 66.1). If eosinophils have been in the airway at high numbers for a fairly long period of time, Charcot-Leyden crystals (elongated, diamond-shaped bodies 15 to 50 μm in length) may be seen.

Cell-mediated Immunity (CMI)

Patch Testing

Patch testing is the preferred method for diagnosing allergic contact dermatitis that is a result of a type IV hypersensitivity response. Performance of this testing requires an experienced investigator who is knowledgeable in the limitations of patch testing, experienced in the application of the test, and capable of interpreting skin reactions and counseling the patient regarding the avoidance of materials that may contain the offending allergen.

A standard set [TRUE test kit (Glaxo Wellcome, Research Triangle Park, NC)] containing 24 common contact allergens is commercially available (20). Most of the allergens used in testing are mixed in white petrolatum, but occasionally an aqueous vehicle is preferred. Only physicians well experienced in patch testing

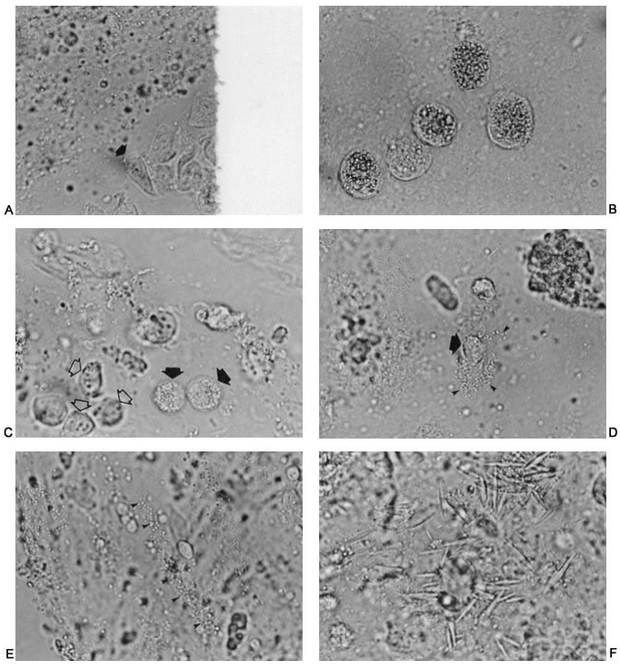

FIGURE 66.1. Photomicrographs of a sputum sample from an asthmatic patient. All of the micrographs were taken of unstained sputum samples pressed between a cover slip and a clear microscope slide. A sample was observed using the 40X objective and the 10X eyepiece. The final magnification of the micrographs is 1860X. (**A**) The broad arrow points to the brush border of a ciliated epithelial cell. Note the cell's apical nucleus and its pointed tail, which serves to fix the cell to the basement membrane. These cells often are sloughed in an inflammatory condition such as asthma or bronchitis. (**B**) A cluster of alveolar macrophages. Note the large intracytoplasmic inclusion bodies and granules. (**C**) The empty arrows point to neutrophils and the solid arrows point to eosinophils. The eosinophils are best distinguished by their fine granules, which easily stand out, especially if one gently focuses with the fine adjust knob on the microscope. The neutrophils are approximately the same size as the eosinophils, but their granules are much less distinct. (**D**) The large arrow points to an eosinophil that is degranulating, and its granules have spilled extracellularly (fine arrows). (**E**) In sputum samples that have been allowed to stand, only eosinophil granules may be seen and intact eosinophils may be difficult to locate. The fine arrows point to eosinophil granules that are somewhat linearly distributed in the sputum sample. (**F**) After sitting at room temperature for several hours, the granules themselves disrupt, allowing proteins to leak. Charcot-Leyden crystals form when lysophospholipase crystallizes out of solution. The presence of these crystals indicates that eosinophils have been present in the past, and it is often difficult to find intact eosinophils where Charcot-Leyden crystals are seen.

should prepare a test material that previously has not been investigated. Unstandardized materials raise the risk of irritant reactions, and marked allergic and toxic reactions can occur if the concentration of the allergen is too high. In addition to avoiding the use of unstandardized testing materials, placing patches on areas with active dermatitis must be avoided.

Testing material is applied from the squeeze bottle to filter paper disks spaced on an aluminized paper strip. The strip is then fixed to a hypoallergenic strip of tape and applied to the patient's back. Care must be taken to be sure that the tape is securely in place; to prevent the tape from loosening when the skin on the back is stretched, the patient should have the back bent forward while the strips are affixed. Once in place, the patient should be cautioned to keep the areas dry while bathing and to avoid situations where sweating might occur. The test should be left in place for 72 hours with the patient instructed to remove those tests where intense itching or irritation occur prior to the time when the tests are to be interpreted.

In Vitro Cytokine Production

Incubation of lymphocytes with antigen results in cytokine production with cellular proliferation. The incorporation of radiolabeled thymidine into dividing cells can be used as an index of hypersensitivity to an antigen. This method remains a laboratory tool, and reliable *in vitro* testing for cell-mediated immunity is not widely available.

Lymphocytes and other leukocytes can be incubated with mitogens, antigens, or peptides for stimulation and response studies. Various lymphokines, cytokines, and interleukins (IL) can be measured in supernatants by enzyme-linked immunoassay using commercially available kits. Interferon-gamma and migration inhibition factor are correlates of cell-mediated immunity. IL-4 production is a correlate of IgE production. Production of IL-2, interferon-gamma, and tumor necrosis factor is typical of Th1 responses and production of IL-4 and IL-13 are typical of Th2 responses. IL-5 induces maturation of and is chemotactic for eosinophils.

In Vivo Challenges

Food Hypersensitivity

Besides the history, the first step in diagnosing IgE-mediated food hypersensitivity is percutaneous skin testing. Foods identified as possible allergens can be confirmed by oral challenges. If a patient has had a life-threatening adverse reaction to a food to which he or she is sensitive, oral challenges should not be performed. Indeed, oral food challenges are rarely necessary in clinical practice but have been used as a research tool to prove that food hypersensitivity can exacerbate some disorders. Double-blind food challenges have been helpful in demonstrating that food hypersensitivity can contribute to atopic dermatitis; egg, peanut, and milk account for the majority of the adverse reactions. A major drawback to this testing is the difficulty in the preparation of gelatin capsules containing freeze-dried foods or food extracts.

NSAIDs

Up to 15% of all chronic asthmatics may have exacerbations of their asthma on ingesting an NSAID. This figure may rise to 70% of patients who have chronic asthma and paranasal sinusitis or nasal polyposis. Many of these individuals will not have a history of adverse reactions because pulmonary function values may not have dropped sufficiently to result in symptomatology. If, however, an asthmatic suspected of having NSAID hypersensitivity requires an NSAID for another condition, an oral challenge may be required under close supervision. Several precautions need to be taken because adverse reactions to these compounds can be life threatening. First, the FEV-1 (forced expiratory volume at 1 second) should be 70% of predicted or better prior to testing. It may be necessary to give a short course of corticosteroids to bring the lung functions up to an acceptable level for testing. One proposed method suggests administering a placebo at 3-hour intervals beginning at 8 a.m. for a total of three doses (21). The FEV-1 is recorded hourly during this time period and for 3 hours following the last dosage. On the second day of the challenge procedure, aspirin is given at 8 a.m. Either a 3-mg or 30-mg dose is used initially, depending on whether or not there is a prior history of a serious adverse reaction to aspirin. Again, the FEV-1 is measured hourly or if symptoms develop. A second dose (30 mg if 3 mg was the first test dose) of aspirin may be given at 11 a.m., and a final dose of 100 mg is given at 2 p.m. Again, the FEV-1 is measured hourly after each dose. If no adverse reaction occurs, the patient returns to the clinic on the third day and is then given 150 mg at 8 a.m., 325 mg at 11 a.m., and 650 mg at 2 p.m., provided that the FEV-1 has not dropped by greater than 20% at any dosage. Such a drop is an indication of a positive test and hypersensitivity to NSAID.

Sulfite

The suspicion of adverse reactions to sulfite (or metabisulfite) should occur after a person has had an adverse reaction following the ingestion of a food or beverage. The adverse reaction may be because of sulfite contained in the food or beverage, to an IgE-mediated hypersensitivity reaction to a food protein, or to some other food additive, such as monosodium glutamate (MSG). It is reasonable to do a sulfite challenge in such individuals to help determine the presence or absence of sulfite sensitivity. In aqueous solutions, sulfite is in equilibrium with sulfur dioxide. Most likely, the sulfur dioxide inhaled during the ingestion of a food or beverage that contains sulfite is the cause of the adverse reaction in the lung. Therefore, sulfite is placed in acidic solutions, such as a commercial lemonade preparation. Sulfite is prepared at 100 mg/mL in water on the day of the challenge. Spirometry is performed, and the FEV-1 must be greater than 1.5 L or 70% of predicted prior to performing the challenge. Theophylline and inhaled corticosteroids are continued. Inhaled bronchodilators are discontinued on the day of the challenge, and cromolyn is discontinued for 24 hours prior to the challenge. The patient is challenged with progressively increasing doses of sulfite (1, 5, 10, 15, 25, 50, 75, 100, 150, and 200 mg) by adding the sulfite to 20 mL of the lemonade mixture and asking the patient to swish the solution in the mouth for 15 seconds before swallowing (22). This allows the sulfur dioxide that is in equilibrium

with sulfite to effervesce and be inhaled into the lung. Increasing doses are given at 10-minute intervals with spirometry being performed just prior to the next dose. A positive test occurs when the FEV-1 drops 20% or more below the baseline value. Placebo challenges may be given periodically among the sulfite challenges to be sure that there is not a spontaneous drop of the FEV-1 occurring as the challenge progresses. Positive challenges should be repeated in a double-blind fashion.

Occupational Asthma

Asthma occurring in the workplace can be from a type I or other immune response or may have an idiopathic etiology. Several approaches can be taken to document occupational asthma (23). The easiest way to reproduce the environmental workplace is to have the patient perform spirometry there. However, this may be time-consuming and cumbersome, and the performance of a peak expiratory flow rate (PEFR) is a practical alternative. The subject should record the PEFR prior to the work shift and at regular intervals throughout the day. Careful notation should be made of what exposures occurred prior to the drop in the PEFR. The PEFR should be followed after the work shift to determine if a late response occurs. Despite positive data on a drop of the PEFR at the workplace, bronchoprovocation with specific materials may be required if compensation is being sought or if there may be several potential offending materials. Bronchoprovocation should be performed by clinicians familiar with the evaluation of occupational lung disease and who are aware of the test's limitations. Detailed guidelines have been published (24). Spirometry performed before and after exposure is necessary to make the diagnosis. The same precautions outlined in the sections above on sulfite and NSAID hypersensitivity should be observed while performing bronchial challenges. In some cases, a specific compound, such as toluene diisocyanate (TDI), may be suspected, and challenge may be performed with this material. For volatile compounds such as TDI, special challenge chambers are required that usually are not available in clinical settings. Challenges to proteins, however, can be performed by mixing the material in an aqueous solution and inhaling the material with a dosimeter delivery system. The protein concentration is increased serially 10-fold until the FEV-1 drops by 20% or more. If concentrations for challenge have not been standardized, it may be necessary to first perform a percutaneous skin test with the material to find a concentration that does not elicit a large response. In most situations the most effective evaluation can be made by monitoring the worker at intervals as he performs his normal duties. This method was particularly useful in dealing with reactivity to colophony in soldering. In all cases where bronchial challenges are performed, the physician must be aware that late responses may occur 4 to 8 hours following the initial drop of the FEV-1. The patient may be at home when this occurs, and instructions must be given on the proper procedures necessary to treat the response. If severe drops in the FEV-1 occur with a challenge, it may be necessary to administer corticosteroids (such as prednisone, 1 mg/kg) at the time of the initial challenge to help prevent the late phase response from occurring. If milder reactions occur, it may be informative to monitor the patient for late phase responses, either as an inpatient or with PEFR monitored at home.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis has an immune basis, but a specific hypersensitivity type cannot be ascribed to any of these conditions. A type III response has been implied because of the frequency in which IgG precipitating antibodies can be detected against a specific antigen. The clinical features of the disease, however, more closely resemble a type IV immune response with granuloma formation, and an eventual progression to pulmonary fibrosis can be seen.

Patients suspected of having hypersensitivity pneumonitis should have a radiograph of the chest. During the acute phase of the illness, a rather diffuse, small nodular appearance is noted. Occasionally, infiltrates can be seen. Eventually, the patient enters a chronic fibrotic phase, and the typical radiographic features of interstitial fibrosis are prominent. Generally, pulmonary function testing reveals a restrictive defect with impaired gas exchange. Thus, spirometry should reveal a proportionate decrease in both the FEV-1 and the forced vital capacity (FVC) with an FEV-1/FVC ratio of 0.75 or greater. In severe cases, the single breath diffusion capacity for carbon monoxide (DLco) will be impaired, and there may be a fall of the PaO2 with exercise.

Heavy exposure to organic dust may result in the production of IgG antibodies to antigenic proteins in the dust. Commonly available antigens for screening for hypersensitivity pneumonitis include thermophilic actinomycetes (*Micropolyspora* and *Thermoactinomyces* species), and avian proteins. The presence of precipitating antibody in the patient's serum is determined by double immunodiffusion in agarose gels. Many other antigens have been implicated in causing hypersensitivity pneumonitis, and these antigens may not be readily available for testing for precipitating antibodies (15). It may be necessary to send the patient's serum to a specific research laboratory where a standardized antigen and the appropriate negative and positive control sera are available. Persons working in an environment with a heavy exposure to an organic dust may develop precipitating antibodies without the presence of clinical disease.

A related disease can be seen with fungal colonization of the sinuses. Precipitating antibodies and IgE antibodies are usually found in allergic fungal sinusitis.

Allergic Bronchopulmonary Mycosis

Allergic bronchopulmonary mycosis (ABPM) occurs when fungal species reside in the airways of allergic asthmatics. Their proteins are very antigenic, and high titers of IgE and IgG antibodies are produced. Additionally, cell-mediated hypersensitivity is likely to occur. Persons suspected of having ABPM should have total serum IgE and precipitins (IgG antibody) to fungi determined, a skin test to fungal extract, a chest radiograph, and a total eosinophil count (25). Some research laboratories are capable of measuring specific IgE and IgG antibodies to *Aspergillus fumigatus*. At present, these tests generally are not available. The majority of patients with ABPM will react on skin testing to the offending fungal allergen. In most cases, *Aspergillus* species are responsible, but sensitivity to other fungal species should be determined if there is a high enough suspicion that aspergillosis exists and testing to *Aspergillus* species is negative. Similar syndromes

have been seen with other fungi, including *Candida*, *Curvularia*, *Stemphylium*, and *Helminthosporium*. Chest radiographs also are important in following the disease process. Thick-walled bronchi, infiltrates, and mucoid impaction may be seen. If the disease is not recognized early, progression to central bronchiectasis and pulmonary fibrosis with bulla formation may occur. Response to treatment can be followed with periodic chest radiographs and total serum IgE levels.

Hereditary Angioedema and Acquired C1 Esterase Inhibitor Deficiency

Complement Measurements

Approximately 15% of patients with HAE will have the antigenic presence of the C1 esterase inhibitor (C1EInh); assays utilizing an antibody to C1 esterase will indicate normal levels and will not reflect the functional impairment of the molecule. Therefore, if the patient is suspected of having HAE and has a normal immunologic assay for the C1 esterase inhibitor, a functional C1 esterase inhibitor assay can be obtained. Because of this inhibitor deficiency, there is excessive activation of C4 and C2. For this reason, serum C4 or C2 levels are the most convenient screening tests for diagnosing this condition. The C4 level is in the low normal or below normal range between attacks and always drops to a very low range during acute attacks. C2 levels exhibit similar behavior. If the C4 level is low normal or below, the diagnosis should be confirmed by measuring functional C1 esterase levels. In addition to low C4 and C1EInh levels in serum, patients with acquired C1EInh deficiency have low serum levels of C1.

Controversial Methodologies

To help diagnose allergic disorders, a number of controversial methods have arisen that have not utilized the scientific method to determine their validity. One such procedure is cytotoxic testing.

This test depends on the addition of food, chemical, and inhalant extracts to peripheral blood leukocytes, which are then observed for microscopic changes. This testing procedure has been demonstrated to be invalid, and federal agencies and many insurance companies have refused to pay for this testing. As a consequence, its use has declined in recent years, but other tests, without scientific merit, claiming diagnostic efficacy in food hypersensitivity continue to appear.

In an effort to find a lower, safer dose of allergen to be used for immunotherapy (desensitization therapy), a test (Rinkel method) that depends on an endpoint titration was developed. This concentration directed the clinician to a treatment dose that typically was considerably lower than the levels used in conventional immunotherapy. As a consequence, many patients on this form of therapy never reached a dosage that could benefit their symptoms. Very weakly sensitive individuals, however, could approach an effective concentration because of the higher concentration of allergen extract subsequently used for immunotherapy. Controlled studies have demonstrated the method to be ineffective in controlling symptoms of ragweed hay fever, while conventional immunotherapy resulted in improvement significantly greater than that of placebo-treated individuals.

Subcutaneous and sublingual provocation testing are used currently primarily by clinical ecologists in their treatment of allergic disorders and any of a variety of conditions that they consider to have an allergic basis, such as migraine headache or multiple somatic complaints. The therapy is based on the principle of finding a dosage of an allergen or chemical that provokes objective or subjective signs in the patient. A neutralization dose that is either slightly weaker or stronger than the provoking dose is then chosen and is injected subcutaneously in an effort to “neutralize” the symptoms. Others have proposed that sublingual solutions of chemicals or allergen extracts also can neutralize symptomatology. At present, no controlled studies have demonstrated that subcutaneous or sublingual neutralization techniques have any validity.

INTERPRETATION

Part of "66 - Allergic Conditions"

IgE-mediated Disease

Skin Test Size and Scoring

Generally, an epicutaneous skin test reaction is considered significant if it results in erythema (flare) greater than 20 mm in diameter and definitely is considered positive if there is an accompanying wheal. The advantages of the epicutaneous (prick) test are its ease and speed of application, infrequency of false-positive reactions, sensitivity, cost, and the rapidity with which results can be obtained. Intradermal skin test reactions generally are considered positive if the erythema has a diameter of greater than 21 mm with an accompanying wheal of 5 to 10 mm. If the erythema is greater than 30 mm with an accompanying 10 mm wheal, the reaction is definitely considered to be positive.

Epicutaneous skin testing is relatively sensitive and specific. Intradermal skin tests are more sensitive and less specific. Quantitative intradermal skin testing with serial dilutions is the standard method for hymenoptera venoms and is recommended for some drugs. Positive skin tests are not uncommon in individuals who do not have active allergic disease. Testing for hymenoptera venoms, drugs and foods should not be performed on individuals who have not experienced allergic reactions. It is important to verify that drugs and unusual extracts do not have nonspecific reactivity.

Despite the wide degree of popularity, there are some problems with skin testing. A mild degree of discomfort is experienced, and there certainly is intersubject variation in the skin reactivity that results in the wheal-and-flare response. Persons with dermatographism can develop erythema and wheals simply from the irritation of the skin with the test device. Patients with extensively inflamed skin, as in atopic dermatitis, may not have enough clear surface area for the test to be applied. Furthermore, patients with atopic dermatitis often have a minimal flare response to the skin test, making the results more difficult to interpret. In these cases, *in vitro* testing may be required. The major role for skin testing is in the determination of IgE-mediated hypersensitivity to inhaled aeroallergens, food allergens, insect venoms, pharmaceuticals that are proteins and penicillin. Most

other pharmaceuticals have not been standardized as skin test reagents, thus dramatically reducing the effectiveness of the skin test in diagnosing the mechanism of possible drug hypersensitivity reactions. Furthermore, skin testing is ineffective in diagnosing hypersensitivity to radiocontrast media or to nonsteroidal antiinflammatory drugs, and it is not capable of detecting persons sensitive to sulfite and other pharmacologic sensitivities.

Total Serum IgE

Total serum IgE should be reported as international units (IU) per milliliter of serum. Results should be interpreted using tables of values by age and country or region, because levels vary widely because of infections and infestations with parasites. Serum from newborns may contain very low levels of IgE. Therefore, two sets of standards may be required, one for the adult range and one for the range of IgE values seen in the pediatric population (26).

Specific IgE Antibody Scoring

Specific IgE antibody usually is scored by arbitrarily breaking down the total radioactivity counts into classes. The interpretation of the test results should be restricted to the class designation and not to the actual total radioactivity counts. The class determination is made by comparison of the allergen-specific IgE content in test samples to positive and negative controls. The most common scoring systems assign ranges from zero to four or zero to six. Zero indicates a clearly negative result and one usually an equivocal result. Scores of two and higher are increasingly positive. There is little correlation between severity of allergic manifestations and degree of positivity. There are a number of factors that can lead to false results including high levels of total IgE, the presence of low affinity IgE antibodies, low amounts of some allergenic proteins coupled to the solid-phase, and the presence of low, but clinically significant amounts of specific IgE antibody. The presence of specific antibodies of IgG, IgA, and IgM classes may decrease the levels of specific IgE antibody by competing for allergen sites, but usually does not reduce the level to negative. This effect can be overcome by the use of matrices that have a very high protein binding capacity, and the use of enriched extract preparations with interfering materials removed by dialysis or gel filtration.

Some manufacturers recommend the use of quantitative scoring systems, which are calibrated with either a total IgE binding curve or by IgE binding to a specific allergen, commonly birch pollen. These systems are somewhat misleading because they are not truly quantitative, and they are dependent on binding equilibrium. Comparison of specific IgE binding to calibration curves assumes that the magnitude and distribution of antibody binding affinities are similar in both systems. In addition almost all patients demonstrate an IgE response to multiple allergenic components and epitopes of allergenic components. One cannot assume that each of these components is present on the solid phase in sufficient excess to not be a limiting factor in binding capacity. An additional complication is the binding of IgE to epitopes that may be clinically insignificant, such as carbohydrate side chains and low affinity cross-reactions. These are very common in food allergens.

The standard commercial assays for specific IgE do not utilize negative controls for each allergen and are usually not performed in duplicate. Controls also may be necessary for verifying that certain sera do not bind to the matrix and do not exhibit high nonspecific binding (27). It may be necessary to dilute some high total IgE sera before measuring specific IgE antibodies. Methods that use larger amounts of serum and longer incubation times more commonly exhibit high non-specific binding. Because multiple specific IgE tests usually are performed on each serum and several sera are typically tested at one time, there are errors that can result from mistakes in pipetting serum or the solid phase as well as from spilling labeled antibody, losing or transferring solid phase, or sticking to tubes. These can be decreased substantially by performing the assay in duplicate and rejecting results that do not agree within 35%.

Correlation of Specific IgE Antibody and Skin Testing with Clinical Disease

Either skin testing or specific IgE antibody testing can be used to determine the etiology of allergic disease (28). Intradermal skin testing is the most sensitive and least specific method. Prick and puncture skin tests are somewhat less sensitive and more specific; and are the most commonly employed methods for determining etiology. Specific IgE antibody testing is significantly less sensitive and appears to be more specific than skin tests, when compared to provocation tests. There are some relative indications for specific IgE antibody testing as described in Table 66.4.

TABLE 66.4. ADVANTAGES OF *IN VIVO* AND *IN VITRO* METHODS FOR DIAGNOSING ALLERGEN-SPECIFIC HYPERSENSITIVITY

Advantages of Skin Testing	Advantages of *In Vitro* Testing
High specificity	Useful when skin disease (e.g., eczema or dermatographism) preclude skin testing
High sensitivity	Useful in epidemiological studies of atopy
Results with minutes of application	Useful for identifying cross-reactive allergens (RAST inhibition)
Low cost	

The correlation of specific IgE antibody results with skin test results is allergen dependent. For most reasonably well-characterized allergen extracts the range is from 60% to 98% correlation, with an average of 75% to 80% agreement. Allergen extracts used for skin testing and for preparing solid-phases for *in vitro* testing vary widely in potency and composition. The standardized potency extracts used for skin testing for common aeroallergens are not optimal for preparing solid phase reagents. There are no standards of potency for most extracts, which vary by orders of magnitude among both manufacturers and lots. Source materials are not always consistent and proprietary methods may be used in preparation. Fungal extracts are a particular problem with both identity of genus and species and variation among strains, and with continued passaging in culture. Although most extracts are glycerinated to control proteolysis and degradation, this does not always provide a high degree of stability. Diluted extracts may degrade rapidly and may need to be replaced daily.

The finding of the presence of specific IgE antibodies by either skin testing or laboratory testing does not establish the presence of allergic disease. A complete medical evaluation correlating the presence of IgE-mediated reactivity with clinical history, medical findings, and symptoms is necessary. In some cases, challenge testing may be necessary. A significant fraction of the population has IgE-mediated reactivity with either subclinical or inactive allergic disease. The presence of IgE against foods and hymenoptera venoms is common particularly in patients with no histories of adverse reactions. IgE antibodies against a series of related foods in patients with a single food sensitivity may reflect low affinity cross-reactivity without clinical manifestations.

Cell-Mediated Immunity

Patch Test Scoring

The patch test results are interpreted 72 hours after their application. Before removing the test strips, care must be taken to ensure that sites where the test materials were placed can be identified accurately. The sites must be analyzed by an experienced clinician who is adept at interpreting the differences between irritant and true allergic responses. If only mild erythema is present at the site, the reaction should be recorded as doubtful. A site with erythema and some induration and possible papule formation may be interpreted as weak. Strong reactions have erythema with papules and vesicles, and extreme reactions will have bulla formation. Irritant reactions, if strong, will have a sharply demarcated border of erythema, but in allergic reactions, the border will not be so clearly defined. It is very difficult, however, to distinguish between weak irritant and weak allergic reactions.

In Vivo Challenges

Spirometry

Besides skin testing for IgE-mediated disorders, respiratory challenge in association with spirometry offers one of the most sensitive, objective determinations of an individual's clinical reactivity to a given allergen or other provoking substance. A positive response usually is defined as a drop in the FEV-1 by 20% below baseline values. If a positive response is found to aspirin, cross-sensitivity to other NSAIDs is implied because of the pharmacologic ability of these compounds to inhibit cyclooxygenase. Because some NSAIDs are more potent in this ability than others, adverse reactions may be more severe with compounds other than aspirin. Patients should be advised to avoid all aspirin and aspirin-containing compounds and be given a list of currently available NSAIDs. They should be told to notify their pharmacy on the assumption that other NSAIDs may appear on the market in the future. Acetaminophen usually is tolerated but also may cause a drop in the FEV-1 when given at high doses to NSAID-sensitive individuals. Should a patient who has a positive aspirin challenge require a NSAID, a desensitization usually can be accomplished. The patient can then take the drug without adverse effects as long as the medication is taken regularly. If several days elapse between doses, sensitivity may recur. Persons found to be sensitive to sulfite and other food additives should be counseled about foods and beverages that contain the material. Accidental exposure may occur, however, and patients should have a ß-adrenergic inhaler or epinephrine for subcutaneous injection should a reaction occur. Persons with adverse reactions to environmental materials in the workplace should be relocated. Retraining may be necessary for extremely sensitive individuals if avoidance in the particular environment is not possible. Persons with a hypersensitivity pneumonitis must avoid the material to which they are sensitive or face the possibility of a progressive obstructive and possibly restrictive pulmonary disease.

Allergen challenge tests can be used as a definitive method for diagnosis of respiratory allergy. These methods are used routinely in Europe, but primarily restricted to research centers in the United States. Bronchial inhalation challenge should be performed by a standardized method (28), using spirometry to determine reactivity. Nasal inhalation challenges can use several methods to detect reactivity including rhinomanometry, sneeze reflex, mediator production and blockage. Conjunctival provocation is less expensive, because it does not require instrumentation.

Reproduction of Clinical Symptoms

In some *in vivo* challenges, it is difficult to obtain an objective measure as sensitive as spirometry. The method of choice for diagnosis of non–life-threatening food allergy is the double-blind, placebo-controlled food challenge (29). Skin testing and/or specific IgE antibody determination should be used in patients with histories of severe anaphylaxis. Before challenge testing the patient should be maintained on a strict elimination diet for the suspected foods, especially if the manifestations are of a chronic nature.

Sting challenge testing is considered by many to be the most reliable method to evaluate *Hymenoptera* venom allergy (30). Various studies show 25% to 60% of patients with recent histories of systemic reactions from insect stings react to an intentional sting challenge. This method is usually restricted to research centers and, for the most part, has been supplanted by skin testing.

Hypersensitivity Pneumonitis

Precipitins can be found in the serum of most individuals suffering from hypersensitivity pneumonitis. However, precipitins can be detected in the serum of as many as 50% of persons with similar but asymptomatic exposure. Therefore, clinical data including chest radiographs are necessary for establishing the diagnosis. Lymphocyte transformation to antigen is seen less often (16%), but this is not a readily available laboratory test and is done only in research centers at present. Definitive diagnosis may require extended removal from exposure and rechallenge. Antibody tests are of very limited value in the diagnosis of hypersensitivity pneumonitislike conditions because of exposure to small molecules including isocyanates, formaldehyde and other reactive chemicals. Challenge tests with reactive chemicals are potentially dangerous and may result in long-term or irreversible changes. Histories of exposure and spirometric and radiographic evaluation, and lung biopsy, when needed, should be sufficient for diagnosis of these cases.

Allergic Bronchopulmonary Mycosis

Diagnostic criteria for allergic bronchopulmonary mycosis (ABPM) include the presence of asthma, a positive immediate skin test reaction to the fungus, an elevation of the total IgE, and precipitins to the fungus. Additional unessential criteria include the radiographic findings of infiltrates and central bronchiectasis. The best screening test for allergic bronchopulmonary aspergillosis (ABPA) is the presence of a very high level of specific IgE against *Aspergillus* allergens. Tests for IgE antibody against single allergens that exhibit a high correlation with the presence of ABPA are under development. Responsiveness to therapy can be monitored by following the total serum IgE and the chest radiograph. Persons with sufficiently advanced disease may require continuous corticosteroid therapy. Remissions can be achieved in patients in whom the disease has been detected at an early stage, before irreversible changes have occurred.

Hereditary Angioedema

A patient with angioedema who had the onset of clinical symptoms before the age of 20 years and who has a low serum C4 should be suspected of having hereditary angioedema (HAE). If the C4 is low, an immunologic assay for the C1 esterase inhibitor (C1EInh) should be obtained. A low level confirms the diagnosis of HAE. In 15% of individuals with HAE, however, the immunologic assay may be normal, indicating the presence of an antigenic material in plasma that is functionally inactive. In cases of angioedema where the C4 is low and the immunologic assay for C1EInh is normal, a functional assay for C1EInh should be obtained. A low functional assay confirms the diagnosis.

In patients with angioedema beginning in the third decade or later, a C4 and C1EInh should be determined. Many cases of acquired C1EInh deficiency are caused by immune complexes activating C1 with the subsequent binding and consumption of C1EInh. If abnormal, a search for another underlying disorder should be sought, as indicated in the methodology section.

Receptor Assays of the Clinical Laboratory

Barry G. England

James B. Smart

The coordinated behavior of all cells within a multicellular organism is necessary if the organism is to function normally. Intercellular communication is a prerequisite of coordinated cell behavior and must be maintained throughout growth and development of the organism, as well as during the period of adult homeostasis. Any serious breakdown in the communication system inevitably leads to malfunction of one or more cells within the organism, perhaps leading to a disease process, or a more serious disruption that may result in death. A variety of communication or signaling mechanisms exist within the body that include nervous connections, short and long distance chemical signaling compounds that are borne by blood or lymph, and intracellular and transcellular signaling compounds that perform an autocrine or paracrine communication function. It is the interplay between the various signaling compounds and their respective target cells that maintains normal cell growth and function. Loss of communication may lead to uncoordinated growth of a cell, or group of cells, that if not corrected, may result in the uncontrolled and aggressive growth of a subset of cells (such as cancer) with resultant injury to normal tissues. A hormone is “a chemical substance, formed in one organ or part of the body and carried in the blood to another organ or part. Depending on the specificity of their effects, hormones can alter the functional activity, and sometimes the structure, of just one organ or of various numbers of them.” Blood-borne hormones are equally accessible to all vascularized tissues, yet it was recognized very early by Bayliss (1) that hormone action was restricted to specific target tissues. This observation lead to the concept of a recognition site in the target cells that is capable of concentrating the hormone and an effector site that elicits the specific hormone action (2). Nonresponsive tissues lack the hormone binding and/or effector sites.

The past two decades have witnessed great advances in the knowledge of receptors and hormone-mediated receptor action in hormone responsive tissues. This chapter will be devoted to the discussion of a selected few of the host of cell regulatory or signaling substances (hormones, growth factors) and their receptors, that provide for specificity in hormone/growth factor interaction with cells and tissues within the organism. In this discussion, we will refer to the hormone or any other signaling substance that binds to a receptor as a ligand. Formation of a ligand-receptor complex in a cell initiates a sequence of reactions that elicits a function specific to that cell. Target cells have receptors that are specific for that cell type, although a cell may have many different receptors, each of which regulates a different process within the cell. The binding affinity of a receptor-ligand complex defines the strength of attraction between the ligand and the receptor, whereas binding *specificity* describes the ability of the receptor to recognize a specific ligand.

CURRENT CONCEPTS IN RECEPTOR STRUCTURE AND FUNCTION

Part of "67 - Receptor Assays of the Clinical Laboratory"

Cell growth and differentiation is regulated by a variety of chemical regulators that act via cell surface receptors or via intracellular receptors. These include hormones that are released into the blood and act on distant targets, and growth factors and cytokines that effect regulation of cell function through autocrine or paracrine mechanisms. Several regulators such as steroids, vitamin D, retinoic acid, and thyroid hormones interact with intracellular receptors, which bind to hormone dependent transcription regulatory regions (hormone response elements) on DNA and effect gene expression. Other regulators of cell function are hydrophilic molecules that exert their action upon the cell through their respective cell surface, or membrane-bound receptors. These include the peptide hormone products of the endocrine glands, and a host of other regulatory compounds, including growth factors that exhibit local control of cellular growth. Amongst these are the peptide class of regulators, known collectively as peptide regulatory factors (PRF). The nomenclature used in the identification of PRF has been based upon their biological action, or the assay system used in their original identification and isolation. For example, two growth factors that were isolated from transformed cells and shown to be capable of inducing the phenotypic transformation of untransformed cells, were identified as transforming growth factors (TGFα and TGFß) (3). Epidermal growth factor (EGF), gonadotropin releasing hormone (GnRH), somatostatin (SS), insulinlike growth factor I (IGF-I), insulinlike growth factor II (IGF-II), and the several fibroblast growth factors, are all growth regulating agents for which receptors have been found in normal and malignant

tissue (4). Cellular receptors can be conveniently classified into two general groups based upon their location within the cell: (i) those that are located within the cell (nucleus or cytoplasm), and (ii) those that are associated with the plasma membrane. Extensive investigations currently are underway to ascertain the role these molecules may play in the growth of normal and tumor tissue, and to examine their utility in determining the prognosis or treatment of endocrine responsive tumors.

Intracellular Receptors

The first steroid receptor was described by Jenson (5) who characterized the binding of tritiated estradiol in tissues that respond to estrogenic stimuli (estrogen target tissue). Radioactive estradiol administered to the animal was found only in target tissues and other gonadal steroids did not accumulate in estrogenic target tissue (uterus, vagina, and pituitary). Early characterization of the estrogen receptor relied upon the use of sucrose density gradient separation of nuclear and cytosolic cell fractions, which yielded semipure fractions of the estrogen binding protein. Further purification was accomplished by gel electrophoresis and column filtration methods. In these early receptor studies, it was observed that unoccupied receptor was recovered from the “cytosolic” fraction of the cell and that only steroid-receptor complexes were found in the nucleus. This observation led to the two-step theory of steroid receptor action. In step 1 the lipophilic steroids freely migrate through the plasma membrane into the cell where they bind to the unoccupied receptor and the complex then is transported rapidly to the nucleus where the step 2 is binding of the complex to the DNA (6).

Estradiol, and the other ligands that bind to intracellular receptors, usually are hydrophobic and lipophilic, a property that facilitates their movement through the lipid-rich cell membrane. These hormones alter the pattern of gene expression and are responsible for slower and lasting effects on the cell. Although it generally had been well accepted in the 1970s and 1980s that steroid hormone receptors were present in the cytoplasm of the cell, and that rapid translocation of the complex to the nucleus preceded gene expression; understanding of the nature and action of intracellular receptors continues to evolve. In target cells that previously had been exposed to hormone, the hormone-receptor complex is bound tightly to the nucleus and is no longer found in the soluble fraction (cytosol) of tissue extracts. It now is thought that unoccupied gonadal steroid receptors are present in the nucleus in a loosely bound form and are contained in the “cytosolic” fraction of tissue extracts because it is removed easily from the nuclear envelope with low salt buffers. Data verifying the intracellular localization of steroid receptors awaited the development of specific monoclonal antibodies against the steroid receptors. These studies yielded a wealth of information regarding the location of these receptors within the cell, as well as permitting immunoaffinity purification of these labile proteins. Immunocytochemical staining of frozen sections of human breast cancer tissue showed clearly that the gonadal steroid receptors, which appear in the cytosol after tissue homogenization, are localized within the nuclear compartment of the intact cell. Similar observations have been made using the technique of enucleation to minimize contamination between the cytoplasm and nucleoplasm (7). Thus, procedures capable of localizing gonadal steroid receptors within intact cells or isolated cellular components have shown that ER and PR are confined to the nucleus of the responsive cells (8). The exception seems to be that unoccupied receptors for glucocorticoids and mineralocorticoids are located in the cytoplasm and the ligand-receptor complex translocates to the nucleus. Therefore, current interpretation of the location and function of nuclear receptors is more complex than originally thought and must accommodate an increasing variety of nuclear receptors and subforms of several of those receptors.

The successful cloning of nuclear receptors during the 1980s and the introduction of molecular biology techniques to the study of nuclear receptors has greatly increased our understanding of the structure-function relationships among the various nuclear receptors, and their similarities and differences (9, 10, 11, 12, 13). This receptor superfamily comprises approximately 150 distinct proteins that show similarities in their molecular structure, that function via a similar ligand-dependent mechanism of action, and are thought to share a common ancestry. Their primary function is to reconcile the transcriptional response of target cells to the gonadal steroids (androgens, estrogens, and progestins), adrenal steroids (glucocorticoids and mineralocorticoids), thyroid hormones, retinoid hormones, or Vitamin D3. Members of the nuclear receptor superfamily (Fig. 67.1) share the following characteristics; (i) a variable amino-terminal transcription activating domain (TAD) that shows specificity of binding to the respective ligand, (ii) a central and well-conserved DNA-binding domain (BDB) that binds to specific hormone response elements (HRE) on the nuclear DNA, and (iii) a carboxy-terminal ligand-binding and dimerization domain (LBD) that interacts with various factors of the transcriptional machinery, and the DNA-binding domain (DBD) (14).

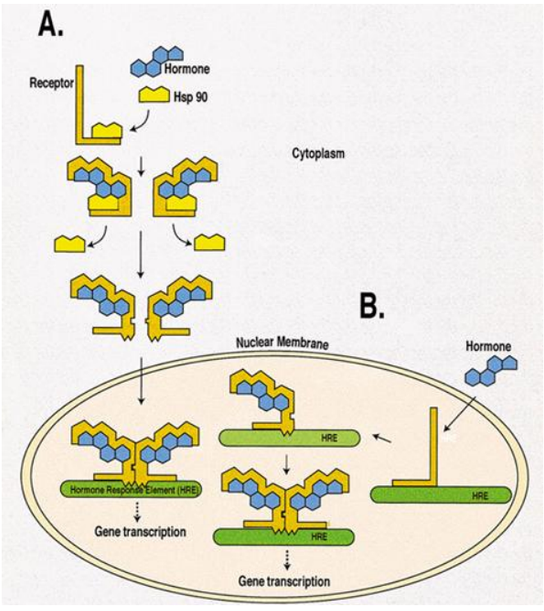

FIGURE 67.1. Members of the nuclear receptor superfamily contain (i) a variable amino-terminal transcription activating domain (TAD) that shows specificity of binding to the respective ligand, (ii) a central and well conserved DNA-binding domain (BDB) that binds to specific hormone response elements (HRE) on the nuclear DNA, and (iii) a carboxy-terminal ligand-binding and dimerization domain (LBD) that interacts with various factors of the transcriptional machinery, and the DNA binding domain (DBD). Type I nuclear receptors in the absence of the cognate hormone are maintained in an inactive state. Heat shock protein (Hsp) 90 (and perhaps Hsp70 and Hsp56) inhibitory proteins bind to the receptor, covering the DBD, and prevent binding to DNA. Ligand binding to the receptor induces a conformation change in the ligand-receptor complex that affects the release of the Hsp binding proteins. Loss of Hsp converts the receptor to a smaller, active form (4S) capable of binding to DNA. Hormone binding and the resultant dissociation of the inhibitory protein enable formation of homodimers, which bind with high affinity binding to the DNA HRE. The DBD of approximately 70 amino acids is highly conserved and forms two fingers (putative DNA-binding site) that are stabilized by a chelated Zn^{++} ion and interact specifically with HRE on the target genes. Activation of receptor-mediated gene transcription then occurs in response to the activated ligand-receptor homodimer complex binding to the HRE.

The nuclear receptors have been divided into three subfamilies within the nuclear receptor superfamily (15). Type I, classical or steroid receptors include those that bind androgens, estrogens, progestins, glucocorticoids, and mineralocorticoids. Type II receptors include those that bind the thyroid hormones, retinoic acid, and vitamin D3 (14). A third class of nuclear receptors (Type III) has been identified through cDNA clones that encode for polypeptides with structural features suggestive of cryptic steroid hormone receptors. These putative nuclear receptors that have not been linked with any known biologically active hormone or ligand, are described as orphan nuclear receptors (16, 17, 18).

Within the Type I steroid hormone receptors subfamily, there are two different forms for the following steroid receptors: glucocorticoid receptors α and ß, progesterone receptors A and B, and estrogen receptors α and ß. Type I nuclear receptors in the absence of the cognate hormone are maintained in an inactive state. Heat-shock protein (Hsp) 90 (and perhaps Hsp70 and Hsp56) inhibitory proteins bind to the receptor, covering the DBD, and prevent binding to DNA. Ligand binding to the receptor induces a conformation change in the ligand-receptor complex that affects the release of the Hsp-binding proteins (19, 20) from the 8S form of the receptor. Loss of Hsp converts the receptor to a smaller, active form (4S) capable of binding to DNA (6, 21, 22, 23). Hormone binding and the resultant dissociation of the inhibitory protein enables formation of homodimers,

which bind with high-affinity binding to the DNA HRE (17). The DBD of approximately 70 amino acids is highly conserved and forms two *fingers* (putative DNA-binding site) that are stabilized by a chelated Zn^{++} ion (24) and interact specifically with HRE on the target genes. Activation of receptor-mediated gene transcription then occurs in response to the activated ligand-receptor homodimer complex binding to the HRE. The mechanism by which activated receptor binding to DNA effects gene transcription, although incompletely understood, is under active investigation (15, 16, 17). It appears to involve a hormone- and ATP-dependent phosphorylation-dephosphorylation cycle (25). Some altered proteins appear to have the ability to “turn on” the transcription of certain proteins, without evidence of binding to DNA (26). Another highly conserved domain of approximately 250 amino acids, the ligand-binding domain (LBD), exhibits 70% to 95% homology for the same steroid receptor when examined in different species (27). Binding affinity of the receptor to DNA increases dramatically upon formation of the hormone-receptor complex.

Type II receptors of the nuclear receptor superfamily include

the thyroid hormone receptor, the vitamin D receptor (28) and the retinoid receptors (29). These receptors are not associated with Hsp molecules and bind to DNA even in the absence of ligand. Receptors bound to DNA in the absence of ligand interfere with the preinitiation complex and cause “silencing” of gene transcription. Binding of the ligand to the DNA associated Type II receptor reverses the “silencing” effect and initiates gene activation. Modulation of gene transcription often requires the presence of additional protein factors that bind to DNA response elements (enhancers, repressors, silencers). The specific transcription factors also may be activated by receptor phosphorylation. Structural changes of certain receptors within this superfamily have been described, which affect the ability of the receptor to regulate normal cell function, e.g., the variant T3 receptor, rat (c-erb-Aα2) binds DNA but lacks the ability to bind T3 or to activate gene transcription (30, 31, 32).

Neoplastic changes could be envisioned in which hormonal control of cell growth is lost because of the inability of an altered receptor to bind ligand, or alternatively DNA binding may be lost and ligand-binding ability maintained. Either of these changes may prevent the hormonal signal from reaching the specific gene and eliciting its subsequent action.

The identification of the orphan nuclear receptor subfamily has stimulated research into the discovery of new hormone response systems in which the receptor's ligand/function are currently unknown. The existence of a large number of potential new receptors offers the opportunity to develop novel therapeutic agents that may be efficacious in the treatment of a variety of illnesses. For a more complete review of this intriguing area of research see (18, 28).

Membrane-Bound Receptors

The membrane-bound receptors possess three distinct segments: (i) an extra cellular domain that includes a recognition site that exhibits ligand-binding specificity, (ii) a transmembrane domain, and (iii) an intracellular domain containing an effector or catalytic site. Membrane-bound receptors can be classified broadly into three different categories: allosterically activated enzymes; receptors coupled to an enzyme system via the G protein; and membrane-bound receptors that form a channel through which the transport of ions and other small molecules into and out of the cell is regulated. Water-soluble hormones, growth factors, or PRF occupy binding or recognition sites on the extracellular domain of membrane-bound receptors and generate an intracellular signal by eliciting a hormone-receptor response that is specific to the occupied receptor. Receptor-mediated responses may include activation of any of a number of receptor-associated enzymes such as: adenylate cyclase, guanylate cyclase, phosphodiesterases, protein kinases, phospholipases, and lipid methylases. Receptors also may elicit their response by interacting with stimulatory or inhibitory G proteins that are part of a complex allosteric enzyme system, or they may control the transport of specific ions or selected small molecules into or out of the cell. Other receptor actions may result from an interaction with select cytoskeletal elements, membrane lipids, chromatin proteins, or the receptor enzymatic activity may be regulated by hormone mediated phosphorylation or glycosylation. In contrast to intracellular receptors, activation of membrane receptors usually results in a rapid response by the target cell, usually within seconds or minutes.

Tyrosine Kinase Receptors

The single membrane-spanning tyrosine kinase receptors include: insulin, epidermal growth factor receptor (EGFr), platelet-derived growth factor receptor, fibroblast growth factor receptor, hepatocyte growth factor receptor, and Ephlike receptor protein kinases (33, 34). These receptors (Fig. 67.2) are monomeric molecules, with a single membrane-spanning moiety and tyrosine kinase activity on the intracellular domain. Upon binding to the ligand, the receptor dimerizes and undergoes conformation changes that activates the tyrosine kinase, autophosphorylating the tyrosine residues in the intracellular domain of the receptor. In addition, autophosphorylation of the tyrosine kinase receptor enhances receptor kinase activity toward cytosolic and membrane substrates that are external to the receptor. Signaling proteins bind to the phosphorylated tyrosine sites through a specialized domain, the src homology domain (SH2) that recognizes the phosphotyrosines in specific amino-acid sequences. The unique combinations provide binding specificity for the interaction of each receptor with its respective SH2-containing signaling proteins. Binding of the signaling proteins to the phosphorylated intracellular domain may elicit any of several actions; the recruitment of soluble proteins in the cytosol to the plasma membrane, allosteric activation or inactivation of specific enzymes, enhancement of mitogenic effects and cell growth, control of Ca^{++} metabolism, induction of gene transcription, activation of glycolytic enzymes, stimulation of cell motility, etc.

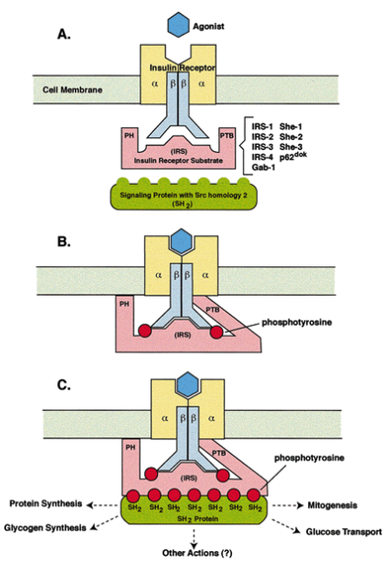

FIGURE 67.2. The single membrane-spanning tyrosine kinase receptors are monomeric molecules, with a single membrane-spanning moiety and tyrosine kinase activity on the intracellular domain. Upon binding to the ligand, the receptor dimerizes and undergoes a conformation change that activates the tyrosine kinase with autophosphorylation of the tyrosine residues in the intracellular domain of the receptor. Signaling proteins bind to the phosphorylated tyrosine sites through a specialized domain, the src homology domain (SH2) that recognize the phosphotyrosines in specific amino-acid sequences. Binding of the signaling proteins to the phosphorylated intracellular domain may elicit any of several actions; the recruitment of soluble proteins in the cytosol to the plasma membrane, allosteric activation or inactivation of specific enzymes, enhancement of mitogenic effects and cell growth, control of Ca^{++} metabolism, induction of gene transcription, activation of glycolytic enzymes, stimulation of cell motility, etc.

The insulin receptor also belongs to the family of receptors with intrinsic tyrosine kinase activity. However, this receptor is a disulfide bound heterotetramer with two α subunits and two ß subunits. The α subunits form the extracellular binding site for insulin and the ß subunits form the transmembrane and intracellular aspects of the insulin receptor molecule. Ligand binding to the extracellular binding site causes autophosphorylation of the receptor but does not create effective binding sites for the SH2-containing signaling proteins. Rather the phosphorylated intracellular domain binds to one of a family of insulin receptor substrate (IRS) phosphoproteins. Phosphorylation of tyrosines on the IRS protein creates docking sites for the various signaling proteins that transmit the signal downstream. The final cellular effects include actions such as the translocation of vesicles containing GLUT4 glucose transporters from the intracellular pool to the plasma membrane, activation of protein or glycogen synthesis, initiation of gene transcription, etc. Several IRS domains have been described that interact with sites on the receptor, with structural components of the plasma membrane, or with SH2 domains on signaling proteins. The pleckstrin homology (PH) domain recognizes polar lipids in the plasma membrane that are adjacent to the receptor, the phosphotyrosine binding (PTB) domain that recognizes phosphotyrosine in the amino acid sequence asparagine-proline-x amino acid-phosphotyrosine (NPXpY), and multiple phosphotyrosines that are bound by the SH2 domains of the signaling proteins. SH2 adaptors often have SH3 domains that recognize specific amino acid sequences of other intracellular signaling proteins (34).

IRS form a growing family of proteins that are phosphorylated, bind to the insulin receptor, and provide docking sites for the SH2-containing signaling proteins. Nine members of this fam-ily have been described to date (IRS-1, IRS-2, IRS-3, IRS-4, Gab-1, three Shc isoforms, and $p62^{dok}$). The PH and PTB domains of the IRS recognize phosphotidylinositides in plasma membrane locations adjacent to the insulin receptor and phosphotyrosine 960, which forms part of the NPXpY recognition site on the insulin receptor ß subunit just inside the membrane, respectively. The exact function of these IRS binding domains and their respective recognition sites is not presently known. Two different types of SH2-containing proteins have been described,

SH2-adaptor proteins and SH2-enzymes. Each of the two SH2 protein types consists of several different entities with their own unique actions that account for the multiplicity of cellular effects observed in response to insulin stimulation. Mutational changes in the insulin receptor are rare and unlikely to account for the insulin resistance that is observed with non–insulin-dependent diabetes nor has a single susceptibility gene for type 2 diabetes been identified. However, the multiplicity of insulin receptor signaling cascades that have been identified and genetic and nongenetic factors that can disturb insulin signaling could account for the wide variety of insulin sensitivities observed in diabetes [For a detailed description of the alterations in the insulin signaling cascades see Virkamaki (33).].

G Protein-Coupled Receptors

The guanine nucleotide-binding protein (G protein) coupled, seven-transmembrane segment, receptors comprise the largest family of membrane-bound receptors with an exceptional variety of agonists that utilize members of this family of receptors. Approximately 1,000 different receptor members of this superfamily have been identified since the first G protein receptor was cloned (35, 36, 37). Not only do many of the peptide and glycoprotein hormones, biogenic amines, lipids, nucleotides, and ions utilize members of this superfamily of receptors, they also are used to convert exogenous stimuli such as light, odors, and taste to intracellular signals. The receptors do not have inherent enzymatic activity, nor do they form an ion channel through the plasma membrane. The G protein-coupled receptors (Fig. 67.3) function as activators of G protein in the intracellular space. The function of the G protein is to transmit the receptor signal to effector molecules on the plasma membrane. The various heterotrimeric G proteins are made up of an α subunit (40 to 46 kd), a ß subunit (35 to 38 kd), and a γ subunit (7 to 9 kd). The ß and γ subunits, which are tightly bound and function as a single unit, are loosely bound to the α subunit forming a single protein complex. The α subunit contains a guanine nucleotide-binding site that binds either GDP or GTP. The G protein (αßγ heterotrimer), with GDP bound to the guanine nucleotide-binding site, is associated with the resting stage receptor. Binding of the hormone, or agonist, to the receptor induces a conformation change in the G protein complex, reducing the binding affinity for GDP, which leaves the guanine-binding site and is rapidly replaced with GTP. Upon binding GTP to the α subunit, the α subunit-GTP complex disassociates from the βγ complex, yielding two protein complexes that are capable of eliciting a cellular response by binding with effector proteins at the plasma membrane. The specific cellular action of the many elicited by agonist-G protein-coupled receptors depends upon the agonist, its cognate receptor, and the type of G protein and effector proteins that are activated. There are four families of G proteins: those that stimulate adenylate cyclase (G_s), those that inhibit adenylate cyclase (G_i), those that stimulate phospholipase C (G_q), and those that regulate ion channels (G_{12}). The activated G proteins carry signals along the plasma membrane but do not cross the cytoplasmic space. Rather, they regulate the concentration of small second messengers that can diffuse across the intracellular space, by the activation or inhibition of specific “second messenger” enzymes. The activated GTP-α subunits regulate intracellular concentrations of second messengers by controlling the cAMP enzyme (adenylate cyclase), and the phospholipase Cß enzyme [inositol 1,4,5-triphosphate (IP_3) and 1,2-Diacylglycerol (DAG)]. $G_{s\alpha}$ stimulates adenylate cyclase, Gi_{α} inhibits adenylate cyclase, and $G_{q\alpha}$ activates phospholipase Cß. $G_{ß\gamma}$ subunits regulate the activity of adenylate cyclase II and IV, phospholipase C subtypes ß1, ß2 and ß3, phospholipase A, K^+ and Ca^{++} channels and form links to the tyrosine kinase pathways (34). The second messenger DAG stimulates protein kinase C, a membrane bound enzyme that phosphorylates serine and threonine amino-acid–containing side chains in proteins. IP_3 induces the release of stored Ca^{++} from the endoplasmic reticulum (ER) by binding to a calcium channel in the ER. Calcium and cAMP are important intracellular mediators of a number of cellular events including gene transcription. Calcium and cAMP can both synergize or antagonize in their regulation of gene expression through actions on several transcription factors, including the cyclic AMP response element binding (CREB) protein. The dephosphorylated form of CREB, normally bound to the transcription response element, is inactive until serine-133 is phosphorylated. In general, cAMP promotes gene transcription through the protein kinase A mediated phosphorylation of serine-133, and calcium prevents transcriptional activation by the phosphorylation of serine-142. However, another calcium dependent kinase, calcium-calmodulin–dependent protein (CaMK IV), promotes transcription by phosphorylating serine-133. Thus, calcium can promote or prevent the activation of gene transcription.

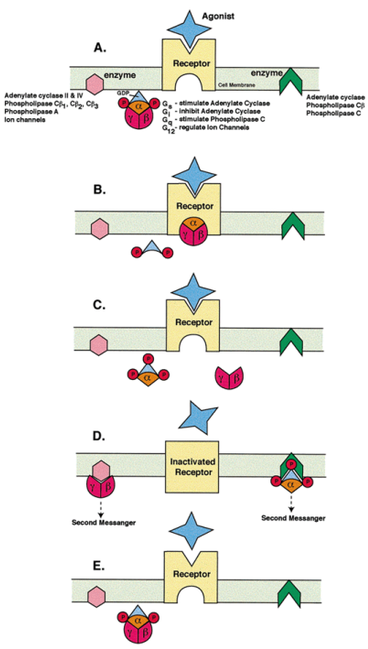

FIGURE 67.3. The G protein coupled, seven-transmembrane segment receptors comprise the largest family of membrane bound receptors. The G protein functions as a transmitter of the receptor signal to effector molecules on the plasma membrane. The various heterotrimeric G proteins are made up of an α subunit (40 to 46 kd), a ß subunit (35 to 38 kd), and a γ subunit (7 to 9 kd). The ß and γ subunits, which are tightly bound and function as a single unit, are loosely bound to the α subunit forming a single protein complex. The α subunit contains a guanine nucleotide-binding site that binds either GDP or GTP. The G protein (αßγ heterotrimer), with GDP bound to the guanine nucleotide-binding site, is associated with the resting stage receptor. Binding of the hormone, or agonist, to the receptor induces a conformation change in the G protein complex, reducing the binding affinity for GDP, which leaves the guanine-binding site and is rapidly replaced with GTP. Upon binding GTP to the α subunit, the α subunit-GTP complex disassociates from the βγ complex, yielding two protein complexes that are capable of eliciting a cellular response by binding with effector proteins at the plasma membrane. The activated GTP-α subunits regulate intracellular concentrations of second messengers by controlling the cAMP enzyme (adenylate cyclase), and the phospholipase Cß enzyme [inositol 1,4,5-triphosphate (IP3) and 1,2-Diacylglycerol (DAG)]. $G_{s\alpha}$ stimulates adenylate cyclase, $G_{i\alpha}$ inhibits adenylate cyclase, and $G_{q\alpha}$ activates phospholipase Cß. $G_{ß\gamma}$ subunits regulate the activity of adenylate cyclase II and IV, phospholipase C subtypes ß1, ß2 and ß3, phospholipase A, K^+ and Ca^{++} channels and form links to the tyrosine kinase pathways (34). The second messenger DAG stimulates protein kinase C, a membrane bound enzyme that phosphorylates serine and threonine amino-acid–containing side chains in proteins. IP_3 induces the release of stored Ca^{++} from the endoplasmic reticulum (ER) by binding to a calcium channel in the ER.

The deactivation or turning off of a hormone signal is as important to appropriate cellular function as is signal induction. This is true in the normally functioning cell and may be extremely important in neoplastic cells. Desensitization can occur rapidly within seconds to minutes, or it can occur gradually over the course of several hours or days. Some receptors are desensitized through the phosphorylation of the intracellular domain of agonist-stimulated receptor by specific enzymes. These phosphorylated receptors are able to bind agonist but are unable to stimulate the Gs protein. Removal of the phosphate groups by protein phosphatases will reverse the desensitization over time.

Receptors also can be desensitized through a process called receptor-mediated endocytosis. Agonist-stimulated receptors aggregate on the surface of the cell and are internalized in an endocytotic vesicle. The internalized vesicles eventually fuse with lysosomes where the agonist-receptor complex is degraded or a certain percentage are recycled and returned to the surface as active receptors. This method of recycling of receptors is not very efficient and *de novo* synthesis of receptors is necessary to restore receptor numbers to normal.

Receptors and Disease

Disease States (Steroids and Their Receptors)

Binding of a hormone to its receptor is required for receptor activation and subsequent biological action. Any molecule that can occupy the receptor-binding site without activating the receptor can prevent hormone action by competitive inhibition. Attachment

of a molecule, such as an antibody to an epitope, to a location on the receptor that is in close proximity to the binding site can prevent hormone action by steric hindrance. Either of these events would inhibit normal receptor function. In addition to these inhibitory actions on receptor function, any change in the molecular structure of the hormone or its receptor that prevents binding, or reduces binding affinity between the hormone and receptor, can reduce or completely prevent hormone action on the target cell. Each of these events has the potential of altering cell function. Clinical disease may result from an unwanted negative

effect of receptor function, or a form of disease treatment may be realized by regulating cell growth through the use of synthetic ligands that will prevent binding and subsequent biological action of endogenous hormones or growth factors. This type of therapy may be particularly useful in the regulation of hormone dependent cancers. A number of clinical examples of receptor mediated disease, or treatment of disease, have been described. Estrogen and progesterone receptor concentrations are widely used in the determination of prognosis and appropriate treatment regimens to be followed in several endocrine responsive tumors, with breast cancer being the best example. Long Acting Thyroid Stimulator (LATS) (38, 39, 40) stimulation of TSH is an example of a disease process in which antibody stimulation of normal receptor results in overproduction of a hormone stimulated gene product. Myasthenia gravis is a defect in which the acetylcholine-mediated nerve impulse transmission is impaired and is an example of the steric hindrance of the hormone-binding site by endogenous antiacetylcholine receptor antibody (41). Testicular feminization syndrome (TFS) and familial hypercholesterolemia (FH) are two examples of disorders resulting from receptor changes; the lack of function or absence of the androgen receptor in TFS, and of the low-density lipoprotein (LDL) receptor in the case of FH (42).

The first report implicating hormonal regulation of breast cancer was in 1896, when Sir George Beatson (43) reported the dramatically beneficial effect of oophorectomy in premenopausal women with advanced breast cancer. The first evidence for the existence of tissue receptors for estrogens was obtained *circa* 1960 when Jensen and Jacobson (5) and Glascock and Hoekstra (44) reported the specific uptake of ^{3}H-estrogen in target tissue after systemic administration of labeled hormone. Folca (45) administered tritiated estrogens to women with breast cancer and observed the uptake of radioactivity by the tumor. It was later shown that a significant accumulation of ^{3}H-estradiol occurred in tumors from patients who responded to hormonal therapy while those that were unresponsive to therapy lacked the receptor. The presence of progesterone receptor (PR) in human breast cancer tissue is indicative of estrogen responsiveness (46). The repertoire of prognostic cellular receptors that may be used as markers that are predictive of, or may be predictive of, tumor response to endocrine and chemotherapeutic treatment regimens is expanding and now includes both intracellular and membrane-bound receptors. The gonadal steroid receptors ER and PR are used widely in the prognosis and treatment of breast, endometrial, vulvar, and cervical cancer while active investigations are examining the potential role that receptors for many of the PRF may play in prognosis and treatment of a variety of cancers. Several of the small peptides, oncogene products, growth factors, and their respective receptors currently are being examined as potential candidates for improving prognostic accuracy and possible sites of drug interdiction in cancer treatment regimens. These include EGF, TGFα, TGFβ, luteinizing hormone-releasing hormone, and somatostatin; and the c-*erb*-B2 (AKA neu) oncogene product, as well as Ki67, a nuclear proliferation antigen.

Normal endocrine responsive, or target cells, contain intracellular or membrane-bound receptor sites for each of the hormones known to influence the growth and function of the target tissue. When malignant transformation of a cell occurs, the cell may retain all or part of the normal receptor population, or undergo a structural change in the receptor that alters its function. If the cell retains intracellular receptor sites, steroid control of cell growth and function probably will be maintained as in a normal cell. However, malignant transformation that induces structural alterations may cause the receptor to lose the ability to bind the steroid, or to bind to the HRE on cellular chromatin and thereby lose its transcriptional function. These cells may no longer recognize circulating hormones and lose endocrine, autocrine, or paracrine-mediated functions and fail to respond to endocrine therapy (47). The regulation of the growth and function of endocrine target tissues, e.g., breast, and male and female genital tissues, and endocrine-responsive tumor growth within these tissues, in many cases is dependent upon hormonal factors produced by endocrine glands, and by growth factors elicited by both normal and malignant cells. The roles that peptide hormones, gonadal steroids, autocrine and paracrine growth factors play in the regulation of growth and function of normal and malignant tissue are becoming more clear, almost on a daily basis, as are the roles of the increasing number of recently identified oncogene protein products. Many of these recent advances are being put to use in the clinical laboratory as aids in determining the prognosis and appropriate treatment of cancers of various endocrine responsive tissues.

Current clinical use of receptors includes the analysis of intracellular receptors for estrogens, progesterones, androgens, and glucocorticoids. Perhaps the best-known example of the clinical utility of laboratory analysis of receptor function is that of estrogen and progesterone receptors in predicting patient response to adjuvant therapy or endocrine therapy in breast cancer. The membrane-bound receptors for EGF, TGFα, TGFβ, and the oncogene protein product from the gene c-erb-B2, also have been employed as predictors of response to hormonal therapy and prognosis in carcinomas of the breast, prostate, uterus, ovaries and cervix, and may be of some assistance in treating glucocorticoid responsive leukemias. The basic molecular structures of intracellular and extracellular receptors have been determined by the work of a number of research groups, with continuing investigations that relate structure with function.

The clinical utility of tumor levels of ER is well accepted and widely used, even though only about 60% of breast cancers contain ER. Approximately two thirds of the ER(+) tumors respond to endocrine therapy and between 5% and 10% of ER(-) tumors also respond to endocrine therapy. Estrogen is known to regulate the production of the progesterone receptor and the determination of both steroid receptors in breast tumors increases the prognostic value of hormone receptor measurements. Approximately 70% of PR(+)ER(+) tumors, and 25% to 30% of PR(-)ER(+) tumors respond to hormonal therapy and the prognosis of receptor positive mammary tumors is better than receptor negative carcinomas. Because the measurement of steroid receptors in tumor tissue does not give absolute information regarding tumor response to endocrine or adjuvant chemotherapy, but rather provides an imprecise indication of the response that individual tumors will display, other factors undoubtedly play a role in the regulation of malignant tumor growth. Until the putative cell regulatory factors have been determined,

identification of ER or PR receptors in malignant tumors will continue to provide the best standard of care for predicting which patients should receive endocrine therapy or adjuvant chemotherapy.

DISEASE STATES (GROWTH FACTORS AND THEIR RECEPTORS)

Part of "67 - Receptor Assays of the Clinical Laboratory"

The protein mitogen, EGF, a 6 kd, 53 amino acid single chain polypeptide, plays an important role in regulating the growth of many ectodermal and mesodermal derived cells and is found in significant levels in the urine, saliva, tears, bile, prostatic fluid, seminal fluid, milk, and sweat. The receptor for EGFr has been identified in most normal cell types with an abundance of receptors in brain, thyroid, lung, liver, skin, placenta and fetal membranes. EGFr apparently is involved in fetal growth and has been implicated in a number of development events, including palate and skin differentiation, growth of follicles, eye opening, tooth eruption, lung maturation, gut and liver growth and differentiation of neurons. EGFr are present in normal mammary epithelium (48), on the basal layer of epithelial cells, in normal urothelium, and on cervical and vulvar squamous-cell surfaces (49). EGF binding sites have been identified in a variety of tumors including breast cancer cells (50), in bladder malignancy where EGFr were found throughout several layers of cells in the urothelium with a rich presence on the surface layer, and in psoriatic skin lesions. There appears to be increased expression of EGFr in some ectodermal-derived tumors over that found in contiguous normal tissue (51). Although it is well known that cell proliferation is the predominant response of normal cells to EGF, the relationship between increased EGFr and tumor growth has only recently come under intensive study. At the present time, there is no consensus on the clinical utility and prognostic value of EGFr determination in tumor tissue. Points of consensus appear to be that approximately 45% to 50% of breast cancer patients display EGFr (+) tumors, and there is a negative correlation between the levels of EGFr and the steroid receptors ER and PR. Perhaps the wide variety of methodologies used in the determination of EGFr tissue levels, the lack of uniform measures of positivity (cutoff values) of the test, and the relatively small number of patients studied, has hampered the clinical utility of this test. Many investigators are calling for standardization of EGFr methodologies, similar to what was done with the ER and PR methods, in an attempt to make the test more useful and facilitate interlaboratory comparisons. A wealth of information regarding EGF and EGFr (and other growth factors and their receptors) is available in a number of different reviews (52) and an abbreviated review follows in this chapter. This line of research certainly will lead to a better understanding of the endocrine, autocrine, and paracrine control of normal and malignant tissue, and may aid in treatment of all types of cancer. If the uncontrolled growth of cells that is characteristic of cancer is subject to some combination of endocrine, autocrine, or paracrine control, as seems likely, then understanding the systemic and local regulation of GF and GFr may provide new treatments for endocrine responsive cancers, and perhaps those that appear to be independent of endocrine control.

The virus growth factor EGF-like protein also binds to the EGFr and is thought to be used for cell access by the virus. Other members of the family of small proteins that bind to EGFr are transforming growth factor α (TFGα), platelet derived growth factor (PDGF), and amphiregulin. While EGF and TFGα bind with almost equal affinity, amphiregulin has a significantly lower affinity for the receptor. Amphiregulin is a weaker growth stimulator than either EGF or TFGα except for the stimulation of keratinocyte growth where it is equivalent to the other two proteins. Since the binding affinity of amphiregulin for the EGFr is much lower than the other two proteins, it is natural to assume that there is a primary binder for amphiregulin, but this site has not yet been found (53).

EGF and the TGFs α and ß (54) are capable of enhancing or inhibiting *in vitro* cell growth in human endometrial carcinoma cell line (RL95-2) cultures depending upon GF concentration and cell plating density. TGFß inhibits cell proliferation at both high and low plating density and induces the appearance of large cuboidal cells that are distinct from EGF or TGFα treated cells. EGF, TGFα and TGFß effects appeared to be similar in hCG producing tumors transplanted into nude mice (55). Low concentrations of EGF stimulated tumor growth and increased EGFr levels, whereas high EGF concentrations inhibited tumor growth and reduced EGFr in the tumors. TGFα mimicked the effects of EGF and actively competed for EGFr binding sites, whereas TGFß competed only slightly with EGF for EGFr binding sites. EGF and TGFα levels have been compared between extracts of malignant and nonmalignant tissues (56). Approximately 30% of ovarian, endometrial, and cervical carcinomas and 16% of breast carcinomas had elevated GF levels compared to normal tissues. In nonmalignant tissue, the mean GF concentration was 1.5±0.7 ng/mL, whereas, concentrations in endometrial, cervical, and breast carcinomas were significantly higher (4.2+1.5 ng/mL). Increased GF levels may indicate an autocrine or paracrine control of growth in neoplastic tissue through autologous control of GF production by the tumor. An action that is independent of endocrine control or perhaps loss of endocrine control of cell growth as the neoplastic process proceeds.

Distribution of EGFr appears to differ between normal and malignant urothelium. Messing showed that most (95%) normal urothelium contained EGFrs in the basal layer of the epithelial cells, whereas in patients with urothelial carcinomas there was a significant concentration of EGFrs on the surface as well as in the deeper layers, and EGFr density was correlated with tumor grade (57). Tumor growth and EGFr levels appear to be correlated, and an increase in the production of EGFr may enhance the autocrine or paracrine stimulation of cell proliferation and may thus relate to tumor growth and metastatic potential. Gene amplification and overexpression of EGFr and mRNA of the erb-B2 oncogene have been found in mammary carcinomas and the increased EGFr levels may provide a growth advantage in cells in which over-expression of the EGFr has occurred. In contrast, EGFr concentration and prevalence is lower in endometrial adenocarcinoma than in normal endometrium (58, 59). Further, tumor grade and its relationship to EGFr is confusing. Berchuck (58) reported no correlation for these two variables, whereas Reynolds (59) showed a clear decrease in EGFr levels with advancing

tumor grade. Reynolds (60) also has shown that EGFr can be regulated in endometrial adenocarcinomas by estradiol and progesterone. Endometrial cells cultured with estradiol showed a decrease in EGFr in normal and malignant tissue while progesterone treatment increased EGFr concentrations. Increasing density of EGFr sites on the cervical and vulval squamous-cell carcinomas has been related to the aggressiveness of this type of tumor. In particular, it was found that levels of EGFr >100 fM/mg of protein had poor prognosis while levels <100 fM/mg of protein had more favorable outcomes (relative to recurrence and five year survival) (49). ER concentration was inversely correlated with EGFr in normal and neoplastic breast and endometrial tissue, whereas IGF-I binding was not affected by estradiol or progesterone treatment (61), perhaps indicating that down regulation of EGFr is one of the biological effects of estradiol.

Certain oncogene products show striking similarities to some GF receptors. The c-erb-B2 oncogene protein product is a molecule in which the transmembrane and cytoplasmic regions are homologous to the 170 kd single membrane spanning receptor, EGFr. This glycoprotein has an extracellular domain that is highly protease resistant, heat stable and contains the EGF binding site, an intracellular domain that contains intrinsic tyrosine kinase activity (62), and a transmembrane portion that connects these two domains. The cytoplasmic region of the EGFr is homologous to the protein product of the v-erb-B1 oncogene. The c-erb-B2 is an oncogene that has been localized to chromosome 17, codes for a 185 kd transmembrane protein that, although structurally similar to EGFr, lacks part of the extracellular EGF recognition site.

It is noteworthy that while the capacity of the receptors increased, the affinity did not. This leads to the conclusion that it is simply an increase in the number of EGFrs and not a change in the actual receptor. In some cases, amplification of gene coding has been demonstrated. However, overexpression of this gene did not always result in increased EGFr. Other factors that might come into play here are: increased transcription of the gene (over other genes); reduced degradation of the mRNA allowing more “readings” by the ribosome; and reduced receptor degradation which might keep the cell “turned on” longer.

Growth factors with TKA stimulate cell growth and proliferation by attaching phosphates to proteins through the tyrosine or serine residues, effect cell proliferation, and may induce the phenotypic transformation of cells. The enzymatic activity is directed against several protein substrates, including the receptor itself. This latter activity includes autophosphorylation and evokes phosphorylation of a variety of cellular substrates, which is the initial step of signal transduction (63). TKA is constituently active in the oncogene protein product whereas EGFr requires the presence of EGF bound to the extracellular moiety of the receptor for kinase activity to be initiated.

Comparisons of GF receptors in normal endometrium and endometrial cancers are important because tyrosine kinase genes have the potential to mutate to an oncogene form and produce malignant transformations. Information gained by the determination of GF receptor concentrations and their binding affinities in normal and neoplastic tissues may lead to various new treatment regimens and provide prognostic information that is not currently available. Treatments may take the form of: (i) biologically inactive analogs of growth factors that are capable of binding to and inactivating the receptor, (ii) receptor-specific antibodies that recognize epitopes on the extracellular domains of the receptor and sterically hinder binding of the GF to the receptor, (iii) antibodies with attached cytotoxins that can be released into the cell following endocytosis, or (iv) regulation of GF receptor production with estrogens, progesterones, or their biologically inactive competitive inhibitors.

There appears to be a clear relationship between the overexpression of EGFr and clinically aggressive malignant disease. EGFr is a significant predictor of response to systemic endocrine treatment in metastatic breast cancer patients and levels of EGFr correlates with the aggressiveness of the disease (64). Cultured A431 cancer cells overexpress EGFr and EGF treatment of this cell type stimulates tumor cell proliferation, cellular protein phosphorylation, and matrix metalloproteinase (MMPs) secretion, suggesting that these effects may be mediated at least partly through EGFr (65). The complexities of the mechanism of action of EGFr may provide treatment opportunities, through the inhibition of signaling molecules, such as the EGFr family and their associated ligands, in a number of areas of cancer therapy, including proliferative, angiogenic, invasive, and metastatic aspects. Evidence of the potential benefits has been obtained from a multiplicity of laboratory experiments, although clinical trials are needed to evaluate the therapeutic advantages of such agents (66). In recent years, strategies to modulate either EGFr, or the downstream signal beyond the cell surface receptor have been investigated. One promising strategy involves the use of anti-EGFr monoclonal antibodies, either alone or in combination with conventional cytotoxic modalities such as chemotherapy or radiotherapy (67).

Because overexpression of TGF-α and its receptor (EGFr) also has been associated with aggressive disease, and a poor prognosis, the blockade of EGFr activation has been proposed as a means of anticancer therapy. Topotecan, a cytotoxic drug that specifically inhibits topoisomerase I in ovarian, breast, and colon cancer cell lines, which express functional EGFr and the monoclonal antibody C225, an anti-EGFr humanized chimeric mouse MAb that is presently in Phase II clinical trials in cancer patients, have been evaluated. Combination therapy showed an *in vitro* dose-dependent inhibition of growth when cancer cells were in a sequential schedule. Treatment with MAb C225 also markedly enhanced apoptotic cell death induced by topotecan. Almost complete tumor regression was observed in all tumor-bearing mice treated with the two agents in combination. These results support the evaluation of the combination therapy of topoisomerase I inhibitors and anti-EGFr blocking MAbs in clinical trials (68).

EGF and TGF ß1 exert opposite effects in most cells. MDA-MB-231, a breast carcinoma cell line that overexpresses EGFr, demonstrated EGF-mediated reduction in TGF ß1 levels in culture media collected after 11 days of growth. The converse was also true, as TGF ß1 reduced the secretion of EGF in media from cultured cells, suggesting regulatory relationship between EGF and TGF ß1 (69). In cultured cancer cells, EGF and TGF ß1 elicits an increase in type IV collagenases, stromelysin and urokinase-type plasminogen activator and thymidine phosphorylase/platelet-derived endothelial cell growth factor. Thus, EGF

and TGF ß1 appear to act as positive regulators on the invasion process of gynecological tumor cells through their stimulatory action on the motility of tumor cells, the expression of proteases and the angiogenic phenotype (70). Combination antitumor therapy aimed at the inhibition of mitosis and induction of apoptosis is also a potentially useful approach for cancer therapy. The cell growth inhibitor - CGP52411- and the naturally occurring inducer of apoptosis TGF ß1, alone and in combination decreased growth rate in two ovarian carcinoma cell lines (PEO1 and OVCAR3). In both cell lines, TGF ß1 enhanced apoptosis and reduced EGF stimulated cell growth. Dual therapy showed an additive effect in PEO1 (71). The observation that preexposure of tumor cells to EGF alters their response to cisplatin and lymphokine-activated killer (LAK) cytolysis, an action that depends upon the degree of EGFr expression, may prove helpful in preselection of patients for appropriate therapy (72). Luteolin (Lu) and quercetin (Qu), two flavonoids with potent antiinflammatory, antimutagenic, anticarcinogenic, and anticancer effects, inhibit EGFr tyrosine kinase activity and autophosphorylation of EGFr and EGF promoted growth of A431 cells and thus may be good anticancer and antimetastasis agents (65).

Thus, in summary, preclinical and clinical data have established a link between EGF receptor/ligand expression and poor prognosis in cancer patients. Whereas, recent progress in understanding the mechanism of EGFR action has aided in the design of more effective tyrosine kinase inhibitors with improvements in potency, specificity, and *in vitro* and *in vivo* activity. The recent availability of very specific, irreversible inhibitors of the EGFR family that provide unique pharmacological properties, exceptional efficacy and improved *in vivo* performance has led to promising clinical trials. A review by DW Fry (1999) addresses the targeting of the EGFR family for cancer therapeutics, and highlights promising kinase inhibitors that are in development (73).

METHODOLOGIES

Part of "67 - Receptor Assays of the Clinical Laboratory"

Intracellular Receptor Analyses

In 196l Folca (45) demonstrated that the uptake of [3H]-hexestrol *in vivo* by breast cancer tissues was higher in four patients who responded to adrenalectomy than in six others who did not respond to the surgery (74). This observation led to the development of *in vitro* techniques using [3H]-estradiol to study tissue binding in primary and metastatic breast tumors. Estrogen receptors in organs have been measured *in vitro* using either tissue slices or cell-free preparations. The first quantifications were performed by sucrose-density gradient (SDG) analysis, which demonstrates the molecular forms of the receptor (75). While these early studies concerned themselves with ER, the importance of understanding the role of all receptors in general has become apparent. This has led to a need to quantify and characterize receptors as a class and the last few years have witnessed a flurry of activity aimed at this goal. The longer history of study of ERs has produced a body of knowledge about these receptors that is not yet accumulated for the other receptors. Thus some of the specific comments in the methodology descriptions may only be applicable to ER. Even though these methods have general applications, the newer receptors (e.g., EGFr) suffer from the lack of accepted standards and protocols so quantitative comparisons are often not meaningful. Of particular importance has been the recent application of monoclonal antibodies to this endeavor, which has led to the development of techniques that are rapidly replacing the other methodologies.

In addition to new methodologies, our models also are changing. In particular, until recently, ERs were thought to reside in the cytosol in the unbound state and were transferred to the nucleus when they became activated through binding to estradiol. Studies with newer methodologies have shown us that these receptors in fact are all in or associated with the nucleus. Thus, when reviewing some of the more “classical” procedures it is necessary to keep in mind that the model of intracellular ER location has evolved. Finally, it should be noted, that the only assays currently performed in the clinical laboratory are the Dextran Coated Charcoal (DCC), immunoassays and Immuno Cytochemical Assays (ICA).

Specimen Collection and Preparation

Hormone receptors are heat-labile proteins. It is necessary that they be stored immediately at 4°C if the sample is assayed within an hour. Otherwise, they should be quick frozen and stored in liquid nitrogen. Dry ice may be utilized for short storage (a few days) if liquid nitrogen is not available. Lyophilization of cytosol and storage at 4°C also has been used. The receptor is pH sensitive with maximum stability at pH=7.4. Low protein content can lead to underestimation of receptors in the DCC assay. Thus, with a low concentration of receptors, a minimum of 3 mg/mL of protein is suggested, but for higher concentrations of receptors, the protein concentration can be as low as 1 mg/mL. Miller (76) has reported that inclusion of molybdate (10 to 20 mM) in the extraction buffer increases the assay levels of both PR and ER. A tumor with an ER or PR concentration of 3 to 10 fM/mg of protein or higher usually is considered estrogen receptor-positive. There is not complete agreement between laboratories regarding the exact cutoff value, some laboratories have suggested that recent information shows the value of 10 fM/mg is more clinically relevant.

Receptor inactivation can occur within intact tissues, e.g., through prolonged exposure of excised intact tumor tissue to high temperatures. Further, steroid receptors may be inactivated during the tissue handling procedures before and during the cytosol preparation through high temperatures or excess homogenization. Finally, steroid receptors may be inactivated after they have been partitioned into the cytosol fraction of the tissue during the receptor assay procedure. These cytosolic receptors may be inactivated by such agents as high temperature, high ionic strength, pH changes, exposure to active proteases or phosphatases, and oxidation of sulfhydryl groups.

Physical Separations

Centrifugation

DCC Assay. Determination of receptor concentrations using dextran-coated charcoal utilizes the adsorptive properties of

charcoal to remove small and large-molecular-weight compounds from solution at different rates (77, 78). Small-molecular-weight compounds are removed very quickly, leaving the larger compounds in solution. This procedure is very time and temperature dependent with dextran being used to partially coat the charcoal particles and reduce the adsorptive properties of charcoal thereby reducing the rate and extent of adsorption of large molecular weight compounds such as proteins. This has been the most widely used methodology for the separation of free and receptor-bound radioactive ligands in the quantification of most steroid receptors. It is a sensitive and popular assay procedure and has formed the basis for most of the quality assurance, or proficiency testing programs such as the College of American Pathologists and Southwest Oncology Group. The assay is performed by using increasing concentrations of radiolabeled hormone and a concurrent range of unlabeled hormone competitor to titrate the receptor to a saturation end point. Specific and saturable binding can be determined by subtracting the nonspecific (nonsaturable) binding from the total binding to both specific and nonspecific sites. Specific binding can be converted to the total number of binding sites, generally expressed as femtomoles per milligram of protein. The dissociation constant is a measure of the affinity of the receptor for the steroid and is approximately equal to the concentration of free steroid at which one-half of the receptors are saturated. Kilodalton is the reciprocal of kilo annum and also can be obtained from a Scatchard plot (79). The values obtained from the DCC method correlate well with those of the sucrose gradient methods (see below). It is sensitive, inexpensive and relatively easy to perform. A modification designed to hasten this assay is to use only two data points, and assume a linear relationship. This can give workable results but if more than one binding site is present on the receptor, the value for kilodalton is greatly underestimated (80).

Sucrose Density-gradient Ultracentrifugation. This was the first ER assay applied in a routine clinical setting. The measurable quantity here is sedimentation velocity of proteins as a function of MW and density. It is a long procedure because of the required centrifugation times (16 hour in a swinging bucket rotor). The cytosol is incubated with labeled hormone and centrifuged through a sucrose gradient. The layers are counted and compared to known markers [e.g., BSA (4.6S), and IgG (6.8S)] with established molecular weights. Resolution is limited but most tumors display the presence of an 8S-estrogen receptor and some also the 4S form. It has been suggested that only the 8S form of the receptor complex has predictive value for the endocrine responsiveness of a given tumor (77). The presence of molybdenum in the gradient increased the amount of receptor observed in the assay. This is especially true when the progesterone receptor is being measured. This method estimates the quantity and size of the receptor molecules, but it is a slow and expensive procedure.

Precipitation. The receptor is precipitated with protamine (81) followed by incubation with excess-labeled hormone. At 4°C the receptor sites bind to the labeled hormone leaving unbound-labeled steroid in solution. The method has a very high nonspecific background and tends to give low concentrations when compared to other techniques.

When using ammonium sulfate to precipitate the receptor fraction, Chen (82) reported that at 50% saturation 77% of the ER and 53% of the PR precipitated. Saturation of less that 50% resulted in a significant reduction in the recovery of receptor. ERs and PRs salted out in the ammonium sulfate pellet are stable and store better than does the cytosol preparation.

Chromatography

Gel Filtration and Immobilized Antisteroid Antibodies. This assay is infrequently performed and has no advantages over the other commonly performed assays. After incubation of the cytosol with labeled hormone, the mixture is passed through a Sephadex column with the receptor-hormone complex eluting in the void volume (83). Sephadex does compete with the receptor for E2, which can cause some dissociation of the receptor-hormone complex (about 15%) leading to a false decrease in the amount of receptor measured. Columns packed with gels containing bound anti-E2 have been used in a similar fashion with similar results. The primary advantage of the use of this immunoaffinity method is the ability to quantify receptor levels with samples where only small volumes are available.

Hydroxyapatite Assay (83). The hormone-receptor complex is adsorbed onto hydroxyapatite either in “batch” or column form and the free steroid and plasma contaminants are removed by washing. The assay is more reliable at low protein concentrations than the DCC method, and it can be performed on small sample sizes.

DEAE Anion Exchange Chromatography. Steroid receptors are acidic proteins that will bind to anion exchange resins such as DEAE-cellulose (84). The major problems of this method include the tendency of free E2 and testosterone to bind to DEAE at low ionic strength and the inability of receptors to bind to the column at high ionic strength. Analysis of molecular forms of the receptor and separations from nonreceptor binding proteins is easily achieved.

Controlled Pore Glass Beads. The receptors bind strongly to controlled pore glass beads, followed by saturation by labeled hormone and elution from the column by ethanol for analysis (85).

