Editor

Kenneth D. McClatchey M.D., D.D.S.

Professor and Chairman
Department of Pathology, Loyola University Medical Center, Loyola University/Foster G. McGaw Hospital, Maywood, Illinois

SECTION CHIEFS

Serhan Alkan M.D.

Associate Professor
Department of Pathology, Loyola University Medical Center, Maywood, Illinois

Emanuel Hackel Ph.D.
Department of Medicine, Michigan State University, East Lansing, Michigan

David F. Keren M.D.

Medical Director
Warde Medical Laboratory; Clinical Professor, Department of Pathology, The University of Michigan, Ann Arbor, Michigan

Elizabeth Lee-Lewandrowski Ph.D., M.P.H.
Clinical Chemistry, Massachusetts General Hospital, Boston, Massachusetts

Kent B. Lewandrowski M.D.
Clinical Chemistry, Massachusetts General Hospital, Boston, Massachusetts

Kenneth D. McClatchey M.D., D.D.S.

Professor and Chairman
Department of Pathology, Loyola University Medical Center, Loyola University/Foster G. McGaw Hospital, Maywood, Illinois

Harold A. Oberman M.D.

Director
Blood Bank and Transfusion Service; Professor, Department of Pathology, University of Michigan Health Center, University of Michigan, Ann Arbor, Michigan

Douglas A. Triplett M.D.

Vice President
Medical Education; Director, Midwest Hemostasis and Thrombosis Laboratories, Ball Memorial Hospital; Assistant Dean and Professor, Department of Pathology, Indiana University School of Medicine, Muncie, Indiana

Daniel L. Van Dyke Ph.D.

Chairman
Medical Genetics, Henry Ford Hospital; Professor, Department of Genetics, Case Western Reserve University, Henry Ford Health Science Center, Detroit, Michigan

Patrick C. J. Ward M.D.

Professor and Head
Department of Pathology and Laboratory Medicine, Duluth School of Medicine, University of Minnesota, Duluth, Minnesota

Gail L. Woods M.D.
Department of Clinical Biology, University of Texas Medical Branch, Galveston, Galveston, Texas

Ruth W. Weinberg

Acquisitions Editor

CONTRIBUTING AUTHORS

György Ábel M.D., Ph.D.

Director
Clinical Immunology Laboratory, Department of Laboratory Medicine, Lahey Clinic, Burlington, Massachusetts

Serhan Alkan M.D.

Associate Professor
Department of Pathology, Loyola University Medical Center, Maywood, Illinois

Hesham M. Amin M.B., B.Ch., M.Sc.

Hematopathology Fellow
Department of Pathology, Loyola University Medical Center, Maywood, Illinois

F. Philip Anderson Ph.D., D.A.B.C.C., F.A.C.B.

Assistant Professor of Pathology; Co-Director of Clinical Chemistry
Medical College of Virginia Campus, Virginia Commonwealth University, Richmond, Virginia

Mary E. Barkus M.D.
Department of Pathology, Medical College of Virginia, Richmond, Virginia

Patrick G. Beatty M.D.

Professor
Department of Internal Medicine, University of Utah, Salt Lake City, Utah

Miriam G. Blitzer Ph.D.

Professor and Chief
Department of Human Genetics, University of Maryland School of Medicine; and, University of Maryland Medical Center, Department of Pediatrics, Baltimore, Maryland

Bruce F. Bower M.D., F.A.C.E.
Clinical Endocrinology, Hartford Hospital, Hartford, Connecticut

John T. Brandt M.D.

Senior Clinical Research Pathologist
Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana

Eric Brestel M.D.
Department of Medicine, East Carolina University, School of Medicine, Greenville, North Carolina

Arlene M. Buller M.D.
Genetics and Pathology Department, Medical College of Virginia/Virginia Commonwealth University, Richmond, Virginia

Robert W. Burnett M.D.
Department of Pathology, Hartford Hospital, Hartford, Connecticut

Kai Cao M.D.

Scientist I
American Red Cross, National Histocompatibility Laboratory, Baltimore, Maryland

John L. Carey III M.D.
Department of Pathology, Henry Ford Hospital, Detroit, Michigan

Thomas E. Carey Ph.D.

Otolaryngology
Head, Neck and Surgery Department, The University of Michigan, Ann Arbor, Michigan

Aaron Carroll M.D.
Seattle, Washington

Karen C. Carroll M.D.
Department of Pathology, University of Utah School of Medicine, Salt Lake City, Utah

Stephen Cordner M.D.
Victorian Institute of Forensic Medicine, Monash University, Melbourne, Australia

Tina M. Cowan Ph.D.

Emanuel Hackel Ph.D.
Department of Medicine, Michigan State University, East Lansing, Michigan

Curtis A. Hanson M.D.

Associate Professor
Laboratory Medicine and Pathology, Mayo Clinic, Rochester, Minnesota

Alfred E. Hartmann M.D.

Associate Professor
Department of Laboratory Medicine, University of South Dakota School of Medicine; and, Medical Director, Department of Pathology, Avera McKennan Hospital, Sioux Falls, South Dakota

Gerald A. Hoeltge M.D.

Head
Section of Transfusion Medicine, Department of Clinical Pathology, The Cleveland Clinic Foundation, Cleveland, Ohio

Donald R. Hoffman Ph.D.

Professor
Department of Pathology and Laboratory Medicine, Brody School of Medicine at East Carolina University, Greenville, North Carolina

Earle W. Holmes Ph.D.

Professor
Department of Pathology, Loyola University Stritch School of Medicine; and Director, Special Chemistry, Endocrinology, and Immunoserology Laboratories, Loyola University Medical Center, Maywood, Illinois

James D. Hoyer
Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, Minnesota

Jane C. Huang M.D.

Clinical Assistant Professor of Pathology
Harborview Medical Center, University of Washington, Seattle, WA

Karen James M.D.

Adjunct Associate Professor
Walker College of Business, Appalachian State University, Boone, North Carolina

Stephen G. Jenkins
Department of Pathology, University of Florida Health Science Center, Jacksonville, Florida

Susan T. Johnson M.T. (A.S.C.P.) S.B.B.

Manager
Immunohematology Services, The Blood Center of Southeastern Wisconsin, Milwaukee, Wisconsin

M. John Judd F.I.B.M.S., M.I.Biol.

Professor
Division of Immunohematology, Department of Pathology, University of Michigan Medical Center, Ann Arbor, Michigan

Malek Kamoun M.D., Ph.D.

Director
Clinical Immunology and Histocompatibility Testing Laboratory, Department of Pathology and Laboratory Medicine, Hospital of the University of Pennsylvania; and, Professor, Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Jeffrey A. Kant M.D., Ph.D.

Director
Division of Molecular Diagnostics, Department of Pathology, University of Pittsburgh Medical Center; and, Professor, Department of Pathology and Human Genetics, University of Pittsburgh, Pittsburgh, Pennsylvania

David F. Keren M.D.

Medical Director
Warde Medical Laboratory; and, Clinical Professor of Pathology, University of Michigan, Ann Arbor, Michigan

Rhett P. Ketterling M.D.

Assistant Professor
Department of Laboratory Medicine, Mayo Medical School, Rochester, Minnesota

Franklin P. Koontz Ph.D.

Co-Director of Clinical Microbiology; and Professor
Department of Pathology, University of Iowa Hospitals, Iowa City, Iowa

Alexander Kratz M.D., Ph.D.
Department of Epidemiology and Public Health, Yale University School of Medicine, New Haven, Connecticut

Brian D. Kueck M.D.

Assistant Clinical Professor
Department of Pathology, Medical College of Wisconsin, Milwaukee, Wisconsin

Tai C. Kwong Ph.D.

Professor
Department of Pathology and Laboratory Medicine, University of Rochester; and, Director, Toxicology Laboratory, Strong Memorial Hospital, Rochester, New York

Michael Laposata M.D., Ph.D.
Department of Pathology, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts

Elizabeth Lee-Lewandrowski Ph.D., M.P.H.
Clinical Chemistry, Massachusetts General Hospital, Boston, Massachusetts

Kent B. Lewandrowski M.D.
Clinical Chemistry, Massachusetts General Hospital, Boston, Massachusetts

Brian J. Linehan M.B., Ch.B., Dip., Obst. F.R.C.P.A.
Medlab Hamilton, Hamilton, New Zealand

Naomi L. C. Luban M.D.

Director
Transfusion Medicine, Department of Laboratory Medicine, Children's Hospital; and, Professor, Departments of Pediatrics and Pathology, George Washington University School of Medicine and Health Sciences, Washington, DC

Kenneth D. McClatchey M.D., D.D.S.

Professor and Chairman
Department of Pathology, Loyola University Medical Center and Loyola University/Foster G. McGaw Hospital, Maywood, Illinois

J. Philip McCoy Jr. Ph.D.
Cooper Hospital/University Medical Center, Robert Wood Johnson Medical School at Camden, Camden, New Jersey

Steven Mechanic
Yale University School of Medicine, Blood Bank, New Haven, CT

Jay E. Menitove M.D.

Executive Director and Medical Director
Community Blood Center; Clinical Professor of Medicine, University of Missouri-Kansas City; and, Clinical Professor of Medicine, Kansas University School of Medicine, Kansas City, Kansas

Fredrik Mertens M.D., Ph.D.

Senior Consultant
Department of Clinical Genetics, Lund University Hospital; and, Associate Professor, Department of Laboratory Medicine, Division of Clinical Genetics, Lund University, Lund, Sweden

Derek Middleton Ph.D.

Director
Northern Ireland Histocompatibility and Immunogenetics Laboratory, City Hospital, Belfast, Northern Ireland; and Visiting Professor, School of Biomedical Science, University of Ulster, Coleraine, Northern Ireland

Robert E. Moore Ph.D.

Associate Director of Clinical Chemistry
Department of Pathology and Laboratory Medicine, Hartford Hospitals, Hartford, Connecticut; and Professor, Department of Pathobiology, University of Connecticut, Storrs, Connecticut

S. Breanndan Moore M.D.
Division of Transfusion Medicine, Mayo Clinic, Rochester, Minnesota

Imaad B. Mujeeb M.D.

University of Iowa, College of Medicine, Iowa City, Iowa

Frederick S. Nolte Ph.D.

Laboratory Directory
Clinical Microbiology and Molecular Diagnostics, Clinical Laboratories, Emory University Hospital; and, Associate Professor, Department of Pathology and Laboratory Medicine, Emory University School of Medicine, Atlanta, Georgia

Harold A. Oberman M.D.

Director
Blood Bank and Transfusion Service, Department of Pathology, University of Michigan Health Center; and Professor, Department of Pathology, University of Michigan, Ann Arbor, Michigan

James C. Overall Jr. M.D.

Professor Emeritus
Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, Utah

Catherine G. Palmer Ph.D.

Emeritus Professor
Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, Indiana

Darryl E. Palmer-Toy M.D., Ph.D.

Assistant Professor
Department of Pathology, Johns Hopkins Medical Institutions, Baltimore, Maryland

Michael A. Pfaller M.D.

Professor
Department of Pathology, University of Iowa College of Medicine; and Co-Director, Clinical Microbiology Laboratory, Department of Pathology, University of Iowa Health Care, Iowa City, Iowa

Carl L. Pierson Ph.D.

Director
Clinical Microbiology Laboratory, Department of Pathology, University of Michigan Health System; and, Assistant Professor, Department of Pathology, University of Michigan, Ann Arbor, Michigan

Michael Pins M.D.
Department of Pathology, Northwestern University Medical School, Chicago, Illinois

Michele D. Raible M.D., Pharm. D.
Loyola University Medical Center, Maywood, Illinois

Jayashree Ramasethu D.C.H., M.D., M.B.B.S.

Fellow
Department of Pediatrics, Division of Neonatology, Georgetown University Hospital, Washington, DC

James H. Ray Ph.D.

Director
Cytogenetics, Quest Diagnostics, Inc., Teterboro, New Jersey

Barbara S. Reisner Ph.D.
Department of Pathology, University of Texas Medical Branch, Galveston, Texas

Mary J. Reznicek M.D.

Pathologist
Greater Milwaukee Pathologists, Aurora Consolidated Laboratories, West Allis, Wisconsin

Alan Richter Ph.D.
GED Consulting

Roger S. Riley M.D., Ph.D.
Department of Pathology, Clinical Hematology, Medical College of Virginia Hospitals/Virginia Commonwealth University, Richmond, Virginia

Michael G. Rinaldi Ph.D.

Professor
Departments of Pathology and Medicine, University of Texas Health Science Center; and, Director, Veterans Affairs Reference Laboratory, Pathology and Laboratory Medicine, Audie L. Murphy Memorial Veterans Hospital, San Antonio, Texas

Jacquelyn R. Roberson M.D.
Medical Genetics Center, Clara Ford Pavilion, Detroit, Michigan

Marisa Saint Martin M.D.
Loyola University Medical School, Maywood, Illinois

Ramon L. Sandin M.D.

Clinical Pathologist; Medical Director, Clinical Microbiology and Virology Laboratories
H. Lee Moffitt Cancer Center & Research Institute; and, Associate Professor, Department of Pathology, University of South Florida, College of Medicine, Tampa, Florida

Michael A. Saubolle Ph.D., D.(A.B.M.M.)

Director
Clinical Microbiology, Laboratory Sciences of Arizona, Good Samaritan Regional Medical Center, Phoenix, Arizona; and Clinical Associate Professor, Department of Medicine, University of Arizona, Phoenix/Tucson, Arizona

Morton K. Schwartz Ph.D.

Chairman
Clinical Laboratories, Memorial Sloan Kettering Cancer Center; and, Professor, Molecular Pharmacology and Therapeutics, Sloan Kettering Division, Graduate School of Medical Sciences, Cornell University, New York, New York

Stuart Schwartz Ph.D.

Director
Center for Human Genetics Laboratory, University Hospital of Cleveland; and, Professor, Department of Genetics, Case Western Reserve University, Cleveland, Ohio

David L. Sewell Ph.D.

Director
Microbiology Section, Pathology and Laboratory Medicine Service, Veterans' Affairs Medical Center; and, Professor, Department of Pathology, Oregon Health Sciences University, Portland, Oregon

James B. Smart Ph.D.
Department of Pathology, University of Michigan, Ann Arbor, Michigan

Gary Stack M.D., Ph.D.

Assistant Director
Blood Bank, Yale/New Haven Hospital; and, Department of Laboratory Medicine, Yale University School of Medicine, New Haven, Connecticut

Peggy J. Stupca M.S.

QA Education Specialist
Laboratory Medicine and Pathology, Mayo Clinic; and Assistant Professor, Department of Laboratory Medicine, Mayo Medical School, Mayo Clinic, Rochester, Minnesota

Deanna A. Sutton M.S., M.T., SM (ASCP), RM, SM (NRM)

Administrative Director
Fungus Testing Laboratory; and, Assistant Professor, Department of Pathology, University of Texas Health Science Center at San Antonio, San Antonio, Texas

Karl S. Theil M.D.

Associate Professor of Clinical Pathology
Department of Pathology, Ohio State University, Columbus, Ohio

John G. Toffaletti Ph.D.

Director of Blood Gas Services
Clinical Laboratories; and, Associate Professor, Pathology and Clinical Laboratories, Duke Medical Center, Durham, North Carolina

Eleanor M. Travers M.D.
Potomac, Maryland

Douglas A. Triplett M.D., F.A.C.P., F.C.A.P.

Vice President
Medical Education, and Director, Midwest Hemostasis and Thrombosis Laboratories, Ball Memorial Hospital; and, Assistant Dean and Professor, Department of Pathology, Indiana University School of Medicine, Muncie, Indiana

Daniel L. Van Dyke Ph.D.

Chairman

Medical Genetics, Henry Ford Hospital; and Professor, Department of Genetics, Case Western Reserve University/Henry Ford Health Science Center, Detroit, Michigan

Patrick C. J. Ward M.D.

Professor and Head
Department of Pathology and Laboratory Medicine, University of Minnesota, Duluth School of Medicine, Duluth, Minnesota

Jeffrey S. Warren M. D.

Warthin-Weller Endowed Professor
Department of Pathology, University of Michigan Medical School; and, Director, Division of Clinical Pathology, University of Michigan Hospitals, Ann Arbor, Michigan

Anne Wiktor B.S.M.T.

Senior Technologist
Cytogenetics, Henry Ford Health System, Detroit, Michigan

David S. Wilkinson M.D., Ph.D.

Professor and Chair
Department of Pathology, Virginia Commonwealth University; and, Chair, Department of Pathology, Medical College of Virginia Hospitals, Richmond, Virginia

Gail L. Woods M.D.
Clinical Microbiology, University of Texas Medical Branch, Galveston, Galveston, Texas

Alan H. B. Wu

Director
Clinical Chemistry, Department of Pathology and Laboratory Medicine, Hartford Hospital, Hartford, Connecticut; and Professor, Laboratory Medicine, University of Connecticut Health Center, Farmington, Connecticut

William A. Wyatt B.A.

Assistant Supervisor
Department of Laboratory Medicine, Mayo Clinic, Rochester, Minnesota

Jane M. Yang M.D.
Department of Chemistry, Massachusetts General Hospital, Boston, Massachusetts

Chester M. Zmijewski Ph.D.

Emeritus Professor
Departments of Pathology and Laboratory Medicine, University of Pennsylvania Medical Center, Philadelphia, Pennsylvania

DEDICATION

To my wife, Martha, and our children: Sean, Suki, Suni, and Stephen. All of whom provide constant support yet remind me of the balance that must be maintained in one's life —no matter what the venture.

PREFACE

It is an honor to be the editor of the second edition of *Clinical Laboratory Medicine*. This textbook should ultimately educate a wide variety of readers—from medical laboratory technicians, medical technologists, medical students, residents in pathology and internal medicine—to clinical laboratory scientists, pathologists, and other physicians with an interest in clinical laboratory medicine.

From beginning to end, this textbook is devoted to providing the reader with the latest in clinical laboratory medicine in an organized, well-illustrated manner. The general outline of every chapter in the text is as follows:

I. Introduction
II. Disease status (including pathophysiology)
III. Diagnostic methods
IV. Interpretation (including sensitivity, specificity, precision, and accuracy issues, where applicable)

Since the late 1950s, there has been a rapid increase in clinical laboratory automation. The concomitant emergence of quality management issues and molecular pathology appplications across multiple disciplines has made it difficult for textbooks in clinical pathology and clinical laboratory medicne to keep up with the advances in this diverse science. There was even difficulty in defining the new technologies. This textbook has been designed to include as many of the “new” technologies as is humanly possible at this time. For example, the “new” technologies in this revision include molecular pathology, cytogenetics, HLA, molecular biology, and even such areas in the general section as quality management, cost accounting, and informatics.

The eleven sections of this textbook start with a beautiful color plate and a short introduction. Chapters are designed to allow the reader to focus on necessary information quickly and efficiently. Finally, the section editors and chapter authors feel that this text provides a relevant, comprehensive, scientific, and artful approach to the ever-widening scope of clinical laboratory medicine. We welcome the readers' input regarding this second edition so that future editions will be even better.

Kenneth D. McClatchey M.D., D.D.S.

ACKNOWLEDGMENTS

It is with deep satisfaction and gratitude that I acknowledge the collaboration of my esteemed colleagues as section editors. Each section editor has performed his or her tasks in a diligent and professional manner. In addition, the chapter authors have completed, in a timely and professional manner, chapters that bring to the reader the latest science from the ever-widening universe of clinical laboratory medicine. They have accomplished their task using a format that allows both students and practicing health professionals to efficiently learn the many disciplines of clinical laboratory medicine. The textbook would not have been designed and written if I had not been influenced during my career by laboratory professionals such as Drs. John G. Batsakis, and Adam J. French. Their inspiration to pursue a career in clinical laboratory medicine was immeasurable.

I would also like to thank Ray Reter and Ruth Weinberg at Lippincott Williams & Wilkins.

Finally, and most importantly, *Clinical Laboratory Medicine* is written to acknowledge the many laboratory professionals who have devoted their lives to better patient care by constantly striving to improve the art and science of clinical laboratory medicine.

2 Business Management of the Clinical Laboratory

3 Laboratory Safety

4 The Interpretation of Laboratory Tests

5 Laboratory Information Systems

6 Ethics in Laboratory Medicine

Management in the clinical laboratory consists of the many processes of planning and organizing, leading the efforts of staff, and using other laboratory and hospital resources to achieve stated goals. As clinical laboratory medicine continues to grow as a service industry, modern management theory and practice have become more and more a part of our lives. At the same time, patients faced with escalating medical costs, are insisting that they receive value for their health insurance dollar. Such requirements are vividly reflected in the actions of hospital and laboratory accrediting agencies, as well as payors such as insurance companies. It is no longer satisfactory to ignore the business aspects of our practices. Now we must know the language of quality assurance, quality improvement, quality systems utilization management, cost analysis, billing, collecting, etc. In addition, being a responsible manager requires a solid foundation in risk management and laboratory safety. Furthermore, the manager, as a health professional, must provide accurate laboratory data for his or her patients, knowing full well that variability is a part of the preanalytic and analytic test process. This variability must be kept to a minimum, yet it should be clearly explained, when necessary, to colleagues. In the laboratory of today and tomorrow, laboratory information systems are the backbone of success. The ability to communicate accurately in the high-volume environment of a clinical laboratory is a prerequisite for successful management of a clinical laboratory. Knowing the basic requirements of laboratory information systems (as well as having a basic knowledge of contract negotiation for information systems) allows the health professional an opportunity to control his or her destiny in result reporting, order entry, archiving, test menu selection, etc.

This section is intended to acquaint the reader with selected basic management skills that will hold him or her in good stead as quality management becomes more and more a part of the laboratory professional's life.

1

Basic Laboratory Management

Eleanor M. Travers

Kenneth D. McClatchey

GENERAL MANAGEMENT ISSUES

Part of "1 - Basic Laboratory Management"

Laboratory professionals in the 2000s must be versatile and effective as medical scientists, managers of people, clinical consultants, and business managers. Without the integration of these skills and attributes, and the active participation of pathologists, the profession of laboratory medicine is likely to be drawn into increasing conflict with other health professions and health administrative agencies. Patients, clinical laboratories, and clinicians will not be well served by such divisions (1,2). In fact, without flexibility and adaptability, clinical laboratory managers might find themselves quite frustrated in today's "bottom-line" environment.

After World War II, clinical laboratory medicine grew rapidly, but managers primarily focused on only quality control (1,2). Quality control provides assurance that a laboratory functions properly for the benefit of the patient using daily or run-to-run data points plotted over time on charts (3). However, there has been a major paradigm shift to business practice in the philosophy and the role of the laboratory manager. An astute laboratory manager will respond to this paradigm by plotting the laboratory's financial data points as often as quality control and other performance indicator data points.

With the advent of clinical laboratory reimbursement losses and increasing scientific discoveries in medical practice in the 1990s, the control of budgeted dollars became a major problem for managers of clinical laboratory services. By the late 1990s, the spiraling growth of laboratory medicine tests and services was increasingly viewed as a major financial loss by third-party reimbursement agencies and payers.

In reality, what happened was that the health care industry, including laboratory medicine, sped toward a trillion dollar price tag by the turn of the century despite continued efforts to control costs.

At the same time and at the same breakneck pace, reimbursement policies and mechanisms for laboratory medicine were developed to create disincentives for the use of tests and services. During the decade of the 1990s, both federal and private payers severely limited payments to both providers and laboratories, which had negative impacts on laboratory management and practice (1,4). The events leading up to the era of reduced payment (reimbursement), the framework for the punitive policies of the late 1990s, are summarized thusly:

1960s

Medicare: Publicly funded health insurance for all citizens over age 65)

Medicaid: Health insurance for citizens receiving public assistance

1970s

Health maintenance organizations (HMOs) are established)

Professional standard review organizations are established

1980s

Diagnosis-related group (DRG) system of reimbursement is introduced)

Deficit Reduction Act developed to control outpatient fees, including laboratory fees

HMOs begin to flourish, with enrollment of more than 30 million

Preferred provider organizations (physicians and hospitals contracted with agencies for discounted services) develop rapidly

Independent practice associations (loosely structured groups of physicians and hospitals contracted to provide discounted services) become established

Exclusive provider organizations (strict contracts with physicians and hospitals to provide discounted services to a select group of patients) make their appearance

1990s

Resource-based relative value units, a complex reimbursement program for physician services that is based on overall work effort and includes a correlation of multiple disciplines of medicine, are established to replace DRGs)

Clinical Laboratory Improvement Amendments of 1988 (CLIA '88), which applies to laboratories licensed for interstate commerce under the Clinical Laboratory Improvement Act of 1967 as well as laboratories certified to receive reimbursement from Medicare and Medicaid, were implemented through the publication of final regulations in 1993. Major provisions of the final regulations include

Laboratory administration

Proficiency testing

Patient test management

Quality control
Personnel standards
Quality assurance
Laboratory accreditation
Enforcement and sanctions

This, above all other federal regulatory actions, set the standard for reimbursement policy in 2000 and beyond. No laboratory is allowed to receive reimbursement from Medicare/Medicaid unless it is CLIA licensed or has received a waiver from CLIA.

The Balanced Budget Act of 1997 (BBA97) and the Balanced Budget Reconciliation Amendments of 1999 profoundly affected the volume, growth, and reimbursement of clinical laboratories, mostly in a negative manner. Laboratory managers may experience increased workload for preventive tests (e.g., diabetes, cancer) as a result of the BBA97

Basic Management Concepts

In laboratories today, there are four basic economic problems: money, machines, management, and manpower. Economists refer to the same four topics as capital, technology, management, and labor. If one thinks about the problems facing laboratory managers today, the same broad areas are applicable.

Management is probably the world's oldest unheralded profession. In *The History of Management Thought* (5), Claude S. George, Jr., traces the profession of management from the ancient Egyptians, who engaged in planning, organizing, and controlling the activities of their numerous workers, to China, where planning and control systems were established around 1100 BC; to the United States, where Joseph Wharton established college courses in business management at the University of Pennsylvania in 1881. George also wrote that in 400 BC, Socrates noted the universality of the management function in human behavior. In 350 BC, Plato established the principle of specialization for human efficiency. In 1436, the Arsenal of Venice employed more than 1,000 people. They used accounting systems, planning, inventory control, assembly line techniques, interchangeable parts, and a formal system of personnel management to build ships and armament. The first “clinical” manager was probably Robert Owen, an industrialist in Scotland who, in the 1820s, first tackled the problems of productivity and motivation, the relationship of worker to work, worker to enterprise, and worker to management. These basic problems are still applicable in management venues in health care and the clinical laboratory.

The science of management in the United States began in the late 1800s with the efforts of Frederick W. Taylor. Taylor defined his work on scientific management as a systematic or scientific investigation of all the facts and elements of the work being managed. It was the antithesis of “management by tradition,” which was the rule before his work (and incidentally used widely today in medicine in teaching clinical skills). Beginning with the industrial revolution to today's explosion of science and technology, management theory evolved, bringing with it the involvement of the tools of the behavioral sciences. As a discipline, it is young—barely a century old (5,6).

Certainly management is a science, but more important, it is people interacting with one another. As Peter F. Drucker states,

> Every achievement of management is the achievement of a manager. Every failure is a failure of a manager. People manage, rather than forces or facts. The vision, dedication, and integrity of managers determine whether there is management or mismanagement. Management must always be done in organization—that is, with a web of human relations (7).

Interestingly, Drucker further compares a manager to a teacher: “Only a teacher has the same twofold dimension, the dimension of skill and performance and the dimension of personality, example, and integrity” (7).

Managers come in different forms and with different labels: administrator, commander, and executive, for example. They have evolved with the growth of institutions in the industrialized world. Drucker (7) states that in the early 1900s, people asked, “What do you do?” Today they tend to ask, “Whom do you work for?” (7).

The science of management in this country that has been practiced for decades is being challenged. The traditional scientific approach to management is changing; learning to look on people as human resources and opportunities rather than problems, costs, and threats. In such approaches, the art of leadership is critical (8,9,10 and 11).

According to Max DePree (11), leadership is “liberating people to do what is required of them in the most effective and humane way possible.” A leader, according to DePree, has the following attributes:

- Has consistent and dependable integrity
- Cherishes heterogeneity and diversity
- Searches out competence
- Is open to contrary opinion
- Communicates easily at all levels
- Understands the concept of equity and consistently advocates it
- Leads through serving
- Is open to the skills and talents of others
- Is intimate with the organization and its work
- Is able to see the broad picture (beyond his or her own area of focus)
- Is a spokesperson and diplomat
- Can be a tribal storyteller (an important way of transmitting corporate culture)
- Tells why rather than how

DePree goes on to state that the measure of leadership is “not the quality of the head, but the tone of the body” (11). The sign of outstanding leadership appears primarily among the followers. It is fundamental that leaders endorse a concept of persons, thus an understanding of the diversity of people's gifts, talents, and skills.

There are two types of relationships in our industrialized society that influence the management of people: *contractual* and *covenantal*.

Contractual relationships cover the *quid pro quo* of working together. Contractual relationships break down during the demands of conflict and change. Alexander Solzhenitsyn states that

whenever the tissue of life is woven of legalistic relationships, an atmosphere of spiritual mediocrity that paralyzes men's noblest impulses is created (11).

Covenantal relationships induce freedom, not paralysis. A covenantal relationship rests on shared commitment to ideas, issues, values, goals, and management processes. Covenantal relationships are open to influence (11).

A good manager studies to improve his/her management skills and applies them in daily practice. A good manager is also an entrepreneur; one who tends to accept change as part of the business of managing. A good manager is a "high-performance" manager (6). The high-performance manager is:

A strategist. One who looks to the future, makes educated guesses about the major forces and trends he or she can see, and interprets them in terms of opportunities for growth and progress.

A problem solver. One who clearly perceives the differences between the anticipated future and the unfolding present and who decides what must be done with those factors under his or her control to influence the environment or to adapt to it most effectively.

A leader. One who offers those who answer to him or her a clear course of action that will gain their commitment and serve their individual objectives as well as the higher objectives of the organization.

A teacher. One who guides others and helps them to identify and solve problems so that they can perform their tasks effectively and can develop themselves as individuals as well as workers.

It is of utmost importance in the management process to realize that the human resources of an organization make the organization successful. Human resource management is an art form. The basic components of human resource management are motivation, delegation, and supervision. *Motivation* is a basic psychological need of any employee, thus an important task of any manager is to create motivational work environments. *Delegation* is the critical ability to place tasks and responsibilities at the level at which they can best be accomplished. *Supervision* is the combination of technical and human relations skills that ensures that organizational goals are met and policies followed.

The management process has been artfully diagramed by Hardwick (1) to delineate the tasks associated with the basic elements of management: ideas, things, and people (Fig 1.1).

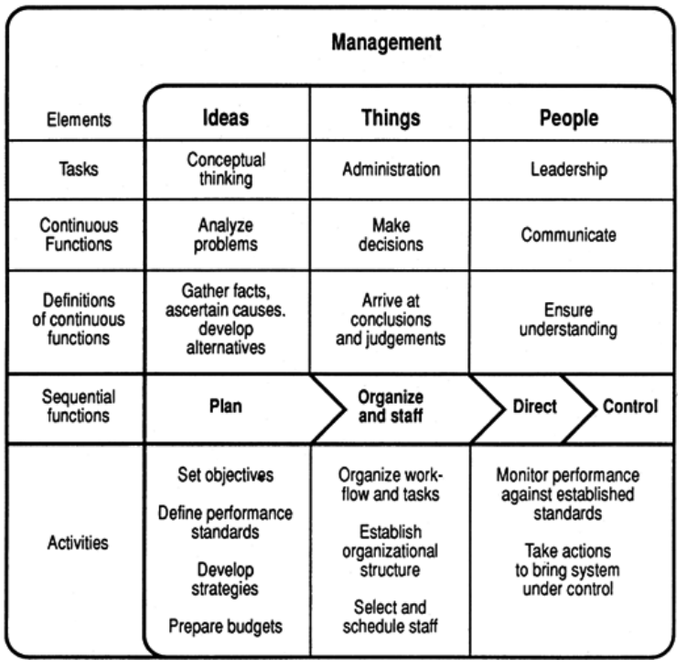

FIGURE 1.1. The management process. (From Hardwick DF. *Directing the clinical laboratory*. New York: Field and Wood, 1990:2, with permission.)

The Evolution of Quality Management Concepts

The evolution of quality concepts begins with the publication of Shewhart's *Economic Control of Quality of Manufactured Product* in 1931 (12). This book put quality on a scientific footing. Shewhart developed the concept of statistical control and describes it as follows:

> A phenomenon will be said to be controlled when through the use of past experience we can predict, at least within limits, how the phenomenon may be expected to vary in the future. Here it is understood that prediction means that we can state, at least approximately, the probability that the observed phenomenon will fall within the given limits (12).

An outgrowth of such a method was the process control chart, well known in every clinical laboratory in this country (Fig. 1.2).

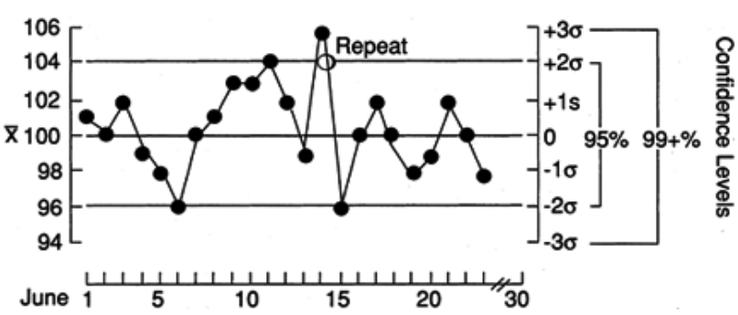

FIGURE 1.2. Levey-Jennings or Shewhart process control chart. (From Weisbrot IM. *Statistics for the clinical laboratory*. Philadelphia: JB Lippincott, 1985:64, with permission.)

Joseph Juran worked with Shewhart at Bell Laboratories and eventually played a prominent role in the evolution of quality

management from the 1960s through the 1980s. In 1951, Juran published a book entitled *Juran's Quality Control Handbook* (13). He subsequently developed a system of management called “managing for quality” (14). His system is based on what he calls the Juran trilogy:

- Quality planning
- Quality control
- Quality improvement

Quality planning includes

- Determining who the customers are
- Determining the needs of the customers
- Developing product features that respond to customer needs
- Developing the processes to produce the product features
- Transferring the plans to the operating forces

Quality control includes

- Evaluating actual product performance
- Comparing actual performance to product goals
- Acting on the difference

Quality improvement includes

- Establishing the infrastructure
- Identifying the improvement projects
- Establishing project teams
- Providing the teams with resources, training, and motivation to:

  diagnose the causes

  stimulate remedies

  establish controls to hold the gains

The Juran trilogy can be diagramed to demonstrate how beneficial change can be used to develop improved levels of performance (Fig. 1.3). There is no question that improved levels of performance place an increased workload on all levels of the management team. An example of workload allocation is demonstrated with the Itoh model. In the Itoh model, time is allocated to (a) development, (b) improvement, and (c) control and maintenance throughout the management structure (Fig. 1.4) (14).

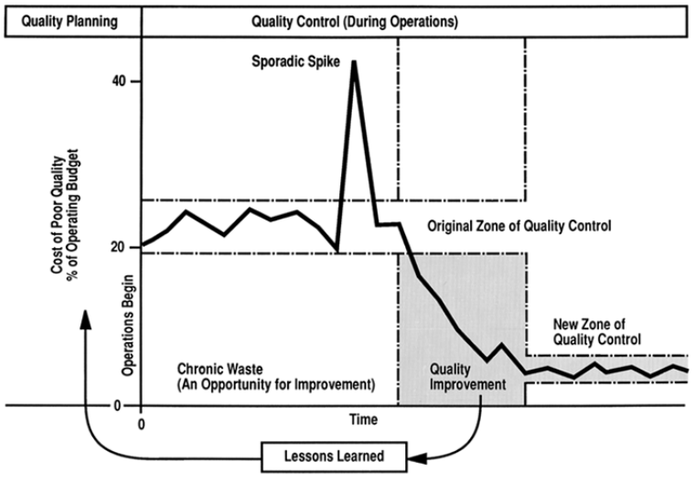

FIGURE 1.3. The Juran trilogy. (From Juran JM. *Juran on planning for quality*. New York: The Free Press, 1988:12, with permission.)

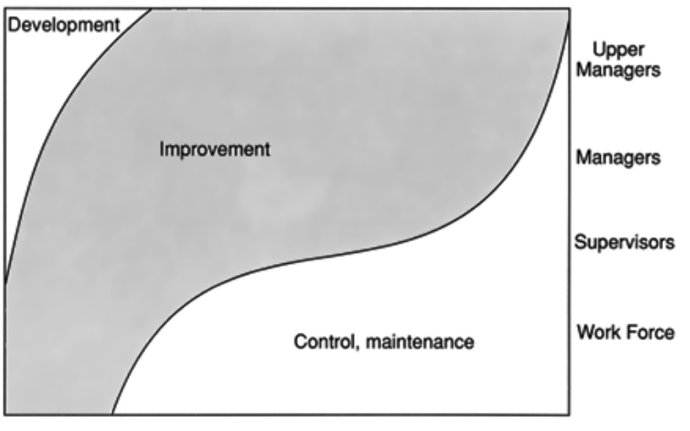

FIGURE 1.4. The Itoh model. (From Juran JM. *Making quality happen: upper management's role*. Wilton, CT: The Juran Institute, 1993, with permission.)

After World War II, W. Edwards Deming, another associate of Dr. Walter Shewhart, also espoused a philosophy of management that calls for organizations to produce products and services that help people live better. Deming believes that real profits are generated by loyal customers. In addition, Deming radically departs from the classic relationships among quality,

costs, productivity, and profit. According to Deming, as quality is increased, cost decreased due to elimination of repeats and waste. Improved quality leads to lower costs and higher productivity. Lower costs and higher productivity lead to lower prices. A competitive edge, it is hoped, is established (15).

"Companies," including hospitals and clinical laboratories, that follow Deming's philosophy have some distinct differences from the "standard" company (Fig. 1.5). Advocates of Deming's quality management philosophy believe that it is workers who pay for management errors—when profits go down, management cuts back on labor costs. They also believe that quality is difficult to define, yet the lack of quality is easy to define. The Deming philosophy ultimately describes quality as "anything that enhances the product from the viewpoint of the customer." In laboratory practice, there are two customers: the physician (the patient's advocate) who orders tests and the hospital/corporation that uses the services provided by laboratories to make revenue and measure contribution (nonprofit) or profit (for profit).

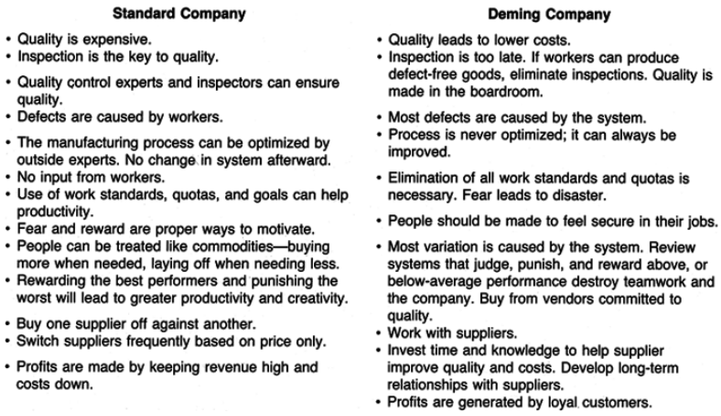

FIGURE 1.5. Comparison of Deming management principles and traditional management principles.

Development of a Service Economy

Integrated with the evolution of management in this country is the transition from an industrial economy to a "service economy." The evolution of a service economy in the United States parallels the increasing importance of quality improvement programs (16,17 and 18). A service economy is also directly related to the purchasing power of the targeted market population. The health industry has grown because both the consumers (patients with health insurance) and the providers who order laboratory tests and services have no information on the true costs of health care. Naisbitt (19) noted that in 1956 for the first time in American history, white-collar workers in technical, managerial, and clerical positions outnumbered blue-collar workers. He called such a change the "era of the information society" (Fig. 1.6). The "information society," throughout its evolution and maturation, requires a service economy. The "classic" management pyramid structure (Fig. 1.7), therefore, is now an inverted pyramid (Fig. 1.8) because the workers are empowered to participate in the management decisions that affect the workplace.

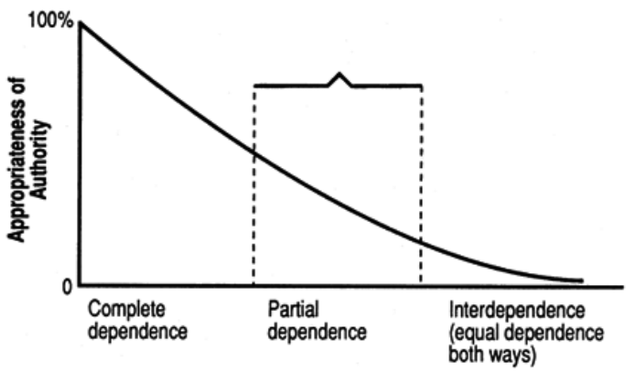

FIGURE 1.6. Dependence of subordinates in U.S. industry today. (From Naisbitt J. *Megatrends: ten new directions transforming our lives*. New York: Warner Books, 1982, with permission.)

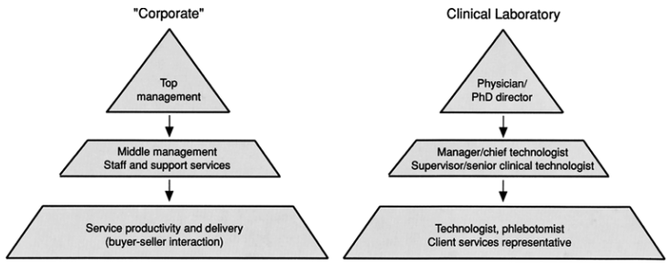

FIGURE 1.7. Classic management structure.

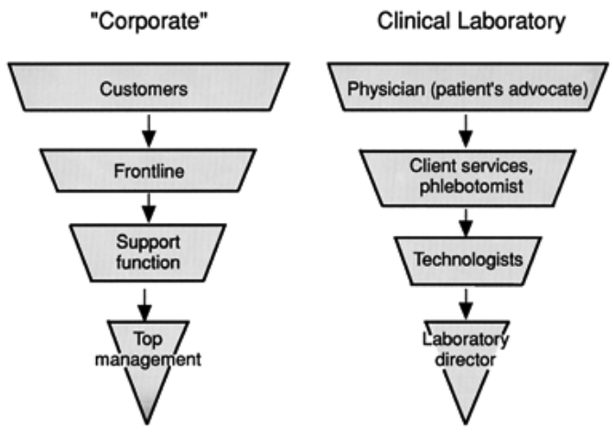

FIGURE 1.8. Service-oriented management structure.

A service economy meets customer expectations in the course of selling and postsales activity as well as providing a series of functions that match or better the competition in a way that provides an incremental profit for the producer of laboratory tests and services. For most services, four basic characteristics can be identified:

1. Services are more or less intangible.
2. Services are activities or a series of activities rather than things.
3. Services are at least to some extent produced and consumed simultaneously.

4. The customer participates in the production process at least to some extent.

In 1990, Christian Gronroos (18) described the “hidden service sector” and the “official service sector” in our economy. Such service sectors have direct relationships with laboratory medicine. Gronroos states that today, service firms have come to realize that competition is now so severe that mere technical solutions offered to customers are not sufficient to create a competitive edge. Further, Gronroos points out that in so-called “industrial sector” of the economy, manufacturing firms must offer customers a variety of services, as an integral part of their total offering, to succeed in business and survive competitive threats.

If one analyzes laboratory medicine today, especially in the outpatient environment, the outcome of the analysis is the same; performing a package of tests at an average cost and selling them at a reasonable price is no longer sufficient to create a competitive edge. An important reason for this is the array of “hidden (indirect) costs” required in the outpatient environment, which include information services (i.e., computerized order entry, line connects, printers, and terminals), couriers, specimen containers, laboratory consultation costs of marketing and advertising, the costs of regulatory compliance, inspection, accreditation, and retraining staff, and many other costs to run the business.