High-performance Liquid Chromatography (HPLC). Although equipment is expensive, the required solvents are inexpensive and good column separation usually can be obtained between the analyte and other compounds present in the sample. There are several different kinds of HPLC analyses with the differentiation being based on the type of column used.

i. High performance size exclusion chromatography (HPSEC) utilizes polyethylene glycol (PEG) gel beads to prepare columns, which separate mixtures based on their molecular size and configuration. This has the ability to separate the various aggregates that the receptor displays. These columns are usually run at lower pressures and employ aqueous buffers. It gives the same type of information as obtained in sucrose gradient method with better resolution and in less time (86).

ii. Reverse-phase liquid chromatography (RPLC): The elution of a receptor protein from a RP column requires high concentrations of organic solvent in the mobile phase, which may irreversibly denature the proteins (87). Affinity columns have also been employed with HPLC.

iii. High-performance hydrophobic interaction chromatography (HPHIC) is the mildest application of HPLC to the separation of protein molecules with retention of their biological activity. The stationary phase is nonionic and binds the hydrophobic patches present in the protein. Unlike most HPLC procedures, which employ denaturing solvents, this column allows the use of physiological pH buffers (88).

iv. High performance ion exchange chromatography (HPIEC). This methodology relies on the same principle as the DEAE method (see DEAE Anion Exchange Chromatography, above). The column is packed with an anion exchange resin. The elution gradient proceeds from low to high ionic strength, which can be as high as 500 mM Phosphate (88).

v. High performance chromatofocusing (HPCF) is a technique that separates proteins based upon their surface charge properties. The column is a weak ion-exchange resin and the gradient is again from low to high ionic strength (88).

Electrophoresis

Agar Gel Electrophoresis. The receptor-hormone is separated and found on the anodal side of the well, while two peaks representing steroid hormone binding globulin and free steroid are found on the cathodic side (89). The method compares favorably with other methods, particularly when the cytosol is treated briefly with DCC before electrophoresis to remove most of the free and albumin-bound steroid.

Isoelectric Focusing. Separation is accomplished through charge properties. In comparison with other methods, isoelectric focusing is sensitive and rapid (1.5 to 2 hours). Vollmer (90) describes an assay employing two different isotopes (125I and 3H) for the simultaneous determinations of ER and PR with correlation coefficients to the single isotope assay of 0.93 and 0.8, respectively.

Immuno Assays

The development of the monoclonal antibody has had a significant impact on the assay methodologies for receptors. To develop the antibody, the receptor is first isolated by affinity chromatography. The respective steroid or protein is bound to the column (usually a gel) and the homogenate containing the receptor passed through. The receptor binds to the immobilized ligand and, after washing the column, is eluted off (usually, through change in pH or ionic strength). This purified receptor then is employed to develop a monoclonal antisera using standard techniques.

Immunoradiometric Assays (IRMA)

A typical immunoradiometric assay (IRMA) would incorporate two monoclonal antisera, which bind to different sites on the receptor (91). One of the antibodies is attached to a solid phase to serve as the capture antibody. After incubation of the solid phase capture antibody with the homogenate, the unreacted (unbound) material is washed away. Then the second monoclonal antibody, which is labeled with 125I, is introduced. The solid phase is given another wash and then counted. This assay gives good correlation to earlier biochemical methods. The method is independent of binding of E2 to the receptors as that apparently does not affect the antigenic sites of the two monoclonal antibodies to the receptor.

Enzyme Immunoassay (EIA)

Recently, commercial monoclonal-based EIAs were made available (92) for both ER and PR. The assay methodology is identical to the radiometric method except that a horseradish peroxidase labeled second antibody is employed. The assay is read by development of o-phenylenediamine (OPD). Results are consistent with other receptor assays (93, 94), but with somewhat higher values. The sensitivity of the PR EIA falls off for values below 10 fM/mg (95, 96), while the ER assay can be extended to 5 fM/mg (94). To date no putative threshold value for the ER-EIA has won acceptance (97, 98).

Bound Receptor Assays

The continuing studies aimed at understanding the intercellular localization of the steroid receptors have already been discussed. This had an impact on the development of ER assays. Historically, nuclear estrogen receptors were considered to be bound receptors and those in the cytoplasm to be “free” receptors. Here “bound” receptors means complexed to their respective steroid. For ER and PR, two receptor sites appear to be present. For the ER, the site with the higher affinity for estradiol has the characteristics (concentration, affinity, and specificity) attributed to the receptor. The second site, called type II EBS, displays the steroid and tissue specificity but it is not the true ERs. It is present in higher concentration but displays a lower apparent affinity. There appears to be a close relationship between increased levels of type II receptors and true uterine growth.

The currently accepted models for depicting the intercellular location of receptor sites for the ER and PR show that both the bound and free receptors reside exclusively in the nucleus. The receptors for glucocorticoid (GR) appear to reside in both the cytoplasm and nucleoplasm. This leaves us with the task of understanding what the earlier ER assays were measuring in the cytoplasm, for both biochemical and cytochemical assays. In the biochemical assays, it is necessary to first prepare a cytosol. The preparation involves extensive homogenization of the tissue, freezing and centrifugation. This treatment artificially separates the total cellular ER into nuclear and cytosolic fractions. Many researchers also feel that the free receptors are not as tightly bound in or to the nucleus and the addition of buffer in this process causes the migration of free receptors into the cytoplasm. While this can explain what is biochemically measured in the cytoplasm, the preparation of slides may not be so destructive toward the cell and may require a different explanation. One possibility is that it is the type II receptors that are being measured here.

Biochemical assays of bound receptors are based on the principle that the receptor-estrogen complex dissociates slowly at low

temperatures and rapidly at higher temperatures. The nucleus contains both bound and free receptors. To effect an exchange with the exogenous labeled estradiol the nuclear fractions are incubated in the presence of labeled estradiol at elevated temperatures (usually 25°C to 37°C). The relative quantities of free to bound receptors vary according to the hormonal milieu at the time of tumor excision. In premenopausal or a postmenopausal tamoxifen treated patient, the unbound receptors should be lowest and bound receptors highest, while the opposite would be true in postmenopausal women. Thus it is sometime desirable to evaluate both occupied and unoccupied receptor sites. In these assays, conditions are controlled (e.g., temperature) to reduce the amount of exchange.

Sucrose Pad Nuclear Exchange Assay (99)

This approach incorporates centrifugation of tissue homogenates through 1.2 M sucrose, which removes the large amounts of lipid present. This effects reduction of the NSB from 80% to 10% to 40%. The lipid components sediment only to the buffer/sucrose interface, while the desired nuclear material continues through to the bottom of the tube. The SPA can be modified to optimally measure the type II EBS that is thought to be related to estrogen-dependent growth. The assay is very tedious requiring technical skill and cannot be used as a single point assay.

Protamine Sulfate Assay (100)

By incubating a KCL-extracted nuclear fraction at 25° to 30°C for several hours, the previously bound hormone can be exchanged, while at 4°C only unoccupied receptor sites bind to labeled hormone. A major disadvantage of this method is degradation of the receptor at the higher temperature due to the proteolytic activity found in human tumor nuclear extracts.

Hydroxyapatite Exchange Procedure (101)

Both bound and unbound receptors bind to hydroxyapatite (HAP). This is similar to the procedure with protamine sulfate, except that the labeled hormone is incubated with the (HAP) bound receptors at the requisite temperature. This method appears to be superior to the protamine sulfate assay.

Mersalyl Exchange Method (102)

Exchange of bound nuclear receptor complexes may be achieved at 0 to 4°C in the presence of molybdate and Mersalyl acid. Specific binding is subsequently measured by the hydroxyapatite procedure. This assay does not lead to receptor degradation or incomplete exchange as often occurs with temperature dependent exchanges.

NaSCN Exchange Assay (103)

This assay uses NaSCN during the exchange process, which solubilizes the receptors, while exchange is carried out at 4°C in the presence of NaSCN

Analysis of mRNA Using Polymerase Chain Reaction (PCR) Techniques

McGuire's group (104) describes a simplified PCR technique sensitive enough to detect ER mRNA in breast tumor specimens from 1 µg of total RNA. In a preliminary evaluation of this method on a small series of breast tumors, the ER message was found in tumors that were positive by the DCC assay. One tumor that was ER-negative by the ligand binding assay but positive for PR was examined by the PCR method and found to contain the ER mRNA. It is known that about 2% to 11% of breast cancers are apparently ER negative but PR positive in the DCC assay (105). It is tempting to speculate that because PR is an end product of estrogen action, one might speculate that an ER in these tumors is defective in ligand binding but capable of stimulating PR.

Membrane-Bound Receptor Analyses

The need to quantitate membrane receptors is a recent one. Analysis of membrane receptors accommodates techniques employed for cytosolic receptors with the added complication that we are now dealing with tissue. Preparation of the membrane sample is critical since it is necessary to eliminate residual cytosol, which, if present, will give artificially low results. This washing also releases most of the EGF receptor trapped in the nuclear pellet. For clinical use, one washing cycle may be adequate (62). EGFr values >10 fM/mg of protein appear to be significant and >100 fM/mg of protein is significant in cervical carcinoma.

Saturation and Displacement

The most common assays for membrane receptors are radiometric saturation and displacement assays employing 125I labeled ligands (106). As in the saturation assay for cytosolic receptors, increasing amounts of labeled ligand are reacted with fixed amounts of tissue sample. This also requires determination of NSB, which requires that each of the points be performed, both in the presence of a large excess of cold ligand and in absence of the cold ligand.

A variation of this is the displacement assay. Here a fixed amount of tissue and labeled ligand are equilibrated with increasing amounts of cold ligand. The separation of free from bound in tissue assays is usually done by centrifugation (15,000 g for 5 minutes), with the resulting tissue pellet being counted in a gamma-counter. Polyethylene glycol (PEG) has been utilized to enhance precipitation. Rapid filtration also has been utilized, with the membrane material being trapped on the filter and subsequently counted. Both the saturation and displacement assays are analyzed with Scatchard plots. Both methods give comparable binding capacities (or specific binding), but the displacement assay generally underestimates the association constant.

The saturating and displacement assays require multiple points and thus a sizable amount of tissue sample is necessary (100 µg of tissue for each assay tube) in order to reduce the tissue requirement and simplify the procedure a single point saturation assay has emerged (107). In this assay two points are needed: (i) the tissue sample with a fixed amount of labeled ligand, and (ii) the tissue with labeled ligand plus a large excess (usually about 100 fold) unlabeled ligand. The difference in binding between these two points, which is the specific binding, is converted into percent of total (B/T) and multiplied by the concentration of labeled ligand. This then is converted into femtomoles

of receptor/milligram of protein. The assay must be calibrated for each type of receptor and type of tissue to determine the optimum amount of tracer (usually the 50% point on a Scatchard curve) and cold ligand.

Immunoadsorption

Tissue receptors can be solubilized with Triton X-100. However, for some receptors (i.e., EGFr) Triton X-100 also deactivates the receptor (108). This effect appears to be Triton X-100 concentration dependent and thus utilization of this methodology requires awareness of this potential problem. EGF tissue receptors solubilized with Triton X-100 are immunoadsorbed onto microtiter wells coated with mouse anti-EGFr (109). From this point, either a radiolabel or an enzyme label can be introduced.

Use of a radiolabel requires incubating the captured EGFr with increasing concentrations of 125I-EGF in the presence and absence of excess unlabeled EGF. After washing the wells and counting, a Scatchard analysis is carried out.

When an enzyme is utilized as a label, a second anti-EGFr (MoAb) is incubated with the immobilized EGFr and is subsequently analyzed through bonding of this sandwich complex to a goat antimouse IgG labeled with peroxidase. A colorimetric signal is generated through treatment of the wells with o-phenylenediamine. The results are compared to a standard curve from which the binding capacity can be read. Solubilized A431 cells were used to prepare the standard curve. While this procedure does not yield a binding constant, because only a single point is needed for the unknown sample, the amount of sample tissue needed is thus greatly reduced.

Western Blot

A Western Blot procedure has been developed for EGFr (110). Purified membranes were solubilized with nonionic detergent and resolved by electrophoresis. This is followed by electroblotting onto nitrocellulose and rehybridizing with 125I-EGF. The receptor was identified by bands at 150 and 170 kd. The presence of 1% hemoglobin and 0.05% Tween 20 during the hybridization step optimized the radiogram signal.

Cytochemical Analysis

In these procedures, the object is to detect the receptors by attaching a label to the receptor that can be visualized. Because the cell is left intact, the methodology is applicable to both intracellular and membrane bound receptors. It is performed by fixing sections of the tumor tissue in graded ethanols, on uncoated glass slides, followed by incubation with the appropriate labeling material.

Ligand-Conjugate Label

Various different types of labels have been employed, the earliest being tritium tagged estradiol which is then read by autoradiography (111). Conjugating steroid molecules to proteins to which fluorescent molecules or peroxidase are attached allows the direct visual identification of receptor sites in the cells. Early studies showed an accumulation of label in the cytoplasm and this was assumed to be depicting the location of the receptor binding site, which was consistent with the steroid binding assays where ERs were found in the cytoplasmic fraction of the tissue extracts. Quantification of the binding sites is obtained by estimating the intensity of the fluorescence. Also demonstrated by this technique was the mosaic distribution of ER positive cells in the tumor. Because there is neither uniformity of distribution of binding sites, nor of intensities, a system was developed to give an average intensity. This was to provide some correlation to the DCC assay results. Using this averaging technique the results were comparable to the reference assay (DCC).

One major problem with the cytochemical assay is that it does not supply information about the affinity of the binding site (112). Without this information, it is difficult to show that the ER sites that were being measured by the biochemical assays were the same ones visualized by the cytochemical methods. In fact, we now have good evidence that the primary ER sites, which have the highest binding affinity, reside in the nucleus. This then leaves us the question of what the earlier cytochemical analyses were identifying in the cytoplasm. It has been suggested that the cytoplasmic estrogen binding sites represent secondary, low affinity sites. Scatchard analysis of the data of DCC assays shows two binding sites for estradiol with the Kd of the second site about 100 fold less that the Kd of the first.

Antireceptor Antibody Methods (47)

ICA is performed by fixing sections in graded ethanols, on uncoated glass slides, followed by incubation with labeled monoclonal antibodies. The bound antibodies can be visualized by the indirect immunoperoxidase method (113) or through the use of fluorescent or chemiluminescent labels. Using this technique in determining the presence of ER, it was observed that the staining was almost exclusively in the nucleus as opposed to the cytoplasm where earlier studies had observed it (Interestingly, earlier cytochemical work using a tritium label also located the receptor in the nucleus but apparently these data were not widely accepted). Further, the intensity of the nuclear staining correlated to the amount of ER determined by the sucrose density gradient analysis and detectable staining was always absent in the receptor-negative tumors. Presently, the method is only semiquantitative and it usually is considered as an adjunct to the biochemical assays. However, the continued development of intensity analysis will improve the quantitative aspects of this assay. As with the cytochemical analysis, ICA does not provide any quantitative information about the binding strength of the receptor.

One of the puzzling aspects of the application of steroid therapy to the treatment of breast cancer is the large number of positive ER tumors that do not respond to this therapy (20% to 40%) and conversely, the number of ER negative tumors that do respond to therapy (about 10%). The application of cytochemistry has highlighted one facet of this problem, which is the heterogeneity within the breast tumor. There can be within the tumor, benign tissue that is ER positive, while the rest of the tumor is ER negative. Conversely, an ER-positive sample might be so diluted with fibrous tissue that it gives a negative ER bioassay.

Another interesting application combines flow cytometry and

ICA to quantify PR and simultaneously perform a DNA assay (114). This allowed the assignment of PR levels in subsets of cells segregated by their DNA content. In T47D cell, PR was present throughout the cell cycle and levels doubled in G2 and mitosis.

Localization of Receptors

Receptors have been employed for *in vivo* visualization of tumors and metastases (115) or for the localization of receptors in organs and endocrine glands (116). Intestinal adenocarcinomas and some endocrine tumors express large numbers of high-affinity receptors for vasoactive intestinal peptide (VIP). Iodine-123 labeled VIP was shown to be useful in the successful localization of tumors and metastases of gastrointestinal adenocarcinomas, carcinoids, and insulinomas. The binding of the labeled VIP to the receptors was measured by the resulting radioactivity, which was 2 to 7 times background in these carcinomas.

Fluorescent Labels

The localization of receptors within a cell always has been more of a challenge. Recently, techniques based on the use of fluorescent labels have shown great promise (117). The development of the ability to fuse green fluorescent protein (GFP) with a variety of molecular species has opened a whole new area in monitoring events in the living cell. When fused to cellular proteins, GFP retains its fluorescent properties without altering the behavior of the protein allows the observation of detailed cellular events such as nuclear translocation of receptors. Htun (118) has fused jellyfish GFP with the rat glucocorticord receptor (GR) giving the resulting GFP-GR protein chimera. Using a variant of GFP that was resistant to photo bleaching, they were able to use time-lapse video to record the course of cytoplasm-to-nucleus translocation of GR in a single living cell. When not bound to a ligand, the GFP-GR resides exclusively in the cytoplasm. Upon binding to dexamethasone (DMS), the resulting complex moves directly to the nucleus. The rate of this translocation was dependent on the DMS concentration. Shortly after the translocation of the GFP-GR-DMS complex enters the nucleus, foci of bright fluorescence appear in an organized reproducible three-dimensional structure. When the GFP-GR is activated with the agonist RU486, which is known to bind with GR but not elicit observable activity, the RU486 activated GFP-GR translocates to the nucleus and in this case accumulates almost exclusively in a reticular pattern found throughout the nucleus.

In a similar fashion, the GFR fusion protein with androgen receptor (GFP-AR) was studied (119, 120). The GFP-AR was detected through out the cytoplasm in the absence of androgen. After incubation with the hormone, the fluorescence rapidly became localized in the nucleus. The mutant GFP-AR-del4, which lacks its carboxy-terminal function and thus has no androgen-binding function, remained localized in the cytoplasm after incubation with androgen. Luciferase activity (from the reporter gene TAT-tk-luc) was used as an indicator of the transcriptional activity of GFP-AR and AR in the presence of androgens or antiandrogens. Both demonstrated a dose dependence on the induction of luciferase activity, with GFp-AR being about one-half that of AR. Studies of the trafficking of GFP-AR in the presence of various ligands also was carried out. 100% localization to the nucleus never was achieved. For synthetic androgen and dihydrotestosterone at concentrations of 10-6 M, about 65% of the fluorescence was localized in the nucleus. Similar concentrations of testosterone yielded about 55% localization in the nucleus while the two antiandrogen ligands, cyproterone acetate and hydroxy-flutamide were at about 30% localized. Carey (121) studying the same GFP-GR and DMS translocation noted that various mutants of the enzyme Ran/TC4GTPase (Ran) when present inhibited the translocation of GFP-GR to the nucleus, and that those mutants of Ran also inhibited cell growth.

Fluorescence Resonance Energy Transfer (FRET)

Mutagenesis of the GFP protein sequence generates a variety of variant forms with differing brightness and spectral characteristics. One particularly useful form is the so-called “blue” variant (blue fluorescent protein of BFP) with an emission maximum at 445μm. This is easily differentiated from the GFP, which has an emission maximum at 511 μm. These two mutants can be used to label the ligand and the receptor separately. When these labeled proteins are used in conjunction with dual channel fluorescence microscopy, it is possible to observe the movement of the two different proteins in the same cell. Formation of the ligand-receptor complex can be visualized by the “overlapping” of the two colors giving rise to an intermediate color. The light microscope has a resolution of 2,500 Å, which really is not adequate to determine whether or not these two labeled proteins are interacting.

The resolution of the light microscope can be extended dramatically through the utilization of a technique known as fluorescence resonance energy transfer (FRET). This detects the increase in emission intensity, which is the result of a transfer of excitation energy from a fluorescent donor to a fluorescent acceptor molecule. Two important requirements are that the emission energy of the donor must overlap the activation energy of the acceptor and they must be spatially oriented for this to occur. The increase in the intensity of the acceptor fluorescence is also inversely related to the distance between the two proteins. Because of this FRET can only occur over a distance limited to approximately 20 to 100 Å. However, this technique only can be used to verify interaction. A negative result does not negate the possibility of interactions. FRET successfully observed the interaction between the pituitary-specific transcription factor Pit-1 and the c-Ets-1 receptor using BFP-Pit-1 and GFP-Ets-1 as the fluorescent species (122). This interaction, as well as the association of the Pit-1 protein and the estrogen receptor has been demonstrated previously through biochemical studies. The latter association, with Pit-1 and the estrogen receptor, was not verified in this FRET system.

Fluorescence Correlation Spectroscopy (FCS)

FCS is a technique that has been around for about 20 years. It is based on observing fluorescence emitted from as little as one molecule in a very small observation volume — the confocal volume. The fluorescence is initiated by a very narrow laser beam (approximately 0.2 μm) such that only one or two molecules are excited at a time. Experimentally, one observes (measures) the

intensity and duration of the fluorescent molecule or complex, which is contained in a dilute buffer, as it diffuses through observation region. The time that fluorescent species resides in the observation region depends on the rate of diffusion. An unbound fluorescent ligand would diffuse faster through the observation region than if it was bound to a receptor because the whole system gained mass and thus diffuses slower. If more than one ligand bound to the receptor it would diffuse even slower and would also yield a more intense fluorescence (because each ligand would add a fluorescent label). The diffusion time is compared to a previously determined standard, such as just the uncomplexed fluorescent ligand or receptor from which we should be able to get a good estimate on the number of ligands bound to one receptor.

The intensity of the fluorescence also should give us an estimate of the number of ligands as well, but rotation of the complex might reduce what we observe. If unlabeled ligand were now introduced into the mixture, it would displace some of the labeled ligands and such an observed particle would show a sudden increase in diffusion (less mass). This behavior provides a model from which we can estimate binding constants (123,124 and 125).

Wohland (126) compared the data obtained from an FCS study to that obtained from a radioligand binding analysis of the serotonin type 5HT3AS cell membrane receptor using the antagonist 1,2,3,9-tetrahydro-3-[(5-methyl-1H imidazol-4-yl)methyl]-9-(3 aminopropyl)-4-H-carbazol-4-one (GR-H). Several fluorescent labels were studied. They were: fluorocein (Flu), rhodamine 6G (6G), N-[7-nitrobenz-2-oxa-1,3-diazol-4-yl] (NBD) and the cyanine dye Cy5 (Cy5). To standardize the analysis determination of the unbound labeled ligand diffusion rates were obtained. The binding studies all showed a 1:1 ligand to receptor complex, even though the 5HT3AS receptor as a homopentameric structure would suggest the existence of up to five ligand-binding sites. The 1:1 ratio was consistent with the radioligand results. The binding affinity was dependent on the fluorescent label used. The GR-6G was particularly difficult to work with as it bound to surfaces and its complexes had a strong tendency to aggregate. Using the GR-Flu it was possible to make reasonable determinations of the mass of the receptor.

Molecular Biology

The tools of molecular biology are beginning to show up in receptor research (127). These tools are helping to fill a gap in our current methods. PCR techniques can be employed to indirectly identify the existence of receptors when there are no known selective ligands for that receptor. The also can be used to study what happens to the distribution and possible change (mutation) in receptors under changes in pathological states.

To study the function of a receptor *in vivo* generally has involved the development of an animal strain with the gene responsible for that receptor eliminated (knock-out). This is fraught with difficulties, and a long-time commitment. The knock-out sometimes proves to be lethal. A new approach involves the use of gene targeting by antisense oligodeoxynucleotides. This involves the development of a short single strand, which will bind to a complementary DNA or mRNA strand. This greatly inhibits the transcription or translation of that gene. This process has been given the label “knock-down.” Lai (128), in a study of the delta opioid receptors, employed this technique. There is good evidence that there are multiple delta receptors but radioligand binding has not been able to establish clear identities. By using antisense oligodeoxynucleotides, they were able to determine the existence of at least two subtypes of the delta receptor. The next level to study in the ligand-receptor scheme is to the level of second messenger coupling. Specifically, the formation of the complex initiates a “signal” that is sent generally to up-regulate or down-regulate a process. And this information is delegated primarily to the G-proteins. While it is not the intent of this section to pursue the receptor studies to this point, it is the obvious next step and the use of antisense oligodeoxynucleotides will play a big roll in that study (129).

Errors in Receptor Measurements

Receptors are thermolabile, pH and ionic strength dependent, and they can be mechanically destroyed during homogenization. Addition of reducing agents as dithiothreitol, molybdate, or glycerol to protect from oxidation can be helpful. Low values can result from too little protein in the sample. Another problem is interference by nonreceptor binders such as albumin, corticosteroid-binding globulin, and sex-hormone–binding globulin (SHBG).

INTERPRETATION

Part of "67 - Receptor Assays of the Clinical Laboratory"

Tissue Receptors and Cancer

Familial Hypercholesterolemia

Cholesterol plays an essential role in the normal function of nearly all cells and is required by all steroid-producing cells. Cholesterol, as are most steroids, is a lipophilic molecule that circulates in blood bound to binding proteins that increase steroid solubility. Cholesterol is packaged in lipoprotein complexes referred to as high-density lipoprotein (HDL), low-density lipoprotein (LDL), and very-low-density lipoprotein (VLDL). Much of the cholesterol in the circulation is bound to LDL (LDL-C), and in normal individuals LDL-C enters the cell by binding to LDL receptors (LDLr) located in the plasma membrane. Mutational changes in the LDLr gene produce structural changes in the LDLr that may impair binding of LDL-C to the cell surface and/or inhibit internalization of the complex into the cell. One consequence of the failure of cholesterol to enter the cells is that it builds up in the plasma, thereby producing high circulating levels of LDL-C. It is well accepted that elevated plasma levels of cholesterol are responsible for plaque formation in the coronary arteries leading to coronary artery disease.

Familial hypercholesterolemia (FH) is an autosomal-dominant disorder characterized by high circulating levels of cholesterol, and the tendency to develop coronary artery disease, tendinous zanthomas, and corneal arcus very early in life. Mutational changes in the LDL gene cause abnormal forms of LDLr to be produced in FH-affected patients and prevent, or impede, the normal uptake of LDL by target cells (42). About 1 in 500 people

express a single mutant LDL gene allele and it is known that patients with one normal and one abnormal LDL receptor gene express a lower than normal number of LDL receptors and show circulating cholesterol levels that are much higher than unaffected individuals. Patients with homozygous alleles for defective LDL receptors are very rare and exhibit very high plasma levels of cholesterol during childhood with attendant coronary artery disease. These patients usually die during adolescence of severe coronary artery plaque formation. Patients who are heterozygous for LDL receptor defects can be treated with drugs that lower cholesterol and stimulate the production of LDL receptors in liver cells. The combination of decreased liver cholesterol production, increased production of LDL receptors, and measures designed to reduce intestinal absorption of cholesterol can force circulating levels of LDL cholesterol into the normal range. Advances in the analytical procedures for detecting mutational changes in the LDLr gene are extremely helpful in management of FH patients and family members. For example, single-strand conformational polymorphism (SSCP) analysis allows rapid scanning of DNA fragments for any sequence variation in situations where high-throughput mutational analysis is required. Humphries et al. describe the application of this technique in the screening of patients with familial hypercholesterolemia for LDLr gene mutations (130). Many mutations in the LDLr gene have been described in various countries around the world and disease incidence appears to be higher in certain nationalities and geographical areas with elevated cardiovascular risk. However, the identification of these individuals is difficult because of the wide variety of mutations that exist in the country. The 42 mutations that have been detected in Italy account for only about 30% of FH cases, leading to the speculation that over 100 different mutations are present in Italy (131). It also appears that certain of these genetic changes are present in areas of relatively high incidence (FH-clusters) (21i) and may represent “founder effect.” Many mutations of the LDLr gene have been described and the specific point mutations, deletions, frameshifts, inheritance patterns and geographical distribution can be reviewed on line through the “Online Mendelian Inheritance in Man” web site (132).

Cancer

Clinically, endocrine-responsive tumors are assayed for receptor concentration and affinity. These include intracellular receptors for estrogens, progesterones, androgens, and glucocorticoids. Recent developments have implicated the membrane-bound receptor EGFr and its related oncogene product from the gene c-erb-B2 in predicting the response to hormonal therapy and prognosis in breast, endometrial, prostatic, certain renal carcinomas, and may be of some assistance in treating glucocorticoid responsive leukemias.

Breast Cancer

Breast cancer accounts for 30% of all cancers and 18% of all female cancer deaths. Although there is a 10% lifetime risk of breast cancer in females, there is a 90%, 5 year, survival rate if treatment is initiated in Stage I disease. Survival drops to 60% if the cancer has metastasized before treatment is instituted (133). Mammography and self-examination are the best methods of early detection in risk populations. Prognosis and treatment are based on tumor size, clinical stage, histologic grade, axillary lymph node status, and the presence and binding capacity of ER and PR, and more recently, the experimental use of growth-factor receptors and oncogene protein products. Generally, patients with nodal metastases have a worse prognosis than those without. However, about 25% to 35% of the so-called axillary-node-negative patients die from their disease within 10 years. A further problem using nodal status as a prognosis marker is the extensive and mutilating surgery that does not enhance survival. Patients are opting for more conservative treatment.

A good prognostic marker should provide information on the tumor-cell proliferation rates and metastatic potential, and it also should indicate what therapy is appropriate. Lastly, it should be attainable with a minimum of surgical intervention. In recent years, many potential biochemical markers have been described. These included steroid hormone receptors, growth-factor receptors, activated proto-oncogenes and proteolytic enzymes (134, 135).

Estradiol and Progesterone Receptors. While receptor assays identify patients who have a significant chance of successful estrogen treatment, the overall predictive value of the information obtained from receptor assays shows considerable disagreement in the literature. In 1977, Knight (136) showed that the absence of ER in breast tumors was associated with early recurrent disease. The role of ERs has been studied since then and still is not clearly understood. Using the DCC assay to look for the presence of ER and PR in 4,000 cases of breast cancer, Thorpe (137) found three categories or types. Those that were positive for ER and PR, or negative for ER while positive for PR were hormone responsive; negative ER and PR were nonresponsive, and positive ER with negative PR gave unpredictable responses (this latter category consisted mostly of postmenopausal patients).

One confusing aspect that arises when attempting to use ER content as a prognostic factor in breast cancer lies in the assays themselves. Some assays measure only unbound (to estradiol) receptor while other assays measure total ER (see Methodologies). Thus, Syne (75) noted that there were ambiguities of response to estrogen therapy in premenopausal women containing low levels of ER, as determined by a binding assay, (which primarily measures the “free” receptor). He questioned whether the low unbound receptor level in the cytoplasm was a result of the influence of high levels of circulating estrogens or whether the tumor truly lacks estrogen receptor. Conversely, the high ER content of a breast tumor from an elderly postmenopausal woman may indeed indicate a strongly ER-positive tumor or the lack of endogenous estrogen production needed to bind the usual amount of estrogen receptor to the DNA. Other studies have shown that in some so-called “false-negatives,” there is a lack of unbound ER, but they do contain bound ER. Conversely, some false-positives (patients with ER that do not respond to estrogen therapy) show that the tumors do contain unbound ER but no hormone bound ER.

McGuire (138) has shown that for the Stage 1 cancer patient, ER status and tumor size were the two most important prognostic factors. In stage 2 breast-cancer patients however, Progesterone

Receptor (PR) status appeared to be a better prognostic marker.

Other factors have been evaluated as prognostic indicators. Hill (139) tried grouping the occurrence of ER in premenopausal patients based on body mass. He found that women with a lean body mass have a greater proportion of negative ER tumors and a higher concentration of EGFr than heavier women. In males, with the exception of a predominance of centrally located lesions and a uniquely high frequency of positive hormone receptor status, carcinoma of the breast appears biologically similar to the disease in women, and treatment should be guided by similar principles (140).

While different methodologies for receptor assays are a factor in these contradictory observations, there are other operative variables which include: (i) different cutoff points used, (ii) different patient follow-up times, (iii) different patient populations with respect to menopausal status, disease stage and adjuvant treatment, (iv) different statistical test used to analyze the data, (v) small numbers of patients used in some studies, and (vi) nonstandard criteria used to assess date of first recurrence. Also, the comparisons of immunocytochemical and the newer receptor EIAs serve to point out the importance of cellular heterogeneity as a cause of variation (141, 142). Prognostic significance of ER values does not appear to depend upon the type of tissue biopsied for assay as ER values from primary tumors or metastatic tumors predict equally well (7).

Tamoxifen, [1-(4-ß-dimethylaminoethoxyphenyl)-1,2-diphenylbut-1-ene], is a synthetic nonsteroidal compound that shows varying degrees of estrogen agonist and antagonist activity. The antiestrogenic properties of this compound have led to its clinical use in the treatment of a number of human malignant tumors especially estrogen-receptor positive (ER+) metastatic breast cancer. Tamoxifen exerts its effects, at least in part, via the specific estrogen receptor proteins of estrogen responsive cells. A secondary, saturable, high-affinity tamoxifen-binding site is present in ER+ but not ER- tumors. Raam (143) recently has described a solid phase EIA for this secondary binding site. This secondary site is present at an order of magnitude greater than the concentration of the high-affinity estradiol receptor site measured in the same tissue. In receptor assays, tamoxifen is bound predominately by this secondary binding site in ER+ human mammary carcinoma cytosol, which is distinct from the classical estrogen receptor site. No saturable tamoxifen-binding sites were detected in any of the ER- tumors studied. Elucidation of the roles if any, of this tamoxifen-binding site in mediating the antitumor activity of tamoxifen in human breast cancer awaits further experimentation (144).

Valavaara (145) in the study of 113 postmenopausal patients with advanced breast cancer that were ER positive and treated with toremifene concluded that the concentration of the ER predicts the duration of the response, but not the rate of response. In this instance, PR status was not useful as a predictor of therapy response.

Growth-factor Receptors. In breast cancer, a strong inverse relationship between EGFr and ER status was found for EGFr values >10 fM/mg of protein. There appears to be an increased expression of EGFr in some ectodermal-derived tumors over that found in contiguous normal tissue. Expression of the EGFr appears to be increased in neoplastic tissue and usually is associated with increased aggressiveness of the disease. EGFr status has been used for classifying the prognosis of ER(-) tumors. ER(-)/EGFr(+) patients had a significantly worse prognosis than did patients that were negative for both receptors (104). Scatchard analysis showed that most tumors have two EGFr binding sites. A high affinity site with K_d = 2 nM/L and the second a low-affinity site with K_d = 9.5 nm/L.

TGFα, a peptide isolated from cultures of malignant cells, stimulated the growth of malignant tissues through binding to the EGFr. There appears to be an increased expression of EGFr in some ectodermal-derived tumors over that found in contiguous normal tissue. EGFr, or the closely related erb-B2 oncogene, induced gene amplification and mRNA overexpression have been found in mammary carcinomas. High concentrations of EGFr in breast cancer have been related to a poorer prognosis suggesting that it might be an index of greater aggressiveness of the disease. One study (146) concluded that the only significant marker for disease-free survival was the absence of the EGFr, but it did not correlate significantly with overall survival. Finally, EGFr status was a valid criterion for dividing ER-negative tumors into those with good and poor prognosis (i.e., ER-negative/EGFr-positive patients had a significantly worse prognosis that did patient's negative for both receptors).

Amplification of the c-erb-B2 oncogene had a positive relation to the number of axillary-node metastases as a prognostic marker. It was a stronger prognostic marker than PR status, tumor size, or ER status for both disease-free interval and survival (147). The presence of any of these oncogene products provides for a poor prognosis, perhaps because each is involved with the stimulation of cell growth. Further, permanent activation of TKA in the case of c-erb-B2 may indicate that it is involved with progression of the tumor and development of metastases. Measurement of gene amplification is relatively difficult and not suitable for the routine pathology laboratory. Preliminary data suggest that other oncogenes/oncoproteins can be used to provide prognostic information in breast cancer. Clair (148) has shown that breast cancers with high concentrations of the *ras* protein have a greater likelihood of developing recurrent disease than do tumors containing low concentrations of this protein. Similarly, amplification of both the *int*-2 and c-myc oncogenes have been associated with aggressive breast cancer. With gene amplification, it is noteworthy that while the capacity of the receptors increased, the affinity did not. This leads to the conclusion that it is simply an increase in the number of EGFrs and not a change in the actual receptor. However, overexpression of this gene did not always result in increased EGFr. Other factors that might come into play here such as increased transcription of the gene (over other genes); reduced degradation of the mRNA allowing more “readings” by the ribosome; and reduced receptor degradation, which might keep the cell “turned on” longer.

Endometrial, Cervical, and Vulvar Cancers

The incidence of endometrial adenocarcinoma is 11 to 12/100,000/year, and rising in developed countries (American Cancer Society, 1986). The majority of endometrial cancers are adenocarcinomas (80%) with the remaining 20% composed of

adenoacanthoma, adenosquamous carcinomas, papillary and clear-cell carcinomas (149). 5-year survival of patients with treatment initiated during stage 1 disease varies between 70% and 94%, depending upon the histological grade and receptor content of the tumor. 5-year survival drops to 55% to 88% with stage II disease, whereas the rates drop to 30% to 32% and 0 to 10% with stage III and stage IV disease, respectively (150,151,152,153,154 and 155). Cervical carcinoma occurs at the rate of about 10/100,000/year (156). Mass screening programs and early detection have been successful in reducing the incidence to about 3.6/100,000/year. Cervical carcinoma is primarily squamous, although cervical adenocarcinoma is increasing in incidence and currently makes up about a 10% of invasive cervical cancers (157). The 5-year survival rate for stage I disease is 62.8% to 100%, however if treatment is not instituted prior to metastases, survival rate drops below 10% (158). Vulvar carcinoma has an incidence of only 1 to 2/100,000/year, and a 5-year survival rate of about 90% (157, 158).

Growth, development, and maintenance of the female genital tract is controlled by sex steroids, estrogen, and progesterone receptors that are found in the highly differentiated target tissues of the normal female reproductive tract and growth factor receptors, e.g., EGFr. In the endometrium, estradiol stimulates mitosis and increases progesterone receptor concentration. The progesterone/receptor complex induces differentiation of the secretory function of endometrial cells. Normal endometrium contains higher concentrations of steroid receptors than those found in endometrial carcinoma and the malignant endometrium has a low PR to ER ratio (159). As dedifferentiation occurs in a carcinoma, it appears to be accompanied by a concomitant loss of receptors and a reduction in receptor concentration (118,119,120,121,122,123,124,125,126,127,128,129,130,131,132,133,134,135,136,137,138,139,140,141,142,143,144,145,146,147,148,149,150,151,152,153,154,155,156,157,158,159,160,161,162 and 163). Receptors of both types are found in highly differentiated tumors and poorly differentiated tumors while primary tumors with metastases usually lack them (160). Taken together, these data indicate that endocrine control of endometrial cancer may be lost or reduced because of modifications that occur during the malignant process. In tumors that lack or have low concentrations of estrogen and progesterone receptors, the rate of adnexal spread of the tumor is increased and the recurrence rate of stage I cancer is higher (149). Progesterone receptor, and not the estrogen receptor, appears to correlate significantly with tumor grade and histology with the greatest decline in receptor positivity occurring between grade 2 and grade 3 tumors.

The predictive value of receptors in determining the course of endometrial carcinoma currently is a topic of controversy. Differing cut-off values have been reported by different investigators and these numbers do not reflect those obtained in breast carcinoma. This is partly due to the absence of standardized assays and reference materials. Apart from that, the presence of receptors is a predictive factor.

Creasman et al. (164) first reported that estrogen and progesterone receptor-positive endometrial tumors were less aggressive than estrogen and progesterone receptor-negative tumors and longer survival time is associated with high levels of these receptors. Ensuing work (165, 166) indicated that the concentration of estrogen and progesterone receptors was prognostic. Palmer et al. (167), using cutoff values of 70 fmole ER/mg protein and 30 fmole PR/mg protein showed that stage, age, and each of the steroid receptors, were associated independently with survival. Recently, a number of reports confirming the utility of ER and PR levels on predicting survival time have been published (168,169,170 and 171). In contrast, Erlich described overall survival as superior for patients with progesterone receptor-positive tumors ($p < 0.001$) but could not find any statistical relationship between estradiol receptor status and survival. In a subsequent study of 309 malignant endometrial tumors, Kleine (172) likewise observed that estrogen receptor had no significant prognostic relevance over that obtained by PR determination. In an examination of survival in early endometrial cancer, Sutton et al. (171) determined, using a Cox proportional hazards model, that tumor grade, peritoneal cytological results, PR status, and age were the most closely associated with disease-free survival. In 1989 and 1990 reviews, Kauppila (159) and Podratz (173) both concluded from an examination of a number of studies of endometrial cancer that PR is the best receptor measurement for the prognosis of survival and response to progesterone therapy. In summary, a negative ER or PR both give similar information in identifying nonresponders and a positive PR provides better accuracy in determining patients that will respond to progesterone therapy. However, as many as 70% of patients with endometrial cancer that have receptor levels above the cutoff limits normally used to identify candidates for endocrine therapy fail to respond to progesterone therapy. Lack of response in PR positive tumors to endocrine therapy suggests the presence of a defect(s) in the cellular machinery distal to the steroid binding site, cellular heterogeneity within the tumor (i.e., some cells possess receptors and others do not), cellular control mechanisms that are hormone independent, or increased hormonal metabolism (174,175 and 176).

EGF is excreted in high concentration in the urine in a biologically active form. The presence of the EGF receptors in close contact with this milieu provides the opportunity for the EGF to incubate with normal, premalignant, and malignant transitional epithelium of the bladder for long periods of time. With such favorable conditions, it is not too surprising that the density of receptor expression reflects the degree of malignancy in the bladder. It also is worthwhile noting that the expression of EGFrs on the superficial cells often precedes the standard histological evidence for a preneoplastic state.

Attempts have been made to control the progress of malignancy through the use of toxins or radioisotopes attached to ligands or antireceptor antibodies. The idea is for the compound to seek out the receptor and deal a lethal dose of toxin or radiation. Other approaches are the use of unconjugated antireceptor antibody designed to block the receptor-binding site, and anti-EGF antibody intended to inactivate EGF. None of these has proven successful. Explanations for the lack of success focus on the object of the therapy. Thus, those aimed at EGF have to deal with a large, continuous, and fresh supply of EGF (excreted in the urine). It would be very difficult to nullify this nonending influx of EGF with outside agents. The methods aimed at the EGFr need to penetrate deep into the tumor mass to get all of the receptor sites.

It appears that the increasing density of EGFr sites on the cervical and vulvar squamous-cell carcinomas can be related to the

biological aggressiveness of these malignancies. In particular, those neoplasm's with levels of EGFr >100 fM/mg of protein show a poor prognosis while those with levels <100 fM/mg of protein had more favorable 5-year survival (49).

Prostatic Cancer

In 1983 Barkovitz (177) made the observation about carcinoma of the prostate (PC) that “an incidence of 50% is reported in 80-year old men — but it is extremely rare before age 40.” Localized PC can be cured by surgical removal or radiation therapy. When the general health and age of the patient or progress of the disease (metastases) prevents this course of treatment, hormone therapy is the next option. Treatment of prostate carcinoma (PC) through hormone therapy has been successful with up to 80% favorable response. Therapy commonly consists of androgen ablation through orchiectomy or treatment with estrogen, diethylstilbestrol (DES) or luteinizing hormone-releasing hormone (LH-RH) or its analogs. Orchiectomy often is combined with the administration of DES. Cyproterone acetate with DES has been used successfully (178). However, the tumor eventually becomes resistant to the hormone therapy and again progresses.

Analogous to the work in breast cancer, where receptors have been moderately successful in predicting the course of the disease, studies have been carried out to determine the utility of receptor concentrations and affinities to aid in the prognosis of PC. While receptors for androgen receptors (AR), ER, PR, EGF, LH-RH, and PRL have been quantified in PC tissue, their prognostic value has not been obvious. In fact, the presence or absence of receptors is not even a factor when PC is initially diagnosed because of the high success rate with hormone therapy.

The most studied prostate receptor is the intracellular AR. Genetically, the AR is a single unique gene product. The gene itself can be divided into eight coding exons and corresponds closely in organization to the human estrogen gene. It is X-linked and defects have been observed in males who carry only a single copy of the gene. The receptor is a 110 kd single protein chain, with three distinct regions; the ligand-binding region, the nuclear interaction region (containing two zinc fingers) and a third region that modulates the protein synthesis process. The hormone and DNA binding domains are analogous to the respective domains in other steroid receptors and much of these regions are highly conserved between the steroid receptors. In contrast to other steroid receptors, AR is present in considerably lower tissue concentrations, extremely labile, and susceptible to proteolytic breakdown. AR is capable of binding a large number of agonist molecules, but activation of the receptor appears to depend upon binding to testosterone or dihydrotestosterone (DHT). The affinity of the receptor for DHT is two-fold greater than for the unsaturated testosterone and the dissociation rate from AR for the latter is significantly higher than for DHT. It has been speculated the testosterone is functionally a prohormone for DHT and estrogens such as 17β-estradiol.

The AR has been found in both the epithelial and stromal cells. As with the other steroid receptors there has been an evolution of models depicting the location of the AR. In the nucleus, the AR is present in a salt-extractable and salt-resistant form. The presence of molybdate or dithiothreitol solubilized all of the nuclear AR. It has been speculated that the molybdate interacts with the DNA binding domain of the AR. This leads to the conclusion that the salt-resistant nuclear AR is that which is associated with DNA. It generally has been assumed that the AR also is present in the cytosol and Mulder (179) describes the presence of AR aggregates in the cytosol with sedimentation coefficients of 8S and 4S. The relative proportion of these two species is dependent on the presence of molybdate or salt where the 4S is favored. Immunocytochemical studies, however, find little evidence of AR in the cytosol and locate the receptor almost exclusively in the nuclear region (180). It should be kept in mind that this technique depends upon the antibody recognition and aggregates of the AR may hide or alter the antigenic site(s).

Androgens promote cellular growth and EGF regulates the growth of both normal and tumor epithelial cells of the prostate. There is evidence that ARs also act as secondary promoters through the increased expression of EGF receptors (also found in prostate tissue) on the cellular surface membrane because the binding capacity of EGF receptors increases in the presence of androgens. Both of these receptors appear to act through enhancing the cells sensitivity to growth factors. It is not clear whether the mechanisms follow autocrine or paracrine control. In addition, it should be noted that the presence of AR alone is not sufficient for stimulating growth. The other condition is the ability of the tissue to convert testosterone to DHT, which is the active species.

Other receptors found in prostate tissue are estrogen, progesterone, growth hormone, hCG, and prolactin (PRL) receptors. The expression of EGF receptors in benign prostatic hyperplasia (BPH) is about twice that found in prostate carcinoma (PC) (181), while the reverse is found for AR. In PC tissue, an increase in receptor content appears to be associated with a corresponding decrease in AR and loss of differentiation (182). Both EGF and androgen receptors are more commonly found in highly differentiated then in poorly differentiated tumors and generally not found after prolonged estrogen therapy. Patients treated with DES showed up to 50% decreases in hCG receptors after 7 days of treatment, and after six months of treatment with DES, levels had dropped to 25% of the original value (183). High- and low-affinity–binding sites for estrogens are found in normal prostate tissues, but only the only low affinity site is present in tissue from BPH or PC (184).

Kadar (185) reports that rat PC tissue contains receptors for LH-RH, somatostatin and PRL. Treatment with the LH-RH agonist, [D-trp6] LH-RH, or the somatostatin agonist, RC160, resulted in shrinkage of the tumor mass with a corresponding decrease in the above receptor expressions. The decrease for PRL receptors was the greatest (about 50%). The authors speculate that tumor growth is inhibited by down regulation of these receptors through binding to these agonists.

The current direction of study is toward finding prognostic indicators after therapy has been initiated. Benson, et al. (186) observed that 85% of patients with nuclear androgen binding of ≥26 fM/mg did not show progression of the disease after 3 years, compared to only 40% of patients with androgen nuclear binding of <26 fM/mg. However, in grade 4 lesions, androgen binding is not a useful indicator and the PC is generally resistant to hormone therapy. They concluded that, excluding grade 4, measuring the amount of androgen bound by the nuclear AR

was a gross predictor of response to endocrine therapy. But these numbers are not sufficient to make a determination to withhold therapy. In fact, the presence or complete absence of ARs does not predict the response, as 80% of AR-positive and 25% of AR-negative patients respond favorably to hormone therapy.

After relapses from hormone therapy, further evaluation of AR does not appear to provide any useful guidance. Here it is of interest that the concentration of DHT present in the tumor may be a prognostic marker. Connelly (187) reports that “patients whose tumors contained more than 2 ng DHT/g of tissue were more likely to experience remission after endocrine treatment than those whose tumors contained lower concentrations of DHT.”

There is no evident correlation between AR concentration and disease stage. The latter is best evaluated through determination of tumor size. One contributing factor to this observation is the large amount of heterogeneity of AR's in PC tissue. This may explain why response to hormone therapy and PC tissue AR concentrations are not necessarily parallel (188). The problem of heterogeneity also is dependent upon the method of obtaining samples. For example, while needle biopsy is a simple procedure, the sample probably is not representative of the whole tissue. Samples obtained by electro-resection render PC tissue unsuitable because of the heat generated.

There are significant errors in current assays, which often invalidate correlations between the amount of AR and therapy response. In addition to the problem of heterogeneity (188), other significant problems include contamination with a plasma protein; the presence of significant amounts of sex hormone binding globulin (SHBG), which competes for DHT; and the presence of large amounts of endogenous DHT. When there are large amounts of endogenous DHT, many of the receptor sites become bound *in vivo*. This requires doing an exchange assay, which is slow at low temperatures, while at elevated temperatures the receptor is unstable. The use of DHT as the label is limited because of potential metabolism of DHT during the assay procedure. More commonly, the synthetic steroid methyltrienolone (R-188) or 3H-mibolerone is utilized as the ligand. They do not bind to SHBG and are not subject to metabolism during the assay procedure. The disadvantage of R-188 is that it binds to both AR and PR. This is eliminated by swamping the PR with triamcinolone acetate.

Unfortunately, in spite of the high level of response to endocrine treatment of prostatic carcinoma, at some point all PCs progress to an androgen-resistant state at which time the disease continues to advance. Thus, the obvious need is to understand why these tumors become androgen resistant. Perhaps the receptor becomes inactive through genetic processes that result in truncation or production of chimeric forms of the receptor.

Hormone-Resistant States

Hormone-resistance disorders may be related to a defect in the hormone itself, although a receptor or postreceptor defect that prevents normal functional activity of the receptor usually causes them. Normal function of a receptor involves a number of intricate prereceptor, receptor and postreceptor events that are very clearly dependent upon the structure of each of the participating molecules. The change of a single nucleotide in the genetic DNA sequence can cause an amino acid substitution and a resultant structural change that, if located in a strategic position in the molecule, may reduce or completely inhibit receptor activity. The list of identified endocrine disorders that result from inherited receptor defects continues to increase. Amino acid, gene or chromosomal deletions are responsible for many of the known receptor defects, although point mutations are much more common and the amount of genetic polymorphism present in a normal population probably accounts for at least some of the normal physiological diversity in hormone action. There are several examples of heterogeneity in the structure and function of specific receptors as a result of point mutations. This is particularly true for the LDL receptor in which 10 different point mutational changes have been described (189). Nearly all of the genes that code for hormones, growth factors and their receptors will probably show the same degree of genetic heterogeneity as has been described for the LDL receptor. Although several receptor-deficient diseases have been described, this still is a new area of research in which the analytical procedures are still largely experimental. Moreover, they are performed by a relatively small number of research laboratories, and the clinical diagnosis, as a general rule, does not utilize laboratory analysis of receptor status. Difficulties that may be encountered in the analyses of receptor characteristics in hormone resistant disease are the procurement of appropriate specimens upon which to perform the analysis, nonuniformity of analytical procedures, the lack of standardization materials that permit interlaboratory comparisons, and the relatively low number of patients involved. However, because most of these diseases reflect genetic disorders, the mutational changes responsible for receptor or postreceptor defects will very likely be determined in the future in clinical laboratories equipped to amplify the appropriate DNA sequences by the Polymerase Chain Reaction (PCR) and determining polymorphisms using molecular biology procedures.

Insulin Resistance

Insulin is the primary hormone involved with glucose, lipid, and protein metabolism. Its actions are varied, ranging from: increased glucose transport, increased glycogen synthesis, and antilipolysis (initiated within minutes of insulin binding to the receptor), to the initiation of gene transcription and protein synthesis that occur some hours after the hormone has bound to the receptor. In diabetes mellitus, carbohydrate metabolism is compromised, either through insulin deficiency, or because of target cell refractoriness to insulin. The former condition is referred to as type I diabetes, or insulin-dependent diabetes mellitus (IDDM) and the latter as type II diabetes, or noninsulin dependent diabetes mellitus (NIDDM). Thus, diabetes, classified into two broad categories, is not a single disease entity, rather it appears to be a constellation of conditions that may result from any of a number of environmental insults and/or genetic defects. For example, in type I diabetes most patients suffer from the lack of insulin because of autoimmune destruction of the pancreatic ß cells, although, mutational changes in the insulin gene can produce a nonfunctional hormone that is incapable of activating its receptor, also causing a form of type I diabetes. Clinical signs

of type I diabetes are permanently elevated blood glucose levels, weight loss, polydipsia, polyuria, and glycosuria, conditions that can lead to ketoacidosis. Successful treatment of type I diabetes is based upon the replacement of normal physiological levels of insulin.

Type II diabetes is the most common form of diabetes (80% to 90% of all diabetics) with a very complex etiology. This condition characterized by elevated insulin levels normally occurs later in life. NIDDM was referred to as mature-onset diabetes because it tends to occur later in life. Because this form of diabetes tends to be a heritable disease, a family history of NIDDM is much more frequent in new cases of NIDDM, and is a greater risk factor than is true for IDDM. No single susceptibility gene for type II diabetes has been identified, nor are mutational changes in the insulin receptor alone likely to account for the insulin resistance observed with most NIDDM because these mutations are rather uncommon in the general population. However, genetic anomalies in this receptor do occur. An “online” source of information on this and other genetic information is “The Online Mendelian Inheritance in Man” (132). This Internet source currently lists 35 mutational changes in the insulin receptor that have been described in the literature. Regardless, it is certain that they (mutations of the insulin receptor) do not occur at the prevalence rate of type II diabetes and likely account for a small percentage of type II diabetes. A more likely target of mutational changes responsible for NIDDM comprises the multiplicity of individual proteins involved in the extremely elaborate insulin receptor signaling cascades. This myriad of interacting proteins quite obviously presents numerous opportunities for genetically derived changes in protein structure, changes which have the potential to perturb insulin signaling and account for a wide variety of the different insulin sensitivities observed in type II diabetes. In addition to the genetic component of type II diabetes, this condition is further complicated by environmental factors such as obesity and physical inactivity that are known risk factors for patients with a family history of NIDDM.

Mutational changes that have been reported in the insulin receptor include single point, and reading frame shift mutations in the insulin receptor gene, resulting in a variety of receptor defects. These defects include: (i) inhibition of tyrosine kinase activity, (ii) inhibition of receptor transport to the plasma membrane, (iii) decreased dimerization of the α and ß subunits, (iv) decreased binding affinity for insulin, (v) impaired posttranslational processing, (vi) inhibition of proreceptor proteolysis, (vii) facilitated constitutive activation of the receptor, and (viii) inappropriate placement of stop codons. In general, mutations in the α chains reduce or prevent insulin binding and changes in the transmembrane or cytosolic region of the receptor may inhibit receptor autophosphorylation, and subsequent tyrosine kinase activity. The post-receptor signaling cascades also may be disrupted by mutational changes that prevent or reduce expression of the insulin receptor gene through the slowing or total inhibition of gene transcription. Normal insulin signaling may be impaired by a reduction in receptor numbers at the plasma membrane or decreased binding affinity of the receptor. Any of these structure-function changes can cause diabetes, even if the patient is heterozygous for the genetic change because of the reduced number of functional molecules. This is particularly true later in life when metabolism begins to slow down and the fat content of the body increases, increasing the level of stress on glucose metabolism.

Androgen Resistance

The spectrum of androgen-resistant syndromes ranges from complete androgen insensitivity syndrome (CAIS), in which genetic males present as phenotypic females, through the incomplete, or partial form of the syndrome (PAIS) in which the predominant phenotypic form is a male but characterized by any of several examples of incomplete virilization. Other conditions such as ambiguous genitalia, primary amenorrhea, prostate cancer, spinal bulbar muscular atrophy, male infertility, rheumatoid arthritis, breast cancer, hirsutism, baldness, and acne also are found in individuals with CAIS. The spectrum of partial virilization ranges from hypospadias in severely affected individuals, to gynecomastia and azoospermia in mildly affected patients (190). Some phenotypically normal men with oligospermia have been found to suffer incomplete testicular feminization with qualitative deficiencies in the androgen receptor (191). Severe cases of this syndrome usually are associated with the complete absence of the androgen receptor (AR), whereas the incomplete forms of the disorder are associated with qualitative changes in the receptor, perhaps responding to point mutations in the androgen receptor gene.

A single copy gene in the X chromosome encodes AR and defective forms of the receptor are attributable to one of several mutational changes. In most cases, a single point mutation occurs, resulting in frameshifts or nucleotide substitutions that are responsible for inappropriately sited stop codons (192) or amino-acid substitutions that lead to structural changes in the ligand binding (193, 194, 195, 196, 197, 198, 199) domains of the gene. Amino-acid substitutions, resulting from single point mutations, account for the majority of AR defects that lead to CAIS, or to PAIS. The steroid-binding domain appears to undergo more mutational changes than other domains of the AR protein. For example, one mutation, N758T, in a linker region between the fifth alpha helix (H5) and the first beta strand (S1) displayed normal binding affinity to DHT but abnormal dissociation kinetics. Receptor transactivation capacity also was reduced about 50% (198). In another mutation (TYR 571 CYS) that occurred in the DNA binding domain, gene transcription was disrupted, but 5 α-dihydrotestosterone-receptor-binding characteristics were not affected. These data confirm that a single mutational substitution in the DNA binding domain of AR was related to the pathogenesis of CAIS (199). Single-point mutational changes in AR have been described that have caused frameshifts with resultant stop codons, abbreviated AR structural protein, and abnormal function in the transactivation of the receptor (200). In another example, a point mutation in the donor splice-site of the second intron caused the entire second exon to be lost, exons 1 and 3 directly linked to each other, and mRNA exhibited a premature termination between codons 598 and 599. This change produced a truncated AR protein with no *in vivo* function and with abnormally low levels of transcript and protein (201). In addition to the single-point

mutations described above, deletions of two or more base pairs have been described in CAIS cases in which androgen binding is absent.

A change in the number of CAG trinucleotide repeats in the AR ligand-binding domain of the gene also may affect AR activity (202). The CAG repeat in exon 1 is important for the transactivation function of AR, and consequently for many androgen-dependent processes (203). [Further, the transactivation domain of AR is of great interest because of its causal relationship with a fatal neuromuscular disease, spinal bulbar muscular atrophy (Kennedy's syndrome)]. In infertile males, 20% had an increase in the length of a polymorphic trinucleotide (CAG) repeat segment. The increased risk of male infertility associated with long CAG lengths is accompanied with reduced risk of prostate cancer. Conversely, short polyglutamine tracts are (204). Other mutations of the AR gene occur commonly in prostate cancers and appear to be significant for prognosis of the disease (205). Although the change in the number of CAG repeat segments is the most commonly reported mutational change in the polymorphic-trinucleotide-repeat segments, single point mutations do occur. The insertion of a single adenine (or equivalently, a GC-dinucleotide deletion) has been found in a large kindred of phenotypic females with CAIS. This change in exon 1 of the AR gene produced a frameshift at amino-acid 60 and premature termination of the receptor downstream of the mutation (206).

Two functionally different ARs (Kd1: 5.58 nM = mutant, Kd2: 0.06 nM = wild type) were described in one AIS individual, suggesting the presence of somatic mosaicism in the patient. In this patient, androgen action was expressed in somatic cells through the wild type AR, demonstrating that the AR can modulate *in vivo* androgen action and emphasizes the importance of evaluation of somatic mosaicism (207). Thus, somatic mosaicism may be clinically relevant in AIS. The possibility of functionally relevant expression of the wild-type AR needs to be considered in all mosaic individuals, and treatment should be adjusted accordingly (208).

In summary, androgen insensitivity syndrome (AIS) exhibits a wide spectrum of phenotypic and physiological manifestations of the inability to respond to androgenic steroids. These range from complete androgen insensitivity syndrome (CAIS), in which genetic males present as phenotypic females, through the incomplete, or partial form of the syndrome (PAIS) in which the predominant phenotypic form is a male but characterized by any of several examples of incomplete virilization. The inability to respond to the presence of androgenic steroids is because of mutational changes in the androgen receptor that render it inoperative, either through the inability to bind the steroid, to translocate, or to bind to DNA an effect transcription. The advent of molecular cDNA cloning procedures in recent years has vastly improved our understanding of the molecular structure and mutational changes that may occur in the androgen receptor and how it plays in the syndrome of androgen insensitivity. It has been suggested that because of the wide phenotypic heterogeneity and variability in AR gene mutations, proficient bioassays of AR function would improve diagnostic efficiency and comprehensive evaluation of male under-masculinization (209).

The extent to which biomedical science has enhanced our understanding of the molecular mechanics of AIS is impressive and in families with well-characterized AR mutations, carriers can be identified and prenatal testing offered. An unexpected finding is that an AR mutation also causes X-linked spinobulbar muscular atrophy (210).

APPENDIX

ABBREVIATIONS

NONSTANDARD ABBREVIATIONS

AR	Androgens receptors
BPH	Benign prostatic hyperplasia
DCC	Dextran-coated charcoal
DES	Diethylstilbestrol
DHT	Dihydrotestosterone
EGF	Epidermal growth factor
EGFr	Receptor for epidermal growth factor (EGFr)
EIA	Enzyme immunoassay
ER	Estrogen receptor
FH	Familial hypercholesterolemia
GF	Growth factors
GFr	Growth factor receptors
GnRH	Gonadotropin releasing hormone
GR	Glucocorticoid
HAP	Hydroxyapatite
hCG	Human chorionic gonadotropin
HPCF	High-performance chromatofocusing
HPHIC	High-performance hydrophobic interaction chromatography
HPIEC	High-performance ion exchange chromatography
HPLC	High-performance liquid chromatography
HPSEC	High-performance size exclusion chromatography
HRE	Hormone responsive element
HSP	Heat shock protein
ICA	Immuno cytochemical assays
IGF-I	Insulinlike growth factor I
IGF-II	Insulinlike growth factor II
IRMA	Immunoradiometric Assays
LATS	Long acting thyroid stimulator
LDL	Low-density lipoprotein
LH-RH	Luteinizing hormone-releasing hormone
moAb	Monoclonal antibody
NSB	Nonspecific binding
OPD	O-phenylenediamine
PC	Prostate carcinoma
PCR	Polymerase chain reaction
PDGF	Platelet derived growth factor
PEG	Polyethylene glycol
PR	Progesterone receptor
PRF	Peptide regulatory factors
PRL	Prolactin
RPLC	Reverse phase chromatography
SDG	Sucrose density gradient
SHBG	Sex hormone binding globulin
SPA	Sucrose pad nuclear exchange assay
SS	Somatostatin
TFS	Testicular feminization syndrome
TGFα	and TGFβ Transforming growth factors
TKA	Tyrosine kinase activity

Section 11
Blood Bank/Transfusion Medicine

Blood Bank/Transfusion Medicine - Introduction

Harold A. Oberman

Section Chief

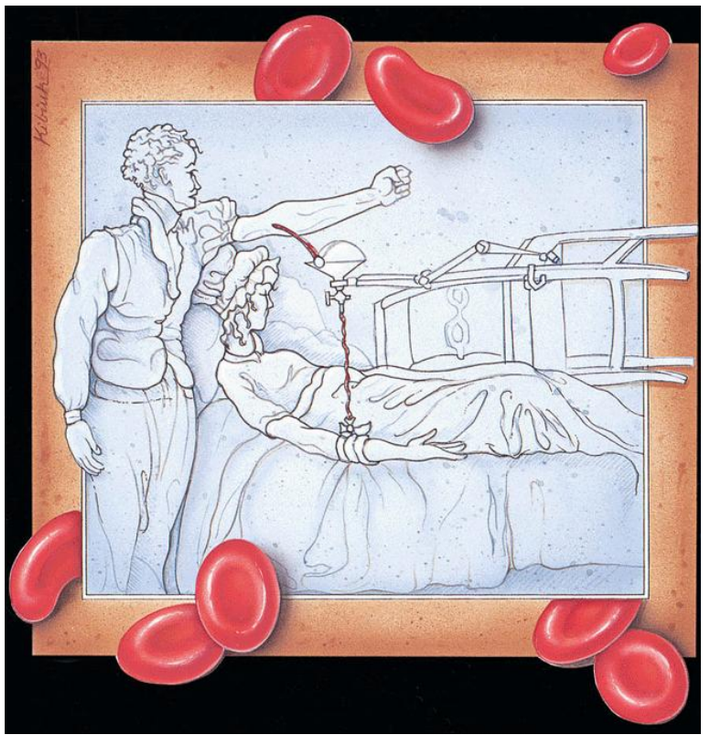

Figure.

The title of this section reflects the remarkable change in this area of clinical laboratory medicine in recent years. The term blood banking is far too restrictive, and its implied scope too limited, to characterize this subspecialty. The procurement and processing of blood for transfusion is only one facet of this field, as it has been modified to include a breadth of activities unforeseen only a few decades ago. The discipline has been clearly established as one that bridges the activities of the laboratory with those of clinical medicine. The uniqueness of this practice resulted in its recognition as a medical subspecialty by the American Board of Pathology, with the creation of a certifying examination 20 years ago. Similarly, the role of the medical technologist in this area has become more sharply defined, and also has resulted in the creation of subspecialty certification. The transfusion medicine medical specialist must translate the laboratory's results and activities to the patient's bedside. Therefore, it is insufficient for such an individual merely to be cognizant of immunohematology in a restrictive sense.

The following chapters address critical clinical activities such as apheresis procedures, blood component therapy, clinical consultation regarding adverse reactions to transfusion, the clinical significance of various blood group antibodies, and the transfusional management of various hematologic conditions. The laboratorian who assumes responsibility in this area must combine an understanding of clinical medicine with knowledge of the laboratory aspects of immunohematology.

Organization, Functions, Regulation, and Legal Concerns of Blood Banks

Harold A. Oberman

THE EVOLUTION OF BLOOD TRANSFUSION

Part of "68 - Organization, Functions, Regulation, and Legal Concerns of Blood Banks"

The Dawn of Blood Transfusion

Although blood has been considered as a therapeutic agent since ancient times, there was little rational, scientific basis for its use, nor was there full realization of its properties or of its dangers until the present century. Among the earliest references to blood transfusion are those in the Bible and in the writings of Ovid. At several points in the Scriptures there is admonition against transfusion (1), and this has resulted in the religious basis for the refusal of transfusion by such groups as Jehovah's Witnesses.

Ovid, in the eighth book of *The Metamorphoses*, describes restoration of youth to Aeson by the sorceress Medea through a “transfusion” of a magical potion. Unfortunately, she was unable to duplicate this remarkable feat. As other evidence of the mysticism associated with blood, Galen advised the drinking of the blood of a weasel for the cure of rabies, and Pliny described the drinking of the blood of dying gladiators as a cure for epilepsy (2).

Any rational approach to transfusion required an understanding of the circulation of the blood, and this was not available until the work of William Harvey in the early 17th century. By the middle of that century Richard Lower in London and Jean Denys in Paris were experimenting with blood transfusion in dogs, and both subsequently transfused humans with canine blood (3). Unfortunately, Denys, in 1667, transfused one of his subjects on three separate occasions, and the final transfusion eventuated in the first recorded example of a fatal acute hemolytic transfusion reaction. Even though a trial relieved Denys of guilt for this mishap (the subject's wife was subsequently found to have poisoned him), the controversy stemming from this case led to a multitude of decrees forbidding the practice, and resulted in the virtual elimination of transfusion for the next 150 years.

Nineteenth Century Blood Transfusion

The reawakening of interest in transfusion in the early 19th century was led by James Blundell, one of the most prominent obstetricians in London. He looked to transfusion as the most appropriate treatment for postpartum hemorrhage, and, in contrast to his 17th century forebears, reasoned that the father would be a more likely source of the blood than an animal (4). After the seemingly successful transfusion of a man dying of gastric carcinoma (5), Blundell undertook transfusions of patients with postpartum hemorrhage and consulted with other obstetricians who shared his enthusiasm for the procedure.

Transfusion during the 19th century was, at best, primitive. Among the indications cited in an 1849 publication were dyspepsia, esophageal stricture, dysentery, and prolonged fever (6). Moreover, the increased use of the technique without knowledge of blood groups or of immunology led to untoward complications. Therefore, by the last quarter of the century, popularity of transfusion waned, and substitutes for blood were sought. Among these substitutes were milk, alcohol, and saline solution.

The Modern Era

Landsteiner's recognition of the ABO blood group system at the outset of the 20th century permitted a rational approach to blood transfusion (7). Within the subsequent few years, Ottenberg recognized the value of reacting the blood of the donor with that of the recipient before transfusion to detect incompatibility (8). At the same time, the technique of direct transfusion was popularized, initially by vascular surgeons adept at anastomosing blood vessels of donor and recipient, and subsequently through the use of a variety of mechanical devices.

The problems of anticoagulation, preservation, and storage of blood had to be solved before indirect transfusion could be accomplished. The first World War served as an impetus to resolution of the first of these problems, as, near simultaneously, several investigators advocated citrate as an anticoagulant in 1914, and 2 years later Rous and Turner documented the value of adding sugar to the citrate as a preservative (9). This allowed the use of preserved blood for the transfusion of casualties by 1918 (10).

Use of anticoagulated stored blood for transfusion, so-called indirect transfusion, was slow to achieve greater popularity than direct transfusion because of the large amount of anticoagulant required in the early formulations. World War II, with the need

to transport blood for long distances, hastened development of improved preservative solutions so that by the early 1940s direct transfusion had all but vanished. Preservative solutions were modified initially through variations in the proportion of sodium citrate, citric acid and dextrose (11), and more recently through addition of sodium phosphate and adenine.

The development of organized centers for blood preservation also awaited the availability of reliable mechanical refrigeration equipment. The first blood banks did not appear until the mid-1930s, and not until 1937 was the first blood bank organized in the United States (12). World War II provided a remarkable impetus for blood banking. More than 13 million units of blood were collected during the war, principally by the American Red Cross, although much of it was used for fractionation into dried plasma.

The developments in this field in the years since World War II have been remarkable. One must appreciate that only the ABO, Rh, P, and MNS systems were known before 1945. Since that time, the understanding and complexity of these systems has increased and a multitude of new systems has been identified. In 1945, the antiglobulin reaction was introduced (13), and this facilitated detection of blood group antibodies.

In a contemporary development, stemming from attempts to meet the blood requirements of the Texas City, Texas, disaster, the American Association of Blood Banks was formed in 1947. While the major initial goal of the organization was to enhance blood availability through a national network of blood banks, of even greater significance were its additional contributions to safe and effective blood banking. The American Association of Blood Banks provided a focus for educational activities in the field, and its promulgation of standards of practice and its inspection and accreditation program were to play a major role in enhancing the safety of blood transfusion throughout the world.

The advent of plastic transfusion equipment, an innovation of the past 30 years, circumvented such complications of transfusion in glass bottles as pyrogen-related reactions and air embolism. It also permitted separation of blood components in a closed system, thereby providing the impetus for the current emphasis on component therapy. Plasmapheresis, first described in 1914 (14) was applied to large-scale plasma collection in the 1960s and, in the following decade, to treatment of disease. The latter has resulted in the technical subspecialty of therapeutic apheresis. By the end of the 1960s, in another major development with far-reaching clinical implications, the pathogenesis, treatment, and prevention of hemolytic disease of the newborn were defined.

During the past two decades, there has been increased emphasis on the infectious complications of transfusions, spurred by the development of tests for posttransfusion hepatitis and the advent of the AIDS epidemic. Continued refinement of these tests, enhanced by use of molecular biologic techniques, as well as pretreatment of some blood components to eliminate infectious organisms, has exemplified the yet unachieved effort to provide a blood supply free of risk of posttransfusion infection. Finally, the breadth of this field and the multitude of clinical issues it embraces have led to the recognition of Transfusion Medicine as a medical specialty.

BLOOD BANKS AND TRANSFUSION SERVICES

Part of "68 - Organization, Functions, Regulation, and Legal Concerns of Blood Banks"

Definitions and Functions of Blood Banks

The Standards of the American Association of Blood Banks defines a blood bank as an organization that collects, stores, and processes human blood. In contrast, a transfusion service tests the blood of the intended recipient and is concerned with the transfusion of the blood and its components. While this definition may be useful in distinguishing the roles of a community blood bank and a hospital transfusion program, it must be appreciated that it is an arbitrary and somewhat artificial distinction.

Blood banking embraces a variety of functions, including the recruitment and selection of blood donors; collection and typing of blood; preparation of blood components; testing of the blood for transfusion-transmitted diseases; distribution of the blood to the transfusing facility; pretransfusion testing and issuance of the blood to the patient; consultation on antibody-related problems and on indications for transfusion; and investigation of adverse reactions to transfusion.

Apheresis procedures play an important role, both in community and hospital blood banks. The technique is utilized for collection of blood components and for therapeutic procedures. Collection of peripheral blood stem cells by apheresis has facilitated both autologous and allogeneic bone marrow transplantation. A major therapeutic use of apheresis, or plasma exchange, is for treatment of thrombotic thrombocytopenic purpura/hemolytic uremic syndrome. This has allowed a successful therapeutic approach to these once-uniformly fatal conditions. Recent applications of therapeutic apheresis have included lipo-apheresis for reduction of low-density lipoprotein (LDL) cholesterol in patients with homozygous familial hypercholesterolemia and photo-pheresis for treatment of cutaneous T-cell lymphoma.

Many blood banks perform testing for resolution of disputed parentage, histocompatibility testing, and processing of bone marrow for autologous or allogeneic bone marrow transplantation. Finally, some institutions provide a program wherein outpatients come to the blood bank for their transfusional therapy, or, in some instances, are responsible for a program of home transfusion.

Therefore, the scope of the specialty is broad, embracing a variety of personnel, including donor recruiters, specialized administrators, nurses, technologists and physicians. In recent years the medical aspects have been grouped under the rubric of Transfusion Medicine.

Sources of Blood

Approximately 12.5 million units of blood are collected annually in the United States, and use of blood component therapy permits a much larger number of patients to be transfused. The number of donated units of blood available for transfusion purposes has declined in recent years for several reasons. Ill-founded concern regarding transmission of AIDS made people reluctant to donate in the mid-1980s. More recently, the more selective screening tests used to reduce the risk of transfusion-related infections have resulted in an increase in positive test results, resulting in loss of blood donors.

Most of the donated blood in the United States is collected by independent community blood banks, or by subsidiaries of the American Red Cross Blood Program. Many of the former blood banks are organized under the title of America's Blood Centers, formerly termed the Council of Community Blood Centers. These blood banks and the Red Cross program collect more than 90% of the blood transfused in the country, and hospital blood banks supply the rest (15). Centralization of the blood collection and processing function has been spurred by increased computerization of these functions as well as the advent of sophisticated tests for reducing the risk of transmission of transfusion-related infectious disease.

Fear of transfusion-transmitted infection, precipitated by the advent of AIDS, resulted in increased interest by the public in autologous blood provision and in directed donation programs, wherein a friend or relative provides blood for the patient. However, the introduction of more sensitive tests for Hepatitis C virus (HCV) and human immunodeficiency virus (HIV), accompanied by publicity emphasizing the increased safety of the blood supply, has occasioned a decline in both programs. Another factor in the decreased popularity of these programs is the failure of medical insurance carriers to reimburse such donations.

The Hospital Transfusion Service

Pretransfusion testing and issuance of the blood to the patient for transfusion is the responsibility of the hospital transfusion service. However, in some locales this function has been assumed by community blood banks. The latter centralized transfusion service is associated with cost savings in personnel and equipment for the hospital, as well as uniformity in the utilization of blood in the community. Therefore, it would be seen as a positive step in the current era of managed care. However, centralizing this function in the community or region likely inhibits the presence of an active transfusion medicine consultation program in the hospital.

The physician responsible for the hospital transfusion program not only is administratively responsible for all of the technical and medical policies and procedures of the laboratory, but also for serving as a consultant for any related problems (16). These responsibilities include designation of the source of the blood and components utilized in the hospital, the storage, processing and issuance of the blood and provision of a consultative service to enhance patient care. This includes responsibility for implementation of a quality-control program and for compliance with the requirements of accrediting agencies. The blood bank physician also may chair the transfusion committee of the medical staff and serves as an educational resource for the hospital's physicians on appropriate use of blood and components.

REGULATION OF BLOOD BANKS AND TRANSFUSION SERVICES

Part of "68 - Organization, Functions, Regulation, and Legal Concerns of Blood Banks"

The Standards of the American Association of Blood Banks (AABB) form the basis for the Association's accreditation and inspection program. The Standards were first published in 1958 in an effort to improve the quality and safety of blood transfusion. Prepared by the Committee on Standards, a group of knowledgeable physicians and technologists, each specified standard results from a consensus decision by the committee. It generally is agreed that the Standards are the most definitive statement of minimum performance guidelines of the practice of blood banking.

The AABB inspection program is a voluntary one, and is conducted every 2 years. Inspections are conducted as a prescheduled peer review undertaking, and there is an opportunity to correct deficiencies. Following correction of deficiencies a certificate of accreditation is issued. Therefore, the inspection should be perceived as an educational, as well as an accrediting, exercise.

Blood Banks also are inspected by the College of American Pathologists (CAP) as part of their extensive biannual inspection program. This program also is conducted by physicians and technologists, and is prescheduled. In contrast to the AABB inspection, it covers all hospital laboratories including the blood bank. Like the inspection of the AABB, the inspected laboratory is provided with a list of deficiencies and is given an opportunity for correction; therefore, the inspection also has a major educational component.

Federal responsibility for regulation of blood banks is vested in the Food and Drug Administration (FDA). Whereas only blood banks engaged in shipment of blood across state lines must be federally licensed, since 1975 all transfusion facilities have been required to register with the FDA. Regulation is based on conformity to the *Code of Federal Regulations* (CFR), published by the Center for Biologics Evaluation and Research of the FDA. All of the material pertaining to blood banking is contained in Title 21, Chapter 1 of the booklet. This forms the basis for the FDA inspection program, required of all licensed establishments.

In contrast to the peer-conducted AABB and CAP inspections, the annual inspections conducted by the FDA, which are necessary for maintenance of licensure, are unannounced. They are conducted by specially trained FDA personnel, who often lack any work experience in blood banking.

Similarly, the Department of Public Health of many states may conduct periodic unannounced inspections. This is based on statutory vestment of responsibility in such a department for the procurement, processing, distribution and use of blood, its components and its derivatives.

Finally, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) inspects all hospital laboratories, including blood banks, in the course of their annual or biannual inspection. This is a prescheduled inspection conducted by JCAHO-trained inspectors. The inspecting team includes a physician and nurse, as well as other individuals, one of whom may be a medical technologist. Like the inspections of the AABB and CAP, the JCAHO inspection includes a summation conference with the inspected institution and an opportunity to correct deficiencies before issuance of a final report. The type and number of deficiencies determines whether the institution will subsequently be reviewed annually or biannually.

Finally, specialty functions of blood banks also may be inspected. For example, those blood banks having a blood irradiator are inspected by the Nuclear Regulatory Commission. Similarly,

the bone marrow or stem cell processing function, as well as the histocompatibility testing area, is inspected by the Foundation for the Accreditation of Hematopoietic Cell Therapy (FAHCT). In addition, the blood bank may be inspected during external review of various hospital programs wherein they play an ancillary role, such as support of a trauma program.

LEGAL ISSUES IN BLOOD BANKING

Part of "68 - Organization, Functions, Regulation, and Legal Concerns of Blood Banks"

While a complete review of the subject of liability of blood banks is beyond the scope of the following discussion, it is appropriate to present a summary of some of the major issues confronting blood banks and transfusion services in this area. Of all clinical laboratories, the blood bank is most subject to legal action. Moreover, the variety of activities that may result in such actions is much wider than those present in any other clinical laboratory. In recent years, many claims have related to transfusion-transmitted infection, especially AIDS and hepatitis. Plaintiffs have sought damages on such disparate allegations as improper screening of blood donors, failure of compliance of the transfusion with clinically accepted guidelines, failure to inform the patient of the dangers of the transfusion, or failure to advise the patient of the alternatives to homologous transfusion.

Because the current litigious atmosphere promises increasing activity in this arena, the following comments are intended to serve as a framework to understand this important topic.

Malpractice

Malpractice is a lawsuit brought by an allegedly injured plaintiff against a defendant, in this instance a health-care professional, for breach of a recognized standard of care. In most instances, the defendants in a transfusion-related suit will include the director of the hospital blood bank, the hospital, the blood bank that provided the blood, and, very likely, the patient's physician. The independent acts of the patient's physician do not necessarily insulate the laboratory's responsibility, or vice versa (17).

A successful action requires demonstration of negligence on the part of the defendant, wherein there has been a breach of duty that has resulted in damages to the plaintiff. The plaintiff may be either a blood donor who has been injured pursuant to the donation procedure or a patient who has suffered an adverse reaction to transfusion or has acquired a posttransfusion infection.

The basic elements of such a lawsuit embrace proof that the defendant had a duty to the plaintiff, that the duty was breached, that this breach of duty caused the injury to the plaintiff and, finally, that there were compensatory damages.

The definition of the duty of the defendant to the plaintiff usually results in allegations that there was lack of compliance with the standard of care. Definition of the standard of care may be a point of contention. In some instances, this can be established by statements in such authoritative sources as the CFR of the FDA or the Standards of the AABB. In this regard, it is important to note that the words, “must” and “shall,” are carefully utilized in the Standards, in contrast to “may” and “should,” to distinguish mandatory practices from suggested practices, respectively. In other situations, expert witnesses are required to define and interpret this issue.

Expert witnesses also are used to determine whether or not the defendant breached the acknowledged duty and also to demonstrate that, but for that failure, the plaintiff's injury would not have occurred. Damages are awarded on the basis of medical costs, loss of earning power and pain and suffering; moreover, they commonly vary between jurisdictions.

Most states have legislation defining blood transfusion as a service, rather than sale of a product, in an attempt to protect blood banks from lawsuits based on the theory of strict liability. In the latter instance the defendant may be held guilty even in the absence of proof of negligence. For example, a blood bank could be liable for a patient acquiring a transfusion-related infection even if there is no test to detect that infection in the donor or in the unit of blood (18).

Consent for Transfusion

The blood donor and the patient receiving the transfusion must be informed of the risks of the procedure, and the patient also must be informed of the benefits and available alternatives. This must be done in a language that can be understood, and the subject must have an opportunity to ask questions and to refuse. Therefore, informed consent actually is a process wherein the subject, once informed, is allowed to make a choice.

In the instance of blood donation, the donor signs a form attesting to understanding of the performance of the venipuncture and removal of the blood or component, and also to his or her provision of truthful answers to the screening procedure. Patient informed consent is somewhat less straightforward. The manner of obtaining and documenting consent are subject to wide variation, and was the subject of a recent symposium (19). Recently, several states have mandated that written consent be obtained before elective transfusion through use of standardized forms.

In deciding how to comply with requirements for obtaining consent for a blood transfusion from an informed patient, one must consider when this should be done, who should be responsible for doing it, and how it should be documented. It is self-evident that the risks of transfusion must be discussed with the patient well in advance of the time of the transfusion if the patient is to have an opportunity to utilize such alternative procedures as autologous transfusion.

The physician responsible for the patient's care will be the one determining the need for the transfusion; therefore, this must also include responsibility for explaining the risks and benefits of the transfusion and detailing alternatives. This is best done at the time the need for a procedure requiring elective transfusion is first discussed with the patient. In most instances this function should not be performed by the hospital transfusion service.

The rationale for this activity is to provide the comprehending patient with an opportunity to understand the risks inherent in a potentially dangerous procedure, and, if appropriate, to take an alternative action. In addition, it allows the physician to demonstrate at a later date, if necessary, that the patient agreed

to accept the risk of the transfusion. Of course, the latter requires some form of documentation of the consent.

Documentation is necessary only to make it easier for the patient's physician to prove at a later date that the dialogue took place. In many instances this is accomplished by documentation on a special form or as a note in the patient's medical record. In some situations a signed form or a progress note in a medical record is considered unworkable or undesirable, and the information is provided to all patients through use of a brochure; however, it is necessary that the brochure advise the patient of a mechanism to ask questions or clarify areas of misunderstanding.

Refusal of Transfusion

From the foregoing discussion, it is evident that a competent patient has the right to refuse transfusion. This issue most often presents in the treatment of Jehovah's Witness patients who are unconscious and hemorrhaging or whose children require transfusion. The objection to transfusion is based on a strict interpretation of the recurrent biblical admonition against “eating” of blood.

In most instances when there is a serious threat to a minor's life if transfusion is not given, the juvenile court will order the transfusion even if this is contrary to the wishes of the parents. The court always will take into consideration the extent of the medical emergency and the extent of risk to the patient if transfusion is not performed. It is far less predictable that a court will order transfusion of an unconscious adult in a similar situation. In this situation, the court will attempt to balance the rights of the patient with the rights of society, may attempt to determine whether the patient expressed any wishes relative to transfusion when mentally competent, as well as the medical need for the procedure.

DONOR RECRUITMENT

Part of "69 - Blood Collection"

It has been estimated that, of an American population of approximately 270 million people, at least 150 million may be eligible to be blood donors. However, only approximately 8 million of them actually donate, providing an average of 1.6 units of blood every year or a total of 12 million units of blood. Almost none of these donors receives payment because paid donors have been shown to be more likely to be positive for markers for infectious disease and to transmit hepatitis by transfusion, even when appropriate screening tests are performed to eliminate the apparently dangerous units. Despite genome testing for known viral agents, it remains inappropriate for donor recruiters to offer financial incentives (including gifts or raffle tickets) as an inducement to give blood.

The most common approach to blood donor recruitment, community responsibility, assumes that everyone who is able to give blood should do so, so that all who need it can obtain it without an implied recruitment burden on the potential or actual user of blood. Alternatively, some favor an approach using individual responsibility, with each person responsible for providing his or her blood needs, either by accruing blood donation “credits” against which needs can be drawn or by obtaining replacement donations from family and friends after blood has been used.

Of all eligible donors, almost half have given blood at some time in their lives, and half of these, or 25% of the total, have given within the past 4 years (1). These data do not suggest any lack of understanding of the donation process or of the need for blood on the part of the public at large. When those former donors who remain eligible are asked why they no longer give, the two most common responses are the lack of a personal request and the lack of a convenient donation site. Although support of blood donation through the media is important as a reminder, without a convenient site and a personal request, blood donation is unlikely to occur.

The typical successful blood drive involves a blood center recruiter working with a designated individual in a business (or community or school) to develop a campaign that should include (a) an informational campaign that includes a strong statement of support from the person in charge, (b) informational meetings of committees of employees, (c) the personal solicitation by committee members of all other employees before the date of the drive for pledges to donate and for a specific donation appointment time, and (d) a personal reminder to donors the day before or the day of the drive. In addition, those organizations that regularly have successful blood drives will have a program to recognize those who have worked to organize the blood drive as well as the donors themselves. From the donor's perspective, the most convenient site for blood collection is the workplace, utilizing a cafeteria or recreation facility and equipment brought by truck and set up by blood center staff. With smaller businesses that have insufficient space, a self-contained bloodmobile, typically holding four to six donor beds, can be used. Blood collections at blood centers or other fixed sites often depend on the recruitment of individual donors by telephone.

Particular characteristics are desirable for any blood donation site: The physical environment must be pleasant, clean, and uncluttered; furniture should have no sharp edges and be capable of thorough cleaning and decontamination. Adequate space must be provided for auditory and visual privacy in donor interviews.