Another way to address the issue is that the clinical laboratory “test” in today's service economy, especially in the ambulatory care setting, is not simply a number or a brief statement; it is a cluster of issues that surround the laboratory test, such as:

- The ethical and moral responsibility to provide the best care for each patient,
- The need to rapidly provide medical information to a provider,
- The seller's (the laboratory or its representative) need to avoid financial losses,
- The organization represented by the laboratory (e.g., private corporation, hospital, university, and clinic) and its need to avoid financial losses,
- The laboratory service's reputation, which needs to be maintained in the eyes of the public it serves,
- The laboratory service's personnel and management's need to retain highly qualified staff,

TABLE 1.1. SYNOPSIS OF EXTERNAL (MACRO) AND INTERNAL (MICRO) LABORATORY MANAGEMENT BENCHMARKING PROGRAMS (2)

Programs	Scope of Program	Management Focus	Primary Users	Management Uses
Global management				
1. Labtrends™	External	Macro	Hospital administrators Laboratory directors/managers Laboratory section supervisors	Operating characteristics and performance Operating characteristics and performance Operating characteristics and performance problems
2. Laboratory Management Index Program	External	Macro	Laboratory directors Laboratory managers Laboratory section supervisors Hospital administrators	Global laboratory productivity, efficiency, utilization, and cost effectiveness
3. Mecon-Peer	External	Macro	Hospital administrators Laboratory directors/managers Laboratory section supervisors	Performance benchmarks Identify improvement opportunities Network operational issues
4. Data Comparison Reporting System (DCRS)	External	Macro	Hospital administrators in voluntary hospitals Laboratory directors/managers	Decision support systems Comparative financial and resource utilization data
5. Canadian Institute for Health Information (CIHI)	External	Macro	Hospital administrators (Canada) Laboratory directors/managers Laboratory section supervisors	Budgeting, productivity, utilization, efficiency
6. Welcan UK System	Internal	Micro	Section supervisors in chemistry, hematology, cytogenetics, histopathology, immunology, microbiology, and automated testing	Work load unit reporting
Labor/equipment management				
1. Equipment Test Labor Productivity index (ETI)	Internal	Micro	Laboratory managers Laboratory section supervisors Lead technologists	• Finds *total productive* minutes of time, based on lab's own unique equipment and methods • Finds total *billable test* productive time
2. CAP Workload Recording Method (Discontinued in 1993)	Internal	Micro	Laboratory managers Laboratory section supervisors Lead technologists	• Finds *average analytical* minutes used for staffing decisions Comparison of equipment and methods Labor cost estimates for equipment/methods

This table provides a synopsis of the currently available laboratory management bench-marking programs in the United States, showing their scope, management focus, primary users, and management uses. Management bench-marking programs are important for cost control in a reimbursement environment demanding lowered utilization and higher productivity.
From Travers EM. *Clinical laboratory management*. Baltimore: Williams & Wilkins, 1996:663, with permission.

- The buyer (the physician as the patient's agent) of laboratory tests and services,
- The organization represented by the buyer,
- The image of both organizations in the marketplace.

It is argued that ultimately the intangibles—the service activities that companies or laboratories offer their customers or patients—may be the most important source of value added in the service economy. It has been noted by Albrecht and Zemke that the marketplace prefers to do business with those who serve and declines involvement with those who only supply materials and goods (17).

The first evidence of interest in service quality began in the 1980s. At the same time, interest in quality assurance in laboratory medicine grew very rapidly. Quality assurance applications for laboratory medicine are currently updated and well defined by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) (20,21) and the federal mandates of the Clinical Laboratory Improvement Act amendments.

At the core of a successful service economy and, coincidentally, at the core of a successful quality improvement program are four commonly shared principles:

Involvement: Recognition by management that a situation exists.

Measurement: Necessary but cannot be used alone as a measurement of success or failure.

Reward: The success of employee-owned companies demonstrates the need for rewards.

Follow-through: Successful service economies or successful quality improvement programs become a way of life.

The overall success of these entities is incumbent on the leadership of management. Service and quality improvement require management's personal, visible involvement.

In discussing service management and marketing, Gronroos (18) observed that “far too often people in an organization view customers as an abstract phenomenon or a mass that is present somewhere. Customers are seen in terms of numbers. When someone stops being a customer there are always new potential customers to take their place. Customers, individuals and organization alike are numbers only.” In reality this is, of course, not true. Every single customer forms a customer relationship with the seller that the firm has to develop and maintain (18). This applies to laboratory practice in its managerial sense, i.e., the laboratory manager must make his or her customers (the physicians) happy with the laboratory's services. If one were to substitute the physician (the patient's advocate) for the customer and the hospital (or corporation) for the organization, this discussion could not be more timely, as health care and clinical laboratory medicine jointly struggle to emphasize the clinical importance of laboratory tests and services, while decreasing their costs.

Gronroos developed a “customer relationship life cycle” (CRLC) that can be modified or adopted to health care and clinical laboratory medicine. In the CRLC, the initial stage is when the customer establishes a need that a firm may be able to satisfy. The customer subsequently makes him- or herself aware of a firm's services. A first purchase follows if all is viewed positively. Subsequent purchases follow if a positive relationship continues. “During this process the customer may observe the firm's ability to take care of his or her problems and provide services which the customer determines to have an acceptable technical and functional quality.” Such a service certainly fits the patient's health care provider “life cycle” (Fig. 1.9).

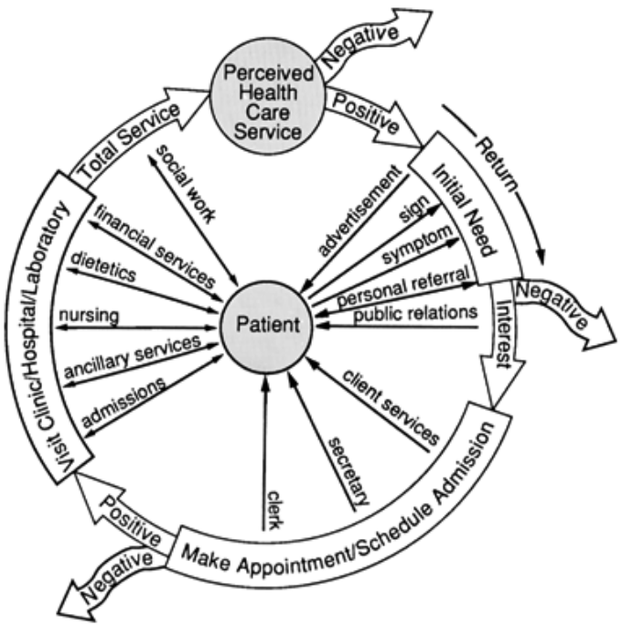

FIGURE 1.9. Patient-health care provider “life cycle.” (Modified from Gronroos C. *Service management and marketing*. Lexington, MA: DC Heath, 1990:130.)

Theory X, Theory Y

In 1960, Douglas McGregor (22) contrasted two types of companies. The first, X, was organized to demonstrate that no one works unless they have to or are made to work. Because of this human characteristic of dislike of work, most people must be coerced, controlled, directed, or threatened with punishment to get them to put forth adequate effort toward the achievement of organizational objectives. Thus, theory X assumes that the average human being prefers to be directed, wishes to avoid responsibility, has relatively little ambition, and wants security above all else.

McGregor's alternative theory, Y, demonstrates that, on the contrary, people love to work and, given the right conditions, will strive to do their very best. Theory Y leads to a preoccupation with the nature of relationships, with the creation of an environment that will encourage commitment to organizational objectives and will provide opportunities for the maximum exercise of initiative, ingenuity, and self-direction in achieving them. McGregor further explains that the appropriateness of authority varies as a function of dependence (Fig 1.6). For example, when the dependence in a relationship is complete, such as between a parent and child, authority can be used almost exclusively. Conversely, when dependence is almost equal, such as two staff physicians working on the same patient, authority is useless as a means of control. In today's clinical laboratory with numerous

highly trained professionals, the predominant relationship is one of partial dependence; thus, persuasion and application of professional guidelines are the ways to achieve goals.

Toughness is the hallmark of theory X. A company or laboratory that relies on the objectives of theory X applies hire-and-fire techniques.

Conversely, theory Y companies or laboratories operate with a velvet glove. Theory Y gives people room to exercise initiative instead of strict supervision. With the development of quality management systems such as continuous quality improvement and total quality, theory Y companies and laboratories are in vogue.

Further evidence for promoting quality management programs is provided by the widely accepted need-hierarchy theory developed by Abraham Maslow (23). Maslow describes an ascending hierarchy of human needs, which each individual strives to achieve in his or her personal and work environments (Fig. 1.10):

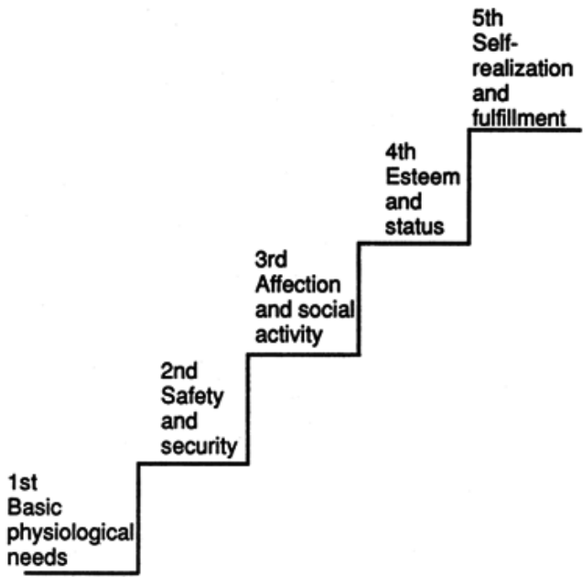

FIGURE 1.10. Hierarchy of human needs. (From Maslow A. *Psychol Rev* 1943;50:370–396, with permission.)

1. Physiologic or survival needs
2. Safety or security needs
3. Social needs
4. Esteem or ego needs
5. Self-actualization or self-fulfillment needs

Modern methods of quality management address these needs.

Continuous Quality Improvement

As quality assurance has matured, there has been a shift to a more consumer-oriented, more positive approach to health care management. Such an approach is called continuous quality improvement (CQI). CQI is a consumer-oriented, proactive response to negative public perceptions of the health care business (Fig. 1.11).

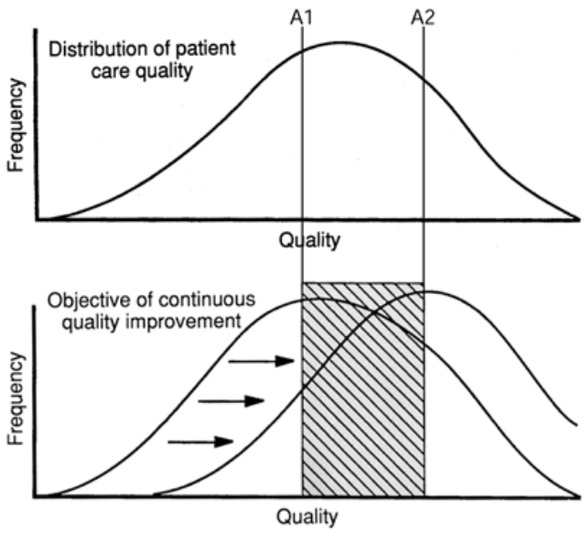

FIGURE 1.11. Shifting the mean: quality assurance to AI. **A**, quality assurance; **B**, continuous quality improvement.

As described by Richard E. Thompson, M.D. (24), there are 11 essential points that differentiate quality assurance from CQI:

1. The goal of CQI is to *improve* the norm of practice and behavior rather than to strive to comply with a standard based on normative behavior.
2. CQI uses supportive, positive approaches to change behavior rather than more investigative techniques.
3. In CQI, individual and corporate attitudes are as critical and as valid and/or useful as quality assurance data.
4. In CQI, performance indicators rather than quality criteria may be easier to define and implement.
5. CQI, using a cooperative effort, avoids the separatist approach to quality assurance, utilization review, and risk management that is often seen in hospital management settings.
6. CQI, because of the overall approach, is open to applications research.
7. CQI methods appear to be less complex than quality assurance methods simply because many quality assurance methods are developed by a committee.
8. CQI changes traditional medical staff functions such as credentialing and peer review to a patient-protective methodology.
9. In contrast to the absolute confidentiality of quality assurance, CQI allows public comparison of physicians and/or hospitals without providing litigious information to anyone.
10. CQI affects medical staff bylaws and organization structure by allowing physicians to feel comfortable about “taking responsibility for yourself.”
11. CQI provides a system that the JCAHO will find *functionally* useful.

Quality System Management

Recently, quality system management has gained attention as a method to provide consistent, high-quality, cost-effective laboratory medicine. Much of a quality system approach to management is based on a comprehensive/coordinated effort to meet quality objectives modeled after the International Organization for Standardization 9000 series quality standards.

A quality system approach to management requires that clinical laboratory personnel have a clear vision of the essentials of what needs to be managed, for example:

- organization
- personnel
- equipment
- purchasing and inventory
- process control
- documents and records
- occurrence management
- internal assessment
- process improvement
- service and satisfaction

Typically the essentials of a quality system can be applied to all aspects of a laboratory operation.

Modeled after the National Committee for Clinical Laboratory Standards approved guideline, *A Quality System Model for Health Care*, a laboratory should apply the essentials of what needs to be managed to a laboratory's path of work flow (25).

The ultimate goal for such a management approach is to provide an environment that the managers of clinical laboratories can apply to all the services in the clinical laboratory environment.

JCAHO—The Agenda for Change

In 1975, the Joint Commission on Accreditation of Hospitals (now called the JCAHO) published in their *Accreditation Manual for Hospitals* a requirement "to demonstrate that the quality of care was consistently optimal by continually evaluating care through reliable and valid measures." Subsequently, in 1980 the Joint Commission adopted the quality assurance standard for hospitals. The 1980 quality assurance standard (a) emphasized the value of a coordinated hospital-wide quality assurance program, (b) allowed greater flexibility in approaches to problem identification assessment and resolution, and (c) emphasized the importance of focusing quality assurance activity on areas where demonstrable problem resolution is possible (20,21,26).

In addition, the Joint Commission launched the Agenda for Change in 1986 to focus HCOs and the general public on quality of patient care. The goals of the Agenda for Change are

1. To use valid and reliable clinical indicators as screening devices to identify potential problems in the organization, provision, or monitoring of care
2. To apply more relevant organizational standards and related indicator measures in evaluating the effectiveness of organizations' governance and management
3. To render accreditation decisions that reflect more accurately the adequacy of an organization's attention to providing high-quality care.

The quality assurance activities of the Agenda for Change must follow a monitoring and evaluation process. The monitoring and evaluation process has 10 basic steps:

1. Assign responsibility
2. Delineate the scope of care (inventory clinical activities)
3. Identify important aspects of care (e.g., high risk, high volume, and/or problem prone)
4. Identify indicators (e.g., variables related to outcome of care)
5. Establish thresholds for evaluation
6. Collect and organize data
7. Evaluate care
8. Take action to solve problems
9. Assess the actions and document improvement
10. Communicate relevant information to the organization-wide quality assurance program

The 10-step process for monitoring and evaluation can also be used for such hospital-wide programs as infection control, utilization review, risk management, and safety management. In many hospitals, such programs are under the governance of the quality assurance administrative team, usually directed by a physician.

Conclusion and Summary

The quality management issues of quality assurance and CQI, including the JCAHO Agenda for Change, have had and will have a profound impact on the bottom line of the practice of laboratory medicine. When these are combined with the key variables of business performance, as described by Garvin (9):

- price
- advertising
- market share
- cost
- productivity
- profitability

The laboratory of the future will be assured of success, both in quality of care and in management. However, unless quality management is practiced assiduously, such entities as quality assurance, CQI, and even the Agenda for Change certainly will lose their impact.

An understanding of the principles of managing laboratory costs is vital to the business success of the laboratory. The section that follows provides the tools needed to manage successfully a cost-effective laboratory. A balance between the principles described in the preceding section and those contained in the next section is the secret to management of a productive, efficient, cost-effective, and profitable (contributory) laboratory (Fig 1.12).

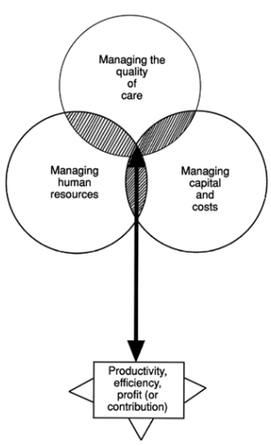

FIGURE 1.12. Key elements for success in laboratory management.

MANAGING LABORATORY COSTS

Part of "1 - Basic Laboratory Management"

Strategies, Problems, and Principal Areas of Laboratory Expenditure

Strategies

Establishing strategies for cost-effective laboratory management begins with an assessment of the laboratory's *external* and *internal* fiscal environments.

In the external environment, the laboratory manager must understand both the organization's and the laboratory's strategic plan. Its market share and product line, its financial goals, its role in supporting the local medical community, its administrative responsibility to its source of operating capital (i.e., a hospital, corporation, multihospital group, HMO, or federal,

state, or municipal government), its capital asset structure (where applicable), and the limitations on current budget, known as operating funds. In the internal environment, the laboratory manager must assess the age and condition of equipment, staffing adequacy and balance, salary structure, and types of reimbursement received and their multiple sources, and must analyze the volume and complexity of the laboratory's input (workload), especially tests created by the explosion of molecular biology and genome-related technologies. If the laboratory is engaged in teaching resident physicians or laboratory professionals or is performing research and development, the additional impact of these resource-consuming programs must also be assessed.

The Fiscal Management Team

Accomplishing this comprehensive fiscal assessment is impossible without the cooperation and interaction of a management team in the laboratory that works closely with hospital, corporate, or institutional management. Although the overall responsibility for cost-effective management rests with the laboratory director, the task ultimately requires an integrated effort between top management, middle management/supervisory personnel, and laboratory technical staff (Fig. 1.13).

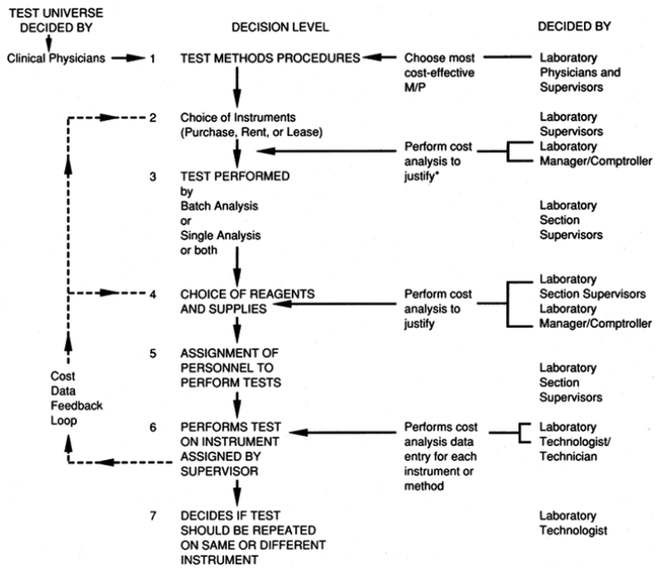

FIGURE 1.13. Laboratory financial decision flow chart. *Cost analysis may indicate that it is more cost effective to send out tests to other laboratories, rather than purchase, rent, or lease an instrument. (From Travers EM. *Managing costs in clinical laboratories*. New York: McGraw-Hill Information Systems, 1989:5, with permission.)

The Pathologist's Role in Laboratory Fiscal Management

The pathologist's role is critical to success in fiscal management and rests on recognizing medical care priorities, good planning, excellent control, and recognition of the major differences in managing the costs of anatomic and clinical pathology. The value of a good laboratory manager is directly related to his or her ability to foresee future technological and workload trends, anticipate and deal with sudden environmental changes, and make critical decisions for managing limited resources, based on these abilities.

Problems

Principal Fiscal Management Problems

The major fiscal problems facing laboratory managers include (a) managing enormous increases in workload, mandated regulations, compliance and quality management requirements, (b) managing “hidden” and uncontrolled costs, and (c) finding and installing adequate fiscal and management information systems to capture the majority of data input and relieve the technical and administrative staff of the onerous, inefficient task of manual data entry. A subset of this problem (as of this writing) is that there is still little or no compatibility between different laboratory computer vendor's information systems, let alone fiscal and management systems. This makes it difficult if not impossible for a laboratory manager to compare the laboratory's fiscal and utilization data with those of laboratories of similar complexity and workload in the same community. However, several external programs to assist managers in benchmarking operating characteristics, financial, productivity, utilization, efficiency, billable tests, and other management indicators can be purchased (Table 1.1).

Lack of Cost Control Measures

Additional measures that can be used to control costs include (a) controlling automation, primarily by avoiding additional or excessive labor costs associated with the acquisition and operation of unnecessary and excessive automated equipment; (b) avoiding the additional costs for reagents and supplies associated with excessive automation (and workload/quality control demands); (c) providing more efficiency in chemistry and hematology (70% to 80% of total laboratory workload) (27); and finally (d) controlling the total laboratory budget more closely (especially labor costs) by consolidating groups of tests and convincing clinicians to reduce unnecessary routine, daily testing practices.

Principal Areas of Laboratory Expenditure

Direct Costs

Labor costs. Of all costs in laboratories, the most difficult to control are labor costs. Labor costs account for the majority of expenditures, regardless of the complexity and size of the laboratory (70% to 85%, depending on seniority, benefits, and number and size of the staff) (27). A categorization of labor costs appears in Table 1.2.

TABLE 1.2. LABOR SUBACCOUNT CATEGORIES

Operating (or standard cost) labor	
	Labor, quality control at standard cost
	Labor, variance from standard cost
	Supervisors' salaries
	Physician remuneration
	Doctoral level salaries
	Technologist salaries
	Technician salaries
	Secretarial/clerical salaries
	Aide and other operating salaries
Nonoperating labor	
	Executive personnel remuneration
	Maintenance personnel salaries
	Supervisors' salaries
	Driver salaries
	Pilot salaries
	Data processing personnel salaries
	Other nonoperating personnel salaries

Adapted from Gaither JF, Resinger HE. *Cost accounting in the laboratory*. Mundelein, IL: American Pathology Foundation, 1981:V-20.

Reagent Costs. The second major category of laboratory expenditure is for reagents and supplies (consumables). These usually account for 10% to 15% of total laboratory expenditures, depending on how carefully discounts are obtained and how efficiently reagents are used. In fact, the inefficient and excessive use of quality control and standards, especially in chemistry, can accumulate

to 30% to 35% of chemistry costs if not carefully monitored (Table 1.3).

TABLE 1.3. MAJOR SUPPLY REAGENT AND BLOOD SUBACCOUNTS

Materials and supplies, total
Materials, laboratory, total (or at standard cost)

Costs for Blood and Components. Costs for blood and components are far more difficult to control based on the shortage of raw products from donors, the cyclical and unpredictable nature of patients' illnesses, and the need for emergency or operative treatment. One of the most difficult areas of cost to control is the blood bank's transfusion service because the hospital's case mix and clinical factors will have a profound influence on the type and volume of blood and components purchased and utilized. Furthermore, laboratories that do not collect and process their own blood are dependent on outside sources and have limited ability to control their costs and/or optimally set their annual charges for blood and components.

A major factor that has escalated the cost of collecting and processing blood is the cost of testing for transmissible disease, new improvements including leukocyte reduction, nucleic acid amplification testing, and viral inactivation make the transfusion service a costly operation (29). In transfusion-related services, one must not forget that the cost of the testing reagents and labor may not be the major source of cost. The major cost is dependent on the charges for blood products that suppliers of blood impose on hospital laboratories to recover their labor costs to perform mandated safety tests.

Fee-Basis Testing Costs. Fee-basis tests are send-out tests that cannot be performed in-house due to lack of equipment, technical expertise, or personnel or for other reasons. This category of expenditure may be a major source of additional expense for laboratories that do not have a large, highly trained staff with special testing expertise and/or state-of-the-art equipment. Also, fee-basis testing may be necessary if the type and complexity of tests ordered are of a complex or esoteric nature, i.e., those ordered in teaching or tertiary care settings.

Large increases in fee-basis testing expense can be avoided by controlling the test-ordering process at the clinical level and by choosing the lowest cost for the desired tests through competitive bidding and comparison of prices. It is also important for laboratory management to advise clinicians of test costs and turnaround time using published lists of tests with this information.

Capital Equipment Acquisition Costs. There are several ways to acquire equipment, each of which has its advantages and disadvantages (28). The principal methods are purchase, lease, rental, and special rental contracts (e.g., cost per test, reagent rental, and other customized contracts). Without consideration of the cash flow requirements of each method, appropriate planning is necessary to ensure that the laboratory's budget can accommodate the acquisition because additional equipment may escalate operational costs.

The criterion for choosing among the different alternatives is the minimization of the cost of acquiring the equipment and the yearly net cost outflow associated with each alternative. These areas are usually best handled by an accountant who understands laboratory operations and who will perform the required analysis to compare purchase with a time-sale contract, financial lease arrangement, rental, or other contractual method.

However, the current difficulties with availability of money for investment in capital equipment make it imperative that hospital laboratory managers present a complete and convincing presentation to hospital or corporate management when requesting *purchase* of new or replacement equipment. The process itself is segmented into five distinct categories:

1. Development of depreciable costs
2. Estimation of appropriate depreciation life and timing
3. Isolation of related cash flow variables
4. Forecast of production volume and revenue
5. Measurement and comparison with hospital criteria

The laboratory manager should realize that other equally important factors must be considered in the capital acquisition process, namely, turnaround time, rapid response, precision, accuracy, reproducibility, availability of service, and safety (29).

A combination of the two processes discussed above should result in a smooth final acquisition determination. A detailed description of the elements of this process is beyond the scope of this chapter but can be reviewed in an article by Oszustowicz (30) and in textbooks by Travers (27,31), which provide a format for a marketing opportunity package for capital equipment (see Methods for Acquiring Equipment section).

Indirect Costs

Indirect costs are the costs of specimen collection, processing, testing and reporting that cannot be directly traced to test production. A partial list of basic items used in estimating indirect costs for tests is included in Fig. 1.14. A detailed explanation of

indirect costs using formulas and examples can be found in *Cost Accounting in the Clinical Laboratory*, published by the National Committee for Clinical Laboratory Standards (32), and textbooks by Travers (27,31).

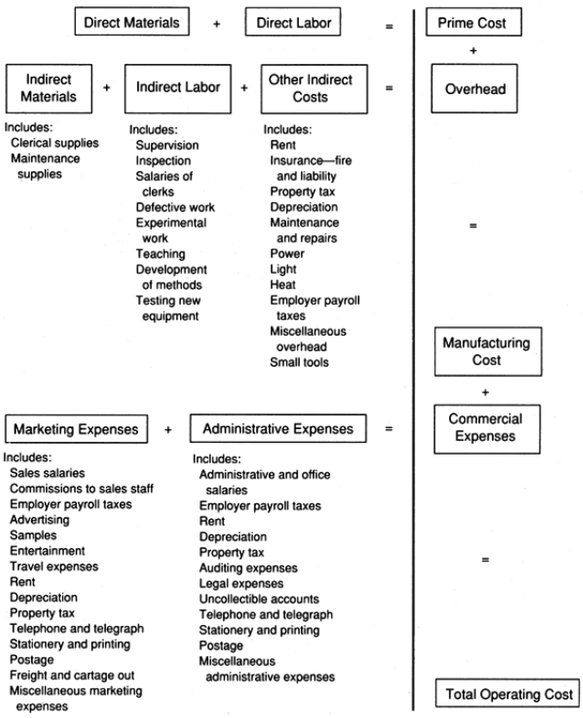

FIGURE 1.14. Analysis of total operating cost. (Adapted from Matz A, Usry MF. *Cost accounting: planning and control*, 7th ed. Cincinnati, OH: Southwestern Publishing, 1980:45.)

Indirect costs are assigned to total cost based on a multitude of factors that are part of hospital or corporate operations. They are added to the cost of tests as a percentage rather than as actual amounts for each item.

Total indirect costs to operate an organization or department must be recovered by reducing operating expenses, by charging for research, epidemiologic, or environmental tests, or through the pricing of tests and services. The total cost of performing a test or procedure is the sum of the direct cost plus a proportionate share of indirect costs.

The indirect cost percentage will vary in each laboratory based on the total number of factors that the organizations and the laboratory uses to calculate indirect costs. These are considered as highly significant expenditures because in some private sector settings, indirect costs may be as high as 148% of total cost (27,31).

The Laboratory Fiscal System

Every organization—regardless of its size or complexity, profit or nonprofit status—must maintain a system for financial data collection and coding for recording in journals and ledgers. The prerequisite for accomplishing these tasks is a properly established account structure. This fiscal system is known as the chart of accounts.

The Chart of Accounts

The organization's chart of accounts is the fundamental means for budgetary and control accounting. It provides control accounts for the recognized elements of cost, and it segregates and details all expenses not included in prime cost (the total cost of direct materials and labor in test production). The chart of accounts is the foundation of the financial management system for the laboratory. It includes information on the historic financial database and current financial information about the laboratory and is a future financial planning aid. It also allows consistency of financial data collection for planning and control. The comprehensive chart of accounts (Fig. 1.15) provides management data breakdown in categories needed by management, namely, assets, liabilities/equity, revenues, and costs (expenses).

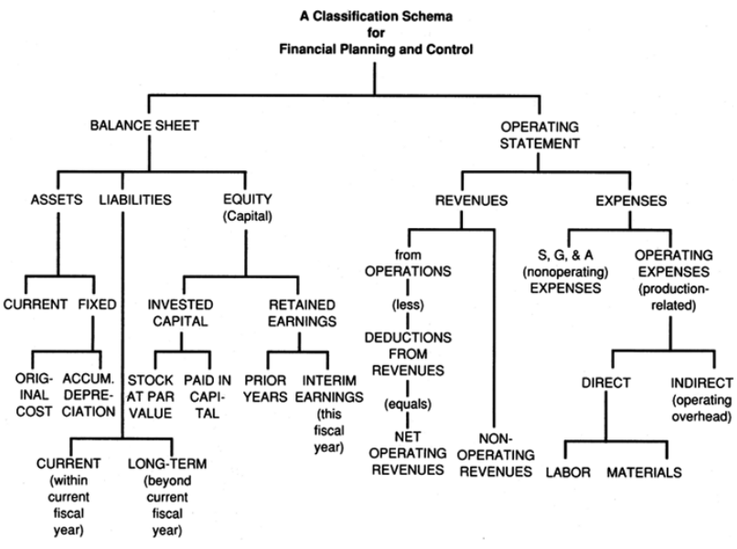

FIGURE 1.15. The chart of accounts for laboratories. (From Travers EM. *Managing costs in clinical laboratories*. New York: McGraw-Hill Information Services, 1989:36, with permission.)

The chart of accounts has two major sections: (a) the balance sheet and (b) the operating statement (income statement). The balance sheet is divided into three major sections: assets, liabilities, and equity. The operating statement is divided into revenues and expenses. Because laboratories vary in their activities and complexity, the chart of accounts will also vary, according to the information that the managers believe they need to accomplish the task of sound fiscal management. Not even a large, independent laboratory will use more than a small fraction of the

available accounts, but the accounts they need are available, because the fine structure of the chart of accounts meets virtually every conceivable need for detail (27).

The Balance Sheet

The purpose of the balance sheet is to report the financial position of the laboratory at a particular time. Financial position refers to the amount of resources (i.e., assets) and liabilities of the laboratory on a specific date. The balance sheet provides the laboratory manager with a recorded, systematic statement of each transaction involving assets, liabilities, or equity. The accounting process provides the raw data for each subaccount, whether it is handwritten, mechanized, or computerized. Each transaction is recorded in one of the major sections of the balance sheet and is ultimately used to construct the laboratory's financial statements. The basic formula for the fundamental accounting model is:

Assets = Liabilities + Equity

This formula leads to an understanding of the basic and broad perspective of accounting as it relates to overall fiscal management. The basic objective of cost-effective laboratory management is to balance this equation. In situations in which improved profit is desired, the need to minimize and reduce liabilities is even greater, while maximizing assets and equity. In not-for-profit situations, in which assets or profit are not desired, minimizing liabilities becomes even more important to preserve operating capital (27,32). Major categories of liabilities are listed in Fig. 1.15.

The Operating (Income) Statement

This section of the chart of accounts includes a format for determining the laboratory's revenues, expenses, and profit (or losses).*a* Revenues are obtained from operations or from nonoperating sources. Operating revenues are characterized by type of payment agreement and type of guarantor. Nonoperating revenues are obtained from categories such as technical school operations, grants, investments, rent, and miscellaneous revenue-generating activities other than laboratory operations.

In a hospital, the laboratory is one of many cost centers; however, it is also a revenue center, i.e., it charges and/or is compensated for its services. It is necessary, then, for the laboratory and other hospital revenue centers to produce revenues in excess of expenses to offset losses incurred by other nonrevenue-producing centers. In laboratories, the operating statement is used to report the profit performance of the laboratory for a specific time period (e.g., year, quarter, month). Profit (or net income) represents the difference between revenues and expenses, i.e., the results of operations. Even not-for-profit laboratories need to make a profit (e.g., efficiency or savings) to survive, expand, and make a “contribution” to the nonrevenue-producing departments.

Therefore, the income statement reflects one of the fundamental principles of accounting, i.e., Revenue - Expenses = Net income or (Net operating revenues + Nonoperating revenues - Expenses) = Net income (Profit or Contribution).

Revenues include sales of laboratory tests, whereas expenses include the general categories of costs of test specimen collection, processing, performance and reporting, marketing and selling expenses, general and administrative expenses, financial expenses, and income tax expenses.*b* More detailed information and a listing of income statement categories can be found in Gaither and Resinger (33) and Travers (27,31).

DETERMINING PROFIT OR LOSS

Part of "1 - Basic Laboratory Management"

One of the techniques used to establish profit or loss is known as cost-volume-profit analysis, also known as marginal analysis in general industry. It is used to provide relevant information for selecting product lines, pricing individual products, and developing market strategies. It is a valuable method for analyzing profitability in many firms. Cost-volume-profit analysis permits the study of the relationships between prices, variable costs, fixed costs, and workload volume to aid in management decision making. In laboratory use, the key relationship is the difference between test price and variable costs per test, otherwise known as the *contribution margin*.

Distinction between Contribution and Profit Margin

There is an important distinction between profit and contribution. As noted previously, profit (or net income) represents the difference between revenues and expenses. However, contribution is computed by deducting the costs for which the laboratory is responsible (both direct and indirect) from the revenues gained for the tests generated by the laboratory. Contribution can also be applied to laboratory sections, e.g., contribution for hematology section is calculated by taking all fixed and variable costs that are the responsibility of the hematology section and deducting them from the revenue generated in the hematology section for the period in which the cost was incurred.

Impact of Contribution on the Rate-Setting Process

The impact of contribution on the rate-setting process by hospital or corporate management is significant because it affords hospital management the opportunity to calculate the approximate level of patient service revenue required to cover budgeted economic costs. The portion of the rate charge that directly affects the operating margin is the contribution factor.

There are both internal and external reasons for placing minimum and maximum limitations on departmental rate increases

and decreases. Among these factors are competition, governing board policy, limitations imposed by rate-setting authorities, and contractual arrangements. Each of these factors is reviewed as applicable, and upper and lower limits are established within which rates may be charged. For example, suppose hospital administration has determined that the room rate is well below that of neighboring hospitals and a room rate increase of 5% to 25% is desirable. However, emergency department charges are slightly higher than acceptable. A survey has shown that laboratory rates could be increased by as much as 20%, but the hospital's governing board has indicated that a 10% reduction would be desirable. Finally, the radiologists' contract provides that there be no reduction in departmental rates while their contract is in effect. Based on this information, the hospital establishes the following rate change limitations:

	Lower Limit	Upper Limit
Routine care	+5%	+25%
Emergency department	-5%	0%
Laboratory	-10%	+20%
Radiology	0%	+10%

By applying rate increases to the departments with the highest contribution factors and rate decreases to those with the lowest contribution factors until the target profit contribution factor is reached, the aggregate rate change will be minimized (33).

Management Responsibilities and Contribution Margin

During times of unrestrained resource available, profit-maximizing decision makers will elect to produce all the products they can as long as their marginal revenue (MR) (the price or charge) exceeds marginal cost. However, in times of limited resource availability, profit-maximizing decision makers should (and will only) select those tests for market expansion that will have the greatest effect on producing a high contribution margin.

The next major management topic concerns the manager's responsibility to plan the future use of operating funds, known as budgeting.

BUDGETING

Part of "1 - Basic Laboratory Management"

Principles

A budget is generally defined as a comprehensive plan or guide for some future period of time, usually, by convention, a year, a quarter, or a month. Budget plans can be expressed in a variety of ways, e.g., in man-hours, dollars, outputs. A budget, however, is primarily a financial plan and is therefore expressed in dollars. Thus, the term budget might be defined more explicitly as a comprehensive financial plan, based on anticipated outputs and predetermined hospital goals and policies for future operations, that is expressed in dollars of expense and corresponding dollars of revenue.

For purposes of understanding and discussion, the budget translation process can be viewed as consisting of two primary steps: (a) converting the hospital's or corporation's strategy into an operating plan for the laboratory and (b) expressing the operating plan as a budget for the laboratory. The first step involves defining the specific workloads, projects, and other operating activities that must be undertaken to transform the corporate strategy into reality. The second step focuses on expressing the operating plan in financial terms, for example, dollars of expense, revenues, capital purchases. Therefore, there are four basic types of budgets: statistical (e.g., workload), expense, revenue, and capital budgets.

Before constructing the budget, an additional element is necessary: a budget preparation procedure. This includes the technical, mechanical aspect as well as the management of the entire process. The technical part focuses on (34)

- projecting workload (volume)
- converting volume estimates into resource requirements and revenue estimates
- converting resource requirements into direct cost estimates
- calculating indirect costs
- adjusting revenues and total costs to obtain the necessary equality

Sectional Budget Analysis

Once the basic concepts of budgeting are understood, the actual construction of budgets for laboratory-specific elements can begin. A general sectional analysis format (Fig. 1.16) is adaptable for all laboratory sections and includes entries for all major areas of laboratory instrumentation and manual methods. Direct costs are established first, using a microcost analysis method (see Appendix A), then these data are entered into the appropriate section for instrument based or manual methods. The cost is then multiplied by the raw test count (the workload) for each category for the period in which the budget is constructed. The final product for each instrument or method is added to produce the total direct cost for test production. Added to this figure are other major sectional costs, namely, professional salaries and fees, blood and component costs, transportation, fee-basis (send-out) costs, costs for operations, administration, travel, depending on the laboratory's organization structure and fiscal control points. This basic worksheet combines the principles of (a) where resources are consumed, (b) how rapidly they are consumed, and (c) assigning a site to link the cause and the site to where the cost was generated.

	Instrument Name	Cost/Test†	Test/Year	Cost/Instrument
Chemistry				
Instrument	1_____	$_____	_____	$_____
	2_____	_____	_____	_____
	3_____	_____	_____	_____
	4_____	_____	_____	_____
	5_____	_____	_____	_____
Manual Tests	1_____	_____	_____	_____
	2_____	_____	_____	_____
	3_____	_____	_____	_____
		TOTALS: 1. Instrument Costs		_____
		2. Cost Professional Salaries Administrative Salaries		_____
		3. Cost Blood/Components		N.A.
		4. Cost Transportation/Travel		_____
		5. Cost Fee Basis		_____
		6. Cost Operations/Administration		_____
		TOTAL COST Operations/Laboratory/Year for Chemistry		$_____

FIGURE 1.16. Worksheet for sectional analysis of chemistry costs based on equipment configuration manual procedures. *This format can be utilized for all laboratory sections. Chemistry is used here as an example. For instance, if used for the blood bank section, item 3 in TOTALS would be applicable. Cost/test includes direct costs (labor [technical/clerical/phlebotomy], reagents and supplies) and indirect costs (amortization, depreciation, maintenance, site preparation, and all other costs). (From Travers EM. *Managing costs in clinical laboratories*. New York: McGraw-Hill Information Systems, 1989:130, with permission.)

These are the principles of activity-based costing, a newer method than product costing for only one test/service.

Departmental Budget Analysis and Allocating Costs across Sections

Although direct costs noted in the previous section comprise the major costs per section, it is important to allocate costs to a budget format that also include the costs for the time of general employees who are not specifically assigned to a laboratory section but whose work helps to produce or interpret tests (e.g., secretaries, couriers, computer personnel, maintenance personnel). These are known as indirect costs. Some laboratories use formulas

for allocation; however, there is no uniform set of formulas that will apply to every laboratory. An experienced manager should be able to create accurate formulas for each production area and the department. The only requirement is that the formulas must realistically reflect the section's or department's use of that function. Examples of allocation within a laboratory section budget are given in Fig. 1.17 and within a departmental budget in Fig. 1.18. Figure 1.19 further illustrates budgeted expenses for a total laboratory, by breaking major cost categories into their cost accounting subcomponents.

		A (Demand)	B (Astra)	C (ACA)	G (ABL Blood Gas)	H (Centrifichem)	
Example 1:	General Function That Varies per Instrument						Total Chemistry Tests
	Total Billable* Procedures	39,232	65,068	23,922	5,052	6,890	140,164
	Percent of Total Chemistry Tests	27.9	46.4	17.1	3.6	4.9	
		x	x	x	x	x	
	Phlebotomy Salaries† for Chemistry	$100,128	$100,128	$100,128	$100,128	$100,128	
		=	=	=	=	=	
	Cost of Phlebotomy per Instrument	$ 27,936	$ 46,459	$ 17,122	$ 3,605	$ 4,906	
Example 2:	General Function That Applies Equally to All Instruments/Sections						Total Professional Salaries for Chemistry¶
	Pathologist's Salaries (Professional Fees)‡	12,500	12,500	12,500	12,500	12,500	62,500

*Test result actually billed to patient. Example: a chemistry profile with 18 determinations counts as one billable procedure, not 18 tests.
†Determined by the following ratio:
1. $\frac{\text{Total Billable Procedures/Chem}}{\text{Total Billable Procedures/Lab}} = \frac{175,999}{394,000} = .447 = 44.7\%$ 2. 44.7% × Total Phlebotomy Salaries/Lab = .447 × $224,000 = $100,128
‡Pathologist's time in this lab is allocated as follows:
50% Histology/Surgical Pathology
10% Chemistry
10% Microbiology
10% Hematology
10% Immunology
10% Blood Bank
¶For Chemistry:
a. 10% × Total Prof. Fees/Lab = 10% × $625,000 = $62,500/Chem
b. 62,500/5 (instruments) = $12,500 Prof. Fees/Instrument

COST ACCOUNTING

Part of "1 - Basic Laboratory Management"

Definitions

Accounting focuses on measuring and reporting the input and output of resources in an organization and the resources controlled by the organization. It provides an information base that allows decision makers to assess the potential financial implications and potentials of various alternatives being considered. Berman (35) and Horngren (36) point out that "the essential strength of the managerial cost accounting process is that it links 'promises' made during the budget process back to the responsibility center" (36).

The subject of accounting can be divided into two distinct major specialties: financial accounting or external financial reporting to shareholders, creditors, the IRS, and regulatory and other external bodies and managerial accounting, which deal with internal reporting. Within managerial accounting (also known as responsibility accounting), the subject of cost accounting defines, measures, reports, and analyzes the elements of costs associated with providing a unit of output—in the specific case of laboratories, a test or service, also known as a procedure in reimbursement coding manuals.

In the past, cost accounting referred to the methods for accumulating and assigning historical costs to units of products and departments, primarily for purposes of inventory valuation and income determination. Cost accounting is now indistinguishable from management accounting because it serves multiple purposes. Fundamentally, cost accounting now refers to the gathering and providing of information for decision needs (which range from large-scale needs such as management of recurring operations to the making of nonrecurring strategic management decisions) and for the formulation of major organizational policies. The smallest unit able to be costed is a product. The cost accounting method needed to find the costs of a laboratory's product(s), tests, and services is known as job-order costing.

Cost Categories Used to Determine Operational Expenses

Figure 1.19 lists the categories of costs that encompass both the traceability of costs (direct or indirect) and the behavior of costs (fixed or variable). Figure 1.19 also illustrates how laboratory costs fall into both traceable and behavior categories and breaks down total costs for each major laboratory expense into direct or indirect, fixed or variable costs. Direct costs are test-specific costs that can be directly traced to the production of tests and services. These include all costs for labor and supplies needed to produce a test. Indirect costs (common or joint costs) cannot be traced to a particular test; however, they contribute to the provision of an adequate work environment. Examples are section-specific and general supervisory salaries, general quality control, miscellaneous supplies, education, travel, and global costs such as administrative costs, computers, maintenance, and security (Fig. 1.14). Ultimately all indirect costs must be allocated to each laboratory section and to each test. Variable costs are costs related to changes in the volume of tests produced. Examples are reagents, supplies, and labor that can be controlled by laboratory supervisors by obtaining the best discounts, purchasing only when necessary, and using the instrument and method that uses the least costly labor and material. Fixed costs are costs that remain constant regardless of the volume of tests produced. They buy the capacity to do business—space, equipment, and administrative and other general personnel (e.g., preventive maintenance contracts, equipment depreciation, insurance policies, automobiles for courier service).

Cost Accounting for Laboratory Tests and Services

Accounting for the cost of a laboratory test or service considers the prime cost aspects of analysis: (a) labor costs and (b) material (reagent, supply) costs, and (c) indirect costs, also known as overhead. The interrelationship of these three areas is illustrated in Fig. 1.14, which also shows the business elements of test cost that must be added if the test is produced in a corporate setting, e.g., marketing and administrative expenses.

In 1989, Travers (27) published a detailed generic cost accounting method (Appendix A) that can be used in any section of the laboratory to derive a total cost for any test produced, using any procedure, instrument or test method. Known as the instrument cost accounting technique (ICAT), the method utilizes generally accepted business accounting techniques to construct actual total test costs. If charges or prices need to be established, ICAT provides the basis for identifying actual costs for labor, reagents, supplies, and instrument-related (and other indirect) costs incurred with the performance of the test. Using the total actual cost as a base amount, laboratory managers can realistically project test charges and prices by adding desired profit and contribution margin elements (see Setting Test Price and Charges section). Standard laboratory cost management texts and guidelines provide worksheets that can be used to develop test costs (27,31).

Cost Accounting for Disease Categories

In the future, laboratory medicine will become even more dependent on accurate and realistic total reimbursement to survive financially. Therefore, the value of the ICAT becomes more important because it can be used to calculate the actual laboratory costs for all tests and services performed for a patient's hospitalization by the patient's disease category. Once the cost per test for each type of test (e.g., sodium, potassium, glucose) is determined for the instrument or method used, the cost of a particular pattern of disease-related tests ordered can be established (Fig. 1.20). This technique will become more important as cost accounting software is developed that will rapidly associate workload and activities as tests are produced with the costs of each test or service.

			Cost Per Test					
			Direct			Indirect		
Test	Value of Test(s)	Equipment	Reagents/ Supplies	Instrument	Labor GS-9 GS-7	Indirect	Frequency	Total Cost
BUN	Highly Valuable	Demand	$ .13					
Potassium	Highly Valuable	"	.22					
CO_2	Highly Valuable	"	.21					
Chloride	Highly Valuable	"	.22					
Creatinine	Highly Valuable	"	.09	$ .04	$ 7.01	$ .79	1	$ 9.45
Sodium	Highly Valuable	"	.13					
Glucose	Highly Valuable	"	.13					
24-Hour Creatinine	Highly Valuable	"	.09					
Protein	Highly Valuable	"	.15					
Cholesterol	Moderate Value	"	.24					
Urine Microscopic	Highly Valuable	Manual	.15	.03	1.55	.19	1	1.92
Hematocrit	Moderate Value	Coulter S + IV	.27	.36	2.09	.30	1	3.02
Hemoglobin	Moderate Value							
TOTAL COST/LDRG/NEW ADMISSION			$2.03	$ .43	$10.65	$1.28		$14.39

FIGURE 1.20. Example of a cost analysis worksheet. Major diagnostic related group: 294.MDC 10M. Diabetes ≥ 36. Principle diagnosis: 250.40 adult-onset type (diabetes mellitus with renal manifestations/noninsulin dependent). Patient status: new admission, stable. Frequency of test(s) ordered: order once on admission only. LDRG, laboratory diagnostic related group; MDC. (From Travers EM. *Laboratory diagnostic related groups*. Department of Academic Affairs, Continuing Education Workshop, Washington, DC, May 1984, with permission.)

Activity-Based Costing

Activity-based costing links fiscal resources consumed in the cause of the activity (workload generated) and the site where the cost was generated. Activity-based costs consider the direct cost of the test/service produced, multiplied by the volume of the test/service produced. Indirect costs are separately allocated by

tracing costs associated with the production process and adding them to the total direct cost of production. Known as allocation, the process is described in Fig. 1.17.

Contrasted with actual (job order, product) costing, activity-based costing is less accurate. However, activity-based costing is more helpful to managers responsible for budget formulation and make-or-buy decisions.

The Role of Cost Accounting in Variance Analysis

Variance analysis is the comparison of the deviation of actual costs from budgeted or expected standard costs. Cost accounting provides the tools to develop actual costs, and over time, the averaging of actual costs provides the expected or standard cost figure. In times of shrinking economic resources, variance analysis provides a tool to monitor the financial performance of an operating department. The significance of variance analysis is its ability to break the total difference between standard and actual costs into elements such that the causes of the difference are revealed. This allows the manager to decide what action should be taken, by constructing an explanation worksheet to use as a basis for mutual resolution of variance problems (Fig. 1.21).

Expense Item	Amount	Explanation of Variance	Current Corrective Action
Direct Materials Material Usage	(380)	Poor reagent handling-outdating.	Variance should be eliminated with new plan for handling.
Direct Labor Labor Efficiency	(8855)	Lost three experienced workers. New replacements need training on equipment and upset routine of entire department.	New replacements not envisioned in setting standards last year. Expect training to be completed soon. Will be included next year. No standard revision believed necessary now.
Labor Rate	(150)	New union contract rate for workers at higher rates than used in planning standards.	No standard revision believed necessary. Will set up separate action for rate variance.
Overhead Efficiency	(4679)	Caused by 1519 excess hours of labor.	See Labor Efficiency above.
Overhead Spending Supervisor	300	Budgeted as fixed expense with provision for salary increase at midyear.	Not required, since variance will disappear by year end.
Indirect Labor	(752)	Cost of working every Saturday during quarter for extra volume.	Short-term contract completed.
Employee Benefits	200	Budgeted as fixed expense with provision for rate increase at midyear.	Not required since variance should disappear by year end.
Supplies	50	Actual supplies used less than anticipated.	Not required. Year-to-date excess use has been reduced.
Maintenance & Repair	(884)	Repair of equipment causing down-time.	Temporary situation, now corrected.
Power & Light	(30)	Additional power requirements based on Saturday work.	Not required.
Taxes & Insurance	(20)	Not controllable.	Not required.

FIGURE 1.21. Example of a variance explanation worksheet. (Adapted from Gaither J, Resinger H. *Cost accounting in the laboratory*. Half Day, IL: American Pathology Foundation, 1981:10–14.)

For example, if the department chairperson claims that the purchase of a certain analyzer will result in labor savings, but no labor savings are experienced, then this shortfall in performance needs to be either (a) explained by exogenous circumstances beyond the manager's control or (b) utilized annually to discount the judgment and the budget of the manager in question (36). More detailed explanations of variance analysis can be found in standard laboratory cost management references (27,32).

Setting Test Prices and Charges: Make-or-Buy Decisions

One of the ultimate goals of a for-profit institution is to provide a profit or contribution for the organization's shareholders through the production of a product. The preceding section developed a rationale and methods for deciding whether a test (product) is profitable to perform, using cost accounting templates and variance analysis. Both the complex, active tertiary care laboratory and the less active laboratory must manage critically short resources by establishing actual cost and determining whether their prices or charges are adequate to cover costs and provide a profit (or contribution) margin to satisfy hospital or corporate management. Similarly, decisions must be made to determine whether certain tests should be discontinued in-house and sent to other laboratories on a fee basis. The latter analysis is known as make-or-buy analysis.

Pricing Strategies

There are several ways to arrive at a price or charge for a test, which range in complexity from using the price charged by neighboring hospitals or commercial laboratories to elaborate computerized systems. The most widely used method is comparison pricing, using rates from competing HCOs in the community. Price or rate setting is not often considered until hospital or corporate management asks for additional revenue from the laboratory. Frequently, increasing the price or charge still may not generate sufficient revenue; therefore, hospital or corporate fiscal managers may take the initiative to raise prices or charges on certain high-volume tests higher than the competitor's price or charge, regardless of how inaccurately the test prices

or charges reflect the laboratory's actual cost. Very often, the laboratory manager and director are never advised of this action. All too often, there is so little communication by corporate decision makers that laboratory managers do not ever know what is charged for their tests and services.

The comparison pricing approach is not recommended but is widely used. However, the only truly accurate comparison pricing method to set prices or charges is to measure actual direct and indirect costs incurred in test performance, using the microcosting approach discussed in the Cost Accounting section and in Appendix A. However, pricing tests does not simply consist of the mechanical task of adding up costs and tacking on a percentage that represents the desired profit margin. Price setting is one of the most difficult fields of business because the manager's intuition, ability to understand the marketplace, reimbursement regulations, legal and government regulations (such as the Robinson-Patman Act), and awareness of the competition's prices (in the case of commercial laboratories) are all parts of the process.

It is interesting to note that many laboratories do not have a problem with pricing tests. This is especially true for commercial laboratories. If a market price exists, customers will usually not pay more than this price, and there is a little reason for the test to be sold at a lower price. This is especially true for small laboratories that must compete in an industry in which one or a few large companies exercise price leadership. In this case, the laboratory makes no pricing calculations; it simply charges the market price.

There are situations, however, in which ethics must prevail. In some laboratories that offer the market price or lower than the market price, there is always the chance that management may decide to cut corners on the quality of service to obtain more business. Examples of “corner cutting” include failure to spend adequate time screening cytology slides (laboratory costs are the highest costs for any test) or similar activities that might reduce the quality of a test result. Making the decision to charge more for a test is difficult, especially if the costs for labor are higher, but the ethical laboratory manager should be prepared to explain to customers why the added cost will make a difference in the quality of patient care. This subject is not to be taken lightly. Severe federal penalties are assessed by the Department of Justice auditors when instances of price setting to destroy the laboratory's competitors are discovered and corroborated.

The Economic Basis for Setting Prices or Charges

The description of pricing in standard economics textbooks is stated in the law of supply and demand, i.e., the demand for a test is determined by how many customers want to buy it. It is only reasonable to assume that the lower the price, the more customers will be attracted to use that laboratory's tests and services. The supply part of the law refers to the test's cost. Similarly, the supply curve reflects the fact that unit costs decrease as test volume increases. This is because the fixed costs of a laboratory are distributed over more tests as test volume increases (examples of fixed costs are given in Fig. 1.19.) Figure 1.22 demonstrates the general rule that the most commonly used way to arrive at the best selling price is to estimate revenue and costs at several possible

selling prices and select the price at which the difference between revenue and costs is the largest (37).

Unit Selling Price	Estimated Quantity Sold	Total Revenue	Fixed Cost	Variable Cost (at $100 per unit)	Total Cost	Profit
$250	500	$125,000	$50,000	$ 50,000	$100,000	$25,000
200	1,000	200,000	50,000	100,000	150,000	50,000*
150	1,500	225,000	50,000	150,000	200,000	25,000
125 *	2,000	250,000	50,000	200,000	250,000	0

FIGURE 1.22. Pricing analysis example. *Preferred alternative. (From Anthony RN, Welsch GA. *Fundamentals of management accounting*. Homewood, IL: Richard D. Irwin, 1974:134–140, with permission.)

The Selling Price

The selling price (or charge or rate) for a test should be high enough to (a) recover direct costs, (b) recover a fair share of all applicable indirect costs, and (c) yield satisfactory profit (for the for-profit corporation) or provide a contribution back to the hospital. Stated another way, profit is for the for-profit organization and efficiency is provided for the not-for-profit organization. This must be understood as a statement of general tendency, rather than a prescription for setting the selling price for each test. There are some situations, however, in which the process works in reverse, i.e., the selling price that must be charged to meet competition is taken as a given; the problem then is to determine how much cost the laboratory can afford to incur if it is to earn a satisfactory profit at the given price. The laboratory manager must then design equipment configurations and methods to “fit” the desired price. If the test cannot be produced at the desired price, then it may have to be discontinued or the calculations should be redone, taking the next higher price point as a given (37).

The Billable Test

Billable tests are defined as those that, when charged to a patient, physician, or another entity, will generate revenues for the laboratory. Repeats performed to achieve a billable test must not be counted, provided that the original test was counted. Typically, billable test records can be obtained through many sources; the source chosen will vary based on the accuracy of the data in a given institution. Potential data sources include (a) actual manual test counts, (b) instrument meter readings, (c) computerized workload summaries, (d) laboratory accounting system summaries, health insurance information, insurance registers, and (e) hospital billing system summaries derived from encounter forms.

Whichever method is used, an audit should be performed before or during the data collection to ensure the accuracy of the information being compiled. Since 1998, severe penalties have been imposed by the federal government for false claims for Medicare reimbursement, even though fraud could not be proved.

Methods for Computation of Prices or Charges

Price-setting procedures are difficult and there are many methods for price setting, which vary in complexity. The manager should always consult a qualified attorney who is familiar with laboratory regulations and billing requirements before setting prices for tests. The techniques noted below, which are beyond the scope of this chapter, are discussed in other textbooks (27,33,35,37). The method recommended in this chapter is full cost pricing because it includes all resources expended for a test and is traceable back to the actual base cost of production of a specific test or service, in the event of an audit. Other methods include

1. *Profit maximization*, which relates total revenue to total cost; the objective of this method is to obtain a price that contributes the largest amount to profit.
2. Pricing based on *return of capital employed* is based on a percentage markup on cost.
3. *Conversion cost* pricing attempts to direct the manager's attention to the amount of labor and indirect costs required to produce tests.
4. The *contribution margin* approach to pricing indicates a laboratory's contribution to the recovery of fixed costs and to profit; this method sets the price below full cost (see method 7) but above the variable cost, where the difference between price and variable cost per test is contribution margin.
5. *Standard cost* pricing represents the cost that should be attained in an efficiently operated laboratory at normal capacity.
6. *Direct cost* pricing sets prices at a certain percentage above the direct cost incurred in producing a test; it is used by those who believe that the results of using indirect costs are not sufficiently valid to be useful; they prefer to base pricing decisions on direct costs because these costs can be measured with a high degree of accuracy, using microcosting methods.
7. *Full cost* pricing (total cost method) includes all the resources expended for a test; it is nearly identical to the ICAT discussed above. Appendix A provides worksheets for this technique.
8. *Relative value* pricing assigns a weighting factor to each test, based on the labor effort required to perform the test or procedure; it is lengthy and time-consuming and requires that detailed, up-to-date information is included for all techniques, instruments, and methods; its weakness is the use of average values for each procedure because it is known that some laboratories produce the same test faster and more efficiently than others.

Make-or-Buy Decisions

Laboratory managers have the responsibility to decide where it is most expedient to perform tests—in-house or in another laboratory.

This problem arises particularly in connection with the use of idle equipment, idle space, or idle labor or with not enough equipment, space, or labor to perform tests. Faced with a make-or-buy decision, the manager should (a) consider the quality of the tests offered, (b) compare the cost of buying the test with performing it in-house, (c) determine the medically necessary turnaround time, (d) evaluate consultation and clinician review capabilities, and (e) estimate the problems with the logistics of sample transport.

If the decision is made to send tests to another laboratory, the laboratory's financial manager should prepare a statement that compares the laboratory's cost of performing needed tests with the potential vendor's price. The statement should present the differential costs of the tests as well as a share of existing fixed expenses and a profit figure that compares the costs on a comparable basis. The laboratory's budget should also be revised to indicate the effect of the change once the transfer of tests is made. A worksheet for calculating in-house test costs and pricing to aid make-or-buy decisions can be found in Appendix B.1.

The Break-Even Point

The break-even point is the point at which there is no profit or loss, or, in other words, the point at which total revenues and total expenses are equal and profit is zero. The most useful purpose of break-even analysis in the laboratory is for making decisions on pricing tests. It is calculated by dividing the laboratory's total fixed costs plus desired profit by the difference between revenue per test and variable cost per test.

The general formula for the break-even point is as follows:

$$\text{Break-even point} = \frac{\text{Fixed expenses} + \text{Desired profit}}{\text{Revenues} - \text{Variable expenses}}$$

Using the graphic technique, the break-even point can be plotted with dollars of revenue on the *y* axis and test volume on the *x* axis. The graph is a composite of (a) the revenue in dollars plotted against test volume, (b) total variable expense plotted against test volume, and (c) total fixed expense plotted against test volume (Fig. 1.23). More detailed examples and techniques for determining the break-even point are presented in Gaither and Resinger (33) and Travers (27). Figure 1.23 shows not only the break-even point but, as revenues increase beyond it, it also shows the development of net income (profit). The break-even volume is useful for determining whether a procedure should be performed in-house or sent to a reference facility. If the calculated break-even volume is higher than current volume, it is not economically feasible to perform the test in-house (27,31,35,37).

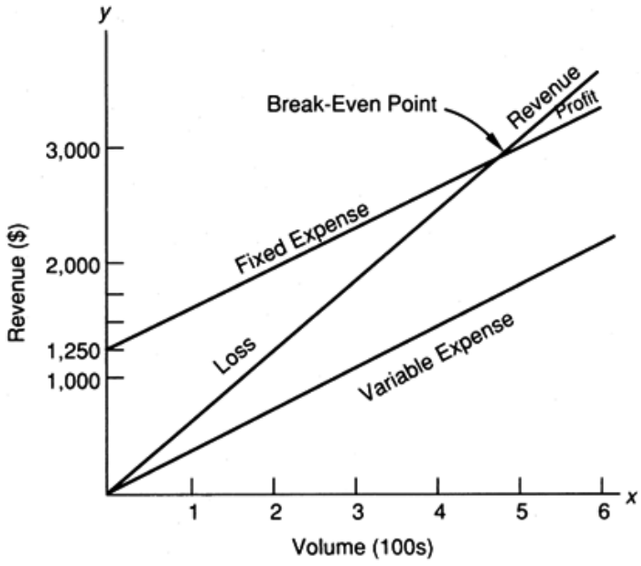

FIGURE 1.23. Break-even chart. (Adapted from Gaither J, Resinger H. *Cost accounting in the laboratory*. Half Day, IL: American Pathology Foundation, 1981:10–14.)

Cost Control and Cost Avoidance

Causes

When all problems and sources of difficulty in managing laboratories have been considered, there are several general conclusions that can be drawn and easily recognized by experienced managers who have long struggled with the dynamics of workload and budget. These basic assumptions are (27)

- The supply (output) of tests is directly proportional to clinical demand
- Costs are directly proportional to laboratory test output until the maximum point of efficiency is exceeded and compliance with regulatory actions and quality control requires more procedures
- Continuous test-order input, without reduction in output, will escalate costs

As previously noted (in the Strategies, Problems, and Principal Areas of Laboratory Expenditure section), there are three basic areas that need correction before any improvement can be made in reducing or avoiding costs. There are (a) lack of information about clinical user needs, (b) lack of physician/provider education in the use of diagnostic procedures, and (c) increasing workload, quality control, inspection, compliance, and accreditation requirements. Problems with uncontrolled costs in laboratories arises first from the inefficient use of automated equipment, primarily from the acquisition and operation of too many high cost analyzers in the automated sections of the laboratory. It is critical to perform a workflow and configuration analysis to determine the actual need for each analyzer, based on the input (workload demand) from clinical services (38). The problems with operating too much automated equipment are (a) it generates too many labor costs, (b) optimum discounts are not always available unless test volume per instrument is very large, (c) it causes a requirement for additional quality control, standards and maintenance, and (d) it is usually not used to full capacity in noncommercial settings (39). Furthermore, if excessive or additional equipment is operated when staffing is less than optimal, the staff will be overstressed, will exceed its point of maximum efficiency, may produce errors, and will increase expenditures by using more reagents and supplies to keep up with the unchecked demand (Fig. 1.24).

SOLUTIONS

Finding solutions to the combined clinical-laboratory problems noted above is not an easy task. In the preceding section, only a few of the most significant problems were outlined. In fact, there is little evidence that clinicians have made any attempt to alter their test-ordering behavior. Even restrictive reimbursement policies have not succeeded in reducing the annual volume of laboratory tests. The only way to begin to reduce unnecessary demand is for the laboratory physician and clinical scientists to take the lead in promoting test use appropriateness in the health care environment.

Test Appropriateness Education

In 1990, the JCAHO encouraged test appropriateness education when it published a standard that provided laboratory physicians with a strong policy to support education of clinical physicians in test appropriateness (40). The standard (PA 1.2.7), part of the pathology and medical laboratory standards in JCAHO's annually published *Accreditation Manual for Hospitals* (40), stated: "Within the hospital's overall assurance program, the director of pathology and medical laboratory services assures that the department/service participates in the monitoring and evaluation of the quality and appropriateness of the services provided."

Furthermore, this standard (now part of a matrix of factors) is a key factor in the decision-making process for accreditation. The standard allows the laboratory director and managers to set up education guidelines, working in conjunction with clinical physicians and other providers for test appropriateness training.

The Pareto Principle (80/20 Rule)

The task of deciding appropriateness for all tests in the laboratory's armamentarium is impossible to accomplish unless a method is used to select the tests and services that are most commonly employed. Therefore, the Pareto principle (the 80/20 rule) can be applied to measure utilization of the most commonly performed tests. The most commonly performed tests account for the major portion of the laboratory's resource expenditure. The application of this concept is discussed in *Cost Accounting Guidelines* published by the National Committee on Clinical Laboratory Standards (32), which describes a method for selecting tests.

Management Control through Interpretive Reporting

Proceeding hand-in-hand with test appropriateness education for clinicians, the laboratory director and managers must always take the lead by providing consultations (where allowed by reimbursement regulations) and by providing interpretive reporting of laboratory test results, especially for abnormal values. There is a great need for proper use guidelines for newer, esoteric tests now ordered in large numbers because of new discoveries in molecular biology and the human genome. Also, written educational information, improved cumulative laboratory reports with narrative statements, and electronic information about proper test use should be available to providers at their workstations. Some areas to begin this exercise are therapeutic drug monitoring for antibiotics, cardiac, pulmonary, and other commonly used therapeutics (40), immunologic tests, DNA probes, thyroid function tests, and other tests as they emerge on the market.

The philosophy is to convince the clinician that when a patient is seen in inpatient practice, the hospital is only prospectively reimbursed at a fixed rate for DRGs, which does not include an equitable rate for laboratory tests. If the tests ordered are excessive or inappropriate, the laboratory spends its valuable resources that could be used for other tests. As of this writing, the outpatient reimbursement for the top 25 laboratory tests has been cut back to 74% of actual cost by the Health Care Financing Administration. The need for interpretive reporting is obvious, to conserve scarce resources and help our clinical colleagues who no longer have the time or learning resources to educate themselves on proper test use.

Management Control Using Optimized Test Groupings

This method allows laboratory management to establish optimized sets of diagnostic criteria that are "customized" for each practice setting. Using the Delphi technique, minimum diagnostic criteria are designed by the hospital's top clinical specialists, agreed on by the physician staff and medical executive board. The laboratory's role is to provide the test selection forms, educate the clinical staff, prove to clinicians that smaller, optimized test groupings for diseases and conditions provide greater quality of care because they avoid "reflex" testing, iatrogenic anemia from multiple phlebotomy episodes, and faster turnaround time. An additional benefit accrues when clinicians are advised which tests are not eligible for reimbursement.

Optimizing Diagnostic Patterns of Care

This method was established in 1985 to advise clinicians on how to set up customized, unique test patterns, based on the standard of medical practice in their own hospital setting (41,42). A similar

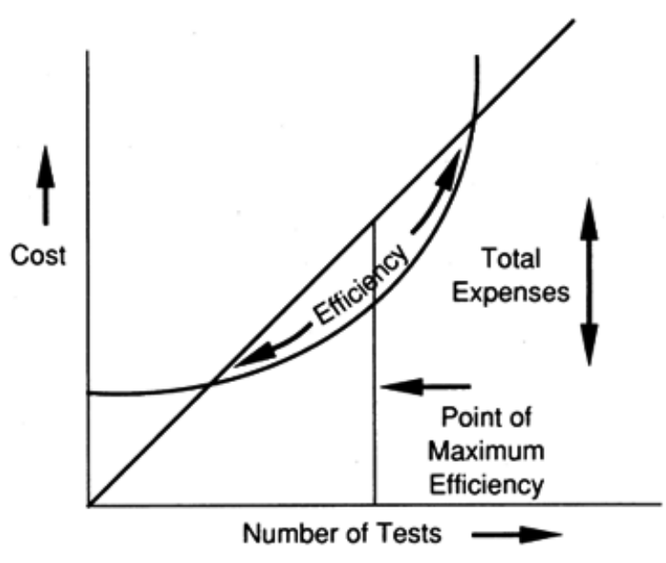

FIGURE 1.24. Effect of exceeding the point of maximum efficiency in the clinical laboratory. (From Craig TM. Dupont Insight. Wilmington, DE: Clinical Diagnostics Division, H.I. Dupont De Nemours Co, Inc., 1983, with permission.)

method, known as “preferred practice patterns” was introduced in 1985 in three Boston hospitals where a group of diseases and operations was studied to identify the lowest cost, highest quality preferred practice patterns. Their approach was to identify the “least resource usage for the same quality output” (43).

Management Control by Clinical Service Leaders

In 1980, Martin et al. (44) emphasized that clinical service leaders have the greatest amount of control and influence over the test-ordering behavior of their house staff in teaching hospitals. This factor helps to reduce unnecessary testing when the laboratory computer system interfaces with clinical service providers to provide them with computerized information about the test menu and frequency and volume of testing by each clinical service and subspecialty. Again, the importance of interpersonal relationship, communication, and networking cannot be emphasized enough in this setting. It is a management control system of great importance for controlling test costs in daily hospital practice.

Deemphasizing the Use of Multitest Profiles

The wasteful practice of multitest profiling, a vestige of past “brainwashing” from the early days of laboratory automation in the 1960s, created a “shotgun” approach to testing because most clinicians believed that it was faster and cheaper to perform large groups of tests simultaneously. It is wasteful because it perpetuates reflex (repeat) testing profiles with larger numbers of tests to verify a previously abnormal test result, causes workload and cost increases, promotes iatrogenic anemia, and gives the false impression that screening for other diseases provides better patient care. In fact, multitest profiling has failed to demonstrate an improved health yield because there is no longer a continuing channel for long-term patient follow-up (44). It is laboratory management's responsibility to make these facts known to clinical providers. Reimbursement for multitest profiles was no longer allowed by Health Care Financing Administration in 1999 for tests listed on the Clinical Laboratory Fee Schedule.

Providing More Efficiency in Automated Areas of the Laboratory

As previously emphasized, the injudicious selection of automated equipment and its inefficient operation causes costs to escalate, especially labor costs, which account for 75% to 85% of all costs. Workflow and optimum configuration studies must be performed before additional equipment is added. Personnel must be utilized more efficiently to perform highly complex, manually oriented tasks, whereas instruments should be chosen to perform high-volume tests at the lowest possible cost per test for tests that are not labor intensive.

Monitoring Laboratory Budgets More Closely

Bulk discounts must be obtained, based on high-volume test needs. Unnecessary testing must be discouraged, and actual and/or activity-based cost analysis must be performed on the high-volume tests that account for 80% of the laboratory's expenditures (see Cost Accounting section). If a test cost is too high and there is insufficient test volume ordered in-house to break even or make a profit, then the test should be sent to another laboratory. Labor scheduling should be seriously looked at, and wasted time must be identified and eliminated. In situations in which part-time staff can be utilized, this option should be exercised to reduce salary costs and provide optimum staffing for the peak periods of workload.

Justifying Capital Equipment Acquisition

The difficulties with availability of capital dollars for investment in laboratory equipment has made it imperative that laboratory managers present a complete, convincing presentation to hospital or corporate managers when requesting additional or replacement equipment.

There are basically four ways to acquire equipment: purchase, rental, lease, or special contractual arrangements with vendors for a cost-per-test fee, in which the equipment is owned by the vendor, who charges a set fee for each test performed.

Regardless of the type of acquisition, the laboratory manager's task is made more complex because of the need to justify the acquisition based on the presentation of cost data to hospital or corporate management, the promise of improved service, and the presentation of data on revenue impact (45). Failure of existing equipment or failure of management strategies to expand the laboratory's market share can further complicate the matter.

WORKFLOW IMPROVEMENT

Part of "1 - Basic Laboratory Management"

It was noted earlier that improving laboratory workflow is the most important goal in acquiring a new analyzer. An instrument should not be selected because of its technology unless the technology has a direct positive impact on improving workflow and use of personnel. The laboratory's workload and test menu must justify additional equipment and the new equipment's throughput must improve turnaround time (27). An analyzer that is forced into an old workflow pattern rarely makes use of all its capabilities. Broader test menus on an instrument are also important because they reduce the total number of pieces of equipment in the laboratory by consolidating workstations, eliminating or reducing batching, replacing existing equipment, and, if possible, reducing staff (10).

COST ANALYSIS

Part of "1 - Basic Laboratory Management"

In addition, before acquisition, a cost analysis should be performed to compare the (i) cost of performing a test (or tests) on the existing equipment with (ii) the cost on the new equipment (see Cost Accounting section). Appendix C provides a worksheet for comparing cost alternatives for the acquisition of laboratory equipment.

METHODS FOR ACQUIRING EQUIPMENT

Part of "1 - Basic Laboratory Management"

Purchase

Purchase of major equipment also requires the performance of complicated analytical techniques to provide hospital or corporate management with information to assess several aspects of financial burden for the hospital or corporation. These include (a) development of depreciable costs, (b) estimation of appropriate depreciation life and timing, (c) isolation of related cash flow variables, (d) forecast of production volume and revenue, and (e) measurement and comparison with hospital corporate criteria. Appendix D provides a guideline for the recommended steps in a capital acquisition process for laboratory equipment. A format for deriving labor management indicators for instrument selection can be found in standard laboratory and business cost management texts (27,30,31,46,47).

If purchase is the desired method of acquisition, then the following key factors should be considered:

- The merits of each capital expenditure
- Future net increases in cash inflows or net savings in cash outflows
- Required total or lifetime investment

Economic or cost-benefit ratios are not the only quantitative considerations to be used in evaluating capital expenditures. The following are also very important:

- The number of patients who benefit
- The degree to which the patients will benefit
- Demographic characteristics of the patients who will benefit
- The benefit to the parent organization for marketing new tests and services

The following factors are also key elements to analyze cost benefits:

- Anticipated time span (years) of project
- Original capital investment
- Annual operating expenses
- Present value of all expenditures
- Average annual savings or net earnings
- Number of patients served
- Age of patients served
- Average cost per patient served
- Intangible short- and long-term health care benefits

Leasing/Rental Arrangements

Many HCOs have entered into leasing or rental arrangements out of necessity, rather than choice. Lease financing has turned into an important source of financing because of the scarcity of capital and the financial squeeze in which many HCOs have found themselves. Leasing, if used properly, can offer advantages. However, financial losses can also occur as a result of not fully understanding the factors involved in a lease arrangement and not properly evaluating the cost of a lease versus other alternatives. The principal advantage of leasing is that it serves as a protection against technological obsolescence and gives the laboratory greater flexibility in the replacement of equipment. With the purchase of equipment, private-sector hospitals will ordinarily be reimbursed only for depreciation and operating costs. Depreciation is calculated on the basis of the original cost of the equipment and may be estimated according to an unrealistic depreciation schedule.

With a lease, the private sector HCO avoids tying up capital. It can use the equipment and (in the private sector) still be reimbursed for the full cost of ownership and the net worth of the equipment is not affected by acquiring the services of the equipment. Federal and state HCOs also avoid the expenditure of capital but will also incur the additional cost for reagents, supplies, and incidentals required for test performance. The vendor also profits by deducting the lease (or rental) costs over time from corporate taxes.

The disadvantages associated with leasing result from the fact that the HCO does not own the asset. Therefore, the residual value at the end of the lease period belongs to the lessor. Second, the failure to correctly estimate the correct technological life of the equipment might result in significant costs.

Cost-per-Test Contracting (Reagent Rental)

This type of acquisition is beneficial in that the vendor provides all reagents, supplies, disposables, automatic data processing, training, installation, maintenance, and all other needs except labor. The HCO or laboratory incurs the burden of labor expense (which encourages the optimal use of the equipment, as well as the more efficient use of labor). The vendor charges a fixed cost per test and provides quality controls, standards, and calibrators. Therefore, it behooves the laboratory to utilize the analyzer judiciously and to perform tests only in the efficient way, avoiding unnecessary tests, repeats, duplicates, wastage, and all other tests that ordinarily would be charged (because they are billed for all reportable results). This arrangement is commonly found in health care networks and multihospital corporations. In 1990, it was established for federal and military hospitals by a contract negotiated with laboratory equipment vendors through the General Services Administration (27).

The advantages of this type of contracting include vendor ownership of equipment, thus avoiding depreciation, maintenance costs, shipping costs, and training costs. Reagents and supplies are provided at the lowest possible cost for the duration of the contract between the HCO and the vendor. An additional advantage for federal and military hospital laboratories is the fixed reagent and supply costs that are negotiated, for instance, for a 5-year contract period.

CONCLUSION

Part of "1 - Basic Laboratory Management"

In summary, before prospective payment and overwhelming reductions in reimbursement of tests and services, the purchase of an analyzer could be justified on the basis of its technology alone. Currently, a good cost-benefit analysis must be performed as well as sensitivity analysis, computations of net present value break-even analysis, internal rate of return, and potential reduction in

variable costs of production. These tools are applied to find the true acquisition costs, as well as lifetime operational costs (45).

Measuring Laboratory Productivity

Managing laboratory costs is impossible without managing laboratory productivity. As the cost of hospital care has increased, the pressure for higher levels of productivity in the provision of services has also increased. One of the interesting aspects of laboratory operations is the potential for substantial improvements in productivity. An increase in productivity will have occurred if (a) the quality of tests provided increases for a given level of technical effort, (b) the quantity of technical effort used to produce a given quality of tests decreases, or (c) given amounts of tests and technical effort remain constant but the quality of tests increases (27,47).

An assessment of laboratory productivity implies that many factors must be included in an analytical process that determines the relative productivity of one laboratory compared with another or to determine total laboratory productivity (Table 1.4). For the purpose of this discussion, the concepts of work units and standard test times, usually thought of as “productivity” standard for laboratories, are considered only as one of several factors required for the total assessment of laboratory productivity. The shortcomings and limitations of using work units or standard times for tests as measures of planning and controlling labor activity are discussed in standard laboratory management references (27,31,32,47). More important, however, is the fact that relative value work units and standard test times by themselves lack the basic ingredients necessary to enhance the improvement of productivity in a managed-care era clinical laboratory (48,49).

TABLE 1.4. TYPES OF PRODUCTIVITY

Major Type	Measures	Subtype	Components	Methods of Measurement	Measurement Tools
Operational	Timeliness of services provided	Labor	Technical staff, clerical staff	Industrial engineering time standards	Task list, list of test times per instrument or method times, analysis sheets, personnel utilization report
	Quality and timeliness of services provided	Automation	Instruments, computers	Maintenance standards, temperature standards	Maintenance checklists, manufacturer's tolerance limits
	Quality and timeliness of agency	Clinical	Test turnaround time, precision, accuracy, reproducibility	Quality control standards	Quality control reagents, reference standards
	Quality of services provided	Workload	Tests, quality control standards	Raw test count, relative value per test	Manual recording, computerized recording
Fiscal	Economic efficiency	Departmental, sectional, inpatient, outpatient	Laboratory work stations, laboratory sections	Cost accounting, cost allocation	Standard costs, operating expenses = actual costs, operating revenues, ratios

From Travers EM. *Managing costs in clinical Laboratories*. New York: McGraw-Hill Information Systems, 1989:204, with permission.

Instead, it is more important as a whole that total laboratory productivity, rather than the workload output of individual technical and clerical workers, must be the center of management's concern.

Types of Laboratory Productivity

There are four types of operational productivity: labor, automation, clinical, and workload productivity, and four types of fiscal productivity: departmental, sectional, inpatient, and outpatient productivity (Table 1.4). Although all are important and must be integrated to achieve successful laboratory operations and financial performance, the most important of all eight types is labor productivity because all other categories of productivity and successful financial outcome depend on the efficient utilization of labor resources.

Labor Productivity

The growing importance of the role of management in improving labor productivity in clinical laboratories is especially pertinent in times of reduced reimbursement and economic constraint. The basic concepts underlying productivity and productivity measurement in businesses are quite clear and simple. However, in a clinical laboratory environment, measuring output in terms of a vast test universe of more than 900 tests and services is not always simple. Laboratory tests are subject to technological changes in methodology, and their performance times vary greatly, depending on the equipment and/or method used to perform the test. Furthermore, the laboratory manager is not always equipped with the knowledge or the time to apply workload measurement criteria precisely. Consequently, a more global approach

is required to assess the laboratory's labor productivity. Appendix E provides a basic checklist/score sheet and a list of solutions for managers to assess their own causes of low labor productivity, as well as solutions for low labor productivity.

The Productivity of Automation

This subtype of productivity is difficult to separate from labor productivity, but it does have distinctly different characteristics that can be improved to enhance the quality and timeliness of services provided and provide more cost-effective utilization of equipment. Unfortunately, automation is often purchased and utilized in this era based on empirical needs, and is not always matched to workload volume or test complexity, which causes under- or over-utilization. Table 1.5 provides suggestions for improving the productivity of automation.

TABLE 1.5. STEPS FOR IMPROVING THE PRODUCTIVITY OF AUTOMATION

Consolidate priority tests.
Multichannel vs. discrete test costs should be determined.
Optimize test groupings (laboratory disease-related groups).
Interact with clinicians to prioritize/consolidate test/disease profiles.
Utilize cost accounting techniques for instruments, sections, and departments.
Utilize automatic data processing to decrease turnaround time- decrease telephone/clerical/billing time.
Improve capital productivity.
Use cost accounting. Determine most/least expensive procedures. Evaluate cost of lease/purchase or rent vs. capital purchase.

From Travers EM. *Managing costs in clinical laboratories*. New York: McGraw Hill Information Systems, 1989:2135 with permission.

Clinical and Workload Productivity

Clinical productivity is synonymous with quality. The importance of producing a product (test) of the highest quality is especially important in view of increasing regulations from private sector accrediting bodies (JCAHO, College of American Pathologists) and federal regulatory action (CLIA '88). A laboratory manager's greatest concern is balancing quality with economic productivity and financial outcome, and there is no room for a trade-off of one or the other. However, there is some concern in today's highly computerized laboratory that there is too much quality control, especially when analyzers have been programmed to recognize errors instantaneously. This can be an additional area of unnecessary expense and, if carefully reviewed, might result in considerable savings without reducing the quality of test results.

The other aspect of clinical productivity is the need to perform more cogent, specific test patterns, as discussed in the Test Appropriateness Education section. Table 1.6 provides recommendations for improving clinical productivity. These recommendations, if implemented, can improve workload productivity by reducing unnecessary testing.

TABLE 1.6. RECOMMENDATIONS FOR IMPROVING CLINICAL PRODUCTIVITY

Develop laboratory disease-related test groups.
Interact with clinical physicians to prioritize and consolidate tests/disease.
Integrate test groups into laboratory's quality assurance plan.
Interact with clinical staff to determine their optimum test choices.
Provide interpretive reporting for clinicians.
Interact with hospital management to demonstrate cost avoidance and encourage administrative decisions that discourage un-necessary testing.

From Travers EM. *Managing costs in clinical laboratories*. New York: McGraw-Hill Information Systems, 1989:213, with permission.

Improving Fiscal Productivity

Improving the economic efficiency of a laboratory can be applied to an entire department, a laboratory section or workstation(s), or to a hospital component to which services are directed, namely, inpatient or outpatient services. The causes of inefficient fiscal operations are most commonly related to salaries that are too high and/or being paid to too many laboratory staff members. Other nonlabor expenses can be inordinately high (Table 1.7)

but should be considered for review after labor costs have been streamlined because labor costs account for 75% to 85% (or more) of total costs.

TABLE 1.7. CAUSES OF HIGH NONLABOR EXPENSES

Waste
Too many dollars spent on research, development, and nonpatient care
Excessive controls, standards, and repeat tests
Nonlaboratory-related expenses charged against laboratory by the hospital or corporation
Too little spent on capital equipment, too much on reagent rental
Poor purchasing practices, poorly negotiated deals
An inconsistent definition of capital equipment (capital vs. noncapital expenses threshold is high)
Excessive inventory and/or poor inventory control
Excessive send-outs or too few send-outs, with no emphasis on true cost analysis
Excessive preventive maintenance
Poor preventive maintenance practices resulting in high equipment failure
Excessive travel and education expenses
Poor monitoring of long-distance telephone costs
Courier services are not cost controlled
Inappropriate use of substitution products (such as in blood bank, the use of more expensive, but clinically equivalent blood products)
Capital equipment not properly sized for the laboratory workload flow
Stat equipment has high reagent cost, yet fast turnaround time is used for routine testing
Excessive accrediting agency fees
Excessive proficiency testing fees
Excessive dues to organizations
Excessive, unnecessary subscriptions
Excessive, unnecessary consulting fees
An unusual laboratory test mix, based on the hospital patient population
Lack of instrument standardization, resulting in excessive repeats
Need for backup instrumentation
Computer paper wastage

a Profit is defined as relative efficiencies of scale (or break-even + adjustment for inflation) for government-operated laboratories and other not-for-profit laboratories; relative efficiencies of scale include cost avoidance and cost savings produced as a result of efficient management of personnel (most costly aspect of operational costs) and operational resources; these "saved" resources are usually recorded by the not-for-profit hospital's finance department and are redistributed by hospital management during the current fiscal year in which they "saved."

b Publicly funded laboratories will not use these categories unless they generate revenue for the hospital by performing tests for other laboratories using "sharing" agreements that specify that a fee will be collected for a service shared between hospitals. Ordinarily, the revenue collected will only cover costs incurred for tests performed for the duration of the sharing agreement.

APPENDICES

APPENDIX A: INSTRUMENT COST ACCOUNTING TECHNIQUE

If one component of laboratory operations can be identified as the controlling influence, it is the instrument configuration of the laboratory. It determines the major portion of costs (labor) for any laboratory and determines actual costs for the next largest component—reagents and supplies. The information and formats in this section provide laboratory managers with a microcosting "bottom-up" method for determining cost per test per instrument. This is the basic starting point in any laboratory cost accounting technique (Fig. 1.A1).

I. TEST INSTRUMENT

Name: GC/MS — Life Expectancy in Years: 5
Model Number: 59708 — Annual Maintenance Cost: 9442
Manufacturer: H-P — Site-Preparation Cost: 2000
Purchase Price: 90000 — Evaluation Period in Days: 1
Starting Date: 9/15/89
Completion Date: 9/15/89

II. DIRECT TEST MATERIALS

Name of Test/Profile	Total No. Tests/Profiles	Per Test/Profile in Evaluation Period: $ Reagents	$ Test-Related Supplies and Parts	$ Equipment-Related Disposables
A	B	C	D	E
1. Benzoylecgonine	30	$27.57	$12.56 (supplies)	$1.89
2.			$9.00 (parts)	
3.				
4. Controls	10	$190.00	included above	.63
5. calibrators	10	$190.00	" "	.63
6.				
7.				
8.				
9.				
10.				
Totals	30 tests	$407.57	$21.56	$3.15

III. TEST LABOR

Time Segment per Test/Profile	Total FTE Minutes/ Procedure	Annual Salary + Benefits
Preanalytical	21 min.	$33880 + 4404 = $38284
Analytical	180 min.	38284
Postanalytical	120 min.	38284
Totals	321 min. ÷ 15 PRD FACTOR = 3692	

FIGURE 1.A1. Completed ICAT worksheet showing cost accumulation for gas chromatography/mass spectrometry procedure. See Fig. 1A.2 for instructions. (Adapted from Travers EM. *Workbook for managing costs in clinical laboratories*. New York: McGraw-Hill Information Services, 1989:72–73.)

IN THE FIRST PART (I):

1. Enter the trade name of the instrument.
2. Enter the instrument model number, if applicable.
3. Enter the manufacturer's name.
4. Enter the purchase price of the equipment.
5. Enter the anticipated life expectancy of the equipment in years.
6. Enter the annual maintenance cost of the equipment.
7. Enter the site-preparation cost.
8. Enter the evaluation period (in whole days) and the starting date of the evaluation period.