Because it is easier to retain a regular blood donor than to recruit a new one, a positive donation experience is critical. Interpersonal skills on the part of collection staff are as important as technical knowledge. Although the frequency of infectious disease markers is clearly lower in repeat donors, this may be a reflection of prevalence; it is not clear that the incidence of such markers (and, by inference, the risk of transfusion-transmitted disease) is lower in repeat donors.

DONOR SELECTION: HISTORY

Part of "69 - Blood Collection"

Donors are selected by history, physical examination, and laboratory testing to protect themselves and the recipient of their blood. Donor selection criteria are based on the Code of Federal Regulations (CFR) of the U.S. Food and Drug Administration, the Standards for Blood Banks and Transfusion Services of the American Association of Blood Banks (AABB) (Standards) (2), state and local regulations, and internal procedures of organizations such as the American Red Cross.

Donor Safety

Because there is no tangible benefit to blood donation, it is important that the risk of the procedure be kept to an absolute minimum.

Standards require that donors be at least 17 years old.

Although some centers allow donation only to age 66, others have extended the age for donor eligibility to 70 or 75 years of age, with no apparent increase in adverse donor reactions. Donors are asked questions about their current state of health, to determine that they are healthy enough to give blood. Donors with a history of cancer or abnormal bleeding and pregnant women usually are deferred.

Blood donation frequency has been limited to no more than once every 8 weeks to maintain the iron stores of the donor. More frequent donation is acceptable where there is clear benefit to a specific recipient, such as with autologous donation or with programs designed to limit donor exposure by providing several units for a given recipient (typically a newborn infant) from the same donor.

Recipient Safety

Most questions asked of the donor are related to recipient safety, such as those related to a potential risk of transmitting infectious disease. Donors are deferred if they have a history of hepatitis or of a positive test for hepatitis, or if they were the only donor involved in a case of posttransfusion hepatitis. Because hepatitis A does not have a prolonged carrier state and childhood hepatitis is most likely to have been hepatitis A, it is reasonable to accept for donation those prospective donors who have a history of hepatitis before age 11.

Donors who know that they have antibody to hepatitis B surface antigen (HBsAg) are accepted because such individuals are immune but not infectious and may have developed this antibody as a result of vaccination. Donors with known antibody to hepatitis B core antigen (anti-HBc) are deferred because anti-HBc may be present without detectable surface antigen in an infectious donor early in the course of the disease and also because anti-HBc may serve as a marker for the presence of other infectious sexually transmitted diseases, such as non-A, non-B, and non-C hepatitis or retroviral agents that are as yet uncharacterized. Finally, donors are deferred for 12 months from sexual or household exposure to hepatitis, parenteral exposure to blood, incarceration for more than 72 hours, or exposure to tattooing or other potentially unsterile skin puncture.

Donors are deferred if they have engaged in practices known to increase risk of human immunodeficiency virus (HIV) infection, such as intravenous drug use, male homosexual or bisexual activity, or heterosexual activity with people at such increased risk. Donors also are questioned about a positive test for anti-HIV (3). In addition, donors from some parts of the world are deferred from time to time, as new HIV variants, poorly detectable by current tests, are recognized in those areas. Although the donor is asked to read a pamphlet that describes in detail the kinds of exposure leading to deferral, as well as signs and symptoms of acquired immunodeficiency syndrome (AIDS) or AIDS-related conditions, it is preferable to repeat some of this information orally to ensure communication to the illiterate or inattentive donor.

Transfusion malaria has not been seen in the United States with any frequency since the end of the Vietnam War. Nevertheless, it remains a cause of concern, as malaria eradication in endemic areas has become more difficult and drug-resistant malaria more of a challenge. For this reason, special criteria must be used for donors who have traveled to areas considered endemic for malaria by the Centers for Disease Control and Prevention. Such donors are deferred for 1 year if they are asymptomatic. Those with a history of malaria or natives of countries endemic for malaria must be asymptomatic for 3 years before being accepted as blood donors.

Patients with tick-borne parasitic diseases, such as Lyme disease and babesiosis, may have infectious agents in the blood, but infected individuals usually are so sick during such episodes that they would be otherwise ineligible to be blood donors. Transfusion is a significant mechanism of transmission of Chagas' disease (American trypanosomiasis) in Latin American countries, but the disease is not endemic in this country. Only rare cases of transfusion-associated Chagas' disease have been recognized in this country to date (4). Nevertheless, because of the possibility of a chronic carrier state, donors with a history of Lyme disease, babesiosis, or Chagas' disease are deferred indefinitely.

Donors are indefinitely deferred if they have received human growth hormone or dura mater transplants because of reports of transmission of Creutzfeldt-Jakob disease (CJD) from these products. The recognition that bovine spongiform encephalopathy (BSE) and variant CJD (vCJD) are probably caused by the same agent strain and produce the same neuropathological picture, the temporal association in Great Britain between BSE and vCJD, and concern about the theoretical transmissibility of vCJD to humans by transfusion (5) all have led to deferral of donors who have spent time in Great Britain, and to a lesser extent, continental Europe.

Donors recently immunized with live attenuated viral or bacterial preparations are deferred temporarily. Donors taking specific medications thought to be teratogenic in trace amounts are deferred until the medication has cleared: etretinate (Tegison), indefinitely; acitretin (Soriatane), 3 years; and finasteride and isotretinoin (Proscar or Propecia, and Accutane, respectively), for 1 month.

Finally, the donor is asked to indicate that he or she has read and understood the contents of provided informational pamphlets, understands the risks of blood donation, the potential for donor reactions, and consents to the process.

DONOR SELECTION: PHYSICAL EXAMINATION

Part of "69 - Blood Collection"

As part of the donor screening process, donors' vital signs are determined and the arms are examined for evidence of intravenous drug abuse. The following types of donors are deferred: (a) those who are febrile (temperature above 37.5°C), to reduce the potential for transmission of infection; (b) those who are hypertensive (blood pressure greater than 180/100 mm Hg); (c) those who have abnormalities of pulse rate (less than 50/min or more than 100/min) or rhythm indicative of underlying heart disease; and (d) those who are so small (less than 50 kg) that the removal of 450 to 500 mL of blood could lead to more frequent donor reactions than with larger donors.

A hemoglobin or hematocrit determination (or equivalent) is performed on every potential donor to ensure that donation does

not cause or aggravate anemia. Both the CFR and Standards have a minimum hemoglobin requirement of 12.5 g/dL; neither the FDA nor the Standards consider normal variations of hemoglobin levels with sex or altitude.

A sample of blood obtained from the earlobe will provide a value for hemoglobin or hematocrit of up to seven volumes percentage higher (6) than one obtained by fingerstick or venous sampling; donors may be accepted after earlobe sampling who would otherwise be deferred. Neither Standards nor the CFR specifies the sampling technique.

A copper sulfate hemoglobin screening method is frequently used. If a drop of blood has a hemoglobin content of 12.5 g/dL or greater, it will sink in a copper sulfate solution with a specific gravity of 1.053. Although this test is fairly sensitive, it is not very specific, and blood centers often test those who fail the copper sulfate screening test with a more specific test such as a microhematocrit (7). This testing combination is unlikely to accept as a blood donor someone whose hemoglobin is below acceptable levels, nor will it lead to the deferral of those whose hemoglobins are truly satisfactory. Portable spectrophotometers may also be used for hemoglobin testing. All techniques used must be adequately monitored with a quality control program.

Repeated blood donation can lead to depletion of iron stores, particularly in women of childbearing age who may already have marginal iron stores. Some workers have advocated protective measures, such as the use of specific tests for iron deficiency in blood donors, prolonging the acceptable period between blood donations for selected groups, or the use of oral iron supplementation for regular blood donors. Others conclude that although depletion of iron stores is common, morbidity owing to iron deficiency will not occur without the development of anemia. Thus, the hemoglobin screening tests are adequate to prevent disease. Both groups are concerned about the safety of the donor, and both recognize that women of childbearing age are frequently deferred because of anemia. Blood donor iron supplementation may become more common in this country, particularly if oral iron in a form nontoxic to small children becomes available.

COLLECTION PROCESS

Part of "69 - Blood Collection"

Blood collection techniques are designed to ensure the safety and efficacy of the product obtained. These techniques include positive identification of the donor and assigning a unique identifying number for the donation that is placed on the bag, the donor history card, and any pilot samples needed for laboratory testing. After finding a suitable vein, the phlebotomist prepares the skin by extensive cleansing with surgical soap in an area several inches around the site of intended venipuncture. This is followed by the application of an iodine-containing solution (typically PVP iodine, less sensitizing than tincture of iodine) to complete the process of making the skin as aseptic as possible (8). After this skin preparation, the needle is inserted and 450 to 500 mL of blood (less if the donor weighs less than 50 kg) is collected in a bag containing an anticoagulant-preservative solution. During collection, the blood is mixed regularly, either manually or with a mechanical agitation device, to ensure adequate mixing with the anticoagulant and prevention of formation of clots. When the collection is completed, tubing from the donor to the bag is sealed, after which the needle is withdrawn. At all times, attention is paid to the need to prevent anything other than donor blood from entering the preconnected sterile plastic bags.

Pressure is applied directly to the donor's venipuncture site to ensure stoppage of the blood flow, and the bag is prepared for transport to the component preparation laboratory after stripping the blood in the still-attached plastic tubing into the bag. This ensures that this blood has been adequately mixed with anticoagulant. The plastic tubing is then sealed into segments that remain attached and can be used for subsequent testing in the laboratory or in the hospital.

After a few minutes, an appropriate bandage is placed on the arm, the donor sits up for brief observation by the phlebotomist, and then is escorted to a refreshment area. Here the donor is encouraged to drink several glasses of liquid, while under observation for potential reactions. Donors are given verbal or written instructions after donation regarding care of their arms, the need to drink fluids to replace lost blood volume, and permissible activity levels.

PROCESSING OF DONOR BLOOD

Part of "69 - Blood Collection"

Each unit of donor blood must be tested for ABO group and Rh type, and blood from donors with a history of transfusion or pregnancy must be tested for unexpected antibodies. In addition, all donor blood is tested to determine its potential for transmission of infectious diseases. Required tests include a serologic test for syphilis, HBsAg, anti-HBc, anti-HIV-1/2, HIV p24 antigen, anti-human T-cell lymphotrophic virus I/II, and anti-hepatitis C virus (HCV). The results of these tests must be negative before the blood is released for transfusion. Some centers test for alanine aminotransferase, but this is not required. Genome detection by nucleic acid amplification techniques is now performed for HCV and (for most centers) HIV, in addition to traditional antibody detection. Although most needs for cytomegalovirus-safe blood are met by prestorage leukoreduction techniques (9), some clinicians may request blood found negative for anti-cytomegalovirus.

DONOR REACTIONS

Part of "69 - Blood Collection"

Donors may develop insignificant post-phlebotomy hematomas and local pain or paresthesias. Although some of these complications may require a visit to a physician for reassurance, they usually resolve within a brief interval.

A more difficult problem is the vasovagal reaction, seen in 1% to 3% of blood donors. Early symptoms and signs include pallor, nausea, and diaphoresis. Some donors become apprehensive and hyperventilate, producing signs of hypocalcemia. Often these early signs are recognized and the reaction reversed, with cool compresses and leg elevation, or, for hyperventilation, rebreathing of expired air. More severe reactions proceed to a loss of consciousness, associated with a significant drop in systolic blood pressure (rarely as low as 50 mm Hg) and a pulse rate ranging

from 40 to 60 per minute. Signs of severe reactions may include convulsive movements, vomiting, and (rarely) fecal or urinary incontinence. These reactions are frightening but inconsequential in otherwise healthy donors.

Although the primary cause of this vagal stimulation is thought to be psychological, it is associated with the volume of blood removed, the age and donation experience of the donor, and the ambience of the collection facility. Prevention includes assuring that underweight donors are not bled to excess and that additional attention is paid to young and first-time donors or donors otherwise apprehensive because early reactions often can be reversed. It is important to ensure that donors are under observation in the immediate post-donation period so that signs and symptoms are noted before fainting and potential injury occur.

Treatment involves keeping the donor supine, with legs elevated to enhance blood flow to the head. Recovery usually takes 5 to 15 minutes. Although some facilities are prepared to provide intravenous fluids, oxygen, or vagus nerve–blocking medications, these interventions are almost never necessary. The donor who has had a reaction should be advised that these reactions may recur within the next several hours, and extra caution should be used in driving or operating heavy machinery. Donors with severe reactions should be discouraged from attempting to give blood again in the near future.

SPECIAL COLLECTION ISSUES

Part of "69 - Blood Collection"

Blood Safety

Despite varied approaches to exclude those at high risk of infection from the donation process, there is serologic evidence that individuals infected with hepatitis and HIV-1 continue to donate. Continued effort must be made to reduce donation frequency by those at high risk. In addition to adequate privacy for the donor interview and verbal questioning about high-risk activity, accurate donor identification must be obtained for comparison with donors who have been deferred previously and whose identification has been entered into a permanent donor deferral record. Some centers use automated systems to perform such screening before donation. Sites other than the blood center should offer confidential and inexpensive infectious disease testing to minimize donation merely to obtain a test result. Finally, the donor should be given the opportunity to indicate confidentially after donation that his or her blood should not be used for transfusion. Opportunities for such confidential exclusion can be provided at the time of blood donation and by providing a telephone number that the donor may call afterward.

Staff Safety

Collection staff should be protected as much as possible from exposure to blood. Sharp objects must be placed in a container that allows disposal without fear of accidental puncture. Staff who are at risk of exposure to blood should be encouraged to be vaccinated for hepatitis B. Those preparing segments from the plastic tubing of the blood bag need to be protected from breakage and spraying of blood from these segments at the time of sealing.

Universal precautions (including the use of gloves by phlebotomists) are appropriate whenever dealing with patients, whether hospitalized or at the blood center for therapeutic phlebotomy or autologous donation. Collection staff is at minimal risk of infectious disease acquisition from the occasional exposure to blood of volunteer blood donors because there is no increase in frequency in such workers for markers for highly infectious agents such as hepatitis B (10). Nevertheless, gloves should be available for those phlebotomists who wish to use them and should be worn in every situation in which a phlebotomist has broken or abraded skin.

Directed Donations

Fear of infectious disease transmission has prompted many potential recipients of transfusions to seek blood from family and friends rather than from the general blood supply. No data exist to show greater safety of such donations. In fact, because of a higher percentage of first-time donors, directed units are likely to have a higher frequency of markers for infectious diseases. Despite concern that the availability of such blood tends to make the general blood supply less attractive in the eyes of the public, this practice is generally tolerated.

One special situation in which the use of a designated donor has merit is in the attempt to limit the number of donors to whom an individual recipient is exposed. For instance, for a pediatric recipient with limited blood requirements, several donations could be obtained from one donor, thereby limiting the exposure of the recipient to blood from other allogeneic donors. In special situations of this sort, the benefit to the recipient may outweigh the additional risk incurred by the donor with modification of established standards for blood donors, for instance, by decreasing the interval between donations and lowering of the hemoglobin standard.

Some indications for directed donation are prompted by medical need and not patient demand. These include plateletpheresis of siblings to provide products for a bleeding patient found to be refractory to platelets from random donors or the use of maternal platelets for neonatal thrombocytopenia.

Preoperative Autologous Donation

Patients may donate their own blood preoperatively for anticipated transfusion during elective surgery. The ideal candidate for preoperative autologous donation is someone who is otherwise in good health undergoing a procedure that is likely to require transfusion. Patients undergoing orthopedic or plastic surgical procedures often fall into this category.

There is more controversy regarding patients who have a significant systemic disease, such as patients scheduled to undergo coronary artery bypass procedures or patients with cerebrovascular disease. In these situations, a severe donor reaction with hypotension would be especially dangerous because of preexisting compromise of blood flow to critical organs. In fact, reactions leading to hospitalization occur 12 times more frequently (1/17,000) in autologous than in allogeneic donors (11). Nonetheless, such patients are often accepted as autologous donors (with the exception of those with significant aortic stenosis,

transient ischemic attacks, and active angina pectoris). Because the risk of disease transmission from allogeneic blood transfusion is constantly decreasing, it is difficult to justify significant risk to these patients.

Patients scheduled for operations in which blood is not expected to be used are not candidates for autologous donation. Autologous donation in pregnant women is particularly controversial. There is little benefit to those in whom bleeding at the time of delivery is not expected; moreover, there is a theoretical risk related to potential compromise of the fetal blood supply.

Preoperative autologous blood was 5% of the blood collected in 1997, after reaching a peak of 8% in 1992 (12). This reduction in autologous collections stems in part from the recognition of the general safety of the blood supply, and therefore this expensive procedure may be cost-effective only with younger patients undergoing operative procedures requiring several units of blood. Because blood from autologous donors has a higher frequency of markers for infectious diseases, it is not subsequently made available for allogeneic transfusion if not used by the autologous recipient.

When preoperative autologous transfusion is indicated, it is acceptable to modify the standards set for volunteer blood donors: the increased benefit to the patient justifies some modest increase in risk to the patient as a donor, such as a minimum hemoglobin of 11 g/dL rather than 12.5 g/dL and allowance of repeated donation at short intervals.

BLOOD COMPONENT PREPARATION AND STORAGE

Part of "69 - Blood Collection"

General Principles

The desirability of providing patients with those elements of blood that are needed and, to the extent possible, limiting exposure to unneeded components was recognized long before it was generally possible to practice such an approach. The widespread use of plastic bags in the late 1950s allowed centrifugal separation of the formed elements of blood in a closed, presterilized system without bacterial contamination. As a consequence, the often fatal septicemia resulting from introduction of bacteria into blood and blood components at the time of preparation or further manipulation has become rare. Sterile “docking” devices provide additional flexibility, allowing the coupling of two sterile plastic containers that were not connected at the time of manufacture. If, during component preparation, the system is opened aseptically without the use of a sterile docking device, the components can be stored for no longer than 24 hours at 1 to 6°C or 4 hours at room temperature.

Red Blood Cells

Cell Aging

Red cells in the body have a life span of approximately 120 days. Although minimal destruction of cells of all ages occurs normally, by far the more common pattern is the destruction of senescent red cells. This process is related in part to a loss of lipid in the red cell membrane and a loss of the ability of the membrane to maintain its shape. When red blood cells (RBCs) are stored *in vitro*, the process is associated with depletion of adenosine 5′-triphosphate (ATP). Length of storage of RBCs is related to the ability of the cells to maintain adequate levels of ATP. Energy is needed not only to drive the sodium-potassium pump but also to support the shape of the RBC and to prevent loss of the lipid from the membrane. Ideal storage *in vitro* would provide RBCs with a posttransfusion survival equal to, or better than, cells of a similar age remaining in the body. Because blood drawn from a normal donor contains RBCs with an average age of 60 days, it would be desirable to store those cells in *vitro* so that at the end of 30 days, or another 25% of the RBCs' normal life span, no more than the oldest 25% of the RBCs would die. In fact, it is possible to store RBCs for longer periods of time with greater survival of the remaining cells.

Measurement of RBC Preservation

Transfused RBCs circulating 24 hours after transfusion have a survival that is comparable with normal RBCs. It is therefore possible to use 24-hour posttransfusion recovery as an index of posttransfusion survival. Seventy percent of the RBCs transfused after a period of storage should survive in the circulation 24 hours after transfusion. Because cells from one individual have post-storage survival characteristics different from those of another, the use of a 75% 24-hour survival of transfused RBCs will ensure that at the end of the allowed storage period, most units of blood will have adequate recovery and survival despite individual variation.

In the evaluation of anticoagulant-preservative solutions, posttransfusion recovery and survival are currently assessed by the transfusion of radiolabeled autologous RBC. Although technically more difficult, it is probably important to utilize a double-radioisotope technique. The loss of some RBCs immediately after transfusion may lead to falsely high levels of recovery if a single-label technique is used.

Red Cell Function

The primary role of the RBC is the delivery of oxygen to tissues. Storage of RBCs *in vitro* leads to the depletion of 2,3-diphosphoglycerate (2,3-DPG), important for the release of oxygen from hemoglobin. Although this substance is regenerated within 24 hours after transfusion in storage-depleted RBCs, it would be ideal to maintain 2,3-DPG levels during storage. Rats, resuscitated after hemorrhage to half-normal hematocrits with 2,3-DPG–depleted blood, have compromised survival compared with those resuscitated with 2,3-DPG replete blood (13). However, it has not yet been possible to demonstrate in the human that absence of 2,3-DPG from transfused RBCs, even when such cells are given in massive amounts, has been associated with adverse effects, perhaps because of other compensatory mechanisms such as the Bohr effect.

Transfusion of blood toward or after the end of the allowable storage period has no apparent ill effect for the recipient, aside from a posttransfusion increase in hemoglobin catabolites, such as bilirubin and lactate dehydrogenase.

Anticoagulant-Preservative Solutions

Citrate has long been the anticoagulant of choice. It is readily catabolized in the body on transfusion. By chelating calcium, it inhibits several calcium-dependent steps of the coagulation sequence. It is commonly used in a sodium citrate/citric acid buffer and is provided in substantial molar excess to calcium. Anticoagulants such as ethylenediaminetetraacetic acid and heparin have been used from time to time but have deleterious effects on stored RBC over all but the shortest time span.

Dextrose was added to anticoagulant solutions because of the empirical recognition that it improved posttransfusion RBC recovery and survival. Buffering of the anticoagulant-sugar solution to a lower pH allowed heat sterilization without caramelization of the sugar. With greater awareness of the role of ATP and 2,3-DPG in RBC preservation and function, preservative solutions have been fashioned to optimize amounts of these materials in RBC during storage.

Standard anticoagulant-preservative solutions have long included a sodium citrate/citric acid buffer, adjusted to provide an initial pH of the stored blood of 7.5 to 7.6 (at 37°C), and dextrose. Although inorganic phosphate has a minimal effect on posttransfusion recovery, it has been shown to enhance maintenance of 2,3-DPG and ATP. Adenine prolongs RBC storage *in vitro* by serving as a substrate for synthesis of ATP. These elements provide the basis for a commonly used solution, CPDA-1, which contains a citrate buffer with phosphate, dextrose, and adenine.

Currently, collection container techniques allow increased amounts of adenine to be added selectively to the red blood cells, after removal of plasma or platelets, to provide still better RBC storage. The amount of adenine added is ultimately limited by the potential for precipitation of adenine metabolites in the kidneys after massive transfusion. Some adenine-enriched solutions contain a small amount of mannitol to reduce hemolysis after extended storage. Because these adenine solutions allow the separation and recovery of larger amounts of plasma and allow RBC to be stored for a longer period, they have become the favored anticoagulant-preservative solutions.

RBCs can be prepared simply by sedimentation, followed by separation of the supernatant plasma into an attached container. Most facilities that collect blood in substantial amounts separate platelets, fresh frozen plasma, or both, from the whole blood by centrifugation techniques soon after collection, leaving either CPDA-1 RBCs with a volume of 250 mL, a hematocrit of 70% to 80%, and 35-day dating or adenine-enriched (AS-1, AS-3, or AS-5) RBCs, with a volume of 350 mL, a hematocrit of 50% to 60%, and 42-day dating. Storage of RBC *in vitro* causes changes in plasma pH and potassium and RBC ATP and 2,3-DPG. The nature of these changes is shown in Table 69.1.

TABLE 69.1. BIOCHEMICAL CHANGES IN BLOOD STORED AT 5°C

	CPDA-1		AS-1[a]	
	WB	**WB**	**RBCs**	**RBCs**
Days stored	0	35	35	42
% Viable cells (24-hr posttransfusion)	95–100	79	71	80
pH (at 37°C)	7.6	6.98	6.71	6.6
ATP%	100	56	45	64
2,3-DPG%	100	<10	<10	<5
Plasma K^+ mmol/L	4.2	27.3	78.5	50

[a]As an example of adenine-enriched preservatives; AS-3 and AS-5 are not substantially different.

WB, whole blood; RBCs, red blood cells.

Modified from Vengelen-Tyler, V, ed. *Technical manual*, 13th ed. Bethesda, MD: American Association of Blood Banks, 1999.

Rejuvenation

RBCs severely depleted of ATP and 2,3-DPG during storage can regenerate these substances with the addition of “rejuvenating” solutions, such as one containing pyruvate, inosine, phosphate, glucose, and adenine. These solutions are potentially toxic and cannot be transfused, so after rejuvenation, the RBCs are washed and transfused or glycerolized and stored in the frozen state for subsequent transfusion.

pH

Because of continuing slow RBC metabolism of glucose to lactate during storage, the accumulation of hydrogen ions in the plasma lowers the pH over time. RBCs stored for 35 days in CPDA-1 may have a pH as low as 6.7 (37°C). There is no evidence that the massive transfusion of blood with a pH at this level has any deleterious clinical effect because of numerous *in vivo* mechanisms to compensate for acidosis.

Potassium

Potassium is gradually lost from RBCs during storage and increases in the plasma overlying whole blood at a rate of approximately 1 mEq/day. The potassium concentration is higher when accumulated in smaller amounts of plasma, such as with RBCs, in either CPDA-1 or adenine-supplemented preservative solutions. The infusion of RBCs containing potassium at these high concentrations (as much as 80 mEq/L toward the end of the storage time) is of no consequence in most clinical situations, including the transfusion of massive amounts of stored blood. There are concerns, however, about potassium levels in blood used for exchange transfusion of neonatal patients and for blood given to patients with renal failure. The concern is focused on the rate of infusion of hyperkalemic plasma rather than the amount of potassium infused, which is minimal in relationship to the total body potassium. Further, potassium-depleted RBCs will act as a sponge and reabsorb plasma potassium in hours. In these situations, provision of blood that is relatively fresh (stored for less than 7 days) provides levels of potassium that although elevated are safe for clinical use.

Washed RBCs

RBC washing can remove most (99%) of the plasma, so it can be used for the treatment of patients for whom some plasma components can be deleterious. For instance, some clinicians treat

patients with paroxysmal nocturnal hemoglobinuria with washed RBCs to prevent the infusion of complement components. Washing RBCs may be sufficient to prevent reactions in patients who lack IgA and who have had reactions to blood components containing these immunoglobulins. In a few cases, however, this procedure has been insufficient to prevent such reactions, and products from donors known to be IgA deficient are preferable. Finally, washing has been used to remove plasma containing elevated levels of plasma potassium, where this is thought to represent a hazard to neonatal patients.

Frozen RBCs

RBCs can be stored for 10 years in the frozen state. It is possible that little additional loss of posttransfusion recoverability is seen after several decades. Such storage requires either extremely rapid freezing of RBCs and maintenance at very low temperatures (obtained with liquid nitrogen freezers that maintain a temperature below -120°C), the addition of large amounts of cryoprotective agent, or some combination of these approaches (14). The inconvenience of transport of RBCs stored in liquid nitrogen has led to the widespread use of 40% wt/vol glycerol as an intracellular cryoprotective agent. The glycerol must be added to the RBCs slowly with mixing to minimize hemolysis. Glycerolized RBCs may be stored with mechanical refrigeration at below -65°C for as long as 10 years and may be transported in dry ice. After thawing, most of the glycerol in the RBCs must be removed to prevent posttransfusion osmotic hemolysis. Removal of glycerol is commonly performed by washing the thawed RBCs first with a hypertonic saline solution, followed by resuspension in normal saline. RBC recovery from a freeze/thaw/wash process must be at least 80%, and the RBC viability at 24 hours posttransfusion must be at least 70%. Because of cost, this technique is not widely used, but it is valuable for storage of RBCs of rare phenotype or for autologous transfusion situations when extended storage is needed.

Leukocyte Reduction

Background

It has been recognized for many years that transfused “passenger” leukocytes can cause deleterious effects in recipients of transfused RBCs. Even crude techniques such as removing a 50-mL buffy coat containing as many as 80% of the leukocytes of a unit were effective in preventing many transfusion reactions. For more complete leukocyte removal, RBCs were washed, in some cases with red cell rouleauxing agents to facilitate separation. A more sophisticated technique involved the filtration of stored, centrifuged blood through a microaggregate filter. This filter was designed to remove the aggregates of leukocyte and platelet debris found in RBCs on storage. Although widely used, this filter probably provided little beneficial effect except in patients on cardiopulmonary bypass because the lungs removed such microaggregates without demonstrable untoward effect.

Leukoreduction Filters

Current leukoreduction filters are effective in removing leukocytes, initially present in RBCs at a level of approximately 10e9, to a level of less than 5 × 10e6, with recovery of at least 85% of the red cells.

Platelets can also be filtered to a level such that a pool of six will contain 5 × 10e6 leukocytes but still meet Standards for platelet content. More commonly, leukoreduced platelet components are readily produced by newer apheresis processes to the same leukoreduction standards. Fresh frozen plasma prepared from platelet-poor plasma may contain sufficient leukocytes to warrant consideration of leukoreduction.

Leukoreduction to less than 5 × 10e6 of red cells and platelets will have several beneficial effects (15). Febrile transfusion reactions caused by infusion of leukocytes or cytokines are significantly reduced. This reduction is seen most clearly in patients who have received multiple platelet transfusions. Alloimmunization to platelets, manifested by the development of lymphocytotoxins and a platelet refractory state, is also significantly reduced. Disease transmission by agents found in leukocytes, such as cytomegalovirus and human T-cell lymphotrophic virus (and other herpes viruses, trypanosomes and toxoplasma, by inference) are reduced. Experimental evidence suggests that transfusion-transmitted bacterial infection should be reduced as well. Although leukoreduction is advocated in some countries to reduce the risk of vCJD, this is a hypothetical benefit at present.

The transfusion of allogeneic leukocytes has been known for years to have an immunomodulatory effect: such transfusions improve renal allograft survival and reduce the frequency of spontaneous abortion. There are increasing data, both clinical and in experimental animals, showing that allogeneic leukocytes cause immunomodulation that is manifested by postoperative infection (and perhaps by cancer recurrence) and that leukoreduction may reduce such infection and thereby shorten hospital stay.

Leukoreduction is preferably carried out in the blood center (prestorage) rather than at the bedside because leukoreduction is more consistently complete, with quality and process controls, and with better removal of white-cell fragments and reduced opportunity for cytokine development. Because leukofiltration can itself cause transient activation of cytokines, bedside leukoreduction has caused severe hypotensive reactions (16).

The use of current leukoreduction techniques has virtually eliminated use of older white-cell removal methods, including the use of microaggregate filters and washing of RBCs for leukoreduction.

Platelets

Platelets are the lightest of the formed elements of the blood. After slow centrifugation of whole-blood, platelet-rich plasma can be found at the top and can be readily separated. Subsequent hard centrifuging of this plasma will sediment the concentrated platelets, and the platelet-poor plasma can then be removed. Collection of blood into a closed system containing several preattached plastic bags allows this manipulation without opening the bag system; therefore, platelets in concentrated form can be prepared and stored at room temperature for several days after collection without fear of growth of bacteria introduced at the time of preparation.

The techniques used to provide consistently good platelet concentrates begin with collection of blood from the donor.

Blood collection should be fairly rapid and uninterrupted. The collection of blood over a prolonged period of time, or with interruptions, could lead to the initiation of coagulation on a scale too small to be detected but sufficient to cause the initiation of platelet activation. After collection, the temperature of whole blood is maintained above 20°C until platelets are prepared.

In the laboratory, optimal platelet recovery is best achieved by using a force as low as reasonably possible for the centrifugal preparation of the platelet-rich plasma. Although yield can be slightly increased by extending down into the lymphocyte-rich top layer of buffy coat, this usually is unnecessary. Furthermore, the increase in white cells from such a procedure adds to the metabolic storage burden and to a greater possibility of sensitization (unless white cells are removed pre–storage). The platelet-rich plasma is then recentrifuged to concentrate the platelets. This spin should be as hard as necessary to provide adequate concentration but not so hard that platelets are damaged in the process. The platelet-poor plasma is then expressed, leaving a final product volume of between 50 and 70 mL, depending on the type of container used.

Platelets may be stored for 5 days at room temperature by meeting critical storage requirements in areas of pH, plastic, and agitation. The pH of the platelet concentrate is inclined to fall as a result of normal metabolic activity during storage. Nevertheless, it must be maintained at levels at or above 6.2 to preserve posttransfusion function. Plastics with improved gas permeability can allow development of an abnormally elevated pH; this may also be deleterious to platelets.

The type of container used for platelet storage has special requirements. Polyvinyl chloride bags have in their formulation a plasticizer to provide flexibility. A common plasticizer, diethylhexylphthallate (DEHP), is leached from the polyvinyl into lipid-containing plasma, where it has a protective effect on red cell membranes, facilitating extended storage of RBCs. Because of the remote possibility of toxicity from the transfusion of this material and because of prolonged storage of DEHP in the body, manufacturers have sought formulations that would minimize its content (17). The plastics most often used for storage of platelets consist of polyolefin, which does not require a plasticizer, thinner polyvinyl with reduced DEHP, or polyvinyl with a different plasticizer, butyrye–trihexylcitrate, which is readily catabolized. Such approaches could reduce the current theoretical concerns related to the infusion of DEHP. In general, plastic designed for platelet storage provides better exchange of CO_2 and O_2 across the bag and therefore minimizes the reduction in pH in the stored platelet concentrate.

Another constant requirement for prolonged storage of platelet concentrates is agitation. Immediately after removal from the centrifuge, the concentrate should be allowed to stand undisturbed for an hour or two. After this, the component is placed on a mechanical device for continuous agitation. Some types of agitation are particularly harsh and provide poor platelet recovery. The common types currently utilized are to-and-fro, rotary, and elliptical agitation with the bag laid flat on the rotator. The most desirable type of rotator varies to some extent with the type of bag used (18). The temperature must be maintained between 20°C and 24°C, during storage.

Plasma at room temperature is a bacterial growth medium. Donors must not be bacteremic at the time of donation and platelets cannot be pooled in an open system to provide a typical dose for transfusion and then subsequently stored at room temperature. Even with these precautions, a few bacteria present at the time of collection may proliferate to unacceptable levels in platelets stored at room temperature. As a result, there is a maximum storage time of 5 days, even though survival characteristics of the platelets would permit their storage for longer periods with some containers.

Before platelets could be stored for 5 days, there was a considerable interest in their storage in the frozen state. The traditional and still preferred technique uses dimethyl sulfoxide (DMSO) rather than glycerol as a cryoprotective agent. However, platelets are more fragile than RBCs, and the recovery of platelets in the recipient after freezing and thawing is poor. Storage of platelets in the frozen state has little use today except when autologous platelets are obtained from patients with leukemia in remission and stored in the frozen state to provide support at the time of the next therapeutic induction. This may be especially helpful when patients are refractory to homologous platelets.

A small number of units of platelets prepared every month must be tested at the end of their storage time to be certain that a pH of at least 6.2 is maintained in all units tested and to confirm that the number of platelets present exceeds 5.5×10^{10} in 75% of the units tested. Some platelet preparation techniques result in the presence of substantial numbers of RBCs in the final product, giving it a pink tinge. The presence of more than 0.5 mL of RBCs is thought to be excessive. Rh-negative patients who are given repeated transfusions of platelets from Rh-positive donors with this level of RBC contamination will develop Rh antibodies, although this occurs in only 8% of Rh–negative patients. However, it is not difficult to produce products with much lower RBC contamination. Furthermore, if Rh-positive RBC-containing platelets must be given to Rh-negative recipients, Rh human immunoglobulin can be administered within 72 hours of the transfusion to prevent sensitization.

Fresh Frozen Plasma

The primary concern in the preparation of fresh frozen plasma is that it be frozen quickly, before deterioration of labile clotting factors. For this reason, the time of collection should be noted. The plasma must be placed in the freezer within 8 hours of this time and should be frozen solid in the next 2 hours (within 10 hours of the time of collection of the whole blood). Because the time to preparation of a frozen product and the time of freezing are important, rapid freezing techniques have been used. Plasma may be immersed in an ethanol/dry ice bath or other liquid heat exchange mixture or placed in a freezer designed for the rapid freezing of 200 to 250 mL of plasma. When frozen, there is little deterioration of labile clotting factors in fresh frozen plasma, so that it can be stored for a year below -18°C without appreciable loss of activity. Plasma frozen within 24 hours of collection has similar amounts of labile clotting factors (except factor VIII) and can be used in place of fresh frozen plasma for most purposes.

To minimize transfusion-transmitted disease, fresh frozen plasma is being replaced for some patients with products less likely to transmit infectious disease. Two such products are available

in this country. Pooled plasma, solvent/detergent-treated has been treated by a process that inactivates all lipid-encapsulated viruses, including HIV and hepatitis B virus. It has been shown to be safe and effective in treating conditions for which fresh frozen plasma would be used. Because of a theoretically increased risk of transmission of nonlipid-encapsulated agents resulting from the pooling process, other single-unit approaches to reducing the risk of transfusion-transmitted disease have been used. These include the European approaches of methylene blue, ultraviolet light, or pasteurization, and in the United States, donor retested fresh frozen plasma that has been stored until the donor can be retested after the window period of the infectious agents of concern (19). Plasma components are still used inappropriately for volume expansion. The risk of disease transmission, compared with pasturized albumin or plasma protein fraction, makes it undesirable for this purpose.

Cryoprecipitated Antihemophilic Factor

When fresh frozen plasma is thawed at 5°C, some material does not go into solution. The remaining precipitate contains much of the factor VIII [antihemophilic factor (AHF)] and fibrinogen, some of the factor XIII, and large multimers of von Willebrand factor from the original unit. The cold precipitation property of these proteins is important in the further manufacture of factor VIII preparations for the treatment of hemophilia. Cryoprecipitate can be separated from the precipitate-poor plasma by centrifugation of the plasma containing the cryoprecipitate. After centrifugation, the precipitate will adhere to the plastic bag sufficiently to allow transfer of the precipitate-poor plasma into another container. Between 7 and 15 mL plasma is usually left in the bag. Each cryoprecipitate is then refrozen, thawed when needed, and pooled for transfusion. In some facilities, small amounts of saline are added to the cryoprecipitate to facilitate its recovery. At least four units are assayed each month to determine factor VIII activity. Units tested must contain at least 80 units of AHF activity (compared with the approximately 200 to 250 units present in the original fresh frozen plasma), and at least 150 mg of fibrinogen.

Cryoprecipitate poor plasma (plasma from which the cryoprecipitate has been removed) has been shown to be useful for the treatment of thrombotic thrombocytopenic purpura, especially in patients unresponsive to therapeutic plasma exchange with fresh frozen plasma. The cryoprecipitation process removes from the plasma the large von Willebrand factor multimers that contribute to the pathophysiology of the disease, although the plasma transfusion allows the replacement of the metalloproteinase responsible for the cleavage of these multimers *in vivo* (20).

CYTAPHERESIS PRODUCT PREPARATION AND STORAGE

Part of "69 - Blood Collection"

Principles

Apheresis devices are available that allow the collection of an adequate dose of platelets or granulocytes from a donor at one setting. The most commonly used devices utilize a continuous flow of donor blood, using principles developed in the dairy industry for separation of cream.

The donor typically is connected to a machine by a single or double needle for a period of 1 to 2 hours, during which time blood is continuously collected, the desired component is separated by centrifugal techniques, and the unneeded components are returned to the donor through a second venous line. Both continuous and discontinuous flow devices may be used for the procedure. This process is carried out in a closed system; platelets collected by such techniques can be stored with agitation for 5 days at 20° to 24°C.

Donor Selection

The historical, physical, and laboratory criteria used for the selection of apheresis donors are similar to those of whole blood donors. In addition, there are some special concerns. Although these donors can be drawn as often as every 2 days (but no more than 24 times a year), the cumulative loss of RBCs must be less than 200 mL every 8 weeks and of plasma, less than 1 L (1.2 L for persons weighing more than 80 kg) every 7 days, with a maximum of 15 L in 12 months. If formed elements of the blood are removed on a frequent basis, the donor's safety must be protected by measuring levels of these formed elements during the course of a series of donations. Because two large veins are required for most procedures, the adequacy of venous access is important.

Plateletpheresis donors should not have taken aspirin-containing medication within the preceding 36 hours because aspirin blocks the generation of thromboxane A_2. This blockage inhibits the platelet-release reaction and renders the donated platelets less effective, particularly when the donor is the sole source of platelets for the recipient. The granulocytapheresis process is usually facilitated by the use of special agents given donors; these are considered below.

Untoward Consequences of Cytapheresis

Lymphocytes have a density similar to that of heavier platelets, and intensive plateletpheresis will remove large numbers of lymphocytes. This will deplete long-lived T lymphocytes and, in theory, could lead over time to a weakening of immune function. However, although reduction in lymphocytes and immunoglobulin levels has been noted (21), no clinical change in immune response has been seen. The removal of large numbers of platelets in a plateletpheresis procedure causes a drop in the peripheral blood platelet count of perhaps 30,000/μL. It is important, therefore, that the initial platelet count be adequate to support such a loss. For sequential donors, the postprocedure count from one plateletpheresis can be used as the initial count for the subsequent procedure.

The most common donor reaction during and after a cytapheresis procedure is the reaction to infusion of the anticoagulant sodium citrate, which can produce symptoms of hypocalcemia. Therefore, it is desirable to reduce the amount of infused citrate as much as possible. When such a reaction occurs, it is treated by slowing the infusion rate or providing oral calcium-containing antacids.

There are special concerns for donors asked to provide granulocytes collected by apheresis. To collect adequate numbers of

granulocytes, donors must be given a rouleaux-inducing agent, such as hydroxyethyl starch (HES). Because this material has been reported to cause both anaphylactic reactions and persistent localized skin reactions, donors must be asked about related allergies. In addition, products of this type are colloid volume expanders. Consequently, when given over several days, they can cause localized edema, headache, and other symptoms of fluid retention. The total product dose given to a donor should be monitored; it may be possible to reduce the dose for a given donor from one procedure to the next. A donor given a corticosteroid to improve granulocyte collection, particularly when the donor is used repeatedly over a short period of time, must be asked about underlying diseases that might be exacerbated by corticosteroids, such as peptic ulcer disease and tuberculosis. Granulocyte donors have also been given granulocyte colony–stimulating factor (G-CSF). This product improves granulocyte yield dramatically (22). However, it causes untoward effects: most donors given several doses have bone pain and flulike symptoms, amenable to analgesic treatment. Donors receiving G-CSF and subjected to large-volume apheresis for peripheral blood progenitor cell retrieval may develop significant thrombocytopenia (less than 100,000/μL). There is also a theoretical risk with G-CSF of the agent's stimulating neoplastic transformation or mobilizing such neoplastic forms.

There have been isolated reports of donor reactions related to the equipment. Kinks in tubing have been reported to cause hemolysis. Faulty rotating seals have caused particulate carbon to be found in collection containers (but without apparent ill effect for the donor). Cytapheresis devices generally have bubble detectors to guard against dangerous reactions resulting from air embolization during reinfusion.

Plateletpheresis

Indications

Patients refractory to random platelets are often responsive to platelets from donors matched at the HLA-A and -B loci or shown to be serologically compatible by cross-match techniques. Adequate amounts of such platelets from a single donor can be provided only with cytapheresis techniques. Furthermore, use of cytapheresis platelets reduces the number of donors to whom a recipient is exposed with each dose of platelets from six to one, producing a similar reduction in risk of transfusion-transmitted disease and in the potential for febrile transfusion reactions.

Most apheresis platelets are produced routinely to have fewer than 5 × 10e6 leukocytes. These leukoreduced apheresis platelets produce the beneficial effects of leukoreduction, including decreased febrile transfusion reactions, decreased alloimmunization, reduced disease transmission (particularly of cytomegalovirus), and a reduction in the effects of immunomodulation caused by transfusion of allogeneic leukocytes.

Collection Techniques

Platelet collection times vary from 1 to 2 hours. Most current procedures involve the use of a needle in each arm, although both intermittent and continuous techniques are available that use one arm. Each technique should be able to produce a product containing 3 $\times 10^{11}$ platelets in at least 75% of the units tested. Many of the products contain enough platelets to allow splitting into two doses. To be labeled leukoreduced, a plateletpheresis product must contain fewer than 5 × 10^{6} leukocytes.

Granulocytes Pheresis

Granulocytes are collected by procedures utilizing continuous flow techniques with differential centrifugation. Because granulocytes have densities only slightly less than RBCs, it has been difficult to provide a clean centrifugal separation. Therefore, it is customary to utilize a rouleaux-inducing agent, such as HES, to enhance the sedimentation of RBCs with centrifugal force. Even with the use of such an agent, it is difficult to obtain doses of granulocytes that meet standards without pretreatment of the cytapheresis donor with corticosteroids to increase the numbers of circulating granulocytes by mobilizing them from the bone marrow and by increasing the number in the circulating pool. Typical protocols include giving the corticosteroid in at least two doses, for instance, at 12 and 3 hours before beginning the cytapheresis procedure. In addition, donors may be given G-CSF, which induces leukocytosis in the donor and improves granulocyte recovery dramatically. Use of this approach, particularly if coupled with a rouleauxing agent and corticosteroid, produces levels of granulocytes that produce readily detectable increments in recipients. Standards requires 1 × 10^{10} granulocytes in 75% of the products tested; with HES, G-CSF, and corticosteroid levels of 7 to 8 × 10^{10} are readily achieved (23). Although this product may be lifesaving, its indications and clinical efficacy are still being defined.

Granulocytes may be stored at room temperature for as long as 24 hours after collection; however, they should be transfused as soon as possible.

Peripheral Blood Progenitor Cells

Modest modification of the granulocyte collection procedure allows collection of peripheral blood progenitor cells in donors pretreated with G-CSF. Typically, a donor selected as a candidate for autologous or allogeneic peripheral blood progenitor cell transplantation is premedicated for 5 days with G-CSF and then undergoes one or two large-volume (15 to 25 L processed) apheresis procedures (22). The donor/patient is subject to the side effects of G-CSF but avoids the bone marrow retrieval procedure.

Erythrocytopheresis

Apheresis technology can be used to obtain RBCs. Typically, two units of RBCs are collected at one 45- to 60-minute session but with the total volume removed not exceeding 571 mL. This procedure requires special considerations for donor safety (minimal hematocrit, 40; weight, more than 130 lb for males and 150 lb for females; donation, no more frequently than every 112 days) but allows collection of two units of difficult-to-obtain blood groups or from autologous donors, with one rather than two donor visits (24).

Therapeutic Cytapheresis

Cytapheresis techniques may also be used therapeutically to reduce dangerously elevated levels of leukocytes (greater than 100,000/µL, especially in acute myelogenous leukemia) or platelets (greater than 1,000,000/µl), before or as an adjunct to chemotherapy (25). In addition, RBC exchange by cytapheresis may be indicated for some patients with sickle cell anemia.

PLASMAPHERESIS

Part of "69 - Blood Collection"

Plasma can be obtained from donors by automated apheresis techniques to provide two units of plasma for preparation of fresh frozen plasma or to provide plasma for the manufacture of blood derivatives. A two-unit withdrawal can be performed as often as twice weekly on an ongoing basis, with the removal of as much as 1 L of plasma per week (1.2 L for persons weighing more than 80 kg). Individuals who donate plasma more frequently than every 8 weeks must have predonation serum protein determinations and periodic determinations of immunoglobulin levels.

Therapeutic Plasma Exchange

Automated plasmapheresis equipment is used for the therapeutic removal of plasma, using albumin and saline as replacement fluids (plasma products are used for patients with thrombotic thrombocytopenic purpura). With adequate venous access, a one-plasma volume (approximately 3 L) exchange can be performed in 90 minutes. This technique has been shown to be effective for patients with such conditions such as thrombotic thrombocytopenic purpura, Guillain-Barré syndrome, myasthenia gravis, and hyperviscosity syndrome (26).

70
Pretransfusion Testing

W. John Judd

Pretransfusion testing comprises a series of policies and procedures including laboratory tests, the goals of which are to provide blood for transfusion that will have the optimal clinical effect without causing undue harm to the recipient. These elements of pretransfusion testing can be placed in one of three categories: those related to donor unit testing and processing, those related to patient sample collection and testing, and those that serve as a final check between the donor unit and intended recipient (Table 70.1). Proper performance of each element will enable the right unit of blood to be transfused to the right patient (1). This chapter addresses each element of pretransfusion testing. However, before embarking on such detailed discussion, it is appropriate to provide some background relative to the principles of immunohematology and the human blood groups. This background enables the reader to appreciate the rationale for the serologic procedures used in pretransfusion testing.

PRINCIPLES OF IMMUNOHEMATOLOGY

Part of "70 - Pretransfusion Testing"

Blood Group Antibodies

Blood group antibodies are proteins that react with antigens on the surface of red blood cells (RBCs). They can either be acquired naturally or through immunization with foreign RBCs (2).

IgM Antibodies

Naturally acquired antibodies are IgM proteins found normally in plasma from persons whose blood cells lack the corresponding antigen. They are stimulated by antigens present in the environment (3). Antibodies to A and B antigens are of this type. Bacteria constituting normal intestinal flora carry blood group A- and B-like polysaccharides. As these flora establish in the gut, they provide the immune stimulus for anti-A and anti-B (3). The antibodies thus formed react *in vitro* as hemagglutinins or hemolysins; their ability to do so is a reflection of their size and number of sites available for antigen-binding (4) (Table 70.2).

IgG Antibodies

Most blood group antibodies are IgG, which are immune in origin and do not appear in plasma/serum unless the host is exposed directly to foreign RBC antigens. The usual stimulating event is blood transfusion or pregnancy. IgG antibodies are smaller than IgM, have only two sites for antigen-binding, and may only coat RBCs rather than act as direct agglutinins.

All antibodies to RBC antigens, other than naturally occurring anti-A and anti-B, are considered unexpected. They can either be alloantibodies, directed toward non-ABO-system antigens absent on the RBCs of the antibody producer, or autoantibodies directed toward self-antigens. The latter may cause autoimmune hemolytic anemia. Unexpected antibodies in donor plasma may destroy recipient RBCs, whereas antibodies in the recipient may cause accelerated destruction of transfused RBCs. In pregnant women, such antibodies may cross the placenta and cause hemolytic disease of the newborn (5).

ANTIGEN-ANTIBODY INTERACTIONS

Part of "70 - Pretransfusion Testing"

Interaction between blood group antibodies can be observed either directly by examination of RBC and antibody mixtures for agglutination (or clumping) and hemolysis or indirectly by use of the antiglobulin test. These two serologic techniques are summarized in Table 70.3.

Direct Agglutination

Because of their size and number of antigen-binding sites, IgM antibodies react directly with RBCs in tests performed on glass slides or in test tubes. For the latter, RBCs are mixed with antibody, briefly incubated at room temperature, and centrifuged. The centrifuged tests are examined for agglutination and hemolysis.

Examination for hemagglutination may be performed either macroscopically or microscopically, but the latter is not encouraged because it leads to the detection of nonspecific reactivity. Shown in Fig. 70.1 are a series of tests manifesting varying degrees of agglutination. The strength of the observed reactions can be graded. The values given are based on a scoring system in common use (6).

Hemolysis

Anti-A and anti-B also cause direct lysis of group A (or B) RBCs, especially if tests are incubated at 37°C. This hemolysis results from the action of complement, a series of α and ß globulins that

act in sequence as enzymes (e.g., esterases) to attack the RBC membrane and cause holes to be formed through which the intracellular hemoglobin can escape (Fig. 70.2). For initiation of the complement cascade, two pairs of immunoglobulin heavy chains must be bound in close proximity to each other on the RBC surface. Initiation of the complement cascade readily occurs when a single pentameric IgM antibody molecule is bound; for it to oc-cur with IgG antibodies, there must be two IgG molecules bound in close proximity to each other. Further, not all IgM antibodies bind complement to RBCs and complement binding does not always proceed to complete RBC lysis by membrane attack complex. Rather, activated C3b may be cleaved to C3d, which does not initiate the binding of C5; hence, no membrane attack complex is formed. However, C3d remains bound to RBCs and can be detected by the antiglobulin test (see below) (4,5).

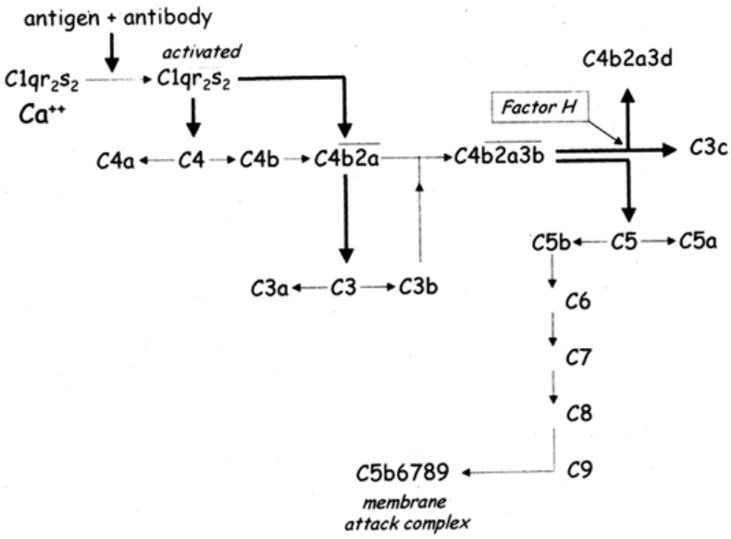

FIGURE 70.2. The complement cascade (classic pathway).

Antiglobulin Test

IgG antibodies and complement components bound to RBCs by either IgM or IgG antibodies are best detected by the antiglobulin test, in which antibodies raised in animals (usually rabbit or sheep) or prepared by hybridoma technology, are used to detect human IgG and complement bound to RBCs. The principles of this test are as follows:

1. Antibody molecules and complement components are globulins.
2. The injection of human globulins, either purified or in whole serum, into an animal stimulates the animal to produce antibodies against the foreign globulins. These antibodies are antihuman globulins; they can also be produced by hybridoma technology. The antihuman globulins that are important for blood group serologic work are anti-IgG and anti-complement (anti-C3d).
3. Anti-human globulin (AHG) will react with human globulins, either bound to RBCs or free in serum. Thus, RBCs must be washed free of unbound globulins before testing with AHG. This is crucial to the avoidance of false-negative tests owing to neutralization of AHG by unbound globulins.
4. Washed RBCs coated with human globulin are agglutinated by AHG.

Antiglobulin tests can be performed either indirectly after *in vitro* incubation of RBCs with serum or directly to demonstrate that RBCs are coated with globulins *in vivo*. The indirect antiglobulin test (IAT) is used to detect and identify unexpected antibodies in the serum of blood donors, prospective transfusion recipients, and prenatal patients. The direct antiglobulin test (DAT) is used to detect antibodies bound to RBCs *in vivo*; such antibodies may be seen in patients with hemolysis owing to autoantibodies or drugs, infants with hemolytic disease of the newborn, and patients manifesting an alloimmune response to a recent transfusion (5).

ANTIGENS, GENES, AND BLOOD GROUPS

Part of "70 - Pretransfusion Testing"

Approximately 300 distinct blood group antigens have been identified on human RBCs. Biochemical analysis has revealed

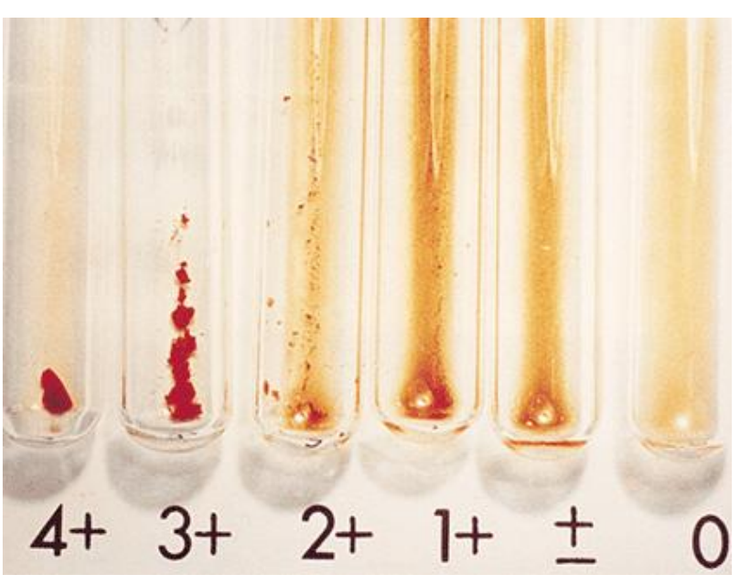

FIGURE 70.1. Hemagglutination reactions ranging from 4+ (strong positive) to 0 (negative). Based on the scoring system of Marsh (6).

that most antigen structures are either protein or lipid in nature. In some instances, blood group specificity is determined by the presence of attached carbohydrate moieties. The human A and B antigens, for example, can be either glycoprotein or glycolipid, with the same attached carbohydrate structure. With few exceptions, blood group antigens are an integral part of the cell membrane.

Several different notations are used and different concepts have been put forth to explain the genetics of the human blood groups. The presence of a gene in the host is normally reflected by the presence of the corresponding antigen on the RBCs. Usually, a single locus determines antigen expression, and there are two or more alternative genes or alleles (e.g., *a* and *b*) that can occupy a locus. Each individual inherits one allele from each of their parents. For a given blood group, when the same allele (e.g., *a*) is inherited from both parents, the offspring is said to be homozygous for *a* and only the antigen structure defined by *a* (a) will be present on their RBCs. When different alleles are inherited (i.e., *a* and *b*), the individual is heterozygous for *a* (and *b*) and both a and b antigens will be found on their RBCs.

In some blood group systems, several loci (or subloci) govern the expression of multiple blood group antigens within that system.

TABLE 70.1. ELEMENTS OF A PRETRANSFUSION TESTING PROCESS

Donor testing	
	ABO and Rh typing[a]
	Detection of unexpected antibodies to RBC antigens in plasma[a]
	Testing for infectious disease markers[a]
	Confirmation of ABO type, and Rh type of units labeled Rh negative
Recipient testing	
	Positive identification of patient before collection of blood samples
	Procurement and labeling of blood samples
	ABO and Rh typing
	Detection of unexpected antibodies to RBC antigens in plasma/serum
	Comparison of current test results with records of previous tests
Donor/recipient testing	
	Selection of RBC components that are compatible with the intended recipient's ABO group and with clinically significant unexpected antibodies, if present or previously detected
	Performance of tests to detect ABO incompatibility (and other known incompatibility) between selected RBC components and the intended recipient
	Positive identification of patient before transfusion
	Confirmation of concordance between donor unit label information and patient name and unique hospital identification number

[a]These tests, if performed by blood supplier, need not be repeated by transfusion service.

TABLE 70.2. CHARACTERISTICS OF BLOOD GROUP ANTIBODIES

Characteristic	Naturally Acquired	Immune
Immunoglobulin	IgM	IgG
Sedimentation constant	19 S	7 S
Molecular weight	900–1,000 kDa	150 kDa
Electrophoretic mobility	Between β and γ	γ
Bind complement	Often	Some
Placental transfer	Yes	No
Direct agglutinin	Yes	No
Hemolytic *in vitro*	Often	No
Example	Anti-A, anti-B	Rh antibodies

TABLE 70.3. TWO TYPES OF RBC SEROLOGIC TESTS

Direct Tests	Indirect Tests
Mix serum and RBCs	Mix serum and RBCs[a]
Incubate (room temperature, optional)	Incubate (37°C)
Centrifuge	Centrifuge, examine for agglutination and hemolysis (optional)
Examine for agglutination and hemolysis	Wash to remove unbound globulins
	Add antihuman globulin reagent
	Centrifuge
	Examine for agglutination
	Confirm negative tests with IgG-coated RBCs

[a]An enhancement reagent to promote antibody uptake may be incorporated here.

These loci are usually closely linked, located adjacent to each other on the chromosome. Such complex loci may contain multiple alleles and are referred to as haplotypes (2).

BLOOD GROUP SYSTEMS

Part of "70 - Pretransfusion Testing"

Some 200 antigens have been assigned by the International Society for Blood Transfusion (7,8) to 25 different blood group systems (Table 70.4). For a system to be established, the genes involved must be distinct from other blood group system genes and must either be polymorphic (i.e., two or more alleles, each with an appreciable frequency in a population) or the chromosome location must be known. Other antigens that do not meet these criteria have either been placed into collections, based primarily on biochemical data or phenotypic association, or into a series of either high- or low-frequency antigens.

TABLE 70.4. HUMAN BLOOD GROUP SYSTEMS

System Name	ISBT[a] Symbol	System Number	Number of Antigens	Chromosome Location	Gene Product(s)
ABO	ABO	001	4	9q34.1-q34.2	*A* = α-*N*-acetylgalactosaminyl transferase
					B = α-galactosyl transferase
MNS	MNS	002	43	4q28-q31	*GYPA* = glycophorin A; 43-kDa single-pass glycoprotein
					GYPB = glycophorin B; 25-kDa single-pass glycoprotein
P	P1	003	1	22q11-qter	α-galactosyl transferase
Rh	RH	004	45	1p36.13-p34	*RhD* and *RhCE*, 30–32-kDa multipass polypeptides
Lutheran	LU	005	18	19q13.2	78- and 85-kDa single-pass glycoproteins
Kell	KEL	006	23	7q33	93-kDa single-pass glycoprotein
Lewis	LE	007	6	19p13.3	α-fucosyl transferase
Duffy	FY	008	6	1q22-q23	38.5-kDa multipass glycoprotein
Kidd	JK	009	3	18q11-q12	43-kDa multipass glycoprotein
Diego	DI	010	18	17q12-q21	Band 3; 95–105-kDa multipass glycoprotein
Cartwright	YT	011	2	7q22	Acetylcholinesterase; GPI-linked glycoprotein
Xg	XG	012	1	Xp22.32	22–29-kDa single-pass glycoprotein
Sciana	SC	013	3	1p36.2-p22.1	60–68-kDa glycoprotein
Dombrock	DO	014	5	12p13.2-12p12.1	47–58-kDa GPI-linked glycoprotein
Colton	CO	015	3	7p14	28- and 40–60-kDa multipass glycoproteins
Landsteiner-Weiner	LW	016	3	19p13.3	37–43-kDa single-pass glycoprotein
Chido/Rogers	CH/RG	017	7	6p21.3	Complement (C4), glycoproteins adsorbed onto RBCs
Hh	H	018	1	19q13	α-Fucosyl transferase
Kx	XK	019	1	Xp21.1	37-kDa multipass glycoprotein
Gerbich	GE	020	7	2q14-q21	*GYPC* = glycophorin C, 40-kDa single-pass glycoprotein, glycophorin D, 30-kDa single-pass glycoprotein
Cromer	CROM	021	10	1q32	DAF (CD55); GPI-linked glycoprotein
Knops	KN	022	5	1q32	CR1 (CD35); single-pass glycoprotein
Indian	IN	023	2	11p13	CD44; 80-kDa single-pass glycoprotein
Ok	OK	024	2	19pter-p13.2	CD147; 35–69-kDa glycoprotein
Raph	RAPH	025	2	11p15.5	MER2; glycoprotein

[a]International Society of Blood Transfusion notations.

[b]Nonglycolipid antigens on red blood cells are either single-pass/multipass proteins or glycosylphosphatidylinositol (GPI)-linked proteins.

ABO Blood Group

Discovered by Karl Landsteiner in 1901 (9), ABO was the first human blood group system to be described. Three major alleles at the ABO locus on chromosome 9 govern the expression of A and B antigens (10). Gene *A* encodes for a protein (α-*N*-acetylgalactosaminyl transferase) that attaches a blood group specific carbohydrate (α-*N*-acetyl-D-galactosamine) and confers blood group A activity to a preformed carbohydrate structure called H antigen. Gene *B* encodes for an α-galactosyl transferase that attaches α-D-galactose and confers blood group B activity to H antigen. In both instances, some H remains unchanged. The *O* gene has no detectable product; H antigen remains unchanged and is strongly expressed on the RBCs (Fig. 70.3a).

These three genes account for the inheritance of four common phenotypes A, B, AB, and O. A and O blood types are the most common, and AB the least common (5). The *A* and *B* genes are codominant; that is to say when the gene is present, the antigen can be detected. The *O* gene is considered an amorph because its product cannot be detected. When either A and/or B antigens are present on the RBCs, the corresponding antibody(ies) should not be present in the serum or plasma. In adults, when A and/or B are absent from the RBCs, the corresponding naturally acquired antibody is present in the serum (2,3). This reciprocal relationship between antigens on the RBCs and antibodies in the serum is known as Landsteiner's law (5). Other ABO phenotypes do exist, but these are quite rare. Further, the A blood type can be subdivided, based on strength of antigen expression, with A1 RBCs having the most A antigen (3).

At the molecular level, *A* and *B* allelic cDNA are identical except for seven nucleotide substitutions resulting in four amino acid substitutions between A and B transferases. The majority of *O* alleles have a single nucleotide substitution close to the N-terminal of the coding sequence that shifts the reading frame of codons and results in translation of a protein lacking A or B

transferase activity (2). In addition to the ABO locus, expression of A and B is influenced by *H*/*h* and *Se*/*se* genes on chromosome 19. The *H* gene–specified transferase attaches fucose to paragloboside, a RBC membrane glycolipid. Paragloboside is synonymous with type 2 chains (Fig. 70.3a). The H antigen thus formed is the structure on RBCs that serves as the substrate for A and B gene–specified transferases described above. In rare individuals, absence of H (i.e., homozygous h) results in absence of H structures on RBC membranes and no substrate on which A and B gene products can act. The resulting phenotype is referred to as Bombay (or O_h) (2,3). The *Se* gene governs the addition of fucose to type 1 chains in the secretions (e.g., saliva, plasma, urine) to form water-soluble H-active structures (Fig. 70.3b). *Se* is present in approximately 80% of the population; depending on genes present at the ABO locus, the secretions of *Se* individuals will contain A and/or B antigens in addition to H antigens. *Se* gene products also interact with products encoded by genes at the LE (Lewis) locus also present on chromosome 19 (Fig. 70.3c).

Rh Blood Group

Currently 45 antigens are assigned to the Rh blood group system, although D is the most important. Other important Rh antigens are C, c, E, and e (5). Rh antigen expression is controlled by two adjacent homologous structural genes on chromosome 1 that are inherited as a pair or haplotype (11). The *RhD* gene encodes D antigen and is absent on both chromosomes of most Rh-negative subjects. The *RhCE* gene encodes CE protein. Amino acid substitutions at two different positions on the CE protein account for the Cc and Ee polymorphisms.

RBCs that carry D are called Rh positive, RBCs lacking D are called Rh negative. Approximately 85% of the white population are Rh positive and 15% are Rh negative (2). An additional consideration in pretransfusion testing is the existence of a weak form of D called D^u; this weak form of D can be detected by the IAT after incubation of RBCs with anti-D (5,12). Donor blood is tested for weak expression of D, by either the IAT or an equally sensitive method. However, it is not necessary to test the RBCs of apparent Rh-negative prospective recipients for weak expression of D; they can be transfused with Rh-negative blood.

ELEMENTS OF PRETRANSFUSION TESTING

Part of "70 - Pretransfusion Testing"

Donor Issues

Collection Facility

The initial ABO, Rh, and antibody detection tests on donor bloods, tests for infectious diseases, the interpretation of these tests, and correct labeling of donor units are functions normally carried out by a regional donor center. However, some hospital-based transfusion services continue to procure a portion of their blood needs from the population at large (allogeneic donors), and in recent years, efforts have been made for patients awaiting elective surgical procedures to deposit their blood for later use (autologous donors). In addition, some patients request that they receive blood from relatives or friends (directed donations). Regardless of the type of donor, each unit of blood must be subjected to tests for ABO, Rh, and unexpected antibodies, and for serologic markers of hepatitis B and C, human immunodeficiency viruses (HIV) 1 and 2, human T-cell lymphotrophic viruses type I, and syphilis (13). Donor blood must also be tested for alanine aminotransferase (ALT) that is elevated in hepatitis and other liver disorders. In addition, nucleic acid testing (NAT) is currently being performed to detect early evidence of exposure to HIV and hepatitis C.

The volume of testing that needs to be done at donor centers often necessitates use of automated equipment. Instrumentation currently in use is often based on microplate technology, and tests results may be interpreted electronically. ABO grouping entails testing both donor RBCs and serum/plasma. RBCs are tested with anti-A and anti-B, and the serum/plasma is tested with A_1 and B RBCs. Anti-A,B and A_2 RBCs may also be utilized,

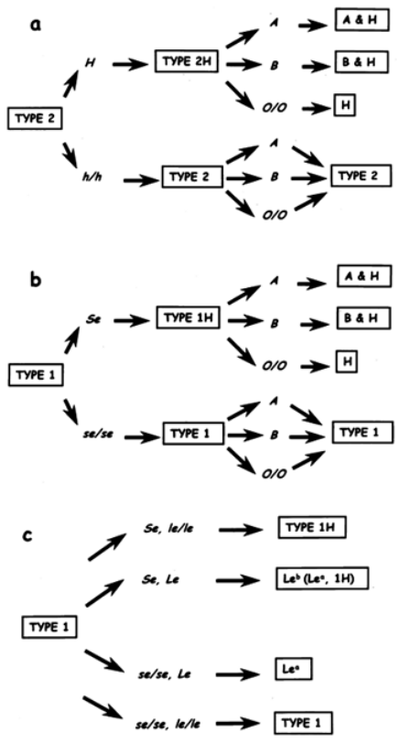

FIGURE 70.3. The interaction of the *ABO*, *H*/*SE*, and *LE* genes.

as results with these reagents serve to detect subgroups of A that may be nonreactive in direct tests with anti-A alone.

Rh typing is performed with anti-D. Because D is highly immunogenic (5), it is presumed that even weak expression of the antigen will evoke an immune response; consequently, donor RBCs that initially type as Rh negative in direct agglutination tests are tested further for weak D, usually by the antiglobulin test (Table 70.3). Only those units that are negative with anti-D by this method, or an equivalent procedure, can be labeled Rh negative (13). All straightforward D-positive and weak D-positive bloods are considered Rh positive.

Transfusing Facility

The ABO group of all units of whole blood or RBCs and the Rh group of those labeled Rh negative must be confirmed before transfusion (13). This must be done using a sample from an attached segment after the original ABO and Rh label has been affixed. Only tests with reagent antisera and donor RBCs need to be done; units labeled group O can be tested with anti-A,B alone (5). For D typing of units labeled Rh negative, only direct tests with anti-D are necessary; testing for weak expression of D is not required nor is repeat testing for unexpected antibodies or for markers of infectious diseases (13).

PATIENT ISSUES

Part of "70 - Pretransfusion Testing"

Sample Collection

The importance of the following measures cannot be overstressed because the major cause of fatal, hemolytic transfusion reactions is ABO incompatible transfusion resulting from patient/sample misidentification.

Requisition

Forms requesting blood and blood components must contain the first and last names and unique hospital registration number of the intended recipient (12). The name of the requesting physician, gender and date of birth of the patient, clinical diagnosis, and transfusion or pregnancy history are additional useful information.

Patient Identity

The collection of a properly labeled blood sample for pretransfusion testing from the correct patient is critical to safe blood transfusion. The person collecting the sample must positively identify the patient (5). This is facilitated through use of a wristband containing the patient's full name and unique hospital registration number that remains attached to the patient throughout the hospitalization. The information on the requisition form should be compared with that on the wristband; blood samples should not be collected if there is a discrepancy. In the absence of a wristband, the nursing staff should identify the patient; this should be documented on the requisition form. Nursing staff should be reminded to attach a wristband to the patient to validate patient identity at the time of transfusion. In an emergency, a temporary identification number should be used and cross-referenced with the patient's name and hospital identification number once they are known.

Labeling

Blood samples must be drawn into correctly labeled stoppered tubes. The tubes must be clearly labeled at the bedside with the patient's first and last names, the patient's unique hospital identification number and the date of collection (13). The phlebotomist should initial or sign the requisition form so that there is a means of identifying the person who collected the sample. By filing the requisition form with the patient's medical records, a permanent record is made of the phlebotomist's name (5).

Confirmation of Sample Identity

On receipt of blood samples for pretransfusion testing, the information on the label must be compared with that on the requisition. A new sample must be obtained whenever there are discrepancies or if there is any doubt about the identity of the sample. It is unacceptable to correct an incorrectly labeled sample.

Type of Sample

Either serum or plasma may be used for pretransfusion testing, but most workers use serum to avoid introducing small fibrin clots into serologic tests. Such clots may be mistaken for agglutination. Fibrin clots may also form when samples from heparinized patients are collected into nonanticoagulated tubes. These samples will clot properly after the addition of protamine sulfate (5). Some workers prefer to use serum rather than plasma for compatibility testing to facilitate detection of antibodies that primarily coat RBCs with the C3d component of complement. Bound C3d will not activate the lytic phase of the complement cascade but can be detected with AHG reagents containing anti-C3d (4,5). Ethylenediaminetetraacetic acid (EDTA), citrate, and other commonly used anticoagulants chelate calcium ions that are essential for complement activation. However, as discussed later, the use of AHG reagents containing anti-C3d for compatibility testing is not mandatory (5).

Age of Specimen

To ensure that the specimen used for compatibility testing is representative of a patient's current immune status, serologic studies must be performed using blood collected no more than 3 days in advance of the transfusion when the patient has been transfused or pregnant within the preceding 3 months or when such information is uncertain or unavailable (12) because both transfusion and pregnancy may stimulate alloantibody production. From a practical standpoint, it is simpler to stipulate that all pretransfusion samples must be collected within 3 days before RBC transfusions rather than determine whether a patient has been recently transfused or pregnant.

Storage

Blood samples used for compatibility testing, including donor RBCs, must be kept at 1° to 6°C for at least 1 week after each transfusion (5). This ensures that appropriate samples are available for investigational purposes should adverse responses to transfusion occur.

ABO Typing

Both reagent antisera and RBCs for ABO typing are available commercially. Anti-A and anti-B are monoclonal antibodies prepared by hybridoma technology. Reagent RBCs are usually suspended in a preservative medium containing EDTA, which chelates calcium ions essential for complement activation, thereby preventing lysis of the RBCs by lytic anti-A and anti-B (5). ABO grouping is performed using a direct agglutination technique (Table 70.3) (14). RBCs are tested with anti-A and anti-B, and the serum or plasma with known A_1 and B RBCs. Use of anti-A,B and A_2 RBCs is optional but generally considered unnecessary when ABO typing potential transfusion recipients (5). The expected findings for each of the four common ABO phenotypes, are shown in Table 70.5. When interpreting the results of ABO grouping tests, it is important to note the reciprocal relationship that exists between the absence of A and/or B antigens on RBCs and the presence of the expected anti-A and/or anti-B in the serum. If there is conflict between cell and serum ABO tests, group O blood should be provided for transfusion until the discrepancy is resolved and the ABO group of the patient can reliably be determined (13).

TABLE 70.5. EXPECTED REACTIONS OF THE FOUR COMMON ABO PHENOTYPES: RESULTS OF BLOOD TYPING TESTS

Blood Type	Anti-A	Anti-B	A_1 RBCs	B RBCs
O	0*	0	4+	4+
A	4+	0	0	4+
B	0	4+	4+	0
AB	4+	4+	0	0

O, no agglutination; 4+, strong agglutination (see Fig. 70.1).

Rh Typing

Only tests for D are performed routinely on the RBCs of prospective transfusion candidates. There are two different types of reagent anti-D available for Rh typing. High-protein reagents are prepared with human IgG anti-D diluted in bovine albumin and other substances that potentiate agglutination. Their final protein concentration may be greater than 20 g/dL. Such a high protein level is needed to potentiate IgG antibody reactivity so that positive and negative tests can be recognized almost instantaneously using a direct agglutination technique. Low-protein reagents (protein content less than 7 g/dL) are a blend of monoclonal IgM and monoclonal/polyclonal human IgG anti-D. With monoclonal-polyclonal anti-D blends, the IgM component causes direct agglutination of Rh-positive RBCs and the IgG component permits detection of the weak expression of D by application of the antiglobulin test (5). Only direct tests with anti-D are required on patient samples; the test for weak D (D^u) is not necessary (5,13). To avoid incorrect designation of an Rh-negative recipient as Rh positive because of autoantibodies or abnormal serum proteins, a control system appropriate to the anti-D reagent in use is required (13). For low protein anti-D, a concurrent negative test with anti-A and/or anti-B is considered an appropriate control system. Apparent AB Rh-positive samples should be retested concurrently with anti-D and an inert Rh control reagent (14).

Tests for Unexpected Antibodies

Methods for detecting unexpected antibodies in the serum or plasma of prospective transfusion recipients must be those that detect clinically significant antibodies (13). An IAT after 37°C incubation of patient's serum or plasma with reagent RBCs that are not pooled is usually required. When unexpected antibodies are detected, they must be identified (details are given in reference 5). If antibodies of specificities known to cause accelerated destruction of transfused incompatible RBCs are identified, then blood that lacks the corresponding antigen and is cross-match compatible by IAT should be selected for transfusion.

Several options exist regarding the selection of methods for pretransfusion antibody detection (Table 70.6 and Table 70.7). Decisions relative to these options are within the purview of the blood bank medical director. They should be made based on the type of patient served, the causes and frequency of previous significant antibody-mediated transfusion reactions, the availability of resources, and with the realization that no one method will detect all clinically significant antibodies.

TABLE 70.6. ACCEPTABLE METHODS FOR PRETRANSFUSION ANTIBODY DETECTION

	Serum	RBCs	Incubation	AHG
Saline	2–3 drops	1 drop	30–60 min, 37°C	IgG/PS
Albumin	2–3 drops	1 drop	15–30 min, 37°C	IgG/PS
Low ionic strength saline	Equal volumes		10–15 min, 37°C	IgG/PS
Gel test	25 µL	50 µL	15 min, 37°C	IgG
Polyethylene glycol	Equal volumes		15–30 min, 37°C	IgG
ReACT system	1 drop	1 drop	10 min, 37°C	None
Solid-phase adherence	1 drop		10–15 min, 37°C	IgG
Low ionic polycation	100 µL		1 min, RT	None

AHG, antihuman globulin; IgG, immunoglobulin G; PS, polyspecific AHG; RT, room temperature.

Tube Test Methods

Various RBC suspending media or additives are used either to enhance antibody uptake or to potentiate the agglutination phase of antibody-antigen interactions. Low ionic strength saline (LISS) solution (15), normal saline, or RBC preservative (modified Alsever's solution) are used as RBC suspending media. Bovine serum albumin (22% or 30% wt/vol), LISS additives, and polyethylene glycol are commonly added directly to serum-RBC mixtures (5,16). In the low-ionic polycation technique, serum is incubated with RBCs suspended in LISS solution to enhance antibody uptake (17). The second phase of the reaction is facilitated by aggregating RBCs with the polycation Polybrene® (hexadimethrine bromide). Aggregation is reversed with sodium citrate, but agglutinates formed by antigen-antibody interactions are not dispersed.

Because of enhanced antibody uptake in a low-ionic environment, use of either LISS for RBC suspension or LISS solution additives permits adequate detection of clinically significant antibodies after short incubation times (10 to 15 minutes). In contrast, incubation times of 30 to 60 minutes are required when albumin or saline tests are employed (5,14). For antiglobulin testing, either anti-IgG or polyspecific AHG, containing anti-IgG and anti-C3, may be used (5). However, use of polyspecific

AHG leads to the detection of an inordinate number of unwanted positive tests, and its use in routine antibody detection tests is not recommended (18,19).

Column Technologies

A gel test for detecting RBC antigen-antibody interactions was first described in 1990 by Lapierre and colleagues (20). Cards consisting of six microcolumns, each containing a viscous barrier below which is an agarose gel suspended in anti-IgG are commercially available. Atop each card is an incubation chamber in which reagent RBCs and test plasma are dispensed; the cards are incubated at 37°C, then centrifuged. As the RBCs pass through the viscous barrier, they are separated from the serum/plasma and come into contact with anti-IgG. If the RBCs become coated with antibody during incubation, they will be agglutinated by anti-IgG. The agglutinated RBCs become trapped in the gel; unagglutinated RBCs pellet to the bottom of the microcolumn. A procedure for the gel test is depicted in Fig. 70.4.

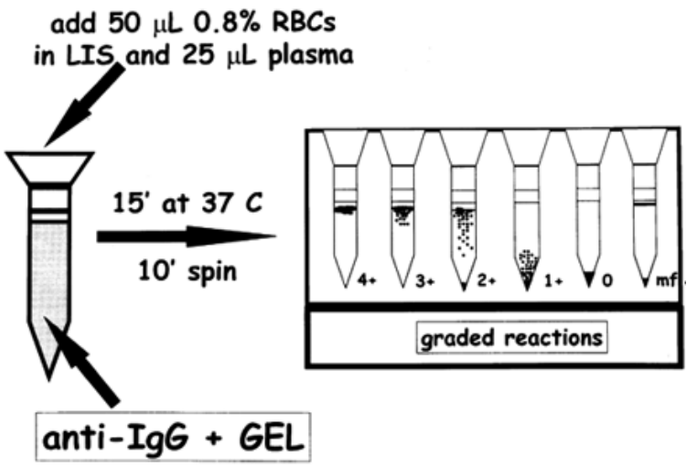

FIGURE 70.4. The gel test for detecting unexpected antibodies.

The gel test has proven to be equivalent to standard tube technologies (strength LISS, polyethylene glycol) for the detection of unexpected antibodies. The sensitivity and specificity of gel for potentially significant antibodies are 92% and 96%, respectively. This compares with 98% (sensitivity) and 90% (specificity) for a tube LISS procedure (21). Column technologies offer several advantages over conventional test tube procedures:

1. Simplified testing, as follows:
   a. Dispense measured volumes of test plasma/serum and RBCs (in LISS) into gel card incubation chambers.
   b. Transfer cards to an incubator (15 minutes) and then to a centrifuge (10 minutes).
   c. Read and record results.
2. When compared with conventional tube tests, there are no centrifugation/reading for direct agglutination after incubation, no addition of antiglobulin reagent, no need to validate negative tests utilizing IgG-coated RBCs. Omission of these manipulations (especially the associated, repetitive transfer of test tubes between racks and centrifuges) provides significant hands-on time savings.
3. Increased time savings through batch testing; a technologist can perform 36 to 48 antibody screens in approximately the same amount of time it takes to process 12 samples by conventional tube techniques (21).
4. Increased reproducibility of results, through use of measured volumes of reactants, elimination of the washing process, less subjective reading of tests.
5. Stability of reactions, facilitating validation of results by second technologist. With conventional tube methods, there is only one opportunity to read reactions; with the gel test, reactions can be read as many times as needed as long as 48 hours after centrifugation.
6. Reduction in the detection of cold agglutinins (anti-I/HI -M, -P_1, -Le) of no or doubtful clinical significance (seen during our initial evaluation of the gel test last year), with consequential reduction in the number of samples requiring antibody identification.
7. Can be automated or semiautomated using liquid sample handling devices, thereby further reducing hands-on time.

Two other column technologies are worthy of mention here. The BioVue (Ortho Clinical Diagnostics, Raritan, NJ) procedure is similar in many respects to the gel test except that fine glass particles are used instead of gel to separate agglutinated from unagglutinated red cells. This product is not currently available in the United States but is utilized in other parts of the world. The ReACT System (Gamma Biologicals, Houston, TX)

TABLE 70.7. OPTIONS IN PRETRANSFUSION TESTING

Option	Laboratories Performing
ABO/Rh	
Recipient ABO red cell tests with anti-A, B	50.9%
Recipient ABO serum tests with group A_2 red cells	8.4%
Detection of weak D on recipient red cells	Unknown
Antibody screen	
Immediate spin test	65.7%
Room-temperature incubation	6.9%
Polyspecific antihuman globulin, containing both anti-IgG and anti-C3d	31.4%
Pretransfusion direct antiglobulin test or autocontrol performed concurrently with screening tests for unexpected antibodies	55.4%
Microscopic examination of antiglobulin tests	52.8%
More than two reagent red cell samples for 61% detection of unexpected antibodies	61%
37°C reading, for direct agglutination after 37°C incubation.	86.7%

Laboratories' Performing percentages from, Maffei LM, Johnson ST, Shulman IA, et al. Survey on pretransfusion testing. *Transfusion* 1998;38:343–349.

is based on the affinity of staphylococcal proteins for immunoglobulins. In this procedure, RBCs and serum/plasma are incubated in a low-ionic environment and centrifuged through a column of protein G, which has a high affinity for the Fc fragment of human IgG. If antibody is bound to the RBCs during incubation, the passage of the coated RBCs through the protein G column is retarded. Uncoated RBCs will pellet to the bottom of the column (22).

Solid Phase Adherence Methods

Two forms of solid-phase adherence assays are available for RBC serologic testing. In direct tests, antibody is fixed to wells of a microplate, and RBCs are added (e.g., anti-A and anti-B for direct testing of donor/recipient ABO typing). After centrifugation, RBCs expressing the corresponding antigen will efface across the well; RBCs lacking the antigen will pellet to the bottom of the well.

In indirect tests (e.g., for detecting unexpected antibodies to RBC antigens), RBC membranes are affixed to microplate wells; test serum or plasma is added and the plates washed to remove unbound globulins. Indicator RBCs, which are coated with anti-IgG, are then added and the plates centrifuged. The indicator RBCs efface across the well in a positive test and pellet to the center of the well in a negative test (22). An overview of a solid phase adherence assay for antibody detection is depicted in Fig. 70.5.

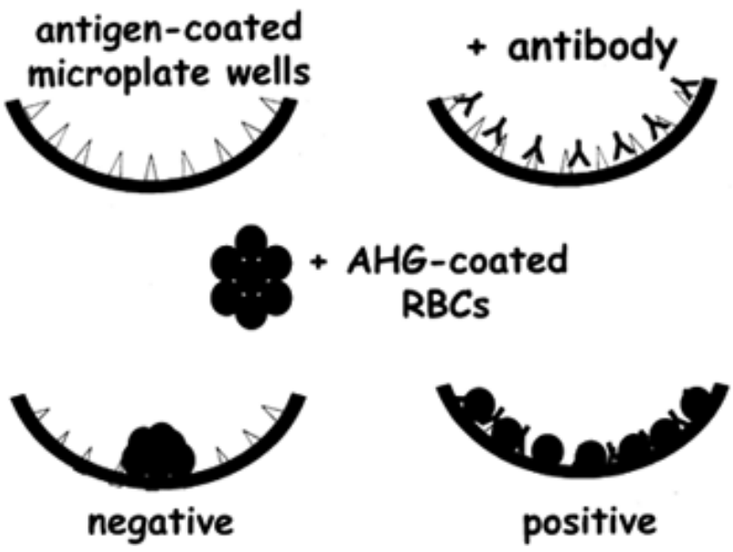

FIGURE 70.5. Solid phase adherence assay for detecting unexpected antibodies.

Reagent RBCs for Antibody Detection

The U.S. Food and Drug Administration (FDA) (23) currently mandates that sets of reagent RBC samples licensed for use in pretransfusion antibody detection tests carry expression of the C, c, D, E, e, Fy^a, Fy^b, Jk^a, Jk^b, K, k, Le^a, Le^b, P_1 M, N, S, and s. Such RBCs must not be pooled (1,13).

It is impossible to find a single donor with RBCs that carry all these antigens, for adults rarely, if ever, have strong expression of both Le^a and Le^b on their RBCs. Thus, reagent RBCs for antibody detection are available commercially as sets of either two or three samples. The Rh phenotypes of RBCs used in two-sample sets are R1R1 (D+C+c-E-e+) and R2R2 (D+C-c+E+e-). In three sample sets, an rr (D-C-c+-E-e+) sample is provided, in addition to R1R1 and R2R2 RBCs. Use of three RBC samples facilitates the inclusion of RBCs from individuals homozygous for particular blood group genes. Such RBCs tend to have a stronger expression of an antigen compared with RBCs from individuals heterozygous for the same gene; this phenomenon is known as dosage. It is easier to find double-dose expression of blood group antigens among three reagent RBC samples than among two samples; however, use of three samples increases the workload for antibody detection by 50% and rarely affords detection of significant alloantibodies that are not detected with two reagent RBC samples (24).