IN THE GRID PORTIONS (II AND III):

9. Enter the name or designation for each test or panel that will be performed on the instrument. If the instrument performs both discrete and batch testing, do this analysis for both modes of operation and duplicate this form if necessary (Part A).
10. Enter the total number of tests or profiles performed on this instrument during the evaluation period (Part B).
11. Based on reagent costs incurred during the evaluation period, enter the reagent cost per test profile (Part C).
12. Based on cost of disposables used during the evaluation period, estimate the test-associated disposable cost per test/profile (Part D).
13. Enter the cost of any other equipment-related disposables per test/profile used during the evaluation period (Part E).
14. Continue with the labor analysis section and enter:
15. *Preanalytical time*—Include *time* to collect specimens from patients and laboratory central receiving. This includes all steps up to the actual testing procedure, such as work-list gathering, start-up, sample cup preparation, and preparation of daily quality controls and standards for this instrument. Phlebotomy or centrifugation is included.
16. *Analytical time*—Include labor to analyze the specimen(s) and to perform all routine procedures up to reporting of results. This includes calculation(s) and checking *but does not include* repeats.
17. *Postanalytical time*—Include labor to manually report results or to enter results into a computer system. This includes sorting, filing, and telephone calls related to the final report(s). Routine, daily maintenance normally performed and shut-down time must also be included.

When all blocks have been completed, provide totals where indicated and proceed to Figure A.9 (Formulas for ICAT).

FIGURE 1.A2. Instructions for completing the ICAT worksheet. (From Travers EM. *Managing costs in clinical laboratories*. New York: McGraw-Hill Information Services, 1989:112, with permission.)

No standard cost accounting format has been developed for use in laboratories, and standard accounting texts are not suitable for most medical applications. The examples in the texts are not pertinent to laboratories and many of the problems are irrelevant. Therefore, the ICAT was developed as a method and in a form that managers can use in any laboratory for any instrument or combination of instruments to calculate the cost of tests or test profiles.

ICAT is based on standard cost accounting techniques and is derived from standard literature and generally accepted accounting principles in the field of accounting. These cover direct labor, materials, and instrument-related costs. Indirect expenses are

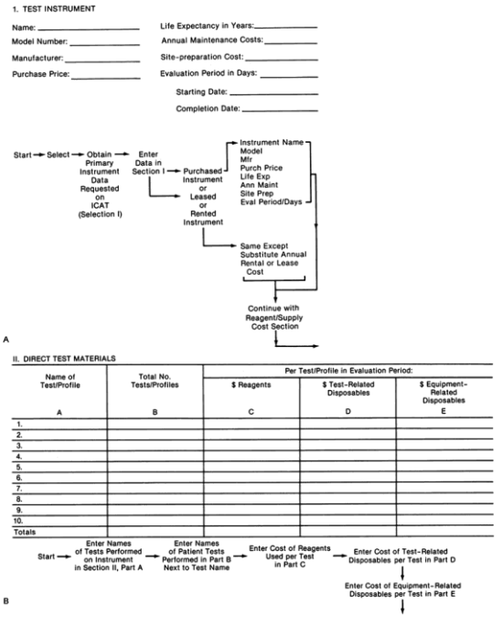

FIGURE 1.A3. Section II. Data entry. **A**, indirect instrument costs; **B**, direct material costs. (Adapted from Travers EM. *Workbook for managing costs in clinical laboratories*. New York: McGraw-Hill Information Services, 1989:52 and Travers EM. *Managing costs in clinical laboratories*. New York: McGraw-Hill Information Services, 1989:126.)

usually estimated in each individual setting and will vary considerably from laboratory to laboratory, based on hospital or laboratory reimbursement. Indirect expenses are discussed in a later section because this important component of total cost is not considered in the overall determination of direct test production costs.

ICAT Format

The ICAT method considers the three prime cost aspects of analysis: (a) instrument-related costs, (b) direct materials cost, and (c) labor costs. No two laboratories are alike in their instrumentation configuration; therefore, ICAT was designed to be generic so that it could be used in each section of any laboratory to profile costs associated with every instrument or test method. Direct material expenses on the ICAT form include expenditures for supplies and reagents required to produce tests. Direct labor costs comprise total compensation required for preanalytic, analytic, and postanalytic personnel necessary to perform tests. By dividing all test production activities into the three major work effort segments, ICAT allows managers to estimate which segment of the test production process has the greatest impact on manpower, and, subsequently, on compensation costs.

Sample ICAT Worksheet

The reader should know that the ICAT method is universal and generic and can be used for any test performed in the laboratory. Regardless of whether an instrument is used, the method will be the same. If no instrument is used, then the section on indirect instrument costs (Section 1 of the ICAT) is left out and the remaining sections are completed. The ICAT worksheet is used to accumulate costs (Fig. 1.A1); instructions for completing each major section of the ICAT appear in Fig. 1.A2.

Examples and algorithms for actual cost analysis for gas chromatography/mass spectrometry are presented in Fig. 1.A3,Fig. 1.A4,Fig. 1.A5,Fig. 1.A6,Fig. 1.A7,Fig. 1.A8,Fig. 1.A9,Fig. 1.A10,Fig. 1.A11,Fig. 1.A12,Fig. 1.A13 and Fig. 1.A14

1. Depreciation costs[a] $= \frac{\$90000}{5\ \text{yrs}} \times \frac{1\ \text{year}}{365\ \text{days/yr}} \times \frac{1\ \text{d.}}{30\ \text{tests/pd.}} = \frac{90000}{54750} = \$1.64/\text{test}$

2. Maintenance costs[b] $= \frac{\$47210}{5\ \text{yrs}} \times \frac{1\ \text{year}}{365} \times \frac{1\ \text{d.}}{30\ \text{tests/pd}} = \frac{47210}{54750} = \$0.86/\text{test}$

3. Site-preparation costs[c] $= \frac{\$2000}{5\ \text{yrs}} \times \frac{1\ \text{year}}{365} \times \frac{1\ \text{d.}}{30\ \text{tests/pd.}} = \frac{2000}{54750} = \$0.04/\text{test}$

Section I: Indirect Costs of Test Production for Test Instrument

Indirect costs are all costs of test production not traceable to a test (unit of output) or to a segment of the equipment or operational requirements for test production. Indirect costs include those of materials, indirect labor, and all other expenses of test production that cannot conveniently be charged directly to laboratory sections, jobs, or products (Fig. 1.A2). They are assigned to the total cost based on a multitude of factors that are part of the hospital or corporate operations. These are commonly added into the cost of tests as a percentage rather than as actual

1. Materials Costs/(Test or Profile) $= \frac{\text{Cost of Reagents + Cost of Test-Associated Supplies \& Parts + Cost of Equipment-Related Disposables}}{\text{\# of Tests or Profiles}}$

$= \frac{407.57 + 21.56 + 3.15}{30 \text{ tests}} = \frac{\$432.28 \text{ run}}{30 \text{ tests}} = \boxed{\$14.40/\text{test}}$

2. Labor Costs/(Test or Profile) $= \frac{\text{Salary Cost*}}{\text{year}} \times \frac{1 \text{ year}}{2080 \text{ hours}} \times \frac{1 \text{ hr}}{60 \text{ min}} \times \text{\# min. per test or run}$

$= \frac{\$38284 \times 1 \text{ yr} \times 1 \text{ hr}}{1 \text{ yr} \times 2080 \text{ hrs} \times 60 \text{ min}} \times 369.2 \text{ min per run} = \$0.31 \times 369.2 = \boxed{\$114.45/\text{run}}$

or $\div 30$ tests $= \boxed{\$3.82/\text{test}}$

3. Instrument Depreciation Costs/(Test or Profile) $= \frac{\text{Instrument Purchase Price}}{\text{Anticipated Instrument Life Expectancy (in years)}} \times \frac{1 \text{ year}}{365 \text{ days}} \times \frac{\text{\# Days in Evaluation Period}}{\text{\# Tests in Evaluation Period}}$

$= \frac{\$90000 \times 1 \text{ yr} \times 1 \text{ day}}{5 \text{ yrs} \times 365 \text{ days } 30 \text{ tests/pd.}} = \frac{\$90000}{54750} = \boxed{\$1.64/\text{test}}$

4. Maintenance Costs/(Test or Profile) $= \frac{\text{Total Cost for Maintenance, Service, and Repairs}}{\text{Anticipated Instrument Life Expectancy (in years)}} \times \frac{1 \text{ year}}{365 \text{ days}} \times \frac{\text{\# Days in Evaluation Period}}{\text{\# Tests in Evaluation Period}}$

$= \frac{\$47210 \times 1 \text{ yr} \times 1 \text{ day}}{5 \text{ yrs} \times 365 \text{ days } 30 \text{ tests/pd.}} = \frac{\$47210}{54750} = \boxed{\$0.86/\text{test}}$

5. Site-Preparation Costs/(Test or Profile) $= \frac{\text{Costs to Install Instrument (Elec., Plumb., A/C, Constr., etc.)}}{\text{Anticipated Instrument Life Expectancy (in years)}} \times \frac{1 \text{ year}}{365 \text{ days}} \times \frac{\text{\# Days in Evaluation Period}}{\text{\# Tests in Evaluation Period}}$

$= \frac{\$2000 \times 1 \text{ yr} \times 1 \text{ day}}{5 \text{ yrs} \times 365 \text{ days } 30 \text{ test/pd.}} = \frac{\$2000}{54750} = \boxed{\$0.04/\text{test}}$

6. Indirect Costs = (Materials + Labor + Instrument Costs) $\times$ 60%†

$= (\$14.40 + 3.82 + 1.64 + .86 + .04) \times .60 = \boxed{\$12.46}$

FIGURE 1.A9. Formulas used for test cost determination for laboratory tests. * Benefits at 13% rate included in salary cost (see Fig. 6); if benefits are not included in salary cost, then a factor must be added to this equation to multiply the results by 1.13 if the benefits are 13%. Percentage will vary in each laboratory/hospital; see Fiscal Services for rates. (Adapted from Travers EM. Managing costs in clinical laboratories. New York: McGraw-Hill, 1989:227-228.)

amounts for each item (see Formula 6, in Fig. 1.A9 and Fig. 1.A10.)

Depreciation, Maintenance, and Site-Preparation Costs Ten entries in part I of the ICAT form (Fig. 1.A1 and Fig. 1.A3) provided the format for indirect instrument-related cost calculations. They include the instrument's name, model number, manufacturer's name, purchase price, life expectancy in years, annual maintenance cost, cost of site preparation, length of the evaluation period in days, and date that the evaluation was started and completed. A cost accumulation worksheet is provided in Fig. 1.A4, which is coded to the formulas that follow. From this information, three different equations are used to calculate each instrument's deprecation, maintenance expenses, and site-preparation costs per test or profile. They are as follows:

$$\text{Depreciation costs} = \frac{\text{purchase \$}}{\text{years life}} \times \frac{\text{1 year}}{365} \times \frac{\text{\# evaluation days}}{\text{\# total tests}}$$

$$\text{Maintenance costs} = \frac{\text{Total maintenance \$}}{\text{years life}} \times \frac{\text{1 year}}{365} \times \frac{\text{\# evaluation days}}{\text{\# total tests}}$$

$$\text{Site-preparation costs} = \frac{\text{site \$}}{\text{years life}} \times \frac{\text{1 year}}{365} \times \frac{\text{\# evaluation days}}{\text{\# total tests}}$$

Section II: Test-Performance Analysis: Direct Materials Costs

It is important to analyze the cost of direct materials used in test production for each test or panel to be performed. If an instrument performs both discrete and batch testing, the analysis should be done on separate ICAT forms as required for both modes of testing. After the name of every test or panel, direct test-performance costs are divided into four segments (Fig. 1.A1, section II; Figure 1A3.B provides a data entry algorithm for direct materials costs):

a. The total number of patient tests or profiles performed during the evaluation period (Fig. 1.A3.B, part IIB)
b. The cost of reagents per test or profile during the evaluation period (Fig. 1.A3.B, part IIC) (use Fig. 1.A5 to accumulate materials costs)
c. The estimated cost of test-associated disposables used per test or profile based on the total cost of disposables used during the evaluation period (Fig. 1.A3B, part IID) (Fig. 1.A5)
d. The cost of any other equipment-related disposables per test or profile used during the evaluation period (Fig. 1.A3B, part IIE) (Fig. 1.A5)

Laboratory activity and consumables to be considered in test-performance analysis include some or all of the following components, depending on whether kits, containerized reagents, or batch or discrete (single) tests are performed: (i) the price per kit or total reagent costs, (ii) the number of tests per kit or total reagent volume, (iii) the number of controls run per test or profile, (iv) the number of standards run per test or profile, (v) single or replicate analysis, as done during each test or profile performance, (vi) the price for expendable items used to perform the test per batch or specimen, (vii) the expense of specimen collection and processing, and (viii) the total number of tests or profiles

= Total cost per test	$33.22	

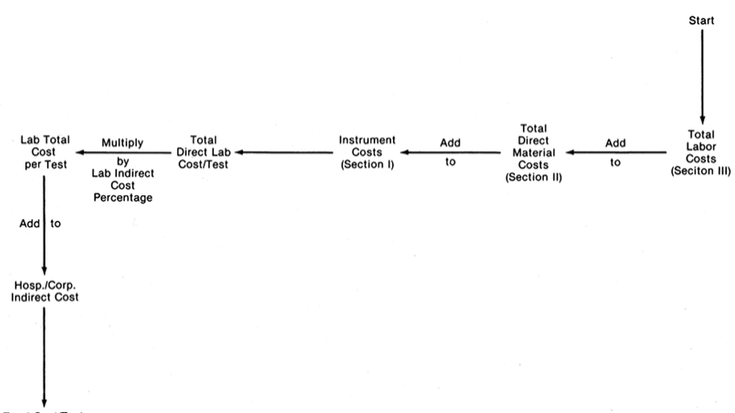

FIGURE 1.A10. Summary sheet-test cost determination. * Exclude all other indirect costs other than instrument-related indirect costs, e.g., rent, insurance, power, heat, lights, taxes, etc.; 11% is only an example since indirect costs are different for each hospital or corporate laboratory; private sector indirect costs may be as high as 146%. (Adapted from Travers EM. *Workbook for managing costs in clinical laboratories*. New York: McGraw-Hill Information Systems, 1989:57.)

FIGURE 1.A11. Section III, part 2: Calculation of direct labor cost and summary sheet. (Adapted from Travers EM. Managing costs in clinical laboratories. New York: McGraw-Hill Information Services, 1989:128.)

performed during the evaluation period. A flow diagram accumulation of test materials cost is shown in Fig. 1.A6.

To calculate direct materials test costs per test or profile, use the following formula:

$$\text{Material costs} = \frac{\begin{array}{c}\$\ \text{reagents} \\ +\ \$\ \text{test-associated disposables} \\ +\ \text{Equipent related disposables}\end{array}}{\#\ \text{of tests or profiles}}$$

Section III: Labor Costs

Labor costs are divided into three labor-intensive segments of test performance: preanalytic, analytic, and postanalytic time. The total full-time equivalent required to produce a test must be measured in minutes using a stopwatch, and the total compensation (annual salary plus cost of benefits) in dollars of the staff person or persons performing the test are entered for each segment. Figure 1.A7 provides a flow diagram for cumulating labor costs. Figure 1.A8 is a labor-time accumulation worksheet that is used to outline specific labor tasks that are divided into the following times:

1. *Preanalytic time* includes the time to gather specimens from laboratory central receiving and time for all the steps up to the actual testing procedure, such as work-list gathering, startup, sample-cup preparation, preparation of daily quality controls, and standard for this instrument. Preanalytic time includes phlebotomy and centrifugation.

	INSTRUMENT NAME	COST/TEST	TEST/YEAR	COST/INSTRUMENT
Chemistry Instrument	1	$		$
	2			
	3			
	4			
	5			
Manual Tests	1			
	2			
	3			
TOTALS:	1. Instrument Costs			
	2. Cost Professional Salaries/ Administrative Salaries			
	3. Cost Blood/Components			N.A.
	4. Cost Transportation/Travel			
	5. Cost Fee Basis			
	6. Cost Operations/Administration			
TOTAL COST Operations/Laboratory/Year for Chemistry				$

FIGURE 1.A12. Worksheet for sectional analysis of chemistry costs based on equipment configuration/manual procedures. This format can be used for all laboratory sections. (Adapted from Travers EM. *Managing costs in clinical laboratories*. New York: McGraw-Hill Information Services, 1989:130.)

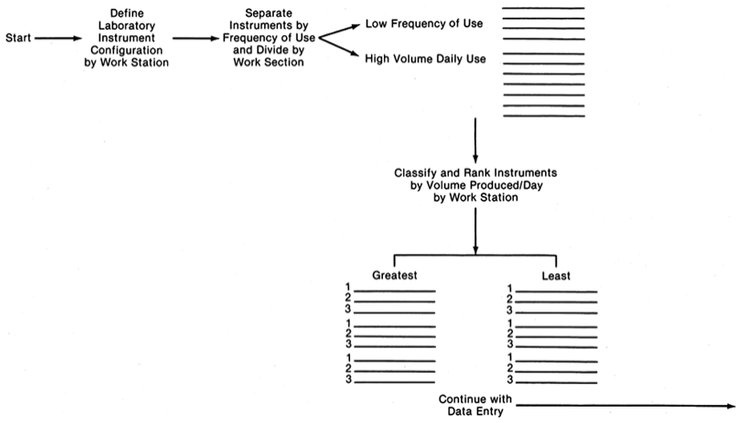

FIGURE 1.A13. Classification of laboratory's configuration by volume. Algorithm for identification of high-volume instruments. (Adapted from Travers EM. Managing costs in clinical laboratories. New York: McGraw-Hill Information Services, 1989:125.)

2. *Analytic time* includes time for the labor effort required to analyze the specimen or specimens and to perform all routine procedures up to reporting of results. It includes calculation(s) and checking but does not include test repeats. Detailed instructions on analytic time-study performance are given.
3. *Postanalytic time* includes time for the labor effort required to report results manually or to enter results into a computer system as well as the sorting, filing, and telephoning related to final reports. Routine, daily maintenance time, and shutdown times are also postanalytic efforts.

After the minutes of time for each task are entered in column D of Fig. 1.A8, they are divided into the categories noted above. The cumulative time for each category (preanalytic, analytic, and postanalytic) is then entered in section III of the ICAT Cost Accumulation Worksheet (Fig. 1.A1).

Formulas Used for Test Cost Determination There are six basic formulas that must be used to calculate material, labor, and indirect costs for test production (Fig. 1.A9). This information accumulated on the ICAT worksheet (see Fig 1.A1) is transferred to each of the formulas that appear in Fig. 1.A9.

When all the formulas have been solved, their totals are entered on the test cost determination summary sheet (Fig. 1.A10) and added to a subtotal. The subtotal is multiplied by the indirect cost percentage for the hospital or corporation to provide a cost per test total (Fig. 1.A11).

Section IV: Synthesis of Test Costs for Laboratory Instruments by Laboratory Section

When the total costs for each instrument-selected analysis in each laboratory section has been calculated, the manager can synthesize costs for all instruments in the section. The format appears in Fig. 1.A12. Laboratory managers should determine which instruments

account for the major workload (Fig. 1.A13) and then proceed to the next phase to perform sectional cost analysis.

The algorithm presented in Fig. 1.A13 allows the manager to apply the 80/20 rule and to select instruments and methods that account for the highest volume (and highest costs) of test production.

Phase V: Sectional Cost Analysis

The generic sectional analysis format is adaptable for all laboratories and includes entries for all major areas of laboratory instrumentation and manual methods. It is assumed that the user will first establish the cost for an instrument's operation using the ICAT and then enter these data into the appropriate category in Fig. 1.A12. A category is also included for entry of manually performed test costs for smaller laboratories that rely on the latter for a significant number of tests.

Once the cost per test for each instrument is established using the ICAT, the laboratory manager must then determine the raw count of tests and profiles per year that have been (or will be) performed on each instrument and multiply this by the cost per test. The final product for each instrument in each section is added together to produce the cost for the equipment configuration of the laboratory.

INSTRUMENT	A	B	C	H	
Example 1: General Function That Varies per Instrument					**Total Chemistry Tests**
Total Billable* Procedures	39,232	65,068	5,052	6,890	116,242
Percent of Total Chemistry Tests	27.9 ×	46.4 ×	3.6 ×	4.9 ×	
Phlebotomy Salaries† for Chemistry	$100,128 =	$100,128 =	$100,128 =	$100,128 =	
Cost of Phlebotomy per Instrument	$ 27,936	$ 46,459	$ 3,605	$ 4,906	
Example 2: General Function That Applies Equally to All Instruments/Sections					**Total Professional Salaries for Chemistry¶**
Pathologist's Salaries (Professional Fees)‡	12,500	12,500	12,500	12,500	50,000

* Test result actually billed to patient. Example: a chemistry profile with 18 determinations counts as one billable procedure, not 18 tests.

† Determined by the following ratio:

1. $\frac{\text{Total Billable Procedures/Chem}}{\text{Total Billable Procedures/Lab}} = \frac{175{,}999}{394{,}000} = .447 = 44.7\%$
2. 44.7% × Total Phlebotomy Salaries/Lab = .447 × $224,000 = $100,128

‡ Pathologist's time in this lab is allocated as follows:

50% Histology/Surgical Pathology	10% Hematology
10% Chemistry	10% Immunology
10% Microbiology	10% Blood Bank

¶ For Chemistry:

a. 10% × Total Prof. Fees/Lab = 10% × $625,000 = $62,500/Chem

b. 62,500/5 (instruments) = $12,500 Prof. Fees/Instrument

FIGURE 1.A14. Allocating costs for general functions among chemistry workstations. (Modified from Sharp JW. A cost accounting system targeted to DRGs. *Med Lab Observer* 1985;17:34–41.)

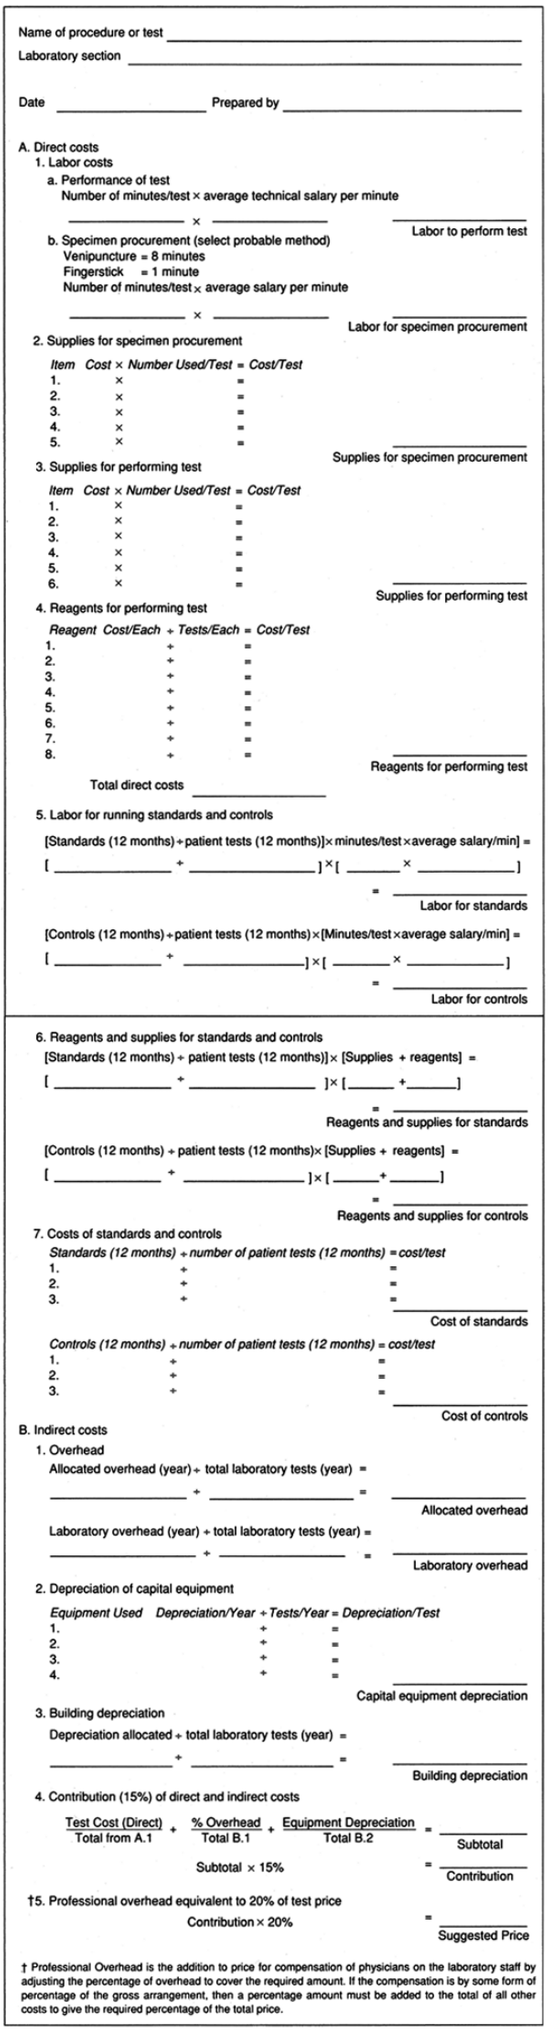
The format can also be used to cumulate other sectional major costs, e.g., professional salaries (professional fees), blood and component costs, transportation costs, fee-bases (send-out) costs, costs for operations, administration, travel, depending on the organizational structure and fiscal control points of the laboratory.

Many cost accounting techniques are concerned only with direct costs for technical and clerical labor and materials for test production, and others use an estimation cost allocation technique for each laboratory section to include nontechnical and professional functions. These functions are not usually assigned to a particular workstation, or even to a section, and they are part of the cost of test production, interpretation, and reporting. This approach is used to distribute the total costs of the laboratory section equally among the total number of workstations. When all costs have been allocated, the total cost of each type of test in the section can be calculated.

Allocating Costs Across Laboratory Sections for All Costs

If physicians, clinical scientists, and technical managerial and general employees such as secretaries and other clerical workers are not specifically assigned to a laboratory section, yet their work helps to produce or interpret tests, then an allocation schedule that spans all departments should be developed. For instance, Sharp uses allocation schedule formulas to assign the costs of nontechnical personnel, profession functions, and other miscellaneous functions to each production center. The formulas may differ for each group or item allocated, and there is no uniform set of allocation formulas that will apply to every laboratory. A good manager should be able to create accurate formulas for each production area and the department based on his or her familiarity with laboratory operations. The only requirement is that the formulas realistically reflect the section's or department's use of that function. For example, allocation of expenses for phlebotomy and for clerical, reception, professional, and other miscellaneous functions allocated to each workstation in chemistry is presented in Fig. 1.A14.

APPENDIX B: PRICE SETTING FORMAT



Name of procedure or test _____

Laboratory section _____

Date _____ Prepared by _____

A. Direct costs

1. Labor costs

a. Performance of test

Number of minutes/test × average technical salary per minute

_____ × _____ = _____ Labor to perform test

b. Specimen procurement (select probable method)

Venipuncture = 8 minutes

Fingerstick = 1 minute

Number of minutes/test × average salary per minute

_____ × _____ = _____ Labor for specimen procurement

2. Supplies for specimen procurement

Item	Cost	×	Number Used/Test	=	Cost/Test
1.		×		=	
2.		×		=	
3.		×		=	
4.		×		=	
5.		×		=	

_____ Supplies for specimen procurement

3. Supplies for performing test

Item	Cost	×	Number Used/Test	=	Cost/Test
1.		×		=	
2.		×		=	
3.		×		=	
4.		×		=	
5.		×		=	
6.		×		=	

_____ Supplies for performing test

4. Reagents for performing test

Reagent	Cost/Each	÷	Tests/Each	=	Cost/Test
1.		÷		=	
2.		÷		=	
3.		÷		=	
4.		÷		=	
5.		÷		=	
6.		÷		=	
7.		÷		=	
8.		÷		=	

_____ Reagents for performing test

Total direct costs _____

5. Labor for running standards and controls

[Standards (12 months) ÷ patient tests (12 months)] × minutes/test × average salary/min] =

[_____ ÷ _____] × [_____ × _____]

= _____ Labor for standards

[Controls (12 months) ÷ patient tests (12 months) × [Minutes/test × average salary/min] =

[_____ ÷ _____] × [_____ × _____]

= _____ Labor for controls

6. Reagents and supplies for standards and controls

[Standards (12 months) ÷ patient tests (12 months)] × [Supplies + reagents] =

[_____ ÷ _____] × [_____ + _____]

= _____ Reagents and supplies for standards

[Controls (12 months) ÷ patient tests (12 months) × [Supplies + reagents] =

[_____ ÷ _____] × [_____ + _____]

= _____ Reagents and supplies for controls

7. Costs of standards and controls

Standards (12 months)	÷	number of patient tests (12 months)	=	cost/test
1.	÷		=	
2.	÷		=	
3.	÷		=	

_____ Cost of standards

Controls (12 months)	÷	number of patient tests (12 months)	=	cost/test
1.	÷		=	
2.	÷		=	
3.	÷		=	

_____ Cost of controls

B. Indirect costs

1. Overhead

Allocated overhead (year) ÷ total laboratory tests (year) =

_____ ÷ _____ = _____ Allocated overhead

Laboratory overhead (year) ÷ total laboratory tests (year) =

_____ ÷ _____ = _____ Laboratory overhead

2. Depreciation of capital equipment

Equipment Used	Depreciation/Year	÷	Tests/Year	=	Depreciation/Test
1.		÷		=	
2.		÷		=	
3.		÷		=	
4.		÷		=	

_____ Capital equipment depreciation

3. Building depreciation

Depreciation allocated ÷ total laboratory tests (year) =

_____ ÷ _____ = _____ Building depreciation

4. Contribution (15%) of direct and indirect costs

$$\frac{\text{Test Cost (Direct)}}{\text{Total from A.1}} + \frac{\%\ \text{Overhead}}{\text{Total B.1}} + \frac{\text{Equipment Depreciation}}{\text{Total B.2}} = \text{Subtotal}$$

Subtotal × 15% = _____ Contribution

†5. Professional overhead equivalent to 20% of test price

Contribution × 20% = _____ Suggested Price

† Professional Overhead is the addition to price for compensation of physicians on the laboratory staff by adjusting the percentage of overhead to cover the required amount. If the compensation is by some form of percentage of the gross arrangement, then a percentage amount must be added to the total of all other costs to give the required percentage of the total price.

FIGURE 1.B1. An example of a format used for single test price setting using the full costing (total cost) method. (Modified from Perryman M. Cost accounting of test procedures. In: Karni KR, Viskochil KR, Amos PA, eds. *Clinical laboratory management*. Boston: Little, Brown, 1982:348–349.)

APPENDIX D: CAPITAL ACQUISITION PROCESS FOR LABORATORY EQUIPMENT

Depreciation Costs

1. Provide generic and trade name of equipment; provide operating description
2. Provide total capital acquisition cost
3. Provide cost of first-year service contract
4. Provide cost of service arrangement included in the total cost, which extends beyond the first year
5. Provide installation cost
6. Provide shipping costs
7. Provide training cost
8. Calculate supply and other costs included in the price of the equipment; which items will be consumed less than the equipment's depreciable life and/or less than the financing term
9. Subtotal items 3–8
10. Calculate value of cash payment discount
11. Subtotal items 9 and 10
12. Calculate the pure capital equipment value (item 11 minus line 2)

Depreciation Life and Timing

13. Assign the equipment's proposed depreciable life
14. Project equipment arrival date
15. Forecast date of equipment acceptance
16. Forecast date of first use of equipment for testing

Related Cash Flow Variables

17. Provide other costs from outside vendors/contractors not included in equipment price
    a. Remodeling costs (outside contractor)
    b. Moving costs (outside contractor)
    c. Other costs (detailed list)
18. Calculate undepreciated value of equipment being replaced on date of first testing use for patient care
19. Provide trade-in value, if any, on the equipment being replaced
20. Calculate the value of departmental depreciation expense recorded for the last time during the year prior to the year of new equipment acquisition
21. Provide manufacturer's payment terms
    a. Amounts to be paid
       1. At signing of purchase order
       2. At time of equipment production
    b. Payments to be financed through internal and/or external sources
       1. At time of delivery
       2. At time of acceptance
    c. Total to be internally/externally financed

Production Volume and Revenues

22. Calculate production forecast data
    a. Test procedures—expected annual average
    b. Relative Value (minutes/test)
    c. Total Relative Values (a × b)
23. Calculate average test market price
24. Forecast gross patient revenue (item 22a × item 23)
25. Determine cost payers
    a. Medicare
    b. Medicaid
    c. Other third-party payers
26. Bad debts and charity expenses
27. Convert production forecast into man-hours

$$\frac{(22b \times 22a)}{60}$$

28. Annualize gross patient revenue per full-time equivalent employee forecast

$$\frac{\text{Actual full-time employee man-hours}}{\text{Annualized FTE man-hours}} = \frac{1500 \text{ man-hours}}{2080 \text{ man-hours}}$$

Raw tests for full-time equivalent employee

$$\frac{\text{Raw tests produced}}{\text{Actual FTE}} = \frac{30{,}000 \text{ tests}}{.72} = 41{,}667 \text{ tests/FTE}$$

29. Calculate hospital planned rate of return (%)
30. Calculate department planned rate of return (%)
31. Calculate net present value
32. Calculate internal rate of return
33. Determine payback period

Financial Profile Summary

Equipment cost	$82,194
Depreciable life	5 years
Date of return	15%
Tests/year	30,000
Total relative values (weighted workload units)	90,000
Average price/test	$10
Estimated cost payer adjustments	
Medicare	25%
Medicaid	5%
Bad debts/charity care	5%
Forecast net income	$59,319
Forecast depreciation/year	$16,439
Annual cash flow (income−depreciation)	$75,758
Net present value	$157,923
Internal rate of return	74%
Payback period	460 days

APPENDIX E: CAUSES OF SOLUTIONS FOR LOW LABOR PRODUCTIVITY

	Condition Present In This Laboratory YES	NO
1. There is inadequate automation.	____	____
2. There is poor skill level.	____	____
3. Consistency of reporting CAP WLUs needs to be assessed.	____	____
4. There is poor work flow caused by poor facility design.	____	____
5. There is poor information flow; computerization is lacking or is a problem.	____	____
6. Infrequently ordered tests are performed in-house	____	____
7. There is inappropriate batching of tests (tests are run seven times per week when three times per week are adequate.	____	____
8. Tests are performed in lab when they should be sent out.	____	____
9. There is inappropriate service level demands by physician staff.	____	____
10. There is a high percentage of stat testing.	____	____
11. There are inappropriate test turnaround time standards.	____	____
12. There are inappropriate quality control programs, resulting in test repeats.	____	____
13. There is excessive machine breakdown, resulting in repeat testing.	____	____
14. There is poor distribution of work between shifts, departments, and benches (could more tests be done during night shift?).	____	____
15. There is excessive paid time off due to staff longevity.	____	____
16. There are dollars spent on medical/technical schools or training programs that are not properly assigned to that function.	____	____
17. There is excessive orientation due to staff turnover or poor hiring practices.	____	____
18. The specialization and generalization of technical staff is not properly balanced.	____	____
19. There is an incorrect assessment of workload units.	____	____
20. There is unnecessary quality conytrolling.	____	____
Note: A predominance of "Yes" answers implies low labor productivity may exist in this laboratory; recommended solutions appear in Table 9–4.	TOTAL SCORE	

FIGURE 1.E1. Self-analysis checklist for causes of low labor productivity. (From American Hospital Association. *Assessing laboratory operations*. Chicago: Clinical Services Division, 1987, with permission.)

TABLE E.1. SOLUTIONS FOR LOW LABOR PRODUCTIVITY

1. Evaluate lab consolidation opportunities.
2. Increase work volume and batch sizes by marketing services.
3. Shift routine work to other shifts.
4. Make sure there is adequate space and design so that work flows smoothly.
5. Investigate flexible vs. fixed staffing
6. Increase automation using low cost/test, nonlabor intensive equipment.
7. Computerize laboratory.
8. Increase personnel expectations and performance with consistent hiring, training, and reward practices.
9. Improve relationships with medical staff, i.e., strengthen pathologist's role in developing appropriate service levels and control inappropriate stat testing orders.
10. Investigate increasing test batching, relax turnaround time requirements.
11. Combine sections and/or consolidate workstations for maximum efficiency.
12. Reduce any duplication of services.
13. Cross-train staff–generalists vs. specialists.
14. Evaluate use of satellite laboratories.
15. Improve preventive maintenance and troubleshooting skills of all staff.
16. Send out infrequently performed tests when staff efficiency remains low.
17. Investigate staff reduction.
18. Motivate staff to give 100% when at work.
19. Evaluate organizational chart and restructure if appropriate, i.e., flatten staffing if too "top heavy" in management personnel.
20. Evaluate appropriateness of research and development time.
21. Improve accuracy of workload.
22. Determine point of maximum efficiency for major automated equipment items.
23. Remove labor-intensive equipment.
24. Avoid highly specialized staff and use cross-trained staff.
25. Determine cost of manual vs. automated tests.
26. Determine "make vs. buy" cost.
27. Avoid too many high-salaried staff.

THE VALUE OF MEDICAL DIAGNOSTIC SPECIALITIES TO PATIENT CARE

Part of "2 - Business Management of the Clinical Laboratory"

Overview

The American health care system may have forgotten, never knew, or never appreciated the value of the clinical diagnostic laboratory to medical diagnosis and treatment. A staggering array of medical diagnostic information is within easy reach of any clinical provider in an era in which the disappearance of the physical examination and other subjective medical decision-making tools signals the importance of quantitation and measurement (1). Medical diagnostic technologies (MDT) are now the method of choice for providers of medical care because they locate and define problems for which a physical examination and history can only provide clues. If an easily available medical diagnostic technology is an alternative, in this generation and the future, it will be used instead of the time-honored but time-consuming, imprecise hands-on traditional bedside diagnostic method. There is now an entire generation of medical care providers who may not be very comfortable with the “bedside” part (2).

Specifically, MDT as objective, factual tools are used more often by providers than subjective, judgmental medical decision-making tools to confirm clinical impressions and establish definitive diagnoses (Fig. 2.1). Combined with the positive attributes of accuracy and speed in providing diagnostic information, their unchecked, repetitive use is known to increase health care costs through complex and interrelated technical, social, ethical, and legal mechanisms (3,4).

In addition, several interacting cultural changes in the practice of medicine in the United States have propelled the medical diagnostic laboratory to a prominent, cutting-edge role never dreamed of before automation was introduced and forever changed the way that physicians make medical diagnostic decisions. These interacting forces are ambulatory and preventive care, primary care, and the provider's reliance on objective data versus subjective impressions to make medical decisions more rapidly. The relationship of each factor to the emergence of the clinical diagnostic laboratory and the provider of medical care is discussed in the sections that follow.

Ambulatory and Preventive Care Causes Greater Need for Tests

In the late 1990s, providers of medical care in American health care organizations (HCOs), highly dependent on medical diagnostic tests, found it necessary to shift the focus of their practices from centralized inpatient to decentralized ambulatory care (outpatient) operations. This was done primarily to satisfy the need of third-party payers to reduce high insurance risks caused by costly inpatient care. Payers also created a dilemma for managers of medical diagnostic support specialties, forced to follow providers and decentralize test performance and/or provide test results and services for providers in near-patient settings to improve the efficiency of the delivery of patient care.

Providing diagnostic services for smaller, sicker inpatient populations in large, centralized HCOs with fixed, complex, and costly medical diagnostic laboratories caused higher operating costs and logistical nightmares. More technical staff was needed to perform tests at the site of patient care. Workload doubled in centralized sites because of the need to analyze both inpatient and outpatient specimens, and new federal legislation introduced in 1997 (Balanced Budget Act of 1997) created a mandate for increased preventive testing for common chronic diseases of the elderly.

Primary Care Emphasis

In addition, the deemphasis of medical specialist and subspecialist intervention in patient care requiring primary care physicians to approve and supervise a patient's care added new meaning to the use of medical diagnostic tests. Primary care physicians in outpatient care settings needed more tests on a repetitive basis to assure good care for outpatients who were not authorized to receive care from a specialist.

The value of the clinical diagnostic laboratory also increased because the Balanced Budget Act of 1997 mandated new preventive tests for the most common diseases found in the elderly population such as diabetes, prostate cancer, and breast cancer.

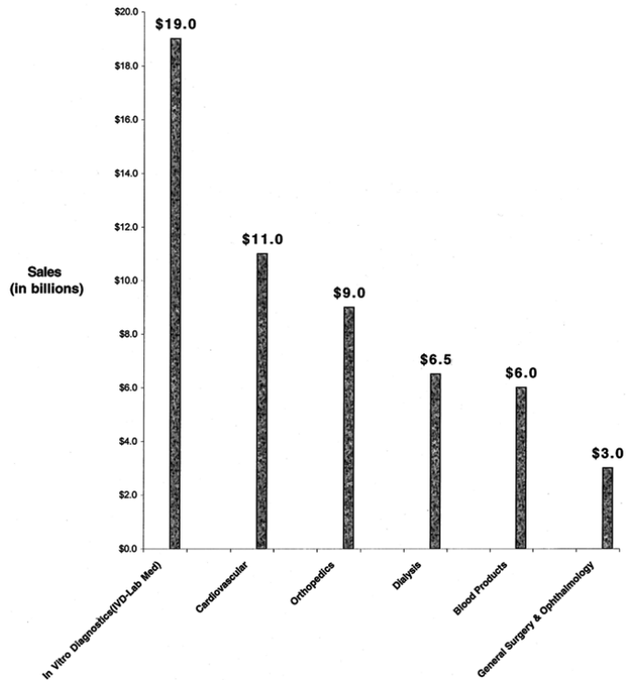

FIGURE 2.1. Medical technology sales by segment: 1998. Laboratory Medicine and other clinical segments that use In-Vitro Diagnostics (IVD) constituted the largest volume of medical technology sales in 1998. Data source: U.S. Bancorp Piper Jaffray Research, Minneapolis, Minnesota.

Provider's Reliance on Objective Data (Technologies) Versus Clinical Findings

It is expected that providers seeing patients in any health care setting must increase their efficiency and productivity. The average time allowed for managed-care providers to evaluate, diagnose, and write up prescriptions and medical records is 20 minutes or less. In many cases, it is not wise or feasible for providers to wait for medical diagnostic test results to be delivered from distant sites, and medical decisions have to be made promptly with simple but reliable point-of-care testing techniques.

It is this reliance on objective and accurate data that makes a provider opt for faster and more complete diagnostic test menus that deliver results promptly to the point of care.

THE COLLISION OF MEDICAL CULTURE CHANGES AND MDT INNOVATION

Part of "2 - Business Management of the Clinical Laboratory"

The interaction of these cultural shifts in medical care delivery increase the value of the medical diagnostic laboratory in the American health care system at the same time that the introduction of new and dynamic diagnostic technologies through research and development offers great hope for better patient care. However, the simultaneous occurrence and entry speed of both these remarkable circumstances into medical care causes considerable stress for managers of medical diagnostic production facilities faced with the responsibility of adding value and reducing costs for his/her organization.

THE IMPACT OF MDT

Part of "2 - Business Management of the Clinical Laboratory"

Despite the need for and demonstrated value of medical diagnostic tests and services to health improvement (5,6), the altruism of providers who assume that ordering a series of medical diagnostic tests will benefit the patient and the federal government's zeal to provide preventive care for the elderly, the steep operating costs of providing medical diagnostic tests as a necessary step in the medical decision-making process is not always considered by those who order them.

The resultant impact of these forces ends squarely at the point of production of medical diagnostic tests causing increased costs for labor and materials to produce, control quality and increase the speed and availability of medical information to providers. Further, the value of testing to providers and investors within the diagnostic testing industry has grown to phenomenal proportions.

Marketing Dynamics

Within the vast universe of medical technology and services, MDT

- constitute the single, largest market segment within the medical technology industry (7,8) (Fig. 2.1),
- comprise nearly 10% of hospital costs (9) (Table 2.1),
- influence the ordering of other more expensive MDT (e.g., the average cost of a diagnostic laboratory test is $0.03 to $0.05, but the use of its result by providers influences $0.70 to $0.80 of subsequent health care spending) (10,11) (Fig. 2.2),

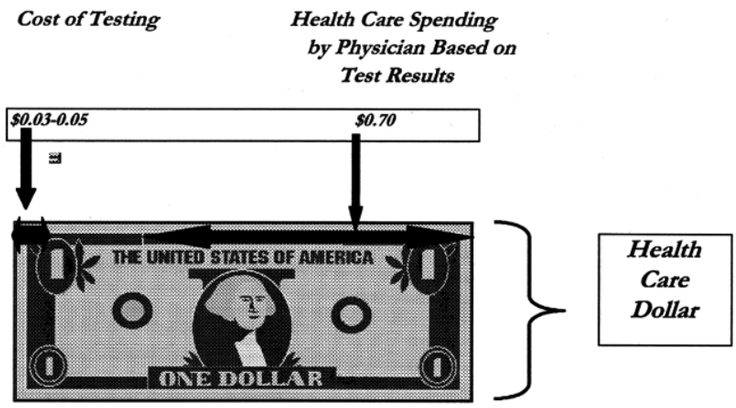

FIGURE 2.2. The impact of a diagnostic laboratory test. Source of Data: Paxton A. Gazing at Tomorrow: CEO Questions, *CAP Today*, 1997:11:25-26.

- are responsible for 80% of patient care data models, based on information developed from interpretation of *in vitro* diagnostics, also known as medical laboratory tests (10).

PRESSURE TO PERFORM MORE SPECIFIC/SENSITIVE MEDICAL DIAGNOSTIC TESTS WITHOUT RECOVERY OF OPERATING COSTS

Part of "2 - Business Management of the Clinical Laboratory"

Urged on by good medical practice and ethics, providers continue to order both existing and newly US Food and Drug Administration (FDA)–approved medical diagnostic tests with greater specificity and sensitivity than existing tests. However, the producer of the test must incur the cost of its production without assurance that costs will be recovered from third-party payers.

Because, in the era of managed care, the directors of insurance and other companies authorized to make payments to HCOs and other providers value greater patient turnaround time and reduced financial risk, the ability of providers to rapidly diagnose and treat patients has become more important in the United States than completeness and continuity of care. To meet this challenge, the research arm of the medical diagnostic industry and other research entities are producing a vast array of new, more specific, and more sensitive products, a costly process when there is no assurance that the research and development costs will be recovered through future sales or reimbursement by third-party payers.

Delayed Reimbursement for New Tests

The reason for this concern about financial losses for tests performed without assured reimbursement is that new medical diagnostic testing products must first be approved by the FDA before they can be used for patient care, a 1- to 2-year process. Other already FDA-approved products must still wait for recognition by the American Medical Association's (AMA) Current Procedural Code (CPT-4) committees, another 1- to 2-year process, before a medical diagnostic laboratory can legally file a claim and bill Medicare or another third-party payer for reimbursement.

The dilemma for managers of medical diagnostic testing laboratories is their inability to inform providers that reimbursement is not authorized for certain tests that do not have approved codes or for tests that have been deleted from the AMA's approved CPT-4 list. Further, changes in the approved codes occur each January, and it takes nearly 2 years for an approved test's code to be printed in the AMA's official CPT-4 Code Book, published on an annual basis (12). Therefore, patient care may be well served because a provider received helpful diagnostic information, but the clinical laboratory manager never recovers operating costs if providers continue to order medical diagnostic tests that have not been assigned an approved procedure code (CPT-4).

PARADOX OF ASTOUNDING TECHNOLOGICAL EXPERTISE (HIGH COST) IN THE ERA OF SYSTEMATIC PRICE CONTROLS BY THIRD-PARTY PAYERS AND MANAGED CARE ORGANIZATIONS

Part of "2 - Business Management of the Clinical Laboratory"

Added to the problem of lost operating dollars is the control of reimbursement rates by Medicare, third-party payers, and managed care organizations (MCOs). This problem has escalated to the point of a formal review of Medicare laboratory test payment practices in 2000 by the National Academy of Sciences.

FLEXIBILITY, ADAPTABILITY, AND ALTERNATIVE OPTIONS

Part of "2 - Business Management of the Clinical Laboratory"

In combat, when chaos surrounds even the well-trained and seasoned soldier, the leader must have more than one alternative strategy to survive during the noise and confusion of battle. Leaders of diagnostic laboratories in similar chaotic, confusing periods must be flexible and adaptable and have more than one plan to survive, using the following recommendations.

TABLE 2.1. Distribution of Hospital Costs for Diagnostic versus Therapeutic Medical Technologies

Clinical Diagnostic Costs (Medical Diagnostic Technologies)	% of Total Clinical Costs	% of All Hospital Costs	Clinical Therapeutic Costs (Medical Therapeutic Technologies)	% of Total Clinical Costs	% of All Hospital Costs
Radiology	6.7	3.88	Radiology	2.1	0.12
Nuclear medicine (isotope)	0.3	0.16			
Clinical laboratory	8.7	5.05			
Transfusion medicine (blood bank)	0.3	0.17	Packed red blood cells and whole blood	2.1	0.12
ECG (cardiology)	0.9	0.51			
EEG (neurology)	0.1	0.05			
Endoscopy (internal medicine)	0.02	0.01			
Laparoscopy (ambulatory surgery)			Intravenous therapy	0.26	0.15
			Respiratory therapy	2.5	1.43
			Physical therapy	2.5	1.43
			Occupational therapy	0.6	0.35
			Speech pathology	0.2	0.13
			Renal dialysis	0.3	0.17
			Home dialysis program	0.02	0.01
			Operating room	6.2	3.57
Total diagnostic costs		9.83%	Total therapeutic costs		7.48%

Data source: 1994 Medicare cost reports (Worksheet A).
N = 6,235 hospitals. ECG, electrocardiogram; EEG, electroencephalogram.
From Woolhandler S, Himmelstein D. Costs of care and administration at for profit and other hospitals in the United States. *N Engl J Med* 1997; 336:769, with permission.

"The Mission No Longer Drives the Costs"

The altruistic mission of patient care is no longer in effect, except in a very few privately endowed, wealthy HCOs—institutions that can care for patients without having worries about meeting expenses. In all other HCOs in which medical diagnostic laboratories are a vital and indispensable component of the patient care, the bottom line is what matters.

Reemergence of the Hospital Laboratory as a Competitor

Although the future role of the hospital-based diagnostic laboratory was undefined and tenuous in the early 1990s, it became a major competitor in the diagnostic testing marketplace in the late 1990s. The massive shift from independent to consolidated hospital systems during this era created larger core laboratories within large health care institutions for the purpose of keeping more tests on-site (13). One of the reasons for this significant shift is the expertise of hospital-based professionals and the need to interface on a timely basis with clinical staff who require the expert assistance of laboratory physicians and professionals. A second reason is the steady erosion in the median price that U.S. hospitals pay for tests sent to outside reference laboratories. In 1996, the median price was $28.73, and in 1998, it was $23.19 (13,14). A third reason is the evolutionary change seen with tests introduced in the mid-1990s, formerly deemed esoteric and complex, now becoming routine tests. For example, polymerase chain reaction testing was a cutting-edge procedure and has migrated into the category of routine testing as a result of increasing hospital integration and consolidation.

Further, the percentage of tests sent out by hospitals is decreasing, while the average complexity of each referred test is increasing (as estimated by the relative value units per CPT code). Portugal estimates that 20% to 40% of the referred tests sent to other laboratories by community hospitals could be performed in-house at lower costs (15).

Another factor that should increase the likelihood of more test performance in hospital laboratories in the future is the 1999 proposal by the Health Care Financing Administration (HCFA) to eliminate the practice of global billing to Medicare from free-standing laboratory sites for hospital inpatients. This portends a doubling of billing costs for independent laboratories because they must make arrangements with the hospital to be paid for the technical components of the services performed for hospital inpatients (16).

Integrated Delivery Systems, decentralization and networking

Laboratory directors and managers in both the public and privates sectors need a strategy to continue to confront challenges associated with the need to contain costs and provide greater value. One strategy is to build and manage integrated delivery systems, also known as organized delivery systems. These terms are used to denote systems that are trying to organize to achieve a greater degree of coordinated care. Integration is needed to appropriately coordinate the laboratory's operating units (the end point at which tests and services are delivered). Organization of the network of operating units is necessary to achieve a coordinated continuum of tests and services to a clinical population (17,18). Integrations are further subdivided into clinical and functional integrations. Clinical integration is the degree to which patient care services are coordinated across people, functions, activities, processes, and operating units to maximize the clinical care delivered to patients. Functional integration is the degree to which key support functions and activities, such as financial management, human resources, information systems, strategic planning, and continuous quality improvement, are coordinated across the spectrum of operating units.

The goal is to achieve the greatest possible value for patients (high quality of care) and the organization with lower costs, greater efficiency, and productivity. Although no single organizational structure exists for an integrated/organized delivery system, some key elements are necessary for its development Table 2.2.

TABLE 2.2. KEY ELEMENTS NECESSARY FOR DEVELOPMENT OF AN INTEGRATED DELIVERY SYSTEM (IDS)

An IDS requires these qualities to allow it to be clinically and fiscally responsible for the health of the defined population:

- The organization must be patient centered.
- Physicians and nonphysician providers who order tests and service must be directly involved.
- The hub of the IDS needs to be the whole system, not one site.
- Information systems must link each operating site.
- The organization must be able to assess the needs of the population it serves.
- The system must adapt quickly when conditions warrant change.
- The system must be based on a cross-function/cross-service line structure.
- Those affiliated with the system must be multiskilled.
- The organization's focus needs to be on the continuum of care, not in the acute care hospital.
- The system must be able to improve continuously.
- Clinical decision making must be based on the clinical staff's approved evidence-based protocols.
- Incentives and compensation must reward appropriate behavior.

Creative directors and managers often experience barriers to change and reorganization, including:

- lack of understanding of the new health care environment
- lack of understanding of the merits of integration
- fear of losing control after an integration
- continued focus on the central operating unit as most important
- lack of commitment in the operating units to the goals for the integrated delivery system
- loss of geographic concentration of operating units (distance between units precludes good communication and cooperation)
- lack of trained staff
- inability to identify the key elements required to integrate (Table 2.2)
- inadequate information systems
- lack of demographic information on the population served and their specific customer needs

Integrated delivery systems require decentralization and networking to flourish—two difficult tasks for any director or manager who has to face the reluctance of older, inflexible staff members to move a centralized workstation or implement new workstations at distant sites that require daily or more frequent travel. Because the clinical staff treating the patient population in a decentralized or remote site determines the timing and workload type and volume for the laboratory, a prudent director or manager will first assess the needs of the clinical staff before deciding to move an established workstation.

Once a decision is made to integrate and decentralize, the barriers to change noted previously should be reviewed and an education program for the involved staff members should be developed. At the education sessions, the leaders of the organization should be present to explain why it is necessary and how the staff will be affected. The most valuable asset of any director or manager is to realize that some, but not all, of the staff will have a desire to participate in the decision-making and planning process. Those who buy into the plan must be encouraged, supported, and rewarded for their ideas and participation as the integration progresses and after it is implemented.

MERGER AND ACQUISITION SHOCK

Part of "2 - Business Management of the Clinical Laboratory"

Unlike integrations, in which the parent organization remains intact, many laboratory directors and managers have had to face a different set of crises when mergers and acquisitions were effected by their organizations. A merger is a fusion or absorption of one entity into another, usually where one of the entities ends up with less status than before the merger. The less important entity ceases to have an independent existence. An acquisition is the takeover of one entity by another; however, both parties retain their legal existence after the transaction (19).

MANAGEMENT COPING SKILLS

Part of "2 - Business Management of the Clinical Laboratory"

Change is a natural and inevitable part of organizational life. Whether driven to reactions to external market demands or regulations (e.g., managed care, the federal government) or internal desires for continuous improvement in patient care and financial success, change is constant.

Regardless of whatever corporate or legal transaction takes place to integrate, merge, or acquire a HCO, of which the clinical diagnostic laboratory is an integral part, the laboratory director and his/her managers must be able to cope with change and continue to lead the staff to assure that patient care does not suffer in the aftermath. In fact, laboratory directors, managers, and even the scientific, medical, and administrative staff are so frequently required to be involved in matters involving integrations, mergers, acquisitions, professional and financial survival that it is difficult to realize that they are still the organization's only experts in providing pathology and laboratory services. They need to fill the dual role of versatile and perceptive leaders at the same time they are needed for their intellectual skills and professional knowledge.

Key Concerns for Managing Transitions

Figure 2.3 illustrates a “triangulation” of the conditional states that directors and managers face when the organization's legal status changes. Note that there is an equilibrium and bidirectional flow between the “present state” condition (Step 1) and the “transition state” (Step 2), as well as between the transition state (Step 2) and the “new or desired state” (Step 3). This is in contrast to a static state between the “present state” and the “new or desired state.”

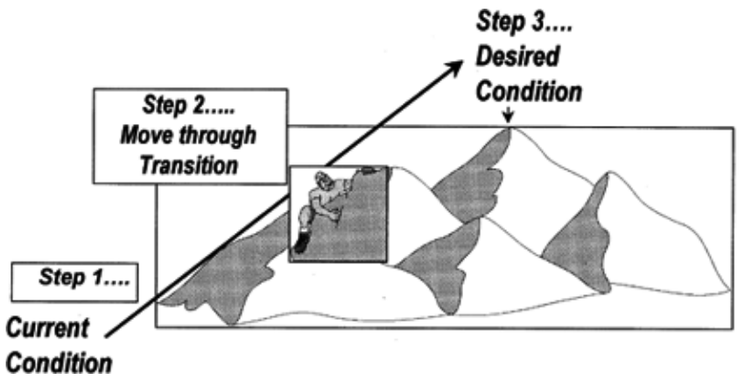

FIGURE 2.3. Key concerns for managing transitions depicted in the diagram are how to assist people effectively in letting go of the present ways of doing things; how to direct and manage people effectively in their movement through the transition period; how to provide the necessary support for people to accept, adopt, and execute new ways of doing tasks. (From Costello SJ, *Managing change in the workplace*. Burr Ridge, IL: Richard D. Irwin, 1994, with permission.)

The key concerns for managing transitions should be focused on the following (20):

- how to assist effectively the staff in letting go of the current ways of doing things
- how to direct and manage people effectively in their movement through the transition period
- how to provide the necessary support for people to accept, adopt, and execute new ways of doing tasks

Technimanagement

Unlike the management culture and environment of the traditional business or commercial organization, the director and managers of the clinical diagnostic laboratory are concerned with mastering the principles of managing human relationships to improve the productivity of a complex scientific/technical/medical organization. The traditional business organization sets its goals as production goals with product(s) produced at a competitive cost and quality. The traditional business manager relies on methods to get others to do what the manager wants (manipulation). Although this concept is now a common goal in the commercial, for-profit laboratory environment, there is a different perception in the noncommercial clinical diagnostic laboratory health care setting. Here, the treatment of illness and other unpredictable

events make the traditional production-process management style unworkable. The major difference between technimanagement and traditional management is primarily one of control. A technidirector or technimanager will see the organization as having a life of its own, with the organization responding to the needs of the individual.

Basically, the increased productivity and efficiency of persons employed in the scientific/technical/medical organization require a major transition from the old to the new, wherein the entire management structure itself undergoes constant and adaptive improvement (21). This is mentally and physically hard work for the director and manager, requiring constant attention to the internal culture and needs of the staff members. Basically, directors and managers need to use a mechanism that works to cope with the fear and anxiety caused by change. The director's or manager's skill is needed to establish the means and environment where each staff member's personal goals are consistent with those of the organization (21). When goals are not consistent, staff will resign, ask for a transfer to a different part of the organization, or make their discontent obvious.

Control of the organization's future success is not gained by controlling every person in the organization. It is gained by allowing the staff who wish to do so the opportunities to express their personal goals, blend them as a team with their co-workers' goals, and apply them as a group that supports and buys into the concept that working together improves value for the patient, offers a secure future for the individual (job security), and allows the organization to be financially successful.

Success in managing the complex scientific/technical/medical organization lies primarily with the director's and manager's understanding of a few basic management principles that generally hold, while recognizing their limitations (21). Management cannot be forced into a formula or equation, and those who try it do not succeed. The reason for this is that people, not products, are center of our success. People are not as simple as machines and procedures—they are totally different from each other, and they change constantly to meet their own internal needs and external threats.

LEGISLATIVE FACTORS

Part of "2 - Business Management of the Clinical Laboratory"

The Balanced Budget Act of 1997

The Balanced Budget Act of 1997 enacted the most significant changes to the Medicare and Medicaid programs since their inception in the 1960s. Many negative implications and operational changes for laboratories resulted from this legislation, including issues of implementing medical necessity, incurring reimbursement decreases, and a proposal for competitive bidding for tests and services provided to Medicare and Medicaid beneficiaries.

While increasing the laboratory's accountability for record keeping and documentation, it also increased the likelihood of major increases in workload by mandating improved screening for the most common diseases found in the U.S. population (e.g., diabetes, cervical cancer, prostate cancer, breast cancer) (Table 2.3). As a direct result of this legislation's implementation, laboratory directors and managers anticipated higher operating

TABLE 2.3. MEDICARE: BUDGET RECONCILIATION ACTION OF THE 105TH CONGRESS

Area Affected	Description	Implementation Date
Medicare-covered preventive services		
Mammography screening	Covered yearly for women age 40+. Part B deductible is waived for this service.	January 1, 1998
Screening pap smear and pelvic examination (including clinical breast examination)	Covered every 3 years. For women at high risk of developing cervical or vaginal cancer, coverage expanded to every year.	January 1, 1998
Prostate screening	For men age 50+, annual test includes one or both of the following: digital rectal examination and prostate-specific antigen blood test.	January 1, 1998
Additional provisions for prostate screening	Secretary of Health & Human Services (HHS) can deem other procedures screening appropriate.	2003
Colorectal screening	Coverage provided for the following procedures; fecal-occult blood test, flexible sigmoidoscopy, colonoscopy for high-risk individuals, and other tests or procedures and modifications to tests and procedures with and at a frequency the Secretary of HHS determines appropriate after consultations with appropriate organizations.	January 1, 1998
Other colorectal screening coverage	Secretary of HHS is required to publish a determination on the coverage of a screening barium enema.	Within 90 days of enactment
Diabetes self-management training	Medicare coverage will include diabetes outpatient self-management educational and training services, but only if physician managing diabetic's condition certifies that services are needed under a comprehensive plan of care to provide the individual with necessary skills to manage his/her condition.	July 1, 1998

This is an overview of some of the changes to Medicare as a result of the 1997 Balanced Budget Act. Listed are the changes that directly affect laboratory workload.

costs to pay for the provider's use of preventive and screening MDT. This is likely because of (a) more intense efforts to establish diagnoses in outpatient, rather than inpatient, settings and (b) more emphasis on preventive health care by Congress. At the same time, HCFA (and private-sector third-party payers) will be paying a much lower percentage of the actual cost for a laboratory to perform these mandated tests (Fig. 2.4).

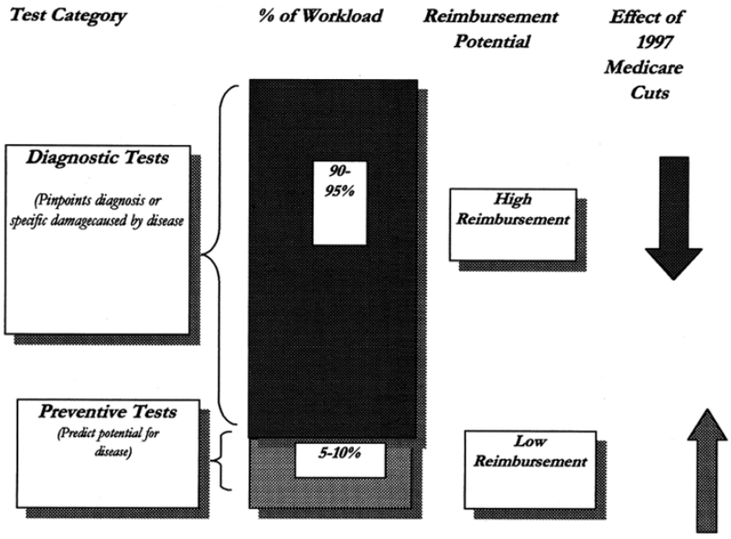

FIGURE 2.4. Potential for Medicare reimbursement for diagnostic versus preventive tests. (This figure provided as a courtesy by Dr. E.M. Travers, Annapolis, Maryland.)

GOVERNMENT'S PUNITIVE INDIFFERENCE

Part of "2 - Business Management of the Clinical Laboratory"

After the Clinical Laboratory Improvement Amendments of 1988 (CLIA ‘88) affected the entire laboratory world in 1993 with its final regulations designed to perform more quality measurement, follow new personnel regulations, and regulate the type of laboratory tests performed in each patient care setting based on complexity levels. Laboratorians reengineered, regrouped, and redesigned their operations—facing certain extinction by loss of licensure if they failed to comply.

Five years later, a massive change occurred in the organizational structure and operation of laboratories within HCOs. Costs and job tasks—not only in response to CLIA ‘88, but to dictatorial policies of MCOs requiring compliance with their contracts—changed radically and added new variable (labor and materials) costs to the cost of each test.

The quality and timeliness of patient care were also affected at the point of care, especially in clinics, group practices, and physicians' offices, where laboratories were closed in response to strict federal CLIA ‘88 and Occupational Safety and Health Administration (OSHA) regulations and the mandates of health management organizations (HMOs) that required laboratory tests and services on their beneficiaries to be sent only to their own contractees—large reference laboratories contracting with the MCO.

These and other burdensome external influences, however, make it difficult for laboratorians to remember that improved patient care was the original reason to provide high-quality, timely test results. These influences included regulatory issues, training, oversight, cost, fraud prevention, and reimbursement.

At the top of the list is the impact of medical necessity legislation, which became effective in 1996.

After the 1993 implementation of CLIA ‘88 and OSHA regulations, the federal HCFA issued instructions to Medicare intermediaries in 1997 intended to reduce government payments for unnecessary laboratory tests. Created by the need to quell fraudulent activities with Medicare reimbursement for laboratory tests on the part of a few commercial and corporate organizations, these necessary but intrusive, costly regulatory measures created a true economic dilemma for hospital and other laboratory administrators.

Fraud prevention is laudable and necessary to avoid misuse of taxpayers' dollars; however, Medical Necessity legislation, instituted in 1996, is causing massive additional administrative and oversight responsibility and increased labor costs for a laboratory's monitoring and verification of the physician's narrative

statement, medical documentation accuracy, and conformance with both the ICD-9 and CPT-4 code books and/or the actual diagnosis codes required before a claim can be made for reimbursement of a diagnostic test or service.

Because reimbursement and capped rates for capitated contracts have already lowered the laboratories' (or parent HCOs) incoming revenue streams, Medical Necessity regulations add more costs with hidden labor and consumables costs for a test or service. The hidden costs are required to account for the valuable time spent by technical personnel and additional administrative/clerical staff who must screen, verify, and act as the final clerical reviewer of the physician's test order (Table 2.4).

TABLE 2.4. MATRIX FOR ESTIMATING THE COST IMPACT OF FEDERAL REGULATORY, COMPLIANCE, INSPECTION, AND SAFETY REQUIREMENTS

	Increased Cost Impact—Requires Additional													
	Labor Effort					Nonlabor								
Federal Requirement	Administration	Supervisory	Technical	Clerical	M.D.	New ADP	New SW	Supplies	Training/Education	Sales	Marketing	Legal	Consult	Potential Revenue Losses
Balanced Budget Act 1997	x			x						x	x	x		Medicare may choose to contract with a competing “center of excellence”
Competitive Bidding														Hospitals lose 10% of HCFA funds by 1999
Medical necessity	x	x	x	x	x	x	x	x	x			x		“No diagnosis, no dollars” “No correct code, no reimbursement”
Operation Restore Trust	x			x	x	x	x	x	x			x	x	Stiff monetary penalties for coding and billing errors
Physicians in Teaching Hospitals (PATH) Audit	x			x	x				x			x	x	Residents not allowed to sign out cases; attending M.D. must sign out and verify
Safety (OSHA & Blood-Borne-Pathology) Inspection/accreditation	x		x	x				x	x					
JCAHO	x	x	x	x				x	x					
CLIA	x	x	x	x				x	x					CLIA failures may close lab/section
CAP/AABB/FDA	x	x	x	x				x	x					
NIDA	x	x	x	x				x	x					
NRC	x	x	x	x				x	x					
States	x	x	x	x				x	x					

This table is provided as a courtesy by Dr. E.M. Travers, Annapolis, Maryland.

With a seemingly punitive and indifferent attitude, the HCFA administrators to date have refused to completely accept the position of clinical laboratories that they should not be held accountable for the medical necessity of tests ordered by providers of medical care who order laboratory diagnostic tests. In fact, HCFA has deemed that the clinical diagnostic laboratory should act as a policing body to assure that providers are accountable for correct medical documentation.

THE COST OF COMPLIANCE

Part of "2 - Business Management of the Clinical Laboratory"

Greed and poor judgment on the part of a few (the need for more power and money) has caused an unstoppable overreaction of the federal government's investigation and compliance arm to find new instances of fraud and abuse. Outside the clinical laboratory world, 10% of the nation's trillion dollar health tab is said to be tainted by fraud or abuse, and prosecutors are following the money trail with highly specific software on computers linked throughout the nation. Computer printouts identify billing anomalies and investigations are born. Sudden popularity of laboratory tests and aberrant increases in the amount of patient billing have all spawned federal inquiries (22).

Since the 1990s, a greedy, unethical few have committed Medicare fraud and abuse to increase federal reimbursement for laboratory tests. Their crimes now incriminate and invoke guilt by association for the entire clinical laboratory profession.

The government has also developed an auditing mandate known as the Physicians in Teaching Hospitals (PATH) program and has placed all teaching hospitals on notice that significant penalties can be avoided when hospitals voluntarily disclose billing discrepancies before the government's actual investigation (22).

Written compliance programs are now nationally required in both public and private HCOs as another control on fraud and abuse, and many HCOs have created new full-time positions for compliance officers to manage their compliance program. A compliance program is a formal regime that methodically identifies reports and resolves billing errors. The structure for government-required compliance programs actually took shape in the 1980s as various defense contractors committed fraud and abuse with Department of Defense moneys.

Now, an independent compliance officer must be put in place when a health care facility receives federal funding through

HCFA (Medicare). This officer must have the authority to report directly to the organization's Board of Directors. With this, the compliance officer must have the freedom to investigate and act on incidents of fraud and abuse (F&A). All employees and contractors may be required to sign a pledge of commitment to avoid F&A. HCFA mandates signatures to assure absolute individual accountability for each person involved in the test ordering, production, and billing process.

Violations and indictments of failure to comply with CLIA, OSHA, and HCFA coding and billing regulations may result in the institution's loss of Medicare reimbursement for a minimum of 5 years. In areas of the United States where 75% to 80% of the patient population treated is in the Medicare age group, risking denial of Medicare funding is a preamble to a HCO's financial failure (22).

Because this additional administrative expense is mandated, the HCO parent organization, which administers the laboratory, or the laboratory which is independently owned and operated, must incur additional operating costs to carry out the mandates. The federal government's joint effort between the Department of Justice, the HCFA, the Office of the Inspector General, and the Federal Bureau of Investigation (FBI) to identify health care fraud and abuse is thriving. As of late 1999, even the FBI has developed a new Health Care Fraud program, and agents are visiting HCOs to review medical records.

Now laboratory and hospital administrators must balance the need for patient care and value with the additional variable costs of compliance and regulation created by CLIA ‘88, OSHA, and Medical Necessity guidelines (Table 2.4).

The decision becomes even more difficult when the cost of providing services increases, and the director or manager must choose between maintaining existing functions or establishing new ones. During the budget cycle, directors and managers must always plan to cover the additional expense for compliance with legislative and regulatory mandates, especially if their organization receives even a small amount of federal Medicare or state Medicaid funding.

BALANCING CARE MANAGEMENT WITH BUSINESS MANAGEMENT

Part of "2 - Business Management of the Clinical Laboratory"

Despite the threats and challenges of the external and internal environments, there must always be a concern for the patient's welfare. Care management has become an important and visible issue in the late 1990s with the advent of legislation in Congress and attempts on the part of the Executive Branch departments and agencies of the federal government to assure patient rights, medical records, and safety. This is a welcome turn of events for the professionals who work in the nation's clinical diagnostic laboratories.

In December 1999, the National Academy of Science's Institute of Medicine issued a seminal report incriminating the nation's health care system as responsible for the deaths of nearly 98,000 patients per year from medical errors and mistakes. Clinical diagnostic tests and services were included in the list of reasons enumerated by the their expert panel (23).

Although there is currently no conceivable way to totally manage the provider's use or interpretation of a test result once it has left the laboratory's sphere of control, there is a way to help protect the patient. The electronic information link between the laboratory and the provider is a major safety factor.

The following sections on managing the clinical interface should be consulted for information on how to balance the need for timely and accurate diagnostic information with the need to maintain direct communication with the patient's provider. This, in fact, is the business link that is critical to both the laboratory's compliance with federal medical documentation regulations (the National Correct Coding Initiative) and the laboratory's entitlement to file a claim if the provider has properly assigned a diagnosis at the time the request (order) for the diagnostic test or service was given.

PROMOTING THE VALUE OF THE LABORATORY

Part of "2 - Business Management of the Clinical Laboratory"

The future survival of any paraclinical health care support service (e.g., laboratory, radiology, nuclear medicine), within or linked to a HCO in the first 10 years of the millennium, depends on how valuable the organization's administration and providers think it is to improve their ability to do their job. Even more important than positive financial margins is the measure of a laboratory's team effort to partner with their clinical and administrative counterparts in the HCO.

The clinical laboratory that installs and supports the programs discussed in the following sections is likely to be viewed as a responsible contributing partner in a HCO.

Each category described is actually in place somewhere in a HCO in some part of the North American continent. Each program has proved its value to increasing the value of the clinical laboratory in the eyes of those who decide whether to keep test production in-house or send it to an outside source.

PATIENT OUTCOME MANAGEMENT

Part of "2 - Business Management of the Clinical Laboratory"

Top-down support from administrators and executive staff of a laboratory organization to encourage better methods for patient outcome management programs is critical to the success of the organization's accreditation, inspection, and reimbursement efforts. With the assimilation of physician practices into provider and health system structures, administrators, directors, and managers need to view physicians as equal partners in charting their organization's course (24).

Even reimbursement is now tied to quality of care initiatives, and clinical physicians are subject to audit in health care venues that receive federal moneys, based on the use of the False Claims Act against entities suspected of providing poor quality care. The audits are conducted by nonmedically trained federal agents who use a standards template to assess whether a problem exists. The central issue is a legal argument. Poor quality care equates to no care provided. If a claim for payment was submitted and paid by a third-party payer to the provider and it was false (no care was provided), the provider should have known this and should not have been paid. The lesson for laboratory directors and managers is that they can also be indirectly involved in a fraudulent claim if they do

not check to verify that a test/service was directly attributed to a real patient with a verifiable disease or condition (25).

This suggests that it is more important that laboratory professionals and managers take a strong, active role to protect not only the patient, but also themselves from incrimination if there is an accusation of failure of quality involving a laboratory result or procedure. Directors and managers can no longer be passive and wait for the clinical staff to initiate an outcome management program. They must make resources available and reward improvement. Accountability is the key element, and the organization's leaders are responsible for initiating ideas and establishing a culture that views measurement and comparison with (preferably) a locally developed gold standard as routine (24).

When the potential exists for a laboratory diagnostic result to be misused or inappropriately used by a provider who has insufficient knowledge of how to use the test(s) result(s), then it is vital that there is an electronic query or other rapid, bidirectional information feedback system between the laboratory and the provider to prevent patient injury.

The following factors summarize the current universal problems that face all HCOs trying to improve patient outcomes:

1. There is too much diagnostic information.
2. There is no universal sorting and matching process in the laboratory that ranks and evaluates the importance (value) of a group of related tests to a patient's expected outcome for a provider making a medical decision, other than the flagging of MDT results to identify critical (life-threatening) abnormals.
3. Patient outcome is improved by ranking, classifying, and interpreting diagnostic data against known clinical findings before it reaches the provider of medical care.

PUBLISHING EVIDENCE-BASED DIAGNOSTIC REASONING PATTERNS FOR PROVIDERS

Part of "2 - Business Management of the Clinical Laboratory"

The Physician's Reasoning Process in Diagnostic Testing: The Role of Logic, Memory, and Intuition

The logic that is used in medical problem solving combines the systems of formal principles of deduction or inference, much like the arguments and concepts of Socrates and Aristotle, with the management of information derived from the patient's database and physician's own information base (1).

Even though the physician is unaware of it, much of his/her logic is not intuitive but is based on syllogisms, strategies, and information that have been programmed into the “silicon chips” of short-term, long-term, and submerged memory. By pressing the correct punch-key in the doctor's brain, the internal logic and natural intelligence of this system are activated; what is displayed on the printout is euphemistically called “medical intuition.”

Data processing in medicine is the method by which a database is transformed into a problem list. It is the important step whereby information gathered about a patient is filtered and clues are selected and grouped into meaningful problem sets. The clustering of clues into meaningful groups is also part of data processing, e.g., symptoms and abnormal physical signs in the same organ system. The cluster of clues that seem to belong together may be stated as a problem, even if there is not enough evidence to make a diagnosis.

The Role of Age and Experience: Clinical Judgment

Studies have shown that an experienced physician forms early hypotheses, tracks a key clue, forms a cluster, spots a triad or tetrad, considers a differential diagnosis right away, pursues only one subset of the database, and rapidly zeroes in on a diagnosis. Younger physicians have many more hypotheses than older physicians and generate more clinical events to prove their hypotheses than older physicians (1).

DIAGNOSTIC PATTERN RECOGNITION OF SIGNIFICANT ABNORMALS AND NORMALS

Part of "2 - Business Management of the Clinical Laboratory"

Similarly, there is a need to provide a clustering or a sorting and matching process in the data management process in the laboratory, ranking and evaluating the importance (value) of a group of related tests to a patient's expected outcome. These diagnostic outcome clusters need to be published in a user-friendly, legally acceptable electronic format that can be easily accessed by the patient's provider as soon as the data are analyzed and interpreted by a laboratory professional.

PUBLISHING EVIDENCE-BASED SENSITIVITY AND SPECIFICITY DATA FOR PROVIDERS

Part of "2 - Business Management of the Clinical Laboratory"

There is a central hypothesis that simplifies the task of integrating the laboratory information base with the clinical user: Providing data-based evidence for clinical providers about the sensitivity and specificity of medical diagnostic tests will improve the quality and speed of patient care by showing the provider which MDT best reflect the patient's disease or condition and/or measure the progress in a course of treatment

Integrating Clinical Findings with Medical Diagnostic Test Significant Abnormals

The value of the clinical laboratory to a HCO is its potential to condense and relate the results of the medical diagnostic tests it produces with data obtained from the physical examination and history.

However, integration of clinical findings from the physical examination and history with laboratory findings has rarely been used owing to the difficulty of accessing the information in the medical record and the failure of direct care providers to enter patient-specific information on laboratory request forms.

Using relational databases to correlate clinical with laboratory findings is now possible because the electronic medical record can be accessed in most modern medical care facilities, if a computerized patient record system with a graphic user interface is installed in the organization's mainframe computer (26).

Data can now be accessed in a format that allows the laboratory professional to view both tentative and final diagnostic conclusions reached by a provider, even before the results of the medical diagnostic tests ordered are completed.

It is critical to the laboratory's operational efficiency to use decision analysis as a major tool for the construction of optimized, effective test groups that correspond to the stages (or intensity) of a disease process.

Impediments to Integrating Clinical and Laboratory Findings

The greatest impediment to providing easily readable, integrated, and interpreted results is the lack of economic incentive to stop using older, outdated laboratory information systems (LIS) that have severely dated characteristics. Simply stated, it is not worth it for software developers to invest millions to write the ideal integrative software when it can only be sold to 100 clinical laboratories rather than 100,000 laboratories.

Medical Necessity and Other Standardized Federal Regulations

Although it may not seem evident, there already is a rules-based standardization process that has had and will continue to have a profound effect on the current and future design of each HCO's and clinical laboratory's information system. This rule-based system is known as *medical necessity* and requires exact compliance with federal regulations to receive Medicare reimbursement.

Redundancy in testing is frowned on by government and other third-party payers, and laboratory managers are now responsible, by federal regulation, for establishing a system of checks and balances that acts as a warning system to identify providers who have ordered redundant tests.

If the clinical laboratory is ready to spend the capital and budget the operating funds to support the installation of a system that will support the information needs to comply with medical necessity, correct coning initiatives and other third-party payer documentation mandates, it must select a system that will grow with the vastly unpredictable information requirements of the third-party payers, both private and public.

Third-party payers are the most important entities in a HCO's financial management structure because they provide the organization with the major portion of its revenue from reimbursement.

User-Friendly Information Systems

Diagnostic test result information databases linked with information management software systems offer clinicians and laboratorians greater ability to manipulate data, interpret results, provide interpretive comments, view graphic displays, analyze trends, and isolate significant abnormals.

The report that is issued must be able to be changed whenever the laboratory's payer's rules and regulations for filing claims for reimbursement change.

DISEASE MANAGEMENT

Part of "2 - Business Management of the Clinical Laboratory"

There are facts that are emerging in the new medical culture that have emerged since federal regulations were loosened to allow professionals, other than physicians trained in the traditional M.D. program, to provide their services for patients: (a) the number of nonphysician providers is increasing and (b) nonphysician providers often do not have adequate training or experience in interpreting medical diagnostic test results.

It follows logically that these facts support a need for a new order in the culture of medicine, to manage more carefully diseases and conditions to avoid misuse and inappropriate use of medical diagnostic tests and prevent patient injury. There is simply too much information for the provider of medical care to have adequate knowledge of how to properly use the nearly 2,000 tests and procedures in the laboratory section of the CPT-4 code book. Laboratory professionals are the logical, trained experts in the specialties and subspecialties of laboratory medicine.

Therefore, there is an emerging role for the laboratory professionals to assure that there is an educational channel or method to provide appropriate education in the use of diagnostic tests and services for all users of the laboratory—regardless of the extent of their training. There is a central, underlying theme that supports this role: Interpretation of significant abnormal and normal medical diagnostic test results before they leave the laboratory will improve the speed and quality of medical care. It is now possible to use an electronic interface between the laboratory and the clinical user (the provider) to make this educational effort successful.

DEFINITION OF “PROVIDER”

Part of "2 - Business Management of the Clinical Laboratory"

The previous paragraph referred to the nonphysician provider as a new and emerging challenge for the laboratory's administration to master and control to avoid potential injury to patients from

providers of all types who misuse or inappropriately use medical diagnostic tests. It is necessary to describe the new order of things, as deemed by reimbursement regulations—not necessarily founded in the same logic.

Table 2.5 describes the federal regulations' broad scope of the definition of provider. The reader should note that there are many variations of providers listed, and they all have variable degrees of education in the fields of laboratory medicine and pathology. The presumption that each provider is capable of making both medically necessary and appropriate decisions when using diagnostic tests and services is not a comfortable thought for experienced professionals in the field of laboratory medicine. Therefore, it is reasonable and ethically correct for laboratory experts in all specialties and subspecialties to provide an assistive and consultative mechanism for all clinical providers in the form of disease management.

WHAT IS NECESSARY TO PERFORM DISEASE MANAGEMENT PROPERLY?

Part of "2 - Business Management of the Clinical Laboratory"

Disease management is a term that emerged during 1990s, the decade of managed care, and denotes that interaction and cooperation are required in a modern medical setting to care for patients with chronic diseases. Further, disease management means that the solo physician is no longer totally responsible for maintaining all the activities of patient care and follow-up him/herself to provide care for a patient with a chronic disease or condition. The team approach is now very common in clinical practice, and physicians, nurses, and specialists of many backgrounds all care for the patient in a continuum.

Although the laboratory professional, both physician and nonphysician, has long been excluded from the hands-on delivery of patient care by some archaic tradition, it is no longer reasonable to exclude the experts who have the correct answers from the continuum of care. The following recommendations are provided for the active, challenged laboratory professional who has no fear of cultural barriers in the clinical sphere and cares about helping their clinical colleagues deliver patient care more effectively.

Interpretation of Significant Abnormals for Nonphysician Providers

Because there is so much variation in the educational preparation of nonphysician providers and because the loosening of the Clinical Laboratory Improvement Act's supervisory rules for monitoring the quality of test performance, this is a new and important area of laboratory professional expertise to be transmitted to those who may not have had sufficient training in laboratory medicine.

Direct Consultation of Laboratory Professionals with Clinician Specialists

For example, in the management of diabetes mellitus, the most critical test that allows the provider to measure the patient's progress is glycohemoglobin, yet providers persist in ordering a wide variety of tests in many areas of clinical chemistry to follow patients. Table 2.6 is an example of a protocol that allows the laboratory professional who is an expert in diabetes test interpretation and management to consult with diabetologists, endocrinologists, and the diabetes treatment team by reviewing a wide spectrum of test results. The objective of the format presented in Table 2.6 is to allow the laboratory professional to teach the provider how to use parsimony and economy in test selection to avoid unnecessary workload and higher costs for the laboratory. This is necessary because many clinical laboratory tests, ordered especially for hospitalized patients, appear to be redundant. Investigators in 1998 found that eliminating redundant tests in just one hospital would have saved nearly $1 million (27).

TABLE 2.6. COST BURDEN FOR DIAGNOSTIC TESTING AND MONITORING OF DIABETES CASES

		Initial Diagnosis			*Diagnosis and Management of Complications and Treatment*								
Clinical Stage		**Detection**	**Confirmation**				**Monitoring of Treatment of Complications**						**Followup**

Provide Information on the Actual Costs of Tests and Services

Most providers authorized to order medical care procedures, tests, and activities do not know about the operating costs of their decision-making process. They have a plethora of information about the technical and safety requirements but do not have instant cost information delivered to them about the actual cost of an operation, procedure, test, new equipment, or medical activity.

Most doctors and caregivers have no idea how to begin to know their costs or the costs of their practice group, whether it is in a hospital, clinic, or office setting. Although articles on cost-effectiveness and sporadic articles focusing on cost-effectiveness (not operational costs) appear regularly in current subspecialty medical and nursing journals, there is no generic, single source for anyone with training and background in health care to quickly grasp the importance of knowing the costs that they incur when caring for a patient.

The national (and international) variation in health care provider activities has become a target for (a) standardizing medical care and (b) denying reimbursement when it does not meet the requirements for reimbursement of third-party payers.

Reduce the Variation in Testing Using Evidence-Based Medicine Protocols

Attempts to reduce test variation have been made using evidence-based medicine. Evidence-based medicine (EBM) is a discipline focused on the avoidance of the use of personal opinion, practical experience, and intuition in the medical care process. Instead, it is a style of medical practice in which the caregiver bases a practice decision on evidence from well-designed studies.

EBM should be used by physicians and other caregivers to provide the best standard of care for each patient.

Manage the Clinical Information Interface

The emergence of the electronic information technology platform has allowed progressive HCOs to thrive, especially with the advent of software that bypasses the manually written requests for tests. Similarly, an electronic return of information to the

or a practitioner who is a Physician	
Nonphysician practitioner (e.g., optometrist, podiatrist)	with a provider number furnished by HCFA or a Managed Care Organization
Nurse (clinician, practitioner, specialist)	
Physician's assistant	
Clinical psychologist	
Clinical social worker	
Medical nutrition support	
Physical occupational therapist	

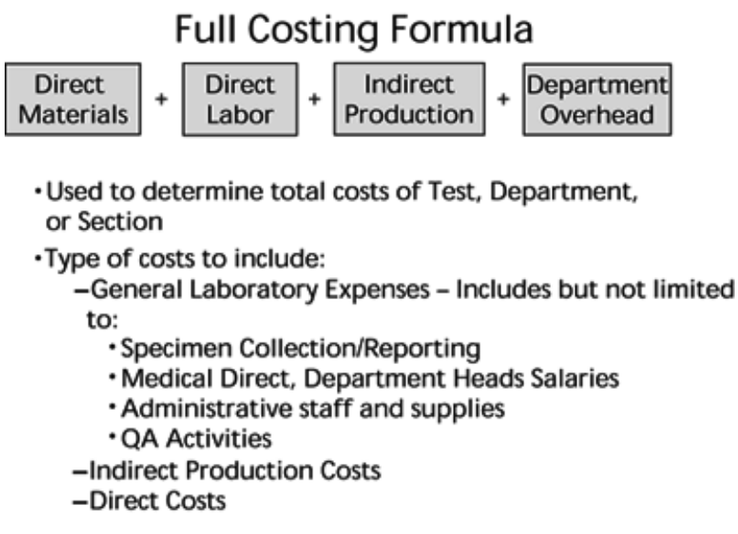

FIGURE 2.5. Full costs, also known as *Total Costs* measure the *actual* direct and indirect costs of providing a service or product.

provider through a bidirectional electronic medical record allows laboratory professionals to interact rapidly in two high-cost, intense areas of hospital practice: transfusion medicine and pharmacy. Hospital spending for operational costs continues to consume the largest portion of the health care dollar (3). In addition to pharmaceuticals, one of the highest categories of operating cost in tertiary care hospitals is for transfusion medicine, blood products or derivatives, and the clinical support services for transfusion, infusion, or therapeutic pheresis of patients (Table 2.1).