Further Options

Anti-IgG Versus Anti-IgG + C3

In addition to the selection of test methods and reagent RBCs for detection of unexpected antibodies, there are other options in pretransfusion testing. Table 70.7 shows the approximate number of transfusion services still performing tests that some workers

consider redundant because such testing is neither mandatory nor required by accrediting agencies (18). Use of polyspecific AHG reagents that contain anticomplement activity in addition to anti-IgG may facilitate detection of some antibodies that coat RBCs with complement components including, notably, anti-Jk^a and anti-Jk^b. Failure to detect such antibodies may lead to acute intravascular destruction of antigen-positive RBCs (5). However, use of polyspecific AHG also facilitates detection of IgM complement-binding autoantibodies that are of no clinical significance (19). Many of these antibodies are autoantibodies directed toward a self-antigen called I and are found naturally in virtually all normal adult human sera (4).

Room Temperature Incubation

The detection of some agglutinating alloantibodies, as well as the detection of IgM autoantibodies, is facilitated by the use of a room temperature incubation phase. However, antibodies that do not react at body temperatures rarely, if ever, cause significant destruction of transfused incompatible RBCs (4). Although room temperature incubation of tests was commonly utilized as recently as the early 1980s, many laboratories have since abandoned the practice (25).

Microscopic Examination of Tests

Examination for agglutination may be macroscopic, performed using an illuminated concave mirror, or microscopic. The latter is rarely necessary in routine practice; indeed, such critical examination of serologic tests can result in incorrectly recording negative tests as positive (4,14).

Autocontrol

Some transfusion services routinely perform an autocontrol as part of pretransfusion testing. The autocontrol consists of testing the patient's serum against their own RBCs under the same conditions as those to which screening tests for unexpected antibodies are subjected. This test, or a DAT, is performed to detect globulins bound to the patient's RBCs *in vivo*. Such *in vivo* coating of RBCs occurs in patients with autoimmune hemolytic anemia or hemolytic disease of the newborn and may also be seen after therapy with some drugs or transfusion with incompatible blood (5). Moreover, a positive DAT may be the earliest manifestation of an alloimmune response to a previous, recent transfusion (26).

Inclusion of the DAT or autocontrol as part of routine pretransfusion testing is no longer advocated; in the absence of detectable serum antibodies, the predictive value of a positive DAT is so low (0.29%) that routine testing is not cost-effective (26). However, the DAT/autocontrol is a good predictive test for immune-mediated hemolysis when performed on patients with clinical manifestations of hemolytic anemia (27).

Prior Records Check

As part of ongoing quality assurance and for compliance with the *Standards for Blood Banks and Transfusion Services* of the American Association of Blood Banks (13), the results of current ABO, Rh, antibody detection, and compatibility tests must be checked against records of previous tests, if performed. This must be done before blood is released for transfusion, preferably at the time that pretransfusion tests are completed. The specific records that must be checked are those for ABO and Rh typing performed within the previous 12 months, and any difficulties in typing, unexpected antibodies, or severe adverse reactions to transfusion recorded in the past 5 years. Any discrepancies between past and present ABO and Rh typing results must be thoroughly investigated; the most likely explanation is that the present sample is not from the same individual whose blood was tested previously. Further, even in the absence of detectable unexpected antibodies in the current sample, a record of such unexpected antibodies in previous samples must be taken into consideration when selecting and cross-matching blood for present and future transfusions.

DONOR-RECIPIENT ISSUES

Part of "70 - Pretransfusion Testing"

Selection of Blood for Transfusion

ABO and Rh

RBCs and whole blood selected for transfusion should be compatible with the serum of the intended recipient. To avoid the hemolytic and often fatal consequences of an ABO mismatched transfusion, RBCs carrying A and/or B antigens should not be transfused to a patient unless the patient's RBCs also carry those antigens. Group O individuals should receive group O RBCs, but AB individuals can receive RBCs of any ABO type. Rh-negative individuals, particularly women with childbearing potential, should receive Rh-negative blood. Rh-positive individuals may receive blood of either Rh type (5).

Unexpected Antibodies

When unexpected antibodies are present, as indicated by positive screening tests, they must be identified. At a minimum, this involves testing the patient's serum against a panel of fully phenotyped reagent RBCs samples and determining the antigen(s) that is(are) common to all reactive samples. A detailed discussion of the approaches to antibody identification is beyond the scope of this chapter, and the interested reader is referred elsewhere (5,14). When the identified antibodies are known to cause accelerated destruction of transfused incompatible RBCs, blood selected for transfusion should be shown to lack the corresponding antigen or antigens (5,13). This entails testing donor units with reagent antisera that are available commercially or prepared in-house from previously investigated samples. Examples of potentially significant antibodies include those directed toward RH, JK, KEL, and FY system antigens and the S and s antigens of the MNS system, as well as most other antibodies active at 37°C and/or by the IAT (2,4). When antibodies with specificities directed toward M, N, P_1, and LE antigens are present, particularly when the antibodies react best at or below room temperature, blood selected for transfusion need only be shown to be compatible by IAT after 37°C incubation; demonstrating that

compatible units lack the relevant antigen(s) is not required (28,29). In instances in which clinically insignificant autoantibodies such as anti-I are present, least incompatible units should be selected for transfusion when it has been established that the autoantibody is not masking a concomitant, clinically significant alloantibody (5).

Cross-match

Before whole blood or RBCs are administered and except in an emergency, a major cross-match must be performed. This usually entails tests between donor RBCs selected for transfusion and the prospective recipient's serum or plasma sample that was used for ABO, Rh, and antibody detection tests. The methods used should be capable of detecting ABO incompatibility and include the IAT. However, in the absence of unexpected antibodies (and absence of records of prior detection of such antibodies) in the intended recipient's serum, only testing to detect ABO incompatibility is required (12).

Antiglobulin Crossmatch

When clinically significant unexpected antibodies are present or a patient's records indicate that such antibodies have been detected previously, blood selected for transfusion must be tested with the patient's serum or plasma by an IAT. Any of the methods described earlier for antibody detection can be used (5,13). An antiglobulin cross-match can also be done routinely on patients with nonreactive screening tests for unexpected antibodies. This will detect ABO incompatibility and may detect unexpected antibodies that were missed in pretransfusion screening tests. Unexpected antibodies to low-incidence antigens and antibodies manifesting dosage may be detected in this manner, as may antibodies missed in screening tests owing to technical error. However, the predictive value of a positive IAT crossmatch after nonreactive screening tests for unexpected antibodies is sufficiently low that many large hospital transfusion services do not perform the IAT cross-match except as required when unexpected antibodies are present or there are records of such antibodies (18,25).

Serological Detection of ABO Incompatibility

Only a procedure for detecting ABO incompatibility is required when screening tests for unexpected antibodies are negative and there is no record of the patient having had such antibodies in the past. Detection of ABO incompatibility can be done serologically or, in some situations, electronically through the use of computers. An immediate-spin cross-match between the prospective recipient's serum or plasma and donor RBCs suspended in EDTA-saline to prevent false-negative tests owing to prozone by complement-fixing, high-titer anti-A and -B is an acceptable serologic method for the detection of ABO incompatibility (30). Alternatively, the ABO groups of both the donor units and a blood sample from the intended recipient can be confirmed immediately before the units are released for transfusion (13).

Electronic Crossmatch

The *Standards for Blood Banks and Transfusion Services* (13) also permit the use of computers to detect ABO incompatibility, provided that:

1. The computer system has been validated on site; the validation process must show that the computer will prevent release of ABO incompatible units.
2. Only detection of ABO incompatibility is required. An antiglobulin cross-match must be done if there are unexpected antibodies present currently or by history.
3. There have been at least two determinations of the intended recipient's ABO group. One of the determinations must be from a current sample; the other determination can be made by duplicate testing of the current sample, by testing a second current sample, or by comparison with previous records.
4. The information in the computer includes the unit number, product component name, ABO and Rh type, and blood group confirmatory test interpretation for the donor unit.
5. The information in the computer includes the name, identification number, and ABO and Rh type of the intended recipient.
6. There is a method to verify correct entry of data.
7. There is logic to alert the user to discrepancies between donor unit label and confirmatory test results and to ABO incompatibilities between the intended recipient and the donor unit.

Facilities wishing to implement an electronic cross-match must submit a request for variance to the Code of Federal Regulations (23). Currently, 30 facilities are currently approved by the FDA to perform an electronic crossmatch (G. Conley, personal communication, 1999). Experience has shown that existing transfusion service computer software and carefully developed SOP (Standard Operating Procedures) can be used together to provide a safe and efficient means of detecting donor-recipient incompatibility without performing a serologic cross-match (31).

Release of Blood for Transfusion

Transfusion Form

A form indicating the intended recipient's name, unique identification number, and ABO and Rh type must be completed for each unit of blood to be released (13). This form must also include the donor unit identification number, its ABO and Rh type, the interpretation of the cross-match, and the identity of the person performing the test. If, as in an emergency, pretransfusion testing is incomplete, the form must indicate the current status of serologic testing (5).

Label

Before blood is released, blood bank personnel must attach a label or tag to the unit containing essentially the same information that appears on the transfusion form, namely, the recipient's first and last names, unique identification number, the donor unit number, cross-match interpretation, and the name of the person performing the test (5).

Inspection

The unit must be inspected visually before release; if any abnormality in color or appearance is noted the unit should not be issued (13). A record should be made of this inspection. The expiration date must also be checked to avoid issuing an outdated unit (5).

Release Records

In addition, there should be a suitable means (e.g., a log book) to record the name of the individual who releases a unit of blood, the patient for whom the blood was released, the date and time of issue, and the person to whom blood was issued or destination of the unit (5).

Bedside Check

Before administering blood, the physician's written order should be reviewed to verify the request for transfusion (5). The transfusionist who administers the blood is responsible for this and for performing a final errors check. Verification of the following must be recorded on the transfusion form (13):

1. Recipient identification: The name and identification number on the patient's wristband must be identical to the name and number on the form attached to the unit.
2. Unit identification: The unit number on the blood container must match the unit number on the transfusion form.
3. ABO/Rh: The ABO and Rh type on the donor unit primary label must agree with that recorded on the transfusion form.
4. Expiration date: The expiration date of the unit should be checked and the unit verified as acceptable for transfusion.

CONCLUSION

Part of "70 - Pretransfusion Testing"

In summary, pretransfusion testing constitutes a quality assurance program designed to detect serologic incompatibility between donor unit and the intended recipient and to prevent both clerical and technical errors that may have serious if not fatal consequences. Assurance of quality requires proper performance of each task. There can be no substitute for proper patient identification, proper sample labeling, and proper performance of serologic tests.

71
Blood Component Therapy

S. Breanndan Moore

BASIC RATIONALE

Part of "71 - Blood Component Therapy"

The basic rationale of component therapy is the idea that a particular patient's blood cell or plasma deficiencies can be identified and precisely what is needed to correct those deficiencies can be supplied in a timely manner. This approach is logical from the standpoints of the individual patient and of those whose responsibility it is to ensure an adequate supply of blood and components for the population at large. By processing each unit of donated blood into multiple subunits containing concentrates of various cellular and noncellular products, one can benefit multiple patients from a single donation. If each recipient is transfused with only the moiety that he or she requires, then the system is truly efficient and effective.

BACKGROUND

Part of "71 - Blood Component Therapy"

At the beginning of the 20th century, medical pioneers began to use Landsteiner's seminal discovery of the ABO blood group system when choosing blood donors for a patient. In those days, their concerns were primarily the patient's desperate clinical straits, the availability of a matchable donor, and the ability to obtain the desired blood and infuse it without causing harm to the donor or recipient. Because of these significant concerns and the lack of standardized instruments and practices, the transfusion of blood was reserved for cases in which all routinely accepted methods of therapy had been exhausted and the patient's deteriorating condition warranted extraordinary measures. The prospect of receiving blood was often feared as much as the operation that might have created the need.

The ability to isolate many fractions or components from donated blood has been a major breakthrough in recent years. This process has been greatly stimulated by the increasing sophistication of both diagnostic acumen and treatment modalities.

The enormous array of complex surgical procedures, as well as the refinements in the management of medical diseases, has resulted in the successful treatment of patients who might, even a decade ago, have died. These advances have been accompanied by an equivalent and concomitant increase in the quantity of blood and blood components used. Many of these surgical and medical therapeutic regimens are directly dependent on the availability of an adequate and safe supply of appropriate blood and components.

Because the demands for blood sometimes outstrip the available supply, it is important to be concerned about the ability to respond not only to current patient requirements but also to the inevitable future demands generated by medical and surgical technological advances. There is no reason to believe that the trends of increasing utilization of blood and, particularly, blood components will change in the future.

Technological Advances

When blood was first collected from donors, it was drawn into glass bottles through rubber tubing. Such bottles and tubing were still being used in this country in the 1950s. In fact, glass bottles were used in Russia until just a few years ago. These glass bottles and rubber tubings were sterilized and reused.

The only component preparation possible from blood drawn into glass bottles was plasma separation by allowing the unit to stand immobile. The advent of disposable plastic bags and tubing created a dramatic new capability, i.e., manipulation of the donated blood in such a manner as to allow the separation of platelet-rich plasma from the red cells. This, in turn, gave us platelet concentrate and fresh frozen plasma (FFP). Subsequently, Pool et al. (1,2) discovered the antihemophilic properties of the cold-precipitated proteins from FFP. Thus, cryoprecipitated plasma was born, which has revolutionized the treatment of hemophilia.

The next major advances were in the development of various anticoagulants and preservatives. These developments progressively increased the functional shelf life of blood and components by providing the necessary substances to maintain the metabolism of the preserved cells at higher levels than was previously possible. The use of newer plastics allowed better gas exchange across the bag, allowing the cells in the bag to breathe and thereby enhancing their function after storage.

The development of both continuous and semicontinuous apheresis machines permitted the selective separation of relatively large quantities of platelets or granulocytes (or both) from single donors. This led to the use of single-donor cellular components for patients who were septic (granulocytes) or alloimmunized (platelets). The use of HLA class I typing to match donor and recipient added another dimension to the efficacy of platelet therapy. This technique has been further modified to permit selective removal of specific plasma contents. This is accomplished by passage of the plasma over columns designed to

remove specific moieties, e.g., IgG antibodies and the pruritogenic factors in biliary cirrhosis. These techniques also have been modified to produce enriched, activated, autologous lymphoid cell preparations for use in the treatment of malignant disease.

Fractionation on a commercial scale has permitted the acquisition and heat treatment of albumin from huge pools of plasma. This product has had extensive use in various situations, as described later.

Donor and Donation Efficiency

When the demand for blood outstrips the supply, episodic blood shortages occur, necessitating cancellation or postponement of elective surgical procedures and dependence on other geographic regions for the needed blood and components. Unfortunately, many large urban populations that have large blood needs also have inadequate donation patterns. This fact alone makes it particularly important that we achieve the maximal use of the units that are donated. Obviously, the manufacture of components from as many units as possible is the best way to achieve such efficiency. Apart from the need to respond to the transfusion needs of patients, we have an obligation not to misuse or underutilize the blood donated.

Economic Factors

The costs of obtaining a unit of blood have increased over the past few years for several reasons. Among these are (a) the increased cost of donor recruitment because of personnel and advertising charges, (b) the cost of the ever-growing list of donor tests mandated by regulatory or accrediting agencies, and (c) the somewhat less clearly defined but real costs incurred as a result of blood banks' greater attention to transfusion safety. These costs include the significant time involved in the administration of autologous, directed, and minimal-exposure transfusion (MET) programs (3).

With the autologous, directed, and MET programs, a specific unit must be clearly identified (from the moment of acceptance by the blood bank) as coming from a specific donor and designated for a specific recipient. This degree of commitment requires considerably more administrative effort and computer support than does the older homologous system. These added costs are inevitably passed on to the patients, but we have an obligation to be as efficient as possible in the use of the donations to minimize these supplementary costs.

COMPONENT PREPARATION

Part of "71 - Blood Component Therapy"

Anticoagulants and Preservatives

Various solutions have been developed to prevent the clotting of donated blood and to preserve its functional elements. These solutions have gradually become more complex as changes have been introduced to prolong the effective shelf life of the component, to alter its flow characteristics, and to increase the yield of components from the donation. The characteristics of these various solutions are discussed in detail in Chapter 69. Suffice it to say that the improvements in these solutions have played a major role in the burgeoning field of component therapy in the past decade.

Basic Techniques

Centrifugation

When blood was collected in glass bottles, most of it was stored and then transfused as whole blood because large-scale processing of these units could not be accomplished easily. Simple gravity separation of plasma could be performed but only by breaking the seal on the bottle. Elaborate efforts were required to carry out this separation aseptically, and although the plasma could be subsequently frozen, the residual red blood cells were often discarded or used for purposes other than infusion into patients.

The development of plastic closed-system multiple bags revolutionized blood banking and the practice of transfusion medicine. The plastic bags were malleable enough to allow centrifugal separation of plasma from red blood cells and subsequent diversion of the supernatant plasma into satellite bags while still maintaining the closed system by the connected plastic tubing. This simple technique, still widely used, permitted the easy and aseptic separation of red blood cells and plasma so that each could be safely stored and subsequently transfused. This simple change provided the ready availability of components that permitted aggressive surgical and medical therapeutic procedures.

The availability of a simple, centrifugation-based separation technique also led to experimentation with the duration and force that could be applied in either the initial centrifugation step or in a second centrifugation of the plasma. These manipulations eventually resulted in the production of platelet concentrates. For example, a gentle spin of a bag of freshly donated whole blood at approximately 2,500 rpm for 3 minutes yields a supernatant platelet-rich plasma that can be separated into a satellite bag. A second strong spin of this latter bag, at approximately 4,100 rpm for 5 minutes, packs down the platelets, allowing separation of the platelet-poor plasma into another satellite bag.

The centrifuges used for blood separation need to be maintained carefully and tested regularly so that they produce the requisite centrifugal forces in a consistent manner. Likewise, they have to be loaded carefully so that the cups are balanced. Otherwise, the rotor will shake and produce turbulence in the bags. The motors of these centrifuges are also susceptible to damage from imbalanced cup holders.

Plasma Separation

Plasma expressors are simple mechanical devices that consist of two flat, rectangular plates (metallic or hard plastic) hinged together at one end. A bag of previously centrifuged whole blood is carefully placed between the plates. A simple spring device pushes the hinged plates into apposition so that the supernatant plasma in the bag is extruded through one of the ports at the top of the bag. This port leads into one of a series of plastic satellite bags connected to one another by flexible plastic tubing. This latter tubing is an integral part of the closed, sterile, multiple-bag system. When the requisite quantity of plasma has been expressed,

the interconnecting tubing can be clamped with two small metal clips placed close together. The primary bag can then be separated by applying a scissors to the short segment of the tubing between the metal clips.

Leukocyte-Reduced Red Blood Cells

Several techniques are available for the removal of the majority of the white blood cells from a bag of whole blood or red blood cells (3). These methods may involve simple centrifugation with subsequent separation of the buffy coat from the remaining cells or the use of various filters to accomplish the same goal. The use of machines to wash the red blood cells will also provide variable degrees of white blood cell removal. The indications and more detailed discussion of the effectiveness of these methods follow later in this chapter.

Cryoprecipitation Techniques

When the plasma is separated from the red blood cells and then frozen at -18°C or lower, some proteins precipitate. These proteins are rich in coagulation factors VIII and XIII and fibrinogen. If frozen plasma is thawed at 37°C, these precipitates go back into solution. However, Pool discovered that, if the thawing occurred between 1° and 6°C, these cold-precipitated proteins remained as a precipitate from which the rest of the plasma can be readily expressed after prompt centrifugation (1). This cryoprecipitated protein should be refrozen within 1 hour.

The variation of this technique used to enhance the concentration of fibrinogen in the product so that it can be used topically as a fibrin glue is discussed below.

Red Blood Cell Washing

Devices are available that use solutions compatible with red blood cells to suspend and centrifuge the mixture in repeated cycles to produce a suspension of red cells in the isotonic saline-based wash solution. Variable quantities of white blood cells, platelets, or plasma constituents may remain with the red blood cells, depending on the assiduousness of the procedure used, and the technique may be modified to decrease the level of these contaminants. Because these washing techniques involve the rupture of the seals on the closed system, the shelf life of the washed red blood cell product is only 24 hours after washing.

Freezing Techniques

To preserve its labile coagulation factors, plasma must be rapidly frozen within 6 hours after blood collection (4). This can be accomplished by the use of a dry ice-ethanol bath or by a mechanical freezer capable of maintaining a temperature of 30°C or lower. When the plasma is frozen, it may be maintained at -18°C for as long as 1 year. Similarly, the supernatant plasma from cryoprecipitation can be refrozen at -18°C or lower and maintained for 1 year. It is preferable to use temperatures of -30°C or lower for optimal factor activity in the product.

Freezing red blood cells is considerably more difficult because the structural integrity, viability, and function of the cells must be maintained. There are several methods described for this, including high glycerol, agglomeration, and low glycerol (4). All three methods utilize the ability of glycerol to preserve the integrity of the red blood cells during freeze/thaw processes. Glycerol, a clear, syrupy fluid, is a trihydric alcohol and is miscible with both water and alcohol. It is relatively inert pharmacologically and does not cause problems except that, if the red cells have been improperly deglycerolized before infusion, there may be shifts in intracellular fluids. Another cryoprotectant that is sometimes used is dimethyl sulfoxide (DMSO), a by-product of petroleum distillation. When given intravenously, it can cause nausea, vomiting, and a strong, pervasive, garliclike taste and odor (5).

The cell injury caused by freeze/thaw seems to be a result of the formation of intracellular ice crystals. Intracellular water freezes more slowly than extracellular water if the rate of freezing is less than 10°C/min. This causes an osmotic gradient that results in the flow of water out of the cells, and damage may result from cellular dehydration (6). At much more rapid rates of freezing, there is little time for this gradient to form; therefore, very little dehydration occurs. However, because the cells do not lose their water, ice crystals tend to form and destroy intracellular organelles. Cryoprotective agents alter the tonicity of cells and thus slow the rate of freezing but not enough that severe dehydration occurs. The high-glycerol method is the one most widely used because (a) it does not require a controlled rate of freezing (the less expensive freezers perform satisfactorily) and (b) it requires only -80°C for its initial freezing as opposed to -196°C for the low-glycerol method, which also requires liquid nitrogen storage.

Multiple variations of the freezing methods have been reported, but some facts apply to all of them. Red blood cells should be frozen within 6 days after collection. Rejuvenation can be carried out several days later than this but before glycerolization. This rejuvenation process is designed to restore red cell adenosine 5′-triphosphate (ATP) and 2,3-diphosphoglycerate (2,3-DPG) levels. Each method has limitations, but all of them yield a product of high red blood cell purity and function, minimal white blood cell and platelet contamination, and virtually no residual plasma proteins. This is important when the presence of such contaminants might cause adverse reactions. Frozen red cells are approximately twice as expensive as ordinary red cells because of the costs of freezing, storage, and thawing. In addition, the deglycerolization and washing, which are obligatory before transfusion, take approximately 45 minutes per unit. Therefore, the cells cannot be used for emergency resuscitation. The method is used to preserve rare or unusual units as well as for autologous blood stored before anticipated surgical use.

PATHOGEN INACTIVATION TECHNIQUES

The emergence of human immunodeficiency virus (HIV) as a major health problem and the demonstration of its transmission by blood components have led to significant improvements in donor selection and deferral processes and focused regulatory attention on blood banking in general. They also acted as a catalyst for the identification, characterization, and development of testing methods for several other transfusion transmissible

viruses [e.g., hepatitis C virus (HCV), human T-cell lymphotrophic viruses (HTLV) I and II]. Although one might speculate about the relative contribution of each of these advances, there is no doubt that transfusions are safer today than they have ever been.

Media and judicial and regulatory attention to transfusion risks have also helped to create a public expectation when one is dealing with a biologically derived product that cannot be rendered completely free of transmissible pathogens. Nevertheless, this expectation has stimulated the development of several pathogen inactivation methods that appear to be quite promising, particularly for the plasma-based components. It has long been recognized that various forms of heat treatment could be effectively used to prevent transmission of hepatitis B virus (HBV) or non-A non-B hepatitis (now known as HCV). Recent developments have utilized methods involving the addition to the blood of a variety of chemical agents usually with some external radiation source to activate the chemical additive.

Heat (Pasteurization) Treatment

Treatment of albumin for 10 hours at 60°C in the presence of stabilizers has been used for three decades to destroy both enveloped and nonenveloped viruses. However, early studies indicated that various coagulant proteins were adversely affected by this method and it could not be used for all plasma-based products. More recently, limited studies have again suggested a possible role for this method with only approximately 10% loss of coagulant factor activity (7). Confirmatory data and clinical studies would be desirable. Interestingly, manipulations of the heating methods have led to some studies of so-called high temperature, short-time heating applied to plasma that had been spiked with several viruses. Processing at 77°C for 0.006 seconds resulted in very high levels of viral killing, e.g., more than 4.4 $\log_{10}$ for HIV. Protein structure and biological activity of some coagulant proteins were well maintained, but factor V was the most labile with 60% loss (8).

Solvent/Detergent Treatment

The discovery by Horowitz et al. (9) that an organic solvent tri(n-butyl)phosphate plus a detergent disrupted lipid-enveloped virus while leaving protein structure and function largely intact paved the way for development of this approach so that it could be applied to plasma products. The same group also demonstrated that gamma irradiation could be effective for viral killing but only at doses likely to produce adverse cellular effects (10).

Initial studies of solvent/detergent (SD) treatment utilized ethyl ether as the solvent, but the highly explosive nature of ether was a significant drawback to its general application. Conversely, tri(*N*-butyl)phosphate is nonvolatile with a proven efficacy for viral inactivation. SD methods work in the following manner: viral lipid membranes absorb the detergent that then disrupts and disintegrates the membrane in the presence of the solvent. This membrane destruction allows release of the nucleic acid core, which is destroyed by various plasma enzymes, thereby rendering the virus noninfectious (11).

SD methodology is effective at rendering noninfectious the following transmissible viruses: HIV-1 and -2, HCV, HBV and HTLV-I and -II. It is not effective against nonlipid-enveloped viruses such as hepatitis A virus (HAV) or Parvovirus B 19 nor is it thought to be useful against the prion responsible for Creutzfeldt-Jakob disease.

Commercial application of the SD method involves pooling large numbers of units of FFP before treatment (approximately 2,500). This pooling of the product raises concerns about the possibility of (hitherto undiscovered) pathogens that may not be inactivated and the scope of whose transmissibility would be greatly magnified by the pooling process. In light of events in the past two decades, this fear cannot be lightly dismissed. Conversely, current estimates of the viral destructive effects of this method are such that it is likely that one vial of contemporary plasma-derived coagulant-factor concentrate prepared by the SD method has less than one chance in 10^{16}, 10^{13}, and 10^{6} of infectious HIV, HBV, and HCV, respectively (12).

U.S. Food and Drug Administration (FDA) licensure was obtained in 1985 for the manufacture of antihemophilic concentrate, and such licensure was granted in May 1998 for similarly treated FFP. Clinical studies of SD-FFP indicate that coagulant factor activity is approximately 10% to 15% less than that for untreated plasma (13), and it is likely that medical indications for SD plasma will be essentially the same as those for FFP (11). The slight reduction in active coagulant factors should not require any compensatory dosage increase in most patients. However, in those requiring more than approximately three units of FFP, some compensation for the 10% to 15% loss should be considered if SD-FFP is to be substituted for FFP.

Cost is likely to be a significant factor in decisions about the use of SD-treated plasma. Resources spent on the SD treatment have already raised questions about its cost-effectiveness (13). Questions are also likely to be stimulated by the possibility that only a single supplier will be producing SD-FFP in the United States for the next few years. Questions about equality of access to the supply are obvious as are fears about the national vulnerability to manufacturer recalls. For these and other reasons, it is unlikely that SD-treated plasma will become the sole U.S. source of plasma-based products in the near future, although this product has completely replaced FFP in Norway and Belgium, and it is widely used in many other European nations. After more than 11 million units of SD-treated plasma blood products have been transfused, there have been no reports of adverse effects owing to the treatment (12). SD-treated plasma has been shown to be as effective as FFP for the treatment of a wide variety of clinical situations including thrombotic thrombocytopenic purpura.

Photodecontamination

As long ago as 1955, Murray et al. (14) demonstrated that ultraviolet (UV) light could be used to inactivate hepatitis viruses, but it also caused significant protein denaturation. Prince and colleagues (15) later showed that the addition of β-propiolactone to UV treatment was associated with inactivation of approximately 10^{7} infectious doses of HBV, whereas approximately 40% of factor IX activity was retained. The use of light sources as activators has some obvious drawbacks because the degree of light penetrance necessary for activation can be extremely difficult to

achieve without undue heat build up, and clearly this method could not be readily applied to units of red blood cells.

Investigators have concentrated their efforts on the treatment of platelet units that could be modified to spread the content very thinly over a relatively large surface area to counteract the low penetrance of the light and the requirement that the treated product not become excessively warm during the treatment.

Experimental devices have been developed to deliver approximately 3 J of UVA (320 to 400 nm) light per cm^2 in approximately 4 minutes to the surface of the bag. Psoralens can be added to the contents of the bag. These are planar aromatic molecules that can bind irreversibly to single- and double-stranded nucleic acids by intercalation. On illumination by UVA light, intercalated psoralens form interstrand cross-links with RNA and DNA. Bacteria or viruses, thus modified, are inactivated because transcription and replication are prevented if sufficient psoralen/UVA-generated lesions are created to overwhelm natural repair mechanisms. In one excellent study (16), very high levels of HIV, HBV, *Staphylococcus epidermidis* and *Klebsiella pneumoniae* were inactivated in platelet concentrates, whereas platelet functions were adequately retained. Practical application of this methodology will require improved methods for delivery of the light without concomitant generation of damaging heat. It is also important to point out that studies of UV light as a method of reducing HLA immunogenicity of platelets have utilized UVB rather than UVA light. Another of the potential problems associated the use of psoralens in units of platelets is the mutagenicity of residual psoralens. It has already been shown that hydrophobic resins can be experimentally used to adsorb residual functional psoralens and thereby significantly reduce their mutagenicity (17). Use of UVA light and psoralens remains experimental and seems unlikely to become a standard and FDA-approved method without some significant technological breakthrough. However, because of the enormous potential for elimination of bacterial, as well as viral threats from platelets, this approach is the object of significant highly focused research.

Methylene Blue

Another chemical additive that has been used to sterilize plasma is methylene blue (MB). Because light must also be used to activate the MB, this method is essentially limited to plasma products. The MB acts similarly to psoralens by intercalating between nucleic acid bases and rendering the virions replication incompetent. As for psoralens, questions of mutagenicity arise because of residual MB in plasma. Methods of adsorption of residual MB have been developed (18). MB methodology also shares another drawback with psoralens in that it does not address the pooling of intracellular viruses. An advantage of the MB method is that it can be applied to single units of plasma, thereby eliminating the pooling that is required for SD treatment. To date, there are no FDA-approved lighting devices that would permit MB treatment of large batches of units of plasma. Any large donor collection center would need to be able to MB treat large batches of units (50 to 100) because they may collect several hundreds of donations each day. MB treatment appears to have minimal effect on coagulation factor activity in plasma and has been used extensively and safely for several years in Germany and Switzerland (19).

Other Inactivation Methods

Unsaturated fatty acids have been shown to inactivate lipid-enveloped viruses in culture media but have significantly reduced activity in this regard in plasma or cryoprecipitated plasma (20) and so are unlikely to generate much interest despite their success in retaining coagulant factor activity in SD-treated plasma. Similarly, gamma radiation has been evaluated for plasma deliberately spiked with HIV. The doses of radiation necessary to inactivate the virus were such that the biological properties of the plasma proteins were compromised (21). A novel approach using cross-linked starch iodine was evaluated for some model viruses (lipid and nonlipid enveloped). This method showed promise because it retained approximately 70% of the coagulation factor activity (22). Further evaluation using truly pathogenic human viruses will need to be carried out. Another interesting method was found with the discovery of a potent oxidant ozone to plasma. As much as 11 log inactivation of HIV-1 was achieved by this method with minimal effect on coagulation factor activity (23).

Although technological advances can catapult any of these (or other) methods into a more prominent position, SD treatment of plasma has a clear lead because of its FDA licensure.

AVAILABLE BLOOD PRODUCTS AND INDICATIONS FOR USE

Part of "71 - Blood Component Therapy"

Whole Blood

A unit of whole blood has a volume of approximately 500 mL (440 mL of blood + 63 mL of anticoagulant/preservative). The hematocrit value is approximately 35% (12 g of hemoglobin per deciliter). When the concept of dividing each donation of whole blood into its constituent components became widely accepted as a rational and efficient way of providing optimal transfusion care, the use of whole blood declined. In the hospital setting, the degree of sophistication of the overall medical and surgical practice was judged, at least partly, by the ratio of red blood cell use to whole-blood use. Some surgeons continued to maintain that, because the patient bled whole blood, it was logical to reinfuse whole blood. Apart from the obvious need to fractionate blood so that components can be prepared, the most cogent argument to be made against the proponents of routine use of whole blood is that whole blood is not whole.

The deterioration of labile coagulation factor activity (largely factors V and VIII) and the virtual absence of platelet or granulocyte function negate claims that whole blood is whole in the functional sense. To make it whole, one would have to collect it and transfuse it rapidly, i.e., within hours, which is a logistic impossibility. Cardiac surgeons sometimes have requested fresh whole blood for use during, and particularly after, cardiopulmonary bypass surgery. In a recent paper, Lavee et al. (24) reported that one unit of fresh whole blood (collected on the morning of surgery) increased the platelet count to the same extent as six units of platelet concentrate did and restored platelet aggregation and volume comparably with eight and 10 units of platelets, respectively. These data must be interpreted with caution because previous data (25) indicate that the use of fresh autologous blood did not decrease blood use after bypass.

Although the use of whole blood is often decried, its use does provide both oxygen delivery and volume in one product. That is precisely what is needed in the treatment of acute hemorrhagic, hypovolemic shock. However, oxygen delivery can be provided by red blood cells, and volume can be provided by giving crystalloid or colloid solution without increasing the number of donors to which a patient needs to be exposed. Blood flow rates are slower with the more viscous red blood cells than with whole blood, but this can be overcome by adding isotonic crystalloid or colloid solution directly to the bag of red blood cells before use. However, in acute or critical clinical situations, the latter manipulation is somewhat cumbersome and time-consuming; this has led to renewed requests for whole blood (26).

More recently, the use of storage additive solutions with anticoagulants such AS-1 or AS-3 has restored the whole-blood flow characteristics to red blood cells (27), thereby facilitating their use in the operating room or the emergency department. In the absence of availability of these types of anticoagulant-preserved blood, with additives, it is reasonable and probably wise to maintain a small stock of whole blood in the blood bank or in the emergency department in an appropriate, blood bank–controlled refrigerator. Parenthetically, if blood for transfusion is stored anywhere in the medical complex outside the blood bank, it is very important that it should be under the direct control and supervision of the blood bank personnel to ensure adequate quality control. It has been widely recognized that, if the blood bank abdicates this responsibility, storage probably will not be carried out properly.

If whole blood is used for emergency resuscitation, it should be used volume for volume relative to blood loss. Because it is nearly impossible to estimate acute blood loss volume in real time, the size of the loss is merely a guess and depends to some extent on the experience of those trying to make that guess. Because of this, as well as other factors, the use of whole blood in such clinical settings is not infrequently associated with volume overload. It is very difficult to judge fluid volume status in a rapidly fluctuating clinical situation unless one has the luxury of having continuous central intravascular pressure measurements. Even this approach is not necessarily foolproof.

Red Blood Cells

This component is essentially the red blood cells that remain after plasma and platelets have been separated from whole blood. The number of red blood cells in this component is the same as the number in the bag of whole blood from which it was derived. The concentration of red blood cells will vary according to the amount of residual plasma in which they are suspended or the volume of additive solution (e.g., AS-1, AS-3) added to the red blood cell bag. The volume of a bag of red blood cells is approximately 250 mL and that of a bag of red blood cells preserved with AS-1 is 330 mL. Other modifications, such as the removal of white blood cells or freeze/thaw/washing, may decrease the volume to as low as approximately 180 mL.

Unless platelets or white blood cells have been selectively removed from the donated whole blood, they will be contained in the final product. After 2 to 3 days of storage at 4°C, there is little, if any, remaining function in the platelets or granulocytes, and they progressively disintegrate with further storage. The degenerating granulocytes in particular contribute to the development of microaggregates in the bag.

The single indication for transfusion of red blood cells is the need for increased oxygen delivery to the tissues. In situations of acute blood loss with intravascular volume deficit, red blood cells provide the means of oxygen delivery, and crystalloid or colloid solution supplements provide the volume. When there is symptomatic chronic anemia unresponsive to various hematinics, the use of red blood cells may be reasonable and appropriate if the risks of withholding transfusion outweigh those of giving it. In other words, the mere existence of anemia or even of the symptoms attributable to it is not sufficient grounds for the transfusion of red blood cells.

The transfusion trigger has long been the subject of considerable controversy. For many years, perioperative transfusion practice was guided by the principle that a hemoglobin value of less than 10 g/dL was an indication for transfusion. Although this simple rule was almost universally accepted and applied, little hard evidence existed to support it other than calculations that indicated a potential for impaired oxygenation of tissues. These data usually did not take into account the appropriate calculation for cardiac output changes, oxygen extraction, or changes in the hemoglobin/oxygen affinity curve (28).

It now is generally accepted that most healthy humans do not experience a compensatory significant increase in cardiac output until the hemoglobin value is below 7 g/dL. Clearly, patients with conditions that compromise their cardiovascular or cerebral blood supply may require therapy before their hemoglobin value reaches this level. Therefore, each patient must be evaluated individually with regard to the effects of anemia before the decision to transfuse is made.

It is also important to note that there is no evidence that wound healing is impaired until a hematocrit value of 15% to 17% is reached (28,29). Minor postoperative anemia clearly is not an indication for transfusion on the basis of wound healing or, indeed, of infection (29). On the contrary, there is some evidence that perioperative transfusions may be associated with an increased incidence of infection (30).

Patients with nonsurgical chronic anemia, such as the anemia associated with chronic renal failure, adapt remarkably well to levels of hemoglobin in the range of 5 to 7 g/dL and can perform everyday duties reasonably well at those levels. It is standard practice to transfuse these patients when the symptoms of the anemia are beginning to incapacitate them or when new or more ominous symptoms appear, such as angina pectoris or central manifestations of anoxia. It is clear that a gradual decline or long-term decrease in hemoglobin level is tolerated by patients much better than a more acute onset.

When the cause of anemia is being investigated, the blood samples for the laboratory studies should be obtained before transfusing the patient. The increase one expects in the hemoglobin value after the transfusion of red blood cells depends on many factors, including the patient's weight and hemodynamic stability and the presence or absence of active bleeding. In a stable, nonbleeding, 70-kg patient, one would expect to see an

increase of approximately 1.5 g/dL or approximately 3% to 4% in hematocrit value per unit transfused. It is necessary to allow an hour or so for intravascular equilibration before the posttransfusion hemoglobin level is determined. Patients with chronic anemia often have an expanded plasma volume, which puts them at particular risk of volume overload, especially if whole blood is transfused rather than red blood cells.

Modified Red Blood Cells: Leukocyte-Reduced Red Blood Cells

Red blood cells can be rendered leukocyte poor by various techniques, including centrifugation to separate the buffy coat or filtration to remove leukocytes. Each method has its intrinsic advantages and disadvantages, and the method chosen may depend on the indication in a given patient. Meryman et al. (31) compared 13 methods of preparing this product, all based on centrifugation, automated red blood cell washing, or freeze/thaw techniques. These authors concluded that centrifugation methods removed 65% to 87% of the leukocytes, but to achieve the higher percentage, one had to use 6- to 10-day-old blood and remove 90 mL of cells, which decreased the hemoglobin content by approximately 30%. Automated washing or freeze/thaw techniques removed as much as 96% of leukocytes and between 5% and 10% of the hemoglobin.

The two main indications for the use of leukocyte-reduced red blood cells are (a) transfusion of patients with a history of febrile nonhemolytic transfusion reactions and (b) prevention of the development of antileukocyte antibodies and platelet refractoriness. More than 25 years ago, Perkins and colleagues (32) first clearly demonstrated that the granulocytes were primarily responsible for febrile nonhemolytic reactions and that this reaction was dependent on both the dose and the rate of administration of the granulocytes. In that classic study, the patients responded, with a minimal degree of temperature elevation, to as few as 0.25×10^9 leukocytes. It is generally believed (33) that the majority of patients with a history of febrile nonhemolytic reactions and antileukocyte antibodies can be transfused satisfactorily with red blood cell preparations containing 0.3×10^9 leukocytes. A much greater degree of removal of contaminating granulocytes can be achieved by various filtration techniques, which also have the advantage of removing fewer red blood cells from the unit.

For a red blood cell product to be designated leukocyte poor, 70% of the white blood cells must be removed, and only 70% of the original red blood cells need to remain (as much as 30% loss of red blood cells).

At the Mayo Clinic (Rochester, MN), the upright spin method yields approximately 80% red blood cell recovery and 80% removal of white blood cells; with nylon-wool filtration, the values are 90% and 95%, respectively. Looked at in another fashion, one unit of upright-spin, leukocyte-poor red blood cells exposes the patient to as few as 0.6 to 0.8×10^9 white blood cells, and the filtered product exposes the patient to as few as 0.06 to 0.08×10^9 such cells.

Most patients can receive upright-spin, leukocyte-poor red blood cells without subsequent reactions, but some break through at this dose and then require filtered red blood cells. After several years of experience with the transfusion of many hundreds of such patients, The Mayo Clinic has yet to see a highly sensitized patient have a febrile nonhemolytic reaction to filtered red blood cells. The patients who are most likely to have febrile nonhemolytic reactions are multiparous women or previously transfused patients (33).

Numerous studies examined the role of antigranulocyte antibodies in these reactions; although there is a correlation, the data are not clear-cut. This probably reflects the difficulty in making the clinical diagnosis with any degree of consistency and confidence because of the confounding factors in many patients. Underlying clinical conditions such as sepsis, autoimmune disease, and medications make this a diagnosis by exclusion. A second reason for lack of clear-cut correlation is the fact that many different tests have been devised for the detection of antibodies to leukocytes, and they probably do not measure antibodies to the same antigenic targets. A few of the tests that have been used are leukoagglutination (slide), leukoagglutination (microcapillary tube), lymphocytotoxin (complement-dependent dye exclusion), granulocyte membrane (fluorescence), and granulocyte membrane (radioimmunometric).

Another factor that plays a role in deciding what is the most reasonable approach is the shelf life of the product. If one uses either centrifugation or a spin/filter, closed-system method, the normal shelf life of the red blood cells is retained. Conversely, if one uses a system that requires breaching the integrity of the system (such as washing or non-in-line filters), the subsequent shelf life becomes 24 hours. Clearly, the latter component is useful only if transfused immediately after preparation. The need to maintain an inventory of leukocyte-poor products in the blood bank with a reasonable shelf life is obvious (34).

Filtration through a white blood cell filter that can be used at the bedside (or in the blood bank immediately before transfusion) has been advocated. The use of such a filter resulted in 87% red blood cell recovery and 6.1×10^6 residual white blood cells (35). Problems noted by those authors were prolonged transfusion time and poor red blood cell recovery if only one unit was infused through the filter. Another type of filter that can be used in this setting is the microaggregate filter, originally designed for the removal of microaggregates from blood before massive transfusion (an indication that is highly controversial). These filters have been used successfully in the blood bank to prepare leukocyte-poor red blood cells just before their infusion (36).

Another recent advance in the preparation of leukocyte-poor red blood cells is the development of a closed-system method that combines centrifugation and filtration steps and the removal of microaggregates (which enhances red blood cell storage) (37). This method preserves the shelf life of 42 days for the product and apparently yields 98% white blood cell removal, i.e., 10^8 cells remaining. This approach is significant because it seems to combine efficiency of white blood cell removal with ease of operation and logistic convenience.

The second indication for the use of leukocyte-poor red blood cells is the prevention of the platelet refractory state. In their landmark paper in 1957, Brittingham and Chaplin (38) recognized the role of leukocytes in febrile nonhemolytic transfusion reactions, and subsequent studies indicated that patients

with preexisting alloimmunization against HLA antigens had decreased graft survival (39). This led to a significant increase in the use of frozen/thawed red blood cells for transfusion in dialysis patients. In 1973, Opelz et al. (40) presented the apparently paradoxical data that transfused patients had better renal graft survival than untransfused patients. Opelz and Terasaki published (41) the definitive data in 1976 that indicated a previously unsuspected effect of transfusions, i.e., immunosuppression.

The fact that transfusions generally led to alloimmunization was not in dispute. Platelet refractoriness was assumed to be owing to exposure of the patients to repeated doses of platelets with their abundant endowment of HLA class I antigens (HLA A, B, and C antigens). However, data began to accumulate suggesting that the platelets themselves did not evoke the immune response, but rather the contaminating white blood cells in the platelet infusions did. Interestingly, these data were analogous to data implicating passenger donor white blood cells in solid organ grafts as the culprits in evoking transplant rejection phenomena (42).

Because of the enormous strides in the past decade in the therapy of patients with hematologic malignancies, these patients achieve more remissions and survive longer. Each attempt at inducing remission usually includes transfusion support with platelets and, sometimes, red blood cells. Clinicians are increasingly faced with the specter of platelet refractoriness. It is logical to try to prevent this rather than to merely respond to its presence by using expensive, HLA-matched apheresis platelets or, occasionally, cumbersome platelet cross-matching systems.

Prevention has been achieved by the drastic reduction of the white blood cell content of red blood cell and platelet preparations used for transfusions. Again, simple centrifugal removal of the buffy coat often suffices to prevent the occurrence of febrile reactions in previously sensitized patients. Prevention of sensitization seems to require that each transfusion deliver less than 5×10^6 leukocytes. Meryman (43) summarized the supportive data for this statement most impressively. In practical terms, to prevent alloimmunization, one must be prepared to process red blood cells (and also platelets) to remove 95% to 98% of the leukocytes to achieve the level of 5×10^6 residual cells. This requires either frozen/thawed red blood cells or the newer filtration methods, which can achieve this level of white blood cell removal with minimal red blood cell loss. Sniecinski et al. (44) showed the value of this approach in a thorough prospective study. In particular, the use of these filters permits patients to have more transfusions over a longer period before they become sensitized.

It is difficult to find hard data on the financial impact of this approach, but keep in mind that perhaps 50% of patients are destined to become refractory if one makes no special effort to prevent it. A policy of deliberately using only leukocyte-poor products for all patients with hematologic malignancies would be expensive (because of the cost of filters and labor). Conversely, however, the cost of providing platelet support to a highly refractory patient who is consuming vast quantities of platelets (even the expensive HLA-matched variety) is enormous.

Indirectly, the transfusion of many units of blood and components exposes patients to various other complications, such as hepatitis and cytomegalovirus (CMV) infection. Meryman (43) pointed out that “it is hard to argue that the prevention of HLA alloimmunization by filtration is an extravagance.”

Platelet Transfusions: Random-Donor Platelet Concentrates

As described above, platelets generally are separated from donated whole blood by a series of centrifugation steps designed first to separate platelet-rich plasma from red blood cells and then to concentrate the platelets in the platelet-rich plasma to decrease the volume of the product and to maximize plasma availability for other purposes. Platelets also can be obtained from the buffy coat, although this method is not widely used (45). The standards of the American Association of Blood Banks state that platelet preparations from whole blood must contain a minimum of 5.5×10^{10} platelets in at least 75% of units. Platelet preparations obtained by cytapheresis must contain 3×10^{11} platelets in at least 75% of units (46). The platelets (either variety) must be stored in sufficient plasma and agitated appropriately at a temperature that permits the pH to remain above 6.0 in all units.

Each bag of platelet concentrate contains 50 to 60 mL of platelets and plasma. Except in small children, platelet concentrates are generally transfused as pooled products from six to eight units of platelet concentrate. This number is often utilized because each unit of platelet concentrate will increase the circulating platelet count by approximately 7,500/μl in an average 70-kg person, and the target platelet count in many patients is 50,000/μL. Although ABH antigens can be detected on platelets in small amounts, in general, ABO matching seems to be clinically important only in alloimmunized patients who get better increments from ABO-matched or -compatible platelets.

The use of platelet transfusions has increased dramatically in the past decade, but not all this increase has been medically justifiable. The success in bone marrow and hepatic transplantation and in leukemia/lymphoma therapy has resulted in considerably more patients who truly need and benefit from platelets, but some experience has shown that the use of platelets in some clinical settings has tended to become arbitrary, with little or no scientific basis for the practice.

Unfortunately, the demands by some accreditation agencies for simplistic algorithms of treatment tend to exacerbate the problem. For instance, if the accrediting agency recommends that there be a transfusion guideline that indicates that a platelet count of fewer than 50,000/μL is one of the indications for platelet transfusion, this may be translated in the minds of some clinicians into a rigid rule that all patients with counts below this value need platelet transfusions. The medicolegal atmosphere may contribute to the problem. Common sense dictates that each patient should be assessed carefully before deciding to transfuse, and this caveat applies to all transfusion settings, not just those involving platelets.

The indications for platelet transfusion are significant thrombocytopenia or thrombopathy. The first question in this regard concerns the platelet count. There are excellent data to show a good general correlation between platelet count and the likelihood of spontaneous bleeding. In general, if the count exceeds 50,000/μL, the patient is unlikely to bleed even intraoperatively and should not be given a prophylactic platelet transfusion unless there is additional evidence of platelet dysfunction (47). Significant risk of spontaneous hemorrhage appears when the

platelet count is below 20,000/μL, and it is greatest when the count is 5,000 or lower (47).

The template bleeding time is sometimes used as an indicator of platelet function, but this test should be interpreted with considerable caution. Bleeding time tests can be performed in several ways, and the method used must be carefully standardized and normal ranges established in each center. Notwithstanding such precautions, there is a poor correlation between the bleeding time and clinical hemorrhage. In one study of patients who had normal clinical hemostasis after cardiopulmonary bypass, the bleeding time was 1.8 times the mean preoperative value (48). It is generally believed that the bleeding time correlates with clinical bleeding only when the value is more than twice the upper limit of normal (49). Even then, the correlation is not strong.

Many leukemic patients have platelet counts between 5,000 and 20,000/μL while undergoing chemotherapy or radiotherapy, and clinicians must carefully balance the dangers of spontaneous bleeding against the problems of alloimmunization (and perhaps disease transmission) generated by exposure to platelets. If a patient has a platelet count of 20,000/μL but has petechiae, gastrointestinal bleeding, or other bleeding manifestations, transfusion may be appropriate. Conversely, many experienced hematologists will not give platelets to a stable patient with levels as low as 5,000/μL when there are no signs of bleeding.

Platelets in Special Situations

General Surgery

Although there have been no controlled, prospective studies on the appropriate transfusion trigger for patients undergoing surgery, it is generally agreed that, for adequate surgical hemostasis, the platelet count should be greater than 50,000/μL in most patients. Judgment must be used in deciding when to transfuse because factors other than the platelet count may be important. For example, platelet dysfunction may exist alone or with thrombocytopenia. The following are associated with platelet dysfunction (50): uremia, fibrinogen/fibrin degradation products, ingestion of aspirin, and medications such as semisynthetic penicillins. In each of these situations, patients may bleed despite having a platelet count well above that normally associated with platelet-related bleeding problems. Therefore, in patients who require surgery, the presence of any of these situations is grounds for further coagulation investigation, including a bleeding time test. If the bleeding time is at least twice the upper limit of normal, prophylactic platelet transfusions might be reasonably considered if the underlying problem could not be corrected before surgery.

There are few objective data to demonstrate the effectiveness of platelets given to patients with diffuse intravascular coagulation and fibrinolysis. Some might even argue that it is tantamount to “adding fuel to the fire” to give platelets in this situation. Every effort should be made to correct the underlying cause rather than to attempt to replace the cells (or coagulation factors) that are being consumed.

Although there are no definitive data to support the practice, the preoperative transfusion of enough platelets to correct the bleeding time or to bring it to below twice normal is logical. One might also use the same reasoning in dealing with patients thought to be at risk of central nervous system bleeding, where even small hemorrhages can have permanent and devastating consequences (51).

Cardiac Surgery

Because cardiopulmonary bypass devices have long been recognized to cause physical damage to circulating platelets, patients undergoing this procedure have been studied extensively. Most have been found to have mild thrombocytopenia and platelet fragmentation with prolongation of the bleeding time. Thus, routine platelet transfusions might seem logical in these patients. However, in multiple retrospective and prospective studies of such patients, several points consistently emerge: (a) the platelet problems are usually self-correcting within 24 hours postoperatively, (b) postoperative bleeding is most often owing to inadequate surgical hemostasis and less often to thrombocytopenia or thrombopathy, and (c) prophylactic platelet transfusions do not seem to diminish blood loss. Therefore, there is no justification for routine prophylactic platelet transfusion after cardiopulmonary bypass (52).

There are clearly some situations in which such transfusions are probably reasonable. Repeat thoracotomy is often associated with oozing from the newly disrupted scar tissue, and this type of bleeding can be difficult to control with cautery or sutures. There are no good data on the effectiveness of platelet transfusions in these patients, but experienced cardiac surgeons seem convinced of their usefulness when surgically correctable bleeding does not seem to be present and the pattern of bleeding suggests capillary oozing.

At the Mayo Clinic, platelet use in cardiac bypass cases has increased from 33% of cases in 1979 to 38% in 1988. This may be owing to an increase in more complicated congenital anomaly repairs, requiring the use of porous artificial membranes for reconstruction. In such cases, it appears that the platelet transfusions play a role in rapidly plugging the pores of the material and halting oozing from its surface. It also may reflect greater use of aspirin-containing drugs or drugs such as streptokinase or tissue plasminogen activator.

Sepsis

It has long been recognized that sepsis seems to be associated with thrombocytopenia in some patients. Likewise, thrombocytopenic septic patients often respond suboptimally to platelet transfusions. Indeed, sepsis is one of the differential diagnoses in a patient who is unresponsive to platelets. The suboptimal transfusion response may be caused by disseminated intravascular coagulopathy, in which platelets are consumed, but it is also seen when sepsis exists but there is little or no evidence of consumptive coagulopathy. Elegant studies by Kelton et al. (53) and Tate et al. (54) demonstrated an increased platelet-associated IgG level in septic patients. Presumably, this leads to an increased rate of platelet destruction and removal by the macrophage/monocyte system. In addition, there is evidence that patients with septicemia have autoantibodies to platelet antigens, which accounts for the increase in platelet-associated IgG. The target antigens are postulated to be crypt-antigens exposed by the septicemia (55).

The logical approach to the thrombocytopenic patient with sepsis is aggressive treatment of the underlying sepsis rather than directing primary attention to the thrombocytopenia. However, there are clinical situations in which one must address both problems simultaneously, and it should be remembered that as long as sepsis is present, posttransfusion increments may be significantly suboptimal and HLA matching or other strategies will not correct the problem. Efforts to cross-match platelets in this situation generally are futile and may distract one from the chief problem—the underlying sepsis.

Uremia

Patients with uremia have varying degrees of platelet dysfunction, which prolongs bleeding time. Since the 1950s, the defect in the availability of platelet factor III in uremia has been known, and subsequently, a defect in platelet aggregation was noted. These measurable defects were often noted to be mild and out of proportion to the prolongation of bleeding time and the degree of clinical bleeding. When dialysis was found to reverse the functional abnormalities of the platelets, various substances, including urea, phenols, and guanidinosuccinic acid, were blamed for the platelet abnormalities, but each claim was somewhat controversial (56).

More recent studies concentrated on the role of coagulation factor VIII and, more particularly, its factor VIII:von Willebrand factor (VIII:VWF) moiety. Alteration of the platelet-membrane receptor for VIII:VWF seems to be a reasonable explanation for the prolongation in bleeding time and the platelet adhesiveness defects seen in uremia (57).

Several clinical studies demonstrated that the use of diamino-8-D-arginine vasopressin (DDAVP) can shorten the bleeding time in uremia (58). This seems to act by causing the secretion into the plasma of increased numbers of the large multimers of VIII:VWF, which may overcome the binding defect in uremic platelets. This property of DDAVP has led to its popularity in treating uremic patients before urgent surgical procedures when there may not be time for dialysis. The lack of serious side effects and the freedom from disease transmission problems have contributed to the popularity of DDAVP rather than the use of platelet transfusions for this purpose (58). The effects of DDAVP are relatively short-lived (hours), and repeated treatments can lead to tachyphylaxis.

Leukocyte-Reduced Platelets

The indications for this product are essentially the same as those for leukocyte-depleted red blood cells: (a) to ameliorate the symptoms of febrile nonhemolytic reactions in sensitized patients, (b) to prevent development of the refractory state, and (c) to decrease exposure to some viruses known to reside in white blood cells (e.g., CMV).

Various filtration methods have been described recently, and these have achieved a remarkable level of leukocyte removal (as much as 99%). This level of removal gives a final product of pooled platelet concentrates with approximately 5×10^6 residual white blood cells per pooling bag. This degree of filtration is sufficient to prevent febrile responses in most sensitized patients. The platelet loss with these filters has been approximately 10% in recent years. Platelet loss greater than this leads to the need for transfusion of additional units of platelets to compensate. Cotton-wool filters remove 100% of granulocytes, 95% of monocytes, 90% of B lymphocytes, and 85% of T lymphocytes (59). Cotton-wool filtration causes almost no activation of platelets and only minimal decreases in postinfusion survival that would be of little or no consequence in a clinical setting (60).

My own experience over several years is that cotton-wool filtration is very effective at preventing febrile reactions in patients with a history of repeated, debilitating reactions to unmodified red blood cell or platelet transfusions. This experience has been corroborated by others (61) who found such an effect when the white blood cell content was decreased to less than 10^8.

Polyester fiber filters remove almost as many white blood cells but are more expensive (62). The use of a special pooling bag for centrifugal removal of the buffy coat eliminates 93% of the white blood cells, so that febrile reactions are prevented (63). The value of this system is its ability to accomplish the white blood cell removal in a closed system shortly after the blood is obtained from the donor. This early removal should improve red blood cell and platelet storage pH while maintaining the original shelf life of all components. Whether this simple and attractive system removes enough white blood cells to prevent alloimmunization is still open to question. The immunizing dose of leukocytes is unknown, but some data suggest that 1×10^8 allogeneic leukocytes may be needed (64).

As yet, the data are insufficient to ascertain whether the use of filtered leukocyte-poor platelets will significantly diminish the occurrence of CMV or other leukocyte-borne viral infections in susceptible hosts. However, preliminary data strongly suggest that this is the case with filters capable of 3 to 4 log white cell reduction.

Other Platelet Preparations

Platelets can be washed to remove plasma proteins for patients with severe allergic reactions. A semiautomated method has been described that removes 96% of the plasma protein and yields 90% platelet recovery (65).

Platelets can be successfully frozen and then thawed for transfusion as long as 3 years later with approximately 25% loss of platelets in the process. This is usually accomplished by using 5% to 10% dimethyl sulfoxide (DMSO) and an ultralow mechanical freezer capable of maintaining temperatures of -80° to -90°C. If storage is at -120°C, platelets can be maintained for as long as 4 years. This is particularly useful for the storage of autologous platelets from alloimmunized patients who achieve leukemic remission with its attendant rebound thrombocytosis (66). It also has been used successfully to treat an infant with neonatal isoimmune thrombocytopenia with its mother's frozen platelets, which had been collected early in pregnancy (67).

Platelets in Massive Transfusion

Patients who undergo massive transfusions within a short period (e.g., one or more blood volumes in 12 to 24 hours) have well-documented coagulation defects resulting from the loss of blood,

the inadequacy of the physiologic response to the rapid replacement of the lost platelets and labile coagulation factors, and the transfusion of blood deficient in these same moieties by virtue of storage losses (68). Because the degree of deficiency is directly related to the duration of storage of the blood, such deficiencies vary among units of blood chosen randomly for transfusion. Although most blood banks generally try to transfuse their oldest units first, during massive transfusion situations, such an elective transfusion practice may be inappropriate.

There is also considerable variation in the degree of clinically significant coagulopathy seen in patients who receive massive transfusions. These factors make it difficult to establish firm correlations between the degree of coagulopathy and the quantities of blood infused. It should be recalled that the platelets may have been removed from the donated blood for processing into platelet concentrates, although this is not a realistic concern because platelets no longer function after 48 hours in stored whole blood at 4°C. Coagulation factors V and VIII are at approximately a 50% level after 1 week of storage. Therefore, massive infusion of stored blood is going to do little for the resultant dilutional thrombocytopenia or for depletion of labile plasma clotting factors.

Logically, one might expect that the amount of blood lost, the degree of thrombocytopenia observed, and the resultant microvascular clinical bleeding would be closely correlated. In several well-conducted studies, this was not the case. Also, prophylactic platelet infusions based on a predetermined replacement formula have not proved to be effective in altering clinical bleeding patterns or in reversing prolongation of bleeding time (69,70). The authors of these studies concluded that such indiscriminate platelet transfusion therapy is unjustified.

Single-Donor Platelets (Apheresis Platelets)

The American Association of Blood Banks Standards stipulate that a bag of platelets acquired by apheresis should contain a minimum of 3×10^{11} platelets in at least 75% of units tested. These platelets must be stored suspended in sufficient plasma so that the pH at the temperature of storage is 6.0 or greater at the end of the allowed storage time. In the newer plastic bags, this storage time is now up to 5 days. The collection of platelets by apheresis achieved popularity because of the recognition that platelet refractoriness was a complication of repeated exposures to random-donor platelet concentrates. This lack of responsiveness occurs in some recipients after only a few exposures; in others, it is delayed or does not appear at all.

In their classic study, Howard and Perkins (71) demonstrated that approximately 30% of patients never became refractory despite repetitive exposures. These so-called nonresponders often have malignancies, including those of the hematopoietic or lymphoid system, and their failure to become refractory raises intriguing questions about their underlying disease, their treatment regimens, or their immunogenetics (72).

Those who do become refractory display great individual variability in both the number of platelet exposures and the time taken to become refractory. The state of platelet refractoriness is said to exist when a patient has progressively smaller increases in platelet counts after platelet transfusions. Many factors may contribute to this state, and each must be considered in the approach to a clinical problem. The most common factors are listed in Table 71.1.

TABLE 71.1. FACTORS CONTRIBUTING TO PLATELET INCREMENT OR FUNCTION AFTER TRANSFUSION

Platelet Factors	Patient Factors
Method of collection	Size of patient
Method and duration of storage	Medications being taken
Presence of appropriate agitation	Sepsis
pH	Splenomegaly
Number of platelets infused	Disseminated intravascular cogulopathy
Type of anticoagulent	Bleeding
Donor taking antiplatelet medication	Circulating immune complexes
	Alloimmunization

A strong association has been found between the presence in the recipient of alloimmune lymphocytotoxic antibodies (often with HLA class I specificity) and failure to achieve the expected posttransfusion increment when other factors (such as those listed in Table 71.1) could be ruled out (71). There is abundant evidence that HLA class I antibodies are responsible for most alloimmune refractory states. This was first demonstrated by Yankee and colleagues (73), who showed that matching for what we now call HLA class I antigens was associated with an excellent response in previously refractory patients.

Although these studies clearly outlined a therapeutic approach for alloimmunized patients, they also brought to light some problems that still plague us. First, the diagnosis of the alloimmunized state is sometimes quite difficult because patients in whom it may be suspected often have one or more of the factors that mimic the alloimmunized state (Table 71.1). Second, when a patient is considered to be refractory and is placed on a regimen of HLA-matched platelets, it is virtually impossible to persuade clinicians to resume the use of unmatched platelets. Thus, the patient may be locked into a dependence on expensive, HLA-matched platelet support. The original diagnosis of alloimmunization may have been erroneous or the patient may have been truly alloimmunized but may have lost the antibodies with time.

There have been occasional reports of patients, particularly those with extensive malignant disease, losing their antibodies (74). This phenomenon has been seen in patients who were not given additional platelets after induction of the alloimmune state (71), but it also has been seen in patients who continued to receive only cryopreserved, autologous platelets or HLA-matched platelets (74). Strangely, it has even been seen occasionally in patients who continue to be transfused with random-donor platelets unmatched for HLA (75,76).

These observations suggest that although a patient may be known to have HLA antibodies concomitantly with a refractoriness to platelets, it should not be assumed that this patient always will be refractory to platelets that are not HLA matched. In a patient with relapse of a malignant disease, it is probably worth giving a trial transfusion of random platelets rather than automatically ordering HLA-matched, apheresis platelets and thus having the associated expense and logistic problems.

Another approach for the alloimmunized patient has been the use of repeated plasma exchanges to decrease the antibody titer. In one study, this approach was used during the preparatory chemotherapy and radiation regimen before bone marrow transplantation (77). It had mixed results, but there was a correlation between apparent success and the presence of preformed antibodies before the plasma exchanges. Those who responded had at least two exchanges before showing some response.

This approach cannot be applied to all alloimmunized patients because of the expense and time involved and the mixed success of the program. Because of the finding that some antigens such as HLA may be adsorbed to the platelet membranes, it has been suggested that these antigens or others may be eluted from the platelets during storage and the platelets might lose some of their antigenicity as a result. Although such elution can be shown in experimental situations, it has been demonstrated that routine platelet storage is associated with no clinically relevant diminution in the antigenicity of HLA, $Pl^{A\ 1}$, or ABO systems on platelets (78). Another study has shown that although some HLA antigens are taken up by platelet membranes in small amounts, the major portion of HLA class I antigens seems to be integral membrane constituents (79). In assessing the clinical response to platelet infusions, the 1-hour posttransfusion platelet count is a reliable predictor of the need for HLA-matched platelets. It is a useful and timely test that permits early decision making regarding therapy (80). These authors also found that the 10-minute increment also correlated very well with the 1-hour count.

To minimize the use of apheresis platelets, the factors associated with the ineffective response to pooled, random-donor platelets were examined in a recent study of 941 pooled platelet transfusions given to 133 patients with bone marrow failure (81). The major factors, by multiple linear regression analysis, that determined the increment at 1 hour after transfusion were previous splenectomy, marrow transplantation, disseminated intravascular coagulation and fibrinolysis, the use of amphotericin B, hypersplenism with splenomegaly, and HLA antibody grade as measured by the reactions of serum against a panel of four random-donor platelets. A linear relationship was found between increasing antibody grade and decreasing increment. Several other factors, such as concurrent antibacterial therapy, clinical grade of bleeding, and pyrexia, did not correlate as clearly (81).

Although hematologists and blood bankers are well aware of the problems involved in providing adequate and effective platelet support for refractory patients, not all heavily transfused patients become truly alloimmunized and require HLA-matched platelets. Approximately 40% to 50% of patients with leukemia and perhaps 10% of those with solid organ malignancy develop the antibodies in question. As mentioned previously, the underlying disease or its therapy may play some role in this apparent selectivity. Also, some intriguing data on the cellular and subcellular interactions involved in the development of the alloimmune state are emerging (82). It appears that, along with the early alloimmune response, there are signs of lymphoid cell activation, such as interleukin-2 (IL-2) and HLA-DR, on peripheral lymphoid cells and measurable increases in interferon gamma, neopterin, and β_2-microglobulin in plasma. However, such responses are not seen when purified thrombocytes are used, even if challenges are repetitive. Conversely, purified platelets will induce the elaboration of immunoglobulins that can block the Fc receptor and inhibit erythrocyte rosette formation. These immunoglobulins are immunosuppressive, and there is evidence that they are induced by stimuli that exhibit only HLA class I antigens (such as platelets).

If HLA-matched platelets are needed, the best possible responses should be from HLA class I perfect matches. Within a family, there is a 1:4 likelihood of siblings being perfect matches, a 2:4 likelihood of a single haplotype match, and a 1:4 chance of total mismatch. Therefore, when HLA-matched platelets are needed, one should try to use family members as donors because a random sibling has a 3:4 chance of being at least one haplotype matched and parents or children are obligatory one-haplotype matches. Thus, even if HLA typing on the patient or family members cannot be obtained, an intelligent guess can be made to make possible a quick response.

It is not uncommon for HLA laboratories to have difficulty in typing the lymphocytes of patients with leukemia even though there are techniques available for the separation of normal from abnormal lymphoid cells. The patient's peripheral lymphocyte population may simply be overwhelmingly abnormal cells. These abnormal cells often show aberrant and increased sensitivity to the complement generally used for the standard, complement-dependent cytotoxicity testing used for HLA class I typing.

If family members are unavailable or unsuitable for some reason, it usually is necessary to use a pool of blood bank donors who have been HLA-typed for this purpose. When one has to select from the population donors who are matched for a highly polymorphic system such as HLA, one can appreciate the need for a large pool of HLA-typed donors to increase the likelihood of finding a good match. One strives to find the closest match at all times. Fortunately, one of the features of the HLA system is that multiple groups of antigens at the same locus (*A*, *B*, or *C*) are highly cross-reactive with one another. Similarly, patients with these same cross-reactive groups of antigens rarely induce antibodies against one another's antigens. This means that alloimmunized patients will not recognize cross-reactive antigens as foreign and thus will be serologically compatible with these antigens. Clinically, the use of such cross-reactive antigen matches works virtually as well as precise antigen matching. The ability to utilize cross-reactive antigens automatically broadens the pool from which one can select clinically effective platelet donors for a specific patient. The donor pool needed to support a population of alloimmunized patients will vary according to the polymorphism of HLA in the particular ethnic group in question, the number of alternative donors one stipulates for each patient, and the degree of matching one stipulates for support.

There are various estimates of the donor pool needed in different populations. For instance, Takahashi et al. (83) calculated that a pool of approximately 5,000 typed Japanese donors is sufficient to provide five perfectly (class I) matched donors 80% of the time for Japanese patients, but as many as 25,000 American donors will be needed to provide similar support to the ethnically diverse American patient population.

Another factor in determining donor pool size is the tremendous variability in HLA class I antigens on platelets from person

to person; this applies to all class I antigens, but particularly to HLA B12 and its subtypes (84). This variability may account for the remarkable variation in incremental responses seen in patients transfused with platelets from donors with the same apparent degree of mismatching. This antigen may be selectively mismatched for patients with excellent results, and this further increases the available pool for alloimmunized patients because B12 is common in the American population (approximately 25%) (84).

The diallelic Bw4/Bw6 system within HLA class I can also be used effectively for matching because many patients who are alloimmunized in fact have antibodies to so-called skeletal antigens or cross-reactive groups (85). Matching for *C*-locus antigens is not generally useful, and these antigens seem to be more deeply embedded in the cytoplasmic membranes and more sparsely distributed than *A*- or *B*-locus antigens (86). Certain cross-reactive groupings such as A3, A1 and A11, or B17, B21, B5, and B15 do not seem to be effective clinically in terms of transfusions (87).

Because of the variable responses to HLA-matched platelets and the expenses and difficulties encountered in their acquisition, it is sometimes debated whether they should be used. It would be foolish to downplay these facts, but it would also be unwise to ignore the effect of continuing to transfuse incompatible or unmatched products. First, this type of transfusion to an alloimmunized patient is highly unlikely to result in clinically meaningful increments. Second, the infusion of unmatched platelets is likely to be followed by increasingly severe febrile nonhemolytic reactions, which are debilitating and frightening to the patient and may confuse the clinician who must try to differentiate such reactions from the onset of sepsis. Third, there are rare instances of severe, prolonged neutropenia after infusion of incompatible platelets (88). In these cases, the median granulocyte count 20 hours after transfusion was decreased 30% and remained decreased for as long as 4 days. These reported cases involved patients with aplastic anemia in whom the normally expected rebound granulocytosis did not occur.

Because of the prevalence of significant platelet refractoriness owing to alloimmunization, various strategies have been devised to maximize the likelihood of obtaining satisfactory incremental responses to platelet transfusion. The most effective strategy is HLA matching, but a considerable body of data supports the concept of platelet cross-matching either alone or in concert with HLA matching. Virtually every type of antiplatelet antibody test has been evaluated: indirect tests such as lymphocytotoxicity tests and direct tests such as immunofluorescence, enzyme-labeled immunosorbent assays, solid-phase red blood cell adherence, radiolabeled antiglobulin, and platelet aggregometry (89,90,91,92 and 93). Nearly all studies demonstrated correlations between HLA matching and increments, between negative tests and increments, and between the degree of matching and negative tests. The data have to be viewed with some circumspection because of the obvious difficulty in finding patients who lack any of the confounding factors such as sepsis.

The concept of an inexpensive, predictive cross-match is appealing because it can be used instead of the expensive pool of HLA-matched donors. This is feasible only if the test can be performed on platelet aliquots stored for long periods of time (92). It could even be used to select groups of random-donor platelet concentrates on an *ad hoc* basis, making use of each day's supply of regular homologous donors. The solid-phase red blood cell adherence method seems to lend itself to this approach, according to early results (94).

Although ABH antigens are present in small amounts on platelet surfaces, in general they do not significantly influence the posttransfusion increments. Therefore, it is not necessary that platelets always be ABO compatible. However, ABO antigens can interfere with sensitive cross-match testing and, in alloimmunized patients, mismatching for ABO may influence increments (95). Lee and Schiffer (95) suggested that one should routinely try ABO-compatible, random-donor platelets before assuming that a patient needs HLA-matched platelets.

It has been suggested that, even though only approximately 50% of leukemic patients become truly alloimmunized, one should begin therapy with HLA-matched apheresis platelets to prevent the development of the alloimmunized state. This question was discussed lucidly by Schiffer and Slichter (96), who concluded that this approach was not cost-effective.

A different approach to the prevention of alloimmunization is the exclusive use of leukocyte-depleted blood components, including platelets. These could be filtered, random-donor platelet concentrates or apheresis products. In one study, the use of leukocyte-poor platelets was associated with platelet refractoriness in only 9% of recipients (97). In another study, 15% of recipients of filtered, leukocyte-poor platelets were alloimmunized (44). The use of UV irradiation to pretreat platelets and other blood components in an effort to render them nonimmunogenic shows some early promise (98), and the development of practical and effective radiation delivery systems probably will revolutionize the transfusion of all patients in the future.

Granulocyte Transfusions

Patients who are neutropenic are susceptible to bacterial and fungal infections, and the degree of neutropenia correlates directly with the frequency and severity of such infections (99). Combating infection with granulocytes was first reported in 1934 by Strumia (100), who used a patient with chronic myelogenous leukemia as the donor. It was reasoned that such patients had a greatly expanded pool of functioning, albeit abnormal, granulocytes. However, it was not until modern cell separators were developed in the 1960s that granulocyte transfusions became part of the routine armamentarium of the hematologist. At that time, it became routine to utilize healthy normal blood donors as a source of the cells, and several techniques were used to boost the yield of granulocytes from them.

Intravenous or intramuscular steroid injections increased apheresis yields by altering the extent of margination of white blood cells, thereby increasing the pool of harvestable cells. With this technique, granulocyte units from normal donors contain an average of 1×10^{10} granulocytes. Because granulocytes are essentially tissue cells and spend only a small fraction of their life span in the circulation, it is impossible to assess their effectiveness after transfusion by evaluating posttransfusion increments. The average adult produces approximately 1×10^{11} granulocytes per day, but only approximately 2×10^{10}, or 20%, circulate.

During severe infections, particularly bacterial, the marrow can respond by increasing the production rate perhaps as much as 10-fold. This increased rate can be maintained for many days or even weeks. If one assumes that such numbers of granulocytes are produced because they are needed to combat microbes, the folly of trying to acquire similar numbers for transfusion from donors and to maintain tissue levels is evident.

This central dilemma, perhaps more than any other, has been a stumbling block to the widespread, effective use of granulocyte transfusions in infected adults. Similarly, the use of other end points for evaluation is plagued by problems. For instance, virtually all treated patients receive large doses of antimicrobial agents and may undergo surgical management of localized septic foci. If defervescence occurs or if local or systemic signs of infection or inflammation decrease, it is often difficult to attribute this to the granulocyte transfusions. Granulocyte transfusions have lost favor in recent years largely because of the availability of new families of effective antimicrobial agents and perhaps also because of improvements in the speed and accuracy of bacterial identification and antimicrobial sensitivity testing.

Because of these difficulties in evaluating efficacy, it seems reasonable to pose several practical questions and to try to provide answers. What is the ability of transfused granulocytes to migrate to sites of tissue infection? How adequate is their function? What are the indications for their use (type and duration of infection, organisms most responsive, most effective treatment regimens, matching requirements, and prophylactic use)? What collection and storage systems are best?

In nonalloimmunized patients, transfused granulocytes have normal circulation characteristics, phagocytose bacteria *in vivo* and migrate to sites of infection. There seems to be a general consensus that these transfusions are indicated for severely and persistently neutropenic patients (fewer than 250 granulocytes/μL) with infection caused by gram-negative bacteria unresponsive to adequate appropriate antimicrobial therapy for at least 48 hours (86). The data supporting these indications were presented convincingly by McCullough (101). There are no good data to support the use of granulocytes in viral or fungal infections or in patients who do not have documented gram-negative sepsis.

Earlier studies indicated that filtration techniques gave a higher yield of granulocytes but that the granulocytes had measurable defects in function. Transfusion of filtration granulocytes ceased when, in addition to widespread severe, recurrent febrile reactions, cases of priapism were reported. The following comments deal only with granulocytes acquired by apheresis and centrifugation. The use of granulocytes tagged with indium 111 permitted elegant studies of the migration and localization of transfused cells (102) and the impact of recipients' antibodies (103) (including ABO) on these phenomena (104). The transfusion of small amounts of indium-labeled autologous granulocytes also became a useful tool in localizing sites of inflammation (102).

Granulocyte transfusions should be ABO compatible because of the large number of contaminating red blood cells in the granulocyte bag. McCullough et al. (104) found that although it was assumed that ABH antigens were found on the granulocyte membrane by some techniques, the intravascular recovery, survival, and tissue localization of ABO-compatible and ABO-incompatible granulocytes were the same. There is no good evidence that HLA matching is advantageous. The presence of preformed leukocyte antibodies in the recipient of granulocyte transfusions influences the fate of these cells. The type of antibody test used may have some bearing on the correlation. Granulocyte agglutinating, but not granulocytotoxic or lymphocytotoxic, antibodies decrease granulocyte recovery and half-life of cells, increase their hepatic sequestration, and inhibit migration and localization of cells to sites of infection (103,105). Other studies compared the clinical outcomes of alloimmunized and nonsensitized patients who received granulocytes. The data from at least one such study (106) indicated that patients with antigranulocyte antibodies, as measured by indirect immunofluorescence, had a significantly worse final outcome when treated with granulocytes. The antibodies presumably played a role in inhibiting the desired effect of the granulocytes.

Whether granulocytes should be used prophylactically has not been satisfactorily determined, despite several studies. Some studies were terminated because of unacceptable numbers of patients with severe reactions. From one multicenter, controlled trial of prophylactic granulocyte transfusions in patients with acute myelogenous leukemia, it was concluded that the incidence of reactions (including pulmonary infiltrates in 57%) was too great to warrant the therapy, which had not reduced the incidence of infections or improved bone marrow recovery, remission rate and duration, or survival (107). One particularly lethal complication is diffuse pulmonary hemorrhage which occasionally occurs when granulocytes are transfused to patients receiving amphotericin B, although this is controversial (108,109).

Clift et al. (110) found substantial benefits in bone marrow transplant recipients. Others found no obvious benefit and significant hazards; therefore, routine use cannot be recommended. If granulocyte transfusions are to be used, it seems prudent to give at least 1×10^{10} cells at least once daily for at least 5 days to ensure even minimal success.

In septic neonates, the use of even one transfusion of granulocytes has been associated with dramatic responses in those with depleted marrow neutrophil reserve (111). This topic is discussed in more detail elsewhere in this text.

Adoptive Immunotherapy

Adoptive immunotherapy can be viewed as the attempt to reconstitute immune competence (usually antitumor) by supplying surrogate lymphoid or other immune system cells.

The role of the immune system in cancer surveillance has been speculative for many years as indirect or circumstantial evidence accumulated. Such data consisted of the increased incidence of various malignancies in patients with disorders that included clinically significant depression of the immune system and similar increases in malignant disease in patients with long-term iatrogenic immunosuppression such as with organ transplants. In addition, the complexity of the various normal cell types and subtypes began to unravel with the discovery of methods to produce monoclonal antibodies to various marker epitopes on lymphoid cell subpopulations. Finally, the identification, categorization, and eventual production (by recombinant DNA methods) of various cytokines permitted further elucidation

of the intricate interplay of cells and cytokines in various aspects of the immune response.

As basic knowledge of immune function grew, the prospects of replacing or augmenting specific steps in the response became more realistic. The development of automated blood cell separators gave clinicians and researchers a tool for collecting large numbers of lymphoid or other immune cells so that they could be manipulated *in vitro*. The transfusion of such cells with or without cytokines is adoptive immunotherapy.

Lymphokine-Activated Killer Cells

In addition to the natural killer (NK) cells that play some role in normal antitumor activity, incubation of mouse or human lymphoid cells with IL-2 generates a population of cells capable of lysing fresh tumor cells *in vitro* (112). These lymphokine-activated killer (LAK) cells seem to differ from both NK cells and cytotoxic T cells. Subsequent studies indicated that LAK cells had a broad range of malignant cell targets, but they spared normal cells and did not seem to be major histocompatibility complex–restricted in their targets. LAK cells are generated after short-term (24 hours) incubation with IL-2. Prior gamma radiation of the lymphoid cells inhibits LAK cell development after IL-2 incubation. This suggests that IL-2–induced proliferation is a prerequisite of LAK cell activity (113).

The origin of LAK cells is still debated, but they seem to be derived from NK cells or from NK-like cells, which are large, granular lymphocytes morphologically and produce NK cell–associated surface markers NKH1 and CD16. However, it should not be assumed that LAK activity is confined to one subtype of lymphocytes. Perhaps it should be thought of as a functional activity rather than a specific cell type.

In animal studies, LAK cells cause regression of established cancers and inhibit growth of pulmonary and hepatic metastatic lesions. These experimental studies yielded a wealth of information on the LAK phenomenon, as summarized succinctly by Klein and Leitman (114): (a) LAK cells alone produce little obvious benefit, (b) IL-2 injected alone has only a modest effect at high doses, (c) a mixture of LAK cells and IL-2 gives striking benefit, (d) for maximal effect, the cells must be cultured with IL-2 for 3 to 4 days, and (e) in humans, a dose of at least 10^{11} LAK cells probably would be needed. It is hypothesized that these cells migrate to sites of malignancy and, when there, expand *in situ* in response to endogenous IL-2. Presumably, they then destroy the adjacent malignant cells by some mechanism.

Early phase I/II studies involved patients with advanced malignancy unresponsive to conventional therapy (114). The regimen was an initial 5-day infusion of IL-2 (100,000 U/kg per 8 hours), followed by five daily leukapheresis procedures. The collected cells were incubated in IL-2 for 3 to 4 days and transfused back to the patient along with another bolus of IL-2. The results in the first group of patients gave grounds for cautious optimism; approximately 10% had a sustained, complete regression of tumor, and perhaps another 10% had a partial response. Renal cell carcinoma, melanoma, and non-Hodgkin's lymphoma responded best (114).

A limiting factor in these early studies was the terminal status of many of the patients. Another practical limiting factor is the enormous cost because of the high doses of recombinant IL-2 needed. Finally, the severe toxicity associated with the therapy is bound to limit its usefulness. At least two treatment-associated deaths have been reported, and virtually all patients have had chills and fever. Other side effects were related to massive fluid shifts resulting in severe hypotension, interstitial pulmonary edema, and massive fluid retention (114).

Another experimental study has demonstrated that LAK cells can be used to purge bone marrow of malignant cells without decreasing or harming its normal hematopoietic cell lines (115). The processing of LAK cells has been automated in a sterilized, closed system. This shows promise because the yield of cells is excellent, and processing time and personnel requirements are decreased (116).

Tumor-Infiltrating Lymphocytes

It is generally true that tumors showing infiltration by lymphocytes have a more favorable prognosis than those without such infiltration. It is reasonable to assume that the lymphocytes seen infiltrating the tumor are in some way responsible for the improved prognosis, and these lymphocytes may well be enriched by cells that have antitumor activity. Recently, lymphocytes that were isolated from murine tumors, expanded under the influence of IL-2, and transfused into mice showed activity against hepatic and pulmonary metastatic lesions that were unresponsive to LAK/IL-2 therapy (117). In the murine model, tumor-infiltrating lymphocytes (TILs) seem to be 50 to 100 times more potent than LAK cells (114). TILs from the tumor are prepared as a single-cell suspension and then incubated for as long as 6 weeks with IL-2. TILs can be seen aggregating at tumor sites for as long as 9 days after transfusion (unlike LAK cells). The long-term effects of the use of TILs are still to be determined in human subjects.

Photopheresis

This is a technique by which a patient's lymphoid cells are removed by apheresis and photoactivated extracorporeally with UVA light. The combination of methoxsalen and UVA light causes loss of viability of nearly 90% of the lymphoid cells. These cells are reinfused. Orally administered methoxsalen transiently intercalates DNA, but when photoactivated by UVA light, it is converted to a form that reacts with the DNA to create permanent covalent cross-links. The photodestruction of these lymphoid cells over the ensuing few days and their recognition by the immune system is thought to lead to a specific immunologic reaction with the malignant clones.

This experimental therapy has been evaluated in patients with cutaneous T-cell lymphoma. In the initial study, 27 of 37 patients showed a mean decrease in cutaneous involvement of 64% after 22 weeks of therapy (118). The mechanism of the beneficial result is unknown, but it is thought to be related to the fact that the therapy is directed extracorporeally to a clone or clones of malignantly transformed cells. The prolonged response in some patients previously shown to have relentlessly progressive disease suggests that this type of T-cell cutaneous lymphoma is at least partly under the control of a specific immunologic response (118).

Early experience with this technique at the Mayo Clinic revealed a 3% patient reaction rate, consisting largely of nausea or vomiting, slight and transient hypotension, or paresthesia. The procedure was generally well tolerated and consistently produced more than 10^9 white blood cells, with minimal red blood cell or platelet contamination, for reinfusion (119).

Noncellular Components

Fresh Frozen Plasma

When plasma is separated from the red blood cells of a donor within 6 hours after donation and is then held at -18°C or lower, it is FFP. If these requirements are not met, it is called liquid plasma. FFP can be stored at -18°C for as long as 1 year. If possible, it is preferable to store FFP at -30°C or lower temperatures to maintain optimal coagulation factor VIII level. Plasma stored at -30° to -40°C retains approximately 90% of such activity, whereas only approximately 60% is retained at approximately -20°C (120). FFP is largely used for its content of the labile coagulation factors V and VIII, but it also contains the so-called stable factors. If properly prepared and stored, each unit contains approximately 200 to 250 mL of plasma and, because of some processing loss, approximately 180 to 200 U of the various coagulation factors.