More than any other tertiary care setting services, these services consume the major portion of hospital's operating budget and cause the organization and the laboratory more difficulty than most services because their products and services ordered by providers are so expensive to purchase and are often in short supply.

They are also high-risk services and often add to the organization's legal burden for allergic, adverse, transfusion, and other reactions. Prompt, direct consultation by any means, verbal, electronic, or telephone, can save lives and avoid adversity, waste, and inappropriate ordering and dispensing of scarce, expensive products.

LEADERSHIP AND BUSINESS RELATIONSHIPS

Part of "2 - Business Management of the Clinical Laboratory"

Outside the laboratory-clinical interface arena, the four most important management issues for the laboratory director or manager of the 21st century are leadership, communications, politics, and management of human resources.

Leadership

A successful leader recognizes and controls the forces that affect the laboratory and its staff. This begins with reading about, listening to, and participating in new educational ventures that instruct on the external and internal changes, trends, and forces that alter the course of the laboratory's daily mission.

The laboratory's leader should encourage the staff to attend courses and seminars that teach the truth and realities of national and regional health care economics. For instance, to know how to cope with rapid, unexplained change in operations, the laboratory's leaders in operations should be encouraged to attend management courses and workshops at local colleges or at national meetings. The compliance staff should attend educational activities promoted by medical and laboratory professional societies and visiting lecturers; attorneys who are specialists in the regulatory affairs that affect laboratories should be invited to speak to the staff who are most likely to interact with the providers who order tests and services.

Leaders may find themselves reading and seeking out information far beyond the traditional references and journals published for laboratory professionals. The health care administration literature is especially thorough in its coverage of global issues affecting hospitals and other health care delivery sites. Journals in the fields of health affairs and health economics concentrate heavily on reimbursement issues that often affect clinical laboratories.

Communications

The interactive skills we learn before we become laboratory professionals often are inadequate to support us in the later years of our professional activities. This is because laboratory professionals traditionally identify themselves as scientists and/or medical caregivers and not managers or politicians. The personality of scientists is one that favors introversion, focus, and concentration, avoiding confrontation at all costs in the best interests of promoting the pure thought needed to enhance the value of the scientific contribution to be made. The personality of the business leader is one that may not enjoy confrontation and conflict, but he/she recognizes that it is the normal daily activity that occurs in every workplace.

Managers who are scientists as well as leaders must reject their nonconfrontational instincts nurtured in the hallowed scientific halls of their early experiences. Leader managers must be willing to develop a new management persona—one that works as a player on a team and not as an individual striving for recognition of solitary efforts.

Successful managers learn to overcome their inhibitory aspects of their “early” personality, accepting change as a given to succeed in the task of management.

Politics

Also recognizing that all American hospitals are now no different than the traditional business workplace, a laboratory's leader understands the politics of the workplace. Unpopular as the term politics has become in the American vernacular of the 1990s, it usually negatively connotes a person or organization who has chosen a lifestyle/method to gain power and personal recognition by compromising a value system.

To the contrary, one of the definitions of politics is defined as “the art or practice of administering public affairs” (19). A hospital or HCO certainly fits the description of a public entity—as a provider of medical care services to the public. The leader in a public organization is expected to carry out the responsibilities and duties that assure the safety and value of services provided to the public.

Because our country is so successful at preserving life, we are experiencing the heavy, complex clinical workload associated with the aging of America. To deal with the cost of caring for our aging parents and relatives, Congress has appropriated money to be administered through a public system of administration. Because the process of allocating funds is totally connected to politics (as we have just defined), we are captured in the process of administering public affairs.

Because so many of our aging citizens are Medicare and Medicaid dependent, the practice of health care in the United States has become, by definition, a public process. Because the majority of American hospitals (more than two thirds) are currently financially nearly totally dependent on federal Medicare funding to maintain their operations successfully, the administration of the process of receiving the dollars (reimbursement) has also become subject to the laws and regulations required to justly and fairly administer the distribution of the taxpayer's dollars.

Therefore, the laboratory's leaders must recognize that they now work in the political system of the health care arena, regardless of where they practice their profession, and must follow

the law of the land to receive adequate compensation for the services performed by the laboratory's staff.

For these reasons, it is more important to understand both the politics of the health care workplace and the politics of the administration of public funds—even though we may personally despise the unscientific nature of the process.

Ultimately, the laboratory's leaders must become skilled in political maneuvering to

- protect the rights and health of a patient who may be denied tests and services that are justifiably needed,
- form alliances with other laboratory professionals in hospitals, clinics, and distant sites where medical care is delivered to assure that adequate tests and services are provided, even though they may not be fully reimbursed by third-party payers,
- become vocal and vibrant supporters of the laboratory's duty to provide the highest quality of care even though it may be opposed by administrative and nonmedical professional decision makers who control the resources (budget) for the laboratory.

INFORMATION MANAGEMENT

Part of "2 - Business Management of the Clinical Laboratory"

Implementation of a responsive, flexible, bidirectional information system is the first line of defense for any laboratory management team determined to increase the value of the laboratory for patient care, comply with regulations, and reduce its operating costs. It will profoundly affect daily operations, both positively and negatively for many years after its installation.

It will either permit you to improve your quality, clinical effectiveness and outreach, business, and revenue position or result in chaos and frustration for clinical staff, your own staff, and the organization's top management.

A simple structured approach to understanding the most important elements of an effective information system in a modern laboratory, integrated or not, include:

I. Primary (active) database
   Interfacing the clinical laboratory with the electronic medical record
   Database connectivity
II. Secondary (passive) database
   Workload
   Coding
   Provider verification of diagnosis
   Financial
   Billing
   Compliance
   Accreditation
III. Networks
   Intranet
   Internet

TOTAL COST MANAGEMENT

Part of "2 - Business Management of the Clinical Laboratory"

Total cost management in a progressive and successful clinical diagnostic laboratory encompasses much more than finding the actual cost of a test or accumulating costs to prepare an annual budget. Total cost management in the clinical diagnostic laboratory is a comprehensive planning process that:

- anticipates all the expected categories of cost to produce and deliver high-quality medical diagnostic information to its clinical users,
- includes a method to estimate when to stop producing products that are not cost-effective or medically needed,
- includes a method to predict when to start producing more products that can be sold to gain new revenue for the laboratory,
- includes the hidden costs required to professionally certify, accredit, and inspect the laboratory,
- includes the support costs to meet the legislative and regulatory mandates of federal and other third-party payers who require verification of the accuracy of medical documentation and medical necessity,
- provides a flexible framework to meet and cover unanticipated costs caused by emergencies, failures, and other unplanned contingencies without financial deficit,
- supports the business expenses of sales, marketing, and outreach to introduce the laboratory's products to new customers,
- supports the information management, Intranet, Internet, and telemedicine linkages needed to communicate with all clinical users in the network.

Achieving efficiencies and productivity improvement depends on understanding the fully allocated (total, true) per unit cost of delivering the result of a test or service performed in the clinical diagnostic laboratory (Fig. 2.5). If a manager does not have a baseline from which to measure cost, it will also be impossible to determine whether there was gain or loss after delivery of a desired level of production.

To improve productivity in laboratory operations, whether it be at the level of the workstation or at the section, division, or department level, a knowledge of fully allocated costs is needed before a manager can begin to reengineer the work process that produces deliverable, billable information to a provider. Precise and meaningful cost management is critical for determining the effectiveness of both human and fiscal resource use—a prerequisite for effectively managing global risk.

In addition to knowing the full cost of the laboratory's tests and services produced, the director or manager has the responsibility to assure the organization's top management that the margin of revenue gained after the receipt of reimbursement and other revenue streams is greater than the cost of producing all the laboratory's products and services. This is known as gaining a positive contribution margin for not-for-profit organizations and gaining a positive profit margin for for-profit organizations.

MANAGEMENT RESPONSIBILITIES AND CONTRIBUTION/PROFIT MARGIN

Part of "2 - Business Management of the Clinical Laboratory"

In a traditional business, during times of unrestrained resource availability, profit-maximizing decision makers will elect to produce all the products they can as long as their marginal revenue

(MR) (the price or charge) exceeds marginal cost (MC) (MR > MC).

However, in times of limited resource availability such as mandatory decreases in laboratory reimbursement caused by the Balanced Budget Act of 1997 (see Legislative Factors section), both contribution and profit-maximizing decision makers should (and will only) select those tests and services for market expansion that will have the greatest effect on producing a high contribution or profit margin.

High-Cost Areas of the Laboratory

There are two high-cost areas of the laboratory that need to have more attention paid to them to reduce operating costs (expenses)—complex, high-cost, low-volume laboratory medical tests and all the elements that comprise the practice of transfusion medicine.

High-Cost, Low-Volume, Esoteric Tests and Services

A generic example of the difficult decisions that have to be made at all levels and in each section of today's clinical diagnostic laboratory environment is given in the following.

Example

A clinical specialist has asked the laboratory to use a series of very sensitive and specific, but very costly screening tests. The justification is made that regular receipt of the results from these tests will greatly improve patient outcome. There are only a few patients in the laboratory's demographic database who will benefit from these tests. The workload volume generated by the provider's request is also very low. We assume that from what the provider has justified in writing that providing a more sensitive test than what is currently being used will greatly improve the quality of care and the outcome for the small group of affected patients.

Solutions

- Use evidence-based medicine to come to a decision. This is a style of medical practice in which the caregiver bases a practice decision on evidence from well-designed studies. The solution can be provided by the maxim “trust but verify.”
- Use the “substitution rule.” In classical economics, a substitute is a good (product) that can be used to replace another good product, with a positive effect on the attitude of the consumer of the good (28). For example, a laboratory professional's search of the Internet and other databases to find a similar test or group of tests to prove or disprove the clinician's supposition that the requested test is truly more specific needs to be done as part of the management decision process. This is classical economics applied to a practical situation. The laboratory professional is best qualified to perform the search and act as a consultant to the provider to find a product (test) that at least partly satisfies the needs of the provider. The laboratory professional finds the “substitute good that satisfies the needs of the provider, while assuring that the good (test) can be performed with a high level of specificity and sensitivity for the patient's disease/condition at a lower cost than the high-cost test that was requested by the provider.
- Use “make or buy” analysis (next section).

As often happens in clinical practice, the provider ordering the tests does not have the time or on-site resources to use evidence-based medicine, does not have a global view, and operates within a narrow, subjective frame of reference directly related to the provider's experience and the current teachings and literature on the clinical specialty or subspecialty. When individual variation is combined with clinical progress in diagnosis and use of the latest medical technologies, physicians and other caregivers blindly opt for the best standard of care and often ask the clinical diagnostic laboratory to resolve the problem objectively with a specific test or tests.

Because of the trend toward more esoteric testing on-site, as discussed in the introduction to this chapter, directors and managers need to have three additional production control methods in their management tool kit in addition to evidence-based medicine and the substitution rule, tools to know when to start and stop testing (make or buy decisions).

Make-or-Buy Analysis (Break-Even Analysis)

After the decision is made regarding the sensitivity, specificity, and applicability of the test to the patient's disease or condition, laboratory directors and managers have the responsibility to decide when and where it is most expedient to perform tests: in-house (“make”) or in another laboratory (“buy”).

This problem arises particularly in connection with the use of idle or underutilized equipment, idle space, or idle labor or with insufficient equipment, space, or labor to perform tests. Faced with a “make-or-buy” decision, the manager should (a) consider the quality of the tests offered by the outside source of testing, (b) compare the cost of buying the test with performing it in-house, (c) determine the medically necessary turnaround time, (d) evaluate consultation and clinician review capabilities, and (e) estimate the problems with cost and the logistics of sample transport.

If the decision is made to send tests to another laboratory, the laboratory's financial manager should prepare a statement that compares the laboratory's cost of performing needed tests with the potential vendor's price. The statement should present the differential costs of the tests as well as a share of existing fixed expenses

and a profit figure that compares the costs on a comparable basis. The laboratory's budget should also be revised to indicate the effect of the change when the transfer of tests is effected. The following worksheets and decision-making aids can be used to assist in the process of evaluation:

"Make" Decisions: When to Start (or Continue) Testing

Table 2.7 is a checklist for determining whether the capacity exists to add a new (or additional) workload to an existing workstation configuration, section, or department. It is a rough estimate of whether there is sufficient support within the laboratory to add more tests to an existing test menu. Simply stated, the laboratory needs to know what its current workload output is by workstation, section, and department before it can make a decision to add new workload. The "normal" rate of utilization (workload) must be determined for the area where the new test(s) will be added, and if the workload is below normal (excess capacity exists), it may be feasible to add the new test.

TABLE 2.7. CRITERIA FOR DETERMINING IF EXCESS CAPACITY EXISTS IN YOUR LABORATORY TO ADD NEW WORKLOAD FOR REVENUE GENERATION

	Yes	No
• Equipment		
Incomplete (not utilized at capacity) utilization of equipment	____	____
Duplicative equipment items not used to full capacity	____	____
The majority of high volume automated equipment is not labor intensive and has "walk-away" features	____	____
Equipment is highly reliable and supported by excellent repair services	____	____
Equipment is adaptable to adding/deleting from menu for low vol/high cost tests	____	____

Test turnaround time is exceptionally good for the 25 most commonly requested tests	____	____
Bar code and other time-saving techniques are used to access, process, inventory, and report	____	____
• Quality/Accreditation		
The laboratory's quality is consistent and regarded highly in the community, is defensible and has been recognized by accepted accrediting bodies	____	____
• Teaching/Research		
The laboratory offers tertiary-level, highly-specialized tests often needed by teaching/research physicians in university settings or by clinical specialists practicing in the local community (when a university hospital is not nearby)	____	____
Interpretation: A predominance of "Yes" answers indicates that your laboratory has excess capacity to add new workload. Whether you can afford to do it depends on cost analysis (see Chap. 27, Appendix 27A.)		
TOTAL		

Major assumptions must be explicitly defined and evaluated quantitatively for incremental cost assessment as shown in Table 2.1. As an adjunct to this table, information on the incomplete utilization of equipment and labor capacity can be readily determined using objective assessment techniques. This is often true for high-throughput routine sections with automated instruments. The "bottom line" is that to be able to add new workload, these criteria must be used to establish that excess capacity exists in the laboratory. From *Increasing Revenue Using Excess Capacity and Decreasing Costs*, © 1997 by E. M. Travers.

marginal revenue (MR) is greater than marginal costs (MC)

From Leiken A. Lecture notes and handouts. State University of New York, Stony Brook, NY, 1996.

"Buy" Decisions: When to Stop Testing (or When Not to Test)

Table 2.8 illustrates a method used to determine when to cease testing, based on the break-even point method. Even if there is excess capacity, it may not be prudent from a fiscal point of view

to perform the new tests in-house. This is when it is important for the director or manager to know:

- the projected volume of tests that will be needed over time,
- the actual (job order, “true”) direct and indirect production costs of the test,
- the rate of reimbursement (charge, fee, price).

Again, the important relationship between MR and MC is illustrated in this table. The goal of the director or manager is to reach the point where MR > MC.

If MC and the laboratory's indirect (fixed) costs are known and they are completely covered by reimbursement, then the total revenue from the production of the test can be maximized by increasing test production. If the costs to produce the test exceed the reimbursement or other revenue received, then it is not wise to expand test production.

Event Costing

Event costing is the technique used to find the cost of any activity, procedure, test, or event that incurs expenses for the laboratory during its production by the laboratory staff.

Two rules are important for event costing:

- Finding the actual (true) total cost of the activity, procedure, test, or event to be produced is critical. It cannot be estimated (it must be calculated to assure accuracy).
- The full array of costs required for the production of the activity, procedure, test, or event must be included in the calculation.

Event-Costing Worksheet

A worksheet for calculating in-house total test costs (TC) for one activity, procedure, test, or event to aid in making make-or-buy decisions can be found in Table 2.9.

Cost Management in Transfusion Medicine

State-of-the-art transfusion medicine practices in academic health care settings, responsible for developing and implementing complicated, cutting-edge transfusion medicine technologies and treatments, are difficult to support and finance. This is primarily because of escalating acquisition costs for blood products and an increasing volume of the sickest oncology patients referred from primary care sources. A third cause of high costs is the increased use of commercially prepared high-cost biologicals and factors derived from blood plasma used to treat rare diseases or promote precursor cell growth for transplantation or platelet generation. In addition, high operating costs for each of these are augmented if the hospital permits the practice of transfusion/infusion or therapeutic pheresis (T/I/P) in multiple locations within the HCO's physical plant, i.e., decentralized satellite T/I/P sites. The most important principles for the laboratory director and transfusion medicine chief to remember include (29):

- Find the cost to procure + test + T/I/P each blood or blood-derivative product line/service
- Estimate the revenue to be received from each payer for this product line/service
- If the cost exceeds the reimbursement, decide whether the product line should continue to be produced in-house (make) or purchased (buy) from an outside source

UTILIZATION MANAGEMENT

Part of "2 - Business Management of the Clinical Laboratory"

Utilization management is a control process used to alter the rate of use of a service, product, or the process of production. In medical care, the production process is primarily a reaction to the orders given by providers on the clinical side of the organization.

TABLE 2.10. DIFFERENCE IN COMPLEXITY OF TESTING PROCEDURES BETWEEN LABORATORY SECTIONS

	[Cost 1 +	**Cost 2 +**	**Cost 3] = Total cost**

(*Note*: There may be more than one interim result, depending on method.)

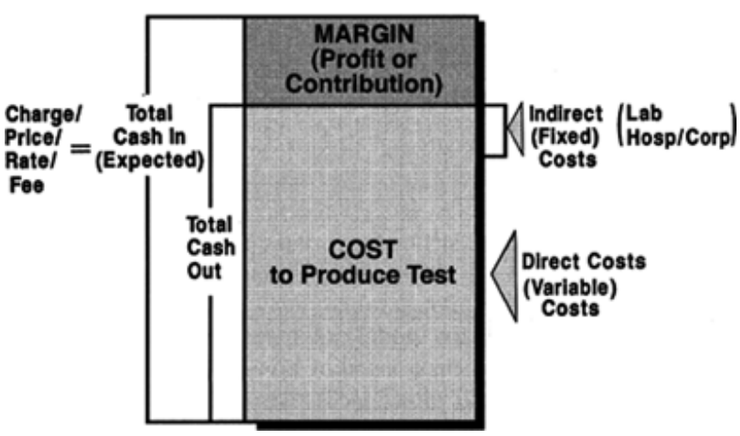

FIGURE 2.6. Normal anatomy of a billable test: the relationship of margin to cost with the anatomy of a billable test, the prime source of revenue/income for a laboratory. The emphasis on the left side of the diagram is placed on the difference between cash in and cash out, showing that cash out is the cost to produce a test. On the right side of the diagram, the cost is composed of two basic parts: direct (variable) and indirect (fixed) costs. Direct costs are controlled by the director/manager and account for nearly 95% of a laboratory's operating expenses.

Often there is no communication between the laboratory and the clinical utilizers (providers), and this usually precludes control of utilization. The facts and hypotheses important to understanding the successful implementation of utilization management include:

1. There is no interpretation of diagnostic information before it reaches the direct care provider.
2. Clinical users of information provided by the laboratory must receive information about their own, unique clinical diagnostic test utilization patterns.
3. Selection of disease-related abnormal and normal medical diagnostic tests and prerelease interpretation reduces utilization.
4. Laboratory professionals must institute an active process of control diagnostic economy over the inappropriate utilization of tests and services if the goal of financial success is important.

Definition of Diagnostic Economy

The definition of the word *economy*, “the efficient and sparing use of the means available for the end proposed” blends nicely with Webster's definitions for the noun/adjective diagnostic. The definitions “a careful, critical study of something to determine its nature or importance” and “the art or acts of identifying a disease from its signs and symptoms” describe the special skill that emerges only after a physician has devoted his/her intellectual and cognitive life during medical training to the accumulation and assimilation of normal and abnormal facts about the function of the human body and its pathologic conditions. Then again, it is not only the training period, but also years of experience using this process that makes the “careful, critical” part of the definition of “diagnostic” meaningful.

Indeed, the two words placed together in sequence are most significant in today's medical economic environment, where the federal government's regulations for reimbursement demand the precise, exact use of descriptive terms to designate diagnoses (ICD) and procedures (CPT), terms to qualify a provider for reimbursement with Medicare or Medicaid moneys (see Coding section).

If the definition of diagnosis means “careful and critical,” then the addition of the word economy to it further enhances the meaning of the phrase *diagnostic economy*. The new meaning becomes “the efficient and critical choice of careful, diagnostic studies that identify a disease to determine its nature or importance.”

Why must we emphasize economy in the diagnostic process? Because previous generations of physicians never had to face the reality of knowing about the costs of the procedures that they needed to establish, confirm, or monitor diseases and conditions. Although it has not entirely been their fault, clinicians have not had the opportunity to learn about test costs. Laboratory professionals in the past rarely took the initiative to present the cost problem to clinicians, because hospitals depended on the income generated from laboratory and other tests. Therefore, a multitude of test results was always passively produced, uncomplainingly, and without question.

Similarly, for-profit hospitals have always emphasized charges—none had to be concerned with actual costs until 1984 when the Tax Equity and Fiscal Reform Amendment produced the paradoxical shift from income-generating revenue centers to cost centers. Market-oriented reformers argue that more care—more tests, more treatment, longer hospital stays—is not necessarily better care.

PRODUCTIVITY MANAGEMENT

Part of "2 - Business Management of the Clinical Laboratory"

It has already been established that to improve productivity in laboratory operations, whether it be at the level of the workstation or at the section, division or department level, a knowledge of fully allocated costs is needed before a manager can begin to reengineer the work process that produces deliverable, billable information to a provider (see Total Cost Management section).

Benchmarking

Benchmarking is the process of setting standards for future performance based on analysis of data and trends from past production processes.

Measuring trends in daily workload and quality control is expected in daily laboratory operations; however, measuring the progress of productivity and efficiency in the laboratory is also needed to improve production and enhance cost management. In quality control, laboratorians use a gold standard, purchased from a manufacturer of laboratory reagents, to assess whether a test result is on the mark, i.e., does the result received come close to what the manufacturer's standard says it should be.

In productivity management, benchmarking is done by the director and manager to measure current production processes and compare them with a gold standard they have established as a goal for future production levels and characteristics. Unlike the reagent manufacturing industry that prepares standards with known values, there is no national benchmarking “manufacturer” to set the goal for what a laboratory's productivity and efficiency (and staffing levels) should be. Therefore, the art of management enters into the process, and the director or manager becomes the leader who sets the goal, the standard, the pace, and the direction in which to head to achieve high-quality patient care and ensure financial equivalency with MR = MC, if not better.

Operational Productivity

All sections and workstations must do more with less to increase operational productivity. This is defined by the equation:

$$\text{Productivity} = \frac{\text{Output}}{\text{Input}} = \frac{\text{Products produced}}{\text{Resources consumed to produce products}}$$

Using the ratio Total Billable Tests/Total Technical Full-Time Equivalents (FTE), to measure productivity shows how technical labor productivity, the laboratory's largest operating expense, is improving or declining. An increase in the number of Billable Tests with the same or fewer Technical FTE is the desired productivity improvement.

Note that the terms billable and technical are italicized for emphasis. It is important to note that the only billable tests and services that can be claimed by the laboratory for reimbursement by third-party payers, even though there are many nonbillable tests, procedures, and activities that have to be “paid” for by the laboratory's budget dollars. Therefore, to increase productivity, it is critical to always produce more billable tests and services than nonbillables.

Departmental “C4” (Consolidation, Constriction, Constraint, Cross-training) and Integration

In 1999, the newly elected president of a major professional laboratory organization summed up the impact of the need to reorganize the way laboratories produce their products in his acceptance speech:

> Pressure to reduce costs will continue to play a major part in how testing is performed. We will respond by consolidating small operations into regional laboratories. Hospital laboratories will either expand testing volume to support appropriate automation or reduce testing menus by outsourcing—to higher volume laboratories—tests that cannot be cost-justified. Such actions will be required to increase efficiency but will also be necessary as a result of a decreasing supply of qualified laboratorians (30).

Corporations, airlines, hospitals, and businesses are all merging to increase productivity. Not only has it worked to reduce operational costs and encourage the economy, but also it provides an example for the reorganization of the “business” of the laboratory. Similarly, the consolidation and integration of the laboratory's “small businesses,” its sections, subsections, and workstations, can greatly improve the volume and quality of products produced (output) per staff member.

However, as the leaders of corporations and businesses agree to merge and consolidate their attributes, the laboratory's managers of departments, divisions, sections, and subsections, must agree to relinquish a certain degree of control and “turf” (space and equipment) to achieve a better result for the laboratory as a whole. This is not an easy task and may not be able to be realized unless the director of the laboratory and the department or section manager display confidence, assurance, and the belief that consolidation and integration are a common goal that projects a “win/win” result for the staff. It is critical to remember that the real issue that defeats any good idea is lack of “buying into” and cooperation from the staff who perform the tasks on the production line.

It is important to remember that the most brilliant strategy and best management theories from famous universities and teachers never reflect real situations on the production line. A time-honored cliché in the senior management cadre is always heeded: “the culture eats the strategic plan every day for breakfast.”

Consolidation, Constriction, Constraint, Cross-training, and Integration

The director's or manager's decision to institute an internal change in the work pattern of the laboratory is certain to add additional stress and concern for the staff who will be directly involved in the change. Because many staff persons may be unwilling to change or may accept change but fear the consequences of the change, it is crucial to involve them in the planning process. Adequate preparation for any merger, consolidation, or integrative activity always starts with the informed consent and briefing of the staff (the culture) to be involved in the proposed change.

Current Trends for Internal Reorganization

The internal and external laboratory restructuring trends across the nation that have emerged in response to management's need to reduce operating costs and increase efficiency center primarily around services that share joint support systems and can easily cross-train staff. The most common specialties involved are general chemistry and hematology, since both have simpler, “one order-one result” work-flow patterns. Some laboratory management structures have consolidated their chemistry and hematology sections into one service, named “chematology.” The concept is sound, because the work processes, time for test result production, and automated nature of the “one order-one result” lends itself to merging these functions. Further, the high volume of screening and monitoring tests most needed by providers to establish a diagnosis and to monitor the progress of treatment are performed by chemistry and hematology, more than any other specialty section of the laboratory.

Table 2.10 illustrates the work complexity of the laboratory's specialties and subspecialties, separating the “one order-one result” specialties from those that require two to six complex processes before a usable test result is produced. Directors and managers desiring cost reduction need to consider consolidation of

sections and workstations where there are similarities in both work flow and work processes, even if the instrumentation differs greatly from section to section. The basis for this action is the more efficient and effective use of the labor time of the staff needed to produce the test output. Whenever test volume can be increased by using the same number of staff, the variable costs for reagents and supplies and labor will increase, but improved productivity and efficiency of the staff will decrease the cost per test produced. If the cost per test is multiplied by the increased volume of *billable* tests (tests for which reimbursement can be claimed) produced, and the laboratory's billing system accurately captures and submits a claim for all billable tests, then the laboratory gains revenue per test because the variable cost has been reduced.

Current Trends for External Reorganization

Unless the laboratory is independently owned and operated, there is often little control of the decision-making process that decides to consolidate, merge, acquire, or integrate laboratory functions across a health care system network, or the continuum of care in which the laboratory is involved. However, there is one area where the laboratory director and manager can have a profound effect to improve efficiency and reduce costs for the organization, because medical management's complex characteristics require special laboratory expertise to assure quality patient care delivery.

This area, with great potential for reorganization and consolidation, is termed transfusion, infusion, pheresis service.

Transfusion, Infusion, Pheresis (T/I/P) Service

As noted in a previous section (see Cost Management in Transfusion Medicine), this is one of the laboratory's highest areas of highest operating cost. One of the recommendations to resolve the problem of increasing costs is to consolidate the various internal and external sites in the HCO where transfusion medicine is called on to provide support for clinical services.

Support for this management approach is found in the application of business principles to hospital operations. The most important of these include:

- Consolidation and merger of similar functions performed in multiple sites
- Reduction in physical plant to decrease fixed costs
- Reduction in redundant, wasteful, and unnecessary functions

When these principles are successfully applied by managers in actual tertiary situations, they result in the following administrative actions:

- Close decentralized sites (T/I/P) used for outpatient T/I/P on inpatient care units
- [*Business reason*: Inpatient fixed costs are always greater than for T/I/P than in an outpatient setting owing to higher fixed labor and indirect support costs]
- Create a central T/I/P center in an outpatient setting for all patients requiring T/I/P who cannot ambulate or be moved from an acute care unit because of severe illness or incapacitation

REVENUE MANAGEMENT

Part of "2 - Business Management of the Clinical Laboratory"

To understand this section, the reader needs to review two equations:

$$\text{Revenue} - \text{Cost} = \text{Margin}$$

$$\text{Revenue expected} = \left\{\begin{array}{l}\text{Billable}\\ \text{product}\\ \text{volume}\end{array}\right\} \times \left\{\begin{array}{l}\text{Price,}\\ \text{rate,}\\ \text{charge, or}\\ \text{fee}\end{array}\right.$$

As always in an equation, the right and left sides must balance.

If there were any written rules to follow to assure the financial viability of a clinical diagnostic laboratory as a part of an organization or as an independent entity, they would probably be:

- Rule 1: Add new revenue streams.
- Rule 2: Avoid loss of revenue.
- Rule 3: Reduce operating costs while adding new revenue streams and avoiding loss of revenue.

Because there are no formalized, written rules for revenue management such as there are for methods and procedures in science and medicine, the director or manager must learn to read and interpret financial statements to understand where the clinical diagnostic laboratory ranks in the order of services within the parent organization. Directors and managers are judged by how well they save budgeted operating dollars and are ranked in order of positive or negative balances at the end of each fiscal reporting cycle.

The organization that owns or is responsible for providing funding for the laboratory's budget usually sets its own rules. They are simple rules:

- Rule 1: Never exceed your allocated budget.
- Rule 2: Plan for unanticipated expenses when submitting annual budget requests.
- Rule 3: Never ask for “new money” in the same budget year.

MARGIN

Part of "2 - Business Management of the Clinical Laboratory"

In the Management Responsibilities section (p. 64), it was noted that in addition to knowing the full cost of the laboratory's tests and services produced, the director or manager has the responsibility to assure the organization's top management that the margin of revenue gained after the receipt of reimbursement and other revenue streams is greater than the cost of producing all the laboratory's products and services. Margin is the term applied to designate the amount left over after all operating, administrative, and selling costs are deducted from the revenue gained from reimbursement and other sources of revenue gained by selling tests and services, sharing agreements, contracts, and other business arrangements. Figure 2.6 illustrates this concept. Margin can be captured for profit-making to provide distributions to shareholders or for making contributions back to the organization that produced the products that generated the revenue for the organization.

A summary of what is necessary to assure positive margins is provided in Figure 2.7. The reader should note that there is a significant difference between the requirements for the public not-for-profit and the private for-profit organizations, where the profit-seeking goal of the private organization engenders the high costs of competition, marketing, advertising, and logistics to bring their products to market.

	What Must be Recovered to:	
Type of Organization	Break-Even (no gain, no loss)	Obtain Positive Margin (gains > losses)
Public (not-for-profit)	All Test Production Costs Direct (Variable) Indirect (Fixed) Laboratory Institutional Inflationary Costs	Avoid Wastage, Duplication,Non-Essential Standards & Controls Eliminate Idle Time & Cross-Train Staff Obtain Volume Discounts on Consumables by Co-op/Sharing Extract Maximun Labor Productivity from Staff Procure & Use only Non-Labor Intensive Equipment & Methods Consolidate, Share/ Merge Testing Sites to Save Labor & Materials Costs Develop and Produce only High-Income, High Volume Tests/Services Discontinue Low-Income, Low Volume Tests/Services
Private (both not-for-profit and for-profit)	All Test Production Costs Direct (Variable) Indirect (Fixed) Laboratory Institutional Inflationary Costs	Avoid Wastage & Duplication Eliminate Idle Time & Cross-Train Staff Obtain Volume Discounts on Consumables Extract Maximun Labor Productivity from Staff Procure & Use only Non-Labor Intensive Equipment & Methods *plus* Recover Losses, Bad Debt, Charity Care, Accounts Receivable Past Due Utilize Excess Capacity to Perform Income-Generating Tests/Services Develop and Produce only High-Income, High Volume Tests/Services Discontinue Low-Income, Low Volume Tests/Services Actively Seek Profitable Capitation Contracts
(for-profit with shareholders)		Consolidate, Share/ Merge Testing Sites to Save Labor & Materials Costs Competitively Price Products to Increase Market Share

FIGURE 2.7. Requirements for positive margins. This figure is provided as a courtesy by Dr. E.M. Travers, Annapolis, Maryland.

PRICE (CHARGE, RATE, FEE)

Part of "2 - Business Management of the Clinical Laboratory"

Although the terms noted in the title of this section are not truly synonymous and interchangable, it is important to cluster them together to indicate to the reader that they are terms currently used to designate the dollar value desired by the producer of a product that designates the expected monetary return of revenue to the producer of the product.

Each term differs in its true meaning. *Price* is usually

1. what must be given in exchange for something,
2. the value of expected revenue to be received in the future, starting with the cost of production of the test or service, and adding what dollar amount is desired to add new revenue streams,
3. the amount of money received to allow a business or organization to meet expenses and provide a positive margin of revenue above the break-even point (the point at which expenses to produce the product are equal to the revenue received for its sale)

Charge has the same definition as price.

Rate is the predetermined dollar value of a test or service to be reimbursed to the provider of the test or service, as determined by

the Board of Directors of a managed care organization (MCO), a contract negotiated with a HMO, or another contractural arrangement that specifies a predetermined maximum amount in writing. The rate usually lasts over a specified time period, as agreed on by the parties who negotiate and sign the contract.

Fee is a term usually reserved for a professional service provided, which may or may not have a preset limit, depending on the policies of the MCO, third-party payer, or HMO.

It is important to note that, before a price, charge, rate, or fee is finalized in a business relationship, the producer of the product knows that the true, actual cost needs to be established first for each and every product (test or service) to be sold. This assures that a fair and equitable return of revenue is received just to cover the product's cost of production (operating cost). This subject is discussed in the Event Costing section and is summarized in the following equations:

1. What **cost** should be recovered?

Price, charge, rate, fee or reimbursement	=	Direct costs of production	+	Indirect (fixed) costs of production	+	Indirect hosp/corp costs

2. What *margin* must be recovered and gained in price/charge?

Price, charge, rate, fee or reimbursement	=	Direct costs of production	+	Indirect (fixed) costs of production	+	Indirect hosp/corp costs	+	Margin (profit or contribution)

RISK MANAGEMENT

Part of "2 - Business Management of the Clinical Laboratory"

What are the risks for the laboratory? There are many new risks, in addition to losing accreditation or not passing an OSHA or FDA inspection. There are now serious risks to financial stability and the risk of being contracted out to a larger laboratory when financial or management failure is detected by top management officers in the HCO's annual financial statement review. There is also the risk that the passive, silent laboratory director or manager will not speak up and be heard in contract negotiations with MCOs and third-party payers and lose out on an opportunity to assure a better reimbursement rate for the laboratory's services.

Risk management is the management process used to protect an organization or entity from the chance of loss. Managers need to be realistic about the task of assuming risk—especially financial risk. They need to understand the complexity of accurately predicting utilization and understanding the cost of delivering clinical diagnostic services. Managers should also realize that the current trend of Medicare, other third-party payers, and MCOs toward relinquishing the danger of financial risk and turning it over to those who deliver health care services (providers of hands-on medical care) does not take into consideration the clinical diagnostic laboratory's losses when providers order tests that cannot be reimbursed.

In fact, the clinical diagnostic laboratory is rarely considered by these entities when they meet to decide the reimbursement rate for an inpatient diagnosis-related group (DRG) or outpatient current procedure terminology (CPT) procedure code. Rather than designate a portion of the reimbursed amount to cover laboratory services, the laboratory function is considered as a necessary support function, an intermediate product, or a commodity in the health care delivery process.

This is why a commitment to the development of a dedicated management plan to manage the clinical diagnostic laboratory's global risk is so important. No one outside the professional organizations that represent a laboratory's professionals is concerned at all about its risk—except the person(s) in charge—the manager and his/her staff. Therefore, the director and manager are responsible for following the notices of meetings and contract negotiations that will involve the laboratory. A powerful voice representing the laboratory's interests must be heard in the boardroom. Otherwise, the rate setting will be conducted by the HCO's fiscal and contract negotiators. This means that the cost of providing laboratory services will not be accounted for in the reimbursement rate unless the laboratory representative can produce data on the true and accurate costs of testing for the population to be served in the managed care or capitation contract being negotiated.

Managers that can demonstrate the following characteristics are more likely to succeed at assuming risk:

- *Control over a comprehensive set of tests and services*. The more services that a laboratory contracts for, the less control it has over the production, accuracy, cost, and use of services.
- *A focused management infrastructure*. Managing risk effectively means devoting adequate resources to the onerous tasks of utilization management, quality assurance, information systems management, and contracting with providers and MCOs in your community. Funding up front for these tasks is necessary to realize a return on investment in the future. Managers must have sufficient understanding of the local market environment to be assured there is enough business in the community to justify the expenditure.
- *Effective relationships with physicians and employees*. Physicians and other nonphysicians who are hands-on providers of medical care will continue to control the use of your laboratory's tests and services unless you are able to build relationships with them to advise and educate them about appropriate utilization and costs of tests and services. The successful manager will get both providers and key clinical and laboratory employees involved in all aspects of risk assumption, share economic incentives for its success, and listen and act on their ideas and recommendations for its success. The ultimate goal is to reengineer the work process to reduce unnecessary utilization by clinical users of the laboratory.
- *Knowledge of costs*. If a manager does not have a baseline from which to measure cost, it will be impossible to determine whether profit or loss has occurred after delivery of a desired level of production.
- To improve productivity in laboratory operations, whether it be at the level of the workstation or at the section, division, or department level, the manager's knowledge of the unit cost per test or service makes the difference between a work area that is financially successful and one that is not.

- *Negotiating savvy*. Many directors and managers underestimate their marketplace strength and must understand that payers compete for business based on reduced risk, healthier patient populations, and their ability to use their “black box” editing software to deny claims for laboratory tests and services. Value and quality are important, but more important is the willingness of the laboratory's contracting officials (or the HCO's officials who speak for the laboratory) to be willing to accept a 20% lower rate than what it actually costs to produce a test or service.

REIMBURSEMENT MANAGEMENT

Part of "2 - Business Management of the Clinical Laboratory"

The increased threat to HCOs in the late 1990s from the federal government's “Operation Restore Trust” efforts to prevent fraud and abuse in Medicare intensified the importance for clinical laboratories of avoiding questionable, missing, erroneous, or faulty documentation practices and understanding correct coding use for filing claims for reimbursement. The following discussion of the categories documentation, coding systems, and billing systems represents the primary areas of management control and oversight for managers and administrators responsible for correct reimbursement practices.

Documentation

In the late 1990s, the slogan “if it wasn't documented, it didn't happen” became the most frequent admonition of third-party payers in government and private-sector organizations. The motive of payers responsible for providing reimbursement (payment) to HCOs and providers for the use of their services, facilities, and raw materials was to avoid potential litigation and penalties for incorrect documentation of medical care activities.

Payers reacted strongly to the news of stiff federal fines paid by three major U.S. HCOs for violating federal Medicare regulations. Scathing indictments of these incriminated HCOs followed the fines, and compliance programs emerged throughout the United States to train all medical care providers and administrative and billing persons, not just laboratory staff, in correct coding and billing.

Payers constitute the “business” of medicine and follow the principles established by the financial and accounting professions to ensure the survival of their organizations. They too face severe civil and criminal penalties if they allow laboratories and health care providers to submit incorrect, inaccurate, or not medically necessary claims for reimbursement.

Coding Systems

CPT Codes

Laboratories are currently totally dependent on the CPT coding system (12) to receive reimbursement for the tests, services, and procedures they perform; however, there are major deficiencies in the coding system that penalize laboratories and other entities that depend on inaccurate existing CPT code numbers and descriptions of tests to claim reimbursement.

Coding of CPT claims for reimbursement is somewhat of an arcane science in which a syntax-based standard word structure created by medical publishing house committees is combined with structured, hieroglyphic-like numerical sequences. This rigid, inflexible nomenclature/code system is endorsed and mandated by the federal HCFA, without frequent scientific review by recognized bodies such as the World Health Organization, the reviewing body for ICD-9 diagnosis codes. In fact, the Evaluation and Management series of CPT codes has been roundly criticized for its inadequacies and inaccurate representation of the actual work performed by physicians when evaluating and managing patients (31).

Lack of frequent review by the committees established by the AMA to oversee the CPT coding methodology (in conjunction with HCFA) leaves the laboratory profession without a court of appeal when either:

1. new tests and procedures are approved by the FDA, yet have not been approved by the HCFA for code assignment (preventing reimbursement) (this often leads to a 2-year delay and/or a loss of operating expenses when a laboratory test or service is performed that is not assigned a CPT code),
2. old, obsolete tests and procedures are no longer used and cannot be quickly or easily removed from the coding book.

ICD-9 Codes

Similarly, the current ICD-9 coding system has flawed, incomplete categories. However, there has been a significant effort contributing to a massive and comprehensive reorganization and revision of the ICD-9 coding system. This new system, ICD-10, was introduced in the year 2000.

Its entire numbering system was replaced with both alphanumeric and Arabic number designations, which means that for all diagnosis codes used in 1999 to claim reimbursement, there now has to be an entirely new process taught to the laboratory's claims, coding, and billing staff. The positive attributes of the ICD-10 system are its greater flexibility and more comprehensive nomenclature of diseases, operations, conditions, and classifiers.

Laboratory directors and managers are required to support new training efforts for the staff after the ICD-10 is released.

Billing Management

The subject of billing management could easily require an entire textbook to explain its complexity and difficulty. Simply stated, it is critical that a laboratory director or manager instruct the claims and billing staff to never send out a claim for reimbursement if they are not absolutely sure that:

- the documentation provided on the order form by the provider of medical care is totally correct and agrees with the documentation in the progress notes of the medical record,
- the diagnosis (ICD) for the patient for whom the test or service was performed matches the CPT code for the test, procedure, or service performed by the laboratory,
- the provider has certified that the test, service, or procedure was medically necessary,
- the provider who orders the test, service, or procedure is a certified attending physician and not a teaching physician, medical student, intern, resident, or fellow.

The reason for these safeguards is that the laboratory may be penalized by the federal government with monetary and/or civil penalties if there is any discrepancy in the items noted above.

Compliance Management

This is an entirely new category of management, necessitated by the federal government's "Operation Restore Trust" effort started in the late 1990s to correct the widespread practice of fraud and abuse in claiming reimbursement for work never performed for a patient. As a direct result of federal indictments and documented incidents caused by major laboratory corporations and HCOs involving laboratory tests, even as early as 1990, the federal government instituted new regulations to prevent future false claims. In addition, the National Correct Coding Initiative in 1998 standardized the software for all 4,000 to 6,000 third-party payers in the United States who are authorized by the HCFA to act on their behalf to disburse federal moneys through the Medicare and Medicaid programs.

This action resulted in a uniform process for review and unannounced auditing of any or all medical records, laboratory data, or other data available in a laboratory's or HCO's database. The audits are performed by authorized FBI agents, Department of Justice agents, or other agents of the federal government, based on random selections or whistle-blower allegations of suspected fraud or abuse in claims for Medicare reimbursement.

The auditing process is based on reviews of:

- Medical necessity
- Correct documentation and coding of medical records and laboratory test requisition completeness
- Justice
- Safety and quality
- Accreditation, inspection, and compliance with the CLIA, OSHA, and FDA regulations

SUMMARY AND CONCLUSION

Part of "2 - Business Management of the Clinical Laboratory"

Because the nature of the business learning process is so different from the scientific/technical, it is important that the reader understand that there is no one standard method for performing many business tasks, such as there is in many scientific, medical, and technical fields. In business, how you got there is a combination of many varied approaches. Combinations that work depend on the balance and "chemistry" of the team players in a business, who combine their backgrounds, experience, and education to make the business successful. The only rigid plan that they follow is a business plan, drawn up by them, that sets goals and a way to reach them within the business itself.

In science, medicine, and technical professions, there is often only one standardized approach to reach a goal because of the need to apply the rigors of the scientific method plus legal, regulatory, and other external influences. Although it is a different way of thinking, the participant who is just beginning to understand the value of using business concepts to better manage a clinical laboratory should be willing to accept the unscientific, loose arrangement of business survival tactics.

Mastery of the topics in this chapter is critical for directors and managers in any clinical diagnostic laboratory setting that sends claims for reimbursement to third-party payers. Sound management education constitutes the basic elements of a director's or manager's strategy for reducing costs and optimizing reimbursement—keys to survival for health care specialties and related industry suppliers and partners. These subjects are not the only important topics in a vast array of business topics that the well-informed, proficient director or manager should know, understand, and be able to apply to daily operations. As the basic sciences of biology, chemistry, and physics are the keystones to the practice of scientific, medical, and technical professions, the basic tools of management briefly summarized in this chapter are the keystones to continued survival in an uncertain health care business environment.

Laboratory Safety

Gerald A. Hoeltge

Clinical laboratories are complex environments. People are surrounded by chemicals, specimens, equipment, and technology. The chemicals may be toxic, specimens may be infectious, equipment can malfunction, and any technology may be misunderstood. Most technological processes and laboratory procedures expose the operator to the risk of injury. Every laboratory hazard can be contained. No clinical laboratory can afford to operate without a safety program, and the best build safety into the culture of the laboratory.

An organized safety program begins with a written plan that defines the scope of the program, its goals, and the individuals responsible for it (1). The administration must provide the necessary resources including time, equipment, and assistance. There should be a comprehensive document that summarizes the laboratory's current safety policies (2). Personnel need to be familiar with its contents. Individual technical procedures may define the specific safety precautions that are relevant to each analytic method. For example, the procedure for the preparation of bacteriologic media should cross-reference the portions of the safety manual that describe the operation of the autoclave as well as specify the types of gloves and face protection needed during the sterilization of culture media. The phlebotomy manual should be specific about the use of gloves and the method for discarding used needles. The measures for the control of hazards associated with flammable and caustic reagents that are handled may be usefully expressed within the chemistry laboratory's analytic procedures manual. All documents that list safety policies and procedures should be reviewed on a regular basis. Annual review is suggested.

One of the most practical ways to ensure regular review of one's safety program is through the establishment of a laboratory safety committee that includes representatives from each major analytic discipline. The membership should reflect the degree of experience and involvement of the average worker in the facility; that is, the committee should be composed primarily of bench-level technologists. All members of the committee should lead by example and promote the principles of safe work practices. The most effective safety programs are found in institutions that value and reward safe work practice.

The appointment of a safety officer (SO) is appropriate for larger laboratories and may be required by regulation (3). This individual helps administer safety policy and serves as an advisor on the management of safety-related matters. The SO may be responsible for maintaining accident records, conducting or coordinating the safety training program, and surveying the workplace for hazards. The SO or another official in the organization sees to it that the facility is in compliance with federal, state, and local regulations.

DEFINITIONS

Part of "3 - Laboratory Safety"

Hazard containment is the system of routine control processes that keeps the incidence of accident and injury within reasonable expectations. Compliance with the appropriate and established safety policies of the facility should limit the risks that are associated with clinical laboratory practice. A determination of the potential dangers that require containment is part of a hazard assessment program. After a safety audit has identified opportunities for improvement in safety policies, new controls may be instituted as part of a hazard abatement program. Many efforts toward hazard abatement are instituted after investigation of a reported accident or after the external review of the facility by an accrediting or licensing agency. A hazard minimization program is a continuous and regular effort that seeks to reduce risk to a level as low as can reasonably be attained. Programs such as these should not be confused with risk management activities, which are focused attempts to reduce a facility's indemnity expenses and liability. Hazard containment, abatement, and minimization programs are directed toward the goal of laboratory safety; risk management strives to mitigate the consequences of unsafe action.

Control systems can be grouped into three broad categories. Engineering controls include all the features and systems that are built into the design of the facility and its fixed equipment. Examples include fume hoods, biosafety cabinets, steam pressure regulators, electrical circuit breaking switches, and the safety devices that are part of the design of technical tools and movable equipment. Sheaths to protect lancets (4) and phlebotomy needles, replacement of glass capillary tubes with shatterproof plastic, centrifuge lids that lock when the motor is energized, immobilizing chains for storage of compressed gas cylinders, and double-walled containers for shipment of etiological agents (5) are additional types of engineering controls. Personal protective devices are barriers from potential hazards that the employee must select before they will be effective. Gloves, respirators, and mechanical pipetting aids are obvious examples. Safe work practices encompass learned skills and techniques such as the avoidance

of aerosol formation, segregation of hazardous wastes, and the proper operation of hazardous equipment. An engineering control is always preferred over any approach that requires a deliberate choice on the part of the worker.

PATIENT AND VISITOR SAFETY

Part of "3 - Laboratory Safety"

Access to hazardous areas should be limited to individuals who have been trained to avoid injury. Patients and visitors to the laboratory should not be allowed free access to technical areas. The laboratory design should incorporate a reception and waiting area that protects untrained individuals from any appliance, fume, or aerosol that may injure them.

The phlebotomy area should be designed with patient safety in mind. The patient arriving in the laboratory for a blood specimen collection should be escorted to a comfortable chair that includes an armrest and a passive restraint system to protect against syncopal falls. Ammonia inhalants should be within easy reach of the phlebotomist.

The patient should be asked about iodine allergies if iodophors are to be used as skin antiseptics. Each step of the procedure must be announced to avoid the patient's making involuntary movements. All needles, lancets, and capillary tubes should be kept out of the reach of patients. Needles and syringes should be kept under lock and key whenever unattended.

Gloves must be worn at all times during the phlebotomy and when handling the resultant specimen. A secondary container, such as a sealed plastic bag, is mandatory whenever the exterior of the container is soiled with blood. All used materials must be properly discarded. Items soiled with blood must be considered contaminated and biohazardous and placed in a properly labeled container.

Phlebotomists are more likely than any other hospital worker to be injured by a needlestick (6). Blood collection devices that minimize the risk of needlestick injury should be used in preference to those with exposed needles. Devices that connect directly to an intravenous line and ones that have retractable or sheathed needles and even self-blunting needles are available. Such devices can be highly effective in reducing the rate of needlestick injury (7).

As a general rule, used, exposed needles are never to be broken nor recapped. Clipping or breaking of needles can spatter blood and spread the area of contamination. Resheathing risks puncture injury of the hand that holds the cap. Although there may be acceptable alternatives, such as specially engineered caps (8) or a one-handed recapping technique (9), the simplest option is to drop the entire collection device into the waste container that is reserved for sharps. (Containers for sharps should never be more than two thirds full to avoid the temptation to force one more needle into the container.)

All spills and spatters of blood or body fluids must be cleaned with aqueous detergent, after which the contaminated surface must be decontaminated. Papers that may have become bloodstained must be replaced with clean copy. Gloves are to be changed regularly and whenever visibly contaminated. Washing hands between every glove change and is encouraged because it reduces the risk further. Regular use of skin emollients helps prevent chapping and fissures in the skin.

ATTIRE

Part of "3 - Laboratory Safety"

The proper attire for laboratory work minimizes exposure to infectious and chemical agents. A distinction is made between personal attire [including uniforms and cloth laboratory coats (lab coats)] and personal protective equipment (PPE). Except in areas where the risk of contamination is extraordinary (such as necropsy), personal attire may be worn in all areas of the facility and outside the building. PPE is designed to protect the employee and his or her personal attire from harmful exposure. Each item of PPE (whether gloves, face protectors, gowns, aprons, or shoe covers) must be constructed of a material through which the infectious or chemical agent of concern cannot penetrate. Protective equipment that is sufficiently damaged to permit entry of harmful materials must be replaced immediately. All items of PPE are removed before leaving the laboratory.

Attire should be matched to the task. For example, phlebotomists must be identifiable as laboratory professionals. A clean, neat uniform can help reduce a patient's anxiety. At the same time, the technician must protect him- or herself from the chance that blood might spray or leak from the collection device. A long-sleeved, buttoned lab coat worn with disposable gloves meets both needs.

The performance of a necropsy demands a higher level of containment and therefore more effective personal barrier protection. Water-resistant gowns that extend from the neck to below the level of the table are needed. The sleeves should be tight at the wrist and tucked inside vinyl or latex gloves. Facial protection (goggles and mask or full face shield) and shoe covers are necessary. Slash-resistant gloves made of steel mesh or a specially selected polymer may be needed (10).

Most tasks in the clinical chemistry laboratory can be safely performed while wearing the same laboratory attire that protects workers elsewhere from common infectious hazards. A fluid-resistant lab coat, gown, or tunic combined with disposable gloves is usually sufficient. Face protection (either worn by the worker or interposed as a barrier shield) must be used whenever splashing or spraying with droplets of blood or other potentially infectious fluids is a risk. The objective is to protect all exposed skin surfaces including the neck and wrists. Some tasks will require additional protection. The handling of caustics and corrosives obligates the use of gloves, aprons, and face protectors that are made of materials known to be resistant to the liquid being manipulated. The handling of even small amounts of carcinogenic substances requires the use of gloves and forearm protection (as well as facial protection if splashing or spattering is anticipated).

Shoes should be rubber soled for effective traction and to decrease the shock hazard precipitated by an electrical accident. Shoe covers made from appropriately resistant materials are needed if splashing is a risk. In particular, individuals who must transport or decant corrosive liquids must not do so wearing unprotected cloth or porous shoes.

Between uses, reusable protective clothing should be hung away from sources of heat and potential ignition. Uncontaminated garments (such as street clothes) should be stored separately from laboratory wear. All items of personal barrier protection should be changed immediately once they are found to have been contaminated with blood or toxic chemicals. Because of the

chance of insensible contamination, protective clothing should be changed regularly. Obviously contaminated, single-use (disposable) gear should be discarded in properly marked containers. Reusable lab coats and gowns should be placed in leak-resistant bags to be laundered in a manner that ensures decontamination. To contain the hazards as much as possible, the laundering of contaminated clothing at home should be prohibited.

Hazard containment applies to hairstyles and personal adornments. Hair should be worn behind the head and off the shoulders to preclude its contact with contaminated surfaces. Disposable hair covers may be indicated for some activities. Hair, beards, and jewelry should not be allowed to overhang into contaminated areas or risk entanglement in moving equipment.

GOOD LABORATORY HYGIENE

Part of "3 - Laboratory Safety"

Handwashing is one of the most effective means to minimize personal exposure. Thorough lavage with a good detergent removes external bacteria and chemicals before they can be ingested or absorbed. Antibacterial agents are not required for a good laboratory hand detergent. Hands should be washed frequently throughout the day. Washing is especially important after removing gloves, before and after contact with patients, before leaving the laboratory, and before eating, applying cosmetics, and using lavatory facilities. The well-designed handwashing sink is operable with elbow blades or foot pedals. Paper towels can be disposed of with the general refuse.

All areas of the laboratory should prohibit eating, drinking, and manipulating items that may contact mucous membranes (e.g., contact lenses, cosmetics, and lip balm) within the technical work areas. Any such activity risks exposure to both infectious agents and toxic substances. Food and drink should never even be brought into the technical work area. Refrigerators used for storage of reagents and specimens off off-limits for food items. Dining areas and refrigerator are to be reserved exclusively for food items.

Individuals who wear contact lenses must take special precautions. Any activity that might splash a toxic, irritating, or infectious fluid into the eyes presents a special hazard for contact lens wearers. Tightly fitting contact lenses can inhibit the naturally protective effects of tearing, permitting substances to contact the conjunctivae for longer periods of time. Irritants can induce immediate inflammation and swelling, rendering the contact lens difficult to remove. Scleral injection hastens the absorption of toxic substances. Although some may prohibit the wearing of contact lenses in the laboratory, goggles or face shields provide an acceptable level of protection. Special precautions also need to be taken by lens wearers who are manipulating solvents that might dissolve the plastic of the corrective lens. In formulating a contact lens policy, it must be remembered that individuals who do not wear such lenses are also at risk for eye injury; the safest strategy is to require the wearing of full facial protection for all employees engaged in tasks that chance splashing or spraying.

Mechanical devices should be always used for pipetting tasks. The pipetting of fluids by mouth must be strictly prohibited throughout the laboratory. Even innocuous fluids such as water should be pipetted mechanically for consistency.

SPACE AND VENTILATION

Part of "3 - Laboratory Safety"

The laboratory should be allotted sufficient space in which all work processes can be done safely (11). The arrangement of equipment on countertops should leave plenty of working area. Having to reach across hot plates or to brush past containers of caustics as a routine invites an accident. Power cords or hoses that cross walkways indicate poor and unsafe laboratory design. Lighting must be bright enough to illuminate all areas of the laboratory.

The laboratory should be designed to accommodate the special needs of handicapped workers. Ramps, wide aisles, and lowered work surfaces are needs of wheelchair-bound workers, for example (12).

Air handling must be engineered to the task. Fume hoods and biosafety cabinets need to be available in appropriate locations. Operations on open benches that generate occasional or low-level fumes should be positioned such that fumes are drawn away from workstations and not across them.

HOUSEKEEPING

Part of "3 - Laboratory Safety"

Cleanliness and good housekeeping are attributes of the best laboratories. Proper storage of laboratory implements when not in use keeps work areas clear to facilitate disinfection, decontamination, and hazard containment. A cluttered aisle is a nuisance that can lead to falls and lower leg injuries. Accumulations of chairs, equipment, and boxes that block exits or otherwise interfere with emergency egress must be forbidden. Smoke doors must remain completely unobstructed so that they will close automatically in the event of fire. Free access to all emergency equipment (such as portable fire extinguishers, showers, and eyewash fixtures) must be ensured at all times. Clothing, signs, and decorations should never be hung over doorways or safety windows in any manner that obstructs the view. Floors and walls are to be cleaned on a regular schedule. All cabinetry, including refrigerators, freezers, incubators, and water baths, should be cleaned and disinfected regularly (usually at the end of each work shift) as well as immediately after spills.

PERSONAL BARRIER PROTECTION

Part of "3 - Laboratory Safety"

Gloves

Gloves, the most commonly used personal protective device, protect the wearer from contact with noxious substances and dangerous materials. Gloves should fit as comfortably as possible. Glove length must be sufficient to extend over the cuffs of the sleeves to protect the wrists.

Heavy rubber gloves made of neoprene, nitrile, or butyl rubber are designed for chemical protection. Choose a material known to resist the specific chemicals to which the worker will be exposed. Glove materials are rated (in hours) as to the duration

of protection provided and/or the rate of chemical permeation through the fabric.

Thin latex or vinyl gloves provide short-term protection against dusts and contaminated aqueous solutions. Minute and insensible defects can develop easily in such gloves, and viruses can slowly penetrate intact glove wear. Such gloves must be changed and discarded regularly to be effective (13). Thin gloves are designed to be single-use devices and must be replaced immediately when torn or contaminated.

Natural latex rubber is an allergen. Cornstarch and talc particles increase the hazard by assisting the delivery of latex proteins to respiratory epithelium. Thin, flexible gloves made of vinyl plastic should be offered as an alternative for those employees (and patients) who are latex sensitive. Powdered latex gloves should be prohibited from the workplace, and reduced-protein latex gloves made available for routine work (14).

Heat-reflective and insulated gloves protect against thermal injury when handling items at blistering temperatures or when working in frigid conditions. Cryostat operators can develop chronic peripheral neuropathies and Raynaud's phenomenon if inadequately protected (15).

Stainless-steel mesh gloves provide shielding when handling sharp items such as knife blades and broken glass.

Outerwear

Lab coats are long-sleeved jackets of sufficient length to extend below the level of the workbench when the worker is standing and to fully cover the individual's lap as he or she sits at the workstation. Lab coats should always be worn fully buttoned and should be made of water-resistant fabric. Coats that are constructed of absorbent cloth must usually be overlaid with a plastic apron or tunic. Gowns provide a greater measure of protection. Gowns fit snugly at the wrists and neck and have either no front openings or a fully fastened front opening. Jumpsuits are fitted to the ankles as well as the wrists; they are appropriate in areas where hazardous dusts or liquids may contaminate stockings or trousers. Water-resistant garments are to be used when performing tasks that risk splashing with infectious or otherwise potentially infectious fluids. When chemical exposure is anticipated, outerwear must be constructed of a material that is resistant to the chemical that is handled. All single-use, protective outerwear should be changed as soon as possible after contamination; PPE designed for reuse should be cleaned or decontaminated as soon as possible after soiling.

Eye and Face Protection

Safety glasses are spectacles made of high-impact plastic; imperforate side shields at the temples are standard. Safety glasses offer a minimal and usually inadequate level of protection. Goggles, which fit snugly around the face, are preferred and should be combined with masks that protect the mouth and nose. A face shield, a shatterproof plastic device that wraps around the face to safeguard all exposed facial skin (including the neck), provides more complete protection. Small, freestanding area shields rest on or are suspended over the workspace, allowing the technologist to manipulate hazardous fluids with an acceptable level of eye and face protection. Activities that risk splashing or spraying with infectious materials or fluids that may irritate mucous membranes should be performed behind shields or while wearing goggles and a mask. Corrosive liquids must always be manipulated with shield protection.

Respiratory Protection

Many types of devices are manufactured for respiratory protection. Such devices must be used to prevent the inhalation of fumes, dusts, or aerosols that may be harmful. The use of properly designed air-handling cabinetry (such as chemical fume hoods) is best, but personal protective equipment should be used whenever engineering controls may offer inadequate protection.

The choice of a device for respiratory protection is based on the nature of the hazard that is targeted for control. Dust masks are simple cloth or paper devices that are nonetheless effective in preventing the inhalation of aerosols and particulates when properly fitted. Fume masks cover half the face and employ replaceable cartridges that contain absorbent chemicals. Each cartridge, chosen to reduce the exposure level of a specific group of noxious fumes, must be changed periodically. An airline or self-contained breathing apparatus (SCBA) offers the greatest level of protection because all inspired air is delivered from an uncontaminated source. Each device must be used in accordance with its manufacturer's directions.

Respirators that fit tightly around the mouth and nose impede ventilation. Although their use is sometimes necessary, only employees who are physically able to breathe properly through the device should be allowed in a work environment in which their use is required. Safe use of the more complicated devices may depend on proper fit and training.

An SCBA is the device of choice whenever no simpler device would suffice to protect the worker. Examples include levels of toxic vapors that exceed safe limits, vapor hazards of unknown toxicity, deoxygenated atmospheres (<19.5%), or any other acute hazard to life or health (16).

Chemical fume hoods that are ducted to the roof of the building provide an engineering alternative that is better than relying completely on personal protective equipment. The rating of the device is based on the airflow velocity at the face of the work area. Airflow is typically controlled by means of a sash made of laminated safety glass. A face velocity airflow of 80 to 120 feet per minute (fpm) is recommended (17). A perchloric acid hood is a special type of chemical fume hood and ducting system that is constructed of corrosion-resistant stainless steel. Some limited tasks that generate minimally hazardous but noxious fumes may safely be performed on a downdraft platform or at a rear-plenum exhaust workstation; both systems draw vapors away from the face of the operator. The absorbent chemical filters of such devices are similar to those in portable fume masks.

WARNING SIGNAGE

Part of "3 - Laboratory Safety"

Regulatory and Advisory Systems

Several systems of signs have been devised to warn individuals of hazards and potential injury. Each addresses a specific target audience,

and a combination of several systems will be necessary for most laboratories.

The Occupational Safety and Health Administration (OSHA) has defined one system for area signs for accident prevention (Fig. 3.1) (18). The colors of the signs indicate the hazard level. Red letters indicate a dangerous location, the nature of which is identified with black letters on a white background. A yellow background with black letters prompts one to use caution. Green signs are advisory and display helpful safety information. Pictographs may be included. By virtue of their clarity and simplicity, OSHA-style signs convey minimal detail. They are intended to alert anyone who is approaching the area, even those with little training. Additional information (such as emergency procedures) may need to be posted nearby.

FIGURE 3.1. Informational signs for accident prevention formatted according to regulations of the Occupational Safety and Health Administration.

The National Fire Protection Association (NFPA) developed a hazard identification system (Table 3.1) specifically for fire fighting (Fig. 3.2) (19). A diamond-shaped emblem is divided into four fields that are color coded to distinguish the type of hazard. Three of the fields display a numeral from 0 (negligible hazard) to 4 (severe hazard). At the pinnacle is a red diamond that indicates the flammability risk of the chemicals stored in the room or cabinet. On the left is a blue diamond for the health hazard posed by acute exposure through inhalation or dermal contact to those chemicals or to their combustion products. On the right, a yellow diamond reflects the instability risk. These are relative rather than absolute ratings and are assigned according to the professional judgment of the SO. The white diamond at the low point on the emblem may have a W with a line through it (do not use water) or the letters OX (oxidizers present). It is important to understand that NFPA 704 is designed for the protection of fire fighters. It is an appropriate system to post at eye level in entryways and on cabinet doors. It is not a good system for individual reagent vessels because the effects of chronic exposure to a chemical are not considered in the health rating. NFPA 704 should be used only with the consent and cooperation of the local fire department.

FIGURE 3.2. Example of fire hazard warning sign (from the National Fire Protection Association standard 704).

The U.S. Department of Transportation (DOT) requires the use of a different signage system (20). Partly pictorial and partly numeric, DOT signs are usually found on cartage vessels, cartons, and containers. The diamond-shaped signs can be useful when choosing the proper response to contain and decontaminate a leaking and otherwise unidentified shipping container.

Additional emblems have been promoted for specific tasks. Figure 3.3 displays standardized symbols that may be helpful in clinical laboratories.

The labels on reagent vessels should clearly delineate the hazards of the contents and their adverse effects on specific target organs. The identity of the chemical is best described in accordance with the International Union of Pure and Applied Chemistry or the Chemical Abstracts Service rules of nomenclature. The label may also specify the personal protective equipment required. Commercially labeled reagent containers often display additional information such as advice on first aid and spill cleanup. Secondary containers into which the contents are transferred should always be labeled with the key safety information. The only exception to this rule is when the individual transferring the chemical is the sole user of the chemical.

Warning labels are not to be removed or obscured unless a revised label will be applied immediately. Unlabeled containers should remain unopened and discarded as an unknown chemical that is presumed to be hazardous.

It is good laboratory practice to indicate on the label the date that each container was opened. Such a practice is also a safety precaution when dealing with chemicals for which the hazard level increases upon exposure to air. For example, diethyl ether slowly but spontaneously can form explosive peroxides when mixed with atmospheric oxygen; because of this, storage must be brief after opening.

CHEMICAL HAZARDS

Part of "3 - Laboratory Safety"

The smaller the quantity of hazardous materials that a laboratory has on hand, the better. The hazards of a laboratory chemical can be described in terms of ignitability, corrosivity, instability, and toxicity. The characteristics of many chemicals belong to more than one hazard class. Containment strategies are based on the nature of the hazards involved. A chemical hygiene plan (CHP) is a strategic approach to reagent and waste chemical hazard control (3). The CHP specifies the safety precautions appropriate for each class of chemical that is in use in the laboratory. The goal is to promote the combination of engineering controls and safe work practices that best protects employees from the hazards of the chemicals that they are using.

Exposures to fumes must be kept within permissible limits (see the section on toxicity). The CHP will identify (a) the criteria that will be used to determine the need for special control measures (such as personal protective equipment), (b) the requirements for chemical exposure monitoring (i.e., anticipation of circumstances during which permissible exposure limits may be exceeded), and (c) the provision for medical attention when dangerous exposures do occur.

Corrosivity

The U.S. Environmental Protection Agency (EPA) defines corrosives based on pH or the ability to destroy steel. Any aqueous waste that is extremely acidic (pH 2.0) or extremely alkaline (pH

12.5), or that can corrode SAE 1020 steel more than 6.25 mm (0.250 in.)/year at 55°C is corrosive (21). As a warning on a reagent label, however, the term may be generalized to refer to any substance that can cause visible destruction or irreversible alteration in human tissues at the site of contact.

Corrosives should always be stored near the floor and below eye level. A catchment basin on the floor near the point of use and the regular use of protective bottle carriers minimizes contact with a spilled chemical. Mutually incompatible chemicals, e.g., hydrocarbons, including organic acids, and strong oxidizers, such as sulfuric, nitric, or perchloric acid, must be stored separately. Personnel must wear the proper equipment when handling corrosives. Gloves, aprons, and other protective garments should be constructed of materials that are known to be resistant to the corrosives in use. Vapors of corrosives are often highly irritating, and the pouring and pipetting of concentrated corrosive

TABLE 3.1. HAZARD RATINGS FROM NFPA 704

Identification of Health Hazard Color Code: Blue		Identification of Flammability Color Code: Red		Identification of Instability Color Code: Yellow	
Signal	**Type of Possible Injury**	**Signal**	**Susceptibility of Materials to Burning**	**Signal**	**Susceptibility to Release of Energy**
4	Materials that, under emergency conditions, can be lethal	4	Materials that will rapidly or completely vaporize at atmospheric pressure and normal ambient temperature, or that are readily dispersed in air and will burn readily	4	Materials that in themselves are readily capable of detonation or explosive decomposition or explosive reaction at normal temperatures and pressures
3	Materials that, under emergency conditions, can cause serious or permanent injury	3	Liquids and solids that can be ignited under almost all ambient temperature conditions	3	Materials that in themselves are capable of detonation or explosive decomposition or reaction but that require a strong initiating source or must be heated under confinement before initiation
2	Materials that, under emergency conditions, can cause temporary incapacity or residual injury	2	Materials that must be moderately heated or exposed to relatively high ambient temperatures before ignition can occur	2	Materials that readily undergo violent chemical change at elevated temperatures and pressures
1	Materials that, under emergency conditions, can cause significant irritation	1	Materials that must be preheated before ignition can occur	1	Materials that in themselves are normally stable but that can become unstable at elevated temperatures and pressures
0	Materials that, under emergency conditions, would offer no hazard beyond that of ordinary combustible material	0	Materials that will not burn	0	Materials that in themselves are normally stable, even under fire-exposure conditions

Adapted from NFPA 704. *Standard system for the identification of materials for emergency response*. Quincy, MA: National Fire Protection Association, 1996, with permission. This reprinted material is not the complete and official position of the National Fire Protection Association on the referenced subject, which is represented only by the standard in its entirety.

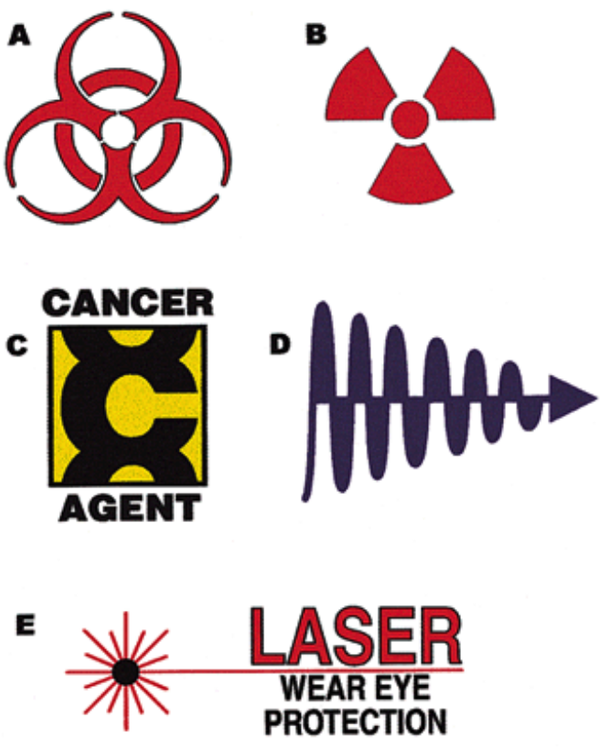

FIGURE 3.3. Standard symbols for biohazards **(a)**, radiation hazards**(B)**, carcinogenic hazards**(C)**, ultraviolet light hazards**(d)**, and laser devices**(E)**.

liquids within a chemical fume hood are highly recommended. The area of the laboratory in which corrosives are used must have an adequate source of water, such as an emergency shower and eyewash station, for rapid decontamination.

Ignitability

The NFPA developed a useful classification system based on hazard potential (13,22). Flammable liquids are those with a very low flash point (the temperature at which a liquid gives off vapors in sufficient concentration to form an ignitable mixture with air) or boiling point (at normal atmospheric pressure) or both. Flammable liquids are divided into three groups. Class IA designates the most flammable liquids:

- Class IA: flash point <22.8°C and boiling point <37.8°C
- Class IB: flash point <22.8°C and boiling point ≥7.8°C
- Class IC: flash point ≥22.8°C and boiling point <37.8°C

For example, diethyl ether (with a flash point of -45°C) and benzene (with a flash point of -11.1°C) are class IA liquids. Absolute ethanol has a flash point of 12.8°C and is a class IB liquid.

Combustible liquids have a flash point that is greater than 37.8°C. Combustible liquids are also classified into three groups:

- Class II: flash point ≥37.8°C and <60°C
- Class IIIA: flash point ≥60°C and <93.3°C
- Class IIIB: flash point ≥93.3°C

As an example, 37% aqueous formaldehyde (the solution usually referred to as undiluted formalin) has a flash point of 85°C and is therefore grouped within NFPA class IIIA.

The value of this classification system can be seen in Table 3.2. The ignitability risk of a stored chemical is a function of the nature of the substance, the type of storage vessel that contains it, and its shielding from sources of ignition. Specially designed flammable solvent containers are safer storage vessels than glass bottles. A safety can is made of metal or polymer. It has a spring-closing cap, a pressure-release valve, and a flame arrestor within the spout. Storing flammable liquids in an ordinary glass vessel is a greater hazard than storing the same amount of material in a safety can.

TABLE 3.2. MAXIMUM ALLOWABLE SIZES OF CONTAINERS OF IGNITABLE LIQUIDS

Ignitability Class	Glass	Metal or Approved Plastic	Safety Can
IA	1 pt (0.473 L)	1 gal (3.8 L)	2 gal (7.9 L)
IB	1 gal (3.8 L)	5 gal (19.0 L)	5 gal (19.0 L)
IC	1 gal (3.8 L)	5 gal (19.0 L)	5 gal (19.0 L)
II	1 gal (3.8 L)	5 gal (19.0 L)	5 gal (19.0 L)
III	5 gal (19.0 L)	5 gal (19.0 L)	5 gal (19.0 L)

Adapted from NFPA 30. *Flammable and combustible liquids code*, 1996. Quincy, MA: National Fire Protection Association, 1996, with permission. This reprinted material is not the complete and official position of the National Fire Protection Association on the referenced subject, which is represented only by the standard in its entirety.

These definitions are derived from the National Fire Code. Regulatory agencies may use slightly different definitions. For example, the EPA uses the term *ignitable* to refer to liquids that have a flash point less than 60°C, are strong oxidizers, or have some other property that contributes significantly to a fire hazard (such as the capability to cause a fire through friction, absorption of moisture, or spontaneous chemical change) (23).

A flammable storage cabinet (FSC) is designed to sequester its contents from heat during a conflagration. The purpose is to allow personnel a short amount of time (approximately 10 minutes) to evacuate the laboratory before the liquids inside ignite. An FSC can be constructed of metal or wood. The door should fit tightly and preferably be self-closing. An FSC may be either entirely enclosed or vented to the exterior of the building. Metal FSCs must be properly grounded. The volume of ignitable liquids that can be stored both outside such a cabinet and within an FSC is limited according to whether the laboratory is located within a health care occupancy (such as a hospital) (24) or in a business occupancy (such as a freestanding clinical laboratory) (17). The maximum volume that is loaded into any FSC must be within the manufacturer's specifications.

A flammable storage vault is a heavily insulated room capable of storing larger quantities of ignitable liquids safely. All storage areas must be chosen to avoid open flames, radiators and other sources of heat, and electrical devices capable of sparking. Solvents are best stored in an area that is separate from the general workflow. Routine storage in a chemical fume hood is usually inappropriate because the containers will be on a working surface.

Cold liquids are less hazardous than warm liquids of the same composition because the vapor pressure is lower. Storage of volatile solvents in refrigerators and freezers is best avoided, however, because of the possibility of accumulation of vapors. When the door is opened, the concentrated vapors are released and may travel considerable distances along the floor to a point of ignition. Refrigerators that must be used for storage of flammable liquids must be explosion proof, i.e., lack interior electrical switches and have motors shielded from vapors that might accumulate within the refrigerator storage unit.

Instability

Chemicals capable of violent decomposition at normal temperatures and pressures form a separate hazard class. This term is reserved for chemicals that can readily detonate at standard temperatures and pressures. It also applies to substances that react violently or form a potentially violent mixture in water or that are capable of explosive decomposition. Examples are hydrazines and elemental sodium.

Toxicity

This term can refer to almost any substance in quantity. Aspirin, vitamin preparations, and other commonly encountered substances have all caused fatal poisonings. Even water can cause an acute intoxication if sufficient quantities are ingested over a short interval. In the context of laboratory safety, the term is generally applied if a substance that is inhaled, ingested, or contacted in small amounts can cause serious biological effects. Toxicity may be short term or long term. Irritants cause a local inflammatory effect on living tissues at the site of contact. Irritants may be identified as either primary skin irritants or as primary eye irritants or both. A sensitizer is a chemical that can elicit an allergic reaction in a susceptible individual after repeated exposure. Asphyxiants are chemicals that exert an adverse effect by displacing atmospheric oxygen or by preventing the metabolic use of available oxygen. Many gases are asphyxiating in large quantity.

Among the long-term toxins, mutagens are chemicals that can cause a heritable change in genetic material. There are many different test systems to detect mutagenic potential. Those that employ living organisms usually measure the effect of the substance on lower organisms such as bacteria, fungi, or insects. Because of this, the term mutagen is frequently applied to substances that have not been shown to cause genetic changes in mammalian species. Reproductive effects are those that affect fertility, cause developmental abnormalities during gestation, or can have adverse effects on newborns. Tumorigens are substances that have been reported to be associated with benign or malignant tumors. Carcinogens are substances that have been shown to cause malignant neoplasms in valid animal tests (using control animals and appropriate statistical methods) or that have conclusively been shown to cause malignant neoplasms in humans. Authoritative sources include the International Agency for Research on Cancer and the U.S. National Toxicology Program. Neoplastinogens cause tumors that cannot definitely be classified as either benign or malignant.

The mode of contact is an important variable in estimating the toxicity of a substance. Some chemicals may produce serious biological effects after only short-term exposure; such chemicals are termed acutely toxic. Standard tests have been developed to measure and define such acute toxins. The toxicity is usually defined by the dose required to kill 50% of test animals (LD_{50}). The route of administration and the stated dose must be provided, followed by the species of animal in which the substance was tested. The lower the concentration at which toxic effects can be measured, the more toxic the chemical. For example, LD_{50} (oral) is 5 mg/kg, LD_{50} (dermal) is 40 mg/kg, and LD_{50} (inhalation) is 1,000 ppm are descriptions of extremely toxic chemicals.

Restrictions should be applied to the use of chemicals that precipitate the most serious consequences. Chemicals of special concern include acutely toxic chemicals as well as carcinogens and reproductive toxins.

Access to areas in which such chemicals can be found should be strictly limited to those who have specifically been trained to contain the hazards. Mandatory apparel may include gloves, tightly fitting goggles, dust masks, and jumpsuits. Disposable items are preferred. All personnel must thoroughly wash their hands and any areas of skin exposure thoroughly following accidental contact with restricted chemicals.

The American Conference of Governmental Industrial Hygienists (ACGIH) is one useful source for recommendations on chemical exposure limits (25). Sources used by the ACGIH include industrial experience as well as human and animal studies. Two major types of permissible exposure limits (PELs), designated as threshold limits values (TLVs), are recognized by the ACGIH. TLVs based on 8-hour, time-weighted averages are used to denote the permissible exposures for substances to which workers are exposed repeatedly, day after day and week after week, without adverse effect. TLVs based on short-term exposure limits are the concentrations of vapors to which workers can be exposed continuously for brief periods (15 minutes) without experiencing irritation, tissue damage, or narcosis. The OSHA has defined an action level (AL) for selected substances. ALs, generally set at one-half of the 8-hour PEL, are administrative decision points that trigger environmental monitoring or other occupational health undertakings. For regulatory details on a particular chemical, one should first determine whether a specific standard exists [as, for example, formaldehyde (26)]. If not, tables of regulated chemicals exist that list PELs (27).

Chemical spill control materials should be located strategically throughout the laboratory. The simplest material is sand (often mixed with soda ash) that can be applied around a spill as a dike to contain the hazard. The CHP should specify the appropriate decontamination procedure for each class of hazardous chemical. Only emergency response personnel should be allowed in the vicinity. If the vapor level of the spilled substance is dangerous, all persons in the room must wear the proper respirators.

An important source of information about the hazards of a chemical substance is the Material Safety Data Sheet (MSDS). These are OSHA-required documents that are supplied by the vendor. MSDS information includes the chemical name and synonyms, its hazards, proper PPE, suggested medical intervention following acute exposure, and spill cleanup details. The MSDS may be the only source of information for some mixtures and proprietary formulations, but MSDSs should not be regarded as complete sources of authoritative data. Other sources are the Registry of Toxic Effects of Chemical Substances (National Institute of Occupational Safety and Health, Washington, DC) (28), TOXLINE (National Library of Medicine, Bethesda, MD), and Chemical Abstracts Service (American Chemical Society, Columbus, OH).

COMPRESSED GASES

Part of "3 - Laboratory Safety"

All compressed gases are hazardous because of the potential of rupture of the container. Many are also toxic or ignitable. The breakage of the regulating valve of a compressed gas cylinder can propel the cylinder like a missile. A heated cylinder will explode when its ability to contain the growing internal pressure is exceeded.

All but the smallest cylinders should be secured upright. Each cylinder should be labeled indelibly as to its contents. Additional, temporary labels that read “in use” or “empty” may be applied. Cylinders should be moved only with handcarts to which they have been secured. The rolling or dragging of cylinders must be strictly forbidden.

Both gas cylinders and piped systems have pressure-regulating devices. These valve systems are designed separately for each family of gases and must not be interchanged. Valve safety covers must be in place until pressure regulators are attached. Threaded fittings must be tightened carefully with the properly sized wrench. Cylinders and connections should always be tested with a soap solution for leaks after attaching, adjusting, or disconnecting the system. Valves should never be lubricated.

The typical valve system has two components: a high-pressure valve at or near the tank to release the contents and a low-pressure valve at the point of use to regulate the flow. Valves should be opened slowly, and personnel should stand to the side of the gauge as a precaution against blowout. Valves should be maintained in the closed position when the cylinder is not in active use (29).

Flammable gases must be used with special caution. Supplies should be minimal. Only cylinders in active use should be in the work area. The storage facility should be a secured room or enclosure reserved exclusively for that purpose. The location should be away from combustible materials, elevators, stairs, and passageways. Oxidizing gases must be separated from flammable gases. Sources of ignition should be carefully insulated from the emplacement of the cylinders.

Empty cylinders awaiting return to the vendor must be treated carefully because considerable pressure may remain within.

MICROBIOLOGICAL HAZARDS

Part of "3 - Laboratory Safety"

All clinical specimens are potential sources of infection. Human blood and body fluids may carry viruses such as the hepatitis B virus (HBV), hepatitis C virus, and the human immunodeficiency viruses (HIV). Control of hazards of this type is a concern throughout the health care industry (30). Workers in microbiology laboratories face the additional risks of the pathogens that are isolated and cultured.

Development of an exposure control plan (ECP) (31) designed to contain the infectious hazards of the laboratory is highly recommended. Each task or procedure that involves the potential for exposure to infectious agents is to be identified in the ECP. Engineering controls should be introduced wherever feasible to minimize the hazards. Work practice controls should be specified. Required PPE should be clearly identified in the ECP for each hazardous task.

Containment systems must be designed with an understanding of the virulence and the route of introduction of the agent into the body. Ingestion of agents may complicate mouth pipetting. Failure to wash one's hands thoroughly when leaving the laboratory before eating or smoking may introduce agents into the mouth. Parenteral exposure can result from direct inoculation or absorption through the mucous membranes of the eyes, nose, or mouth. Even small scratches and abrasions can allow entry of agents that would otherwise be excluded by intact skin. Contact leading to ingestion of agents or parenteral exposure may be either direct or indirect. Direct contact includes splashes and sprays of infectious fluids. The inadvertent transfer of contaminants from inanimate surfaces such as telephones or keyboards to the face or eyes is an example of indirect contact. Scrupulous attention to good work practices and consistent use of personal barrier protection minimizes the risk of ingestion and contact exposure.

Inhalation of aqueous aerosols and fomites can cause respiratory infections. Aerosols may be formed by dropping solutions onto hard surfaces, by the rapid heating of liquids (including moisture on inoculation loops), and by many other inadvertent motions. Containment is possible with careful technique and by performing all operations that predictably generate aerosols (such as centrifugation and sonication) within a biological safety cabinet.

Biological Safety Cabinetry

Microbiological hazards are best contained within a properly engineered biological safety cabinet (BSC) (32). Class I cabinets operate at negative pressure with a minimum face airflow velocity of 75 ft/min. The air in the chamber is exhausted through a high-efficiency particulate air (HEPA) filter. The front of the class I BSC may be either open or fitted with arm-length rubber gloves. A class II BSC features vertical airflow and interior air that is recirculated through HEPA filters. The chamber operates at a negative pressure with respect to the room identical to an open-front class I cabinet, but the purified air within minimizes contamination of the cultures under study. Class I and II cabinets provide a similar level of personnel safety. Class III cabinetry must be used for the most virulent agents. The chamber is entirely

enclosed. The contents must be manipulated by means of arm-length rubber gloves fitted to the chamber wall. All materials entering and exiting the class III BSC must be autoclaved or decontaminated.

Class I and II cabinets are commonly found in clinical laboratories. Class III BSCs are needed in specialized facilities that culture agents such as *Mycobacterium tuberculosis* or systemic fungi and when production-level quantities of less infectious agents such as human immunodeficiency virus are involved.

Biosafety Levels

The Centers for Disease Control (CDC) and the National Institutes of Health have codified a system of increasing levels of containment for microbiological and clinical laboratories (32). Biosafety level (BSL) I is designed for student laboratories using agents not ordinarily infectious for humans. Work may be conducted on open bench tops. Good laboratory practices include use of pipetting devices, prompt spill cleanup, daily disinfection, and proper waste disposal. Clinical laboratories should routinely follow BSL II precautions. BSL II differs from BSL I in that access to the area should be restricted to exclude untrained individuals and that some procedures such as those that generate infectious aerosols are to be conducted in BSCs. BSL II is effective at containing the infectious hazards of blood-borne agents in clinical laboratory specimens. Routine bacteriological procedures such as plating and preparing smears for staining may be conducted at BSL II. Parasitic investigations, most bacterial studies, and some fungal and viral culture manipulations may safely be contained with BSL II precautions. BSL III is appropriate for laboratories that work with agents that may cause fatal disease after inhalation. Access to the laboratory and airflow is carefully controlled. All procedures must be performed in BSCs or similar devices. Personnel must wear fully protective laboratory clothing. Few clinical laboratories other than those culturing systemic fungi and tubercle bacilli need to follow BSL III containment.

Universal Precautions

Most clinical laboratory activities require the handling of blood or body fluids (9,33,34). The CDC and the National Committee for Clinical Laboratory Standards (NCCLS) have developed a system for worker protection commonly referred to as universal precautions. This set of engineering controls, work practice controls, and use of PPE collectively shields the laboratory worker from the potential of exposure to blood-borne infectious agents.

The primary agents of concern are the human hepatitis and immunodeficiency viruses. The HBV is a DNA virus that, before widespread adoption of universal precautions, was responsible for approximately 12,000 infections in health care workers each year. During acute HBV, the virus is in high concentration in the blood and serous fluids (108 to 109 infectious units per milliliter) (9). One percent (or more) of hospitalized patients are chronic carriers of the virus (35). The virus can survive dried on work surfaces, and contaminated benches and equipment must be properly cleaned and disinfected or sterilized before reuse.