FFP can be thawed routinely in a water bath at 30° to 37°C with slight agitation of the bag. Rapid microwave warming can be equally effective (121). When FFP is thawed, its labile coagulation factors (V and VIII) begin to destabilize, although FFP is not usually transfused as a source of factor VIII. The unit should be transfused within 6 hours (FDA regulation) or 24 hours (American Association of Blood Banks regulation). Some studies detected significant alterations in plasma factors associated with microwave thawing. Luff and co-workers (122) reported decreases in factors IX, X, and XI and fibrinogen and similar changes in albumin and total protein. They noted that microwave technology does not provide uniform heating, and they were not able to distinguish between simple denaturation of protein and the presence of a nonspecific coagulative property of the microwave. There can be local superheating of thawed plasma immediately adjacent to still-frozen plasma, giving an unpredictable and uneven thawing cycle.

FFP corrects bleeding abnormalities in some patients with congenital (storage pool disease) or acquired (uremia) platelet abnormalities. The reasons for these responses are probably complex, but one factor may be the platelet microparticles found to contaminate most FFP and especially cryoprecipitate (123).

After the introduction and widespread acceptance of the principle of blood component separation and transfusion, the use of FFP increased dramatically. For example, the national use of this component increased from 180,000 units in 1971 to 1.54 million units in 1980 (124). Several studies indicated that FFP is being used as a volume expander or to reconstitute whole blood and that objective criteria for its use are rarely documented in patient charts. In one such study, only 27% of the transfusions were judged to be appropriate (125). These same studies emphasized the need for the education of clinicians regarding the appropriate use of FFP, and one study (126) demonstrated the dramatic positive response to a daily survey and education program in one hospital.

There are few specific indications for FFP. They are limited to the treatment of deficiencies of coagulation factors for which specific factor concentrates are unavailable or inappropriate. The National Institutes of Health Consensus Conference Summary also stated that FFP was a reasonable therapy for patients with uncontrolled bleeding and multiple coagulation protein deficiencies, even though there are few data to support the efficacy of FFP in these circumstances (127). Its use can also be justified for patients with significant hepatic dysfunction and coagulopathy and as a replacement fluid in therapeutic plasma exchange for thrombotic thrombocytopenic purpura.

For patients with specific deficiencies of factors II, V, VII, IX, X, or XI, the use of FFP may be justified, although the mere presence of such demonstrable defects *per se* is insufficient grounds for transfusion. The levels of the factors that need to be attained for hemostasis vary considerably. For factor X, approximately 10% of normal is needed and can be easily achieved with FFP; patients with severe deficiency of factor IX can rarely be brought to hemostatic levels with FFP alone without incurring serious risk of volume overload (127).

Patients with severe liver disease pose a considerable challenge because of the multiplicity of their coagulation factor deficiencies. The factors differ physiologically, and coupled with the low intravascular recovery of some of these factors after transfusion, judging transfusion needs can be difficult. In a 70-kg person, one unit of FFP will raise the circulating levels of factors VII, IX, and V by 1% to 2%. With ascites or anasarca, the extravascular distribution may be increased, and intravascular recovery correspondingly decreased (126). Bleeding in these patients often can be controlled by as little as 10 to 12 mL of FFP per kilogram of body weight.

Warfarinlike anticoagulants act by causing the release of dysfunctional vitamin K–dependent factors II, VII, IX, and X as well as proteins S and C. This situation is best reversed by the use of vitamin K or its analogs, but this may require 24 hours. For more rapid reversal, FFP can be used (in addition to vitamin K) in doses of approximately 10 mL/kg (128). Because of the different half-lives of these factors, their rates of disappearance and reemergence vary. After vitamin K administration, factor VII increases at the fastest rate, achieving 30% of normal in approximately 24 hours, but factors IX and X lag. Medical or surgical emergencies would dictate the concomitant use of FFP to achieve more rapid reversal.

FFP is indicated in the reversal of antithrombin III deficiency in patients who are undergoing surgery or who need heparin for the treatment of antithrombin III deficiency–related thrombosis.

Numerous studies of FFP use in massive transfusion settings failed to document a significant role for this component in that setting and even failed to demonstrate reversal of documented coagulopathy in these situations. Thus, its empiric or prophylactic use during massive transfusion episodes is not supported.

Single-Donor Plasma

If a unit of FFP has not been used after a year of storage at -18°C or lower, it may be relabeled single-donor plasma and, as such, may be stored for 4 more years at -18°C or lower. Likewise,

a unit of FFP that has been thawed at 30° to 37°C and then not transfused within 24 hours (storage at 1° to 6°C) can be relabeled single-donor plasma. This product contains all the constituents of FFP, except for the labile coagulation factors V and VIII, at levels reasonably comparable with those in FFP. Therefore, it can be used in many of the previously discussed situations. Each unit also carries the disease transmission risks associated with any single-donor product.

Cryoprecipitate-Depleted Plasma

If cryoprecipitate has been removed from a unit of whole blood or FFP, the label must so state because such plasma is deficient in factors VIII and XIII, fibrinogen, and fibronectin. This component can be used for volume repletion, but it carries the risks of disease transmission common to FFP and single-donor plasma.

Plasma Protein Fraction

This product is processed commercially to provide an isosmotic, protein-containing product; the protein is largely albumin (83% to 88%). In addition, it contains no more than 1% gamma globulin, sodium at 130 to 160 mEq/L, and potassium at less than 2 mEq/L. This solution is stabilized by 4 mmol/L sodium acetyl tryptophanate and 4 mmol/L sodium caprylate. The final product is heated at 60°C for 10 hours for sterilization. The shelf life is 5 years at 5°C or 3 years if stored at between 5° and 30°C. Plasma protein fraction can be used as an emergency volume expander during treatment of hypovolemic shock owing to burns, trauma, or even hemorrhage. In young children, it can be used as an initial therapy for shock owing to dehydration or infection. The resulting increase in blood volume lasts as long as 48 hours (129). Like other isosmotic protein resuscitation fluids, it must be used with caution in patients with congestive heart failure, severe anemia, high cardiac output states such as hyperthyroidism, or any other condition associated with increased plasma or blood volumes.

In patients undergoing cardiopulmonary bypass surgery, a profound hypotensive reaction has been documented when plasma protein fraction was administered rapidly (faster than 10 mL/min) (130). This was subsequently shown to be caused by Hageman factor fragments, which have a potent vasodilation effect owing to their generation of bradykinin in recipients (131). These reactions have been accompanied by flushing, urticaria, nausea, headache, and backache in conscious patients. There also have been reports of anaphylactic or anaphylactoid reactions to infusions of various plasma protein solutions in atopic patients. Such severe reactions were estimated by Ring and Messmer (132) to occur rarely (0.003%).

Plasma protein fraction and other protein-containing solutions are sometimes used to treat hypoalbuminemia or hypoproteinemia. However, such therapy is effective only in the short term because the protein must be broken down into its constituent amino acids before it can be incorporated into new protein. This breakdown and reincorporation requires several weeks to complete, and it results in only approximately 45% of the infused protein becoming incorporated into the body protein pool (133).

Albumin

Human serum albumin products are widely used in North America because of their relative purity, their standardization of content, and most of all, their freedom from viral contamination (as a result of heat treatment at 60°C for 10 hours). Albumin is available as a 5% solution or a 25% solution that can be diluted at the bedside. Albumin has a molecular weight of 67,000, contains approximately 600 amino acids, and is conspicuously deficient in tryptophan. The viscosity of albumin solutions is remarkably low, and even 25% albumin is almost isoviscous with blood. The molecule carries a net negative charge of -19 at blood pH, a property that plays a role in the binding of albumin to a large number of compounds such as bilirubin, fatty acids, hormones, and medications. Albumin is synthesized mainly in the liver, and because the liver carries only small reserves, serious hepatic dysfunction quickly leads to hypoalbuminemia and its sequelae. Normally, approximately 15 g is synthesized daily in the steady state, but malnutrition or chronic hepatic disease will decrease this rate significantly.

As with other plasma proteins, albumin penetrates capillary walls more slowly than water and electrolytes, and this property confers the molecule's colloid osmotic or oncotic properties. Albumin contributes approximately 80% of the colloid oncotic pressure of plasma, which is approximately 27 mm Hg. When the total serum protein level drops to approximately 5.2 g/dL (the so-called control valve), the colloid oncotic pressure decreases to approximately 20 mm Hg, and further decreases lead to increases in the interstitial fluid compartment, resulting in ascites, edema, or anasarca.

The most common causes of hypoalbuminemia are burns, chronic hepatic disease, chronic protein-losing enteropathy, and acute nephroses. Extensive burns cause the largest acute losses of albumin from the blood. During the first 90 hours after a third- or fourth-degree burn of 50% of the body surface, albumin losses can be the equivalent of approximately two whole normal pools of circulating albumin. A daily loss of as much as 30 g of albumin can be seen for several weeks after a major burn (134). The albumin infusions have to be carefully monitored in terms of the plasma protein levels to ensure adequate oncotic levels. The same caveat applies, to a somewhat lesser degree, to the use of albumin infusions in the other disease states mentioned previously.

Currently, one of the most frequent uses of albumin infusion is as a replacement fluid in plasma-exchange procedures. These procedures are widely used for the treatment of various neurologic syndromes and as therapy for the pruritus of primary biliary cirrhosis. The use of albumin infusions as a long-term treatment for malnutrition is totally inappropriate, but it may be reasonable as a short-term therapy immediately preoperatively in seriously malnourished persons or in those with severe chronic hepatic dysfunction.

The use of albumin infusions rather than crystalloid solutions in the treatment of hypovolemic shock has been controversial for many years. The generally accepted rationale for albumin rather than crystalloid has been that the albumin enhanced fluid reabsorption for the interstitial spaces and, thus, fluids remained longer in the vascular space. In recent years, however, studies have indicated that, except in the gut and in the renal circulation,

there is not sustained reabsorption of fluid at the venous end of capillaries. There appears to be a transient reabsorption that only lasts for a few minutes (135). It was also pointed out that in many disease states, the tissue damage is associated with increased permeability of the capillary walls. This allows direct drainage of fluids out into the interstitial spaces (135). The leakage of the albumin diminishes its capacity for exerting the oncotic pressure one expects if the capillary walls are intact. Indeed, a recent review of randomized controlled trials of the use of albumin in the resuscitation of critically ill patients suggests that the use of albumin is associated with a death rate 6% higher than that found in patients treated without albumin (136).

Cryoprecipitated Antihemophilic Factor

Pool first described a method of concentrating coagulation factor VIII by freezing freshly obtained donor plasma and then slowly thawing the plasma at 1° to 6°C. This precipitates the cold-insoluble proteins that contain approximately 50% of the original factor VIII. This precipitate can then be separated aseptically from the remainder of the plasma, refrozen within 1 hour at -18°C (or preferably at -30°C), and stored for as long as 1 year. This product revolutionized the therapy of classic hemophilia A.

The original source plasma from which FFP is made must be frozen within 6 hours after collection from the donor, and the cryoprecipitate must not be thawed at any time during storage except for immediate infusion. These restrictions apply because of the extreme sensitivity of factor VIII to heat. Federal regulations require that an average bag of cryoprecipitate contain 80 IU of factor VIII, and American Association of Blood Banks standards require that at least 75% of the bags contain this amount of coagulation factor VIII. A cryoprecipitate bag from a single whole-blood donation may contain 80 to 120 IU of factor VIII, 40% to 70% of VWF and 20% to 30% of factor XIII in the original unit of plasma, 150 to 250 mg of fibrinogen, and approximately 55 mg of fibronectin (α_2-opsonic globulin) in a volume of less than 15 mL. Cryoprecipitate bags are often pooled after final thawing at 37°C, just before infusion, to give an adequate dose of factor VIII.

In patients with classic hemophilia, serious bleeding episodes generally are associated with factor VIII levels below 3% of normal. In these patients, the minimal hemostatic level of factor VIII is approximately 30%; if levels of approximately 50% are attained and maintained for approximately 2 weeks, major surgery can be carried out safely. It is not necessary to achieve levels of 100%, and to attempt to do so would expose patients needlessly to a great many more donors. There are several empiric schemata for the dosage of cryoprecipitate in classic hemophilia, but a reasonable starting dose is one bag for each 6 kg of body weight (137). After the initial therapy, repeat doses will be needed approximately every 12 hours, and the level of such doses will need to be monitored by factor VIII assays.

The use of cryoprecipitate is hampered by the fact that it must be maintained at -18° to -30°C, and its pooling and infusion generally requires direct professional involvement. These factors limit its applicability to home therapy programs, an approach that has freed thousands of hemophiliacs from dependence on medical supervision. Unfortunately, these programs depended heavily on the use of pooled factor concentrates, which became contaminated by HIV and hepatitis viruses several years ago. This led to the disastrous prevalence of HIV positivity in hemophiliacs. Because of this, some hematologists are once again relying on cryoprecipitate for the treatment of young hemophiliacs who have not yet been exposed to HIV in factor concentrates. Monoclonally produced factor concentrates and those that are heat treated are now essentially free of infectious HIV or hepatitis viruses. The availability of factor VIII produced from cloned DNA eventually will eliminate the risk of virus transmission altogether, but it will greatly increase the cost of therapy for hemophilic patients.

There have been numerous modifications made to the standard method of making cryoprecipitate, and readers are referred to the reports in the literature (138,139 and 140).

Fibrin Glue (Cryoprecipitated Fibrinogen)

Because of its high content of fibrinogen, cryoprecipitate has been employed as a source of fibrin for topical use in some types of trauma or surgical situations. For this purpose, one can use a standard bag of cryoprecipitate to which thrombin is added in the operating room to form a coagulum. This has been utilized particularly for oozing on raw surfaces such as a lacerated liver or in areas where adhesions had to be dissected and no discrete, identifiable small vessels could be easily ligated. Cardiac surgeons have found this latter application to be of particular use when repeat thoracotomy must be performed (141). If sufficient time is given, the blood bank can make autologous fibrin glue and eliminate viral transmission risks (142).

Artificial Blood Substitutes

When this term is used, it generally refers to artificial substitutes for red blood cells. Because of the problems encountered with the use of red blood cell transfusions, such as disease transmission, red blood cell alloimmunization, and blood shortages, numerous attempts have been made to develop a substitute for red blood cells to deliver oxygen to tissues. The most promising of these lines of research have involved the use of (a) solubilized hemoglobin, (b) perfluorocarbon solutions, and (c) encapsulated hemoglobins. Each of these approaches has had problems that have prevented its introduction on a broad scale. Hemoglobin that has been rendered free of stroma will carry oxygen; however, its normal tetramer composition is quickly modified to a dimer. These dimers are rapidly excreted in the urine. The hemoglobin in a red blood cell is associated with 2,3-DPG, which interacts with it to allow oxygen dissociation to the tissues. Free hemoglobin has a very high affinity for oxygen and does not release it readily. The oncotic pressure of free hemoglobin is double the normal plasma oncotic pressure. Therefore, the maximal allowable hemoglobin concentration in the circulation is approximately 7 g/dL. Even stroma-free hemoglobin has some nephrotoxicity. The major activities in the development of hemoglobin have centered on attempts to cross-link the hemoglobin and on efforts toward microencapsulation (143).

Fluosol-DA is an emulsion of two perfluorocarbons, perfluorodecalin

and perfluorotripropylamine, in a balanced salt solution with hydroxyethyl starch (143). This product, which must be frozen before use, has an intravascular half-life of approximately 7 hours and transports gases in proportion to the partial pressure of the gas with which it is in equilibrium (Henry's law). If it is used to substitute for red blood cells, the patient must be inhaling a very high concentration of oxygen. The solubility of oxygen at 37°C and a partial pressure of 760 mm Hg is approximately 45 mL/100 mL of perfluorocarbon. Red blood cells have a similar oxygen content at approximately 100 mm Hg. As a result, they work while the patients breathe room air (144). Several toxic reactions resulting from the use of perfluorocarbons have occurred, and this has led to withdrawal of their approval by the FDA. These reactions were variable, but several involved pulmonary problems apparently secondary to complement activation (145).

Encapsulating hemoglobin in liposomes is an alternative method of preparing red blood cell substitutes (146). These liposomes with hemoglobin have a half-life of only 5 hours and tend to be retained in the liver. However, they do seem to function adequately to deliver oxygen, and they have an oxygen dissociation curve similar to that of whole blood. Much work remains to be done before we can transfuse patients with an oxygen-carrying substitute that is nearly as efficient, as desirable, and as effective as the red blood cell.

Transfusion Therapy

Gary Stack

Steven Mechanic

Transfusion therapy is the most commonly practiced form of tissue transplantation. It is an essential component of the overall management of a wide range of medical disorders. Transfusion is most often an adjunct to the major treatment modality, as in the perioperative setting or in patients undergoing bone marrow ablation as a consequence of cancer treatment. Without transfusion therapy, many surgical procedures and cancer treatment regimens would not be possible or would have intolerable risk. In other situations, transfusion therapy is itself the definitive treatment modality, as in thrombotic thrombocytopenic purpura (TTP). This chapter summarizes the role of transfusion therapy in various clinical settings. In some clinical settings, pharmacologic alternatives to transfusion are mentioned.

Transfusion therapy generally follows a semiquantitative dosing schedule. Dosages often have not firmly been established, and the composition of blood components often is not well defined or tightly controlled, at least not to an extent that meets today's pharmacologic practices. Nonetheless, where possible and applicable, this chapter presents dosing recommendations for transfusion. However, in most cases, transfusion therapy continues to demand attentive clinical judgment based on the unique clinical situation of each patient.

This chapter also covers the major issues involved in the administration of blood components to transfusion recipients both in hospital and out-of-hospital settings. Rigorous systems must be in place to assure the proper identification and matching of the transfusion recipient and the blood component selected for that patient. This is vital because transfusion therapy presents hazards of immunologic incompatibility and because it is a common and high-volume activity that presents ample opportunity for error. Proper attention also must be paid to the infusion procedure itself to minimize the adverse effects of transfusion. Component modifications, such as gamma irradiation, leukoreduction filtration, and cytomegalovirus (CMV) risk reduction, should be carried out to reduce some risks of transfusion for some recipients. However, attention should be given to avoiding their inappropriate and costly overuse. When carried out properly and for the appropriate indications, transfusion therapy is a highly effective and generally well-tolerated treatment of anemia, acute blood loss, and a wide variety of other blood-related disorders.

GENERAL INDICATIONS FOR TRANSFUSION OF BLOOD COMPONENTS

Part of "72 - Transfusion Therapy"

Red Blood Cells

The transfusion of red blood cells (RBCs) is indicated in situations in which the loss of the oxygen-carrying capacity of the blood seriously threatens the well-being of the patient and there is inadequate time or possibility for increasing the RBC mass through erythropoiesis. Clinically apparent signs and symptoms of anemia useful in evaluating inadequate oxygen delivery include tachycardia, dyspnea, tachypnea, pallor, weakness, fatigue, light-headedness, syncope, and angina. The most serious health risks of reduced oxygen delivery include organ failure, such as myocardial infarction and stroke.

Guidelines for RBC transfusion are largely consensus driven, although to some extent evidence based. In general, RBC transfusion is considered appropriate for any patient with a hemoglobin level less than 7 g/dL (1). The transfusion trigger may even be set lower, i.e., approximately 6 g/dL, in patients who can better tolerate lower oxygen delivery, such as younger or healthier individuals and those who have adapted to a chronic anemia (2,3). Support for this lower threshold comes from data indicating that an acute decrease in hemoglobin concentration to 5 g/dL in otherwise healthy individuals at rest does not decrease oxygen consumption or increase blood lactate levels (4). For hemoglobin levels between 6 to 7 and 10 g/dL, RBC transfusion is indicated for patients who are symptomatic from their anemia and/or whose medical conditions predispose them to poor tissue perfusion, such as patients with cardiac or other circulatory disorders (1,2 and 3). For patients who are anemic due to vitamin B_{12} or folate deficiency, the first priority is pharmacologic replacement therapy; RBC transfusion is generally not indicated because of the patient's adaptation to the slowly developing anemia. RBC transfusion appears unnecessary for most patients with hemoglobin levels greater than 10 g/dL (1,2,3,4 and 5).

Some transfusion specialists caution that rigid adherence to guidelines can lead to the undertransfusion of some patients. Some evidence exists that higher hematocrits in the range of 30% to 35% give improved oxygen delivery and enhanced hemostasis that may be advantageous for patients who are at high risk for myocardial infarction or perioperative, nonsurgical bleeding (6,7). Transfusion thresholds higher than a 30% hematocrit for adults remain controversial. Neonates in respiratory

distress also may require hematocrits greater than 30% to 35% (3). Outcome studies are needed to resolve the debates over transfusion triggers. Because many variables modify the necessity and urgency of RBC transfusion, including the degree, duration, and etiology of the anemia, as well as the patient's medical condition, the decision to transfuse remains to a large extent a matter of clinical judgment.

Because one unit of RBCs will raise the hemoglobin by approximately 1.0 g/dL and the hematocrit by approximately 3% in a 70-kg adult, the dose of RBC units can be approximated by dividing the desired increase in % hematocrit by 3. For adults and children, the dose may also be calculated as follows:

$$\text{Volume of RBCs (mL)} = \text{EBV (mL)} \times \frac{\text{Desired Hct} - \text{Actual Hct}}{\text{Hct of RBCs}}$$

The blood volume and cardiac status of the recipient should be taken into account in determining the RBC dose and the transfusion rate. Patients with congestive heart failure or those who are otherwise at risk of a hypervolemic reaction may not tolerate the added volume of RBCs transfused. For these patients, transfusion must proceed slowly, and diuretic use should be considered. In some cases, it may be desirable for the transfusion service to split a unit in half so that each half may be transfused over the maximum allowable time period of 4 hours.

Platelets

Patients with platelet counts less than 5,000 to 10,000/μL are at significant risk of spontaneous hemorrhage (8). Fortunately, for patients with intact vasculature, most thrombocytopenic bleeding is not immediately life threatening and is ostensibly limited to skin manifestations, such as purpura, petechiae and hematomas, and minor mucocutaneous blood loss. Nevertheless, because of the risk of intracerebral hemorrhage, it is common practice for prophylactic platelet transfusion to be administered to patients with platelet counts less than 10,000/μL to provide a hemostatic margin of safety (2,9,10 and 11). Increasingly, evidence is accumulating to support the use of a platelet count of 10,000/μL as a safe threshold for prophylactic platelet transfusion in stable, thrombocytopenic patients (12,13,14,15,16 and 17). Some transfusion specialists advocate a higher threshold of 20,000/μL for patients with complications, such as fever, sepsis, coagulopathy, or falling platelet count (16,18).

For surgical procedures and significant bleeding, platelets are typically transfused to maintain a blood platelet count greater than 50,000/μL (2,9,11). Similarly, platelet transfusions sufficient to produce a platelet count increment of approximately 50,000/μL are indicated for patients undergoing surgical procedures or who have a significant hemorrhage if there exists thrombocytopathy related to medication or disease. Fortunately, should microvascular bleeding related to thrombocytopenia or thrombocytopathy develop in the operating room, it is usually readily apparent and readily treatable with platelet transfusion. Transfusion may be indicated even for patients with platelet counts of 50,000 to 100,000/μL in a setting of massive hemorrhage and extensive vascular injury, particularly when hemorrhage is ongoing and platelet counts are rapidly falling (9,11). The decision to transfuse in that clinical setting depends on clinical judgment related to the risk of continued blood loss.

A traditional dose of platelet concentrate is one unit per 10 kg of patient body weight or four units of platelet concentrate per square meter of the patient's body surface area. For infants and children, the dose also may be calculated as 10 mL/kg body mass. However, this represents an inexact approach because the platelet dose will depend on the platelet content per unit, which is variable. Assuming splenic sequestration of 33% in a 70-kg adult and an average platelet count per unit of 8×10^{10}, the transfusion of one unit should produce a theoretical platelet count increment of 10,000/μL. In fact, the rule of thumb is to expect an increment of 5,000 to 10,000/μL per unit of platelet concentrate transfused. For infants and children, a dose of 10 mL/kg should increase the platelet count by approximately 50,000/μL. In reality, the increment varies with numerous factors, including (a) the number of platelets infused, (b) the patient's clinical condition, including the rate of platelet consumption or destruction, (c) the storage time of the platelets, and (d) the immunologic compatibility of the donor platelets with the recipient.

In recent years, improvements in platelet preparation techniques have led to higher platelet counts per platelet concentrate. Because of this, quality control data regarding platelet counts per unit should be used in arriving at an appropriate pool size of platelet concentrates to transfuse. Whereas a decade or more ago, pool sizes were typically eight to10 units, today many centers have reduced pool sizes to four to six units. In contrast to platelet concentrates, platelets obtained by apheresis do not need to be pooled from multiple donors to achieve an effective dose. The number of platelets obtained in the collection of apheresis platelets from a single donor is typically equivalent to that in a pool of four to six units of platelet concentrate. The U.S. Food and Drug Administration (FDA) has set minimum standards for platelet content per unit of platelet concentrate (0.55×10^{11}) and apheresis platelet (3.0×10^{11}). Most blood collection centers exceed those minimum standards. Total platelet dosages per transfusion vary to some extent with local practice but generally fall in the range of 3 to 5×10^{11} for adults. The target platelet increment varies with the patient's pretransfusion platelet count and clinical situation. A target increment of 40,000/μL is practical for many clinical settings (19). In chronically thrombocytopenic patients, the therapeutic goal is to keep the platelet count above a trough level of 10,000 to 20,000/μL between transfusions to prevent spontaneous hemorrhage. Some evidence indicates that transfusing platelets to maintain an even higher trough level of platelets in chronically thrombocytopenic patients would actually require fewer transfused platelets overall owing to the lower clearance rate of platelets at higher concentrations (20,21). The relative advantages of fewer transfusions of higher platelet dose versus more frequent transfusions of lower dose is the subject of ongoing debate (21,22).

A useful formula for the evaluation of the response to platelet transfusion is the corrected count increment (CCI): CCI = [(Posttransfusion platelet count/μL - Pretransfusion platelet count/μL) × (Body surface area in m^2)] ÷ [Number of platelets transfused × 10^{-11}]. Because the CCI corrects for differences in

intravascular volume, which is proportional to the body surface area, and for the actual number of platelets transfused, it provides a better basis for comparison of transfusion responses than platelet count increments alone. Most platelet transfusion recipients should have CCIs greater than 7,500. A patient with CCIs repeatedly less than 5,000 is considered refractory to platelets (23). Patients without obvious risk factors for platelet refractoriness, such as HLA antibodies, platelet-specific antibodies, sepsis, disseminated intravascular coagulation (DIC), hemorrhage, immune thrombocytopenic purpura (ITP), splenomegaly, or some medications (e.g., amphotericin B), have an average CCI of 14,000 to 15,000 (24,25 and 26).

Plasma

The transfusion of fresh frozen plasma (FFP) is indicated for bleeding or prophylaxis of bleeding in the setting of a documented coagulopathy (2,10,27). FFP should not be transfused solely as a volume expander. FFP contains approximately the same levels of all coagulation factors that are present *in vivo*. By definition, 1 mL of plasma from a normal individual contains one unit of coagulation factor activity. Thus, a unit of FFP with an approximate volume of 200 mL contains approximately 200 units of each coagulation factor, as well as approximately 300 to 700 mg/dL of fibrinogen. FFP is indicated for the replacement of multiple coagulation factor deficiencies and for congenital deficiencies of some specific factors for which concentrates are not yet available or licensed, e.g., factors II, V, VII, X, XI, and XIII. It should be noted that cryoprecipitate is not a concentrated form of FFP but rather a concentrated form of a few factors only (see below). Because of this, FFP, not cryoprecipitate alone, should be used for multiple factor deficiencies.

FFP is not the treatment of choice for hemophilia A (factor VIII deficiency), hemophilia B (factor IX deficiency), von Willebrand's disease (vWD), or antithrombin deficiency. The preferred treatments are commercial concentrates, which are viral attenuated as a result of solvent/detergent (SD) treatment, heating, or monoclonal antibody purification or because they are produced using recombinant DNA techniques. Moreover, purified or partially purified concentrates deliver the required dose in a smaller volume, thereby avoiding risks of volume overload in some recipients.

A newer plasma preparation, SD-treated plasma (SD-plasma) is available, which is a pooled product that is treated with the solvent tri(n-butyl)phosphate and the detergent Triton X-100 to inactivate lipid-enveloped viruses (28,29). Although no viral inactivation technique can guarantee complete safety, SD-plasma has a greatly reduced risk of transmission of hepatitis B virus (HBV), hepatitis C virus (HCV), human immunodeficiency virus (HIV), and presumably other lipid-encapsulated viruses (28,29). It also is a uniform product with a standard 200-mL volume, as opposed to the more variable volume and content of FFP. However, SD-plasma compared with FFP increases donor exposures because it is derived from pooled plasma from as many as 2,500 donors. Moreover, the SD treatment used for SD-plasma is not effective against nonenveloped viruses, such as hepatitis A and Parvovirus B 19. Concern exists over the theoretical emergence of a new pathogenic, nonenveloped viruses whose risk of transmission would be increased by SD-plasma because it is a pooled product from many donors. For these reasons, as well as added cost and an exclusive distribution network, SD-plasma has not received immediate, universal acceptance in the United States. SD-plasma does contain significant levels of antibodies to hepatitis A virus (HAV) and Parvovirus B 19, which potentially have neutralizing activity for those particular viruses. In addition, the screening of plasma for HIV and Parvovirus B 19 by nucleic acid testing before SD treatment and the discarding of positive units may address specific concerns regarding these two viruses. SD-plasma has proven effective for most plasma indications (29). Although most coagulation proteins are present in SD-plasma at approximately the same levels as in FFP, some losses do occur. In particular, protein C, protein S, and antiplasmin are moderately reduced, and the high molecular weight multimers of von Willebrand factor (vWF), which have the highest vWF activity, are substantially diminished (28,29). The impact of these reductions is not expected to be significant for most plasma indications, although their impact on the effectiveness of SD-plasma in DIC has not been established.

Another more recently developed product is donor-retested (or delayed-release) FFP (DR-FFP) (29). DR-FFP is FFP that is not released until the donor tests negative for transfusion-transmitted infections both at the time of the initial donation and then again in repeat testing 16 weeks after the donation (29). The repeat testing eliminates most of the window period before the development of detectable antibodies directed against the viruses that are screened for during donor testing. As a result, DR-FFP is safer in theory than standard FFP.

Another plasma alternative to FFP is cryoprecipitate-reduced plasma. This is the plasma/supernatant portion that remains after cryoprecipitate is removed from FFP. It has reduced levels of the cryoprecipitable coagulation proteins (see section on cryoprecipitate). Because of reduced levels of high molecular weight multimers of vWF, it has been used to treat patients with thrombic thrombocytopenic purpura (TTP), especially those refractory to FFP (30,31). Table 72.1 summarizes the properties of various plasma preparations.

TABLE 72.1. PLASMA PREPARATIONS USED IN TRANSFUSION THERAPY[a]

Name	Content	Preparation	Use	Comments
FFP	All plasma proteins present	Frozen within 8 hr of collection	General	Single-donor product; multiple units usually transfused; some variability in volume and coagulation factor content
Solvent/detergent-treated plasma	Reduced content of largest vWF multimers, protein C, S and antiplasmin	Plasma treated with tri-*n*-butyl phosphate and Triton X-100 to inactivate liquid-enveloped viruses	General	Pooled product from as many as 2,500 donors, nonlipid enveloped viruses not inactivated; uniform 200 ml volume
Donor retested FFP (delayed-release FFP)	All plasma proteins present	FFP from donors who have been retested ≥112 d after donation and found negative for infectious disease markers	General	Not widely available; decreased risk only for infectious agents tested
Cryoprecipitate-reduced plasma	Reduced content of vWF, fibrinogen, factors VIII and XIII	Plasma remaining after removal of cryoprecipitate from FFP	TTP	Reduced large vWF multimers

[a]Other products, such as plasma, liquid plasma, recovered plasma, and source plasma are generally not used directly in transfusion therapy.
FFP, fresh frozen plasma; vWF, von Willebrand factor; TTP, thrombotic thrombocytopenic purpura.

The level of many coagulation factors required for hemostasis is approximately 20% to 30% of normal (32,33 and 34). For adult patients with a prolonged prothrombin time (PT) or activated partial thromboplastin time (aPTT) (1.5- to 1.8-fold increase relative to control) who demonstrate abnormal bleeding that is not immediately life threatening, two units of FFP (6 to 7 mL/kg) are a typical starting dose. Further therapy is based on the results of repeat coagulation testing. For significant hemorrhage or immediately life-threatening bleeding in adult patients with a prolonged PT or aPTT, transfusion of four or five units of FFP (12 to 15 mL/kg) may be indicated, followed by repeat coagulation testing. Four to five units of FFP provide approximately 800 to 1,000 mL of plasma, which is equivalent to approximately 30% of the plasma volume of a 70-kg recipient and, therefore, approximately 30% of normal levels of coagulation factors. Intravascular factor recovery will not be 100% for all factors, but because starting levels may be greater than zero, four or five units are a reasonable dose in adults to urgently obtain a minimum necessary hemostatic level of all factors. Dosages should be adjusted based on kilograms of body mass for pediatric patients or adults who are significantly larger or smaller than 70 kg. Because

multiple-unit plasma transfusions carry a risk of fluid overload, physicians must assess before transfusion whether the patient can tolerate the added intravascular fluid volume.

Cryoprecipitate

Cryoprecipitate, formally named cryoprecipitated antihemophilic factor, contains fibrinogen, vWF, factors XIII and VIII, and fibronectin along with some other cryoprecipitable plasma proteins. Cryoprecipitate is not a concentrated form of FFP because it does not contain clinically significant amounts of the other coagulation factors. Cryoprecipitate originally was predominantly intended as a source of factor VIII for the treatment of hemophilia A. However, commercial factor VIII concentrates, including recombinant factor VIII, which have a reduced or zero risk of hepatitis and HIV transmission, have been developed. Therefore, cryoprecipitate transfusion is no longer indicated for factor VIII replacement. A virus-attenuated factor VIII/vWF concentrate also is now FDA licensed and replaces cryoprecipitate as the preferred source of vWF. Cryoprecipitate is more important as a source of fibrinogen. A fibrinogen level greater than 50 mg/dL is necessary for efficient hemostasis (34). Fibrinogen repletion is generally recommended when fibrinogen levels are less than approximately 80 to 100 mg/dL in the setting of hemorrhage or in preparation for surgery (2,10). Similarly, for patients with dysfibrinogenemia, infusion of cryoprecipitate sufficient to give an increase in fibrinogen level of 80 to 100 mg/dL is indicated for the control of hemorrhage or in anticipation of an invasive procedure.

The content of fibrinogen in one unit of cryoprecipitate ranges from 100 to 350 mg and is often in the range of 200 to 250 mg. It is important to check with your blood supplier for quality control data regarding the fibrinogen content of cryoprecipitate because it is useful in dosage calculations. In a 70-kg adult with a 3-L blood volume, one unit of cryoprecipitate will theoretically raise the fibrinogen level by approximately 6 to 7 mg/dL, assuming 100% recovery of transfused fibrinogen in the intravascular space and an average content of 200 mg fibrinogen/unit. An estimate of the number of units of cryoprecipitate to transfuse can be calculated by dividing the desired increment in fibrinogen (in mg/dL) by 6. The dosage calculation can also be approximated using the following formula, assuming a desired level of 100 mg/dL of fibrinogen *in vivo* and a 200-mg average content of fibrinogen/unit:

$$\#\ \text{units} = \frac{(\text{plasma volume in dL})\ (100 - \text{X in mg/dL})}{200\ \text{mg}}$$

where X is the recipient pretransfusion fibrinogen level.

This is an inexact calculation because intravascular recovery may not be 100% and because consumption in many clinical settings may be ongoing. Other dosing approaches include transfusing one unit per 10 kg of body mass, which increases fibrinogen concentration by approximately 50 mg/dL, or to empirically transfuse a pool of 10 units. No matter which dosing approach is used, the patient's fibrinogen levels should be remeasured soon after transfusion to ensure that an appropriate level has been obtained.

Cryoprecipitate also is used in the preparation of fibrin glue or sealant, which is applied topically in surgical procedures rather than being infused intravenously (35,36 and 37). To make the fibrin glue, bovine thrombin is added along with calcium to cryoprecipitate. The thrombin converts fibrinogen to fibrin, which forms the glue. Topical fibrin glue has found multiple uses in various surgical procedures because it forms a flexible seal over suture lines. Autologous cryoprecipitate can be used to make fibrin sealant to address concerns about infectious risks. A commercial fibrin sealant that is treated to reduce the risk of viral transmission is available.

Granulocytes

Patients with severe neutropenia or neutrophil dysfunction are at risk of fatal bacterial, yeast, and fungal infections. Severe neutropenia

is seen in patients undergoing myeloablative therapy during various cancer treatments. Neutrophil dysfunction is seen in patients with chronic granulomatous disease. Neonates may have both severe neutropenia and relative neutrophil dysfunction. Transfusions of granulocyte concentrates have been employed to treat such patients when they have severe infections that are refractory to antibiotic or other therapy (38,39). Unfortunately, granulocyte transfusions administered to treat infections often have met with mixed success at best. For that reason granulocyte transfusions are uncommon at the present time. Therapeutic failures are generally attributed to inadequate doses of granulocytes in the transfused products. The availability of recombinant preparations of cytokines that stimulate endogenous granulocyte production, such as granulocyte-colony stimulating factor (G-CSF), has provided a pharmacologic means to shortening periods of neutropenia in some patients. This has reduced the need for granulocyte transfusions.

Granulocyte concentrates are typically obtained by apheresis from single donors, but can be prepared from buffy coats of single units of whole blood. The granulocytes are labile during storage and should be transfused as soon as possible and no later than 24 hours after collection. Regulatory standards require at least 1×10^{10} granulocytes per apheresis unit of granulocyte concentrate in at least 75% of units tested (40). Although the required minimum dose for therapeutic efficacy has not clearly been determined, transfusions of fewer than 1×10^{10} granulocytes are unlikely to be of benefit in adults. Adults typically receive one unit of granulocyte concentrate per day and neonates approximately 0.5 to 1.0×10^{9} granulocytes per kilogram per day (40).

At present, prophylactic granulocyte transfusions are not indicated because of their unlikely or uncertain efficacy. Granulocyte transfusions should be limited to the treatment of patients who are severely neutropenic (often defined as fewer than 3,000 neutrophils/μL in neonates less than 2 weeks old and fewer than 500 neutrophils/μL for other age groups) or who suffer chronic granulomatous disease and who have severe infections that are unresponsive to antibiotic therapy (38,39). Because one transfusion is unlikely to be adequate, a commitment to a minimum course of 4 to 7 days of daily granulocyte transfusions is recommended. Granulocyte transfusions generally should be continued until the marrow recovers (greater than 500 neutrophils/μL in the peripheral blood for adults) or the infection resolves.

Recent attempts to stimulate donor granulocyte levels by pretreating donors with G-CSF plus corticosteroids have resulted in significantly higher yields of granulocytes per collection (41,42). Because G-CSF does have some side effects, however, it is unclear at this time whether its use in this setting in healthy, volunteer donors will become widely accepted. Although this collection technique appears promising, experience is too limited at this time to know whether transfusion of greater numbers of granulocytes obtained with this new preparative regimen will improve the therapeutic usefulness of granulocytes.

Whole Blood

Whole blood is now almost exclusively used in the setting of autologous transfusion. Whole-blood transfusion is not an effective means of supplying patients with blood elements other than RBCs. The blood bank storage conditions of whole blood are not optimal for the preservation of platelets and coagulation factors. Platelets and factors V and VIII are particularly labile (43). Therefore, the production, storage, and transfusion of whole blood is generally neither an efficient nor a cost-effective approach to transfusion therapy. For patients requiring the transfusion of RBCs only, units of whole blood in some cases may even be undesirable because of their larger volume than RBC units, i.e. approximately 450 mL for whole blood compared with approximately 320 mL for additive-solution RBCs.

Fresh whole blood within several hours of collection still contains viable platelets and normal levels of all coagulation factors. If fresh whole blood were readily available, it would be the component of choice for a small number of patients who require the simultaneous transfusion of RBCs, platelets, and plasma, such as some patients undergoing massive transfusion. The use of fresh whole blood in that situation would limit the number of donor exposures for the transfusion recipient, which could decrease the risk of immunologic or infectious complications of transfusion. However, fresh whole blood from allogeneic donors is an impractical concept today due to the necessity for infectious disease testing of donor blood before transfusion. Moreover, the limited number of patients who would benefit from fresh whole blood is too unreliable a population on which to plan a blood inventory.

Conversely, autologous blood, particularly when collected by a hospital transfusion service, as opposed to a blood center, is often not fractionated into other components. Many transfusion services are not equipped for blood component production. Moreover, because most patients donating autologous blood have no predicted need for blood components other than RBCs, the time and expense of a fractionation effort are not justified. Autologous blood collected immediately preoperatively in the operating room during acute normovolemic hemodilution is fresh whole blood. As such, it contains functional platelets and coagulation factors if it is transfused operatively or immediately postoperatively. Various types of autologous blood collection are described in more detail below (section on autologous transfusion).

TRANSFUSION IN SPECIFIC CLINICAL SETTINGS

Part of "72 - Transfusion Therapy"

Hemorrhage, Surgical Blood Loss, and Anemia

Acute Blood Loss

The American College of Surgeons has classified acute blood loss based on the volume of blood lost and the corresponding clinical manifestations (44). The classification is shown in Table 72.2, along with recommendations for replacement fluids for these varying degrees of blood loss. A loss of as much as 15% of blood volume is classified as a class I hemorrhage. In an otherwise healthy individual, this relatively low volume of blood loss results in minimal symptoms, e.g., perhaps mild tachycardia, and should not require replacement therapy (45,46). The acute blood loss of 15% to 30% of blood volume is a class II hemorrhage,

which produces tachycardia, decreased pulse pressure, anxiety, and restlessness. When a class II hemorrhage reaches a blood loss of 20% to 30%, the patient's extracellular space should be maintained with the infusion of crystalloid solutions. In hemorrhage that results in 30% to 40% blood loss (class III hemorrhage), the patient shows signs of shock, including tachycardia, tachypnea, systolic hypotension, and altered mental status. Otherwise healthy, nonanemic patients still may receive crystalloid alone for class III hemorrhage. However, previously anemic, elderly patients, or patients at increased risk for organ ischemia may require RBC replacement for this or smaller blood losses depending on the degree of preexisting anemia or susceptibility to ischemia. Loss of more than 40% of blood volume (class IV hemorrhage) is life threatening and is characterized by severe shock. The blood volume should be restored rapidly with the infusion of crystalloid solution. Moreover, the restoration of the oxygen-carrying capacity of the blood with RBC transfusion in class IV hemorrhage may be indicated even in otherwise healthy individuals.

TABLE 72.2. CLASSES OF HEMORRHAGE

Class	% Blood Loss	Approx. Blood Lost (mL)	Approx. RBC Unit Equivalents	Replacement Fluid
I	<15	<750	<1.5	None
II	15–30	750–1,500	1.5–3.0	Crystalloid first; RBCs rarely needed if hematocrit previously normal
III	30–40	1,500–2,000	3.0–4.0	Crystalloid first; then possibly RBCs
IV	>40	>2,000	>4.0	Crystalloid; then RBCs

RBCs, red blood cells.

Crystalloid solutions, such as lactated Ringer's solution, as opposed to colloid solutions or RBCs, are the preferred initial choice for volume expansion (44). Oxygen transport is a function of both the hemoglobin content of blood and blood flow, which is volume dependent. In patients with normal hematocrits before the acute blood loss, the loss of blood volume, rather than red cell mass, is usually the most critical concern. Accordingly, volume loss may require immediate correction. For example, in patients with normal hematocrits, a loss of 50% of their RBC mass may decrease the hematocrit to 20% to 25%. This is sufficient to provide adequate oxygen transport for an otherwise healthy adult as long as the blood volume is sufficient for tissue perfusion. However, the loss of 50% of the blood volume leads to shock and death in most patients. Thus, volume replacement, not restoration of the RBC mass, is usually the first priority in acute blood loss. In fact, the transfusion of RBCs during the initial treatment of acute blood loss may even be undesirable owing to their increased viscosity compared with crystalloid solutions. The lower viscosity solutions may more rapidly restore perfusion in smaller blood vessels and in the extracellular space.

When urgent RBC transfusion is indicated for large-volume acute blood loss, ABO- and Rh-identical or -compatible RBCs, and preferably cross match–compatible, RBCs should be used if at all possible. Accordingly, it is important for the patient care team to send a blood specimen from an acute trauma patient to the laboratory immediately so that as much time as possible is available to find compatible blood. The initial correction of the patient's blood volume loss with crystalloid solutions should in most cases sufficiently stabilize the patient hemodynamically to allow the laboratory time to ABO and Rh type the patient. This requires approximately 10 minutes after receipt of the specimen. If the clinical situation permits a 30- to 45-minute delay in transfusion, an antibody screen and a major cross match with the donor unit(s) can and should be performed (40,47). An objective clinical assessment by the patient care team followed by clear communication with the laboratory is required to optimize pretransfusion testing in the setting of acute blood loss. The use of ABO- and Rh-identical units permits better use of RBC inventories. In addition, antibody screening and cross matching lessens the possibility, already small for most patients, that the transfused RBCs will produce a hemolytic transfusion reaction. With the use of ABO-compatible uncross matched units, the primary concern is the possibility that the recipient may have a non-ABO alloantibody. An estimated 0.04% of individuals will have a non-ABO alloantibody if they have not been previously transfused or pregnant. Approximately 0.3% of previously transfused, multiparous women and approximately 5% to 30% of chronically transfused patients, such as those with sickle cell anemia or thalassemia, have non-ABO RBC alloantibodies (48,49 and 50). However, even if the recipient has a non-ABO alloantibody and receives RBCs incompatible with that antibody, it is unlikely that a life-threatening intravascular hemolytic transfusion reaction will occur. Most, although not all, clinically significant non-ABO RBC alloantibodies are IgG molecules that do not fix complement to C9. Thus, they usually produce extravascular, not intravascular, hemolysis. Should a recipient of an emergency transfusion of noncross matched RBCs be found in subsequent testing to possess a RBC alloantibody, antigen testing should be performed retrospectively on any units transfused so that a potential hemolytic reaction can be anticipated.

If the short delay in the provision of RBCs due to the need to perform ABO and Rh typing of the recipient is life threatening, then group O, preferably Rh-negative, uncross matched RBCs should be transfused. For this reason, group O, Rh-negative RBCs are available in monitored refrigerators in emergency departments and trauma centers at some medical centers. These units can be given to those patients for whom the potential risk of incompatibility is small when compared with the risk of delaying the transfusion (51,52 and 53). In general, group O, Rh-negative, uncross matched RBCs can be used for emergency RBC transfusion with little risk for most patients. The infusion of a small amount of plasma (approximately 40 mL in units of additive-solution RBCs) containing anti-A or anti-B antibodies into an ABO-incompatible recipient usually does not pose a significant risk. The recipient may develop a positive direct antiglobulin test, but usually without significant hemolysis or a clinical reaction. Nevertheless, as with ABO/Rh-identical uncross matched RBCs, there

is the small possibility that the recipient may have a non-ABO alloantibody, particularly if the patient has been previously transfused or pregnant. Despite the relative safety of an emergency transfusion of group O, Rh-negative RBCs, clear guidelines for their use should be established to avoid overusage in acute trauma settings because they are a valuable and relatively scarce resource that constitutes only approximately 6% of the available RBCs. Table 72.3 summarizes the various possibilities for abbreviating compatibility testing for emergency transfusions and the corresponding estimated time required for testing in the blood bank.

TABLE 72.3. COMPATIBILITY TESTING FOR EMERGENCY RBC TRANSFUSION

Transfusion Urgency	ABO, Rh(d) Type	Type	Antibody Screen	Cross Match	Testing[a,b] Time
Lowest	ABO, Rh(d) identical or compatible	Yes	Yes	Yes	30 min
	ABO, Rh(d) identical or compatible	Yes	No	Yes	15 min
↓	ABO, Rh(d) identical or compatible	Yes	No	No	10 min
	ABO, Rh(d) identical or compatible	Yes	Yes[c]	No	0 min
Highest	O, Rh(d)–negative	Yes	No	No	0 min

[a]Testing times assume that the cross match is done at room temperature using an immediate spin only and no previous presence of a RBC alloantibody.

[b]Testing time does not include transportation times (variable) or all administrative steps (requiring several additional minutes).

[c]ABO, Rh(d) typing and antibody screen performed earlier on current valid serum specimen (within 3 days of transfusion).

If RBCs are transfused before Rh(d) typing of the recipient, it is preferable to use Rh(d)-negative units, if available. Approximately 15% of recipients will be Rh(d) negative and will be at significant risk of having or developing anti-D. The D antigen is the most immunogenic non-ABO red cell determinant and will result in antibody formation in approximately 85% of Rh(d)-negative individuals receiving 200 mL or more of Rh(d)-positive RBCs (54). The most significant risk is to Rh(d)-negative women of childbearing potential. If they develop an anti-D, any future Rh(d)-positive children may be at risk for Rh hemolytic disease of the newborn. All females of childbearing potential should be assumed to be Rh(d) negative until they are Rh(d) typed and should be transfused with Rh(d)-negative RBCs if at all possible. If Rh(d)-negative females of childbearing age receive Rh(d)-positive RBCs because of the lack of availability of Rh(d)-negative units, they can be given Rh immune globulin (RhIG) for the prevention of Rh alloimmunization.

An intravenous formulation of RhIG has been licensed in the United States and is now the preferred prophylaxis of anti-D formation for the transfusion of one unit or more of Rh(d)-positive RBCs because many injections of the intramuscular formulation would be required in that setting. According to manufacturer's recommendations, the IV RhIG can be administered as long as no more than 20% of the patient's RBCs are Rh(d) positive. Above 20%, the effects of an extravascular hemolytic reaction may become significant. Because anti-D is a relatively common antibody, the use of Rh(d)-negative RBCs for urgent transfusion in both males and females also eliminates the risk of an anti-D-mediated delayed extravascular hemolytic reaction in already alloimmunized patients.

Massive Transfusion

Massive transfusion is the replacement of the patient's total blood volume by transfusion within a 24-hour period. A practical definition of massive transfusion in adults is the transfusion of 10 or more units of RBCs within a 24-hour period because that approximates the normal total adult RBC mass. Although infusion of a large volume of RBCs in a short time period may be lifesaving, it also poses hazards to the transfusion recipient that are not seen after the transfusion of smaller volumes. It is important for the clinical care team to be aware of the complications of massive transfusion so that measures can be taken to prevent, monitor, or treat their development. Some of the major adverse effects of massive and rapid replacement of lost blood volume include dilutional coagulopathy and thrombocytopenia, citrate toxicity, acid-base and electrolyte disturbances, and hypothermia. Another consideration is the possibility of depletion of the hospital transfusion service/blood bank's supply of ABO, Rh(d)-identical blood components for a patient undergoing massive transfusion. This may necessitate switching ABO types for RBCs and plasma.

Dilutional Coagulopathy and Thrombocytopenia

With massive hemorrhage and subsequent large-volume transfusion, platelet and coagulation factor levels may be depleted owing to their consumption and/or dilution (55,56,57,58 and 59). Consumption is due to activation of primary hemostasis and the coagulation cascade secondary to trauma or injury. Dilution is owing to replacement of blood with crystalloid or colloid solutions or units of stored RBCs, all of which are deficient in functional platelets and coagulation factors. Massive transfusion, however, does not always result in platelet or factor deficiencies sufficient to warrant platelet or FFP transfusion. Theoretical models predict that massive transfusion with replacement of one blood volume will leave behind 37% of the original blood volume (60). If starting levels of platelets and coagulation factors are normal, dilution to 37% of original levels should leave hemostatically effective levels of platelets and coagulation factors, assuming no further production or consumption. In fact, the liver may continue to produce coagulation factors, and platelets may enter the circulation from extravascular sites, thus blunting the development of dilutional coagulopathy and thrombocytopenia.

Because of the likelihood of concurrent consumption of coagulation factors or platelets owing to hemorrhage and/or the development of disseminated intravascular coagulation, the extent of platelet or coagulation factor deficiency cannot be predicted reliably from the volume of blood lost or the number of units of components transfused. Accordingly, transfusion of platelets or FFP should be based on observed clinical bleeding as well as on the laboratory measurement of platelet counts and coagulation testing. Transfusion should not be based on predetermined formulas

linked to the number of RBC units transfused (61). Replacement formulas may lead to unnecessary transfusion, particularly if less than 1.0 to 1.5 blood volumes have been replaced (62,63). In addition, component transfusion guided by replacement formulas may be insufficient if a consumptive process such as disseminated intravascular coagulation develops.

A key to appropriate replacement therapy in massive transfusion, is the timely measurement of platelets and coagulation status. Empirical platelet and FFP transfusion should be considered only if the delays inherent in testing and reporting of laboratory results could be life threatening due to continued and uncontrolled hemorrhage. Specimens should be sent to the laboratory as soon as possible and at appropriate intervals thereafter so that further transfusion therapy can be guided by objective laboratory evidence. Plasma transfusion is indicated in the getting of abnormal bleeding with PT or aPTT greater than 1.5 times the normal control (2,10,34). Cryoprecipitate transfusion for fibrinogen (and possibly vWF) supplementation is indicated for fibrinogen levels less than 80 to 100 mg/dL in the setting of hemorrhage. Platelet transfusion is indicated for ongoing hemorrhage if the platelet count is less than 80,000 to 100,000/µL. A platelet threshold of 50,000/µL may be appropriate if hemorrhage is less severe.

Citrate Toxicity

Citrate is used as the anticoagulant in preservative solutions because of its ability to chelate calcium, which is required for the coagulation cascade. Citrate usually is rapidly metabolized by the liver to generate bicarbonate and generally does not result in systemic anticoagulation of the transfusion recipient. However, when large volumes of citrate-containing plasma are rapidly infused, the body's capacity to metabolize citrate may be transiently exceeded. When this happens, ionized calcium levels may be lowered owing to chelation by the unmetabolized citrate. The threshold for exceeding the body's capacity to metabolize citrate depends on liver function. However, even patients with normal liver function who are transfused with whole blood (or presumably its blood component equivalent) at a rate of greater than or equal to 1 L/10 min may develop signs of hypocalcemia (64,65,66 and 67). The effects of hypocalcemia range from minor circumoral paresthesias and muscle tremors to more severe complications such as tetany and cardiac effects. The cardiac effects include prolonged QT intervals and depression of T waves, which could potentially lead to ventricular fibrillation and cardiac arrest. Hypomagnesemia, presumably owing to chelation of magnesium by citrate, has also been reported (68). However, clinical complications have not been well documented.

Citrate toxicity is less likely to result from RBC transfusion today than from whole-blood transfusion in the past. This is because additive-solution RBC units have substantially less plasma and thus less anticoagulant per unit compared with whole blood. Citrate toxicity remains a concern in patients with liver failure who receive rapid transfusions of large amounts of plasma-containing components such as FFP and platelets. Ionized calcium levels should be measured in these patients, and they should be treated with supplemental calcium if the levels are sufficiently low or if prolonged QT intervals or signs of tetany are seen. Early mild reactions may be treated by slowing the rate of transfusion, if permitted by the clinical situation (67). Calcium infusion itself is not without risk and has been associated with the development of ventricular arrhythmias and cardiac arrest (69). Calcium must not be added to a unit of RBCs or infused simultaneously through the same line because it will recalcify the plasma and cause clots to form.

Acid-Base and Electrolyte Disturbances

Stored blood and components have an acidic pH owing to citrate/citric acid buffering and may become more acidic owing to the accumulation of lactic acid with increasing storage time (70). However, this acid load is not likely to significantly worsen the usually already existing lactic acidosis that results from periods of tissue hypoperfusion after massive and acute blood loss. On the contrary, owing to the metabolism of transfused citrate, which results in the generation of bicarbonate, massively transfused patients may suffer a delayed metabolic alkalosis (71). Extracellular potassium levels increase in stored blood at a rate of approximately 1 mEq/day during the first 3 weeks of storage (70). The total extracellular potassium load of stored transfused RBCs may approach 20 mEq per unit. However, even massively transfused patients rarely develop more than transient hyperkalemia (72). Hypokalemia has more often been reported in massive transfusions owing to the development of a metabolic alkalosis from citrate metabolism (see above) (73). The alkalosis provokes a compensatory transmembrane shift of hydrogen ions into the intravascular space. This hydrogen ion shift is electrically balanced by an intracellular movement of potassium ions, which, if of sufficient magnitude, can result in hypokalemia.

Hypothermia

The rapid transfusion of large volumes of cold (1° to 6°C) RBCs at a rate greater than 100 mL/min may lower the patient's core temperature. A drop in sinoatrial node temperature to below 30°C has been associated with the development of ventricular fibrillation (74,75,76 and 77). To avoid this potential complication, RBCs may be administered with a high throughput blood warmer. If the infusion rate imposed by the blood warmer is too slow or if a blood warmer is not available, rapid warming of RBCs by admixture with heated saline is also possible (78,79).

Switching ABO Blood Type

The massive blood transfusion of one or more patients may deplete or threaten to deplete the hospital transfusion service/blood bank of its supply of an ABO, Rh(d) type of RBCs or plasma. In that situation, it may become necessary to switch the ABO type of transfused blood components of the massively transfused patient or other patients. The permissible switches between ABO groups are shown in Table 72.4. In some cases, it also may be necessary to transfuse Rh(d)-positive RBC or platelet units into Rh(D)-negative recipients. This is acceptable in male patients and older female patients beyond childbearing age. Conversely, Rh(d)-positive RBCs and platelets should be avoided in women of childbearing potential owing to the possibility of Rh alloimmunization, which creates a risk of hemolytic disease of the newborn in any future pregnancies. If transfusion of Rh(d)-positive RBCs or platelets is unavoidable in such women, prophylaxis

against Rh alloimmunization with Rh IG should be carried out.

TABLE 72.4. COMPATIBLE ABO TYPES

Patient Type	Donor RBC Type	Donor Plasma Type
O	O	O, A, B, AB
A	A, O	A, AB
B	B, O	B, AB
AB	AB, A, B, O	AB

RBC, red blood cell.

Chronic RBC Transfusion

The two major illnesses that result in life-long requirements for RBC transfusion are sickle cell disease and ß thalassemia major. In sickle cell disease, RBC transfusions are indicated to treat intermittent aplastic and vasoocclusive crises (80,81 and 82). Despite having chronically low hemoglobin levels, patients with sickle cell disease typically have adequate cardiorespiratory compensation at their baseline hemoglobin and hematocrit levels. RBC transfusion is required generally only when these patients experience a decrease in hematocrit from baseline sufficient to induce symptoms of anemia. The goal of transfusion for such crises is to increase the hematocrit to approximately the patient's usual baseline, making sure to maintain the hematocrit below 35% to avoid hyperviscosity. The goal also is to keep the percentage of hemoglobin S-containing cells within the range of 20% to 40% to reduce the likelihood of intravascular sickling, which causes vasoocclusion (3,80). RBC exchange transfusions may be indicated for sickle cell patients with acute chest syndrome, stroke, refractory priapism, or retinal artery occlusion. Chronic RBC transfusions have been administered to some patients who have severe, recurrent vasoocclusive crises such as recurrent cerebrovascular accidents. In ß thalassemia, the major goal of RBC transfusion is to maintain hemoglobin levels in the range of 9.5 to 11 g/dL (3,81). RBC transfusions not only prevent symptoms of anemia but also suppress endogenous hematopoiesis, which in turn prevents bone marrow hyperplasia and skeletal deformities. A chronic transfusion program of RBC transfusions at regular intervals sufficient to suppress endogenous erythropoiesis, known as hypertransfusion, is recommended for ß thalassemia major beginning at a young age.

Patients who receive chronic RBC transfusions are at risk for several adverse effects of transfusion. Owing to frequent transfusion, these patients are at increased risk of febrile, nonhemolytic transfusion reactions. For this reason, the use of leukoreduced RBC units is recommended. In addition, approximately 30% of sickle cell patients and approximately 5% to 10% of ß thalassemia major patients become alloimmunized to one or more RBC antigens (83,84 and 85). Depending on the antibody specificity, this may make finding compatible RBCs difficult. Alloimmunization can be prevented in chronically transfused patients by transfusing units of RBCs that are phenotypically matched not only for ABO and Rh(d) but also for other clinically significant RBC antigens of the recipient. Because patients will make alloantibodies only to antigens that they lack, this approach prevents alloimmunization. However, because most patients do not become multiply alloimmunized, the cost-effectiveness of this approach has been debated (86,87). Some centers follow a compromise approach of providing RBCs that match the recipient's extended RBC phenotype only after formation of the first RBC alloantibody. Even if transfused RBCs are not matched for additional antigens, extended phenotyping of the recipient's RBCs is recommended to help identify alloantibodies should the patient subsequently become multiply alloimmunized. Antibodies to the patient's own RBC antigens can be ruled out.

Patients chronically transfused with RBCs are at risk of developing iron overload or transfusion hemosiderosis. Every unit of RBCs contains approximately 200 mg of iron (approximately 1 mg of Fe^{2+}/mL RBCs). Because the body has no mechanism for excreting iron, the excess iron from chronic transfusions accumulates in organs such as the liver, heart, and endocrine glands. Organ damage can eventually lead to cirrhosis, congestive heart failure, or endocrine dysfunction (88). To decrease or delay the toxic effects of iron overload, iron chelation therapy with deferoxamine is necessary for patients receiving chronic RBC transfusion therapy (88,89). Deferoxamine mobilizes and reduces iron stores via urinary excretion, although the rate of iron removal is slow. With judicious use of RBC transfusion and iron chelation therapy, the risk of iron overload can be reduced.

Autologous Transfusion

Autologous transfusion uses the recipient's own blood or blood components for subsequent reinfusion (90,91 and 92). The goal of autologous transfusion is to eliminate the risks of allogeneic transfusion, such as transfusion-transmitted viral infections and a variety of immune-mediated adverse effects. Autologous blood can be collected preoperatively weeks in advance of surgery or just before surgery in the operating room. Autologous blood also can be salvaged from blood shed in the intraoperative or postoperative periods. The use of autologous blood, however, does not eliminate all risks of transfusion (93,94). Bacterial contamination of the collected blood, which can lead to septic transfusion reactions, can still occur. Also, the possibility of hemolytic reactions resulting from transfusing the wrong patient owing to patient misidentification is not eliminated. Autologous blood, just like allogeneic blood, also may contribute to volume overload in at-risk patients. Collecting or salvaging autologous blood adds expense to medical care compared with the use of allogeneic blood (95,96). The added cost of autologous blood is exacerbated by the waste of approximately half of all autologous units collected preoperatively (97). Moreover, as the ability of infectious-disease testing of allogeneic blood to detect donor viral infections improves through the implementation of such innovations as nucleic acid testing, the relative advantage of transfusing autologous blood decreases. Thus, the cost-to-benefit ratio of autologous blood collection deserves ongoing reappraisal.

Preoperative Autologous Blood Donation

Preoperative autologous blood donations can be stored in liquid form for as long as 35 days as whole blood or for as long as 42 days if additive-solution RBC units are prepared from the autologous blood (40). For a patient to be eligible for preoperative

autologous blood donation, sufficient time must be available before surgery to permit the collection of the desired number of units. In addition, the planned surgical procedure should have a reasonable expectation of requiring the number of units requested by the patient's surgeon (91). A schedule of expected transfusion requirements for specific surgical procedures, commonly known as a maximum or standard blood order schedule, should be prepared jointly by the transfusion service and surgery department. Such a schedule is necessary for determining the number of RBC units the transfusion service should type and screen or cross match for specific surgical procedures. The schedule should call for the availability of cross matched units of RBC if the procedure typically requires transfusion for 10% or more of cases. The number of cross matched units assigned per procedure should be adequate to meet the transfusion needs for 90% of patients who undergo that procedure. This blood order schedule also can be used as a guide for determining patients' eligibility for autologous transfusion and for determining a reasonable number of autologous units to collect. Preoperative autologous blood collection should be considered only if the planned surgical procedure calls for the availability of cross matched RBCs. A typical schedule provides for the donation of one unit per week, with the last unit being donated at least 3 days before surgery. More aggressive collection schedules can be used as long as the patient's hematocrit remains higher than 33% at the time of each donation and provided the patient's intravascular volume is sufficiently maintained (40). Unless intravascular volume replacement is given, the donations should be spaced at least 3 days apart to allow for natural volume repletion. No age limits are established for autologous donation.

The amount of blood collected, 450 mL ± 10%, should be less than 15% of the patient's blood volume. Smaller volumes can be collected from small donors. However, the amount of anticoagulant/preservative solution must be reduced proportionately if the volume collected is less than 300 mL (40). A criticism of preoperative autologous blood donation is that decreasing the patient's hematocrit preoperatively increases the need for operative or postoperative transfusion (90,98,99). Most collection schedules, in which one unit is collected per week, minimally stimulate erythropoiesis, resulting in little increase in overall RBC mass (circulating plus donated) available to the patient at the time of surgery (100,101). This is owing to two limitations: (a) not enough preoperative time to replenish the RBCs lost and (b) failure to stimulate a significant erythropoietic response. Nevertheless, the hemodilution effect may be of some benefit. Patients with lowered hematocrits at surgery will lose less RBC mass for a given volume of blood loss and will benefit from receiving back their predeposited blood, which has the higher preoperative hematocrit, at a time of greater need. This hemodilution effect will be more significant in surgical cases with high blood loss.

Supplemental erythropoietin administration to autologous donors has been shown to improve the yield of autologous collections for patients with hematocrits lower than 40% (102,103 and 104). Although this adds additional cost to autologous collection, it may be a benefit for patients who are at particular risk from allogeneic transfusion, such as patients with multiple RBC alloantibodies for whom compatible RBCs are rare. Erythropoietin also may be administered to patients during the preoperative period for the purpose of increasing the patient's circulating, as opposed to collected, RBC mass, thereby lessening the chance and need for transfusion during surgery. In addition, the stimulation of erythropoiesis preoperatively increases the ability of the bone marrow to replace operative blood loss more rapidly during the postoperative period.

Acute Normovolemic Hemodilution

Acute normovolemic hemodilution (ANH) refers to the collection of units of whole blood in the operating room immediately before surgery after anesthesia is administered. Patients receive simultaneous volume replacement using crystalloid or colloid solutions (105,106 and 107). The blood typically stays in the operating room and may be kept at room temperature for as long as 8 hours until transfused. If not transfused during this time, the blood may be stored for up to 24-hours if placed at 1° to 6°C within 8 hours of collection (40). Normovolemic hemodilution has several benefits. First, it decreases the operative loss of red cell mass because a lower hematocrit causes a smaller loss of red cell mass for a given volume of operative blood loss. Moreover, the blood collected is available for transfusion during or after surgery, when the need for the RBCs may be greater than preoperatively. Furthermore, hemodilution decreases the viscosity of blood and therefore may increase blood flow rate through the microvasculature. Because oxygen transport is a function not only of the oxygen-carrying capacity but also of blood flow, this effect may tend to compensate for the loss in hemoglobin content of blood resulting from the blood donation (108). Hemodilution can be tolerated in many patients because oxygen delivery is normally in excess of that actually required by the tissues.

Blood collected immediately preoperatively and transfused within several hours contains functional coagulation factors and platelets, which may be useful if the patient experiences hemostatic problems postoperatively. For example, this could be a benefit for patients who develop a hemorrhagic syndrome during or after cardiopulmonary bypass (CPB) owing to an acquired platelet defect. Whole blood collected preoperatively before induction of the platelet defect will provide functional platelets and possibly obviate a need for allogeneic platelet transfusion after CPB.

ANH has several advantages over preoperative autologous donation. ANH is more cost-effective because the blood does not have to be tested or stored if it is transfused in the operating room. Also, the patient does not have to make potentially inconvenient trips to a collection facility multiple times preoperatively. ANH has been criticized for yielding limited savings in RBC mass except where large blood loss occurs (109,110). The combined use of ANH with preoperative supplemental erythropoietin (111) or with the intraoperative administration of a hemoglobin-based blood substitute is being evaluated for possible improved benefit. Patients who can potentially benefit the most from ANH are those with a high initial hematocrit and a large expected blood loss who can tolerate the dilutional anemia (112).

Intra- and Postoperative Blood Salvage

Blood salvage refers to the collection of the patient's own blood shed intraoperatively or postoperatively from surgical drainage

sites (113,114,115,116 and 117). After collection, the blood can be reinfused immediately without further processing, or it can be concentrated by centrifugation and saline washed. In all cases, it must be filtered; microaggregate filters are often used. Intraoperative blood salvage is used for patients having surgical procedures with a large anticipated blood loss (greater than two to three units). Intraoperative cell salvage machines or cell washers are available and have been employed for cardiac surgery, hip and knee replacements, as well as major gynecologic, prostate and vascular surgery. These devices recover shed blood from the operative area, centrifuge it, and wash it with isotonic saline. Intraoperative blood salvage has the advantage of being available for many patients who cannot donate autologous blood preoperatively. It is also an adjunct to preoperative autologous blood donation for those patients who have not donated sufficient blood to cover their total transfusion requirements. Blood salvage should not be attempted from any operative site that is potentially contaminated with bacteria. Blood salvage also should not be performed at surgical sites involving malignancies, owing to the theoretical risk of promoting metastases by the intravascular infusion of malignant cells (118,119). The salvage of blood shed postoperatively has been applied most commonly after cardiac and orthopedic surgery. Blood collected postoperatively, except in cases of brisk hemorrhage, usually has undergone extensive coagulation factor activation and defibrination and is substantially hemodiluted (120,121). It is generally partially hemolyzed and contains proinflammatory mediators and tissue debris. Some adverse effects have been reported (121,122 and 123). For this reason, some facilities place volume restrictions on the reinfusion of unprocessed, postoperatively shed blood.

Open-Heart Surgery

Owing to improvements in surgical technique, the use of blood-sparing pharmacologic agents, and acute normovolemic hemodilution, blood component usage has decreased in open-heart surgery. Nonetheless, open-heart surgery accounts for approximately 20% of all RBC units transfused in the United States (124). Significant variability in transfusion practice in open-heart surgery between different medical institutions has been reported (125,126). The variability in transfusion practice is related to variable approaches to the prophylaxis, recognition, and treatment of excessive bleeding that some patients develop after CPB. The etiology of the hemorrhagic syndrome after CPB is probably multifactorial and may be related to platelet dysfunction, mild thrombocytopenia, excessive fibrinolysis, decreased levels of coagulation factors, reduction or alteration in vWF, inadequate heparin neutralization, heparin rebound, and/or protamine excess (127).

The risk factors for excessive bleeding include repeat or redo of coronary artery bypass graft (CABG), greater than 3 to 4 hours of cardiopulmonary resuscitation (CPR) pump/oxygenator time, and cardiac valve replacement surgery (as opposed to CABG) (127). The preoperative bleeding time of patients, many of whom have recently been on aspirin, has not proven to be a reliable predictor of postoperative bleeding (128). Aspirin only modestly prolongs the preoperative bleeding time in most patients (i.e., 2 to 3 minutes) and does not usually lead to excessive bleeding. It is important for the surgeon to distinguish surgically correctable bleeding from microvascular bleeding that is amenable to transfusion. In the immediate postoperative period, excessive bleeding can be recognized as mediastinal drainage of more than 100 mL/h. Very high volumes of chest tube output, defined in one study as more than 300 mL in the first hour, more than 250 mL in the second hour and 150 mL or more thereafter, likely indicates a surgically correctable source of bleeding (129). Surgically correctable bleeding is localized to the operative site and will be seen postoperatively in the chest tube output only. Bright red, pulsatile chest tube bleeding is an obvious indicator of surgical bleeding. Microvascular bleeding, conversely, is generalized. Bleeding or oozing may be seen throughout the surgical field, including all surgical sites (e.g., sternotomy wound, graft harvest sites), as well as intravenous sites. Petechiae and/or purpura may be seen. Surgical bleeding usually requires returning the patient to the operating room for surgical resternotomy and repair of the bleeding source. Transfusion therapy alone would be futile for such cases. Conversely, transfusion therapy for excessive microvascular bleeding is appropriate.

Platelets

During surgery requiring mechanical CPB, platelets exposed to the foreign synthetic surfaces of the extracorporeal blood circuit undergo partial activation and degranulation. As a result, varying degrees of thrombocytopathy can develop (127,130,131 and 132). In anticipation of this thrombocytopathy, some surgical and transfusion specialists recommend that patients have a minimum preoperative platelet count of 100,000/µL. Platelet transfusions are not indicated while patients are still undergoing CPB because the transfused platelets will develop a functional defect. Routine prophylactic platelet transfusions administered after the patient has been removed from CPB are not indicated because the majority of patients do not suffer excessive postoperative bleeding. A controlled trial of routine administration of platelet concentrates failed to show any advantage (133). The risk factors for excessive postoperative bleeding, such as the performance of a redo CABG and prolonged time of CPB (more than 3 hours) and preoperative aspirin use, are not strong enough predictors to warrant prophylactic platelet transfusions. The decision to transfuse platelets must be made largely on clinical grounds. Mild to moderate thrombocytopenia is common after CPB because platelets are consumed during extracorporeal circulation. Thrombocytopenia after CPB is unlikely, in itself, to contribute to excessive bleeding in most cases because platelet counts rarely fall below 50,000/µL. However, a seemingly adequate circulating platelet count can be misleading because those platelets may be dysfunctional owing to the thrombocytopathy associated with CPB. Thus, after CPB, platelets should be transfused when bleeding is excessive and of a diffuse, microvascular nature (e.g., generalized oozing from surgical and intravenous sites), regardless of the patient's platelet count.

Plasma

Patients undergoing open-heart surgery are anticoagulated with heparin during CPB to prevent clotting in the extracorporeal circuit. Heparin inhibits coagulation by activating the natural anticoagulant molecule antithrombin. As a result, during CPB, the patient has a prolongation of the PT, aPTT, activated clotting

time, and thrombin time. At the end of CPB, the heparin effect is reversed by administering protamine, which binds to and inactivates the polyanionic heparin molecule. A residual or rebound heparin effect should be considered as a possible cause of excessive bleeding and abnormal coagulation tests after CPB. A heparin effect should be ruled out before considering coagulation factor replacement with FFP. A heparin-prolonged PT and aPTT can be detected and corrected *in vitro* by the addition of hexadimethrine bromide (Polybrene) or heparinase. Similarly, a prolonged thrombin time owing to heparin can be reversed *in vitro* by the addition of protamine or toluidine blue. Heparin characteristically will prolong the thrombin time, but not the reptilase time, whereas true coagulation factor deficiencies prolong both assays. Abnormal coagulation test results owing to residual or rebound heparin should be treated *in vivo* with the appropriate dose of protamine. FFP transfusion in this setting is ineffective because plasma will not inactivate heparin. A mixing study, in which the plasma used in the coagulation assay is a 50:50 mixture of normal control plasma and the patient's plasma, can help make a diagnosis of a coagulation factor deficiency. Abnormal coagulation tests that are not correctable with heparin neutralization *in vitro* but are correctable by mixing study should be considered the result of an actual reduction in clotting factor levels.

Although a moderate reduction in coagulation factor levels and corresponding prolongations in the PT and aPTT are common after CPB, these changes are rarely associated with excessive bleeding (134). Prophylactic plasma transfusions after CPB are not indicated or useful for most patients. FFP transfusion should be reserved for cases of excessive bleeding, when the PT- or aPTT-to-control ratios are greater than 1.5 to 1.8 and not attributable to heparin. This is based on the observation that PT or aPTT ratios greater than or equal to 1.8 are correlated with an 80% to 85% chance of developing diffuse microvascular bleeding and are associated with a reduction in clotting factor levels to less than 20% of normal (34). Plasma should not be transfused based on laboratory results alone, however, because of the poor correlation between abnormal coagulation tests and excess postoperative chest tube drainage (134).

One approach to treating excessive bleeding after CPB that appears to be diffuse and microvascular is first to transfuse platelets for a presumed platelet dysfunction. While platelets are being administered, laboratory testing can proceed to detect any significant coagulopathy and, if present, to determine whether it is heparin-related. A transfusion of platelets will also provide some plasma. For example, a pool of four to five units of platelet concentrate provides approximately 200 to 250 mL of plasma, a volume equivalent to approximately one unit of FFP. The plasma from platelet concentrates stored as long as to 5 days contains nearly the same levels of clotting factors as FFP, with the exception of the labile coagulation factors V and VIII, which decrease by approximately 50% and 30%, respectively, from initial levels (135).

Cryoprecipitate

Fibrinogen should be measured in settings of excessive postoperative bleeding to determine whether supplemental cryoprecipitate transfusion for fibrinogen replacement is indicated. Cryoprecipitate is transfused for laboratory-documented hypofibrinogenemia (fibrinogen less than 80 to 100 mg/dL) in the setting of excessive, diffuse microvascular bleeding after CPB. A fibrinogen level of 50 mg/dL or less is a sensitive predictor of microvascular bleeding (34). Typical doses of cryoprecipitate are one unit per 10 kg body weight or a pool of 10 bags per adult patient. An alternative guideline is to replenish levels to approximately 100 to 150 mg/dL using a calculated number of units as described earlier in this chapter. FFP transfusions also will provide fibrinogen, although not in a concentrated form. Because normal levels of fibrinogen are approximately 150 to 350 mg/dL, one unit of FFP could be expected to provide from 300 to 700 mg of fibrinogen, equivalent to approximately two to three units of cryoprecipitate. The larger volume of FFP compared with cryoprecipitate for a given level of fibrinogen makes FFP a less effective choice. Because cryoprecipitate does not provide significant amounts of coagulation factors other than factor VIII, factor XIII and fibrinogen, cryoprecipitate alone is not indicated for treating reductions in multiple coagulation factor levels.

Autoimmune Hemolytic Anemia

Warm Reactive Autoantibodies

Autoimmune hemolytic anemias are classified according to the thermal amplitude of the RBC autoantibodies (136,137,138 and 139). Approximately 70% of patients with autoimmune hemolytic anemia have warm autoimmune hemolytic anemia (WAIHA), characterized by the presence in the blood of IgG autoantibodies that are reactive with the patient's own RBCs at 37°C. Because of ongoing uptake and destruction of IgG-coated RBCs by the reticuloendothelial system, patients with WAIHA present with symptomatic anemia, i.e., fatigue, pallor, tachycardia, and dyspnea. This can be a life-threatening disorder, leading to cardiac failure and stroke, although for most patients hemolysis can be controlled with appropriate treatment. Therapy is aimed initially at decreasing accelerated RBC destruction with glucocorticoids, which appear to act at least in part by interfering with Fc receptor function and phagocytosis by splenic macrophages (139). For patients who inadequately respond to glucocorticoids, splenectomy is an option. High-dose intravenous IVIG is also a possible short-term option. Immunosuppressive agents, such as cyclophosphamide, azathioprine, and cyclosporine, are used to treat patients refractory to glucocorticoids and splenectomy. RBC transfusions are generally avoided, if possible. Transfusion is usually only of transient benefit because the autoantibodies typically react against all RBCs, causing transfused RBCs to be subject to the same immune destruction as the patient's own RBCs. Transfusion should not be withheld for patients with severe symptomatic anemia who have not yet responded to other treatments (136,139).

The autoantibodies present a laboratory challenge because they may mask the presence of clinically significant blood group alloantibodies in antibody screens and panels. If possible, the patient's RBC should have an extended phenotype determined before the first transfusion, which includes typing for antigens that stimulate common, clinically significant RBC alloantibodies (e.g., Rh, Kell, Kidd). This information is useful for selecting

compatible RBCs in the future should the patient develop RBC alloantibodies. All RBCs are typically incompatible on cross match with serum from a patient with WAIHA. Special RBC adsorption studies to remove the autoantibodies from the patient's plasma are necessary to determine whether an alloantibody is present (47,140,141). Units of RBCs that are least incompatible are often chosen for transfusion if there is variability in compatibility of different units. However, it is not clear whether the risk of hemolysis is lessened by selecting such units. Sometimes warm autoantibodies show some antigenic specificity, such as reactivity to the e antigen of the Rh system. In some cases, the transfusion of RBCs that are negative for the antigenic specificity of the autoantibody has yielded improved outcomes of the transfusion. Leukoreduced RBCs are preferred to lessen the chance of febrile, nonhemolytic transfusion reactions (FNHTRs). Because fever is a symptom of both FNHTRs and hemolytic reactions, the FNHTR will mimic an early hemolytic reaction and necessitate the discontinuation of a needed transfusion. Thus, FNHTRs should be avoided so as not to waste what might be a least incompatible unit. The transfusion of a smaller volume of RBCs (partial or split unit) at one time is generally advisable in patients with AIHA. This lessens the risk of volume overload and clinically significant hemolysis, which these patients are at increased risk of developing.

Cold Reactive Autoantibodies

Most individuals have clinically insignificant, cold-reactive autoantibodies to RBC surface antigens present at low titer (less than 1:32). These cold autoantibodies react more strongly at 0° to 5°C than at higher temperatures (137,138). The autoantibodies commonly have specificity for the I/i blood group antigens and typically are IgM. Rarely, cold reactive autoantibodies will have a broad enough thermal range to react at physiologic temperature (more than 30°C). Cold agglutinin disease is characterized by hemolysis and/or RBC agglutination and vascular occlusion mediated by pathologic cold-reactive autoantibodies when they have a broad enough thermal amplitude and are present at high titer (usually more than 1:1,000) (137,138 and 139). Serum autoantibody titers in cold agglutinin disease can reach 1:10,000 or more. Anemia is usually mild, although a small number of patients may develop a chronic hemolytic anemia. Hemolysis usually occurs via the uptake of C3b-coated RBCs by hepatic macrophages (138). Less frequently, the entire complement cascade is activated causing intravascular hemolysis.

If transfusion is necessary owing to symptomatic anemia or to replace blood loss in patients with clinically significant cold agglutinins, RBCs may be transfused through an FDA-approved blood-warming device. It is usually impractical or unnecessary to attempt to select RBCs that lack the RBC antigen to which the autoantibody is directed. If the cold autoantibody interferes with RBC antibody screens or cross matches, then cold autoabsorption and/or prewarming techniques may be employed (47,138). The patient's extremities, e.g., fingers, toes, ear lobes, and nose, where cold reactive autoantibody binding to RBCs occurs, should be kept warmer than the upper thermal range of the antibody. Splenectomy is typically ineffective in cold agglutinin disease because most RBC destruction occurs in the liver. Plasmapheresis is an option in severe cases of cold agglutinin disease (139). IgM cold agglutinins are large molecules confined more to the intravascular space than other immunoglobulins and therefore more effectively removed by plasmapheresis.

Thrombocytopenia and Thrombocytopathy

Immune Thrombocytopenic Purpura

Patients with ITP experience autoantibody-mediated destruction of their own platelets (142). ITP is categorized as either acute ITP, occurring predominantly in children with an acute onset often after a viral infection, and as chronic ITP, seen more commonly in adults with a more insidious onset and often with a chronic, relapsing course. Transfused platelets in ITP are destroyed rapidly just like the patient's own platelets and are of limited benefit. Attempts to maintain platelet counts above a specific value, such as 20,000/μL, with platelet transfusion can be futile. Fortunately, the bleeding time and the tendency for hemorrhage are often not increased in proportion to the thrombocytopenia (143) because the platelets in circulation are younger due to increased turnover.

Platelet transfusions are generally reserved as a treatment of last resort only for those patients with significant, life-threatening hemorrhage. Because some patients with ITP can have transient platelet count increments immediately after platelet transfusion (144), a clinical trial of platelet transfusion may be warranted for possible temporary benefit for significant bleeding. Otherwise, the treatment of ITP begins with high-dose corticosteroid and/or immunoglobulin therapy. If there is little or no response, splenectomy, chemotherapy, plasmapheresis, and staphylococcal protein A column absorption are additional treatment options (145). Routine prophylactic platelet transfusions are unwarranted, however, even during splenectomy because there is usually little operative bleeding. Moreover, the platelet count often rises after the splenic pedicle is clamped. If the patient bleeds despite clamping of the spleen, platelet transfusion may be of temporary value.

IVIG is effective in rapidly (1 to 5 days) raising platelet counts in many patients with ITP, although the effect lasts only 1 to 2 weeks. The administration of IVIG just before platelet transfusion may increase the magnitude and duration of the platelet count increment in some patients to a substantially greater degree than platelet transfusion alone (146). This combined approach has been employed for the acute treatment of hemorrhage or in preparation for surgery. The intravenous administration of RhIG to Rh-positive patients with ITP also may be of benefit in transiently raising circulating platelet counts (147). The mechanism of action of RhIG is postulated to be a competitive inhibition of uptake of IgG-coated platelets in the reticuloendothelial system by anti-D (IgG)–coated RBCs. RhIG of course is ineffective in Rh(d)-negative patients and splenectomized patients.

Thrombotic Thrombocytopenic Purpura

TTP is a microvascular occlusive syndrome characterized by thrombocytopenia and microangiopathic hemolytic anemia owing

to the presence of platelet microthrombi in small vessels. The microthrombi are composed in large part of platelets and vWF. The thrombocytopenia is apparently due to the consumption of platelets from abnormal platelet aggregation and adhesion to blood vessel walls. End-organ damage can occur because of microvascular occlusion and typically manifests itself as renal failure and neurologic deficits. Myocardial infarction and cerebrovascular accidents are possible. The platelet microthrombi have been shown to result from the platelet-aggregating activity of abnormally large vWF multimers that arise from a deficiency of vWF-cleaving protease activity (148,149,150 and 151). Patients with chronic, relapsing TTP have a chronic deficiency of this protease, whereas patients with a single acute episode have been found in many cases to have transient IgG autoantibodies to the vWF-cleaving protease that disappear after recovery. Mortality in untreated cases approaches 100%. Platelet transfusions are contraindicated in TTP and have been reported to worsen symptoms (152,153). The transfused platelets may promote the formation of additional microthrombi, especially in the cardiac or cerebral circulations, with potential fatal consequences. Antiplatelet therapy with inhibitory agents such as aspirin and dipyridamole to minimize further platelet adhesion and/or aggregation has been frequently administered but is of theoretical but undocumented benefit. Corticosteroids have been administered frequently as well, although their efficacy is also unproven.

Patients should be treated with daily plasma exchange of at least one plasma volume using FFP, SD-plasma, or cryoprecipitate-reduced plasma as replacement fluid during plasmapheresis (154). Plasma exchange may be therapeutic by providing the rapid infusion of large volumes of plasma containing exogenous vWF-cleaving protease. Plasma exchange also may serve to remove abnormally large vWF multimers and/or autoantibodies to vWF-cleaving protease. Whether the plasma removal actually provides additional therapeutic benefit over plasma infusion is yet unproven, however. Plasma exchange should continue until the clinical status of the patient improves and the platelet counts increase to normal. In addition to following platelet counts, disease status may also be assessed by measuring lactate dehydrogenase and indirect bilirubin to determine ongoing hemolysis and creatinine to assess renal status.

The therapeutic dose of plasma has not been firmly established. Therapeutic responses have been observed with doses ranging from as little as a couple of units of FFP per day to once or twice daily plasma exchange of one to two plasma volumes. Although plasma transfusions alone have been shown to be therapeutic in TTP for many patients, larger volume plasma exchange gives overall improved outcomes and lower mortality (155,156). It has been speculated that larger plasma doses may be required in patients with single acute episodes of TTP when high titers of autoantibodies are present. Conversely, smaller doses of plasma may be needed in chronic releasing patients who have a deficiency of vWF-cleaving protease without autoantibodies.

Plasma transfusions, as opposed to plasma exchange, may be administered initially if there will be a significant delay in the initiation of plasmapheresis and plasma exchange. Simple plasma transfusions have also been used to successfully keep chronic, relapsing cases of TTP in remission. Cryoprecipitate-reduced plasma, i.e., the plasma-derived product that remains after cryoprecipitate has been removed from FFP, has been used successfully in treating TTP. It has been used effectively in some patients who were unresponsive to initial treatment with FFP as well as in the initial treatment of TTP (157,158). It has the possible advantage of providing lower amounts of vWF multimers than FFP (157). SD-plasma, which also has been reported to be relatively deficient in high molecular weight multimers of vWF (157) and a reduced risk of transmission of hepatitis and acquired immunodeficiency syndrome (AIDS), also is efficacious in treating TTP (159,160). In patients with TTP who may receive as many as hundreds of units of plasma, SD-plasma's reduced risk of transmitting HIV and hepatitis may be an important consideration. For these reasons, some transfusion specialists advocate SD-plasma as the preferred plasma product for use in TTP. However, despite the reduced level of large molecular weight vWF multimers in cryoprecipitate-reduced plasma and in SD-plasma, actual improved therapeutic efficacy over FFP has not been demonstrated to date. Some patients with autoantibodies to the vWF-cleaving protease activity are relatively refractory to plasma therapy. Additional treatment modalities, such as splenectomy, vincristine, azathioprine, and protein A immunoabsorption have been employed for these refractory patients with variable results.

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) has similarities to TTP and has frequently been classified as a variant of TTP. However, unlike in TTP, renal failure predominates over neurologic signs and symptoms in HUS. Also, thrombocytopenia is typically less severe in HUS than in TTP. Unfortunately, HUS is usually less responsive to plasma exchange or plasma transfusion than TTP. Patients with HUS, unlike those with TTP, appear to have normal levels of the vWF-cleaving protease (161). Thus, the etiology and pathophysiology of HUS may prove to be different from those of TTP. More study is necessary to clarify the relationship of these two illnesses. Plasma therapy is typically not employed in childhood HUS because it is of unclear clinical benefit and because childhood HUS is generally self-limited (162,163). Plasma exchange using FFP as the plasma replacement is often reserved for the most severe cases of adult HUS. The efficacy of plasma exchange for adult HUS is not as clearly established as it is in TTP. In fact, the potential for confusion in diagnosis between TTP and HUS makes it difficult to distinguish the relative efficacy of plasma therapy in these two disorders based on published studies. Treatment of HUS often consists of dialysis as needed until recovery. Unfortunately, although most patients with TTP will have a full recovery (although some will relapse), the recovery rate is lower in HUS. Many adult patients with HUS experience chronic and irreversible renal failure, necessitating chronic dialysis or renal transplantation.

Hemolysis, Elevated Liver Enzymes, and Low Platelet Count Syndrome

Hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome develops in approximately 4% to 12% of

women with severe preeclampsia or eclampsia at the end of pregnancy (164,165,166,167 and 168). However, HELLP is not always preceded by these other disorders. HELLP is similar to TTP in that microangiopathic hemolysis and thrombocytopenia are prominent findings. However, unlike TTP or HUS, liver abnormality is present as reflected by elevations in liver enzyme tests. It is unclear whether HELLP and TTP are related syndromes. Platelet transfusions have been employed for treating the thrombocytopenia of HELLP, with no reports to date of adverse sequelae, as seen in TTP (164,167). In most women, recovery occurs spontaneously with childbirth or after termination of pregnancy (164,168). In most cases, recovery occurs by 3 days postpartum. The persistence of microangiopathic hemolysis and thrombocytopenia beyond 3 days postpartum may suggest the diagnosis of TTP or a TTP-like syndrome, and the initiation of plasma exchange with FFP should be considered (169). Published outcomes of plasma exchange have been favorable in this setting, except when HELLP syndrome has been complicated by multisystem organ involvement (168). Plasma exchange is not otherwise an accepted therapy for HELLP syndrome and attempts to prolong pregnancies complicated by HELLP syndrome with plasma exchange have had poor outcomes (168).

Posttransfusion Purpura

Posttransfusion purpura (PTP) is an immune thrombocytopenia that can occur approximately 5 to 10 days after transfusion in previously pregnant or transfused women or less commonly in previously transfused men (170,171 and 172). The typical patient is a multiparous woman. Most commonly, the affected individual lacks the HPA-1a (PL^{A1}) platelet antigen, which is present in 98% of individuals, and has been alloimmunized to this platelet antigen by exposure during pregnancy or prior transfusion. Less commonly, platelet antigens other than HPA-1a have been implicated in cases of PTP. After subsequent transfusion, the patient has an anamnestic response owing to reexposure to the implicated platelet antigen that results in the increased synthesis of the previously made antibody. The antibody mediates destruction of transfused antigen-positive platelets as well as, paradoxically, the patient's own HPA-1a–negative platelets. Less commonly, platelet antigens other than HPA-1a have been implicated in cases of PTP.

The mechanism of destruction of the patient's own platelets is not clearly understood. Possible mechanisms include (a) immune complexes adhering to antigen-negative platelets, resulting in their accelerated removal by complement activation or phagocytosis in the reticuloendothelial system, (b) soluble transfused platelet antigens binding to autologous platelets, thereby making them targets for the antibody, and (c) production of autoantibodies or cross-reacting alloantibodies early in the immune response that target autologous platelet determinants. The resulting thrombocytopenia is often severe (10,000 to 20,000 platelets/μL or less). Although this a self-limited condition, the thrombocytopenia may lead to significant and even life-threatening hemorrhage, and the low platelet count may persist for several weeks if untreated.

The therapy of choice is high-dose IVIG (173). Corticosteroids are a possible adjunctive therapy. Plasma exchange has been employed with varying success as well. The transfusion of platelets from HPA-1a–positive or -untested donors is largely ineffective, generally avoided, and may be contraindicated. Theoretically, the infusion of additional antigen may further stimulate the immune response and may also enhance the destruction of the patient's own HPA-1a–negative platelets.

Random platelet transfusions have been associated with severe febrile and anaphylactoid transfusion reactions. Transfused HPA-1a–negative platelets may be rapidly destroyed, as would be predicted based on the destruction of the patient's own HPA-1a–negative platelets (174). However, HPA-1a–negative platelets in conjunction with IVIG have been administered with therapeutic success in severely thrombocytopenic patients (175,176). Owing to the time required to test for HPA-1a antigens and antibodies to confirm the involvement of that antigen and the difficulty in obtaining antigen-negative blood components, the transfusion of blood components, in general, should be avoided. RBCs, if not available from a donor who is negative for the implicated platelet antigen, may be saline–washed or frozen-deglycerolized and washed in an attempt to reduce platelet membrane fragments and soluble antigens. Although frozen–thawed RBCs have been reported to induce a relapse of PTP (177), washed units, nevertheless, have been administered without adverse effect to others (178). PTP has been associated with the presence of HLA B8 and DR3 antigens in the transfusion recipient (179).

Neonatal Alloimmune Thrombocytopenia

In neonatal alloimmune thrombocytopenia (NAIT), a pregnant woman becomes alloimmunized to fetal platelet antigens (179,180 and 181). As with posttransfusion purpura, HPA-1a alloimmunization is the most common cause of NAIT, although other platelet antigens less commonly have been implicated. The mother who lacks the platelet antigen HPA-1a may make antibodies to HPA-1a antigens on the fetal platelets. The antibodies cross the placenta in NAIT and mediate platelet destruction in the neonate, as well as possible suppression of megakaryocyte precursors and reduced platelet production. Thrombocytopenia may be severe and, if untreated, can last for several weeks after delivery. The major complication in severely thrombocytopenic neonates is intracerebral hemorrhage, which occurs most commonly within 24 to 36 hours after delivery (181,182). Prompt treatment with the transfusion of maternal platelets is indicated to prevent life-threatening hemorrhage. Maternal platelets will lack the involved platelet antigen and be compatible regardless of which platelet antigen is implicated. The plasma in the platelet concentrate may be replaced by saline to avoid the infusion of additional platelet antibodies. The platelets should be gamma irradiated to reduce the risk of transfusion-associated graft-versus-host disease (TA-GVHD). Platelets also may be obtained from an HPA-1a–negative donor; however, the antibody involved is not always directed against HPA-1a, and insufficient time may be available to determine the specificity of the antibody before transfusion. Furthermore, the neonate will be placed at additional risk of a new donor exposure. HPA-1a–positive or untested platelets are not contraindicated in NAIT as they are in

PTP (183). An important difference between PTP and NAIT is that the antibody is passively obtained and of limited quantity in NAIT, rather than being actively produced in the transfusion recipient as in PTP. IVIG is another treatment that has approximately a 70% response rate, although its effect is usually delayed 1 to 2 days (184). If maternal or antigen-negative platelets are not available in a timely fashion, a trial of IVIG combined with the transfusion of random platelets may be indicated.

Platelet Refractoriness

Platelets carry HLA class I antigens. Approximately 20% to 50% of patients who receive multiple transfusions become alloimmunized to HLA class I antigens (185). Approximately one third of HLA alloimmunized patients become refractory to platelet transfusion. Refractoriness is reflected by poor posttransfusion increments in platelet count measured within 10 minutes to 4 hours after transfusion, defined variably as a CCI less than 5,000 or 7,500 (Fig. 72.1) (23,24,186,187). Platelet alloimmunization apparently requires the infusion of donor antigen-presenting cells (APCs) such as monocytes, B cells, and dendritic cells, all of which express HLA class II antigens. Alloimmunization appears to occur when donor HLA class I antigens are presented to recipient T cells by donor APCs in the presence of a foreign class II antigen. When donor APCs in platelet concentrates are decreased in number by the use of leukocyte reduction filters (LRFs) or if they are inhibited by treatment with ultraviolet B radiation, the incidence of recipient HLA alloimmunization is reduced by approximately 70% (23,185). Not all patients who are refractory to platelet transfusions are HLA alloimmunized (25,26). In some cases, alloantibodies directed against platelet-specific antigens may be the cause of refractoriness. Patients with autoantibodies to platelet antigens, as in ITP, also will be refractory to platelet transfusion. Nonimmune conditions may be associated with platelet refractoriness, such as sepsis, DIC, splenomegaly, hemorrhage, fever, and the administration of amphotericin B (25,26). Suboptimal posttransfusion platelet increments also are seen with major ABO-mismatched platelets or with platelets near their storage outdate (188).

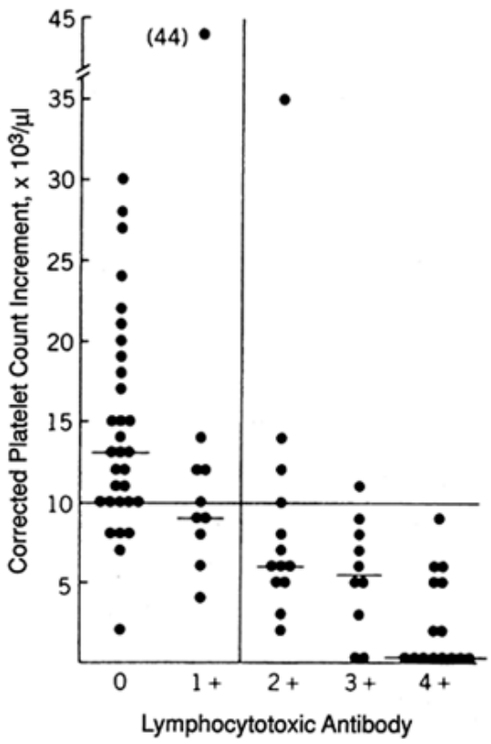

FIGURE 72.1. One-hour corrected count increments (CCI) (see text), after the transfusion of pooled, random platelet concentrates in HLA-alloimmunized thrombocytopenic recipients. The CCI is plotted as a function of the lymphocytotoxic antibody level. Reactions 2+ to 4+ are considered positive for the presence of lymphocytotoxic antibody. Median values are indicated by horizontal bars. (From Daly PA, Schiffer CA, Aisner J, et al. Platelet transfusion therapy; one-hour post-transfusion increments are valuable in predicting the need for HLA-matched preparations. *JAMA* 1980;243:435–438, with permission.)

Several algorithms for addressing platelet refractoriness have been used depending on available resources and locally accepted practices (189). The comparative cost-effectiveness of the various alternatives has not been rigorously studied. Thus, no clear consensus regarding the superiority of one approach compared with another has emerged. The different approaches generally consist of one or a combination of the following strategies: (a) provision of the closest HLA-matched single-donor (apheresis) platelets available (190), (b) provision of HLA-typed single-donor platelets that lack the HLA antigens to which the recipient is alloimmunized (191), and (c) provision of cross match-compatible single-donor platelets (192,193). Each approach has advantages and disadvantages. The initial step employed at many centers is to test and verify the presence of HLA or platelet-specific antibodies in the patient's serum before proceeding with any of these approaches.

To provide HLA-matched platelets, the HLA class I antigenic phenotype of the recipient lymphocytes must first be determined. This typing will delay the initial provision of HLA-matched platelets. An additional delay is incurred if it is necessary to call in donor(s) for apheresis. Table 72.5 lists the grading scale for degree of match of HLA class I antigens between the donor and the recipient. The significant antigens are encoded by two chromosomal loci, designated HLA A and B. Each individual has two alleles at each locus and can synthesize two A and two B antigens. An identical four-antigen match is called an A match. Donor platelets that are a B match have one or two antigens that are either related, i.e., cross-reactive, or unknown. A and B in this context do not refer to the HLA A and B loci. Detection of only one antigen at a locus indicates either that the alleles are homozygous or that the other antigen was untypable. B1U (one antigen unknown) and B2U (two antigens unknown) are potentially, but not necessarily, identical to A matches because homozygosity could explain the unknown antigen. A C match means that one of the four antigens is nonidentical and noncross-reactive with any of the recipient's antigens. In common usage, the term HLA-matched usually implies that the donor and the recipient are a C match or better or that the donor lacks the HLA antigen(s) to which the recipient is sensitized. Rarely are identical A matches available, and most HLA-matched platelets are C matches with the existing donor bases of most collecting facilities. Unfortunately, if the one mismatched HLA antigen in the C match corresponds to the antigenic specificity of the patient's HLA alloantibody, then the C match will not give improved platelet increments over randomly chosen

platelets. Clearly, this approach works best if A or B matches are available.

TABLE 72.5. HLA MATCHING NOMENCLATURE[a]

Match Grade[b,c]	Description
A	All four donor antigens are identical to those of recipient.
B1U	Three donor antigens are identical to recipient antigens; fourth donor antigen is unknown.
B1X	Three donor antigens are identical to recipient antigens; fourth donor and recipient antigens are cross-reactive.
B2U	Two donor antigens are identical to recipient antigens; third and fourth donor antigens are unknown.
B2UX	Two donor antigens are identical to recipient antigens; third donor antigen is cross-reactive with a recipient antigen; fourth donor antigen is unknown.
B2X	Two donor antigens are identical to recipient antigens; third and fourth donor antigens are both cross-reactive with recipient antigens
C	Three donor antigens are identical to those of recipient; fourth donor and recipient antigens are nonidentical and noncross-reactive
D	Two donor and recipient antigens are identical; third and fourth donor antigens are nonidentical and noncross-reactive with recipient antigens.

[a]HLA matching refers to comparisons of the four HLA class I antigens coded by the HLA A and B loci of the transfusion donor and recipient.

[b]Match grade nomenclature (i.e., A, B, C, D) is unrelated to the similarly named HLA chromosomal loci.

[c]An unknown antigen (U) indicates either homozygosity at a locus or the presence of an antigen that is nonreactive with the typing antisera. An X denotes immunologic cross-reactivity of donor and recipient antigens. A number appearing in the match grade indicates how many donor antigens are unknown or cross-reactive.

Adapted from Duquesnoy RJ, Filip DJ, Rodey GE, et al. Successful transfusion of platelets “mismatched” for HLA antigens to alloimmunized thrombocytopenic patients. *Am J Hematol* 1977;2:219–226.

To overcome the problem of incompatible C matches when using HLA-matched platelets, the antigenic specificity or specificities of the HLA alloantibodies can be determined. This can be done in a lymphocytotoxicity assay against a panel of lymphocytes representing different HLA class I phenotypes. When the specificity of the HLA antibody is determined, HLA-typed single donor platelets can be chosen that lack the antigen(s) to which the patient is alloimmunized. This approach can be combined with choosing donor platelets that are also the best HLA match available in an attempt to reduce the stimulus for further alloimmunization.

In an alternative approach, the patient's serum can be tested for platelet-reactive antibodies using, for example, a solid-phase RBC agglutination assay (193). Such an assay has the theoretical advantage of detecting both HLA- and platelet-specific antibodies, regardless of whether they are complement fixing. Platelet-specific alloantibodies mediate platelet refractoriness in a small number of chronically transfused patients and are missed by assays specific for HLA antibodies. If a panel of platelets from apheresis donors already is used in the initial platelet antibody-screening assay, there is a chance that compatible platelet donors may be identified in the process of testing for the presence of platelet alloantibody. If not, additional donors may be screened using the same assay, in what is referred to as a platelet cross match. Platelet cross matching also has the advantage of not necessarily requiring HLA typing. However, if the majority of donors are incompatible by platelet cross matching, then a combination of HLA-matching and platelet cross matching may be attempted. Platelets from the closest HLA-matched donors may be preselected for use in platelet cross matching. A possible algorithm for the use of platelet cross matching in refractory patients is shown in Fig. 72.2.

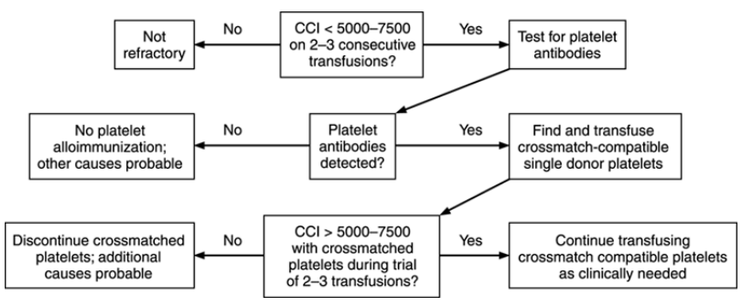

FIGURE 72.2. Algorithm for platelet cross-matching in platelet refractoriness.

Regardless of the approach taken to select compatible platelets for transfusion, the CCI of each transfusion should be measured and compared with earlier transfusions of randomly chosen platelets. Significant improvements in the CCI justify continued use of HLA-selected platelets or cross match–compatible platelets. If no improvement in platelet count increment is seen with selected platelets after a trial of two to three transfusions, this may indicate that the refractoriness is being caused by clinical factors other than HLA or platelet alloimmunization. The continued use of HLA-selected or cross match–compatible platelets might not be justified. If, however, HLA or platelet alloimmunization is likely or has been confirmed by testing, a better HLA match or platelet cross matching, if not available locally, may be sought by your blood supplier from another blood donor center.

Uremia

Patients with severe renal failure have a hemostatic defect owing in large part to platelet dysfunction, but whose etiology is likely multifactorial (194,195,196 and 197). Uremic patients have prolonged bleeding times and a variety of measured defects in platelet function, platelet–vessel wall interactions, and in vascular endothelial and smooth muscle cell metabolism. In addition, the decrease in circulating RBCs resulting from the anemia of renal failure apparently causes rheologic changes that decrease the concentration of platelets closest to the blood vessel wall where they are needed for primary hemostasis. RBCs tend to flow in the midstream, displacing platelets to the periphery of the bloodstream near the blood vessel wall. One possible explanation for platelet dysfunction is the accumulation of metabolites toxic to platelets in the blood of patients with renal failure (197).

Platelet transfusions are not considered an effective therapy in uremia because transfused platelets are expected to become dysfunctional when exposed to the same inhibitory milieu as the patient's own platelets. However, several other treatment options are available (Table 72.6). The nontransfusion treatment of choice is hemo- or peritoneal dialysis (198). Either procedure can temporarily correct the hemostatic defect, perhaps by transiently removing the toxic metabolites that cause the uremic thrombocytopathy. Bleeding times can also be shortened in uremic patients by maintaining their hematocrits 28% to 30% or more either through the use of recombinant human erythropoietin or RBC transfusions (199,200,201 and 202). Desmopressin, a synthetic analog of antidiuretic hormone that stimulates increases in endogenous vWF and factor VIII levels, also shortens the bleeding time in many uremic patients (203,204). Cryoprecipitate transfusions, at a dose of one bag per 10 kg of patient body weight, shorten bleeding times and control bleeding in some patients with uremic bleeding (205,206). The element of cryoprecipitate responsible for this effect is unknown, but vWF and factor VIII are possible candidates. The intravenous infusion of conjugated estrogens has also been shown to shorten bleeding times prolonged by uremia (207,208). The effect of estrogen is delayed compared with that of desmopressin and cryoprecipitate, but its duration of effect is as long as approximately 2 weeks, longer than that of desmopressin or cryoprecipitate. Oral and transdermal administrations of estrogen also shorten bleeding times in uremia, although the onset of action is delayed further (209,210). All these treatments are transient and not curative and also may not be effective for all patients. In some eligible patients with uremic thrombocytopathy, only renal transplantation offers hope for a cure.

TABLE 72.6. THERAPEUTIC OPTIONS IN UREMIA

Treatment	Dose	Mechanism	Time to Peak Effect	Duration
Recombinant human erythropoietin	See product insert	Increases hematocrit to ≥30%, which may increase platelet concentration at vessel wall	Weeks	Sustained if hematocrit is maintained
Desmopressin	0.3 mg/kg once or twice daily	Stimulates release of endogenous vWF and factor VIII	1–2 hr	˜6–8 hr
Red blood cells	Transfuse to ≥30% hematocrit	May increase platelet concentration at vessel wall	Immediate	Sustained if hematocrit is maintained
Cryoprecipitate	1–2 U/10 kg	Mechanism unknown (supplies vWF and factor VIII)	1–2 hr	24–36 hr
Conjugated estrogens	0.6 mg/kg/i.v. daily × 5 days	Mechanism unknown	5–7 d	˜14 d

vWF, von Willebrand factor.

Reversal of Aspirin Effects

Aspirin inhibits platelets by irreversibly acetylating and inhibiting platelet cyclooxygenase-1, which is a key enzyme in the pathway leading to the production of thromboxane A_2, a platelet-aggregating factor (211). The result is a partial inhibition of platelet activation, a prolongation of the bleeding time, and an increased tendency to bleed (212). Platelets remain inhibited for their entire lifetime, and a prolongation of the bleeding time may persist for as long as 4 to 7 days. Aspirin has a plasma elimination half-life of approximately 15 to 20 minutes and is effectively cleared from plasma after approximately 2 hours. Deacetylated metabolites persist longer in the circulation but do not inhibit cyclooxygenase-1. When aspirin is cleared, the aspirin effect is reversible by platelet transfusion.

Of note, not all patients on aspirin who undergo an invasive surgical procedure, such as CABG, will have excessive bleeding compared with patients not on aspirin (213). Since the thromboxane A_2 pathway is only one of several that mediate platelet activation, most patients have only a modest (i.e., 1 to 3 minutes) prolongation of bleeding times (212). Only patients who experience a greatly prolonged bleeding time that may put them at greater risk of surgical bleeding and who need to urgently undergo a major surgical procedure should be considered candidates for platelet transfusion. Even in that setting, platelet transfusion in most cases should be reserved for patients who actually demonstrate excessive intra- or postoperative bleeding. Desmopressin is effective in shortening an aspirin-prolonged bleeding time (214) and is a possible pharmacologic alternative to transfusion for treating or preventing bleeding attributable to aspirin effects.

Coagulation Protein Deficiencies and Defects

Hepatic Failure

Because many coagulation factors are synthesized in the liver, patients with hepatic failure develop multiple coagulation factor deficiencies (215,216 and 217), as reflected in prolongations of the PT and aPTT. Patients with liver failure are also at increased risk of developing DIC (218) owing in part to decreased synthesis of antithrombin, α_2-plasmin inhibitor, protein C, protein S, and other regulatory factors of the coagulation cascade. Vitamin K_1 administration is indicated for patients with liver failure and prolonged coagulation tests to correct a possible vitamin K deficiency. This in itself may improve coagulation factor levels and hemostasis in some patients. FFP transfusion is indicated in a patient with liver failure with PT and/or aPTT elevated 1.5-fold or more over control values in the setting of bleeding or in preparation for surgery. However, prophylactic plasma transfusions are not recommended. They are unnecessary in milder hepatic failure and futile in severe cases, except possibly on a short-term basis if liver transplantation is planned. The short-lived factor VII, with a circulating half-life of only 2 to 5 hours, is rate limiting, necessitating frequent, large-volume transfusions or plasma exchange. Platelet, RBC, and cryoprecipitate transfusions should be administered as needed according to accepted guidelines (see above).

Desmopressin is a possible adjunct to transfusion therapy for the treatment of bleeding episodes in cirrhotic patients who have prolonged bleeding times. Desmopressin has been shown to decrease the bleeding time in such patients even though their vWF and factor Vlll levels are normal or elevated (214,219). However, because a controlled trial failed to demonstrate a benefit of using desmopressin for the treatment of acute variceal hemorrhage, the clinical effect of desmopressin appears to be insufficient for large hemorrhage (220).

Disseminated Intravascular Coagulation

DIC is a state of uncontrolled thrombin generation that can be complicated by both thrombosis and bleeding (221). The thrombotic phase of DIC results from excessive activation of thrombin and the coagulation cascade. The release of procoagulant tissue factor and thromboplastins from damaged tissues is one possible cause of DIC. The hemorrhagic complications of DIC result from the consumption and depletion of clotting factors and platelets. The two main treatment modalities of DIC are supportive blood component therapy and the interruption of the coagulation cascade with antithrombin and/or heparin. The demonstration of improved outcomes from treatment have been problematic because outcomes are generally poor and highly dependent on the underlying, predisposing factors for DIC. Nevertheless, it is common clinical practice to transfuse blood components for treatment or prophylaxis of bleeding. The administration of heparin to treat thrombotic complications is more controversial. Antithrombin concentrate, also administered to decrease thrombosis, has given some promising results.

Some experts argue that providing plasma and coagulation factors only serves to “add fuel to the fire” of DIC, but there exists no clear evidence that this happens. Therefore, if the patient is bleeding seriously and the PT and/or PTT are prolonged by 1.5 to 1.8 compared with normal controls, it is common practice to replace coagulation factors with plasma transfusion. Transfused plasma also contains natural anticoagulants, such as antithrombin, protein C, and protein S, which theoretically may be of benefit in controlling thrombosis. In DIC, there is usually also some degree of thrombocytopenia, with reported average counts of 52,000 to 60,000 platelets/μL in some studies (222,223). In addition, platelet function may be significantly inhibited by circulating fibrin degradation products (224). If a patient is actively bleeding or about to undergo an invasive procedure, platelet transfusion is indicated for the restoration of the patient's platelet count to more than 50,000 /μl (222,225,226 and 227). However, because transfused platelets may undergo rapid consumption (228) and platelet count alone may be a misleading indicator of functional platelet activity owing to the concurrent thrombocytopathy, the end point of platelet transfusion in many situations may need to be more pragmatic, i.e., the control or cessation of bleeding.

Hypofibrinogenemia is common in DIC. Although some experts oppose transfusion for fibrinogen replacement on the basis of “fueling the fire” (224), others contend that restoration of the fibrinogen level to more than 100 mg/dL is desirable to prevent or treat serious bleeding (228,229). Fibrinogen repletion by cryoprecipitate transfusion may be used as a supplement to plasma. However, cryoprecipitate should not be administered alone in the treatment of DIC because it lacks significant concentrations of most of the coagulation factors, with the exception of factors Vlll, Xlll and vWF. The dose of cryoprecipitate can be calculated as described earlier in this chapter. However, because fibrinogen consumption can be greatly increased in DIC, the expected increments may not be achieved.

Interruption of the coagulation cascade can be attempted using heparin and/or antithrombin, a necessary cofactor for heparin and a powerful inhibitor of thrombin. antithrombin levels are typically low in DIC, and replacement may be indicated to help control excessive coagulation without the hemorrhagic risk of heparin. In addition, antithrombin may be administered to facilitate the action of exogenously administered heparin (230). antithrombin is found in plasma and may be supplied in part by plasma transfusion. However, adequate doses of plasma for antithrombin repletion could lead to volume overload in many cases (231). For that reason, a commercial, virus-attenuated antithrombin concentrate is the preferred treatment in DIC if antithrombin repletion is attempted (232).

Reversal of Warfarin Effects

Patients treated with coumarin anticoagulants, such as warfarin, may need to have the anticoagulant effect reversed urgently for surgery or serious bleeding or because of an abnormally high international normalized ratio (INR) that puts the patient at increased risk of intracranial hemorrhage (Table 72.7). When time permits, as with elective surgery, the anticoagulant effect of warfarin can be reversed simply by stopping the drug (233). Vitamin K_1, administered subcutaneously, parenterally, or orally, in combination with holding further warfarin doses, may also be used to reverse the warfarin effect more rapidly when greater urgency exists (233,234). More rapid (within 6 to 8 hours) effects of vitamin K_1 are seen with intravenous administration, as opposed

to the other routes of administration (234). Rare anaphylactic reactions have been reported with intravenous infusion; therefore, slow administration is recommended (1 mg per hour) (234). When 1 or more days are available for correction of the elevated INR, low dose (1.0 to 2.5 mg) oral vitamin K_1 is effective in decreasing the INR, while avoiding relative warfarin resistance that higher doses induce (235). Low-dose vitamin K_1 permits faster reestablishment of the warfarin effect, which is clinically important for many patients.

TABLE 72.7. MANAGING PATIENTS WITH HIGH INR VALUES

Clinical Setting	Recommendations
INR higher than therapeutic range but <5.0; no clinically significant bleeding; no urgent surgical intervention	Lower the dose or omit the next dose; resume warfarin at a lower dose when the INR approaches desired range If the INR is only slightly higher than therapeutic range, dose reduction may not be necessary
INR >5.0 but <9.0; no clinically significant bleeding	Patients with no additional risk factors for bleeding: omit the next dose or two of warfarin, monitor INR more frequently, and resume warfarin at a lower dose when the INR is in therapeutic range Patients at increased risk of bleeding: omit the next dose of warfarin, and give vitamin K_1 (1.0–2.5 mg orally) Patients requiring more rapid reversal before urgent surgery or dental extraction: vitamin K_1 (2–4 mg orally); if the INR remains high at 24 hr: an additional dose of 1–2 mg
INR >9.0; no clinically significant bleeding	Hold warfarin; give Vitamin K_1 (3–5 mg orally); if the INR remains high at 24 hr, vitamin K_1 dose can be repeated; resume warfarin when INR is therapeutic
Serious bleeding or major warfarin overdose (e.g., INR >20.0) requiring very rapid reversal of anticoagulant effect	Hold warfarin; give Vitamin K_1 (10 mg by slow i.v. infusion), with FFP transfusion or prothrombin complex concentrate, depending on urgency and availability; vitamin K_1 injections may be repeated q12h
Life-threatening bleeding	Prothrombin complex concentrate (if available) or FFP, with vitamin K_1 (10 mg by slow i.v. infusion); repeat if necessary, depending on the INR
Resumption of warfarin therapy after high dose vitamin K_1	Heparin, until the effects of vitamin K_1 have been reversed, and patient is responsive to warfarin

INR, international normalized ratio; FFP, fresh frozen plasma
Adapted from Ansell J, Hirsh J, Dalen J, et al. Managing oral anticoagulant therapy. *Chest* 2001;119:225–238. (from the sixth American College of Chest Physicians Consensus Conference on Antithrombatic Therapy, February 2000.)

When even the delay for vitamin K_1 to take effect puts the patient at risk of significant hemorrhage, plasma or prothrombin complex concentrate administration may be indicated (236,237). A dose of 6 to 7 mL/kg of FFP may be adequate for some patients for reversing the warfarin effect. The effect of the FFP should be verified with a posttransfusion PT and INR measurement. Additional plasma may be infused as needed to shorten the PT to approximately 1.5 times the PT control or less or to decrease the INR to the desired range. Larger doses of FFP, i.e., 12 to 15 mL/kg, may be necessary, particularly when the need arises for an immediate and more complete warfarin reversal. Prothrombin complex concentrates, which contain the vitamin K–dependent coagulation factors, can be used to reverse the warfarin effects in patients who need more urgent correction or who are at risk of hypervolemic reactions from plasma infusion (236,237). Prothrombin complex concentrates, presumably because of the higher dose possible of vitamin K–dependent coagulation factors, have been shown to shorten the PT more rapidly than plasma and may be used for the treatment of life-threatening bleeding, such as an intracerebral hemorrhage (236,237 and 238). However, the use of prothrombin complex concentrates has been associated with an increased risk of thromboembolic events and their availability may be limited. Consensus guidelines that incorporate the options for managing patients with high INR values have been published by the American College of Chest Physicians (Table 72.7) (238).

Heparins/Heparinoid/Ancrod

Plasma should not be transfused to reverse the anticoagulant effect of heparin. Heparin acts by binding to and activating antithrombin, which in turn inhibits thrombin as well as factors Xa and XIIa (239). Plasma transfusion is a source of supplemental antithrombin and has been used to treat heparin resistance owing to antithrombin deficiency, when commercial antithrombin concentrate is not available (240). Therefore, if anything, plasma transfusion potentiates the action of heparin rather than reverses it. Heparin, which has a relatively short circulating half-life (approximately 90 minutes), can be reversed by discontinuing its administration (239). Heparin can also be reversed by administering protamine, a polycationic protein that binds to and inactivates polyanionic heparin molecules (241). Protamine is commonly used in neutralizing heparin's effect at the end of open-heart surgery (127). Other methods are currently being investigated and include the administration of the enzyme heparinase, which breaks down heparin, and recombinant platelet factor 4, a cytokine that inactivates heparin (127,242). Just as with heparin, the activities of low molecular weight heparins and heparinoid are not reversed by plasma transfusion. They are, however, not as susceptible to neutralization by protamine as unfractionated heparin and have a longer half-life (243). Desmopressin is reported to shorten the aPTT prolonged by heparin and may be of use in mitigating the anticoagulant effects of these agents (244).

The defibrinogenating agent ancrod derived from the Malayan pit viper, has been used as a heparin substitute, particularly in patients with heparin-induced thrombocytopenia (245,246). Ancrod cleaves fibrinogen to water-soluble fibrin. Ancrod is infused with the goal of achieving anticoagulation by decreasing fibrinogen levels. The reversal of ancrod's effects and the treatment of ancrod overdoses is achieved with cryoprecipitate

transfusion with the goal of increasing fibrinogen to a hemostatic level (100 mg/dL or more) (245,246).

Isolated Factor Deficiencies

Plasma transfusions are indicated for the replacement of documented isolated deficiencies of factors for which no concentrates are available for clinical use, e.g., factor II, V, VII, X, or XI. Specific commercial concentrates, when they are available, are the treatment of choice for factors such as VIII and IX and antithrombin. The clotting factor deficiency should be documented by an abnormal result on the appropriate specific factor assay.

Prothrombin complex concentrates, when available, also may be used for deficiencies of factors II, VII, and X. Caution must be exercised, however, owing to reported thrombotic side effects of prothrombin complex concentrates. The need for replacement therapy varies with the particular factor and the extent of the deficiency. In some cases, the clinical manifestations of a factor deficiency vary widely between patients. For example, in factor XI deficiency, the apparent extent of the deficiency does not necessarily correlate with bleeding (247). In some factor deficiencies, the risk of serious, spontaneous hemorrhage is high, necessitating ongoing prophylactic therapy. In others, increased bleeding may occur only after trauma or surgical procedures, in which case, therapy is reserved only for those settings.

Individuals with a congenital deficiency of factor XIII are at high risk of spontaneous intracranial hemorrhage, and ongoing prophylactic therapy is therefore advisable (248). Factor XIII is a transketolase; it cross-links fibrin monomers and stabilizes fibrin clot formation (249). Factor XIII may be provided with plasma or cryoprecipitate transfusions. The hemostatic levels of factor XIII for bleeding patients are low (approximately 2 to 3 U/dL or approximately 2% to 3% of normal), and the half-life of factor XIII is long (approximately 7 to 12 days). A therapeutic dose for an average adult is four to six units of cryoprecipitate every 3 weeks (250,251). Higher levels are recommended for major surgery or trauma. Factor XIII is concentrated 1.5- to fourfold in cryoprecipitate compared with plasma. For this reason, cryoprecipitate may be preferred over plasma owing to the smaller volume needed. Therapeutic recommendations for other specific factor deficiencies are reviewed elsewhere (248).

von Willebrand's Disease

vWD is the most common inherited bleeding disorder. It is characterized by quantitative and/or qualitative defects in vWF (252,253,254 and 255). vWF is synthesized by endothelial cells, where it is stored in Weibel-Palade bodies. Megakaryocytes also produce vWF, which can be found in platelet α granules. vWF is secreted and circulates in the blood as multimers; the large multimer forms of vWF are required for full activity. vWF mediates adhesion between platelets and damaged blood vessel walls by binding to platelet GPIb and collagen of the exposed vascular subendothelium. It also binds to, stabilizes, and serves as a carrier for factor VIII.

Several treatment options exist for increasing the levels of vWF in patients with vWD who are bleeding or about to undergo an invasive procedure (252,254,256) (Table 72.8). The pharmacologic agent desmopressin is the preferred treatment of mild-to-moderate forms of vWD because it poses no infectious risk (204). Desmopressin stimulates the release of vWF from the patient's own stores of vWF in endothelial cells. Desmopressin can be administered parentally, subcutaneously, or intranasally. Approximately 20% to 25% of patients with vWD do not respond to desmopressin (254). For this reason, responsiveness should be documented with a test dose before an anticipated invasive procedure. Responsiveness can be measured with vWF or factor VIII assays or with a bleeding time. It is useful to determine the vWD type and subtype, if possible, before considering desmopressin use. Responsiveness to desmopressin is expected in type 1, variable in type 2, and unlikely in type 3 (252,254,256). Most experts consider desmopressin to be contraindicated in subtype 2B. The desmopressin-stimulated release of the mutated vWF in subtype 2B vWD can exacerbate the abnormal platelet aggregation and thrombocytopenia characteristic of this subtype and cause thrombotic complications in some patients. Nevertheless some patients with subtype 2B have been reported to respond

TABLE 72.8. THERAPEUTIC OPTIONS IN VON WILLEBRAND'S DISEASE

Treatment	Dose	Mechanism	Infectious Risk	Use	Comment
Desmopressin	0.2–2.4 μg/kg i.v. over 15–30 min.	Stimulates endogenous vWF release	No	Type I vWD; variable efficacy in type II vWD: contraindicated in type IIb; likely ineffective in type III	Not all patients respond; tachyphylaxis reported
Factor VIII/vWF concentrate (humate P)	See product insert; depends on clinical setting	Provides large vWF multimers	Reduced	All vWD types	One FDA-licensed concentrate now available; other factor VIII concentrates may not be therapeutic
Cryoprecipitate	1–2 U/10 kg	Provides large vWF multimers	Yes	All vWD types	Also provides fibrinogen, factor VIII, factor XIII, fibronectin
Platelet transfusion	1 U/10 kg	Provides vWF multimers from platelet α granules	Yes	Type III vWD	Possible adjunct if inadequate response to factor VIII/vWF concentrate

vWF, von Willebrand factor; FDA, U.S. Food and Drug Administration.

therapeutically to desmopressin without adverse effect (257).

Tachyphylaxis has been reported with repeated doses of desmopressin given at intervals of 12 to 24 hours or less. This effect varies from patient to patient and can be lessened with once-a-day dosing (204,254). The most common side effects of desmopressin are facial flushing, headache, mild tachycardia, and a drop in systolic blood pressure (252,256). These are usually mild and transient. The antidiuretic action of desmopressin may result in hyponatremia and water intoxication in some patients, especially infants, small children, and patients receiving repeated doses. For these patients, it is important to monitor serum sodium levels and to restrict their water intake. Desmopressin probably should be used with caution in elderly patients and those with atherosclerotic disease because of a few anecdotal reports of myocardial infarction and stroke associated with desmopressin administration (252,256). However, it should be noted that an attempt at a larger statistical analysis failed to show an increased risk of arterial thrombotic complications with desmopressin use (258).

In clinical settings in which desmopressin is ineffective or contraindicated, patients need to be given exogenous replacement of vWF. The product of choice for vWF replacement is a commercial, heat-treated vWF/factor VIII concentrate that has been FDA licensed for use in vWD (Humate P, Centeon Pharma GmbH) (259). This vWF concentrate has a sufficiently high amount of large molecular weight vWF multimers to be therapeutic in vWD. Because this concentrate is heat treated, it has a reduced risk of viral transmission. This concentrate may be used for all forms of vWD.

Before the availability of the vWF/factor Vlll concentrate, cryoprecipitate in a dose of one unit per 10 kg of the patient's body mass every 12 to 24 hours was the standard vWF replacement therapy (260). It remains an option should the concentrate not be available. One unit of cryoprecipitate contains in a volume of 10 to 15 mL approximately 40% to 70% of the vWF present in the original unit of whole blood from which it was prepared. Thus, vWF in cryoprecipitate is concentrated approximately 20-fold compared with plasma. The disadvantage of cryoprecipitate as a source of vWF is its potential infectious risk. For this reason, the commercial vWF/factor Vlll concentrate is preferred over cryoprecipitate. Because of the presence of vWF in platelet α granules, platelet transfusion has been reported to shorten the bleeding times of patients with type 3 vWD (261,262). vWF from platelets is presumably released locally at sites of vascular injury when platelets undergo the release reaction. Because of the infectious risk of platelet transfusion and the unclear magnitude of its effect, platelets should not be considered a front-line treatment of vWD.

Acquired vWD is an immune disorder caused by autoantibodies to vWF (263). Because of the anti-vWF antibodies, the administration of vWF from exogenous sources or the stimulation of endogenous release with desmopressin may be ineffective or of transient benefit. Some therapeutic success in acquired vWD has been reported with high-dose intravenous immune globulin (264).

Hematopoietic Progenitor Cell Transplantation

Hematopoietic progenitor cell (HPC) transplantation, which involves ablation and reconstitution of the bone marrow with either autologous or allogeneic HPCs, is a transfusion-dependent procedure. The most commonly used sources of HPCs are bone marrow and peripheral blood. Umbilical cord blood is also being investigated as a potential source. Special transfusion needs exist both pre- and posttransplantation regardless of the HPC source. The three major considerations in HPC transplantation are (a) the avoidance of transfusion-transmitted CMV, particularly in CMV-seronegative recipients, (b) the prevention of HLA alloimmunization to avoid platelet refractoriness, and (c) the prevention of TA-GVHD while the patient is immunosuppressed.

Pretransplantation

The avoidance of CMV infection pretransplantation is necessary because reactivation of latent CMV infections posttransplantation is a cause of significant morbidity in HPC transplantation. Common manifestations of CMV infections after HPC transplantation include pneumonia, enteritis, hepatitis, and retinitis (265). Most serious posttransplantation infections occur as a result of reactivation of latent CMV in previously infected patients. If the patient is CMV seronegative pretransplantation, definite precautions should be taken to avoid transfusion-transmitted CMV regardless of the HPC donor's CMV serostatus (266). This is accomplished by transfusion of only CMV-reduced-risk blood components. CMV-reduced risk can be achieved by transfusing RBCs and platelets that are leukoreduced by filtration or that are obtained from CMV-seronegative donors (267,268 and 269). CMV is a leukocyte-associated virus that is transmitted via the passenger leukocytes in cellular blood components. Therefore, the use of leukoreduced blood components, defined as those containing less than 5×10^6 leukocytes per unit (40), significantly reduces the risk of transfusion-transmitted CMV (267). A large, randomized, prospective trial in the setting of allogeneic bone marrow transplantation comparing leukoreduced to CMV-seronegative blood components showed that the two approaches are similarly effective in significantly reducing, although not eliminating, CMV disease (267). FFP has not been reported to transmit CMV, perhaps because its leukocyte content is so low and possibly also because of the freeze-thaw cycle to which it is subjected. For this reason, plasma is not screened for CMV antibodies or further leukoreduced. For transplant candidates who already have a latent CMV infection, there may be a theoretical advantage of reducing the risk of infection with a second strain of CMV. Increasingly, the trend is to transfuse CMV-reduced-risk cellular blood components achieved through filter leukoreduction to all transplant candidates, regardless of CMV serostatus.

The pretransplant patient also should receive blood components that reduce the risk of HLA alloimmunization. Virtually all transplant regimens result in severe thrombocytopenia, requiring platelet transfusion support. If the patient is HLA alloimmunized, this may cause refractoriness to platelet transfusion and increase the risk of serious bleeding (185). In addition, HLA and leukocyte alloimmunization play a role in the etiology of febrile, non-hemolytic transfusion reactions. Avoiding unnecessary transfusion reactions spares the patient considerable discomfort and avoids the time and expense required in their investigation. HLA alloimmunization can be reduced, but not eliminated, by

transfusing RBCs and platelets that have been leukoreduced by filtration to less than 5×10^6 leukocytes per unit (23,185,187). Using leukoreduced, single-donor apheresis platelets appears to provide no additional benefit in preventing HLA alloimmunization when compared with leukoreduced, pooled-platelet concentrates (23). Ultraviolet B irradiation of platelet preparations, like leukoreduction, also appears to be effective in reducing HLA alloimmunization (23).
The routine gamma irradiation of all blood components to avoid TA-GVHD is not necessary before initiation of the myeloablation in allogeneic transplants if the patient is otherwise immunocompetent. However, in peripheral blood stem cell transplantation in which autologous HPCs are collected from the peripheral blood, there is a remote possibility that passenger lymphocytes in cellular blood components transfused precollection could be subsequently collected and cryopreserved during harvesting of the peripheral blood stem cells. These lymphocytes could theoretically mediate graft-versus-host disease on reinfusion with the stem cell product when the patient is severely immunosuppressed. Therefore, it is prudent to irradiate all cellular blood components pretransplantation before autologous peripheral blood stem cell transplantation (270). When the conditioning regimen begins, at which time the transplant recipient's immune system is suppressed, it is important to transfuse gamma-irradiated cellular blood components for all HPC transplants (271,272). Cellular blood components obtained from HLA-matched or genetically-related donors should be irradiated before transfusion regardless of the stage of the transplant regimen or immunocompetency of the recipient. To streamline administrative tracking of patients' transfusion needs and thereby reduce the risk of error, some transfusion services will irradiate all cellular components for pretransplantation transfusions even before myeloablation.

Because the availability of ABO compatible donors may be limited and HLA matching is of paramount importance in HPC transplantation, ABO-incompatible HPC infusion is sometimes unavoidable (273). The harvested HPCs, whatever their source, are accompanied by large numbers of RBCs. Therefore, the infusion of HPCs across ABO types requires special attention. The most important concern is massive hemolysis of the ABO-incompatible RBCs in the infused HPC product by the recipient's naturally-occurring ABO antibodies (274). Techniques that remove incompatible RBCs from the HPC source include simple buffy coat preparation, automated cell separating devices, and various forms of gradient centrifugation in sugar, starch, or gel media. Alternatively, the incompatible ABO antibody in the recipient's plasma can be reduced by serial plasmapheresis, followed by an intentional transfusion of ABO-incompatible RBCs to adsorb any remaining anti-A or anti-B. Severe hemolytic transfusion reactions may occur during this latter process. The severity of the reactions may be reduced by premedicating the patient and transfusing the incompatible RBCs slowly in small aliquots in a carefully controlled setting. This technique has largely been replaced by RBC removal methods.

Posttransplantation

After myeloablation and before engraftment, the patient is severely immunosuppressed. CMV-reduced-risk blood components must be provided, especially to CMV-negative recipients because of the severe adverse consequences of CMV infections (see pretransplantation discussion). Despite the immunosuppression, patients receiving multiple doses of platelets are capable of becoming refractory to platelet transfusion because of HLA alloimmunization; therefore, they should continue to receive leukocyte-reduced blood products. All blood components posttransplantation must be irradiated to avoid TA-GVHD (271,272). Because engraftment does not necessarily correspond with reconstitution of normal immunity and because it is unclear when the patient is no longer at risk for TA-GVHD, it is both prudent and practical to continue irradiating cellular blood components for the rest of these patients' lives. Such a policy should not be burdensome to the blood bank because a successful transplant should eliminate the need for future transfusions.

Before successful engraftment, the patient becomes profoundly thrombocytopenic, granulocytopenic, and, to a lesser degree, anemic. The times to successful engraftment for granulocytes, defined as the time to greater than 500 cells/μL for 2 consecutive days, vary from a low of approximately 8 to 10 days in autologous peripheral blood stem cell transplants to approximately 21 to 28 days in HLA-matched, unrelated transplants. Platelet production takes slightly longer to recover; therefore, platelets are the most frequently transfused product in the HPC transplant patient (275). Granulocyte transfusions are rarely necessary with currently available antibiotics to cover infections and granulocyte colony-stimulating factors to promote more rapid engraftment. The need for RBC transfusion compared with platelets is less, in part because RBCs turn over more slowly and also because RBC precursors are the first to return in the regenerating marrow. Nevertheless, because these patients may have some increased blood loss due to their severe thrombocytopenia and are frequently anemic before the transplant owing to various myelosuppressive chemotherapy regimens, some RBC transfusion can be anticipated.

The choice of ABO type of RBCs, platelets, and plasma for transfusion in the setting of ABO nonidentical transplants can be problematic (270,273). The challenge is to transfuse components simultaneously compatible with both the recipient's original and newly engrafted ABO types and to know when to convert to the ABO blood type of the transplant donor. The simplest approach is to transfuse type O RBCs, washed of their residual plasma, to all recipients. Similarly, it is simplest to transfuse AB plasma to avoid any minor incompatibility with either the patient's own original ABO-type RBCs or with the newly produced RBCs from the engrafted marrow. However, this approach is not always practical because sufficient quantities of these components may not always be available, and this may not be the best way to manage the blood component inventory. Table 72.9 presents a possible set of guidelines for the choice of ABO blood component types to transfuse during the engraftment phase of the transplant for different HPC donor and recipient ABO types.

TABLE 72.9. BLOOD TYPE SELECTION FOR ABO-INCOMPATIBLE HEMATOPOIETIC PROGENITOR CELL TRANSPLANTS

	Hematopoietic Progenitor Cell Donor ABO Type											
	O			A			B			AB

AB	O	AB	A	A	AB	A	B	AB	B	AB	AB	A or B

FFP, fresh frozen plasma; PLT, platelet.

Priority should be given to avoiding major incompatibility of transfused RBCs while significant recipient antibodies are still present in the patient's blood capable of mediating hemolysis. Components containing significant amounts of plasma, such as platelets or FFP, ideally should be compatible with both the HPC donor and the recipient's original ABO type in the immediate

posttransplant phase. However, clinical experience with “out of group” platelet transfusions indicates that transfusing a limited volume of products with minor incompatibility (i.e., passive administration of anti-A or -B) generally does not cause harm to the patient (276,277). Despite efforts to minimize the risks of ABO-incompatible HPC transplants, some hazards still exist. For example, recipients of ABO minor incompatible transplants (e.g., O HPC donor and A recipient) may hemolyze their native erythrocytes after rapid proliferation of donor lymphocytes capable of producing the hemolytic anti-A or -B isohemagglutinins (278,279). In addition, in ABO major incompatible transplants (e.g., A HPC donor and O recipient), the patient's original ABO isohemagglutinins may cause a shortened lifespan of newly produced donor-type RBCs (278,279). When the anti-donor isohemagglutinins are no longer detectable, it is safe to administer the donor-type blood components. Rh-positive recipients with Rh-negative donors should receive Rh-negative products. Rh-negative recipients with Rh-positive donors should receive Rh-positive products, unless they have a preexisting anti-D. They should receive Rh-negative RBCs until anti-D becomes undetectable and Rh-positive RBCs are compatible by crossmatch.

ADMINISTRATION OF BLOOD COMPONENTS

Part of "72 - Transfusion Therapy"

Informed Consent

Patients should be given the opportunity to accept or reject transfusion therapy and need to be given the information necessary to make an informed choice (280,281). The Joint Commission on Accreditation of Healthcare Organizations has required informed consent for blood transfusion since 1996. The purpose of the informed consent is to initiate a discussion of the need for transfusion between the health care provider and the patient and to provide the patient with information about the risks, benefits, and alternatives to transfusion. It is important for the patient's physician to document that informed consent has been given or denied. Consent for transfusion may be included in a general consent for all invasive procedures or as a dedicated consent form just for transfusion. Documentation also may be in the form of a note in the patient's medical record. The person gaining consent must have a thorough knowledge of the risks and benefits of transfusion (282).

Recent reviews are generally available that summarize the incidences of some common risks of transfusion (283) (Table 72.10).

TABLE 72.10. RISKS OF BLOOD TRANSFUSION

Risk Factor	Estimated Frequency		No. of Deaths Per Million Units
	Per Million Units	Per Actual Unit	
Infection			
Viral			
Hepatitis A	1	1/1,000,000	0
Hepatitis B	7–32	1/30,000–1/250,000	0–0.14
Hepatitis C	4–36	1/30,000–1/150,000	0.5–17
HIV	0.4–5	1/200,000–1/2,000,000	0.5–5
HTLV types I and II	0.5–4	1/250,000–1/2,000,000	0
Parvovirus B19	100	1/10,000	0
Bacterial contamination			
Red cells	2	1/500,000	0.1–0.25
Platelets	83	1/12,000	21
Acute hemolytic reactions	1–4	1/250,000–1/1,000,000	0.67
Delayed hemolytic reactions	1,000	1/1,000	0.4
Transfusion-related acute lung injury	200	1/5,000	0.2

HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus.
From Goodnough LT, Brecher ME, Kanter MH, et al. Transfusion medicine (first of two parts), Blood transfusion. *N Engl J Med* 1999;340:438–447, with permission.

Because of the publicity surrounding AIDS transmission by transfusion at the start of the AIDS epidemic, a major concern of the general public is the possibility of viral transmission. However, the incidence of some other adverse effects, such as septic, allergic and febrile reactions, are higher. The benefits of RBC transfusion include the reversal of the signs, symptoms, and sequelae of anemia (inadequate oxygen-carrying capacity) and the prevention of organ ischemia. The benefit of platelet transfusion is the treatment or prevention of hemorrhage owing to thrombocytopenia or thrombocytopathy. The use of plasma, cryoprecipitate, and plasma derivatives benefits patients with coagulopathy. The use of these products should be reserved for instances in which there is no drug or coagulation factor concentrate available as an alternative. Some coagulation factors are now available that have been produced by recombinant methods or have been treated to reduce the risk of disease transmission, e.g., heat-treated or SD-treated. Health care providers should not hesitate to contact the medical director of the blood bank or the pharmacy staff for information if they have questions about the availability of virus-attenuated or pharmacologic products.

Physician's Order for Transfusion

The initiation of a blood transfusion must begin with a physician's order. Transfusion orders must be made by prescription. The ordering physician is responsible for indicating the quantity and any requested special modifications of the product (e.g., leukocyte–reduced, CMV-seronegative, irradiated, volume–reduced). In addition, the ordering physician should indicate on the chart the rate of transfusion and any premedication that should be given to the patient before transfusion. Although the ultimate responsibility for the appropriateness of a transfusion order rests with the physician who is caring for the patient, there are at least two other checks on the suitability of the transfusion in the hospital setting. First, the transfusion service and blood usage committee should monitor transfusion requests for conformance to acceptable standards. Second, the nursing staff who administer most transfusions are responsible for notifying the ordering physician of any problems that they identify regarding the transfusion.

The order for blood must contain unambiguous patient identification, e.g., patient name and a unique numeric or alphanumeric identifier. The request must be accompanied by a current sample of blood from the intended recipient. The sample must be obtained within 3 days of the intended transfusion if the patient has been transfused or pregnant within the past 3 months or if the transfusion history is unknown or unreliable. Otherwise, the sample may be obtained more than 3 days in advance. If the patient has an alloantibody to RBCs, an extension beyond 3 days should not apply.

The accurate identification and labeling of the patient sample is of critical importance in ensuring a compatible transfusion. A recent report indicated that 14% of blood transfusions administered to an unintended recipient result from errors in phlebotomy or sample identification (94). For this reason, the sample must be labeled or the label must be verified at the patient's bedside. The phlebotomist must be identified, and for that reason, the signature of the phlebotomist is often required on the specimen label. Mislabeled blood samples are 40 times more likely to have a blood group discrepancy than correctly labeled blood (284). Transfusion services must have a stringent policy for rejecting mislabeled specimens, in order to protect against such errors.

Identifying the Intended Recipient

Release of a blood component from the transfusion service should require written or electronic documentation of the request for a particular blood component for a specific patient. The American Association of Blood Banks standards require that all blood components for transfusion have a tag or label attached that has the patient's two identifiers, the donor unit number, and the compatibility test results (40). In addition, the blood component must be inspected by transfusion service personnel for any irregularities, such as the presence of clots or discoloration, before it is issued. When blood is issued, care must be taken to ensure that the blood is being transfused to the correct recipient. Transfusion to the wrong recipient is the single most common cause of mortality resulting from incompatible blood transfusions (94). It is good practice for the blood bank to limit the number of blood products released at a time to a given patient, if possible, to reduce the risk and minimize the impact of misidentification errors.

The American Association of Blood Banks standards dictate that that all information “identifying the container” be matched with the patient information in the presence of the patient (40). Most institutions require that identifying information be independently verified by two persons, often referred to as readers or verifiers. One reads the patient wristband identifying the patient and the other reads the information on the blood component container. They must ensure that the intended recipient corresponds to the patient's identification. Patient identification should never rely solely on a patient's name. Moreover, although it is appropriate to ask the patient to identify him/herself, this is not sufficient identification in itself because the patient or transfusionist may misunderstand or make a misstatement. Other methods of ensuring that only the intended recipient receives the transfusion include commercial mechanical barriers (285,286). The use of mechanical barriers requires that a code be entered into a blood administration device that connects to the blood product tubing. Because mechanical barriers can be relatively expensive, easily subverted, or cumbersome, their acceptance and use remain limited at this time. Another possible system for matching the component with the intended recipient involves bar-code reading and matching by the central hospital computer of a barcoded component tag and a bar-coded patient identification bracelet (285,287). Unfortunately, no system is foolproof. All systems require careful attention and rigorous adherence to established procedures.

Intravenous Access and Compatible Intravenous Solutions

Blood and blood products are given intravenously with rare exceptions. The exceptions are intraosseous blood transfusion for emergent transfusions in pediatric patients with no other available access (288) and intraperitoneal transfusion of fetuses *in*

utero. The choice of intravenous site is usually one of convenience and has little bearing on the efficacy of transfusion if good flow rates can be maintained. Large bore intravenous access devices, e.g., 19-gauge or larger catheters or needles, are recommended to allow rapid infusion, if necessary. Smaller intravenous access devices can be used without danger of hemolysis, but flow rates will be substantially lower. Improved flow rates can be achieved if RBCs are diluted with normal saline (289,290). However, this is usually not necessary with additive-solution RBCs because the additive solution itself serves as a diluent.

Generally, only normal (0.9%) saline should be added to blood components during infusion (40). Glucose solutions should not be used because the sugar passes through the cell membrane, making the inside of the cell hyperosmotic. When these hyperosmotic units of blood are transfused, water enters the cell to restore osmotic balance. The RBCs swell in response to the influx of water and may hemolyze. Gross clumping of RBCs also may occur in the administration set when RBCs are mixed with glucose solutions (291). Calcium-containing electrolyte solutions such as lactated Ringers' solution, which contains 3 mEq/L of calcium should not be used to dilute units of RBCs. The calcium may exceed the chelating capacity of the citrate anticoagulant in the blood component, thereby promoting clot formation. Glucose- and calcium-containing solutions also should not be coadministered with blood components for the same reasons. Medications should not be added to a unit of blood component for several reasons. If the patient should experience an adverse reaction, it may be difficult to ascertain what caused the reaction, the blood or the medication. In addition, if the transfusion needs to be halted for any reason, such as for a transfusion reaction, the patient will not receive the full dose of the medication. Finally, information regarding the compatibility of most medications with stored blood components is not readily available.

Blood Filters

Blood filters are a required part of all blood administration sets. There are three general categories of blood filters: (a) standard blood filter, (b) microaggregate filter, and (c) LRFs (47,292). The standard blood filter is a 170- to 260-μm screen that is used to remove blood clots and large aggregates of cellular debris that form in blood components during storage. A standard blood filter is required for all transfusions unless another specialty filter is used instead. Microaggregate filters, conversely, have a smaller effective pore size of 20 to 40 μm. Filters with this sieving capacity can remove microaggregates, i.e., small clumps of degenerating leukocytes, platelets, and fibrin strands that form in cellular blood components after several days of storage. Microaggregates pass through standard blood filters. Microaggregate filters were popularized during the 1960s and 1970s for use in the settings of open-heart surgery and massive transfusion (293). Microaggregate debris from large-volume blood transfusions was believed to occlude end-organ capillaries and contribute to cerebral and renal dysfunction after open-heart surgery and respiratory distress after massive transfusion (293,294,295 and 296). However, later studies showed that microaggregate debris from transfusion was unlikely to be a significant contributor to those capillary occlusion syndromes (297). Because microaggregate filters can remove 80% to 95% of leukocytes from a unit of RBCs, they have also been used for the purpose of decreasing FNHTRs (298,299 and 300). However, the increasing use of more efficient LRFs (see below) has largely eliminated this application of microaggregate filters. Microaggregate filters are still used to filter salvaged autologous blood before reinfusion and for in-line filtration of extracorporal blood during CPB.

The leukocytes in units of RBC and platelet concentrates play key roles in mediating febrile transfusion reactions, HLA alloimmunization, and CMV transmission (301). Leukocyte reduction accordingly reduces the risks of these adverse effects of transfusion. LRFs were developed to selectively remove leukocytes from units of blood components (302). They work on a principle of selective adsorption of leukocytes to the filter media. They also function as clot screens owing to the mesh created by the fibers. These filters can remove 3 logs, i.e., 99.9%, or more of leukocytes from units of cellular blood components. Blood components can be leukoreduced by filtration either prestorage during component production or at the bedside during infusion. Prestorage leukocyte-reduced blood components must still be administered with the standard 170- to 260-μm filter because clots and other aggregates might still form after filtration during subsequent storage. It is critically important that filtration be done properly because filters may clog, leak, or otherwise fail to perform. Prestorage leukoreduction in the donor center or transfusion service is advantageous because more rigorous quality control can be exercised there than at the bedside. Also, platelet concentrates that have been leukocyte-reduced before storage are expected to stimulate fewer febrile transfusion reactions. This is a result of the reduction in release of leukocyte-derived cytokines during blood component storage owing to the early removal of the leukocyte source (303,304).

For a blood product to be labeled as leukoreduced, it must contain no more than 5×10^6 residual leukocytes (40). The effectiveness of this level of leukoreduction in preventing HLA alloimmunization to platelet transfusion has been convincingly demonstrated in a recent large trial, as well as several earlier studies (23,185). In addition, a large, randomized, prospective trial of 502 allogeneic bone marrow transplant patients showed that leukoreduction filtration is an effective alternative to providing CMV-seronegative blood components for the prevention of CMV disease (267). However, neither approach is fail-safe because both leukocyte-reduction by filtration and selecting CMV-seronegative donors still permits as high as a 5% to 7% CMV infection rate from transfusion. Poststorage removal of leukocytes from units of RBCs and platelet concentrates with bedside leukoreduction filtration has not decreased FNHTRs to the extent expected by many transfusion specialists based on the level of leukocyte removal now possible. Some studies documented a decrease in FNHTRs (305,306 and 307), whereas others have not (23,308). The failures appear to be due at least in part to the inability of bedside leukoreduction to remove or prevent the accumulation of pyrogenic cytokines that are released from passenger leukocytes during storage of platelet preparations. Prestorage leukoreduction of platelets is expected to be more successful (303,304). It is important to note that LRFs cannot be used

interchangeably for filtering both RBCs and platelets. LRFs are designed specifically for RBC or platelet leukoreduction; some RBC leukoreduction filters may remove large numbers of platelets.

Another possible benefit of leukoreduction is the reduction or prevention of transmission of variant Creutzfeldt-Jakob disease (vCJD) (309). Although there is no evidence that vCJD has actually been transmitted in humans by blood transfusion, experimental studies in laboratory rodents have shown that transfusion-associated transmission is possible, particularly with buffy-coat, i.e., leukocyte-enriched, fractions (310,311). Because leukocytes, in particular B lymphocytes, are suspected potential carriers of vCJD, leukocyte-reduction may decrease the risk, if any, of transfusion-transmitted CJD.

LRFs should not be used for the prevention of TA-GVHD. TA-GVHD is mediated by passenger leukocytes, specifically T lymphocytes. However, it is unclear how many T lymphocytes are necessary to mediate TA-GVHD or whether LRFs are effective in reducing T-lymphocyte levels sufficiently to prevent TA-GVHD. Prophylaxis of TA-GVHD should instead be achieved through gamma irradiation of cellular blood components, which eliminates the proliferative potential of transfused lymphocytes (271,272). The dose of radiation should be at least 24 Gy delivered to the midplane of the canister or radiation field where the components are placed. The minimal dose at any part of the blood component should be 15 Gy (40).

Rate of Transfusion and Blood Pumps

The rate at which blood components should be administered is dictated by several factors, including the urgency of the clinical setting, the patient's tolerance of added intravascular volume, and regulatory time limits after some manipulations of blood components (e.g., thawing, pooling, removal from refrigeration). Although rapid administration of blood components may be lifesaving in emergent situations, it also leads to several unfavorable outcomes (e.g., increases in allergic transfusion reactions, febrile transfusion reactions, volume overload, hypothermia). In massive transfusion, cardiac arrhythmias have been reported to occur from transfusion of refrigerated blood at rates exceeding 100 mL/min (74,75,76 and 77). A typical and usually well-tolerated rate of transfusion in patients who are not experiencing congestive heart failure is one unit of RBC in 1 to 2 hours. The infusion should start slowly at a rate of approximately 25 to 50 mL over the first 15 minutes while the patient is closely observed for possible transfusion reactions. In patients with cardiac compromise, the infusion rate must be slowed to avoid volume overload, and the patient may need to be treated with diuretics. In addition, units of RBC can be divided into split units, i.e., half units, that can each be transfused slowly over as long as 4 hours each. The other half of a split unit may be transfused as long as 24 hours later as long as it is stored at 1° to 6°C in a blood bank–monitored refridgerator.

Blood components released from the transfusion service should be administered as soon as possible and within 4 hours of release from the transfusion service owing to the possibility of significant bacterial growth at room temperature. RBCs must not be allowed to warm up to more than 10°C if they are not transfused. When a unit of blood has been warmed to above 10°C, it must be transfused within 4 hours or else discarded because of the increased risk of bacterial growth in the unit (40). Temperature sensors are available to attach directly to RBC units to verify that 10°C has not been exceeded. Alternatively, restrictions may be placed on how long a unit may be kept unrefrigerated after release from the transfusion service. In general, the units should be refrigerated or returned to the transfusion service within 30 minutes, if not transfused (312). Platelet concentrates, whose sterility is broken when they are pooled, must be transfused within 4 hours of pooling because of concerns over bacterial growth (40).

Most transfusions flow at an acceptable rate by the force of gravity alone. In some situations, it may be desirable to control more precisely the rate of infusion with an infusion pump (313). For example, maintaining a precise, slow rate may be important for small-volume pediatric transfusions or for adults at high risk of adverse effects of transfusion, such as hypervolemia. When using electromechanical pumps for RBC transfusion, hemolysis is a consideration. It is essential to verify with the manufacturer that the pump has been tested and found safe for infusing RBCs with minimal hemolysis. Similar verification is prudent for use of pumps for other blood components as well (314,315).

Monitoring the Transfusion

Baseline vital signs should be obtained before transfusion. Appropriate documentation, including the type of component, the volume desired, the duration of transfusion, and the infusion rate, should be included in a progress or procedure note in the patient's chart. Use of any blood warmers or filters should also be appropriately documented in the chart. The patient should be observed closely throughout the transfusion. Symptoms of a severe hemolytic transfusion reaction often manifest themselves within the first 15 minutes of a transfusion. Thus, it is advisable to remain with the patient at the beginning of a transfusion. The patient's vital signs should be monitored at various times during the transfusion. In a typical hospital protocol, vital signs are taken pretransfusion, then at 15 minutes into the transfusion, and hourly thereafter. After the transfusion is completed, the patient should be tested to ensure that the transfusion outcome was appropriate and as expected. For example, a platelet count should be measured 10 minutes to 4 hours after a platelet transfusion to ensure that the patient responded to a platelet transfusion, a hematocrit should be measured after a RBC transfusion, and appropriate coagulation testing should be done after a plasma transfusion. Vital signs should be monitored for several hours after transfusion to rule out a late-developing reaction.

Blood Warming

Blood warming is not necessary for most nonemergent transfusions because the rapid transfusion of cold RBCs or plasma is unnecessary for most patients. Conversely, the urgent and massive transfusion of cold (1° to 10°C) blood at a rate of one unit every 5 to 10 minutes has been associated with the development of hypothermia, decreased sinoatrial node temperature, and ventricular fibrillation (74,75,76 and 77). Warming of cold units of RBCs can avoid these cardiovascular complications. The indications for

warming RBC units include rapid transfusion, which can be defined as more than 50 mL/kg/h in adults and more than 15 mL/kg/h in children, particularly if through a central venous catheter, and exchange transfusions in infants (292). Blood warming may also be indicated for the transfusion of RBCs in patients with pathologic cold agglutinins. Warming should only be attempted with devices that are FDA approved for transfusion applications. Blood components can be warmed in several ways (78,292,313). The simplest method is to immerse the entire bag in warm water in a thermostatically controlled water bath. It is recommended that the temperature of warmed blood components not be allowed to exceed 42°C with this or any other warming technique to avoid the possibility of hemolysis (40). Microwave warmers are available for heating plasma. Because they cause focal overheating, which can induce hemolysis in units of RBCs, they are not used for warming RBCs (316,317). Microwave devices rotate the plasma to prevent excessive heating in any one part of the bag. An additional technique for warming RBCs is rapid admixture with heated saline (78,79). This has the advantage of being one of the fastest methods and also simultaneously reduces the viscosity of RBCs, allowing rapid infusion. Admixture with heated saline has been used in the trauma setting where rapid infusion rates are necessary to treat massive hemorrhage. Other warming devices include dry heating blocks with electric warming plates and countercurrent heat exchangers, in which the heated water is rapidly circulated through water jackets surrounding the flowing RBCs (318). All these devices need to be properly quality controlled at regular intervals and monitored to ensure maintenance of the proper temperature. They should have visible thermometers and audible alarms to warn of excessive temperature (greater than 42°C). Despite the availability of warming methods, the routine use of blood warming generally should be avoided because (a) there is a risk of hemolysis when RBC units are warmed improperly, (b) warming adds expense and often time to the transfusion process, (c) warming adds a step that requires quality control monitoring, and (d) warming provides no clinical benefit for most patients.

Out-of-Hospital Transfusion

The delivery of medical care has increasingly shifted from the hospital inpatient setting to an outpatient or ambulatory setting for reasons related to cost and customer service. As part of the ambulatory care movement, transfusions are increasingly being administered in nonhospital settings, such as patients' homes, physicians' offices, convalescent homes, and freestanding outpatient surgical or hemodialysis centers (319,320 and 321). Of the various out-of-hospital settings, the patient's home offers the greatest challenges and risks because of the absence of emergency medical care facilities and staff that may be needed for the treatment of acute transfusion reactions. Nevertheless, many patients have benefited from home transfusion. Elderly patients who lack transportation and are in stable condition are potential candidates, as are some children who find the hospital setting to be stressful and intimidating. Chronically anemic patients, thrombocytopenic oncology patients, or pediatric oncology patients are among those most commonly receiving home transfusion. However, home transfusion should not be performed just for convenience. There should be a sound medical or logistical reason for performing a transfusion in the home, and that reason should outweigh the risk of a serious transfusion reaction in a setting where necessary treatment may not be immediately available. Most patients who are fully ambulatory and can travel to the hospital for transfusion should do so.

The local state laws regarding the infusion of medications by nonphysicians must be checked before initiating a home transfusion program to assure that the planned program is in compliance with local laws. Transfusions in a nontraditional setting should follow the same basic principles and practices as transfusions in the hospital. Standard operating procedures outlining all procedures of the home transfusion must be written and followed. The training requirements of the transfusionist must be established and met (322). Not only should the transfusionists be trained and experienced in administering blood components, but they also should be trained in emergency procedures, including CPR. The blood samples for typing, screening, and cross matching must be appropriately labeled, and a procedure must be in place and followed to appropriately identify the patient and blood component before transfusion. The procedure for transportation of the blood components to the transfusion site must assure that the component bags are protected and maintained within an acceptable temperature range (1° to 6°C for RBCs and 20° to 24°C for platelets) in appropriately insulated containers. A mechanism for verifying that the temperature of the components remains within acceptable limits during shipment to the transfusion site either with a thermometer or other temperature sensor should be in place. A limit to the number of units of blood component administered during home transfusion should be established, such as no more than two units of RBCs or one pool of platelets per day per patient. This will help limit the risk of adverse reactions. In addition, the disposal of waste material, such as sharps and blood-soaked gauze and needles, needs to be planned to ensure compliance with all appropriate safety codes. Quality assurance monitoring should be established for home transfusion to assure that appropriate procedures are followed during all steps of the process, the patient's needs are being met, and patient safety is being preserved.

The home must have suitable space for the patient to receive the transfusion, along with space for the transfusionist to set up a working area (321). The home must have a working telephone for possible use in obtaining emergency assistance. Physician backup, either in an office or emergency department, must be immediately available by phone. The provider should never be alone in the house with the patient; at least one other responsible and physically and mentally competent adult should be present in the home who can speak English. This allows the provider to take care of the patient while the other individual is available to call for help, if necessary. It is important that the blood product(s) be infused at an appropriate rate, i.e., within regulatory requirements (see above), but not too rapidly, to decrease the risks of transfusion reactions. Serious consideration should be given to using only prestorage leukocyte-reduced blood components to decrease the risk of febrile reactions. An adult should stay with the patient, ideally for at least several hours, after the transfusion to obtain help in case the patient suffers a late-developing transfusion reaction. Blood specimens for

relevant posttransfusion laboratory tests should be drawn at an appropriate interval after transfusion to ensure that the patient has responded as expected to the transfusion. Failure of the hematocrit to increase as expected could indicate the possibility of an overlooked RBC antibody mediating a hemolytic reaction or of some other cause of a worsening anemia that needs further treatment or additional transfusion. Failure to obtain an expected platelet count increment could indicate platelet refractoriness or ongoing consumption that needs further workup. With appropriate patient monitoring and when meticulous attention is paid to establishing and following appropriate standard operating procedures, home blood transfusion has proven to be a generally safe medical practice.

Neonatal Transfusion

Jayashree Ramasethu

Naomi L. C. Luban

Transfusion support of the neonatal population requires an understanding of the dynamic interactions of the feto-maternal unit and the physiologic changes that accompany the transition from fetus to neonate and neonate to infant. The small blood volume, immunological immaturity, and compromised organ function resulting from either prematurity, illness, or both, provide little room for error, and unique challenges to the transfusion medicine specialist. Survivors of neonatal intensive care are more likely to suffer the long-term consequences of transfusions, unlike adults who, because of underlying disease, have a posttransfusion mortality of 24% within 1 year of transfusion and 52% within 10 years (1). Blood products utilized in neonates include packed red blood cells (RBC), platelet concentrates, granulocyte concentrates, fresh frozen plasma (FFP) and cryoprecipitate. These products may be transfused as simple small volume transfusions or as part of exchange transfusions (ETs). The indications, requirements, and transfusion techniques differ for each procedure and component (Table 73.1). Most infants who weigh less than 1,000 g at birth receive one or more RBC transfusions, especially in the first few weeks of life (2). Intensive blood bank support is necessary for neonates undergoing extracorporeal membrane oxygenation (ECMO) and cardiopulmonary bypass. Perioperative blood loss and blood product requirement, particularly for platelet concentrates and FFP, is disproportionately greater for neonates following open-heart surgery, than for any other age group (3, 4).

TABLE 73.1. FORMULA FOR TRANSFUSION OF RED CELL PRODUCTS

I. Blood Volumes
Preterm [all equal to] 100–120 ml/kg
Full Term [all equal to] 80–85 ml/kg
Adult [all equal to] 70–75 ml/kg

II. Calculation of volume of packed red blood cell (RBC) transfusion

$$\text{PRBC volume} = \frac{\text{EBV} \times (\text{Hct desired} - \text{Hct observed})}{\text{Hct of packed red-cell unit}}$$

$$\text{EBV} = \text{estimated patients blood volume}$$

III. Calculation of blood needed for exchange transfusion

Severe anemia Exchange volume of PRBC

$$= \frac{\text{EBV} \times \text{desired Hb rise}}{\text{Hb of PRBC} - \text{Hbw}}$$

$$\text{Hbw} = (\text{initial Hb} + \text{desired Hb}) / 2$$

Polycythemia Exchange volume of plasma / 5% albumin /saline

$$= \frac{\text{EBV} \times \text{desired Hct change}}{\text{starting Hct}}$$

IV. Formula for reconstitution of blood to a specific hematocrit for exchange transfusion

$$\text{Volume of packed cells} = \frac{\text{total exchange volume}}{\text{Hct of PRBC}} \times \text{desired Hct of new unit}$$

$$\text{Volume of FFP} = \text{total exchange volume} - \text{volume of packed cells}$$

SMALL VOLUME RED BLOOD CELL TRANSFUSIONS

Hemoglobin concentrations decrease in all newborn infants in the weeks after birth, reaching a nadir of 9.5 to 11 g/dL at 10 to 12 weeks of age in healthy term infants; this phenomenon is termed physiological anemia of infancy. In addition, anemia in the neonatal period may be secondary to blood loss, hemolysis, or impaired production of RBCs (Table 73.2). In preterm infants, an exaggeration of physiological anemia, called anemia of prematurity, results in an earlier and more pronounced decline in hemoglobin levels, which drop as low as 7 g/dL by 4 to 8 weeks of age (5). Anemia of prematurity occurs despite adequate numbers of erythroid progenitors, primarily because of delayed and diminished production of erythropoietin, combined with rapid postnatal expansion of plasma volume and decreased RBC survival. In sick newborn infants requiring intensive care, frequent blood sampling for laboratory tests and monitoring of blood gases overwhelms compensatory mechanisms, resulting in significant iatrogenic anemia, which increases the need for transfusions (6, 7).

In the 1980s, 80% of very low birth weight (VLBW, birth weight ≤1,500 g) infants received multiple transfusions, often from different donors (8). Over the last decade, a concerted effort has been under way to minimize the potential risks of transfusions by reducing the number of transfusions and donor exposures. A retrospective study of transfusion practices in VLBW infants admitted to one tertiary level nursery found that the mean number of transfusions per infant declined from seven in 1982, to five in 1989, to 2.3 in 1993, prior to the use of recombinant erythropoietin (2). Improvements in clinical care, laboratory micromethods, noninvasive monitoring techniques, and the adoption of conservative transfusion guidelines all have played a role in decreasing transfusions. Portable clinical analyzers that use only a fraction of the quantity of blood required for standard micromethods significantly reduce iatrogenic blood loss (9).

Sampling losses and therefore transfusion requirements may be related to the degree of prematurity and severity of illness (10). However, even when adjusted for these factors, considerable variation in transfusion practice is found in different centers, with a significant impact on the number and volume of RBC transfusions, suggesting that the utilization of small volume RBC transfusions often is discretionary (11,12 and 13).

The hemoglobin levels at which blood transfusion would be indicated and the definition of “nonphysiologic” versus “physiologic anemia” in preterm neonates is fraught with controversy. Tissue oxygen delivery is determined not only by the hemoglobin concentration, but also by the proportion of fetal to adult hemoglobin, level of RBC 2,3-diphosphoglycerate (2,3 DPG), cardiac output, and arterial oxygen tension. Fetal hemoglobin, the predominant hemoglobin at birth, has the characteristic of high oxygen affinity making it ideal for uteroplacental oxygen transport to the fetus, but its poor peripheral oxygen unloading may decrease oxygen availability to the hypoxic neonate. The physiological indicators of significant anemia include compensatory responses such as tachypnea and tachycardia, and the consequences of impaired oxygen transport manifested by poor growth, periodic breathing or apnea, decreased

activity, lethargy, poor feeding, inadequate reserve to respond to a stressor associated with increased oxygen demand, and anaerobic metabolism resulting in lactic acidosis (14). However, many of these symptoms are nonspecific and do not correlate well to hemoglobin levels or respond consistently to RBC transfusions (15).

The ability to summarize clear-cut indications for the simple transfusion of infants is hampered by the paucity of adequate randomized clinical studies and lack of acceptable laboratory parameters. Reevaluation of commonly accepted indications and the absence of clear evidence of benefit of RBC transfusions in certain situations has led to the generation of increasingly stringent, although largely empirically derived guidelines (Table 73.3) (16,17,18 and 19). The U.S. Multicenter Recombinant Human Erythropoietin trial conducted between 1991 and 1993 demonstrated that there was no adverse consequence of conservative transfusion practices in VLBW infants, including those on moderate ventilatory support or supplementary oxygen (16). However, infants with severe cardiorespiratory compromise were excluded from the trial. Definitions of significant apnea necessitating transfusion, the hematocrit levels at which transfusion is indicated for infants needing significant support for cardiorespiratory failure, and the requirement for replacing iatrogenic blood loss differ between published guidelines. Guidelines published by British authorities suggest consideration of RBC transfusions for asymptomatic newborns with hemoglobin levels less than 10.5 g/dL and support the replacement of phlebotomy losses by blood transfusion (19).

TABLE 73.2. ETIOLOGY OF ANEMIA IN THE NEONATE

Blood Loss

- Obstetric causes: abruptio placentae, placenta previa, rupture of vasa previa, incision of placenta at C section
- Feto-maternal hemorrhage
- Twin-to-twin transfusion
- Neonatal bleeding: massive subgaleal or intracranial hemorrhage, rupture of liver or spleen, gastrointestinal hemorrhage
- Phlebotomy

Impaired RBC Production

- Anemia of prematurity
- Congenital infections- Parvovirus B19, CMV, Rubella, Syphilis
- Diamond-Blackfan syndrome
- Congenital leukaemia
- Osteopetrosis

Hemolysis

- Immune hemolysis: Rh, ABO, Kell, Duffy etc., maternal lupus
- Hereditary RBC membrane defects: spherocytosis, elliptocytosis
- Hereditary RBC enzyme defects: G-6-PD, pyruvate kinase deficiency
- Hemoglobinopathies: alpha thalassemia syndromes
- Acquired hemolysis: DIC, sepsis
- Macro- or microangiopathic anemia: cavernous hemangioma, large vessel thrombi
- Vitamin E deficiency

TABLE 73.3. GUIDELINES FOR RED BLOOD CELL TRANSFUSIONS IN NEONATES

	US rHuEPO[16]	CAP[17]
Asymptomatic	Hct ≤ 20% retics <100,000/μL	Hct ≤ 20% retics <100,000/μL
Weight gain <10 g/day while receiving ≥100 kcal/kg/day	Hct ≤ 30%	Hct ≤ 25%
Significant apnea or bradycardia	Hct ≤ 30%	Hct ≤ 25%
Tachypnea or tachycardia	Hct ≤ 30%	Hct ≤ 25%
<35% hood oxygen	Hct ≤ 30%	Hct ≤ 25%
CPAP/IMV with Paw <6 cms H_2O		
>35% hood oxygen	Hct ≤ 35%	Hct ≤ 30%
CPAP/IMV with Paw ≥ 6–8 cms H_2O	Hct ≤ 35%	Hct ≤ 30%
IMV with Paw > 8 cms H_2O	not in trial	Hct ≤ 35%
Severe congenital heart disease	not in trial	Hct ≤ 35%
Surgery	Hct ≤ 30%	No recommendation
Phlebotomy loss alone	No transfusion	No transfusion

CPAP, continuous positive airway pressure; IMV, intermittent mechanical ventilation; Paw, mean airway pressure; Hct, hematocrit; Retic, absolute reticulocyte count.

Pretransfusion Testing

ABO groups and Rh types should be determined on samples obtained from both mother and baby. Cord blood may be used for initial testing. The baby's blood group is determined from the red cells alone because the corresponding isoagglutinins anti-A and anti-B in the serum usually are weak or absent (20). Maternal serum should be screened for the presence of atypical antibodies. If maternal blood is unavailable, the neonatal sample should be screened to exclude atypical antibodies. A conventional crossmatch is unnecessary if there are no atypical antibodies demonstrable. Because the formation of alloantibodies in the first 4 months of life is extremely rare, further compatibility testing for repeated small-volume transfusions can be omitted. Compatible blood may be low anti-A, B titer Group O Rh-negative blood or blood of the infant's ABO group and Rh type. If the antibody screen is positive, serological investigation to identify the antibody(ies) is necessary. Full compatibility testing is performed with blood selected to be negative for the antigens to which the antibody is directed.

Anticoagulant-Preservative Solutions

RBCs are stored in one of several anticoagulant-preservative (A-P) solutions to improve red-cell viability and extend storage for up to 42 days. The preservative solutions produce an increase in intraerythrocytic ATP, which is reflected in maintenance of red-cell membrane integrity and contributes to improved *in vivo* survival. The hematocrit of the RBCs in preservative solutions is approximately 60%, producing a less viscous product with a faster flow rate than standard packed RBCs, which usually have a hematocrit of 75 ± 5%. However, the osmotic load from the glucose, and the presence of high concentrations of mannitol and sodium in A-P solutions have raised questions about metabolic and physiologic effects in neonates (21).

Several studies have addressed the use of additive solutions in small-volume transfusions in neonates (22,23,24 and 25). In a randomized, controlled trial in 29 neonates, Strauss et al. (23) found no

significant differences in serum potassium, sodium, or osmolality in neonates transfused ADSOL (Fenwal Division, Baxter Healthcare Corp., Deerfield, IL) units stored to outdate, as compared to neonates transfused with CPDA1 units less than 7 days old. The ADSOL units were packed to remove additive with a resultant hematocrit of 85% to 87%; 47% of the 124 ADSOL transfusions were more than 14 days old. Weekly analysis of infant 2,3 DPG concentrations demonstrated similar levels in infants transfused with either CPDA1 or ADSOL. Goodstein et al. (24) studied 12 premature infants (BW <1,250 g), each of whom received 17 mL/kg transfusions of ADSOL preserved blood packed to a hematocrit of 63%. A battery of pre- and posttransfusion tests revealed no clinically relevant biochemical abnormalities, although increases in ammonia and LDH levels were noted, as well as small decreases in bicarbonate concentration, despite maintenance of pH.

For massive transfusions such as ECMO, ET, or cardiopulmonary bypass, the safety and efficacy of additive solutions have not been studied with the same scrutiny. Measurements of the various constituents of additives in packed cells stored in CPDA1, CP2D, and AS-3 over time have been published recently (26). Theoretical calculations, based on the constituents of the additives, indicate that hyperosmolality, hyperglycemia, hypernatremia, hyperkalemia, and hyperphosphatemia are likely to occur with massive transfusions in neonates (21, 26). Given the risk of toxicity, RBCs stored in additive solutions should be avoided for massive transfusions, or the additive solutions should be removed by centrifugation or by washing.

Donor Exposure

Traditional use of relatively fresh blood (<7 days old) for infants resulted in exposure to 6 to 10 different donors in small premature infants requiring multiple transfusions (27). The desire to reduce the potential risk of acquiring transfusion-transmitted diseases from multiple donor exposures has led to innovations in blood banking practices. Several techniques may be employed to prepare blood for neonates with the goal of decreasing donor exposure. Sterile connecting devices for repeatedly obtaining small aliquots of RBCs from dedicated units, blood bags with multiple satellite bags, and the use of RBCs collected in A-P solutions until the expiration date of 35 to 42 days reduce the number of donor exposures in neonates requiring multiple small transfusions, without undue wastage of blood (27,28,29 and 30). Increased K+ in older, stored blood does not appear to pose significant risks in neonates receiving small-volume transfusions of 10 to 15 mL/kg. Storage of RBCs over time causes depletion of red-cell 2,3 DPG with possible effects on oxygen dissociation (31), but the rapid regeneration of 2,3 DPG in transfused cells makes this irrelevant for small-volume transfusions.

Recombinant Erythropoietin

The benefit of exogenous erythropoietin to stimulate red-blood-cell production and overcome anemia of prematurity still is being debated, despite numerous multicenter trials (32, 33). Randomized, controlled trials in the United States, Europe, and South Africa demonstrated that treatment with recombinant human erythropoietin (rHuEpo) was associated with modest reductions in the number and volume of RBC transfusions in VLBW preterm infants, with maximum benefit being seen in larger, more stable preterm infants (16, 34, 35). However, these trials excluded infants with significant cardiorespiratory compromise, the very infants likely to experience the greatest phlebotomy losses and require the most transfusions. One trial on a small number of extremely low birth weight infants (birth weight <750 g) who were mechanically ventilated showed that early administration of erythropoietin and parenteral iron resulted in fewer transfusions in the first 3 weeks of life (36). The study again was limited by the small number of patients and the exclusion of extremely ill infants, and was too brief in duration to determine if the benefits of early erythropoietin therapy lasted through the hospitalization of these fragile infants. Although rHuEpo has not been shown to avert transfusions completely, it still shows promise as an adjuvant agent for reducing RBC transfusions in selected infants.

Whole Blood Transfusion

Whole-blood or reconstituted whole blood, prepared by adding a unit of RBCs to a compatible unit of FFP is the product of choice in the setting of massive transfusion or acute blood loss, where restoration of oxygen carrying capacity and blood volume are needed simultaneously. Often, the acute resuscitation of the patient is carried out with crystalloid or colloid solutions in conjunction with packed RBCs. Uncrossmatched O Rh-negative blood may be required for transfusion in infants with shock secondary to acute blood loss in emergencies such as splenic rupture, massive subgaleal hemorrhage, or ruptured *vasa previa*. Other blood components may need to be transfused subsequently, because the levels of coagulation factors V and VIII are low and platelet function is grossly abnormal in stored whole blood. In children under the age of 2 years, transfusion of fresh (<48 hours old) whole blood has been associated with significantly less postoperative blood loss following bypass surgery for complex congenital heart disease, than the transfusion of multiple blood components; this has been attributed to better platelet function in fresh blood (37). Other indications for transfusion of whole blood or reconstituted whole blood in the newborn include ETs, cardiopulmonary bypass, extracorporeal membrane oxygenation (ECMO), and continuous hemofiltration. The mechanics, blood product choice, and complications associated with ECMO and cardiopulmonary bypass have been discussed in detail (38).

Directed Donor Transfusions

Directed donations from first- and second-degree relatives rather than from unknown blood donors are perceived by the lay public to have a lower risk of transmitting viral infections, although there is no scientific data to support this contention. The transfusion of blood from biologic parents poses unique immunologic risks to the neonate. Transfusion-associated graft-versus-host disease (TAGVHD), a well-recognized complication of use of familial blood, is described later in this chapter. Maternal plasma may contain antibodies directed against paternal red cell, leukocyte, and platelet antigens that also may be expressed on neonatal cells (39). Transfusion of maternal blood components containing these antibodies theoretically could result in hemolysis, thrombocytopenia, or pulmonary reactions, because current pretransfusion testing may not detect these incompatibilities. Paternal red cells, WBCs, and platelets may express antigens that are not inherited by the infant, but to which the mother may have produced an IgG antibody that crosses the placenta. Transfusion of paternal cells to the infant could interact with transplacentally transmitted maternal IgG antibody in the infant's plasma. Although these dangers are theoretical, it is recommended that mothers should not provide blood components containing plasma; maternal red cells and platelets should be given as washed concentrates. Fathers and paternal blood relatives should not serve as donors for blood components containing cellular elements; a full antiglobulin crossmatch should be performed to detect red-cell incompatibilities if their use is unavoidable. In addition, all blood components obtained from biologic parents and siblings should be irradiated prior to transfusion (40).

Autologous Transfusion

The placenta contains 75 to 125 mL of blood at birth, a substantial volume of fetal blood that could be an ideal source of autologous blood for the neonate, eliminating the potential risks of transfusion-transmitted diseases and TAGVHD. The simple measure of delayed cord clamping at birth has a significant impact on red-cell mass, hematocrit, and transfusion requirement in preterm infants (41), but also may lead to circulatory overload (42). Heparinized placental blood has been used in the delivery room resuscitation of term infants with shock and profound anemia (43, 44), and placental blood stored in anticoagulant media has been used successfully for neonatal transfusion, albeit infrequently (45). Protocols for ensuring proper collection without bacterial contamination and adequate anticoagulation still are being refined (46). Although *in vitro* storage characteristics of placental blood stored for 28 days in anticoagulant media are reported to be similar to adult blood, there is no information about the posttransfusion red-cell survival and other biochemical parameters of transfused autologous placental blood (47).

ALLOIMMUNE HEMOLYTIC DISEASE OF THE NEWBORN

Part of "73 - Neonatal Transfusion"

Alloimmune hemolytic disease of the newborn (HDN) occurs as a result of sensitization of the mother's immune system to fetal red-cell antigens foreign to the mother, inherited by the fetus from the father. This sensitization results in the transplacental transfer of maternal IgG antibodies that bind to the fetal red cells causing hemolysis, and as a consequence of the hemolysis, varying degrees of anemia, extramedullary hematopoiesis, and neonatal hyperbilirubinemia. Anemia may range from mild to severe resulting in fetal or neonatal hydrops, associated with very high mortality. Neonatal jaundice secondary to hemolysis may range from minor exaggeration of physiological jaundice to extreme hyperbilirubinemia, with the risk of bilirubin encephalopathy. This disorder, also called kernicterus, is from neuronal necrosis in the basal ganglia and cerebellum, caused by the deposition of lipid-soluble free bilirubin. Kernicterus may result in death or disability characterized by choreoathetoid cerebral palsy and hearing loss.

The prevalence and severity of HDN varies widely in different races and ethnic groups, because of differences in the prevalence of RBC antigen systems. For example, 15% of Caucasians are Rh negative, compared to 7% to 8% of African-Americans, 5% of Asian Indians, and 0.3% of Chinese. Although the list of antibodies reported to cause HDN include IgG specific for virtually any known red-cell antigen, the most frequent causes of HDN are anti-D, ABO, non-D Rh antibodies (c, C, e, E, cc, and Ce) and those belonging to the Kell, Duffy, Kidd, and MNS systems (48). Transfusion of blood compatible with not only the D-antigen, but also Kell and other Rh antigens has been advocated for premenopausal women to prevent alloimmunization.

ABO HDN is limited to infants of blood type A or B born to blood group O mothers. Although ABO incompatibility exists in 15% of O-group pregnancies, ABO HDN is estimated to occur

only in 3% of births. This is attributed to the fact that most naturally occurring anti-A and anti-B antibodies are of the IgM type and do not cross the placenta; only a small proportion of group O women produce anti-A or anti-B IgG antibodies capable of transplacental transfer. Unlike Rh HDN, ABO HDN occurs with equal frequency in first or subsequent pregnancies. A higher incidence and greater severity is reported in Southeast Asians (49), Latin Americans (50), Arabs, South African, and African-American populations. The most common presentation is neonatal jaundice and anemia requiring phototherapy and small-volume RBC transfusion; ETs are rarely indicated. Severe fetal anemia and hydrops are rare (51).

Sensitization in Rh-D negative women usually is secondary to asymptomatic transplacental passage of D-positive fetal red cells and rarely from exposure to Rh-positive blood by transfusion or by the sharing of contaminated needles. Fetomaternal hemorrhage (FMH) occurs in 75% of pregnancies, increases with gestation, and is maximal at the time of delivery (52). Although the volume is less than 1 mL in 96% of women, FMH of more than 30 mL may occur in 1% of pregnancies. In the absence of Rh immunoprophylaxis, sensitization occurs in 7% to 16% of women at risk with delivery of an ABO-compatible infant, and in 2% after delivery of an ABO-incompatible infant. Fetomaternal ABO incompatibility confers a degree of protection against primary Rh sensitization because incompatible cells are destroyed rapidly by maternal anti-A and anti-B antibodies, reducing maternal exposure to Rh-D antigenic sites. Once sensitization has occurred, ABO incompatibility offers no protection against the brisk secondary immune response that occurs with further exposure to Rh-D–positive fetal cells. Obstetrical procedures such as chorionic villus sampling, amniocentesis, funipuncture, therapeutic abortion, cesarean section, manual removal of the placenta, and pathologic conditions such as abdominal trauma, spontaneous abortion, or ectopic pregnancy are associated with increased risk of FMH and thus of sensitization (53). However, large FMH may occur in women without any predisposing risk factors. Although the volume of blood required to cause sensitization often is minuscule, the diagnosis and quantification of FMH is of paramount importance to determine the appropriate dose of Rh immunoglobulin necessary to prevent sensitization to Rh antigens. Recommendations for the administration of Rh immunoglobulin have been published (54). The rosette test or an enzyme-linked antiglobulin test are recommended for screening for excessive feto-maternal hemorrhage. The Kleihauer-Betke test, based on the ability of fetal hemoglobin containing cells to resist acid elution, permits quantification of fetal red cells in a maternal blood sample. Other assays also are used with varying degrees of accuracy (Table 73.4) (55).

TABLE 73.4. TESTS TO DETECT FETOMATERNAL HEMORRHAGE

Test	Fetal Marker Detected	Advantages	Disadvantages	Sensitivity (%)
Kleihauer-Betke	HbF	easy to perform	difficult to standardize	0.1
Rosette	RhD positive cells	easy to perform	Accurate quantification problematic	0.25
Micro D^u	RhD positive cells	easy to perform	15% of tests fail to detect fetal cells	0.75
Gel agglutination	RhD positive cells	easy to perform	Accurate quantification problematic	0.2
Flow cytometry	RhD positive cells	accurate detection and quantification	dedicated equipment and technical expertise needed	0.1–0.01
FISH* and DNA amplification	cell nucleus characteristics	extreme sensitivity	currently used only as research tool	0.003

*FISH, fluorescent in situ hybridization.

Alloimmunization in Kell-negative women is more often the result of transfusion of Kell-positive blood rather than sensitization by FMH from a Kell-positive fetus; only about 9% of individuals express the Kell antigen (56). Kell HDN is rare even in alloimmunized pregnancies because transplacentally transmitted Anti–Kell antibodies will cause anemia only in a Kell-positive fetus. However, when present, Kell HDN may be somewhat unpredictable, partly because severe fetal anemia disproportionate to the degree of hemolysis may occur, due to specific suppression of fetal erythropoiesis at the progenitor cell level by antiKell antibodies (57).

Antenatal screening programs detect clinically significant antibodies in 0.24% to 1% of pregnant women. In such women, further evaluation is necessary to determine if the fetus is affected, and if so, how severely (58). In both Rh and Kell alloimmunization, the fetus is at risk only if the father is positive for the antigen in question. The probable Rh genotype of the father may be deduced from phenotyping studies, based on gene frequencies in various populations. Fetal blood typing early in pregnancy allows early institution of monitoring and therapy for the antigen-positive fetus at risk, and the avoidance of invasive procedures for the antigen-negative fetus that will remain unaffected. Prenatal determination of the fetal blood type may be performed on samples of blood obtained by percutaneous umbilical blood sampling (PUBS), or very early in pregnancy by flow cytometry or DNA amplification of tissue obtained by chorionic villus sampling or amniocentesis (59, 60). Recently described noninvasive techniques of prenatal diagnosis using fetal cells or fetal DNA isolated from the maternal blood obviate the risk of increasing maternal sensitization or fetal loss (61, 62).

Indirect assessment of the degree of fetal hemolysis is performed by sequential maternal antibody titration, amniotic fluid spectrophotometric analysis, and ultrasonography (63). Measurement of fetal blood counts, direct antiglobulin testing, and assessment of fetal acid-base status by PUBS allows direct evaluation of disease severity. Fetal blood samples with reticulocyte counts >97.5th percentile for gestation, strongly positive direct antiglobulin test, or mild anemia (hematocrit >30%, but < 2.5th percentile for gestation) predict fetuses at high risk of having significant antenatal anemia, thus requiring frequent

monitoring to determine if intrauterine transfusion is warranted (64). Management protocols reduce the need for multiple invasive procedures, because fetal blood sampling is associated with significant risks.

Intrauterine Fetal Transfusion

Intrauterine fetal transfusion has resulted in the perinatal survival of 75% to 90% of severely affected fetuses who would have perished in the 1960s. The first umbilical blood sampling with transfusion ideally should be performed when the fetus is anemic but before hydrops has developed. Intraperitoneal fetal transfusion has been largely replaced by direct intravascular fetal transfusion (IVT) by funipuncture. The intravascular technique offers precise diagnostic evaluation of the fetal status (see PUBS above) and is effective even in hydropic fetuses by circumventing the problem of erratic and often poor absorption of red blood cells from the peritoneal cavity in such fetuses. Other techniques of fetal transfusion reported include intrahepatic venous puncture, combinations of intravascular with intraperitoneal transfusions, and even intracardiac transfusion as a last resort (65). Intraperitoneal transfusions may be necessary when intravascular access is difficult, as in early pregnancy when the umbilical vessels are narrow, or later when increased fetal size prevents access to the umbilical cord. Transfusions are performed at hematocrits of 25% to 30% or less. Generally, the hematocrit drops by 1% to 2% per day in the transfused hydropic fetus; the fall in hematocrit is rapid in fetuses with severe hemolytic disease, necessitating a second transfusion within 7 to 14 days; the interval between subsequent transfusions usually is 21 to 28 days. Very low pretransfusion fetal hematocrits, rapid large increases in posttransfusion hematocrits, and increases in umbilical venous pressure during IVT are associated with fetal-death posttransfusion. The relative merits of direct, simple intravascular transfusion versus intravascular ET have been debated but the shorter procedure time with direct simple IVT has made it the procedure of choice at most centers. Fetuses are at risk for both posttransfusion cytomegalovirus and TAGVHD, so cytomegalovirus seronegative and/or leukodepleted, irradiated blood is recommended. The blood should be as fresh as possible to maximize *in vivo* survival, antigen-negative for the offending antibody, cross-matched against the mother's blood, washed free of the anticoagulant citrate and other additives, warmed, and packed to a hematocrit of 70% to 85% in a volume calculated to increase the fetal hematocrit to between 40% and 45%. Transfusions are provided up to 33 to 34 weeks, with delivery as soon as lung maturity is achieved by antenatal steroid therapy. The decision as to when to deliver the fetus is based on gestational age, fetal weight, and lung maturity, severity of fetal disease and response to transfusions, and the ease of performing the transfusions combined with antenatal ultrasound and Doppler studies. Infants who have received multiple intrauterine transfusions are delivered closer to term, often require less phototherapy and fewer ETs in the neonatal period (66). However, some still have significant hemolytic anemia at birth requiring aggressive intervention, and many require additional simple transfusions for severe and prolonged hyporegenerative anemia secondary to suppression of fetal erythropoiesis (67).

It must be remembered that the circulating red cells in the neonate that have received multiple intrauterine transfusions are the donor cells and this may lead to misleading results on initial blood grouping and a false negative direct antiglobulin test.

Exchange Transfusion

ET for the treatment of severe neonatal anemia and hyperbilirubinemia resulting from Rh incompatibility was first employed by Diamond et al. in 1948 (68). ET removes bilirubin and free maternal antibody in the plasma, corrects anemia, and replaces the infant's antibody-coated RBCs with antigen-negative RBCs that should have normal *in vivo* survival. The indications for early ETs, performed within 9 to 12 hours of birth, although debated, have remained essentially unchanged over the last 40 years, with minor modifications. Cord hemoglobin levels ≤110 g/L, cord bilirubin levels ≥5.5 mg/dL, and rapidly rising bilirubin concentrations ≥0.5 mg/dL/hour despite phototherapy are commonly used criteria for early ETs. Late ETs are performed when serum bilirubin concentrations threaten to exceed 20 mg/L in term infants, the level at which the risk of bilirubin encephalopathy or kernicterus is approximately 10%. Prematurity, hypoxemia, acidosis, hypothermia, and sepsis predispose to kernicterus at lower levels of bilirubin.

A double volume ET calculated as (2 × 80 mL/kg in a full-term infant) replaces 87% to 90% of the infant's blood volume, but eliminates only about 50% of the intravascular bilirubin, because of a slowly equilibrating tissue-bound pool. The use of albumin prior to ET in an effort to mobilize tissue bilirubin is controversial. Equilibration of extravascular and intravascular bilirubin and continued breakdown of sensitized and newly formed red cells by persisting maternal antibodies results in a rebound of bilirubin following initial ET, often necessitating repeated ETs in severe hemolytic disease. Also, drugs are removed during an exchange; therefore, infants on cardiotonic medications or antibiotics should have replacement doses (38).

Blood chosen for the exchange should be ABO compatible, negative for the antigen responsible for the hemolytic disease, and cross-matched against the mother's blood. Irradiated citrate-phosphate-dextrose (CPD or CPDAI) blood is used as whole blood or reconstituted whole blood (red cells suspended in saline, albumin, or plasma) with a hematocrit of 40% to 50% warmed through a temperature-controlled in-line blood warmer. Hypoxemic or acidotic infants should receive blood known to lack hemoglobin S. Additive solution anticoagulants are avoided. The age of the blood may vary, depending on availability, but the blood should be as fresh as possible (<7 days) to maximize the *in vivo* survival of the transfused red cells.

ETs may be performed by the traditional push-pull method with a single vascular access, usually the umbilical vein, or by isovolumetric techniques utilizing two access sites for simultaneous removal of the infant's blood and administration of new blood (69). Aliquots of 5 to 20 mL with a maximum of 5 mL/kg is withdrawn or infused in the discontinuous method, at a rate not exceeding 5 mL/kg every 3 minutes to avoid rapid fluctuations in arterial pressure, which are accompanied by changes in intracranial pressure. When an isovolumetric exchange is being done, volumes to be removed/reinfused should not exceed 2

mL/kg/minute. The duration of the exchange usually is 1 to 2 hours.

Potential complications of ET include hypocalcemia, hyper- and hypoglycemia, hyperkalemia, thrombocytopenia, dilutional coagulopathy, neutropenia, disseminated intravascular coagulation, umbilical venous and/or arterial thrombosis, necrotizing enterocolitis, and infection. Despite advances in the management of critically ill newborn infants, morbidity and mortality associated with ETs remains high, particularly in infants who are premature or sick or both. The risk of death or permanent serious sequelae has been estimated to be as high as 12% in sick infants, compared to less than 1% in healthy infants in a recent study (70). Careful clinical judgment is required in balancing the potential risk of adverse events from ET with the risk of bilirubin encephalopathy in ill infants.

Although the vast majority of ETs are performed for the treatment of HDN, the procedure also has been advocated for neonatal sepsis and occasionally utilized for drug overdose or toxicity (71), correction of life-threatening hyperkalemia (72), and disseminated intravascular coagulation (73). The rationale for the use of whole blood ETs in neonatal sepsis includes removal of bacteria and inflammatory mediators, correction of acidosis, and improvement of tissue oxygenation by the correction of anemia. ETs increase neutrophil counts and enhance neutrophil function when fresh whole blood is used (74); enhance IgG, IgA, and IgM levels (75, 76); and clear endotoxin (77). Improved survival rates have been demonstrated in neonates with Gram-negative sepsis and neutropenia or sclerema, conditions ordinarily associated with extremely high mortality rates.

Partial Exchange Transfusion

Partial ET using packed RBCs is used to correct severe anemia in critically ill hydropic infants with severe HDN until they can be stabilized sufficiently to undergo a complete, double-volume ET.

Partial ET is used more often to decrease the hematocrit in neonates with polycythemia. A hematocrit of greater than 65% is common in infants born at high altitude, or in those with intrauterine growth retardation or maternal diabetes. Although other factors may influence the viscosity of blood, the correlation of hematocrit to viscosity is linear up to 65% and exponential thereafter (78). Because instruments to measure viscosity are not readily available in many centers, the neonatal polycythemia-hyperviscosity syndrome usually is diagnosed by using the high hematocrit as a surrogate marker for hyperviscosity and a combination of symptoms that include poor feeding, hypoglycemia, tachypnea, central nervous symptoms such as hypotonia, tremors, seizures, abnormal renal function, and necrotizing enterocolitis (79). Partial ET to reduce the hematocrit to about 55% causes rapid amelioration in the clinical manifestations of polycythemia and is associated with reversal of cerebral blood flow abnormalities in symptomatic infants (80). However, it is uncertain whether the long-term outcome, particularly in asymptomatic infants, is improved by partial ET (81, 82). The present indications for treatment include infants with hematocrit ≥70% or symptomatic infants with hematocrit between 65% and 70%, but remain controversial. 5% albumin and plasma protein solutions have been utilized as replacement solutions, but isotonic saline has been found to be as effective as colloid (83). Peripheral vessels are preferred for withdrawing and infusing replacement fluid in polycythemic infants (84), but the umbilical vein also may be used. An increased incidence of necrotizing enterocolitis has been described with the use of fresh frozen plasma administered through the umbilical vein, but it is difficult to decipher if the posttransfusion necrotizing enterocolitis was part of the syndrome or a result of the procedure or the nature of the replacement fluid (85).

GRANULOCYTE TRANSFUSION

Part of "73 - Neonatal Transfusion"

Quantitative and qualitative abnormalities in the neutrophil/phagocytic system and defects in humoral immunity make neonates, particularly those born prematurely, uniquely susceptible to developing sepsis with increased risk of mortality following infection. The neutrophil storage pool consisting of polymorphonuclear neutrophils, bands, and metamyelocytes is smaller in infants than in adults, and rapidly exhausted in the presence of bacterial infection, leading to significant neutropenia. In addition, the precursor bone marrow progenitors, colony-forming unit-granulocyte, erythroid, monocyte, megakaryocyte (CFU-GEMM), colony-forming unit-granulocyte, macrophage (CFU-GM), and the committed colony-forming unit-granulocyte (CFU-G) are decreased in number and proliferating at a maximal rate, resulting in an inability to accelerate production of PMNs in response to infection. Diminished production of colony-stimulating growth factors also may be responsible for the poor proliferative response of the bone-marrow precursors (86). Functional abnormalities of the phagocytic system in stressed neonates include decreased deformability, chemotaxis, phagocytosis, bactericidal killing, and oxidative metabolism (87). Studies of the efficacy of granulocyte transfusions for the treatment of life-threatening infections in neonatal patients are difficult to evaluate because of small numbers of patients with varying degrees of illness and supportive care regimens, differing methods of harvesting neutrophils, and different transfusion protocols. The important factors to consider in granulocyte transfusions are quantity, quality, and compatibility (88, 89). In a meta-analysis of clinical studies of the efficacy of granulocyte transfusions in the treatment of bacterial sepsis, the dose of transfused granulocytes emerged as a significant predictor of success, with transfusion of adequate doses ($>0.5 \times 10^9$/kg/dose) producing an 18-fold increase in the odds of survival in septic neutropenic neonates, as compared to controls ($p<0.05$). Transfusion of inadequate doses was not associated with any survival benefit (90). Transfusion of granulocytes collected by continuous-flow centrifugation is more effective than transfusions of buffy-coat isolated granulocytes (91,92,93 and 94). Granulocytes collected by filtration leukapheresis are functionally defective and ineffective, as are leukocytes stored for 24 hours. Donor-recipient compatibility is improved by human leukocyte (HLA) matching or by leukocyte crossmatching in addition to ensuring erythrocyte compatibility. Technical difficulties and the cost of collecting granulocytes for transfusion in a timely manner, together with concern about the potential risks of viral transmission,

TAGVHD from transfused viable lymphocytes, sensitization to cellular blood product antigens and pulmonary leukoagglutinating reactions have limited the more widespread use of white blood cell transfusions. Increased attention is being paid to the potential use of granulocyte and granulocyte-macrophage colony stimulating factors (G-CSF, GM-CSF) for the adjuvant treatment of neonatal sepsis (95).

PLATELET TRANSFUSIONS

Part of "73 - Neonatal Transfusion"

Thrombocytopenia, defined as a platelet count of <150 × 10^9/L occurs in 18% to 20% of low-birth-weight infants admitted to the neonatal intensive care unit, but is much less common in term infants, occurring in less than 1% (96, 97). Low platelet counts may be a result of impaired production or increased peripheral destruction, secondary to congenital or acquired conditions (98). A combination of mechanisms is most likely in the critically ill infant. One fifth of infants with marked thrombocytopenia have evidence of disseminated intravascular coagulation (96). Quantitative and qualitative platelet disorders may cause significant bleeding with resulting morbidity, the most serious being intracranial hemorrhage. The incidence and severity of intraventricular hemorrhage and serious neurological sequelae is greater in low-birth-weight infants with thrombocytopenia than in those with normal platelet counts (99). However, the incidence of new intracranial hemorrhages or extension of existing hemorrhages was not different between infants given prophylactic platelet transfusions to maintain platelet counts of at least 150 × 10^9/L or control infants who were not transfused until platelet counts dropped to <50 × 10^9/L or had evidence of bleeding (100). Based on this study, platelet transfusions are not recommended for nonbleeding preterm infants with platelet counts more than 60 × 10^9/L. Some of the difficulty in determining the minimum level to which platelet counts may be allowed to fall prior to transfusion is that hemostatic competence is determined not only on the platelet count, but also on platelet function, vascular integrity, and levels of coagulation factors. Sick infants may have prolonged bleeding times despite only moderately reduced platelet counts (75 to 150 × 10^9/L). Indications for platelet transfusion are therefore derived by consensus (Table 73.5) (101).

TABLE 73.5. GUIDELINES FOR PLATELET TRANSFUSION SUPPORT OF NEONATES

Prophylactic Platelet Transfusions

- Stable preterm neonates with platelet counts <30 × 10^9/L
- Stable term neonates with platelet counts <20 × 10^9/L
- Sick preterm neonates with platelet counts <50 × 10^9/L
- Sick term infants with platelet counts <30 × 10^9/L
- Preparation for an invasive procedure, e.g., lumbar puncture or minor surgery in neonates with platelet counts <50 × 10^9/L, and for major surgery in neonates with platelet counts <100 × 10^9/L

Platelet Transfusions in Neonates with Clinically Significant Bleeding

- Neonates with platelet counts <50 × 10^9/L
- Neonates with conditions that increase bleeding, e.g., DIC and platelet counts <100 × 10^9/L
- Neonates with documented significant platelet functional disorders (e.g., Glanzmann's thrombasthenia) irrespective of the circulating platelet count

"Sick" infants in this context defined as those with a history of perinatal asphyxia, extremely low birth weight (<1000 g), need for ventilatory support with an inspired oxygen concentration >40%, clinically unstable, signs of sepsis, or those who require numerous invasive interventions.
Source: ref 101.

Two neonatal conditions warrant special attention. Neonatal alloimmune thrombocytopenia (NAIT), a condition analogous to Rhesus hemolytic disease of the newborn, is the result of feto-maternal platelet incompatibility. Sensitization of the mother to paternal antigens inherited by the fetus and present on fetal platelets, result in the production of maternal antiplatelet IgG antibodies, which cross the placenta to the fetal circulation and cause fetal thrombocytopenia. Unlike Rh disease, first-born infants may be affected. The rate of recurrence of the condition among platelet-antigen–positive siblings is 100%. Antibodies to the PL^{A1} (HPA-1) antigen are the most common cause of NAIT in Caucasian populations, whereas the PEN/YUK (HPA-4) antigen is implicated in Asians. Although PL^{A1} incompatibility is present in about 1 in 42 pregnancies, NAIT occurs in only 1 in 20 to 40 incompatible pregnancies, primarily in women who are phenotypically HLA-Dw52a. Intracranial hemorrhage occurs in 10% to 20% of cases of NAIT, half of them occurring antenatally (102). A combination of noninvasive strategies including administration of IVIG and platelets to the mother with monitoring by PUBS, and intrauterine platelet transfusions coupled with cesarean section for select cases may prevent intracranial hemorrhage in the fetus at risk for NAIT. After birth, platelet counts may continue to drop in the infant with NAIT, because of continuing destruction by persisting maternal antiplatelet antibody. Random donor platelets, 98% of which are PL^{A1} (HPA-1) positive are ineffective. Transfusion of maternal platelets washed free of antibody or PL^{A1} (HPA-1) antigen-negative platelets from unrelated donors provides a sustained increase in platelet counts and is the treatment of choice. Adjuvant therapy with steroids and/or intravenous immunoglobulin may be indicated.

Neonatal autoimmune thrombocytopenia is a condition resulting from destruction of platelets by transplacentally transferred antibody, directed to platelet antigen shared by both mother and fetus, most often a result of maternal immune thrombocytopenia. Unlike NAIT, fetal hemorrhage is rare in autoimmune thrombocytopenia (103). Cesarean section is advocated if fetal scalp platelet counts are less than 50 × 10^9/L at the time of labor, but surgery is complicated by increased risk in the presence of maternal thrombocytopenia. Neonatal thrombocytopenia usually is mild to moderate. Platelet transfusions of any antigen type generally are ineffective because the antibodies are reactive against a wide range of platelet antigens.

FRESH FROZEN PLASMA AND CRYOPRECIPITATE TRANSFUSIONS

Part of "73 - Neonatal Transfusion"

The levels of vitamin-K–dependent coagulation factors II, VII, IX, and X and the contact factors XI, XII, prekallikrein and high-molecular-weight kininogen are around 50% of normal adult concentrations at birth in term infants, and are even lower in

preterm infants. Classical “hemorrhagic disease of the newborn,” from the transient deficiency of vitamin-K–dependent factors and characterized by bruising and gastrointestinal hemorrhage in neonates around 2 to 5 days of age, now has been effectively prevented by routine administration of vitamin K at birth. However, two other forms of hemorrhagic disease, secondary to vitamin-K deficiency continue to be reported. Early hemorrhagic disease, presenting within 24 hours of birth, is associated with the ingestion in pregnancy of drugs such as phenytoin, Phenobarbital, and primidone, which interfere with vitamin K metabolism. Late hemorrhagic disease appears between 2 and 8 weeks after birth and may be secondary to vitamin K malabsorption resulting from mild, undiagnosed liver disease. In both conditions, life-threatening intracranial hemorrhage may occur. Intracranial hemorrhage at birth may be the presenting feature in infants with severe forms of inherited coagulation-factor deficiencies, although most infants with inherited coagulation-factor deficiencies do not have bleeding in the perinatal period, unless they undergo an invasive procedure such as circumcision or venipuncture. The most common cause of disordered hemostasis in sick neonates is disseminated intravascular coagulation, secondary to myriad conditions, including asphyxia, sepsis, shock, respiratory-distress syndrome, or necrotizing enterocolitis. Coagulopathy also may be secondary to acute or chronic liver disease.

FFP infusions are indicated for the treatment of clinically significant bleeding as well as for correction of hemostatic defects as a result of a decrease in one or more coagulation factors, prior to invasive procedures. Rationale for the use of FFP in neonates again has been derived from evidence in adult patients (104, 105). The dose of FFP administered usually is 10 to 20 mL/kg, with further doses being determined by the clinical situation, underlying disease process, and laboratory monitoring. The amelioration of hemostatic problems by the transfusion of FFP in neonates with DIC is only temporary, and hence multiple transfusions may be required until the underlying cause resolves. Indeed, the outcome of DIC has been found to be dependent on the success of treatment of the underlying pathologic process and aggressive supportive care, and is not altered by therapy specifically directed at coagulopathy (73). The correction of coagulopathy secondary to liver failure also is temporary, in the absence of recovery of hepatic function.

FFP is not indicated for the treatment of hypovolemic shock in the absence of coagulation abnormalities, for nutritional support, treatment of immunodeficiency states, or for the treatment of isolated coagulant factor deficiencies for which virus-inactivated, plasma-derived or recombinant factor concentrates are available. Although earlier studies demonstrated that the incidence of periventricular — intraventricular hemorrhage was reduced by prophylactic FFP, a recent large, multicenter, randomized, controlled trial provided no evidence that the routine early use of FFP affected the rates of death or disability in preterm infants (106).

Cryoprecipitate is indicated for severe hypofibrinogenemia associated with DIC, and for bleeding as a result of congenital fibrinogen or factor XIII deficiency, if commercial plasma-derived, virus-inactivated concentrates are unavailable.

EXTRACORPOREAL MEMBRANE OXYGENATION

Part of "73 - Neonatal Transfusion"

Extracorporeal membrane oxygenation (ECMO) is the use of prolonged extracorporeal circulation and gas exchange through a membrane oxygenator to provide temporary life support in patients with profound cardiorespiratory failure who fail to respond to conventional therapy. The continuous contact of blood with the prosthetic surface of the ECMO circuit results in activation of the coagulation cascade. The use of heparin to prevent clot formation in the circuit and the decrease in platelet number and function from interaction with the circuit put the infant at risk for bleeding (107, 108). In addition, infants placed on ECMO are critically ill and already may have altered hemostasis secondary to sepsis, shock, or profound hypoxia, predisposing them to devastating intracranial hemorrhage (109).

Two units of group- and type-specific packed RBCs are required to prime the circuit. Subsequently, multiple small-volume transfusions of RBCs are needed to maintain the hematocrit at 40% to 45%. Platelet and FFP support is variable, with postsurgical infants, patients with sepsis, or those on prolonged bypass requiring considerably more transfusions (110, 111). The necessity for multiple blood components for neonates on ECMO often resulted in mean donor exposures as high as 22.8 ± 9.5 per ECMO run in the past (112). Changes in transfusion practices and blood-component management now have limited donor exposures to 7 to 10 in many centers (111,112 and 113). Strategies for limiting donor exposure include increasing the volume of red cells used for small-volume transfusions to 15 mL/kg, using a system of sequential aliquots from the same blood unit, using standard FFP units up to 24 hours after thawing, volume-reduced platelets, or single-donor apheresis platelet aliquots, and eliminating the empirical use of FFP and cryoprecipitate. Most institutions maintain platelet counts of at least 100×10^9/L in neonates in ECMO.

ADVERSE REACTIONS TO BLOOD TRANSFUSION

Part of "73 - Neonatal Transfusion"

The physiological immaturity of various organ systems in the newborn gives rise to significant differences in the incidence and types of adverse reactions when compared to older children or adults. The important differences will be emphasized in this section.

Hemolytic Reactions

Acute hemolytic transfusion reactions are rare in neonates, partly from the absence of naturally occurring anti-A or anti-B antibodies until the age of 4 months, and also from the practice of transfusing neonates with group O blood. Despite multiple blood transfusions and exposure to multiple blood donors, posttransfusion red-cell alloimmunization has been reported infrequently in neonates — again, a feature of immunological immaturity (114, 115).

However, severe immune-mediated hemolysis has been associated with transfusion of adult blood containing anti-T antibodies

in neonates with activation of the normally masked Thomsen-Friedenreich antigen on the surface of the neonatal red-cell membrane (116). Expression of the cryptantigen, known as T-activation, occurs by the removal of N-acetyl neuraminic acid residues from the antigen by neuraminidases produced by bacteria, particularly *Clostridia*. This phenomenon has been reported mainly in neonates with necrotizing enterocolitis, especially in those with severe disease requiring surgical intervention and with Clostridial infection. T-activation should be suspected in neonates at risk who have evidence of intravascular hemolysis with hemoglobinuria and hemoglobinemia following transfusion of blood products or unexplained failure to achieve the expected posttransfusion hemoglobin increment. Routine cross-matching techniques will not detect the polyagglutination from T-activation when monoclonal ABO antiserum is used. Minor crossmatching of neonatal T-activated red cells with donor anti-T–containing serum may show agglutination, but this is not performed routinely. Infants at risk, with discrepancies in forward and reverse blood grouping and evidence of hemolysis on smear should be suspected of T-antigen activation. The diagnosis is confirmed by specific agglutination tests using peanut lectin *Arachis hypogea* and *Glycine soja*. Further hemolysis may be prevented by using washed red cells, platelets, and low-titer anti-T plasma. Exchange transfusion with plasma-reduced components may be necessary for infants with severe ongoing hemolysis.

Numerous nonimmunological causes of hemolysis leading to morbidity and mortality have been described in neonates, including excessive infusion pressure through small-gauge needles (≥28 gauge); accidental overheating of the blood in the administration set; inappropriate storage of red-blood-cell products in freezers or unmonitored refrigerators leading to freezing and lysis; simultaneous infusion of incompatible fluids or drugs; and the transfusion of abnormal donor red blood cells (glucose-6-phosphate dehydrogenase deficiency, sickle-cell trait, or paroxysmal nocturnal hemoglobinuria) (117).

Leukocyte Alloimmunization

Transient anti-HLA antibodies have been described in multiply-transfused, preterm infants but their immunological effects either in the short or long term are not clear at present (115). The passive transfusion of blood containing leukoagglutinins directed against the recipients antigens initiates complement activation, microvascular lung injury, pulmonary edema, and severe hypoxemia, a condition termed transfusion-related acute lung injury (TRALI). This acute, life-threatening complication rarely is reported in neonates, partly because of the difficulty in distinguishing the acute respiratory distress that accompanies the syndrome from other causes of respiratory deterioration (118).

Transfusion-Associated Graft-Versus-Host Disease

TAGVHD occurs as a result of the proliferation and engraftment of viable donor lymphocytes in an immunosuppressed or immunodeficient transfusion recipient who does not recognize the cells as being foreign and is unable to reject them (119). Similarities in HLA antigens facilitate engraftment, and therefore, this phenomenon is much more likely to occur when family members serve as blood donors. TAGVHD in infants has been reported following transfusions from blood relatives, following intrauterine fetal transfusion, after postnatal transfusions in infants who received intrauterine transfusions, in neonates with primary-cell mediated immunodeficiency disease, and rarely, in infants without a definitive diagnosis of underlying primary immunodeficiency. The manifestations of TAGVHD include fever, rash, gastrointestinal symptoms, bone marrow and hepatic failure, similar to many other medical conditions in sick newborn infants, making clinical diagnosis difficult, and probably leading to considerable underestimates of the true incidence of the condition (120). The threshold number of lymphocytes necessary to produce a graft-versus-host reaction may vary depending upon the immune status of the host and the antigenic similarity of the donor-recipient pair. No leukocyte depletion filter or processing has yet been shown to uniformly decrease the lymphocyte count of a product below the critical threshold. Whole blood, red blood cells, granulocyte and platelet concentrates, and fresh plasma have been implicated in TAGVHD. Irradiation at a minimum of 2,500 cGy to the midplane of the bag currently is the only acceptable way to abrogate the disease. Current guidelines recommend the use of irradiated blood components for neonates with known or suspected congenital cell-mediated immunodeficiency states; infants with congenital leukemia, or malignancy undergoing chemotherapy; fetuses receiving intrauterine transfusions; postnatal transfusions in neonates who received intrauterine transfusions; exchange transfusions; and for recipients of cellular blood products from first- and second-degree relatives and HLA-matched donations (121). TAGVHD has not been reported in children or adults with human immunodeficiency virus (HIV) infection despite the severe immunodeficiency associated with the disease, so irradiation of blood products is not recommended for this indication at present. Although preterm infants are known to be immunoincompetent, it is unclear if all preterm infants should receive only irradiated blood products, in the absence of other factors that would predispose them to TAGVHD. Some institutions provide irradiated blood products to all neonates, to avoid TAGVHD in patients with undiagnosed immunodeficiency.

Metabolic Adverse Reactions

Inhibition of the red cell membrane bound adenosine triphosphatase pump during extended storage causes leakage of intracellular potassium, resulting in K+ levels as high as 85 mEq/L in the supernatant plasma in blood stored 42 days, particularly in blood that is irradiated on day 0, prior to storage. Small volume transfusions of red blood cells stored to their expiration date of 35 to 42 days do not result in clinically significant elevations of serum potassium, because infants receiving 15 mL/kg of packed RBCs receive only about 3 mL/kg of supernatant, containing approximately 0.15 mEq/kg of K+ (122). Life-threatening hyperkalemia has been described following rapid infusions of large volumes and exchange transfusions using stored, packed RBCs in sick term and preterm infants. Washed red cells are advisable in

infants with hyperkalemia, renal failure, or when large volumes of blood are infused rapidly.

Hypoglycemia may occur during transfusion of small volumes of CPDA-1 or AS-1 red cells, if dextrose containing intravenous infusion is interrupted. Rebound hypoglycemia is detected frequently after exchange transfusions in infants with erythroblastosis fetalis who often exhibit hyperinsulinemia. Large volume transfusions, as may occur during surgical procedures, may lead to hyperglycemia in small premature neonates with poor glucose-control mechanisms.

Hypocalcemia, secondary to the chelation of calcium by citrate in the anticoagulant, has been observed during exchange transfusions and following massive transfusions both in term and preterm infants.

The plasticizer di-(2-ethylhexyl)-phthalate (DEHP), present in blood bags, intravenous (IV) sets, and ECMO circuits made of polyvinyl chloride, is lipophilic and hence, leaches into almost all blood products. Significant exposure to plasticizer is reported in infants undergoing exchange transfusions and ECMO (123, 124). Although no short- or long-term complications have been identified in infants, studies in animals raise concerns about possible effects on hepatocellular, pulmonary, and reproductive function, and potential carcinogenicity (117).

In addition to metabolic effects, blood transfusions may cause significant alterations in temperature, blood pressure, and pulmonary compliance in fragile preterm infants.

Transfusion-Transmitted Infections

No study has ever clearly demonstrated that neonates are at any higher risk for acquiring posttransfusion infections than are older children, although premature infants appear to be more susceptible to transfusion-transmitted HIV and cytomegalovirus (CMV) infections. The practice of using one unit of blood for many infants has resulted in multiple infants being infected from a single donor. This has been reported with hepatitis A and C, malaria, Epstein Barr virus, and HIV.

Nearly all cases of HIV infection acquired from blood transfusions in the United States occurred before the implementation of routine blood donor screening practices. The median symptom-free period from birth to symptomatic infection is reported to be significantly longer in neonatal transfusion acquired infection as compared to perinatally acquired infection (125, 126). Asymptomatic HIV-1 infection has been identified as late as 5 to 9.5 years posttransfusion in studies in which cohorts of neonates transfused before routine donor screening for HIV antibody have been retrospectively tested (127). Once symptomatic, the progression of transfusion-acquired HIV disease does not appear to be different from vertically acquired infection in neonates. The potential risk of transfusion-transmitted HIV infection from a repeat blood donor with negative serologic tests in the United States is estimated to be 1 in 493,000 (128).

Improvements in donor screening have reduced the incidence of posttransfusion hepatitis, but have not completely eliminated this complication. The hepatitis viruses may be transmitted by cellular and noncellular blood products.

Posttransfusion hepatitis A is rare, and usually asymptomatic in newborn infants. However, secondary horizontal spread has led to large outbreaks in neonatal intensive care units, with symptomatic infection in nurses, physicians, parents, and relatives who have been in direct contact with infected neonates (129,130 and 131). The risk of transmitting the hepatitis B by the transfusion of blood from screened donors in the United States is estimated to be 1 in 63,000. The outcome of transfusion-acquired hepatitis B in neonates is assumed to be similar to perinatally acquired infection, with a 70% risk of chronic carrier state.

The risk of transmitting hepatitis C virus from screened blood units in the United States, using second-generation enzyme immunoassays (EIA-2) for detecting antibody to the virus, is estimated to be 1 in 103,000 (128). One cohort study of children who received transfusions of blood screened by surrogate markers of hepatitis or by EIA-1 antihepatitis C virus testing, during extracorporeal membrane oxygenation therapy in the neonatal period, found 7 of 83 children to be antihepatitis C virus seropositive, with significantly increased alanine aminotransferase levels in four of the seven (132). Another retrospective cohort study of neonates transfused with blood from donors infected with hepatitis C virus prior to the institution of routine screening indicated that infection was asymptomatic in more than 60% of children at the median age of 6.3 years. Children who were hepatitis C virus-RNA positive had mildly elevated transaminase levels; mild hepatitis was evident in those who underwent liver biopsy (133). The persistence of HCV infection in children after transfusions in the neonatal period is particularly disquieting because studies in adults reveal that 70% of hepatitis C virus-infected patients develop chronic hepatitis, 20% develop cirrhosis within two decades, and 1% to 5% may develop hepatocellular carcinoma after 20 years (134).

Persistent hepatitis G virus infection has been observed after neonatal transfusions, but the term “hepatitis” in relation to this virus may be a misnomer because no clinical or biochemical signs of liver disease have been observed on follow up (135).

CMV is widely prevalent in blood donors, and has serious consequences in low-birth-weight neonates. Viral genome has been detected in the white blood cells of CMV seropositive individuals, and even CMV seronegative donors may harbor latent CMV infection in their mononuclear cells. Risk factors for neonatal acquisition of CMV from transfusions include exposure to at least 50 mL of blood, birth weight less than 1,200 g, and maternal CMV seronegativity. Posttransfusion CMV infection in low-birth-weight infants born to seronegative mothers causes a serious clinical syndrome of fever, respiratory distress, hepatosplenomegaly, cytopenias, and may result in death (136). Disseminated CMV infection has been described in a full-term infant following ECMO (137) CMV seronegative blood or leukocyte reduced blood is recommended for transfusions in low-birth-weight infants born to seronegative mothers or those with unknown serostatus, and for intrauterine transfusions (138). Leukocyte reduction may be performed by washing, freezing followed by washing, and filtration using third-generation leukocyte depletion filters. There is a suggestion that the transfusion of CMV seronegative blood products in infants born to CMV seropositive mothers may hasten the decline in titer of protective maternal antibody, making infants susceptible to infection.

In addition to transfusion-transmitted viral infections,

syphilis, malaria, and bacterial infections from transfusions continue to be reported, albeit infrequently. Case reports of transfusion-associated parvovirus B-19 (139), babesiosis (140), Chagas disease, and the potential risk of transmission of Creutzfeldt-Jacob disease (141) emphasize the fact that the goal of zero-risk transfusion is distant.

Complications of Blood Transfusion

Jay E. Menitove

Adverse events following blood transfusion occur within a few hours, or after several days or weeks following transfusion. During the past decade, the risk of posttransfusion hepatitis and retroviral infections decreased and a better understanding of the pathophysiology of hemolytic transfusion reactions and other untoward sequelae emerged. Additional advances relate to the results of randomized, clinical trials aimed at determining whether transfusion, per se, increases the risk of postoperative bacterial infections or shortens the disease-free interval following tumor resection surgery. This chapter reviews the pathophysiology, clinical presentation, laboratory diagnosis, and treatment or prevention of the predominant complications of blood transfusion.

ACUTE TRANSFUSION REACTIONS

Part of "74 - Complications of Blood Transfusion"

Acute transfusion reactions (Table 74.1) occur minutes or hours after infusing red cell, platelet, or plasma components. These reactions involve immune, nonimmune, and infectious etiologies. The clinical presentations of these complications overlap significantly. For this reason, a laboratory evaluation is necessary for determining the specific cause and for ordering the appropriate therapeutic intervention.

TABLE 74.1. ACUTE TRANSFUSION REACTIONS

Reaction	Risk per Unit Transfused
Hemolytic transfusion reactions	~1:33,000
Fatal, hemolytic transfusion reactions	1:600,000
Febrile, nonfebrile transfusion reactions	
red cells	1:50–1:200
platelets	1:4–1:50
Allergic reactions	
red cells	1:200
platelets	1:30–1:100
Anaphylactic reactions	1:150,000
Hypervolemia	infrequent
Nonimmune hemolysis	infrequent
Air embolism	0 (per 9,000,000 observed)
Bacterial sepsis	
red cells	1:500,000
platelets	1:2,000–12,000
fatalities	1:3,000,000
Hypotensive reactions	?

Acute Hemolytic Transfusion Reaction

Hemolytic reactions caused 50% of the transfusion-related fatalities reported to the United States Food and Drug Administration (FDA) between 1990 and 1998 (1) (Table 74.2). Most of these reactions involved ABO incompatibility, in which group O recipients received blood from group A donors. Prevention of this feared complication of transfusion therapy serves as the mainstay of transfusion service policies and procedures that include proper identification of patients from whom blood samples are obtained; labeled requisition forms and tubes; compatibility testing; issuing blood components; ensuring the intended patient receives the appropriate blood component; monitoring the patient for signs and symptoms of an adverse reaction; and conducting an appropriate laboratory investigation if an adverse event occurs.

TABLE 74.2. TRANSFUSION RELATED FATALITIES: REPORTS TO FDA: 1990–1998

	Cases	%
Hemolysis	161	50
Bacterial contamination	46	14
Transfusion related acute lung injury	29	9
Nonbacterial infections	23	7
Transfusion associated graft-vs-host disease	18	6

Lee JH. FDA Workshop on Bacterial Contamination of Platelets. September 24, 1999.

In one study, based on mandated reporting of incidents, accidents, and errors to the New York State Health Department, approximately 1 per 33,000 red-cell transfusions were erroneously ABO-incompatible and an estimated 1 per 12,000 red cell units were infused into an unintended patient (2). The fatality rate was 1 per 600,000 units or 5% of incompatible transfusions. Approximately 43% of the hemolytic reactions resulted from an error involving patient identification, 11% because of a phlebotomist error, 25% as a result of laboratory error, and 15% occurred when administering or issuing the transfusion.

Pathophysiology

Transfusion of incompatible red cells triggers an antibody-antigen reaction and release of inflammatory response mediators, tumor necrosis factor-α (TNF-α), interleukins-1 and -8 (IL-1, IL-8), monocyte chemoattractant protein-1 (MCP-1), and anaphylatoxins C3a and C5a (3, 4). Hageman factor and complement may be activated. The latter is associated with intravascular hemolysis and release of red cell stroma and hemoglobin into the circulation. In the absence of complement activation, opsonized red cells are removed extravascularly within the reticuloendothelial system. In addition to anti-A and anti-B antibodies associated with intravascular hemolytic reactions include anti-K (Kell), anti-JKa (Kidd), and anti-Fya (Duffy). Those commonly associated with extravascular hemolysis include antibodies directed against Rh-antigens, anti-E, anti-C, and anti-D.

In vitro experiments indicate that cytokines play a significant role in the pathogenesis of hemolytic transfusion reactions. An IgM-mediated hemolysis model involves adding nongroup O red cells to group O whole blood, i.e., ABO-incompatibility. In an IgG-mediated hemolysis model, IgG-opsonized red cells are incubated with isolated mononuclear cells (3).

In the ABO-incompatibility experiments, TNF-α levels increased in a dose- and time-dependent pattern, with the maximal response at 2 hours. After 4 and 6 hours, IL-8 and MCP-1 levels increased and remained elevated for up to 24 hours. Complement appears necessary for cytokine production.

In the IgG-mediated red cell incompatibility experiments, IL-1, IL-6, and IL-8 levels increased within 6 hours and remained elevated for more than 24 hours. TNF levels increased transiently and did not reach levels associated with IgM-mediated hemolysis.

Clinical Presentation

Fever (elevation of at least 2°F or 1°C) or fever accompanied by chills occurs in almost all conscious or nonanesthetized patients suffering a hemolytic transfusion reaction. Nausea, vomiting, and chest pain occur less frequently. Wheezing and dyspnea, back pain, restlessness, and discomfort at the infusion site may occur. Additional clinical findings include hemoglobinuria, intravascular coagulation abnormalities, renal failure, and hypotension. In comatose or anesthetized patients, unsuspected hypotension, uncontrollable bleeding, or hemoglobinuria should alert clinicians to the possibility of a hemolytic reaction.

Disseminated Intravascular Coagulation

Two to six hours after group-A red cells are added to group-O whole blood *in vitro*, white cells generate procoagulant activity that presumably contributes to disseminated intravascular coagulation (DIC). Two mechanisms of action are postulated. Complement-binding antibodies such as anti-A or anti-B deposit C3b or iC3b on incompatible red-cell membranes that serve as ligands for white-cell CR3, that, in turn, stimulate monocytes tissue factor — generation. Alternatively or additionally, factor X is converted to factor Xa by monocytes through a mechanism requiring CD11b (a ligand for C3b and iC3b). In addition, TNF-α stimulates internalization of thrombomodulin by endothelial cells that exert a prothrombotic effect by suppressing protein-C activation (4).

Acute Renal Failure

Severe hemolytic reactions involving shock and DIC lead to renal hypoperfusion, fibrin deposition, and renal ischemia. Release of free hemoglobin and endothelial-derived vasoactive compounds has an additional role. Endothelin release and subsequent local vasoconstriction lead to parenchymal ischemia and renal failure. Likewise, circulating free hemoglobin induces vasoconstriction by binding nitric oxide with consequent renal ischemia and renal failure (4).

Vasomotor Instability/Hypotension

Hemolytic reactions activate Hageman Factor with subsequent bradykinin generation and hypotension. TNF-α release leads to capillary leak, neutrophil degranulation, and hypotension. In addition, anaphylatoxins C3a and C5a stimulate histamine release from cells that lower blood pressure.

Respiratory Failure

Although the lungs have not been regarded as a major target organ of hemolytic transfusion reactions, free hemoglobin and nitric-oxide interaction potentially leads to localized vasoconstriction with subsequent pulmonary vascular hypertension and decreased cardiac output. Neutrophil degranulation in pulmonary capillaries creates lung injury and procoagulant mediators lead to localized inflammation and thrombosis (4).

Laboratory Diagnosis

When a hemolytic transfusion reaction is suspected, the infusion must be stopped immediately and a post-transfusion blood specimen should be sent to the transfusion service laboratory (Fig. 74.1). A clerical check to confirm the patient's name, hospital number, and donor unit number should be undertaken quickly. The error may involve the cross match sample, the requisition forms, or the unit of blood. Because one or more units of blood may have been confused, mislabeled, or switched, it is important to determine immediately if another patient is at risk.

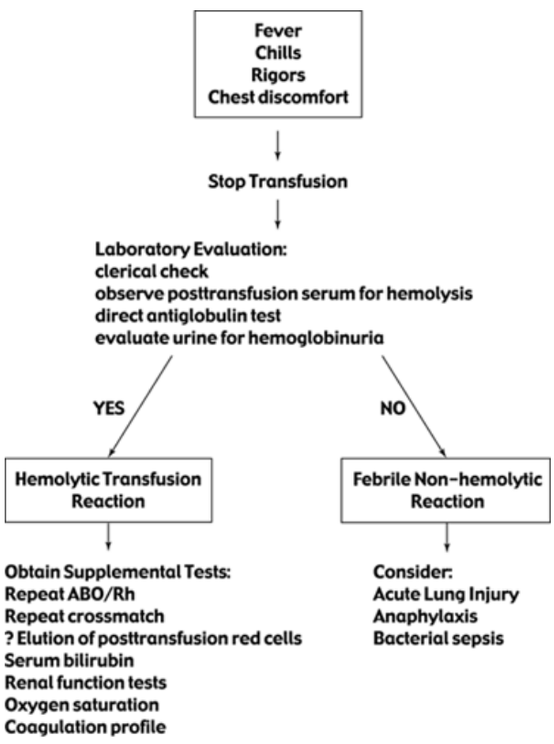

FIGURE 74.1. Algorithm for evaluating patients with fever, chills, rigors, or chest discomfort following a blood or blood-component transfusion.

The laboratory evaluation seeks evidence of hemolysis by visually observing the postreaction serum or plasma specimen for a pink or red hue. The direct antiglobin test is positive in almost all hemolytic transfusion cases. A urine specimen may be examined for the presence of free hemoglobin or, subsequently, for urinary hemosiderin.

If the clerical check, visual inspection, or direct antiglobin test support the diagnosis of a hemolytic transfusion reaction, additional testing should be conducted to determine the cause of the reaction and to provide baseline measurements for future monitoring. These tests include repeating the ABO and Rh typing on pre- and posttransfusion reaction samples and on the unit of blood. A crossmatch should be performed with prereaction and postreaction samples using red cells from the unit or from a stored, sealed segment. If the direct antiglobin test is positive, donor and patient sera should be evaluated for unexpected antibodies and consideration of eluting the antibody from the patient's cells. Plasma hemoglobin and serum haptoglobin measurements may be conducted. Posttransfusion hemoglobin and hematocrit results should be evaluated to determine if the expected

hemoglobin or hematocrit elevation occurred. The unconjugated bilirubin level should be obtained on a specimen drawn preferably 5 to 7 hours after transfusion. Renal function and oxygen saturation testing should be conducted to establish baseline information.

If hemolysis is suspected and an antibody-mediated etiology cannot be ascertained, a Gram stain of blood from the unit of blood may be evaluated, and the unit cultured.

Treatment

Treatment of hemolytic transfusion reactions includes immediate cessation of the transfusion and implementation of supportive therapy.

Monitoring vital signs, urine output, renal function, pulmonary function, coagulation status, and if necessary, cardiac filling pressures, provide data for determining needed therapeutic interventions. Hypotension should be treated with volume infusion as ascertained by invasive hemodynamic monitoring. Vasopressors such as dopamine are indicated if hypotension is not reversed by fluid infusion. Dopamine, when used in low doses, has a vasodilatory effect on renal vascular perfusion and may exert a beneficial effect on renal function. Osmotic diuretics such as mannitol and, other diuretic agents were used previously on the basis of anecdotal reports. The results of clinical findings and pulmonary function monitoring dictate the need for oxygen therapy, intubation, and ventilatory support. Treatment of DIC includes plasma, platelet, and cryoprecipitate transfusions and reversal of hypotension.

Treatment strategies under investigation involve agents aimed at inhibiting or reversing the pathophysiologic alterations (4).

Febrile Nonhemolytic Transfusion Reactions

Febrile, nonhemolytic transfusion reactions (FNHTRs) are characterized by a temperature increase of 1°C or greater during or within 1 hour after a transfusion in the absence of other medical causes of fever including a hemolytic reaction. Additional features of FNHTRs include chills, a cold sensation, rigors, or discomfort. Reports of FNHTRs vary from 0.5% to approximately 2% per red-cell unit transfused and from approximately 2% to 23% for platelet transfusions (5,6 and 7).

Pathophysiology

FNHTRs also called “chill-fever” reactions occur on the basis of at least two distinct mechanisms. Traditionally, FNHTRs result from immune recognition of infused leukocytes or platelets by recipient leukoagglutinin or HLA-antibodies. A second, more recently discovered mechanism, involves passive infusion of inflammatory cytokines generated by white blood cells contained in red cell or platelet components during storage (5,6 and 7).

FNHTRs related to antibodies in the recipient's plasma occur predominantly in patients with a history of previous transfusions or prior pregnancies. Recipient cytotoxic, agglutinating, or HLA-antibodies react against antigens on infused granulocytes, lymphocytes, or platelets. The “threshold” leukocyte count evoking “chill-fever” reactions in susceptible patients varies from 2×10^8 to 2.5×10^9 white cells per component. Most involve reactions against granulocytes. The amount, rather than the type of antibody, the number and subset of leukocyte transfused, and the transfusion rate correlate with reaction severity.

FNHTRs corresponding to passive cytokine infusion relate predominantly to platelet transfusions. Following platelet concentrate preparation in which white cells are not removed, IL-I, IL-6, IL-8, and TNF-α levels increase during storage. Passive infusion of IL-6 and other cytokines present in the plasma supernatant of the platelet concentrates presumably causes one half of the “chill-fever” reactions. Low levels of residual white cells account for the remaining reactions (6, 7). Prestorage leukocyte-reduction reduces the frequency of severe FNHTRs by 50% compared to nonleukocyte reduced platelet transfusions (7).

Clinical Presentation

Classically, FNHTRs consist of an immediate transient reaction marked by a flush, palpitation, tachycardia, cough, chest discomfort, or neutropenia. Following a latent interval of approximately 15 to 60 minutes, the diastolic blood pressure increases and headache, chillness, or rigors occur. Subsequently the temperature rises, apathy, irritability, impaired mentation, and prostration follow and may persist for several hours. A neutrophilic

leukocytosis with a shift to the left occurs 2 to 5 hours following infusion.

FNHTRs complicate and interrupt transfusion therapy, because fever may be the presenting sign of a hemolytic reaction. Onset of fever and/or chills should result in cessation of the transfusion and a subsequent laboratory evaluation to determine whether hemolysis occurred. The signs and symptoms of a FNHTR usually are self-limited. Fortunately, more severe consequences are infrequent.

Laboratory Diagnosis

Despite advances in understanding the etiology of FNHTRs, the diagnosis is one of exclusion, and is made by demonstrating the absence of hemolysis during the evaluation of a possible hemolytic transfusion reaction.

Treatment

Currently, leukocyte-reduction by filtration conducted, preferably, prior to red-cell or platelet storage serves as a preventive measure. Previously used methods of leukocyte-reduction such as buffy-coat removal and freezing and washing are significantly less effective than filtration with specially designed leukocyte-reduction filters.

Treatment of reactions involves symptomatic therapy with nonaspirin antipyretics. Severe rigors respond to meperidine.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI or noncardiogenic pulmonary edema, pulmonary “hypersensitivity,” or severe allergic pulmonary edema) is a clinical constellation of an adult respiratory distress–like syndrome that occurs within hours of a blood transfusion (8, 9).

Affected patients develop fever, substernal chest pain, marked dyspnea, cyanosis, cough, blood-tinged sputum and hypoxemia, hypotension, and bilateral pulmonary edema within 4 hours (usually 1 to 2 hours but up to 6 hours) after transfusion. TRALI has been reported following infusion of whole blood, red blood cells, and fresh frozen plasma, as well as granulocytes, cryoprecipitate, platelet concentrates, and apheresis platelets. TRALI occurs at a frequency of approximately 1 per 5,000 units infused or from 0.04% to 0.16% per patient transfused. The mortality rate is approximately 5%.

Pathogenesis

Granulocyte and/or lymphocyte antibodies are present in the plasma of 50% to 90% of infused components. These antibodies include anti-NA2, anti-5b, anti-NB2, anti-NB1, and anti-HLA antibodies.

The antileukocyte antibodies, when infused into a recipient with corresponding leukocyte antigens, result in white-cell pulmonary sequestration. Complement activation occurs in TRALI animal models. Lung injury results from release of granulocyte contents, an increase in vascular permeability, and fluid and protein exudation into the alveoli.

TRALI does not universally follow infusion of antileukocyte antibodies and leukocyte antibodies are not detected in all cases of TRALI. These observations led to an alternative TRALI hypothesis that involves a “two-hit” model (10). Patients have a predisposing condition such as recent surgery, active inflammation, or infection, and then a second event, such as an infusion of biologically active lipids present in stored blood components leads to neutrophil priming and adherence to endothelial cells. However, the “two-hit” model is inconsistent with clinical observations because TRALI occurs at a relatively low frequency among patients receiving stored blood components with the implicated conditions.

Clinical Presentation

The clinical presentation resembles the adult respiratory distress syndrome and occurs shortly after blood transfusion. Less frequently, the syndrome is delayed for several days after transfusion. The severity relates primarily to the extent of hypoxemia. TRALI is a form of noncardiogenic pulmonary edema and is distinguished from other forms of pulmonary edema on the basis of normal to decreased pulmonary capillary wedge pressures; normal pulmonary artery pressure; absence of jugular venous distention, murmurs or gallops; normal cardiac silhouette on chest radiograph; absence of pulmonary vascular congestion; and no evidence of myocardial infarction.

The protein content of TRALI pulmonary edema fluid is elevated compared to cardiogenic pulmonary edema. The ratio of protein in edema fluid compared to protein in blood usually is greater than 0.7 in noncardiogenic edema and less than 0.5 in cardiogenic pulmonary edema. This relates to increased vascular permeability. Arterial oxygen saturation is decreased, acidosis may occur, and hemoconcentration has been observed.

Treatment

Intubation and mechanical ventilatory assistance is required in as many as three-fourths of patients. TRALI usually responds to supportive therapy within 24 to 48 hours. Pulmonary infiltrates resolve in 80% of patients and arterial blood-gas measurements return to baseline within 96 hours.

Diuretic therapy has been associated with further decreases in pulmonary capillary wedge pressures, cardiac output, and hypotension. Instead these parameters are more likely to improve with saline infusion.

Laboratory Finding

The diagnosis is based on clinical presentation. The laboratory investigation involves detecting antileukocyte antibodies. This usually proceeds in a step-wise fashion in which donors with predisposing conditions for antibody formation are identified and tested for anti-HLA and antigranulocyte antibodies. This includes women with prior pregnancies and donors with a history of blood transfusion. When donors with antibodies are identified, a crossmatch should be performed between donor serum and recipient white cells, if feasible. A positive crossmatch confirms the diagnosis, but a negative result does not rule out the diagnosis.

Future blood donations from implicated donors, if used, should avoid transfusion of components containing plasma. Alternatively, the donor should be deferred from future blood donation.

Allergic Reactions

Allergic reactions, manifest by urticaria and pruritus, occur at a frequency of approximately 0.5% per red-cell transfused and approximately 1% to 3% per platelet transfusion presumably reflecting the lower plasma volume in red blood cell transfusions compared to platelets (5,6 and 7). Severe anaphylactic reactions occur in IgA deficient transfusion recipients who have class-specific anti-IgA. The estimated frequency of transfusion-associated anaphylactic reactions is 1 per 150,000 units and ranges from 1 per 47,000 transfusion to 1 per 770,000 units (11).

Urticaria

Hives and pruritus, usually in the absence of fever, result presumably from a reaction between a protein in infused plasma and a corresponding IgE antibody in the recipient. Significant morbidity results if hives occur in anatomically compromised positions such as the larynx and requires prompt intervention. Otherwise, routine treatment involves stopping the transfusion, administering an antihistamine, waiting for the pruritus to subside, and in most instances continuing the transfusion. Because urticaria is not a sign of hemolysis, laboratory investigation for a hemolytic transfusion reaction is unnecessary. If hives do not respond to symptomatic therapy, recur frequently following subsequent transfusions, or cause significant clinical problems, plasma should be removed from future red cell and platelet transfusions by washing with saline solutions.

Anaphylactic Transfusion Reactions

An immediate, generalized reaction during a blood transfusion should raise suspicion of a hemolytic or an anaphylactic reaction. Anaphylactic reactions occur immediately or may be delayed for as long as 1 hour after exposure. Other causes of anaphylaxis including exposure to allergens such as drugs, foods, or latex gloves should be considered. Signs and symptoms of IgA anaphylactic reactions include skin manifestations (hives, rash, pruritus, angioedema), respiratory findings (dyspnea, stridor, wheezing), cardiovascular events (hypotension, syncope, arrhythmia, shock), and gastrointestinal complications (cramps, diarrhea, vomiting). Anaphylactic reactions have been reported following infusion of whole blood, red cells, plasma, platelets, cryoprecipitate, and IV-gamma globulin.

Anaphylactic reactions may occur in previously untransfused patients and in patients transfused previously without complications. The clinical diagnosis requires laboratory confirmation. Because most affected patients are IgA deficient (serum IgA less than 0.05 mg/dL) and have class-specific anti-IgA, the laboratory evaluation consists of testing for IgA levels and the presence of anti-IgA antibodies (11). IgA deficiency in blood donors occurs at a frequency of approximately 1 per 400. One in 1,200 blood donors are IgA-deficient and also have class-specific anti-IgA. This frequency far exceeds that of observed anaphylactic reactions suggesting that detection of anti-IgA does not predict a risk for anaphylactic transfusion reactions.

Treatment of anaphylactic reactions includes immediate cessation of the transfusion and administration of epinephrine and other supportive therapy.

Further blood transfusions should be delayed until a pretransfusion sample is tested for IgA concentration. If IgA is present, consideration of other causes should be entertained. If transfusions cannot be withheld, red cells or platelets washed with large amounts of saline may be infused. Fresh frozen plasma and cryoprecipitate should be obtained from IgA deficient donors. If IgA test results indicate detectable IgA levels, the likelihood of an anaphylactic reaction related to IgA infusion is considered low and washed components or components from IgA deficient donors generally are not recommended.

Red Eye Syndrome

A cluster of adverse ocular reactions following transfusion occurred in late 1997 through early 1998 (12). Patients experienced severe bilateral conjunctival erythema and/or hemorrhage, eye pain, headache, periorbital edema, arthralgias, nausea, dyspnea, and rash within 24 hours of transfusion. The symptom complex resolved within 5 days (range 2 to 21 days). All of the patients received blood components subjected to leukocyte-reduction filtration using filters from the same manufacturer. The filters were recalled and no subsequent reactions were reported. A toxic or allergic reaction was suspected. A decade previously, severe reactions during platelet apheresis collections were attributed to allergic reactions to the sterilization agent, ethylene oxide gas (13).

Hypervolemia

Patients with impaired myocardial or renal function are at risk of hypervolemia and heart failure. An average unit of whole blood contains 56 mEq sodium, a unit of red blood cells has 8 to 20 mEq sodium, and a unit of red cells with an additive solution has 24 to 30 mEq sodium. With the exception of acute blood loss situations, infusion rates should be 2 to 4 mL/kg/hour but reduced to 1 mL/kg/hour in patients known to be at risk for hypervolemia.

Nonimmune Hemolysis

Transfused red cells subjected to osmotic, mechanical, or thermal stress may burst and release hemoglobin into the circulation. Hypotonic solutions, such as 25% albumin diluted with sterile water, or medications added to blood may lead to osmotic rupture (14). Only normal saline or agents shown to be safe and to not adversely affect the blood component should be added.

Overheating of red cells by blood warmers may result in red cell destruction; only devises with alarms and found in compliance with the FDA should be used.

Infusion pumps should be selected that do not disrupt red cells or have tubing that interferes with red cell flow.

Of note, hemolysis has been reported during cell salvage

procedures in association with turbulence at the air/fluid interface.

A negative laboratory evaluation for immune hemolysis in conjunction with an investigation of the factors associated with hemolysis should provide a cause for the nonimmune hemolytic event and provide information for appropriate corrective action.

Air Embolism

Air embolism is considered by most as an archaic complication associated with vented glass bottles and is not considered to occur with modern plastic containers. Observations by a state health department with mandatory error, accident, and severe adverse reaction reporting support this presumption (15). No cases of air embolism were associated with 9 million routine transfusions. However, fatal air embolism occurred at a rate of 1 per 30,000 intraoperative blood recovery procedures and 1 per 38,000 postoperative blood recovery procedures between 1990 and 1995. In each of the fatal cases, blood recovery and subsequent infusion occurred with a pressure cuff or a pressure infusion devise applied to the bag. Using a model system constructed to stimulate operative blood recovery and pressurized readministration, 200 mL air were infused within 4 seconds; an amount considered fatal in humans.

Techniques for preventing air embolism involve avoidance of direct reinfusion from red cell recovery containers, limiting the reinfusion from the recovery containers, limiting the reinfusion of blood under pressure, and maintaining vigilance.

Symptoms of air embolism include chest pain, cough, and acute onset of dyspenea. The infusion should be stopped immediately by clamping the administration tubing. The patient should be placed on the left side in a head down position and appropriate surgical consultation to remove air from the right atrium and pulmonary artery should be obtained.

Complications of Massive Transfusion

Massive blood loss is defined as replacement of a patient's total blood volume, transfusion of more than 10 units of blood within 24 hours, replacement of 50% of the circulating blood volume in less than 3 hours, or transfusion of more than 150 mL per minute. Both the volume and the time period are relevant to the clinical urgency and the metabolic and coagulation consequences of massive transfusion (16).

Blood bank considerations of massive transfusion include logistic concerns about providing multiple blood components for one or more patients urgently, coagulation abnormalities arising from massive blood replacement, metabolic consequences of infusing large amounts of anticoagulated, stored blood components, and the effect of rapidly infusing large amounts of relatively cold fluids.

Logistical Issues

Urgent situations heighten the probability of misidentifying patient or patients, blood samples, and blood components. Preparing and implementing massive transfusion protocols by multidisciplinary teams should decrease mishaps involving identification errors in emergency situations. Use of group O red cells in lieu of “type-specific” blood and decisions about use of Rh-negative red cells for emergency release should be decided during the planning stages. The time needed to transfer red cells from the transfusion service to the patient, thaw frozen plasma, and prepare platelet transfusions should be part of the discussions with the multidisciplinary team. The ability to restock necessary blood components should be considered by hospital transfusion services in determining the routine level of components stored in hospital inventory.

Hemostasis

Stored red cells are devoid of functional platelets and have minimal plasma and coagulation factor content. Platelet concentrates prepared from whole blood contain an equivalent of one unit of plasma. Factor VIII levels fall to 50% of initial levels after one day of storage and further loss occurs during the 5-day storage period. Factor V levels fall to 50% of initial activity 14 days after storage.

Following massive blood loss, blood volume is expanded by infusing crystalloid solutions. Infusion of red cells lacking platelets and coagulation factors leads to dilution of these hemostatic elements. In addition, platelets, fibrinogen, and factors V and VIII are consumed during the coagulation process. Dilutional thrombocytopenia develops during massive transfusion; platelet counts should be monitored. Platelet transfusion, one unit per 12 kg body weight or one single donor (apheresis) platelet unit should be given to maintain the platelet count above 50,000/uL or 100,000 u/L in patients with central nervous systems injury. The prothrombin time and partial thromboplastin times should be monitored, and, in general, plasma, 10 to 15 mL/kg body weight, should be given when these parameters exceed 1.5 times control values. The fibrogen concentration should be maintained above 75 to 100 mg/dL by infusing one unit cryoprecipitate per 5 kg body weight (16).

Metabolic Factors

Patients suffering massive blood loss are at risk for hypoperfusion with resultant acidosis and hyperkalemia. Red blood cells are stored at acidotic pH ranges and have elevated potassium levels following storage. Red cells containing the anticoagulant/preservation solution CPDA-1 contain 33.2 g sodium citrate compared to only 5.31 g in red cells containing the additive solution AS-1 (17). Reperfusion reverses systemic acidosis, citrate is metabolized by the liver, muscle, and kidneys to bicarbonate with resultant hydrogen ion binding, and stored red cells reabsorb potassium when returned to the circulation. Citrate metabolism is impaired by liver disease and hypothermia. In a healthy 70-kg adult, infusion of two units of citrated whole blood at a rate of 2 mL/kg/minute results in citrate toxicity with circulatory depression, decreased cardiac output, reduced pulse pressure, and hypotension. Citrate also binds magnesium, which can result in hypomagnesemia. Infusion of calcium gluconate (or magnesium) in practice, may be indicated for treatment of severe reactions. Usually, the outcome in massive transfusion is alkalosis and hypokalemia. Infusion of glucose in anticoagulated red cells and low doses of mannitol contained in AS-1 solutions does not result

in hyperglycemia or clinical diuresis. Red cell 2,3 DPG levels diminish during storage but the levels are restored within 8 to 12 hours following transfusion.

Hypothermia

Infusion of cold blood and intravenous fluids lowers body temperature. Hypothermia slows citrate metabolism, potentiates the harmful myocardial depressant effects of hypothermia and hypocalcemia, and reduces oxygen release from red cells. Blood warmers are used, in massive transfusion situations, to prevent these complications.

Bacterial Sepsis

Bacterial contamination of blood and blood components causes 14% of transfusion related fatalities reported to the FDA or 5 to 10 deaths per year in the United States (1). Overall, one death occurs per 3 million units transfused. Of the 86 bacterial contamination-associated fatalities reported to the FDA between 1976 and 1998, 58 occurred among platelet transfusion recipients and 28 among red cell recipients. Clinical sepsis related to red-cell and platelet transfusion is estimated to occur 10 to 100-fold more frequently than fatal reactions.

Pathophysiology

Bacterial contamination of red cell and platelet components occurs as a result of bacterial entry through skin plugs at the time of phlebotomy, transient bacteremia during blood or platelet collection, contaminated containers, minute holes in blood containers, or nonsterile pooling or aliquoting. Bacteria may contaminate bag ports when frozen components are thawed in a water bath (18).

Microorganisms contaminating platelet concentrates include *Staphloccus epidermidis*, *Escherichia coli*, *Bacillus* species, *Salmonella* species, *Protease mirabilis*, *Klebsiella* species, *Staphloccus aureas*, *Serratia* species, *Pseudomonas* species, *Enterobacter*, and *Streptococcus*.

Microorganisms contaminating red cells or whole blood include *Yersinia enterocolitica*, *Clostridium perfringens*, *Pseudomonas acnes*, *Enterococcus*, *Enterobacter*, *Serratia*, and *Klebsiella* (18, 19, 20).

Assuming bacteria enter the containers at the time of phlebotomy, the bacteria enter log phase growth after several days in room temperature stored platelets (Fig. 74.2). *In vitro* studies indicate platelet concentrates stored for 1 to 4 days had 2.6×10^3 to 1.0×10^4 colony-forming units per milliliter compared to 1.2×10^7 to 4.4×10^{13} colony-forming units in concentrates stored for 5 days (21). The contamination rate varies between 0.04% and 0.3% per unit for platelet concentrate prepared from whole blood and from 0% to 0.49% per apheresis (single donor) platelet concentrate.

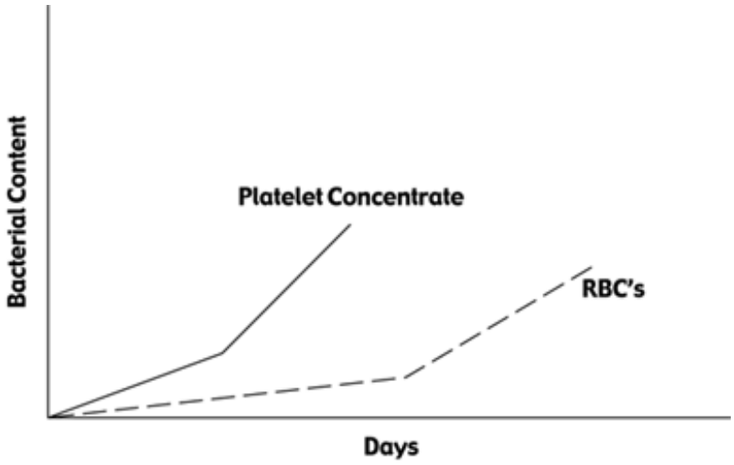

FIGURE 74.2. Bacteria proliferate more rapidly in platelet concentrates (stored at room temperatures) compared to red blood cells (stored at refrigerated temperatures).

Y. enterocolitica causes the majority of septic reactions associated with red cell transfusions. Fourteen deaths caused by *Yersinia*-contaminated red cells were reported to the FDA between 1976 and 1998. Because red cells are stored at 1 to 6°C, psychrophilic organisms such as *Yersinia* and *Pseudomonas* are the most likely pathogens. Assuming bacterial entry occurs at phlebotomy, an approximate 3-week lag period ensues prior to significant bacterial proliferation and accumulation of endotoxin sufficient to result in clinical symptoms.

Clinical Presentation

Criteria for suspecting a septic transfusion reaction include temperature elevations of 1 to 3.5°F or 1 to 2°C accompanied by rigors, tachycardia, and greater than 30 mmHg decreases or increases in blood pressure. Additional clinical signs or symptoms include tachycardia, nausea and vomiting, lumbar pain, shortness of breath, diarrhea, chest pain, and cyanosis.

Laboratory Diagnosis

The container and remaining blood should be evaluated for bacterial contamination by Gram stain and microbiological culture. A Gram stain is most likely to reveal bacteria when more than 10^6 colony forming units per milliliter are present. An acridine orange stain may detect bacteria at 10^5 colony-forming units per milliliter.

Investigation of biochemical parameters associated with bacterial growth are in progress to detect and thereby interdict of infected components. Included are reduced glucose and pH measurements, loss of platelet swirling, color changes, and evolved gases. Additional parameters under study include ribosomal RNA detection and bacterial culturing following storage but prior to release (18).

Treatment

When septic reactions are suspected, the transfusion must be discontinued immediately and should not be restarted. Supportive care and broad-spectrum antibiotic coverage should be instituted promptly. The diagnosis should be sustained despite a negative Gram stain, because this test reveals bacteria in only two thirds of symptomatic cases.

Hypotensive Reactions Following Transfusion

Severe hypotensive reactions following passage of red cells, plasma, or platelets through bedside leukocyte reduction filters have been reported in patients receiving angiotensin-converting enzyme (ACE) inhibitor medications. Severe hypotension occurs within minutes of starting the transfusion and may be accompanied by skin flushing and loss of consciousness. The incidence is unknown but considered infrequent.

The pathophysiology appears related to bradykinin is generation as plasma passes over leukocyte-reduction filters. This vasodilatory, nonapeptide has a plasma half-life of less than 30 seconds. The breakdown of its active metabolite, des-Arg^{9}-bradykinin, is significantly prolonged in the presence of ACE inhibitors (22).

Hypotensive reactions occur more frequently following platelet transfusions than red-cell transfusions, presumably because more plasma is present in platelets than red cells. The reactions have been reported following filtration with negatively charged and positively charged filters. Not all of the reported events involve patients taking ACE inhibitors. However, the hypotensive reactions occurred exclusively in patients receiving components leukocyte-reduced with bedside filters and not with prestorage leukocyte reduction or when filtration was performed in the laboratory. These findings relate, probably, to the short half-life of bradykinin and its metabolites and their degradation prior to infusion.

Leukocyte reduction performed prior to storage should obviate these reactions. Treatment may require intravenous vasopressor agents.

DELAYED TRANSFUSION REACTIONS

Part of "74 - Complications of Blood Transfusion"

In addition to immediate adverse consequences of blood transfusion, some untoward events occur days to years after transfusion (Table 74.3). Nonacute immunologic complications include delayed hemolytic reactions, bystander hemolysis in patients with sickle cell anemia, alloimmunization, graft-versus-host disease (GvHD), and immunosuppressive effects of blood transfusion. Nonimmune complications involve iron overload and transfusion-transmitted diseases.

TABLE 74.3. DELAYED TRANSFUSION REACTIONS

	Risk per Unit Transfused
Delayed serologic and hemolytic transfusion reaction	
serologic	1:1600
hemolytic	1:6700–1:9100
“Bystander hemolysis”	?
Alloimmunization	
red cells	
hospitalized patients	1%–2%
multiply transfused patients	10%
platelets*	
HLA-antibodies	
nonleukocyte-reduced	˜ 45%
leukocyte-reduced	˜ 18%
platelet specific antibodies	6%–11%
refractoriness	
nonleukocyte-reduced	7%
leukocyte-reduced	16%
Graft-vs-host disease	infrequent
Iron overload	after ˜80 units RBC's
Post transfusion purpura	rare
Immunosuppressive effects	?

*TRAP Study results[30]

Delayed Serologic and Hemolytic Transfusion Reactions

Delayed hemolytic transfusion reactions refer to destruction of transfused red cells days to weeks after transfusion by an immune response against recently infused foreign antigens. A delayed serologic transfusion reaction involves production of antibodies against recently infused foreign alloantigens and possibly autoantibodies in the absence of clinical hemolysis.

Diagnostic criteria defining delayed hemolytic/serologic transfusion reactions require that three of the following five criteria are met: (i) compatible crossmatch with pretransfusion serum; (ii) negative antibody screen using recipient's pretransfusion serum; (iii) incompatible crossmatch and a rising titer of the incriminated antibody in postreaction serum samples; (iv) history of blood transfusion, pregnancy, or both; and (v) clinical or laboratory evidence of hemolysis. The incidence of delayed serologic transfusion reactions is approximately 1 per 1,600 red-cell units transfused, and the incidence of delayed hemolytic transfusion reactions ranges from 1 per 6,700 to 1 per 9,100 units on the basis of reports released during the 1990s (23, 24).

Of note, persistence of positive direct antiglobulin tests, long after the infused cells would be expected to have been removed from the circulation, suggests autoantibodies are produced or nonspecific uptake of alloantibodies occurs in patients with delayed hemolytic or serologic reactions (23).

Clinical Presentation

The onset of anemia, fever, and jaundice approximately one week after a transfusion should raise suspicion about a delayed hemolytic transfusion reaction. Fever, at least 2°F (1°C) occurs in up to 75% of patients with delayed hemolytic reactions. Decreases in the hematocrit or hemoglobin occur in almost all of the patients, the bilirubin concentration increases in up to two thirds, and approximately one sixth of patients develop oliguria or an increase in serum creatinine levels. Red-cell destruction occurs 3 to 21 days after transfusion. For most patients, this complication is relatively benign and does not involve the severe reactions associated with an acute hemolytic reaction. However, increased levels of proinflammatory mediators have been observed in the setting of a delayed hemolytic transfusion reaction (25).

Laboratory Diagnosis

All patients with delayed hemolytic/serologic reactions have a positive direct antiglobulin test with anti-IgG reagents and many show reactivity for complement. In two-thirds to three-fourths of cases a single antibody is involved, in the others multiple antibodies have been found through elution studies. Antibodies against Rh phenotypes E, C, e, D, and Cw and antibodies against Kell(K), Kidd (Jka), and Duffy (Fya and Fyb) are involved predominantly. Previously, anti-Jka and anti-Fya antibodies were considered more likely to result in hemolytic reactions rather than isolated serologic findings. However, studies conducted in the mid-1990s show the ratio of hemolytic: serologic reactions decreased from that observed a decade previously. Explanations for this observation include a decrease in the average length of hospital stay in which Fya sensitization would not be reported and use of more sensitive serologic test reagents that detect previously undetected, nonhemolytic Jka antibodies (24).

In many patients, the direct antiglobin test remains positive for 6 months or longer posttransfusion. Eluates from the red cells demonstrate an alloantibody with specificity against transfused red cells or a panagglutinin (23).

Treatment

Treatment rarely is needed because of the relatively benign nature of the hemolytic event. Supportive care is indicated only for serious complications.

Severe Reactions Following Transfusion in Patients with Sickle Cell Disease

Alloimmunization against red cell antigens occurs in approximately 25% of patients with sickle cell disease. Antibodies form, most frequently against E, C, K, and against Fya, Jkb, S, and D antigens. In addition, delayed reactions occur as a result of antibodies against Jka, Fyb, and s antigens.

Pain crises, posttransfusion hemoglobinemia, pulmonary infiltrates, and disseminated intravascular coagulation have been reported after exchange transfusions in patients with sickle cell disease (26,27 and 28). In many cases the direct antiglobulin test is nonreactive. The etiology of these events is not understood completely and, conflicting hypotheses are under consideration. These include suppression of endogenous erythropoiesis and the subsequent fall in hemoglobin concentration, and “hyper-hemolysis” in which transfused red cells are destroyed and endogenous red cell production decreases.

Alternatively, “bystander-hemolysis” occurs in which presumably innocent, bystander cells undergo lysis as a result of a non–red-cell alloantibody-antigen reaction that causes complement activation. Antibody reactions against infused alloantigens, such as HLA and plasma protein antigens, may cause complement activation. Sickle cells have high affinity for complement activation in that the densest sickle cells have increased C5b-7 and C9 binding and subsequent increased susceptibility to C5b-9 mediated lysis. This parallels findings of complement on red cells involved in delayed hemolytic transfusion reactions presumably opsonized by alloantibodies not usually associated with complement binding (Rh system antibodies). As such, the postulated mechanism for “bystander hemolysis” may occur during any delayed hemolytic transfusion reaction.

Several of the reported patients developed profound, life-threatening anemia; transfusions did not result in sustained increases in hematocrit or hemoglobin levels. One approach to treatment involved discontinuing transfusions and prescribing a short course of corticosteroid therapy.

Alloimmunization

Red Cell Transfusions

One to 2% of hospitalized patients have clinically significant red cell alloantibodies. The frequency increases to approximately 10% among transfused patients and approximately 25% in patients with sickle cell anemia. Red cell allo antibodies develop 2 to 24 weeks post transfusion (29).

Compatibility testing prior to transfusion is designed to detect clinically significant alloantibodies. Frequently encountered alloantibodies are directed against, Rh, Kell, Duffy, and Kidd antigens.

Platelet Transfusions

The largest, randomized clinical trial investigating alloimmunization and refractoriness to platelet transfusions, the Trial to Reduce Alloimmunization to Platelets (TRAP), demonstrated that leukocyte reduction by filtration reduced alloimmunization rates in patients with acute myelocytic leukemia (30). Lymphocytotoxic HLA-antibodies were detected in 45% and 18% of patients randomized to receive non-leukocyte–reduced and leukocyte-reduced platelet concentrates. Refractoriness to platelet transfusions was reduced significantly from 16% to 7%, respectively. Antibodies against platelet-specific antigens occurred in 11% of those receiving non-leukocyte–reduced platelets compared to 6% of those receiving leukocyte-reduced platelets; a nonstatistically significant difference. These findings confirmed other reports showing that leukocyte reduction to levels below 5×10^6 white blood cells per transfusion effectively prevents alloimmunization and refractoriness to platelet transfusions.

Graft-versus-Host Disease

Graft-versus-host disease (GvHD) occurs after bone marrow transplantation, presumably by engraftment in recipients of donor-derived immunocompetent donor T lymphocytes.

In transfusion-associated GvHD, bone marrow involvement occurs in addition to skin, liver, and gastrointestinal tract dysfunction seen in marrow-related GvHD. Fever, erythematous maculopapular rashes, anorexia, vomiting, right upper-quadrant pain, cough, and diffuse diarrhea occur. Liver function enzymes, bilirubin, and alkaline phosphatase are elevated. The hepatocellular damage and elevate transaminase levels reflect liver damage in transfusion-associated GvHD in contrast to marrow transplant GvHD where biliary damage and obstruction predominate. Pancytopenia reflects marrow involvement (31).

The pathophysiology includes multidirectional interaction of CD4+ and CD8+ T cells activated by autologous and allogeneic events, cytotoxic antibodies, elaboration of cytokines IL-1, IL-2, and TNF. Host HLA antigens serve as targets of donor effective cells. Different CD4+/CD8+ ratios and Th-1 and Th-2 subpopulations occur in patients with varying underlying disorders (32).

Fever occurs 4 to 23 (median 10) days after the implicated transfusion. A rash develops 2 days later and may evolve to generalized erythroderma, bulla formation, and epidermolysis. Leukopenia occurs 11 to 31 (median 16) days after transfusion. Hepatomegaly and jaundice occur frequently, but lymphadenopathy and splenomegaly occur less often. The mortality rate is approximately 90% at a median 21 days after transfusion. Death usually results from infection or hemorrhage secondary to marrow aplasia and pancytopenia.

The diagnosis is clinically supported by finding donor cells in affected tissues, HLA DNA typing of the donors and the patient, or demonstrating Y chromosome regions in female patients.

An estimated minimal infusion of 10^4 lymphocytes per kilogram of recipient weight results in transfusion-associated GvHD. Implicated blood components include unirradiated whole blood, red blood cells, platelets, granulocytes, and fresh, nonfrozen plasma.

Transfusion-associated GvHD has been reported in immunocompetent patients including those undergoing cardiovascular surgery, cholecystectomy, tumor resection surgery, and an otherwise healthy pregnant woman with mild preeclampsia. These cases may reflect the frequency of transfusions from HLA-homozygous donors to HLA-heterozygous recipients who share a haplotype with the donor. The estimated risk of this event in United States whites is 1 in 17,700 to 1 in 39,000. If the donation involves parents and children (directed donations), the rate is increased 21-fold (33).

Most reports of transfusion-associated GvHD involve patients with impaired cellular immunity, hematologic malignancies, or immaturity (34). Generally accepted categories of patients considered at high risk of transfusion-associated GvHD include bone marrow transplant recipients, congenital cellular immunodeficiency syndrome patients, intrauterine transfusion recipients, granulocyte transfusion recipients, patients with Hodgkin's Disease or nonHodgkin's lymphoma, patients with certain solid tumors such as neuroblastoma and glioblastoma, and patients receiving HLA-matched components or components from biologic relatives. A consensus has not been reached about the degree of risk for patients with hematologic malignancies such as leukemia, term newborns on extracorporeal membrane oxygenators, organ transplant recipients, or patients receiving crossmatch compatible platelet transfusions. Most agree that there is no added risk for patients with acquired immunodeficiency syndrome (AIDS) or HIV infection, most patients receiving chemotherapy, patients with aplastic anemia not receiving immunosuppressive therapy, and full term infants without other risks.

Prevention is the best treatment modality and is accomplished by subjecting cellular blood components intended for patients at risk of transfusion-associated GvHD to 2,500 cGy gamma irradiation to the central midplane of a cannister with a minimum 1,500 cGy irradiation elsewhere. Irradiated red cells undergo an enhanced potassium efflux during storage. This may pose problems for neonates receiving transfusions. Cell washing or irradiation immediately prior to transfusion should be considered for these patients. Irradiated red cells are stored for the lesser of 28 days or the maximum storage interval (35). Use of photochemical inactivation using psoralens and UV-A irradiation to prevent transfusion-associated GvHD is under investigation (36).

Iron Overload

Manifestations of iron overload include increased skin pigmentation, hepatic disease, diabetes mellitus, cardiac dysfunction, arthropathy, gonadal insufficiency, and other endocrine disorders. In hereditary hemochromatosis, symptoms of organ damage develop when iron stores increase from the normal range of less than 1 gram iron to 15 to 20 grams or more. Further increments may be fatal, but some patients tolerate body stores of 40 to 50 grams iron. Transfused patients not receiving iron chelation therapy have cardiac and possibly liver, pancreas, and endocrine organ iron deposition when they have received 100 units of blood, 20 to 25 grams iron based on an average of 200 to 250 mg iron per unit of red cells (37).

Plasma ferritin and iron-binding capacity are used to measure body iron status. However, ineffective erythropoiesis may produce elevations of plasma ferritin unrelated to increases in body iron. The iron chelator, deferoxamine, is available for clinical use, but requires prolonged parenteral infusion and is considered inconvenient and inefficient. Judgment is required for prescribing deferoxamine therapy and should take into consideration the anticipated number of red-cell units needed and the patient's age and prognosis.

Posttransfusion Purpura

Posttransfusion purpura (PTP) is a syndrome in which profound thrombocytopenia appears 5 to 14 days after transfusion. The majority of cases occur in women with a history of prior pregnancy and, almost all patients have a platelet-specific antibody, predominantly anti-HPA-1a and less frequently anti-HPA-1b, anti-HPA-3a, anti-HPA-3b, or anti-HPA-5b (38).

The thrombocytopenia is associated with alloantibodies against platelet-specific antigens not present on the patient's platelets. Hence, it is unclear why patients with such antibodies are thrombocytopenic. Potential etiologies include coexistence of autoantibodies or cross-reacting antibodies, the presence of immune complexes, or binding of transfused soluble platelet antigens to the patient's platelets.

Testing for platelet-specific antibodies includes use of platelet immunofluorescence tests, the monoclonal antibody-specific immobilization of platelet antigens assay, or modifications of these tests. Oligonucleotide hybridization testing is used to determine platelet genotypes in thrombocytopenic patients.

Infusion of intravenous immunoglobins is the treatment of choice. Therapeutic apheresis has been used successfully.

Immunosuppresive Effects of Blood Transfusion

Potential immunomodulatory effects associated with allogeneic blood transfusion include enhanced survival of renal allografts, fewer spontaneous abortions, increased recurrence rates following tumor resection, higher postoperative bacterial infection rates, fewer recurrences of Crohn's disease, and accelerated progression of HIV infection (39). Recent reports contradict earlier studies showing a benefit of alloantigen exposure for preventing spontaneous abortions and for alloantigen exposure accelerating HIV infections (40, 41).

The specific mechanism of transfusion-related immunomodulation is unknown, but is considered to be mediated, in part, by allogeneic white cells. Studies evaluating the role of leukocyte reduction are clouded by lack of consistency in dealing with confounding variables. Meta-analyses of randomized clinical trial data addressing tumor recurrences and postoperative infections do not support an adverse effect of allogeneic transfusions. However, based on the statistical power of the meta-analyses, an adverse effect of transfusion of less than 20 to 33% would not be discernible (39, 42).

One retrospective observational study of patients undergoing coronary artery bypass grafting found the risk of pneumonia increased by 5% for each unit of nonleukoreduced allogeneic red cells and/or platelets infused (43). The risk of pneumonia increased by 1% per day in relationship to the mean storage time of infused red cells. The authors postulated the retained white cells produced bioactive substances that contributed to this effect, and that leukocyte-reduction prior to storage would have prevented it. Alternatively, the authors questioned whether red cells with increased oxygen affinity, nitric oxide depletion, and increased rigidity during storage impeded blood flow in the lungs following infusion that predisposes patients to pulmonary ischemia and pneumonia.

In another study, patients undergoing coronary artery bypass grafting who received leukocyte reduced red cells had a lower incidence of postoperative infections, regardless of whether leukocyte-reduction was performed pre- or poststorage in comparison to recipients of non-leukocyte–reduced blood (44).

The inconsistencies result, in part, because of differences in study design and potential bias attributed to confounding variables. *In vitro* data, in contrast, provide data for determining mechanisms of action. For example, transfused donors cells circulate in immunocompetent surgery patients for up to 2 weeks after blood transfusion and persist for up to 18 months in multitransfused trauma patients (45). Transfusion initiates a microchimeric state in which some transfused cells circulate in the recipient for prolonged intervals (Fig. 74.3). It has been suggested that this leads to an *in vivo* mixed lymphocyte reaction in which T-cells become activated and immunomodulatory cytokines are produced with subsequent differentiation of inflammatory Th 1 cells or helper Th 2 cells. Preliminary data suggest a shift from a Th 1:Th 2 balance towards a Th 2 response. That is, graft rejection, tumor suppression, and bacterial cytotoxicity shift toward graft, infection, and cancer tolerance (46). Conclusions based on published data require careful consideration. Implementation of universal leukocyte reduction of all cellular blood components will alter clinical practice but should not preclude further investigation of the role played by leukocytes in transfusion-related immunomodulation.

TRANSFUSION-TRANSMITTED INFECTIONS

Part of "74 - Complications of Blood Transfusion"

The risk of acquiring hepatitis or a retroviral infection through blood transfusion decreased significantly during the past decade (Table 74.4). Improved tests for hepatitis C, HIV-1 and-2, HTLV I/II and HIV p24 antigen testing were implemented. Concern about emerging infections, such as HIV group O, and the theoretical risk of acquiring new variant Creutzfeldt Jacob Disease (nvCJD) led to deferral of blood donors born in, residing or traveling to endemic areas.

TABLE 74.4. TRANSFUSION TRANSMITTED INFECTIONS

	Window Period	Risk per Unit Transfused Prior to NAT
Hepatitis		
A		Infrequent
B	56–59 days (41–53 days)	1:63,000–1:233,000
C	70–82 days (35–47 days)	˜ 1:120,000
D		Infrequent
Retroviral Infection		
HIV-1/-2		˜ 1:676,000
anti-HIV	22 days	
p24 antigen	16 days (˜11 days)	
HTLV-I/-II		˜ 1:640,000
Cytomegalovirus		Various according to patient's status
Malaria		1:4,000,000
Chagas' disease		Infrequent
Syphilis		No recent cases
Parvovirus		Infrequent
Creutzfeldt Jakob disease (CJD) and new variant CJD		No cases reported

() = estimated window period post Nucleic Acid Amplification Testing-(NAT) (47, 48, 54)

In addition, testing for viral nucleic acids by nucleic acid amplification testing (NAT) began in 1999 under an FDA-approved Investigation New Drug procedure. Using this approach, NAT was performed on mini-pools containing aliquots from 24 or more individuals at approximately 20 locations in the United States. Logistic and cost restraints required pooled samples rather than single samples. NAT is intended to reduce the residual risk of hepatitis C, HIV, and hepatitis B by detecting donations made during the preseroconversion “window period,” the interval between infectivity and serodetection. Sufficient hepatitis C (10^3 to 10^4 copies per mL) and HIV (approximately 10^4 copies per mL) genomic copies are present in mini-pools, whereas hepatitis B copies are detected best in nonpooled samples (47, 48). Initial estimates indicated the HIV “window” would be reduced by 6 days and the window for HCV by approximately 35 days. Animal model experiments suggested the HIV window might be closed sufficiently to interdict transmission (49).

Hepatitis

Hepatitis A

A small nonenveloped RNA-containing virus belonging to the picornavirus family causes hepatitis A. A brief viremic phase occurs 5 to 28 days before onset of clinical disease. Transfusion-associated hepatitis A occurs infrequently because of the short viremic period before symptoms and the lack of an asymptomatic carrier state.

Transmission by donor blood components and by pooled clotting factor concentrates has been observed. Solvent/detergent treatment alone, as a viral inactivation process, is ineffective against hepatitis A.

The case-fatality rate is relatively low. However, fulminant liver failure occurred in some patients with chronic hepatitis C infection who later became infected with hepatitis A (50).

Hepatitis B

Hepatitis B, a partially double-stranded DNA virus, is a member of the Hepadnaviridae family. The infective virion or Dane particle, has a 42-mm diameter and contains surface and core, or nucleocapsid components (51).

Approximately one half of the 140,000 to 320,000 persons with acute hepatitis B annually in the United States develop symptoms and 2% to 10% become chronic carriers. Hepatitis B is transmitted through percutaneous or mucous-membrane exposures including heterosexual and male homosexual contact and intravenous drug use.

The period between infection and clinical symptoms ranges from 45 to 180 days. Hepatitis B surface antigen (HBsAg), hepatitis B DNA, and hepatitis B e antigen are present approximately 6 weeks after infection. ALT levels increase 2 weeks later, and symptoms and jaundice follow by 2 to 4 weeks. Antibodies against hepatitis B core (anti-HBc) appear at the onset of symptoms or ALT elevation and persist indefinitely. The infection resolves within 12 to 20 weeks of infection in all but approximately 5% who develop chronic hepatitis.

Transfusion-associated hepatitis B occurs at a frequency of 1 in 63,000 or 1 in 233,000 depending on the mathematical model selected for determining the risk (52, 53). The 1 in 63,000 estimate does not take into account the impact of anti-HBc testing, which is used routinely. Anti-HBc testing closes the serological windows in the setting of acute, resolving hepatitis B infection when HBsAg levels decrease before anti-HBs appears; infections with low levels of circulating HBsAg; and some hepatitis B variant infections. NAT may reduce the window between infection and hepatitis B infection by 6 to 15 days (54).

Hepatitis C

Hepatitis C, a single-stranded RNA flavivirus, causes the majority of infections formally termed non-A, non-B hepatitis. Approximately 3.9 million American have antibodies against hepatitis C, and 74% are positive for hepatitis C RNA, indicating that 2.7 million persons in the United States are infected chronically (55). Infection with genotype 1 accounts for 74% of those infected chronically (57% with genotype 1a and 17% with genotype 1b).

Risk factors for hepatitis C infection include injection drug use, cocaine use, smoking marijuana 100 times or more, early age at first intercourse, and 50 or more lifetime sexual partners. Employment in a health-related occupation, previously considered a risk factor for hepatitis C, did not have a similar association in a recent survey (55). Persons with evidence of hepatitis B infection are six times more likely to be positive for hepatitis C infection compared to those without hepatitis B infection. Estimates about perinatal transmission are low but vary considerably. In general, the efficiency of sexual transmission of hepatitis C is considered low, approximately 5% (56).

Although the incidence of transfusion-associated hepatitis C infections decreased dramatically following introduction of the initial and improved hepatitis C antibody tests in 1990 and 1992, transfusion-transmitted hepatitis C accounts for approximately 7% of the 3.9 million infected persons.

In addition to testing, efforts to reduce transmission of hepatitis C by blood transfusion incorporate a multi-layered approach. Potential donors are deferred from donation by providing predonation educational information and asking direct questions about risk behaviors for hepatitis C including intranasal cocaine use. Hepatitis C enzyme immunoassays (EIA) available in 1990 detected antibodies directed against epitopes expressed on the recombinant polypeptide, c100, derived from the NS-4 region (Fig. 74.4). Multiantigen or second-generation tests available in 1992 include recombinant polypeptides derived from the NS3 region (c33c), and the core region (c22-3), in addition to c100, contained in a composite antigen c200 comprised of c100 and c33c epitopes. Third-generation assays, providing minimal improvement over second-generation assays, use

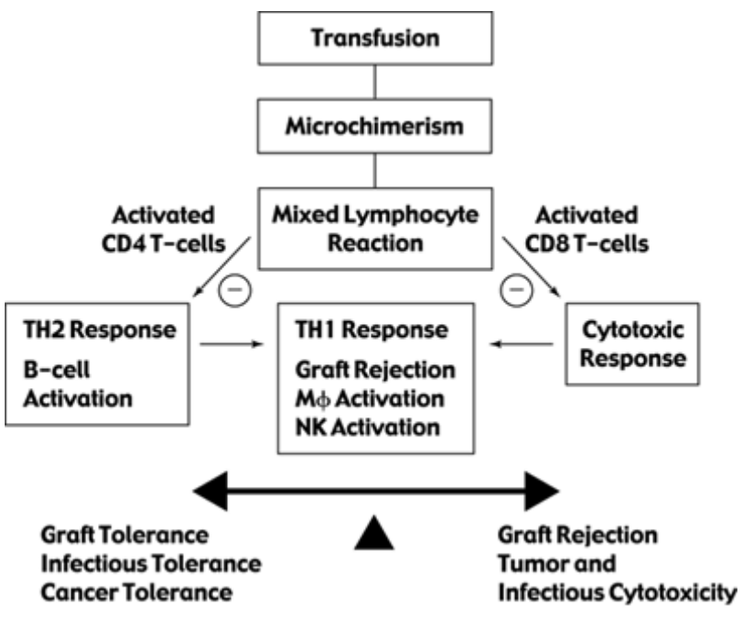

FIGURE 74.3. The prevailing pathophysiologic mechanism for transfusion related immunomodulation situates allogeneic leukocytes in a pivotal role. Transient microchimerism results in a shift towards a TH2 response. Presumably, this action is ameliorated by leukocyte-reduction (46). Mf = macrophage; NK = natural killer.

three recombinant antigens, c22-3, c200, and NS5, derived from four different regions of the HCV genome (57).

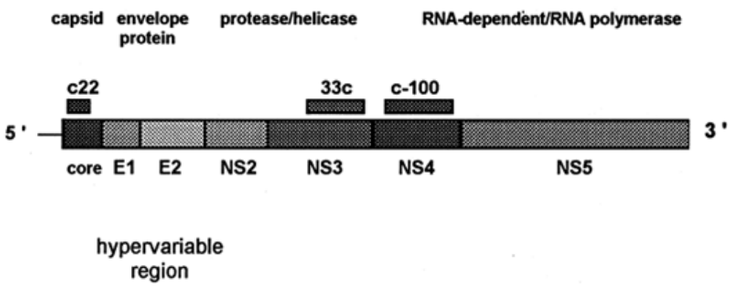

FIGURE 74.4. The hepatitis C virus genomic structure conta core, envelope (E), and various nonstructural (NS) regio c22, 33c, and c-100 refer to expressed viral epitopes. illustrated: c200 comprises c100 and c33c epitopes. (Modif from Centers for Disease Control and Prevention home pa http://www.cdc.gov/ncidod/diseases/hepatitis/hepatitis.h

Nonspecificity of EIA testing is resolved by using recombinant immunoblot assays (RIBA). Detection of hepatitis C RNA is conducted by nucleic amplification testing. Hepatitis C RNA is detectable in serum within 1 to 2 weeks of exposure and several weeks before ALT levels increase. At seroconversion, hepatitis C levels exceed 10^6 copies/mL and those infected chronically have 10^3 to 10^4 hepatitis C genome copies/mL, levels within the sensitivity of current NAT assays (47).

ALT testing, one of the two surrogate tests to prevent non-A, non-B hepatitis, is no longer mandated in the United States, although it is still performed by many blood centers. Anti-HBc has been retained, not to interdict potential donors infected with hepatitis C, but to reduce the risk of posttransfusion hepatitis B.

“Lookback” to identify recipients of blood from donors found hepatitis C antibody positive after 1990 was mandated in the United States by 1999. The “lookback” extends to recipients of blood a decade or more previously, records permitting, despite data suggesting as many as three-fourths of those patients are deceased at the current time and the conflicting data about long-term consequences of hepatitis C infection (58,59,60,61 and 62). Several studies of patients infected by blood transfusion or blood derivatives indicate severe complications such as cirrhosis and hepatocellular carcinoma do not appear for up to two decades after infection (60,61 and 62). Alcohol consumption appears to adversely affect hepatitis C infected individuals.

Hepatitis D

The delta agent, a “defective” RNA passenger virus, requires the hepatitis B virus as a “helper” for assembling envelope proteins. Delta hepatitis occurs only in patients with HBsAg. Efforts aimed at reducing the risk of posttransfusion hepatitis B infection, thereby, have a similar affect on hepatitis D transmission (63).

Hepatitis E

Hepatitis E is a single-stranded RNA calicivirus. Transmission occurs predominantly through the fecal-oral route, although viremia has been detected (64). To date, no cases of posttransfusion hepatitis E have been reported.

Hepatitis G (GBV-C)

Because the etiology of viral hepatitis remains elusive for 10% to 15% of posttransfusion hepatitis cases, the search remains open for detecting the etiologic agent(s) (65, 66). A novel, single-stranded RNA flavivirus has been designated both the GBV-C virus and the hepatitis G virus. Hepatitis G prevalence, determined by finding hepatitis G RNA in serum, approaches 1% to 2% in volunteer blood donors and is efficiently transmitted by blood transfusion. Antibodies directed against E2 serve as a marker of past infection since they occur infrequently in those RNA positive, but appear subsequently when RNA is no longer present. Viremia was found in 15% to 20% of hemophilic patients and intravenous drug users; 80% to 90% have anti-E2.

Although hepatitis G occurs relatively frequently in blood donors and is transmitted by transfusion, there does not appear to be an association with biochemical liver disease. Therefore, causality between the hepatitis G virus and clinical hepatitis has not been established and the term may be a premature misnomer (66).

TT Virus

In pursuit of agents causing “non A-E” hepatitis, a nonenveloped, single-stranded DNA virus in the Parvoviridae family, “TT,” was discovered by means of molecular testing methods (67). The name of the virus reflects the initials of the patient from whom the virus was isolated. While present in up to two thirds of multitransfused patients such as hemophiliacs and 12% of blood donors, it does not appear to be associated with elevated ALT levels in the blood donor population. Further investigation is required to establish whether the “TT” virus is related causally to hepatitis.

Retrovirus

HIV-1/-2

The initial reports of transfusion-associated AIDS appeared in 1982. Since that time, improved donor education about risk behaviors,

donor history questioning, and HIV testing have reduced the risk of transfusion transmitted HIV infections.

The “window” period between HIV infection and occurrence of HIV antibodies is approximately 22 days compared to 56 days when donor HIV testing started in 1985 (53). Testing for HIV-2 was introduced in 1992; 12 persons are known to be infected with HIV-2 in the United States (68). The introduction of HIV p24 antigen testing in 1996 narrowed the “window” to 16 days, and NAT should detect HIV within 11 days of infection (53).

Through June 30, 1999, the Centers of Disease Control and Prevention (CDC) reported 8,430 cases of AIDS in adult/adolescent blood transfusion or tissue recipients and 376 cases in children including 40 who received blood from HIV seronegative donors (68). There were an additional 5,243 hemophiliac and other patients with coagulation disorders who acquired HIV as a result of plasma-derivative therapy. Currently, coagulation factor concentrates are prepared by recombinant technology or undergo viral inactivation procedures such as heat (pasteurization), or physical-chemical disruption (solvent/detergent treatment).

HIV-1 group O viruses were isolated from central and West African patients in 1994. These HIV-1 variants share 65% to 70% homology with HIV-1 and 56% homology with HIV-2. Until test kits incorporating group O antigens are available, donors are asked if they were born in, lived in, traveled to, and received a blood transfusion, or had risk exposures in HIV-1 group O endemic African countries (69). Those providing affirmative answers are deferred from blood donation.

Human T-Lymphotropic viruses-I and -II

Human T-lymphotropic virus type I (HTLV-I) preferentially infects CD4+ lymphocytes and causes adult T-cell leukemia (ATL) or tropical spastic paraparesis/HTLV-associated myelopathy (TSP/HAM). ATL occurs in 2% to 4% of infected persons following a latent period that may extend to several decades. TSP/HAM occurs in less than 1% of HTLV-I infected persons. Those with transfusion associated TSP/HAM develop neurologic symptoms a median 3.3 years after transfusion.

HTLV-II infects CD8+ and CD4+ lymphocytes and macrophages and has been associated with TSP/HAM but not with hematologic malignancies. Persons infected with this virus appear to have an increased incidence of bronchitis, bladder and kidney infections, and oral herpes infections (70).

By 1998, donors were screened routinely with test kits designed specifically to detect both HTLV-I and -II. HTLV-I and -II are intracellular viruses, and are not transmitted by noncellular components such as plasma and cryoprecipitate.

Herpes Virus Infection

Cytomegalovirus

Cytomegalovirus (CMV) is a large, enveloped, double-stranded DNA herpes virus that resides intracellulary in leukocytes. Acute infections and latent recurrences occur (71). Whether secondary cases or reinfections occur is debated. Cellular components transmit CMV, not plasma or cryoprecipitate. CMV-seronegative persons receiving blood not screened for CMV have a 30% (range 10% to 70%) likelihood of seroconversion. CMV seronegative cellular blood components have a less than 1% to 4% risk of CMV. Cellular products subjected to leukocyte reduction by currently used leukocyte reduction filters (residual leukocyte count < 5×10^6) have an approximate 2% risk of transmitting CMV (72).

Approximately 50% of blood donors are CMV seropositive; CMV-reduced risk components (seronegative or leukocyte reduced by filtration) are reserved for selected patients (Table 74.5).

TABLE 74.5. INDICATIONS FOR CMV-RISK REDUCED COMPONENTS

Premature infants (≤1200 g) born to CMV-seronegative mothers
CMV-seronegative allogeneic and autologous progenitor cell transplant recipients
CMV-seronegative, HIV-positive patients
CMV-seronegative recipients of solid organ transplants from CMV-seronegative donors
CMV-seronegative patients who are potential progenitor cell transplant recipients
CMV-seronegative pregnant women

Epstein-Barr Virus Infection

Approximately 90% of the adult population has evidence of infection with Epstein-Barr virus (EBV) (73). This virus may establish latent infections in lymphocytes and cause proliferation of infected cells. Transfusion transmission, although reported, is unlikely because of the high incidence of prior infection in adults and deference of infection by host virus-specific cytotoxic T lymphocytes.

Parasitic Infections

Malaria

Approximately three transfusion-associated malaria cases occur per year in the United States. Malarial parasites, *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* maintain viability in red cells stored at 4°C, in platelet concentrates stored at room temperature, or following red cell cryopreservation and thawing. Malaria is not transmitted by noncellular products. The incubation period following transfusion ranges from 7 to 50 days (average 20 days) (74).

Babesiosis should be considered in the differential diagnosis. The diagnosis may be delayed if fever is attributed to the underlying illness or postoperative infection. Prevention of transfusion-transmitted malaria results from deferring donors emigrating or returning from malaria endemic regions.

Babesiosis

Babesiosis is caused by *Babesia microtia* or *B. equi* that is transmitted by a bite from an infected *Ixodes scapularius* or *I. pacificus* tick. At least 24 cases of transfusion-transmitted babesiosis have been reported in the United States. Persons with a history of

babesiosis are deferred from blood donation, as the infection may persist for months to years (75, 76).

Toxoplasmsis

Toxoplasmosis is caused by the intracellular protozoan parasite, *Toxoplasma gondii*, whose usual host is the domestic cat. Transfusion-associated cases have occurred in immunocompromised patients (71).

Leishmaniasis

No cases of transfusion-transmitted viscerotropic cases of leishmaniasis have been reported.

Chagas Disease

Trypanosoma cruzi, the etiologic agent of Chagas' disease, is endemic in Central and South America. *T. cruzi* is transmitted to humans primarily by a reduviid bug vector, but is transmitted also by blood transfusion and congenitally (77). Acute infections generally resolve in 1 to 2 months, but infected persons have a lifelong, asymptomatic, indeterminate phase in which low-level parasitemia persists. Approximately 10% to 30% of infected individuals develop chronic infections manifest by cardiac and central nervous system involvement.

Since 1987, at least four cases of transfusion-transmitted Chagas' disease have occurred in the United States and Canada. In three of these cases, platelet transfusions were provided by previous residents of endemic areas. This finding raised concern that other new immigrants to the United States could be asymptomatic carriers, and, could transmit the agent through transfusion. Seroprevalence studies indicate that up to 5.6% of donors at some centers may be at risk for *T. cruzi* infection.

Tests for screening blood donors for Chagas' disease are not available in the United States. Screening donors by history questioning to determine previous residence in endemic areas or living in dwellings where vector insects reside may not be effective in light of possible congenital transmission by decedents of women infected several generations previously.

Creutzfeldt-Jakob Disease (CJD) and New Variant CJD

CJD is a subtype of the spongiform encephalopathies caused, presumably, by a prion protein (PrP) or proteinaceous infections particle. The median age of onset is 61 to 67 years. The incidence of chronic CJD is approximately one case per million population, an estimate that has held constant for some time negating the likelihood of a new epidemic (78).

The disease occurs spontaneously, has a familial association, or follows an exposure. The acquired cases involve treatment with contaminated human pituitary-derived growth hormones, dura mater transplants, corneal transplant, and exposure to contaminated depth electroencephalograph electrodes. The latent period following human growth hormone administration ranges from 3 years to more than 20 years and for dura mater graft placement is 89 months (range 16 to 193 months) (79).

No cases of transfusion-transmitted CJD have been reported including recipients of blood from donors who later developed CJD. Regardless, the FDA requires deferral from blood donation by those at high risk for developing CJD including persons who received human pituitary-derived growth factors and dura-mater transplants, and persons whose families are at increased risk of CJD. If a donor develops CJD subsequent to a donation, in-date blood components are destroyed. Physicians caring for the recipients of prior donations are notified so they can decide whether to inform the patient that they received blood from someone who later developed CJD (80).

In 1996, a previously unrecognized variant of CJD was described in the United Kingdom. Patients presented predominantly with psychiatric and sensory symptoms. The median age of death was 29 years. The evidence linking bovine spongiform encephalopathy in the United Kingdom (mad cow disease) and new variant CJD (nvCJD) and experimental studies suggesting nvCJD and CJD maybe dissimilar led to concerns that nvCJD may be transmitted by blood transfusion. Approximately 47 patients died as a result of nvCJD in Europe through 1999. Although no cases of transfusion-transmitted nvCJD have been reported, the FDA issued guidance in June 1999 mandating deferral of persons who traveled or resided in the United Kingdom for 6 months or longer between 1980 and 1996. This affects an estimated 2.2% of the current U.S. blood supply or 285,000 whole-blood collections (80, 81).

Spirochete Infections

Syphilis

Serologic tests for syphilis were introduced for blood screening in the United States in 1938. Only two cases of transfusion-transmitted syphilis have been reported in the past 30 years (82).

Treponema pallidum, the spirochete causing syphilis loses viability at refrigerated temperature after seven days. This observation and the impact of concomitant antibiotic therapy in many patients receiving transfusions makes estimates about the efficiency of syphilis testing difficult to determine.

Lyme Borrelosis

Borrelia burgdorferi, the etiologic agent of Lyme disease, is transmitted to humans by *Ixodus scapularis* tick bites. Spirochetemia probably occurs postinfection, but reports of transfusion-transmitted Lyme disease have not appeared (83).

Other Tick-borne Illnesses

Rocky Mountain spotted fever and ehrlichiosis are transmitted by tick bites. Rocky Mountain spotted fever has been transmitted by transfusion. In a recent report involving blood donors with an extensive history of tick exposure, none of the recipients developed transfusion-transmitted illness (83).

Parvovirus Infection

Parvovirus B19, a nonenveloped DNA virus in the genus *Erythrovirus*, causes fifth disease and has been associated with transient

aplastic crisis, pure red cell aplasia, thrombocytopenia, pancytopenia, and arthropathy. Most infection occurs between 6 and 15 years of age. Up to 90% of adults are seropositive for parvovirus B19 antibodies. The acute infection is self-limiting. The virus is tropic for the globoside conferring the P blood group antigen. Some patients with red-cell hemolytic disorders such as sickle cell anemia and thalassemia develop acute aplastic or hypoplastic anemia following infection. Patients with HIV infection, solid organ transplants, or children with malignancies are at risk for aplasia. Fetal loss may follow acute parvovirus infection during the second trimester of pregnancy (84).

Neither solvent/detergent nor heat treatment inactivate parvovirus. In 1999, the FDA approved NAT for testing parvovirus B19 for the derivative, solvent/detergent treated plasma. Acute viremia occurs in less than 1 per 1,000 donors. Transfused patients adversely affected by parvovirus infection may respond to therapy with intravenous immunoglobulin.

CONCLUSION

Part of "74 - Complications of Blood Transfusion"

Despite the benefits of transfusion, inherent risks occur concomitantly. This chapter provides information about transfusion complications. Recognition of these events is needed to access the risk:benefit ratio associated with transfusion therapy.

Immune Hemolysis

Susan T. Johnson

Immune hemolysis is defined as increased destruction of red blood cells (RBCs) caused by antibody directed against antigens on RBCs. Antibody-mediated destruction of RBCs can be divided into four major categories: autoimmune hemolytic anemia, drug-induced immune hemolytic anemia, hemolytic transfusion reactions, and hemolytic disease of the newborn. Investigation as to the cause of immune hemolysis tells the history of transfusion medicine. Transfusion reactions and hemolytic disease of the newborn led to the discovery of most human blood groups known today. Studying autoimmune hemolytic anemias and drug-induced immune hemolytic anemia led to advances in serologic techniques.

INTRAVASCULAR AND EXTRAVASCULAR IMMUNE HEMOLYSIS

Part of "75 - Immune Hemolysis"

Antibody binding to antigen alone does not cause destruction of RBCs. This complex promotes other interactions to occur. Immune hemolysis is divided into two types depending on the mechanism by which RBCs are destroyed *in vivo*.

Intravascular Hemolysis

Intravascular hemolysis occurs after either IgG or IgM antibody binds to antigen on RBCs and the complement system is activated. Once complement is activated, destruction of red cells in the vasculature occurs and free hemoglobin and red-cell stroma are released into the plasma. This type of hemolysis may be more rapid and severe.

Extravascular Hemolysis

Most immune hemolysis occurs extravascularly. IgG antibody attaches to antigen and occasionally activates complement. Complement activation occurs to a lesser extent than in intravascular hemolysis. When activated, it generally is not complete activation, stopping with only C3b sensitizing the RBCs. IgG and C3b-coated RBCs are gradually removed from the circulation by the reticuloendothelial system. IgG antibody binds to corresponding antigen by its Fab portion, leaving the Fc portion of the antibody free. Fc receptors on macrophages in the spleen and liver capture these RBCs and phagocytize them or remove a portion of the red-cell membrane and release them back into the circulation as microspherocytes. C3b-coated cells are removed by C3b receptors on macrophages in the liver.

CLINICAL FEATURES OF IMMUNE HEMOLYSIS

Part of "75 - Immune Hemolysis"

Intravascular Hemolysis

Activation of the complement cascade resulting in C3 activation causes subsequent release of anaphylatoxins, C5a, and C3a. These proteins bind to receptors on mast cells and basophils causing them to release histamine and serotonin, vasoactive substances that can contribute to hypotension (See Fig. 75.1).

Antigen-antibody complexes also are capable of activating Factor XIIa (Hageman factor). Factor XIIa acts on the kinin system to produce bradykinin, which increases capillary permeability and dilates arterioles causing a drop in blood pressure. This drop in blood pressure stimulates the sympathetic nervous system. Catecholamines (norepinephrine and others) then are released, which causes vasoconstriction, especially in the kidneys.

If RBCs are lysed, circulating red-cell stroma, activated Hageman factor or thromboplastic substances can activate the intrinsic clotting cascade and may result in disseminated intravascular coagulopathy (DIC).

There is increasing evidence that cytokines also play a role in the pathophysiology of immune hemolysis (1). Cytokines are released from leukocytes that have been exposed to antigen-antibody complexes. They can induce fever, cause hypotension, mobilize neutrophils, activate endothelial cells to express adhesion molecules, and activate T and B lymphocytes.

Other clinical features associated with intravascular hemolysis and severe extravascular hemolysis are anemia caused by RBC destruction and subsequent hemoglobinemia. Plasma haptoglobin binds free hemoglobin, but it has a limited capacity. If free hemoglobin levels exceed this capacity, hemoglobin spills into the urine causing hemoglobinuria. Renal failure can result from acute hemolysis as a result of vasoconstriction, hypotension, and thrombi formation.

Extravascular Hemolysis

In extravascular hemolysis, the patient may exhibit symptoms related to a drop in hemoglobin, including fatigue/weakness, pallor,

palpitations, dyspnea, chest pain, and tachycardia. Symptoms related to RBC destruction may include jaundice, history of dark urine, hepatosplenomegaly, and fever.

LABORATORY FINDINGS

Part of "75 - Immune Hemolysis"

Common laboratory findings associated with immune hemolysis, whether intravascular or extravascular, are a drop in hemoglobin and hematocrit values and an increase in reticulocyte count. The peripheral blood smear contains microspherocytes, indicating ongoing red cell destruction, polychromasia, and occasionally nucleated and fragmented red cells. The bone marrow manifests erythroid hyperplasia. Chemistry findings include an increase in total bilirubin as a result of hemoglobin breakdown and a characteristic rise in unconjugated (indirect) bilirubin. Serum haptoglobin may be decreased or absent and lactose dehydrogenase (LDH) levels are increased.

The direct antiglobulin test (DAT) is key to defining immune hemolysis. This test is used to determine if IgG and/or complement is/are sensitizing the patient's red cells *in vivo*. In all but a few unusual instances discussed in this chapter, the DAT will be positive. Strength of reactivity and protein (IgG, C3, etc.) detectable on patient RBCs are unique to each type of immune hemolysis.

Another extremely useful test is the antibody detection test or antibody screen to determine if the patient has either alloantibody or autoantibody detectable in their plasma. In addition to detecting antibody, the reactivity (temperature at which it is detected) of the antibody is also important. Antibody in the plasma, a positive DAT and the patient's clinical history including age, race, sex, diagnosis, pregnancies, transfusions, and medications will present beneficial information when deciding on the type of immune hemolysis occurring in a patient. These characteristics will be highlighted in each section of this chapter.

AUTOIMMUNE HEMOLYTIC ANEMIA

Part of "75 - Immune Hemolysis"

Autoimmune hemolytic anemia (AIHA) occurs when a patient makes antibody (autoantibody) against antigen present on their own RBCs. It occurs in 1 per 40,000 to 80,000 individuals (3). AIHA is classified by the optimal reactivity of the autoantibody causing red cell destruction. Warm autoimmune hemolytic anemia (WAIHA) is caused by autoantibody reacting at 37C. Cold AIHA is caused by an IgM antibody whose optimal reactivity is at colder temperatures, down to 4C, but is capable of reacting at temperatures greater than 30C. Cold agglutinin syndrome (CAS) is the most common form of cold AIHA. It usually is caused by an autoantibody with I or i specificity. The rarest form

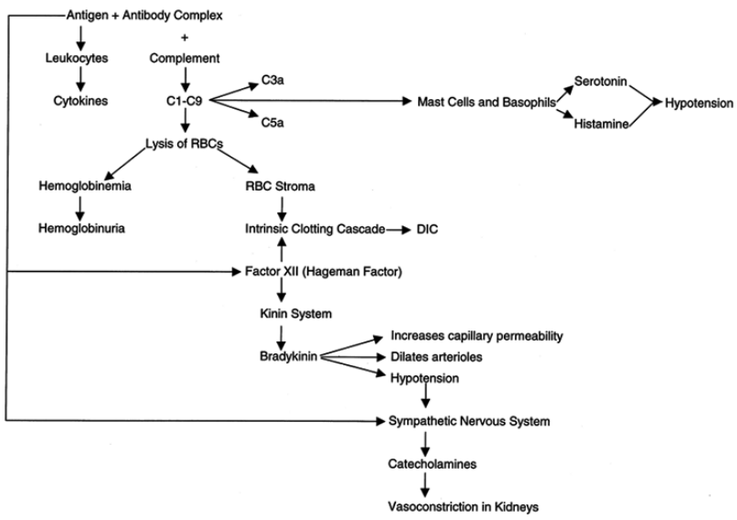

FIGURE 75.1. Pathophysiology of intravascular immune hemolysis. *Modified from Firestone DT (2).

is paroxysmal cold hemoglobinuria (PCH) caused by the biphasic hemolysin, autoanti-P. AIHA may occur rarely as a mixture of both warm and cold-reactive autoantibodies.

The type of AIHA occurring in a patient is established by reviewing the patient's clinical presentation and history, laboratory findings suggesting hemolysis, and results of serologic testing (See Table 75.1). Treatment, including transfusion management, differs for each type of AIHA.

TABLE 75.1. SEROLOGIC FINDINGS IN AUTOIMMUNE HEMOLYTIC ANEMIAS

	WAIHA	CAS	PCH	DIHA
Direct antiglobulin test	3–4+	2–4+	W–2+	W–4+
Anti-IgG	3–4+	0	0–W	W–4+
Anti-C3	0–3+	2–4+	W–2+	W–4+
Eluate	Positive w/all RBCs	Not indicated	Not indicated	Negative
Antibody detection test	0–4+	W–4+	W–2+	O–3+
Reactivity	IAT	Immediate spin, room temperature, (reactive at 37°C &/or 30°C)	Immediate spin, room temperature biphasic hemolysin	Variable, depending on drug and course of therapy
Antibody specificity	Broad	I, i	P	
	Rh			

Warm Autoimmune Hemolytic Anemia

WAIHA is the most common form of AIHA, occurring in approximately 70% of patients with AIHA (3). WAIHA can occur with no underlying or associated disorder. This is referred to as idiopathic or primary WAIHA. More commonly it is a secondary phenomenon associated with another disease. WAIHA may occur secondary to the following disorders: lymphoma, chronic lymphocytic leukemia, system lupus erythematosus, other autoimmune disorders, ovarian tumors, and chronic inflammatory disorders. WAIHA also may follow infection, especially in children.

Clinical Features

Many patients with WAIHA present with symptoms resulting from anemia such as those previously described. Hemoglobinemia and hemoglobinuria may be present in a patient experiencing rapid hemolysis. The extent of anemia is dependent on the degree of hemolysis and on the ability of the patient's bone marrow to respond to red-cell destruction.

Serologic Tests

Direct Antiglobulin Test

The DAT usually is strongly reactive (3-4+) with polyspecific antihuman globulin (AHG) reagent. Tests with AHG specific for IgG and C3 show that IgG alone is found in 67% of patients and IgG plus C3 is present in 24% of cases (4). One percent of cases will react weakly with polyspecific AHG and be negative with anti-IgG and anti-C3b,C3d reagents. Reactivity may be from contaminating anti-IgA and anti-IgM in a rabbit source AHG reagent. Complement alone is found in 7% of cases.

A negative DAT is seen in approximately 1% of patients even though they present with signs and symptoms of immune hemolysis. A well-performed DAT detects approximately 100 to 500 molecules of IgG per red cell. RBCs sensitized with a level of IgG molecules below the level of detection of the standard DAT is one reason for DAT-negative WAIHA. DAT-negative WAIHA also can be due to low-affinity IgG autoantibodies that elute off RBCs during routine washing of the RBCs prior to testing with AHG. Lastly, IgA or IgM autoantibodies are not detected by a DAT performed using monoclonal AHG. More sensitive DATs can be performed in specialized laboratories to try to confirm the diagnosis of autoimmune hemolytic anemia and to characterize the type of DAT-negative WAIHA a patient may be experiencing.

Serum

Approximately 50% of patients with WAIHA have detectable autoantibody in their serum when using standard, no additive, antibody detection tests (screening methods) (3). Autoantibody spills into the plasma *in vivo* when all antigen sites on the RBCs are occupied and there are no antigen sites left for autoantibody binding. Warm autoantibody usually is IgG and reacts optimally at 37C. Autoantibody usually is detected in the indirect antiglobulin test (IAT) and reacts with all reagent red cells tested including the patient's own cells.

It is rarely necessary to attempt to identify autoantibody specificity. Most autoantibodies are directed against antigens in the Rh blood group. Some have apparent, some relative, and some broad specificity within the Rh blood group. An autoantibody with apparent Rh specificity would be directed against normal Rh antigens such as D, C, or more commonly c or e. Antibody in the serum would appear to be anti-D, -C, -c, or -e but the patient's red cells would possess the corresponding antigen and the DAT would be positive.

An autoantibody with relative specificity would react stronger with red cells possessing the corresponding antigen than if the cells lacked the antigen. For example, a relative autoanti-e may be 3+ with e+ RBCs but 1+ with e- red cells.

Most autoantibodies have broad specificity. The only way to confirm that autoantibodies have Rh specificity would be to test them against rare Rh_{null} and/or D-- red cells. This testing is performed rarely because of limited availability of these cells.

Warm autoantibodies may have specificity to antigens in other blood groups. Some of the more common specificities seen include LW, U, Kell system, En^a and Wr^b. Kidd, Duffy, Xg, Vel, AnWj, Sc, R_x, ABO, and I specificities are reported but rarely seen.

One of the biggest challenges in evaluating serum of patients with WAIHA is determining if there are any underlying alloantibodies that would interfere should the patient require transfusion. If the patient's serum reacts with all panel cells, it is difficult to determine if underlying alloantibodies also are present. It is reported that 23% of patients with autoantibodies also have alloantibodies (5).

To determine if alloantibodies are present the autoantibody reactivity must be removed from the patient's serum. This is accomplished by performing adsorptions on the patient's serum using the patient's or other donors' RBCs. There are two types of adsorptions routinely performed. The first is an autologous adsorption performed when the patient has not been transfused recently. Patient's own RBCs are treated to remove autoantibody opening antigen sites and then patient serum is mixed with these treated cells. Autoantibody adsorbs onto the cells and any alloantibody remains in the adsorbed serum. More than one adsorption often is required to fully remove autoantibody reactivity.

When a patient recently has been transfused, allogeneic adsorptions are necessary because multiple populations of RBCs are present in the patient sample. If an autologous adsorption is performed and if the patient is making alloantibody to antigens present on transfused RBCs, the alloantibody could be adsorbed onto transfused RBCs. In an allogeneic adsorption, patient serum is placed on aliquots of RBCs of known phenotype, usually R_1R_1(c- E-), R_2R_2 (e- C-) and rr (D- C- E-), one of which is Jk(a-), or Jk(b-) and/or s- and incubated at 37C. Autoantibody will be adsorbed onto all aliquots regardless of phenotype because of their broad specificity. Alloantibody also will be removed if corresponding antigen is present on the adsorbing cells. Alloantibody will be left in the serum if the adsorbing cells lack the antigen. Selecting adsorbing cells of various phenotypes avoids missing an alloantibody. As with autologous adsorptions, more than one adsorption may be required to remove autoantibody reactivity. As can be imagined, these types of procedures are very time consuming. It normally requires a minimum 4 to 6 hours to determine if a patient has underlying alloantibodies. The extent of the workup, and the resultant time required for testing, needs to be considered when a request for blood is obtained for these patients.

Eluate

An elution procedure is performed to remove antibody from sensitized RBCs. It generally is done in an attempt to identify specificity of antibody coating patient cells. In most cases, it confirms antibody specificity found in serum testing. In patients with WAIHA, an elution may be performed the first time a patient is evaluated to confirm autoantibody and to rule-out the presence of drug-dependent antibody. An eluate typically will be positive with all cells tested showing broad specificity. A negative eluate will be indicative of drug-dependent antibody because the implicated drug must be present in the test for the antibody to react.

Transfusion Management

Many experts believe that transfusion should be avoided in patients with WAIHA. There are several risks associated with transfusing these patients. The first is that no blood selected for transfusion truly will be compatible with the patient's autoantibody. Compatible blood generally is not available for these patients because even if a specificity was determined, the type of blood needed is rare and would not be available for transfusion. Transfused blood will be as incompatible as the patient's own blood and the transfused blood will not enjoy normal survival. Transfusion also may stimulate alloantibody formation. Some fear that a patient's long-term prognosis is worsened by transfusion early in the disease (6).

There are patients in whom transfusion is necessary. If the patient is experiencing severe anemia and is at risk because of underlying heart disease or is experiencing neurological signs, transfusion is necessary. If the patient's clinical condition warrants transfusion before the time-consuming workup is completed, it is better to transfuse than to withhold blood.

Treatment of these patients generally includes corticosteroid immunosuppressive therapy. Transfusion can be avoided if the patient is put on bed rest and oxygen therapy until corticosteroid therapy is effective. Other forms of treatment include splenectomy, cyclosporine A, and intravenous gamma globulin.

COLD AUTOIMMUNE HEMOLYTIC ANEMIA

Part of "75 - Immune Hemolysis"

Cold Agglutinin Syndrome

Cold agglutinin syndrome (CAS), also know as cold hemagglutinin disease is caused by cold-reactive IgM autoantibodies that are capable of reacting at temperatures greater than 30C. Agglutination often occurs in extremities of the body. CAS accounts for approximately 30% of all cases of immune hemolysis (4).

It occurs as an acute or transient form and in a chronic form. The acute form generally is seen in adolescents or young adults following mycoplasma pneumonia or infectious mononucleosis. Chronic CAS often affects older adults occurring as part of another disease process. Lymphoproliferative disorders, including chronic lymphocytic leukemia, lymphomas, and Waldenström's macroglobulinemia are associated with CAS. Chronic CAS also can be idiopathic with no associated disease.

Clinical Features

Individuals often present with symptoms as a result of chronic anemia. Patients exposed to cold may experience acute hemolysis and subsequently show hemoglobinemia and hemoglobinuria. Kidney failure also has been seen in cases of acute hemolysis. Raynaud's phenomenon may be experienced by some patients.

Patients with acute, transient CAS associated with mycoplasma pneumonia or infectious mononucleosis may experience severe hemolysis resulting in a sudden drop in hemoglobin and hematocrit in addition to hemoglobinuria and hemoglobinemia.

Red blood cells in samples drawn from patients with CAS often will spontaneously clump or agglutinate as the sample temperature drops. This clumping makes it difficult to obtain accurate laboratory testing.

Serologic Tests

Direct Antiglobulin Test

Complement is the only protein detected on patient RBCs in most cases. Cold-reactive autoantibodies usually are IgM and bind to red cells at lower body temperatures in the circulation. As red cells move to warmer areas, IgM elutes off the cells and complement remains attached. C3d and sometimes C3b are detected by AHG reagent. Complement component C3 is activated and C3b attaches to the RBCs. Regulatory proteins convert most bound C3b to C3d.

Serum

IgM cold-reactive autoantibodies cause direct agglutination of RBCs. They react optimally at immediate spin and when incubated at colder temperatures. They can agglutinate red cells after the 37C incubation and occasionally positive reactions are seen in the IAT. IgM binding to reagent cells at immediate spin may cause complement activation. If polyspecific AHG is used, positive reactions in the IAT may be from anti-C3d binding to C3d coated red cells.

Most cold autoantibodies detected do not cause CAS. The difference between benign versus pathologic cold autoantibodies is thermal reactivity. Pathologic autoantibodies can attach to red cells *in vivo* at temperatures greater than 30C. The true thermal reactivity of an autoantibody must be determined on a sample that has been drawn and allowed to clot at 37C. The tube must be spun immediately and serum removed quickly. This prevents cold autoantibody from adsorbing onto the RBCs *in vitro*.

Most IgM cold-reactive autoantibodies have I or i specificity. Autoanti-I is seen most often in chronic CAS as well as following mycoplasma pneumonia. Autoanti-i is most often associated with infectious mononucleosis. Other specificities have been reported but are rare.

Eluate

An eluate is performed rarely because in almost all cases the antibody in question is IgM and elution methods work best for eluting IgG antibodies.

Transfusion Management

Transfusion rarely is necessary in CAS. Red-cell destruction often can be avoided if the patient stays in a very warm room. If autoantibody has a wider thermal range and acute hemolysis is occurring, the patient may require transfusion. As with WAIHA, it is essential prior to transfusion to determine if the patient has any underlying alloantibodies. In almost all instances, cold autoantibody reactivity can be avoided by performing a prewarm indirect antiglobulin test or by only reading for agglutination after incubating at 37C and performing the IAT. Once blood is available for transfusion, it may be transfused through a blood warmer. Others feel that this may not be necessary because blood generally is transfused over a 2 to 4 hour period during which time the blood warms to room temperature.

Paroxysmal Cold Hemoglobinuria

Paroxysmal cold hemoglobinuria (PCH) is the rarest form of AIHA. It most often presents as a sudden onset of hemolysis following viral infection in children. In the past, it often was associated with syphilis. PCH is caused by an autoantibody that is IgG in nature, which is capable of binding to RBCs at cold temperatures. When warmed, the antibody causes complement activation and subsequent hemolysis of patient RBCs.

Direct Antiglobulin Test

A routine DAT is positive because of C3 only. Even though PCH is caused by an IgG antibody, it does not remain bound to RBCs at 37C, normal body temperature. More sensitive DATs may detect IgG on red cells.

Serum

A routine antibody detection test may detect positive reactions at immediate spin, sometimes appearing to have anti-P_1 specificity at first glance. If reagent red cells are incubated at colder temperatures positive reactions will be detected with all cells. If the patient's serum is tested against rare P– red cells, negative reactions may be seen since many of these antibodies have P specificity.

The diagnostic test for this disease is the Donath-Landsteiner Test. The patient's serum is mixed with normal red cells and incubated at 4C followed by a 37C incubation. Hemolysis occurs if the Donath-Landsteiner antibody is present.

Eluate

An eluate usually is not indicated because only complement is detected on patient red cells. If an eluate is performed, it generally is negative.

Transfusion Management

Transfusion rarely is necessary in PCH because it usually is self-limiting and recovery occurs within several weeks. If transfusion is necessary, it usually occurs in young children and may be needed as a life-saving measure. Some believe that P-negative red cells survive better than P-positive blood in patients with autoanti-P (6). The incidence of P-negative blood is approximately 1 in 200,000 people. Therefore, if transfusion is urgently needed there often is not time to provide P-negative blood. Moreover, survival of transfused P-positive blood will be about the same as the patient's own blood.

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

Part of "75 - Immune Hemolysis"

Drug-induced immune hemolytic anemia is unusual but when it occurs it may present in a dramatic fashion. The patient often experiences a sudden fall in hemoglobin following ingestion or administration of the implicated drug. These drugs may be varied, being prescription or over the counter, oral or intravenous. Anemia is caused by drug-inducing production of antibody to the drug itself or against new red-cell antigens somehow presented by the drug. The exact mechanism by which this occurs is unknown.

Theories of Immune Response to Drugs

Drug-induced immune hemolysis can be caused by at least three mechanisms, designated Type I, Type II, and Type III (Table 75.2) (8). Mechanisms of causation have been proposed through the years, including drug adsorption, immune-complex formation, nonspecific protein adsorption, and autoantibody production. The latter theories were useful, but there was insufficient data, and current evidence suggests that these proposed mechanisms were inaccurate.

TABLE 75.2. MECHANISMS OF DRUG-INDUCED IMMUNE HEMOLYSIS*

Type	Characteristics	Detection of Drug-Dependent Antibody	Prototype Drugs
I (Hapten-dependent antibody)	Drug binds covalently to membrane proteins and stimulates hapten-dependent antibodies	Antibody reacts with normal RBCs pretreated with drug and then washed.	Penicillin/penicillin derivatives
II (Autoantibody)	Through an unknown mechanism, drug induces autoantibodies specific for red blood cell (RBC) membrane proteins.	Antibody reacts with normal RBCs in the absence of drug.	Alpha methyldopa, procainamide
III (Drug-dependent antibody)	Through an unknown mechanism, drug induces antibodies that bind to RBC only when drug is present in soluble form.	Antibody reacts with normal RBCs when soluble drug is present.	Quinidine, quinine, NSAIDs

NSAIDs, nonsteroidal anti-inflammatory drugs

*Reprinted with permission from *Transfusion 2000*; 40(6):663–668.

Type I drug-related immune hemolysis is likely caused by hapten-dependent antibody. Certain drugs, such as penicillin, penicillin derivatives, and cephalosporins covalently link *in vivo* to red-cell membrane glycoproteins and act as a hapten, triggering antibody production. The patient usually is receiving high doses of the drug (usually intravenous), which leads to the patient's own RBCs becoming coated with drug. Hemolysis usually occurs extravascularly in Type I. The IgG-coated red cells are removed from the circulation by the RE system.

Massive doses of intravenous penicillin causes approximately 3% of patients to develop a positive DAT, but only a small percentage of these go on to develop hemolytic anemia. A more “common” group of drugs, based on current usage, causing hemolytic anemia that likely operates by this mechanism are cephalosporins. The most common of this group are the newer second- and third-generation cephalosporins.

A second type of immune hemolysis (Type II) is associated with sensitivity to drugs such as alpha methyldopa and procainamide. Autoantibody is produced that does not require the drug to be present in order for the antibody to bind to RBCs *in vitro*. The patient serologically presents like a patient with WAIHA.

Alpha methyldopa was a common cause of this phenomenon, but that drug has been replaced by new therapies. In patients continuing to take alpha methyldopa, approximately 15% develop a positive DAT, but only 0.5% to 1.0% develop hemolytic anemia (9). The DAT becomes positive within 3 to 6 months of therapy and the incidence of the positive DAT is dose-dependent. Following cessation of the drug, hemolysis subsides within 2 weeks, but the DAT may continue to be positive for up to 2 years. Hemolysis in Type II DIHA usually is extravascular and is associated with mild to severe anemia.

The third type of drug-induced hemolysis (Type III) occurs when, through an unknown mechanism, drug induces production of antibodies that bind to RBCs only when drug is present in soluble form. Drugs in this group do not bind to RBCs with high affinity. Type III drug-dependent antibodies may recognize compound epitopes (part drug, part protein), or the antibodies may be specific for secondary conformational changes induced by drug on the red cells. Quinine and quinidine are the prototype drugs of Type III antibodies. However, the nonsteroidal antiinflammatory drugs (NSAIDs) currently appear to be a more common cause of immune hemolysis.

Type III antibodies cause acute, intravascular hemolysis with hemoglobinuria, hemoglobinemia, and other signs and symptoms previously described associated with severe hemolysis. Once antibody has been produced by a patient, severe hemolytic episodes may recur after reexposure to even very small quantities of the drug (one tablet in some cases). Numerous fatalities have been reported with this type of hemolysis (9, 10).

In most cases, only one mechanism causes hemolysis. However, some patients appear to have a combination of Types I and III (9, 12) or Types II and III (13). Table 75.3 lists drugs associated with immune heolysis and their reported mechanism for causing heolysis.

Serologic Tests

Type I

The DAT is strongly positive due to IgG coating of the RBCs. Complement sensitization also is occasionally seen but usually is weaker in reactivity.

Routine serum testing is negative. Drug-dependent antibody is demonstrated in the serum by testing against drug-coated RBCs because antibody is directed against the drug (hapten) itself. Caution must be taken when evaluating drug testing as many individuals have naturally occurring drug-dependent antibodies from prior exposure to the medication. Drug-dependent antibody-causing immune hemolysis is high titered, while naturally occurring antibody in an individual with no hemolysis is low titered.

Patients with Type I and III drug-induced hemolytic anemia characteristically have a negative eluate. Test RBCs must be coated with drug in order for drug-dependent antibody in the eluate to bind and cause agglutination.

Type II

Type II drug-induced hemolytic anemia appears serologically identical to WAIHA. The DAT is strongly positive, usually only because of IgG binding. Serum testing shows an IgG, warm autoantibody reacting at 37C and detectable in the IAT. An eluate is positive with all reagent RBCs tested. A separate drug-dependent antibody is not demonstrable.

Type III

The DAT usually is strongly positive because of IgG and complement sensitization of patient RBCs. There are reports of the DAT being positive only because of complement coating the patient's RBCs or being weak from IgG and complement coating.

Standard antibody detection tests will be negative. Drug must be present in the test system in order for the drug-dependent antibody to bind to reagent red cells. When soluble drug in a 1-mg/mL concentration is added to the serum and reagent RBC mixture, positive reactions are obtained. Antibody detected can be either IgG or IgM. Occasionally, the patient may have an antibody that is dependent on a metabolite of the drug. Testing for drug-dependent antibody then requires obtaining a source of drug metabolites. This source is urine and/or plasma from an individual taking the offending drug. Urine and/or plasma, containing metabolites of the drug, is mixed with patient serum and reagent RBCs. The presence of a drug metabolite-dependent antibody results in a positive reaction.

Positive reactions may be obtained in a routine antibody screen if a patient has recently taken the implicated drug and it continues to be present in the patient's circulation.

An eluate will be negative when tested using routine methods. When drug or drug metabolite is mixed with eluate and reagent RBCs a positive reaction will often be seen.

ALLOIMMUNE HEMOLYTIC ANEMIA

Part of "75 - Immune Hemolysis"

Alloimmune hemolysis results from foreign RBCs being introduced into a patient with corresponding alloantibodies. There

TABLE 75.3. DRUGS ASSOCIATED WITH IMMUNE HEMOLYSIS

Drug	Possible Mechanism	Drug	Possible Mechanism
Acetaminophen	III	Interferon	II
Aminopyrine	III	Isoniazid	I, III
Amphotericin B	III	Levodopa	II
Ampicillin	III	Mefenamic acid	II
Antazoline	III	Mefloquine	III
Apazone (azapropazone)	II, I	Melphalan	III
Buthiazide (butizide)	III	6-Mercaptopurine	I
Carbenicillin	I	Methicillin	I
Carbimazole	III	Methotrexate	III
Carboplatin	I, III	Methyldopa	II
Carbromal	I	Moxalactam (latamoxef)	III, II
Catergen	II	Nafcillin	I
Cephalosporins		Nomifensine	II, III
First generation	I	p-Aminosalicylic acid	III
Second generation	III, I, II	Penicillin G	I
Third generation	III, I, II	Phenacetin	II, III
Chaparral	II	Piperacillin	I, III
Chorpropamide	III	Probenecid	III
Chlorpromazine	II, III	Procainamide	II
Cladribine (chlorodeoxyadenosine)	II	Propyphenazone	III
		Pyramidon	III
Cyanidanol	II, I, III	Quinidine	I, III
Cyclofenil	II	Quinine	III
Cyclosporine	II	Rifampin (rifampicin)	III
Diclofenac	II, III	Sodium Pentothal	III
Diethylstilbestrol	III	Stibophen	III
Dipyrone	III, I	Streptomycin	II, I, III
Erythromycin	I	Sulfonamides	III
Etodolac	III	Sulfonylurea derivatives	III
Fenoprofen	II, III	Sulindac	I, II
Fludarabine	II	Suprofen	III, II
Fluorescein	I, III	Temafloxacin	III
Fluorouracil	III	Teniposide	II, III
Glafenine	II, III	Tetracycline	I, III
Hydralazine	III	Thiopental	III
Hydrochlorothiazide	III	Tolbutamide	I
Elliptinium acetate	III	Tolmetin	II, III
Ibuprofen	III	Triamterene	III
Insulin	I, III	Zomepirac	I, III, II

are two forms of alloimmune hemolytic anemia: hemolytic transfusion reactions (HTR) and hemolytic disease of the newborn (HDN). In HTR, the patient with alloantibody is transfused with blood from an allogeneic donor and in HDN, the mother's antibody is exposed to baby's RBCs.

HEMOLYTIC TRANSFUSION REACTIONS

Part of "75 - Immune Hemolysis"

HTR can be classified into two types, immediate and delayed, based on the clinical presentation.

Immediate Transfusion Reactions

Immediate or acute transfusion reactions occur when a patient has preformed antibodies and is transfused with RBCs that possess antigens corresponding to the antibody. Transfusion of ABO-incompatible RBCs accounts for most severe cases of acute, intravascular hemolysis (14).

Symptoms of an acute HTR include any or all of the following:

- Fever with or without chills, defined as a 1C increase in body temperature
- Shaking chills
- Pain at infusion site or in chest, abdomen, or flanks
- Blood pressure changes, either hypertension or hypotension
- Respiratory distress, dyspnea, tachypnea or hypoxemia
- Skin changes: flushing, itching, urticaria, or localized edema
- Nausea
- Circulatory shock
- Hemoglobinemia followed by hemoglobinuria

It is more difficult to identify a HTR in an anesthetized patient. Diffuse bleeding at the surgical site, hypotension, or hemoglobinuria may be the only recognized symptoms.

Evaluation of a Suspected Hemolytic Transfusion Reaction

Personnel transfusing blood usually are the first to suspect a transfusion reaction. When a reaction is suspected, the transfusion must be stopped; however, the intravenous line should be maintained with normal saline or other suitable fluid. Individuals administering blood should perform a clerical check of all labels, forms, and patient identification and the patient's physician should be notified immediately. The patient's physician evaluates the patient and determines if there is probable cause of an immune mediated HTR. A blood sample must be drawn, taking care to avoid mechanical hemolysis and the transfusion service must be notified.

When a transfusion reaction workup is received in the lab, there are three steps that must be taken.

1. Clerical check: A clerical check or review of pretransfusion sample identification, transfused blood product labels, and review of pretransfusion testing is performed, both in the laboratory and by personnel on the patient unit. If an error is found, all transfusions must be stopped until the cause for the error can be determined. When this scenario occurs, it is not uncommon to have two patient samples mixed, thereby exposing two patients to adverse reactions.
2. Visual check for hemolysis: Postreaction serum or plasma must be visually inspected for hemolysis and compared to a prereaction specimen when available. Visible hemoglobinemia occurs when incompatible red cells are lysed and hemoglobin is released into the plasma.

   A postreaction urine also may be examined for evidence of hemoglobinuria. It is important to distinguish hemoglobinuria (free hemoglobin) from hematuria (intact red cells free in the urine).

3. DAT: A DAT must be performed on a postreaction specimen to determine if patient antibody was able to coat transfused red cells. If the postreaction DAT is positive, a DAT should be performed on a pretransfusion sample to validate that it became positive because of transfusion. The DAT will be positive when antibody in the patient coats transfused RBCs and these cells have not been cleared from the circulation. It is usually weakly positive because there are relatively few transfused cells in the individual's total blood volume. Characteristic mixed field reaction as a result of two populations of cells being present often is noted. If all transfused cells are destroyed, or if the sample is drawn, several hours posttransfusion, the DAT may be negative.

Confirmatory Testing

If positive indication of hemolysis is identified in any of the above three checks, additional testing must be performed to confirm the cause of an apparent transfusion reaction.

Eluate

An eluate must be performed on posttransfusion RBCs to determine specificity of the antibody. If the prereaction sample also had a positive DAT, an eluate also should be made from this sample so that a comparison can be made.

ABO, Rh Testing

ABO, Rh typing should be repeated on pre- and postreaction samples. In addition, the ABO and Rh type should be repeated on any units of blood crossmatched for the patient. If there is a discrepancy between the pre- and postsample there has been a mix-up in patient or sample identification or in testing. If there is a discrepancy between patient type and unit type there may be a problem in unit labeling or in selection of blood chosen for the patient.

Antibody Detection Tests

Antibody detection tests must be repeated on pre- and postreaction samples. If a positive reaction is obtained in the pretransfusion sample that was not previously detected, the antibody must be identified to determine if it could have caused the transfusion reaction. If a positive reaction is detected in the post reaction sample, it could be because of an amnestic response following exposure to foreign red cells or it could be because of passive antibody from the transfused unit of blood.

Crossmatch

Serologic crossmatch tests should be repeated using the pre- and postreaction samples. This testing should include an IAT even if it was not performed on the initial crossmatches. Occasionally, an antibody to a low-frequency antigen may be detected in an IAT crossmatch that would not be detected in a standard antibody detection test.

Laboratory Testing

Posttransfusion hemoglobin and hematocrits should be performed to determine if the patient responded appropriately to the transfusion or if there is rapid or slow decline after transfusion. Haptoglobin level testing may assist in determining if hemolysis occurred. A posttransfusion bilirubin approximately 5 to 7 hours after transfusion also may indicate if hemolysis occurred.

Examine Unit Transfused

The unit of blood implicated in the hemologic reaction should be returned to the transfusion service. It should be examined for evidence of hemolysis in the administration tubing or bag itself. If hemolysis is present it could be because of hypotonic solution being added to the bag or a faulty infusion device being used.

The unit also should be inspected for clots and brownish, opaque, muddy, or purple discoloration. If any of these are present bacterial contamination of the unit should be suspected. A Gram's stain and aerobic and anaerobic bacterial culture of the contents of the bag should be performed. Even if the unit looks normal, but the patient experienced a reaction that is unexplained serologically, this testing should be performed.

HLA/Neutrophil Testing

Rarely, the patient may have had signs and symptoms of transfusion-related acute lung injury (TRALI). If this is the case, the patient's pre- and postreaction sample, as well as plasma from the transfused unit should be tested for antibodies to HLA and neutrophil antigens.

Delayed Transfusion Reaction

Antibodies previously formed by an individual with time can fall below the level of detection of antibody screening methods. If red blood cells are transfused that have the corresponding antigen an anamnestic response occurs within hours to days of transfusion. IgG antibodies are produced that are able to bind to transfused antigen positive red cells. Kidd system antibodies (anti-Jk^a and anti-Jk^b) are notorious for causing delayed transfusion reactions. These types of reactions classically occur 7 to 14 days after transfusion.

Many times, the anamnestic antibody production does not cause hemolysis of tranfused red cells. This has been termed a delayed serologic reaction. If hemolysis occurs, the most common signs and symptoms are fever, dropping hemoglobin and hematocrit and jaundice. These patients often present as having an inadequate rise in hemoglobin following transfusion, and additional units of blood are ordered to be transfused. Subsequent pretransfusion testing detects an antibody that was not present in the sample previously tested, and serologic testing will detect a positive DAT. Weaker reactivity (weak-2+) normally is seen because the antibody is binding to transfused red cells, the smaller portion of the patient's total blood volume. An eluate prepared from the patient's red cells usually will show the same antibody specificity as that now found in the serum.

If a new antibody is detected in a posttransfusion sample, it is important that the patient's physician be made aware of this finding so that a possible delayed hemolytic transfusion reaction can be investigated.

HEMOLYTIC DISEASE OF THE NEWBORN

Part of "75 - Immune Hemolysis"

Hemolytic disease of the newborn occurs when IgG alloantibody from the mother crosses the placenta *in utero* and coats fetal red cells. Alloantibody present in mother can be stimulated by previous pregnancies, current pregnancy, or previous transfusions. For antibody to bind to fetal red cells, the corresponding antigen must be fairly well developed. Clinical severity can range from intrauterine death to an infant born with only a positive DAT and no clinical symptoms of red cell destruction.

Antibodies Causing HDN

HDN can be classified into three categories based on the specificity of the antibody involved.

1. Rh Antibodies

   Anti-D is the most common antibody causing HDN and causes the most severe red cell destruction. If left untreated intrauterine death can occur. Prior to the use of Rh immune globulin (RHIG) given to D- mothers bearing D+ infants, anti-D was the most common antibody involved. Most antibodies in the Rh system have been reported to cause HDN including but not limited to anti-C, -E, -c, -e and -G. In many cases the severity of HDN is less than that found with anti-D. If any of these antibodies are detected in a pregnant woman the antibody should be monitored throughout pregnancy.

2. ABO Antibodies

   Anti-A, anti-B and anti-A,B are often a mixture of IgM and IgG.

   Group O individuals are more likely to produce higher levels of IgG ABO antibodies. Therefore, it is not uncommon for group A or B babies born from group O mothers to have a positive DAT. The great majority of cases are subclinical, although some babies may be jaundice and slightly anemic, and there are rare reports of death of the fetus caused by ABO antibodies (15).

3. Other Antibodies

Antibodies to antigens in almost every blood group (Table 75.4) have been described to cause subclinical, mild to severe HDN. The most common is anti-K. In addition, anti-K seems not only to cause red-cell destruction, it also appears to suppress fetal erythropoiesis (16). Incidence of other antibodies is much lower. Many other uncommon or rare antibodies to high and low frequency antigens have been reported to cause red-cell destruction

in infants. Many blood group antigens were first described after causing HDN.

TABLE 75.4. COMMON ANTIBODIES CAUSING IMMUNE HEMOLYSIS*

Antibody	AIHA	HTR	HDN
Anti-A	Rare	No to severe	No to moderate
Anti-B	Rare	No to severe	No to moderate
Anti-A_1	Rare	No to mild/delayed	No
Anti-D	Yes, warm	Mild to severe/immediate or delayed	Mild to severe
Anti-C	Yes, warm	Mild to severe/immediate or delayed	Mild
Anti-E	Yes, warm	Mild to moderate/immediate or delayed	Mild
Anti-c	Yes, warm	Mild to severe/immediate or delayed	Mild to severe
Anti-e	Common warm	Mild to moderate or delayed	Rare, usually mild
Anti-M	Rare, cold	No	Extremely rare
Anti-N	Rare, cold	No	No
Anti-S	Rare	No to moderate (rare)	No to severe (rare)
Anti-s		No to mild (rare)	No to severe (rare)
Anti-U	Yes, warm	Mild to severe	Mild to severe
Anti-Lu^a	No	No	No to mild (rare)
Anti-Lu^b	No	Mild to moderate	Mild
Anti-K	No	Mild to severe/delayed/hemolytic	Mild to severe (rare)
Anti-k	No	Mild to moderate/delayed	Mild to severe (rare)
Anti-Kp^a	No	Mild to moderate/delayed	Mild to moderate
Anti-Kp^b	Yes	No to moderate/delayed	Mild to moderate
Anti-Js^a	No	No to moderate/delayed	Mild to moderate
Anti-Js^b	No	Mild to moderate/delayed	Mild to moderate
Anti-Le^a	No	Hemolytic (rare)	No
Anti-Le^b	No	No	No
Anti-P_1	No	No to moderate/delayed (rare)	No
Anti-Fy^a	Rare, warm	Mild to severe/immediate/delayed	Mild to severe (rare)
Anti-Fy^b	Rare, warm	Mild to severe/immediate/rare; delayed	Mild (rare)
Anti-Jk^a	Yes, warm	No to severe/immediate or delayed/hemolytic	Mild to moderate (rare)
Anti-Jk^b	Yes, warm	No to severe/immediate or delayed/hemolytic	No to mild/rare

*Modified from Reid and Lomas-Francis[27]

There are three commonly occurring antibodies that do not cause HDN: anti-Le^a, anti-Le^b, and anti-P_1. It is much easier to remember these three and beware of all others. There are two reasons that these antibodies do not cause problems. Most are IgM and cannot cross the placenta and secondly these antigens are not well developed on fetal cells.

RECOGNITION OF “AT RISK” PREGNANCIES

Part of "75 - Immune Hemolysis"

The majority of above-described antibodies can be detected in routine antibody detection tests. Serologic studies, including an ABO, Rh type, and antibody detection test, should be performed on all pregnant women as early in the pregnancy as possible (17). If an antibody is detected it must be identified so that its clinical significance can be assessed. The likelihood that the fetus will be at risk often can be predicted by serologically typing the father's red cells to determine if he carries the corresponding antigen. If he possesses the antigen, the fetal red cells also could have the antigen. Fetal genotyping also can be performed by isolating DNA from amniocytes in amniotic fluid, chorionic villus sampling, or fetal blood obtained by cordocentesis. DNA is amplified by polymerase chain reaction (PCR) and typed for the presence of the suspected gene. Genotyping is available for *ABO, Rh (D, C, E, c, e), Jka/Jkb, K1/K2, Fya/Fyb, M* and *S/s*.

Monitoring for HDN

Antibody Titration

If it is determined that the fetus is at risk, or risk is unclear, antibody titrations can aid in monitoring antibody level. This is a semiquantitative method. A baseline titer should be determined in the first trimester and the sample frozen for future comparison studies. Invasive techniques will not be used until 16 to 18 weeks' gestation so repeat titrations are not recommended until that time. Repeat titrations should be performed using the same method and test cells with the same antigen expression as that used previously. The present sample should be titrated with the most current previous sample so that a change can be seen readily. A rising antibody titer does not always predict clinical significance but some institutions have established a critical titer that must be reached before amniocentesis occurs (18).

Amniotic Fluid Analysis

The amount of bilirubin in amniotic fluid is an indicator of the severity of fetal red-cell destruction. Amniotic fluid collected, generally after 27 weeks gestation, is analyzed spectrophotometrically

at wavelength levels of 350 to 700 nm. Peak absorbance of bilirubin is 450 nm. In 1969, Liley described a measurement system in which deviation from linearity at 450 nm (OD) indicates a rise in bilirubin level and increasing severity of red-cell destruction (19). Readings falling in Zone 3 or high in Zone 2 indicate severe disease (the fetus may have hydrops or will develop it within 7 to 10 days) (20). Readings in this zone may require intrauterine transfusion or, if sufficiently late in the pregnancy, immediate delivery (See Fig. 75.2). Readings in Zone 2 indicate moderate disease unless it approaches the higher end of the zone. Repeat analysis usually is required to establish a trend. Zone 1 readings indicate mild or no significant disease or anemia.

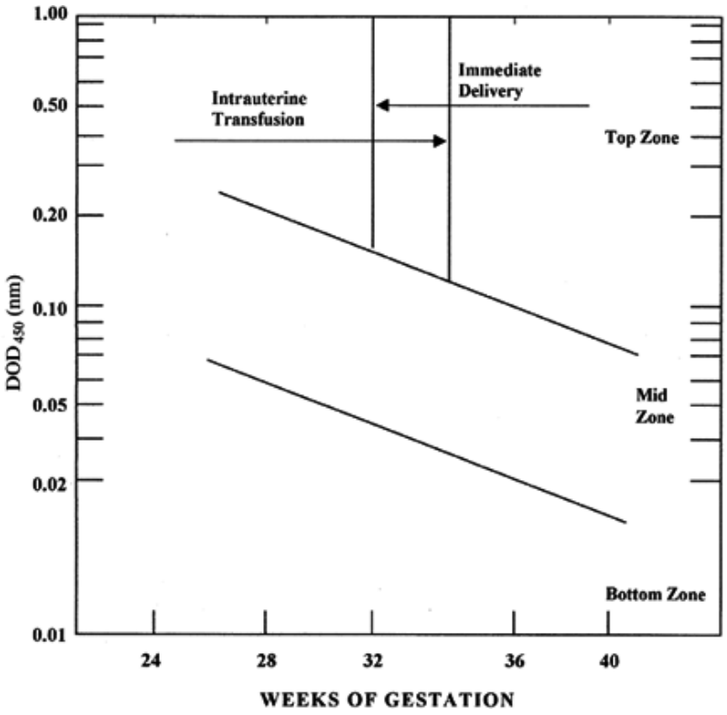

FIGURE 75.2. Liley graph for analyzing amniotic fluid. (Modified from Liley AW. Liquor amnii analysis in the management of the pregnancy complicated by Rhesus sensitization. *Am J Obstet Gynecol* 1961; 82:1359–1370, with permission.)

Percutaneous Umbilical Blood Sampling

Percutaneous umbilical blood sampling (PUBS) became possible in the mid-1980s with the availability of sophisticated ultrasound equipment and skilled perinatologists (21). A needle is directed into the umbilical vessel (usually the vein) that inserts into the placenta. Fetal blood is obtained and laboratory testing to measure immune hemolysis can be performed. PUBS is the most accurate way to determine severity of hemolysis because testing is performed on an actual sample from the fetus. In addition, the technique allowed more direct intrauterine transfusion than infusion into the infant's peritoneal cavity.

Testing at Delivery

When the baby is delivered, a cord-blood sample normally is collected from the infant. Samples usually are stored in the blood-bank/transfusion service for a minimum of 7 days. Serologic testing is performed in the following circumstances: mother is Rh(D) negative and the newborn is Rh(d) positive, mother is known to have an antibody(ies) capable of causing HDN and baby develops signs and symptoms of hemolysis.

Infants of Rh-Negative Women

Cord blood from infants of Rh-negative women should be typed for ABO and Rh(d) at delivery. If the baby is Rh(d) positive, the mother's blood is tested for fetal-maternal hemorrhage (see section on Rh immune globulin prophylaxis).

Infants of Alloimmunized Women

The DAT usually is performed on cord blood from infants born to women with known antibodies. In the case of Rh or “other” HDN, the DAT usually is strongly positive. HDN resulting from ABO antibodies usually presents with a weak or even negative DAT. An eluate may be performed to confirm the specificity of the antibody coating the infant's red cells but is not crucial as long as the causative antibody is detectable in the mother's serum.

If the DAT is positive and the mother's antibody screen is negative, ABO HDN or an antibody to a low-frequency antigen should be suspected. The easiest way to resolve this is to review the ABO types of mother and baby (see previous section on ABO HDN). An eluate can be performed to confirm that ABO antibodies are present or the infant's serum can be tested for the presence of anti-A or anti-B using an indirect antiglobulin test to detect IgG.

If ABO HDN is ruled out, an antibody to a low frequency antigen should be sought. Low frequency antigens are defined as those present in less than 1% of the population. The antibody screen performed on the mother's serum will be negative because the antibody is directed against an antigen not present on reagent red cells. To detect this antibody, a sample is obtained from the father because his red cells should possess the implicated antigen of low frequency. An eluate performed from the infant's red cells and tested against the father's red cells should be positive. In addition, the mother's serum, if ABO compatible with the father, is tested against the father's red cells. A positive result indicates that the mother has an antibody directed against an antigen present on the father's red cells.

Rh Immune Globulin Prophylaxis

Rh immune globulin (RhIG) consists of human IgG anti-D that is administered intramuscularly to Rh(d)-negative women who have had Rh(d)-positive babies. It prevents many of them from becoming sensitized to the D antigen and thus prevents formation of anti-D. Use of RhIG has decreased the rate of alloimmunization. A standard dose of RhIG consists of approximately 300 μg of anti-D. This dose is able to cover about 15 mL of D-positive red cells or approximately 30 mL of fetal whole blood.

Postpartum Administration

Rh(d)-negative women who have Rh(d)-positive babies, who have not already produced anti-D and who have not had an identified excessive fetal-maternal hemorrhage should receive one dose of RhIG within 72 hours of delivery. Occasionally, anti-D is detected in the mother and it is because of RhIG the mother received antenatally. This can be confirmed by checking

the history of the mother to determine if she received RhIG. Evaluating the serologic reactivity of the antibody also can give you clues. More important, if the antibody reactivity is weak in a saline IAT, it is likely to be passively acquired. If there is any doubt, RhIG is given.

If a large FMH occurs, one dose of RhIG will not be enough to cover the bleed. The rosette test is an excellent screening test to determine if excessive bleeding has occurred *in utero*. Red cells from a sample obtained from the mother postdelivery are incubated with anti-D. If fetal D+ red cells are present, the anti-D will bind to these cells. Indicator D+ red cells then are added and they will bind to the exposed anti-D bound to the fetal D+ cells forming rosettes of cells. These rosettes are observed by looking at the mixture microscopically. The rosette test detects about a 10-mL bleed (22). This only is a screening test so an additional test must be performed to quantify the hemorrhage.

The classic test for quantifying FMH is the Kleihauer-Betke acid elution. When a sample of blood from the mother is exposed to acid, adult hemoglobin is denatured and fetal hemoglobin is not. Fetal cells observed microscopically in a field of adult red cells are counted and the volume of bleed is estimated based on the ratio of fetal cells to adult cells observed. This method is known to be imprecise, but it is the one most widely used.

If the bleed is estimated to be less than 30 mL, the standard one vial dose of RhIG will suffice. However, if the hemorrhage is estimated to be greater, additional vials of RhIg will need to be administered. For example:

Kleihauer-Betke is reported 1.5% bleed.

(1.5/100) × 5,000 (mother's assigned blood volume) = 75 mL fetal bleed

75/30 (covered bleed) = 2.5 vials

Because this test is known to have variability, it is not unusual to give additional vials over the calculated dose and one approach follows. If the number to the right of the decimal point is less than five, round down and add one dose of RhIG (23). If the number to the left of the decimal point is 0.5 or greater, round up to the next number and add one dose of RhIG. In the above example, if the calculated dose is 2.5, it would be rounded up to three vials and one additional vial would be added for safety to bring the total to four vials.

Other methods for determining FMH include enzyme-linked antiglobulin test (ELAT) and flow cytometry, but they are not as widely used.

Routine administration of RhIG after delivery has reduced production of anti-D in pregnant women from about 13% to 1% to 2% (24).

Antepartum Administration

To further reduce the risk of alloimmunization, the American College of Obstetricians and Gynecologists (ACOG) recommends giving RhIG at 28 weeks of gestation to all Rh(d)-negative women who do not already have anti-D (25). This is based on the report that approximately 92% of women who produce anti-D during pregnancy, do so on or after 28 weeks (24). The risk of producing anti-D after receiving both antepartum and postpartum RhIG is reduced to 0.1% (24).

Transfusion Support of the Fetus or Newborn

Intrauterine Transfusion - Fetus

Intrauterine transfusion may be necessary if severe hemolysis is occurring in the fetus.

Selection of Blood

The blood selected for transfusion should be O Rh negative because in most cases, the ABO, Rh type of the fetus is not known. In addition, the red blood cells should lack the antigen(s) corresponding to any antibody the mother possesses. The blood should be as fresh as possible to ensure longer survival of transfused red blood cells. It should be irradiated (26) because the fetus does not have normal immunity. Blood provided also should be cytomegalovirus (CMV) seronegative.

The blood can be given using two different techniques, intraperitoneally, or by the umbilical vein. Intraperitoneal transfusion occurs by inserting a needle through the mother's abdominal wall into the fetus' abdominal cavity. The blood is absorbed through lymphatic channels. Direct intravascular fetal transfusion is performed by inserting a needle with the help of ultrasound into the umbilical vein. This method is more effective for the severely affected fetus with hydrops because it does not rely on absorption for the transfused cells to enter the fetal circulation.

Exchange Transfusion — Newborn

In cases of severe HDN, exchange transfusion can be performed. Exchange transfusion consists of replacing the baby's blood that contains mother's antibody, baby's coated red cells and elevated levels of bilirubin with fresh red blood cells. Exchange transfusion removes/reduces all three.

Selection of Blood

Blood selected for transfusion should be compatible with the mother's ABO antibodies as well as with any other antibody the mother may have. Maternal serum or plasma or babies serum or plasma may be used for crossmatching because both will contain the causative antibodies. Again, blood should be irradiated, usually should be CMV-negative, and as fresh as possible.