The HIV-1 and HIV-2 are RNA retroviruses spread by means of blood, semen, vaginal secretions, cerebrospinal fluid, serous fluids, and breast milk. The concentration of HIV in clinical specimens is far lower than that of HBV (100 to 102 infectious doses per milliliter) (9). The virus is slowly inactivated by drying (36). Any disinfectant that is capable of inactivating HBV will be effective against HIV because the latter agent is far more susceptible to such treatment.

Other agents are transmissible in blood and body fluids. The viremia associated with hepatitis A is brief and precedes symptoms by several days. There is no chronic carrier state associated with hepatitis A. The hepatitis C virus may be acquired from contact with blood or body fluids in the laboratory. Delta agent or HBV is an incomplete virus found only in the blood of chronic carriers of HBV. Epidemiological studies suggest that other uncharacterized hepatitis viruses transmissible by blood exist. Other blood-borne illnesses that could be transmitted through exposure to clinical blood specimens that contain viable agents include malaria, syphilis, babesiosis, brucellosis, leptospirosis, arboviral infections, borreliosis, Creutzfeldt-Jakob disease, human T-lymphotropic virus type I, viral hemorrhagic fevers, and cytomegalovirus infection.

The concepts of universal precautions apply to all human blood and tissues. Serous fluids such as pleural, peritoneal, pericardial, amniotic, cerebrospinal, and synovial fluids are included. Semen and vaginal secretions are equally hazardous. All other clinical specimens (such as sputum, stool, sweat, urine, tears, gastric contents, and saliva) are of less concern; universal precautions need apply only if such substances contain visible amounts of blood (9).

Personnel must use proper barrier precautions when handling clinical specimens. Latex or vinyl gloves should be worn and changed regularly. Water-resistant gowns, aprons or smocks, and face protection should be added when there is the possibility of splashing or splatters. Additional, watertight, occlusive dressings should be worn over any area of nonintact skin of the hands or forearms. Frequent handwashing throughout the day (especially whenever gloves are changed) is fundamental. All specimens of blood and body fluids should be collected and transported in containers that prevent leakage; any such container that has the potential for exterior contamination must be transported in a leak-resistant secondary container such as a plastic bag. Workers should be careful not to contaminate work surfaces, containers, requisitions, and reports. Visibly blood-tinged stains and spills must be decontaminated as soon as they occur or are discovered. All work surfaces must be decontaminated at the end of each work shift as well. Techniques that avoid the formation of spatters and droplets should be a regular part of new-employee training and continuing education programs. All pipetting tasks must be performed with the use of mechanical devices. Biohazard warning labels should be applied to all containers that contain contaminated items. IW must be packaged and properly destroyed. All sharps must be handled with respect and discarded in puncture-resistant containers. Selection of technologies that employ less hazardous alternatives (such as avoiding the use of sharp implements or substitution of automated for manual methods) is also part of universal precautions.

Human tissues require special handling. All surgical specimens

should be sealed in leak-proof containers within the operating room. Containers with contaminated exterior surfaces must be placed in plastic bags before transport to the laboratory. Frozen sectioning of unfixed tissue requires special care. Most infectious agents are not inactivated by freezing. Freezing of tissue must be performed cautiously; the spraying of tissue with freezing gases under pressure should be prohibited because it may spatter infectious materials. The interior of the tissue cryostat must be decontaminated regularly.

The entire necropsy suite should be considered a biohazardous area. Only those individuals essential to the performance of the examination should be allowed in the area. The individuals at the prosection table should wear full-barrier PPE including face and eye protection, masks, water-repellent clothing, aprons, shoe covers, and two sets of rubber gloves. Steel-mesh gloves are highly desirable. An assistant whose clothing remains uncontaminated should be assigned to circulate in the clean areas of the morgue. All procedures that may spray or spatter blood or tissue must be performed carefully. Electric bone saws, for example, naturally generate aerosols and particulates; the connection of vacuum exhaust to the saws or the performance of such procedures under plastic shrouds help to contain the hazard. All tissues should be fixed at the necropsy table to limit the number of work surfaces that will inevitably be contaminated with blood.

Special precautions apply to the handling of tissues derived from patients with Creutzfeldt-Jakob disease (37). The agent is resistant to inactivation by formalin and other aldehyde fixatives, alcohols, and heat (38). Strict adherence to universal precautions is required. Aqueous sodium hypochlorite (5.25%) (undiluted household bleach) or 2 N sodium hydroxide is effective for inactivating the agents on surfaces. Contact time should be at least 15 minutes (preferably 60 minutes). Discarded fluids and contaminated instruments may be treated by soaking in 5.25% sodium hypochlorite for 1 hour or by autoclaving at 132°C for 1 hour (39).

Decontamination

Any procedure or technology that reduces the infectivity of a substance or material to a safe (noninfectious) level is a decontaminant. Germicide is a general term for any substance that can kill pathogenic agents. A sterilant completely destroys all infectious agents (including viruses, mycobacteria, and bacterial spores). A disinfectant is effective against selected microorganisms. The spectrum of activity of commercial disinfectants can be found on the product label or in the accompanying literature. Disinfectants may not be effective against bacterial spores or mycobacteria. The effective action of all disinfectants requires adequate contact time; therefore, the manufacturer's instructions should always be followed. Sanitizers reduce microorganisms to levels considered safe by public health codes. They are used primarily in the food industry. An antiseptic is a chemical germicide appropriate for use on skin, tissue, or mucous membranes. Sanitizers and antiseptics are not to be relied on as laboratory disinfectants. Table 3.3 lists some common disinfectants and their spectra of activity.

Spilled blood or tissue samples must be cleaned up and the area decontaminated. Cleaning personnel must wear and use proper PPE. Forceps or scoops should be employed to remove broken glass without the need for manual contact. The bulk of the spill is absorbed onto paper towels, and the towels are properly discarded as IW. Proteins and lipids in the stain can inactivate chemical disinfectants or form a barrier around infectious agents. Therefore, the residuum is next cleaned with detergent and water. After all visible blood has been removed, an appropriate disinfectant is applied. A freshly diluted, 1:10 solution of household bleach (5.25% aqueous sodium hypochlorite) suffices. Iodophors formulated as hard-surface disinfectants may also be used. Aldehydes (as aqueous glutaraldehyde or formaldehyde) and phenols are also effective but are toxic; such substances should only be used in areas of adequate ventilation or with the aid of a chemical fume mask.

The decontamination of laboratory instruments should be a regular event. The frequency of application depends on the intensity of use. Maintenance personnel should wear gloves during all such activities. Additional equipment should be donned for special tasks. Steel-mesh gloves are needed for cleaning microtome knives, and facial protection is important when working with pressurized devices. Accidental spills within instruments must be cleaned and disinfected promptly. Exposure potential can be minimized by sensible technique. Breakage of sample tubes within a centrifuge is an example. The O ring on the lid and the buckets should seal tightly. The rotor must be allowed to come to a full stop and 30 minutes or more should elapse before opening the lid; this allows airborne droplets to settle. Glass shards are removed with forceps. The interior may then be wiped down with detergent and disinfectant. The preferable routine is to use centrifuge cups that are equipped with tightly fitted lids; broken glass and blood will be confined to a single cup (40).

Accidental Exposures and Immunizations

All susceptible clinical laboratory workers who frequently are exposed to blood or tissue should be vaccinated against HBV (41). HBV vaccine is synthesized from recombinant DNA. Three intradeltoid injections are required, the second and third after 1 month and 6 months, respectively. The vaccine is not required for individuals who are known to have adequate titers of antibodies to the hepatitis B surface antigen.

Vaccines for immunoprophylaxis are available for workers who are regularly exposed to specific agents of virulence. Inactivated or live, attenuated vaccines may be considered for veterinary laboratory workers (e.g., anthrax, tularemia, Q fever) or for workers in specialized public health laboratories (e.g., polio, yellow fever, equine encephalitis). All susceptible women of childbearing age who work with rubella should be vaccinated against this virus.

Plans for medical treatment after accidental exposures should be written in the laboratory's policy manual. Immediate treatment can prevent or mitigate an infection. The infectivity of the source and the susceptibility of the injured worker determine the type of therapy and the dosage schedule. For example, an unvaccinated individual exposed to HBV would be treated immediately with hepatitis B immune globulin and then begun on the HBV vaccine series.

There is no commercially available vaccine for HIV, but immediate

prophylaxis with zidovudine and lamivudine may be effective (42). (For this and all prophylactic and therapeutic decisions, the current recommendations of the CDC should be consulted. These are available through hospital departments of infection control and public health clinics.) After acute exposure, the infectivity for HIV should be determined by testing the source material for HIV antibodies (or HIV antigen or HIV DNA). Testing the exposed worker for antibodies to HIV at the time of exposure will allow detection of postexposure seroconversion. Seronegative workers should be followed for seroconversion for at least 6 months (e.g., at 6 and 12 weeks and 6 months). The results of all such studies must be followed by knowledgeable counseling.

RADIATION HAZARDS

Part of "3 - Laboratory Safety"

Ionizing radiation can be one of the most toxic sources of exposure to personnel in the laboratory. Acute exposures can lead to lymphocytolysis, bone marrow suppression, skin damage, and damage to enteric epithelia. Low-level exposure can produce genetic damage to germinal and somatic tissues leading to birth defects and neoplasms. Sources of radiation hazards in the laboratory include both medical devices and reagent materials.

Medical devices that generate ionizing radiation must always be used according to the manufacturers' instructions. Policies should be established to restrict the access of untrained individuals to the areas of radiation hazard. If the source is potent, continuous monitoring of the room to ensure that the shielding is intact is advisable. Moving or repairing the device must be done under the guidance of expert technicians who are skilled in radiation containment.

The radionuclides found in laboratories are generally limited to tracer chemicals that are of insignificant hazard unless ingested or absorbed. The same good laboratory techniques that effectively contain infectious hazards will limit personal exposure to soluble radionuclides. Gloves should be worn when handling radioactive materials, and handwashing after glove removal is to be emphasized. Any manipulation that might lead to hand-to-mouth or hand-to-mucous membrane transfer must be prohibited. Workbenches should always be covered with an absorbent paper toweling, to be changed at the end of each shift (or after overt contamination) and properly discarded.

Reagent nuclides include beta emitters (e.g., ^{3}H, ^{14}C, ^{32}P, and ^{35}S) and gamma emitters (e.g., ^{51}Cr, ^{125}I). Alpha particles are emitted by heavy elements and are unlikely to be found in clinical laboratories. Low-energy beta emitters such as ^{3}H or ^{14}C will produce adverse health effects only if ingested or absorbed; higher energy beta emitters such as ^{32}P can produce significant skin exposure. Gamma and radiographic emissions are penetrating and can cause biological damage without contact. The amount of radiation to which an employee may be exposed is specified by law (43), but the general principle is that exposures be maintained “as low as reasonably achievable” (ALARA) (44). The U.S. Nuclear Regulatory Commission expects employers to have an operational ALARA program.

Warning signs that indicate the presence of radioactivity should be posted in all areas where radionuclides are stored, used, or discarded.

Regulations of the U.S. Nuclear Regulatory Commission and

TABLE 3.3. DECONTAMINANTS AND THEIR SPECTRA OF ACTIVITY

Decontaminant	Concentration of Active Ingredient	Temperature (°C)	Contact Time (min)	Vegetative Bacteria	Lipo Viruses	Tubercle Bacilli	Hydrophilic Viruses	Bacterial Spores
Autoclave (saturated steam)	(15 lb/in^2)	121	50–90	+	+	+	+	+
Autoclave (saturated steam)	(27 lb/in^2)	132	10–20	+	+	+	+	
Dry heat oven	—	160–180	180–240	+	+	+	+	+
UV irradiation (253.7 nm)	40 $\mu W/cm^2$	—	10–30	+	—	+	±	—
Ethylene oxide	400–800 mg/L	35–60	105–240	+	+	+	+	+
Paraformaldehyde (gas)	0.3 g/ft^3	> 23	60–180	+	+	+	+	+
Quaternary ammonium compounds	0.1–2%	—	10–30	+	+	—	—	—
Phenolic compounds	0.2–3%	—	10–30	+	+	+	±	—
Chlorine compounds	0.01–5%	—	10–30	+	+	+	+	±
Iodophor compounds	0.47%	—	10–30	+	+	+	±	—
Alcohol (ethyl or isopropyl)	75–85%	—	10–30	+	+	+	±	—
Formaldehyde (liquid)	4–8%	—	10–30	+	+	+	+	±
Glutaraldehyde	2%	—	10–600	+	+	+	+	+
Hydrogen peroxide (liquid)	6%	—	10–600	+	+	+	+	+

+, very positive response; ±, less positive response; —, negative response or not applicable.

the Canadian Atomic Energy Commission specify procedures that must be followed when shipping and receiving radioactive materials. The individuals responsible for radiation safety in the clinical laboratory must be aware of the applicable regulations and incorporate them into the policies and procedures. Recommendations of this chapter for this reason may be superseded by governmental requirements. All shipments received should have the date and time received, the method of shipment, the condition of the package upon receipt, and the amount and type of radionuclide contained within recorded. Damaged packaging should be checked for contaminating radiation. A leaking package should be sealed in a plastic bag and secured. All areas that may have been contaminated should be surveyed and decontaminated as necessary.

Thermoluminescent dosimetry badges or film-badge dosimeters are suggested for all laboratory workers who are exposed to gamma irradiation, although their use with the usual low-level amounts of tracers found in clinical laboratories is optional. The type of badge device should be chosen by a knowledgeable radiation physicist or safety officer and should be based on the specific type of exposure anticipated.

All workbenches, refrigerators, and other storage areas should be checked regularly for signs of contamination. The most useful surveys are performed immediately after completion of a task; this allows estimation of maximal exposure. Surface activity should be below 200 disintegrations per minute (dpm) per 100 cm^2 (45). Work areas should be surveyed for contamination regularly. This may be performed with a typical survey rate meter. Acceptable levels are usually two to three times background. An alternative is to wipe the work areas with sponges soaked in alcohol or aqueous detergent. The sponges are wiped vigorously over a 100-cm^2 area of the contaminated surface, placed in a counting vial, and read on the usual analytic instrument.

Spills and Cleanup

Personnel engaged in decontamination must wear gowns or coats, aprons, gloves, and eye protection. Disposable items are strongly preferred over clothing that requires laundering. The contaminated area should be scrubbed with water and detergent (preferably using a cleaning compound designed for radiation decontamination). After the area is cleansed, it should be checked for residual radioactivity. The process must be repeated if the radioactivity is greater than three times the background or more than 200 dpm. All disposable materials involved in the cleanup must be discarded as radioactive waste unless survey measurements have indicated the amount of radiation remaining in the materials to be less than twice background. Each spill incident and decontamination episode should be carefully documented. Personnel involved should be advised to seek medical evaluation if the exposure was significant.

FIRE PREVENTION AND CONTROL

Part of "3 - Laboratory Safety"

There are multiple sources of combustible materials in the clinical laboratory. These include ignitable liquids and flammable gases as well as paper and wood construction materials. The laboratory must be designed to minimize these hazards. It is prudent to train personnel to intercede as soon as possible in a fire emergency because fires are most easily extinguished when still small. Emergency evacuation may be necessary to prevent injury to personnel; therefore, plans to clear each location within the laboratory should be made beforehand and explained to the staff. Laboratories located within hospitals are potential sources of ignition that may place bedridden patients and visitors at risk.

The working supplies of all ignitable materials should be minimal. Only modest amounts of reserve supplies should be kept, and these should be stored in proper flammable liquid storage cabinets or vaults. Safety cans should be used for all bulk storage of 5 gal or less in which the steel or polyethylene container will not compromise the purity of the solvent.

All potential ignition sources should be identified and controlled. Obvious sources include open flames and heating elements, but the most common sources are sparking within an electrical switch or motor (46). Static discharges are preventable sources of ignition; grounding of metal containers during transfer of combustible liquids will prevent sparking. Exothermic chemical reactions may also generate sufficient heat to ignite a fuel source. Clear separation of flammable materials from such ignition points is indicated.

The laboratory should be designed for fire protection. Walls and doors should be constructed to contain a conflagration until fire fighting equipment and personnel can be mustered. (In general, this specifies that walls be rated at 1 hour and door assemblies at 45 minutes.) Fire exits must be provided for emergency evacuation of personnel. Rooms that have an area larger than 1,000 square feet and all rooms in which flammability concerns are present should have at least two doors that open to exit corridors or to the outdoors.

A fire alarm system should be located in or near the laboratory. This may be a bell or public address system, but it must be audible in all areas of the facility, including storage areas, darkrooms, and lavatories.

Portable fire extinguishers should be located wherever significant fire hazards exist. Class A devices are appropriate for wood and paper fires, class B devices for ignitable solvents, and class C devices for electrical fires (33,47). Three types are commonly found in clinical laboratories: organic halogen gas, carbon dioxide, and dry chemical. Each is effective against solvent and electrical fires; the label on the device will specify the rating of the unit. Extinguishers using organic halogens are rapidly effective. They are most commonly found in electrical applications such as computer rooms because their vapor will not damage delicate equipment. Carbon dioxide acts by smothering and cooling a fire. Devices of this type are equally rapid but may cause thermal damage to instruments in the vicinity of use. Both types should be used only in well-ventilated areas or by a person wearing a SCBA. Dry chemical types are the least expensive. They are particularly effective against oil and grease fires, but cleanup is laborious and equipment damage can be expected. Water-based extinguishers are effective only against class A fires and should not be used in clinical laboratories. The size of the device should be large enough to extinguish a small fire without being too large for any of the personnel in the work area to manipulate.

Laboratory personnel should practice their responses to fire situations. Training sessions should emphasize sounding the alarm as the first action. Attempts to extinguish the fire should follow, but only if the proper devices are immediately available and the fire appears small enough to manage. Evacuation of the area may be necessary. Employees should be trained to close doors and windows as they leave by the designated exits.

All personnel working in hazardous areas should be trained to use the types of portable fire extinguishers chosen. There is no substitute for hands-on experience. Fire exit drills should be held regularly. Each employee should know the preferred and the alternate exit route for his or her workstation well enough to be able to find them in a darkened, smoke-filled atmosphere. Exit drills should be held at least once a year for the benefit of all employees.

ELECTRICAL SAFETY

Part of "3 - Laboratory Safety"

Electrical hazards are among the most difficult to detect in clinical laboratories. Shock hazards can develop in any electrical instrument or appliance. The laboratory should be surveyed at least once a year as part of an electrical safety inspection. All new instruments should be thoroughly inspected before being placed into service.

The preventive maintenance program should include regular safety inspections of all portable electrical devices by a qualified individual. The power supply cable must be checked for frayed or cracked insulation and for broken wires. Electrical equipment must be properly grounded, i.e., the power cable must be of three-wire construction and the neutral (green) wire must be in electrical continuity from the power supply chassis to the receptacle. (An exception may be made for a device that is doubly insulated or totally encased in plastic.) Attempting to ground electrical appliances to cold-water plumbing may be ineffective.

A qualified electrician should check instruments for current leakage with the ground open. The manufacturer's specifications should be used to determine the maximum allowable current for this test. When such specifications are not provided, a 100-mA current may be used to test most devices.

Electrical receptacles should be checked for ganged plugs, loose fittings, and broken faceplates (48). Electrical tests for polarity and ground continuity should be performed annually. Ground fault circuit interrupters must be installed in “wet” locations. Faulty and potentially unsafe equipment must be removed from service or locked and tagged to prohibit use until repairs have been completed.

Electrical equipment used in areas wherein ignitable vapors might accumulate should be designed and approved for such uses. Examples include flammable liquid storage vaults and applications that require heating of flammable and combustible solvents.

The safety-training program should anticipate electrical accidents. All personnel should know that the first response is to disconnect power to the arcing or burning equipment if it can be done without personal risk. This is especially important for individuals working in the vicinity of high-voltage devices, such as those used for electrophoresis.

SPECIALIZED EQUIPMENT

Part of "3 - Laboratory Safety"

Hazards may accompany any new item of laboratory equipment. Items that have moving parts, thermal elements, pressurized components, or radiant energy may be of particular concern. The manufacturer's instructions that accompany such devices must describe the particular risk and make recommendations for worker protection.

Centrifuges that have large rotors are mechanical hazards. Hair or clothing can become entangled in the mechanism if the centrifuge is allowed to operate with its cover open. Unbalanced cups and broken glass can be especially dangerous. All centrifuges should be fitted with a lid that is connected to a power-interruption switch to prevent operation with the rotor exposed. Spinning rotors must never be slowed or stopped by manual means.

Autoclaves must be operated by trained and knowledgeable individuals. Steam under pressure and heated to temperatures above the normal boiling point of water presents risks of scalding and explosion. The installation and fittings should be examined periodically by a stationary engineer. The pumps and valves should be inoperable when the door is unsecured. The door latch should be automatically disabled after operation until the interior temperature and pressure conditions permit safe access. The personnel who unload the chamber should wear heat-resistant gloves, aprons, and face protection.

A cryogenic liquid is any liquid with a boiling point of less than -130°F (-90°C). The extreme cold of such liquids can freeze tissues—including the fingers of careless workers—instantly. All give off large volumes of gas as they vaporize. For example, liquid nitrogen expands 700-fold as it boils at standard temperature and pressure. Inserting tissues or instruments into a cryogenic liquid will cause it to boil; careful technique and good ventilation are essential. All exposed skin must be covered when working with cryogenic liquids. Insulated gloves should be loose fitting so that they may be removed quickly if liquid is spilled within them (49).

Cell-sorting devices used for unfixed cells can expose the operator to infectious droplets and aerosols. Specific recommendations for minimizing this hazard are available (50). Laser devices may require the operators to wear special eye protection. Electrothermal heating devices may introduce radio frequency wave hazards to pacemaker wearers. It is not possible to list all of the possible hazards within this chapter. No piece of equipment should be placed into service until the special hazards have been defined, appropriate engineering controls have been installed, the requisite personal protective equipment provided, and personnel have been appropriately trained.

HAZARDOUS WASTE DISPOSAL

Part of "3 - Laboratory Safety"

Nearly all laboratory processes result in discarded solutions or materials. Much of it is hazardous (approximately 80 lb/1,000 ft^2 of chemical wastes and approximately 1 ton/1,000 ft^2 of biohazardous waste per year) (51), but all of it must be disposed of safely. Proper disposal implies protection of the workers who will handle the waste as well as consideration of the environment (52).

Waste may be discharged into water, buried, burned (or otherwise destroyed), or transformed for reuse. By U.S. law, the containment or destruction of a hazardous solid waste forever remains the responsibility of the generator regardless of any assistance in handling, transporting, treatment, or disposal of the waste.

Chemical Wastes

According to EPA regulations, chemical wastes may be hazardous because of the properties of ignitability, corrosivity, reactivity, or toxicity. Ignitable wastes include liquids (e.g., acetone, alcohols, toluene, xylene), gases (e.g., hydrogen, propane, butane), or solids (e.g., nitrate salts, peroxides). Corrosives include strong acids and alkalis. Examples of reactive wastes are dry picric acid and aged diethyl ether that contains peroxides. Toxicity is currently defined by the ability to generate dangerous leachates that can contaminate ground or surface water and by lists of specific chemicals.

Hazardous chemical waste (HCW) should not be mixed with each other unless one knows the compounds to be compatible. Likewise, they should not be mixed with nonhazardous waste, radioactive waste, or IW. Each type of HCW should remain segregated throughout transport, storage, and disposal. All workers must use appropriate PPE when handling HCWs.

A safe area for accumulation of HCW materials before transport will be well ventilated, secure from unauthorized access, surrounded by a berm or catchment basin, and provided with proper fire protection. HCWs should not be allowed to accumulate onsite for longer periods than necessary or in excessive amounts. The same principles of safe storage that are appropriate for the parent reagents apply to discarded chemicals: incompatible chemicals must be separated, and all waste containers must be properly labeled as to content and initial date of accumulation. Unlabeled containers of hazardous waste must be treated as hazardous.

Some HCWs may be treatable onsite. Examples include neutralization of acids and bases or precipitation of inorganic metal cations as sulfides. Such activities should only be performed under the direction of a knowledgeable chemist. Other HCWs may be reclaimed for reuse: organic solvents may be distilled; silver may be extracted from photographic darkroom wastes, for example. HCWs should never be discarded into ground water or in natural waterways. All chemicals introduced into the sanitary sewage system must be compatible with the treatment processes of the local publicly owned treatment works.

Infectious Wastes

Wastes capable of transmitting an infectious disease may come from (a) cultures and other discards from microbiological laboratories; (b) human blood, body fluids and tissues, and items contaminated with blood; and (c) contaminated animal carcasses and bedding. Control of the hazards of IW is an occupational health issue (52).

In microbiological laboratories, IW should be handled according to the BSL appropriate for the etiologic agents under study. In all clinical laboratories handling blood and body substances, universal precautions apply.

Packaging materials must be of sufficient strength and integrity to protect all who must handle the containers. Bags should be red or orange or display the universal biohazard symbol (Fig. 3.3). Contaminated sharps must be in puncture-resistant containers; liquid wastes must be in leak-resistant packaging.

Most IWs will be accumulated before disposal. The storage site should have limited access and be protected from rodents or other vermin that could become disease vectors. Steps should be taken to prevent putrefaction, including temperature control and short storage duration. Handling and transport methods must maintain the integrity of the packaging.

Some IWs, such as microbiological cultures, must be treated before disposal. Steam sterilization is preferred. The adequacy of decontamination depends on the exposure time; the temperature; the size, density, and water content of the load; and the penetrability of the containers. Autoclaving operations must be monitored periodically with a biological indicator (or chemical equivalent) that is placed inside a sealed package near the center of the load. Other treatment methods include dry heat sterilization, gas vapor sterilization, and chemical disinfection. The method chosen must be one that is effective against the agents known to be included in the IW.

Radioactive Wastes

All radioactive waste handling must be consistent with the regulations and license under which the laboratory operates. General principles include segregation of such wastes from the normal trash in a properly labeled, designated area. Radionuclides with a short half-life, such as ^{32}P and ^{125}I, may be allowed to decay in a protected area onsite and be discarded as nonhazardous refuse. Materials that cannot be allowed to decay in storage, such as ^{3}H, ^{14}C, and ^{35}S, may be released into the sanitary sewer system or into the atmosphere (as a gas or via incineration) in modest quantities as limited by law. Transfer of radioactive materials to offsite locations for burial or long-term storage is discouraged.

Sharps

Discarded needles, lancets, scalpel blades, Pasteur pipettes, capillary tubes, and shards of glass and plastic can cause penetrating injury (53). Infectious agents contaminating waste sharps can gain a portal of entry into the body through a puncture wound.

All sharps should be discarded immediately into a rigid vessel that resists both leakage and puncturing. Such containers should be located in every work area in which waste sharps may be generated. (This encourages proper disposal and precludes the need to carry pointed items any distance.) The containers should be clearly labeled to warn handlers of the potential for injury. Containers must not be allowed to overfill; injury can result from forceful insertion. Infectious sharps should be treated before disposal. All sharps should be destroyed to prevent injury to waste handlers. Destruction methods include incineration, grinding, shredding, crushing, and melting.

Waste Disposal

The laboratory director must be aware of the disposal processes that are used for all wastes generated by the facility. The methods must comply with all federal, state, and local regulations. With regards to HCWs, federal law identifies the generator as responsible for all personal and environmental injury that may ultimately develop, i.e., transfer of the waste does not transfer the generator's liability.

Incineration is the best overall disposal method, but the incinerator must be able to accommodate the materials in the waste mixture. HCWs should be burned only by appropriately licensed facilities. Incineration is both a treatment and a disposal method for IWs and sharps, but the large proportion of chlorine-containing plastic in the typical IW mix may require special incinerator design. Burial in a landfill should be considered only for nonhazardous wastes. Sewer disposal is appropriate for most aqueous liquid wastes but not for any materials that might interfere with processes in the water treatment facility.

Waste Minimization

All laboratories should develop a program for reducing the generation of hazardous waste. Waste minimization can be achieved either by reducing the volume of hazardous wastes generated or by reducing the degree of hazard of the waste generated. The volume of HCWs can be reduced by (a) substituting less hazardous chemicals in laboratory operations, (b) decreasing the amounts of reagents required by adopting micromethods, (c) recovering spent materials for recycling, and (d) redistributing surplus or unwanted chemicals to laboratories that can use them.

Reduction in the amount of IW generated is best achieved through proper segregation of such waste. The mixture of a small quantity of an IW with a large quantity of non-IW generates a large quantity of IW. Segregation must be performed at the point of generation. All IW must be inserted into the proper packaging, and noninfectious refuse should be kept physically separated to focus the waste handlers' attention on the materials of greatest concern.

Contingency Planning

Spill containment and cleanup procedures must be defined and specified for each type of hazardous waste generated by the laboratory. Fires, explosions, or other unexpected releases that may involve the health of individuals outside the facility or that may contaminate surface water in the vicinity must be included in the plan.

Record Keeping

Hazardous waste manifests must be completed and maintained as required by law. Injuries involving wastes must be reported as required to governmental agencies and to the facility's safety program for quality assessment and improvement.

EMERGENCY PLANNING

Part of "3 - Laboratory Safety"

The laboratory's safety policies manual should define the appropriate actions and responses in case of unforeseen emergency. The types of situations that must be included in the planning will vary with the nature of the laboratory, its equipment, and the materials that it stores. Emergency planning should take into consideration employees, patients, visitors, and the special needs of persons with disabilities.

Power Failure

Loss of electrical power incapacitates a modern clinical laboratory. Emergency lighting must be provided to enable workers to move about the premises safely and to facilitate egress if unsafe conditions prevail. Air-handling devices require electrical power. The exhaust fans in chemical fume hoods and BSCs may shut down in a power failure; all processes that must be performed in such cabinets must cease until power is restored. Laboratory policy should prohibit the use of any equipment that cannot be manipulated safely under conditions of emergency power.

Fires

Fire emergency preparedness is discussed in the section on Fire Prevention and Control.

Natural Disasters

Tornadoes, floods, and similar disasters may devastate the facility. Clinical operations must not be restarted until qualified inspectors have ensured the safety of the workers. Unauthorized individuals must not be allowed premature access to the premises. The building must be structurally sound. Electrical equipment that is not designed for wet locations must be disconnected until all water has been removed. Damaged containers of chemicals must be properly gathered and removed. Potentially infectious materials must be bagged, decontaminated, and safely discarded. In locations where earthquakes are known, movable equipment should be secured to walls or countertops.

Spill Cleanup

All hazardous materials can be spilled, and appropriate provisions must be made for each. All individuals who work in an area should have sufficient understanding of the basic medical, chemical, radiation-related, or infectious problems that can occur there to be able to recognize an emergency and to call for help. Small spills can often be safely cleaned by the spiller following written instructions. Larger spills require the intervention of specially trained personnel.

Medical Emergencies

Laboratories that deal directly with patients must be prepared for clinical crises. Individuals trained in basic cardiopulmonary resuscitation should be immediately available. If emergency supplies

of drugs and equipment are maintained onsite, a program to ensure the freshness of the medications and the proper functioning of the gear must be provided. If all emergency medical care is provided at or by remote facilities, the response time should be brief enough to minimize clinical complications.

Electrical shock injury may result in loss of consciousness. First responders should be trained to approach the victim with caution. The source of the electrical discharge must be inactivated if it can be identified. Power to the defective appliance should be cut, preferably at the junction box, or the device can be pushed away with a wooden broom or another nonconductive implement. Cardiopulmonary resuscitation should be initiated if the individual is not breathing, and emergency response personnel should be called.

The laboratory's CHP includes the assessment of the health effects of all hazardous chemicals. Spills or other acute releases may expose workers to toxic vapors. The CHP should specify the criteria for medical intervention. Such criteria may be based on signs or symptoms of overexposure or on environmental measurements. Splashes or sprays of toxic chemicals may result in exposure by absorption through the skin or mucous membranes. All such incidents should be documented, and medical treatment should be provided according to the CHP.

Similarly, the laboratory's infection control plan should specify the criteria for referral of employees who have been accidentally exposed to infectious agents.

Bomb Threat

Telephoned threats of bombing or other malicious acts should be included among the facility's emergency planning. All such calls should be taken seriously. The police or security services should be notified immediately. The caller should be kept on the line, and all details of the call recorded. The police may direct evacuation of the facility, and if so, the exit should proceed in an orderly manner.

EMPLOYEE TRAINING

Part of "3 - Laboratory Safety"

All personnel must have the information and skills to control the hazards in their environment. Training programs are required under many governmental regulations and for accreditation by various voluntary agencies. The basic elements of a safety-training program are (a) content, (b) target audience, (c) educational methodology, (d) documentation, and (e) monitoring for effectiveness.

Content

All safety policies should be included in the training program. The program for each employee should include the particular hazards applicable to his or her job. The program must give the employee sufficient information to understand the hazards. The controls provided by the laboratory director to contain those hazards must be included, and the requisite work practices must be emphasized. Employees must know how and when to use personal protective devices. Chemical handling, infectious exposures, waste disposal, and emergency preparedness are requisite subjects. The material should be presented in a manner consistent with the educational level, literacy, and language background of the people to whom it is presented.

Employee right-to-know regulations are exemplified at the federal level in OSHA's Hazard Communication Standard (54). Such regulations typically require the employer to provide the employees access to copies of the regulations and to the facility's safety plans. Chemical hazards may be summarized in the CHP, referencing MSDSs and other suitable sources. Training that accompanies a comprehensive ECP will provide employees with information on infectious hazards, methods to contain those hazards, and emergency medical intervention to be initiated in case of an exposure.

Target Audience

All employees who handle or are exposed to hazardous materials must be included. Training is necessary for newly hired employees, for individuals assigned to new work areas, and periodically to familiarize all employees with technological and policy developments. Training must be implemented when new hazards are introduced into the workplace and when policies or programs are changed. Periodic refresher briefings of existing policies for all employees are strongly recommended.

Teaching Methods

Most safety training will be in lecture format, but consideration of hands-on activities is suggested. The operation of portable fire extinguishers, tight-fitting respirators, and spill containment is best presented in safety workshops. Some of the most effective programs are those that encourage workers to suggest safer alternatives to current practice.

Documentation

The date, title, and a summary of each safety presentation should be recorded. Attendance should be documented in each individual's employment records.

Monitoring and Evaluation

The educational plan should provide assurance that all-important aspects of the safety program are included. Attendance by the individuals in the targeted audience must be recorded to ensure that no one is inadvertently excluded. The effectiveness of the program should be tested in an objective manner. Although this may be provided by a multiple-choice test or other academic tool, the best feedback is provided by assessment of resultant on-the-job behavior.

IMPROVING THE SAFETY PROGRAM

Part of "3 - Laboratory Safety"

There is no clinical laboratory that is so safe that it cannot be made safer. A periodic safety audit should be undertaken by the safety committee to assess the needs of the personnel. A checklist

should be constructed from the facility's safety manual to provide a useful tool for this audit. (For an example, see reference 2.) The audit should provide a description of the physical facility, including housekeeping, warning signs, fire prevention and preparedness, electrical safety, storage of compressed gases and chemicals, and containment of infectious and radioactive hazards. The condition of the equipment and its maintenance should be assessed. It is equally important, although perhaps more difficult, to determine the prevailing attitudes of the employees toward safe work practices and their compliance with existing policies. Required documents of the program should be evaluated for completeness.

The role and effectiveness of the safety committee should be reviewed annually. Minutes of the meetings should convey thoroughness and attention to detail. The review of incident and accident reports, whether required by OSHA or not, should be documented. Formal inquiry and follow-up of serious accidents or repetitive problems are essential. Reports prepared for governmental agencies, such as hazardous waste manifests, should be monitored by the safety committee or the laboratory's administration for adequacy and timeliness.

Reports of external reviewers can be especially helpful in assessing the safety program. Safety audits may be provided by governmental inspectors (e.g., OSHA, Nuclear Regulatory Commission, licensing agencies, fire departments) and by voluntary programs (e.g., College of American Pathologists, Joint Commission on Accreditation of Healthcare Organizations, industrial risk insurers). Each itemized area of concern or recommendation is a potential opportunity to improve the safety program.

The program's action plan should prioritize the identified issues of concern according to the types of problems uncovered, their frequency and severity, and the probability of their recurrence. The effectiveness of all measures taken as a result should be assessed after a suitable period of follow-up.

A successful safety program is the result of the combined efforts of everyone in the laboratory. Each individual in the laboratory should contribute to the total effort. The administration of the facility must make a statement of commitment to the goal of a safe workplace. The authority for implementing the program must be vested in the responsible supervisory personnel. Job descriptions should be concrete with regards to employees' responsibilities to comply with safety policies.

The administration must provide a proper training program for all its employees, both those new to the organization and those whose formal training preceded the introduction of current technology. Employees must bring to the attention of the management any identified but unsafe working condition as well as perceived opportunities to improve general safety conditions. Senior managers should be responsive to suggestions for improving the safety program. The attitudes of laboratory workers toward safety practices should be positive.

Work groups inevitably set their own safety standards; management cannot force employees to work safely (55). An ongoing program of audit for compliance with defined policy is important. This is a function that can (and should) be integrated with other quality assessment and improvement activities within the organization.

The Interpretation of Laboratory Tests

Earle W. Holmes

Laboratory tests and the principles on which they are based are a major focus of the discipline of laboratory medicine. The value of laboratory testing to patient care is evident both by the sheer volume of tests that are ordered and by the high level of confidence that clinicians place on laboratory data. This chapter is intended to address the interpretation of laboratory test results, that is, the act of discerning the significance or meaning of a particular test result in the context of the medical question or hypothesis that the ordering clinician is attempting to address. Interpretation is the penultimate, and arguably the most critical, component of a complex series of events that I refer to as the testing cycle (Fig. 4.1). The testing cycle begins and ends with a patient who presents with a medical problem and expects to receive a diagnosis or a prognosis and some type of intervention or treatment. When laboratory testing is required for the further evaluation of a patient, the clinician expects the testing cycle to generate high-quality laboratory information that will facilitate the process of clinical decision making. Under ideal circumstances, all components of the testing cycle will have been optimized to minimize variability and error, and the interactions between the clinician and the laboratory will be free from any confusion or misunderstanding regarding the medical significance of a particular test result. However, in practice, the testing cycle is influenced by many factors that increase the uncertainty associated with a test result and thereby decrease the accuracy of the information that it provides.

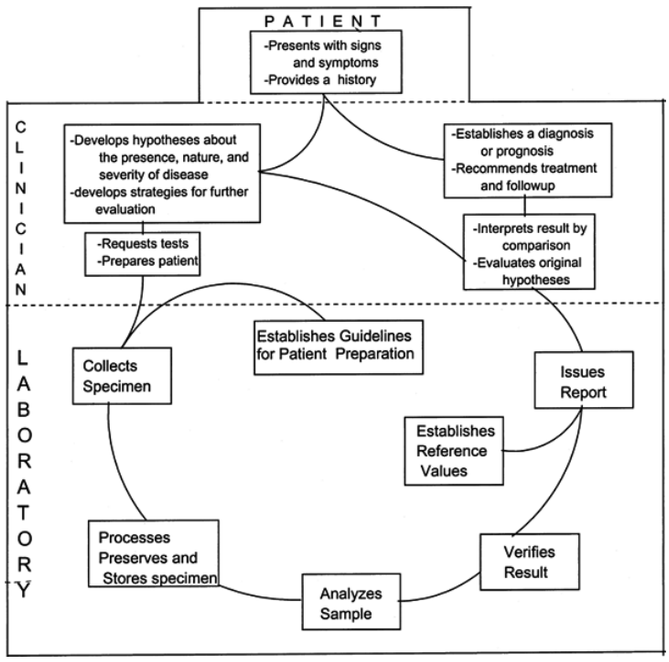

FIGURE 4.1. The testing cycle. The ultimate significance of a laboratory test result depends on a complex series of actions and interactions on the part of the patient, the clinician, and the clinical laboratory. The cycle progresses in a counterclockwise direction.

Factors that have the potential to confound the interpretation of test results occur at all levels of the testing cycle (1). For example, a major source of uncertainty that operates at the patient level is biological variability in the values of laboratory parameters (hereafter referred to as analytes). Variability within the clinical laboratory can enter the cycle during the pre- and postanalytical phases of testing as a result of improper or inconsistent specimen collection or preservation or by the provision of inappropriate or inadequate reference values (RVs) in the laboratory report. Other sources of variability that operate during the pre- and post-analytical phases of the testing cycle and that are largely in the hands of the clinician include the improper or inconsistent preparation of the patient before sample acquisition and the suboptimum selection of laboratory tests relative to the clinical questions that are under evaluation.

Over the past two decades, a great deal of attention has been focused on the analytical variability of laboratory methods. This attention has led to tremendous increases in the quality of test results because of improvements in the precision and accuracy during the analytical phase of the testing cycle. At present, most experts recognize that analytical variation is only a small fraction of the overall variability of most laboratory tests (2). Thus, attention has rightfully shifted to addressing some of the nonanalytical factors that continue to affect the quality and value of laboratory information (3). Specialists in laboratory medicine should become familiar with both the analytical and clinical aspects of laboratory testing so that they are better able to design and implement procedures that reduce variability across the testing cycle and to serve as consultants in the evaluation of unusual or unexpected laboratory results. This chapter deals with three topics of great relevance to the interpretation of laboratory test results: the effects of biological variability on laboratory tests, the establishment and use of RVs, and the evaluation of the diagnostic accuracy of laboratory tests.

BIOLOGICAL VARIATION

Part of "4 - The Interpretation of Laboratory Tests"

Biological variation in laboratory test results is owing to within-subject variation over time and subject-to-subject variation within a population. The principal cause of the former is the existence of endogenous biorhythms for many physiologic parameters, whereas the latter is usually owing to differences among subjects in constitutional factors and/or lifestyle (Table 4.1). Because the principle behind the interpretation of most laboratory tests is to ascribe unusual or extreme test results to the presence of disease, biological variation interferes with interpretation when its magnitude is similar to that observed in diseased subjects. Because small abnormalities in laboratory values are often observed during the early stages of the evolution of disease, biological variation is not only a potential source of false interpretations but can also reduce the diagnostic efficiency of a laboratory test by widening the test's reference interval (RI). Theoretically, the negative effects of biological variation can be minimized through the use of appropriate state-specific RVs; however, the large number of potential sources of biological variation precludes the establishment of RVs that are able to simultaneously account for more than one or two factors. For this reason, it is

crucial that laboratorians and clinicians know how biological variation influences a particular test result and to evaluate the significance of the result in view of this knowledge.

Intercurrent illness

There is a large and complicated literature describing effects of specific biological variables on specific laboratory tests. In many cases, the data for a particular interaction between a variable and a laboratory test are based on the investigation of small samples of subjects. In other cases, conflicting data exist for a particular test–variable interaction. The present review is intended to summarize some of the more important general sources of variability and to focus on those interactions that are well documented. The reader should always be prepared to consult the primary literature and comprehensive reviews on the subject (4,5,6 and 7) when investigating a possible interaction of a specific variable with a specific laboratory test.

Biological Rhythms

Circadian Rhythms

Biological rhythms are frequently observed for many physiologic and laboratory parameters (8,9 and 10). The three types of rhythms that have the most influence on the interpretation of laboratory results are circadian, ultradian, and infradian rhythms. Circadian rhythms (Fig. 4.2a) (11) are responsible for programing the daily sequences of many metabolic and behavioral changes. They have cycle times of approximately 24 hours during which the activity of the rhythmic process (be it laboratory value or physiologic parameter) shows a maximum value (peak or acrophase) and a minimum

value (trough or bathyphase). The amplitude of a circadian rhythm (which by convention is equal to one half of the difference between the peak and trough values) and the clock time at which its peak and trough values occur differs substantially from analyte to analyte (Table 4.2). Circadian rhythms are usually synchronized to the light/dark or sleep/wake cycles and are further modified by social and behavioral cues. A circadian rhythm for a particular variable will generally demonstrate peak and trough values that occur at consistent times in different subjects within the same population. However, a marked subject-specific change in an important entraining cue such as the reversal of the light/dark cycle that occurs in night workers and transcontinental airline travelers can cause a shift in circadian rhythms as they become gradually reentrained to the new cue. Thus, night workers have plasma cortisol rhythms that are reversed relative to their counterparts on the day shift, and an elevated plasma cortisol concentration in a sample drawn at midnight would not be considered to be abnormal. The fact that circadian rhythms are predictable and relatively consistent in a population raises the possibility that rhythm-sensitive RVs can be used to prevent the misinterpretation of test results. Despite this theoretical possibility, rhythm-adjusted RVs are not widely used on a routine basis.

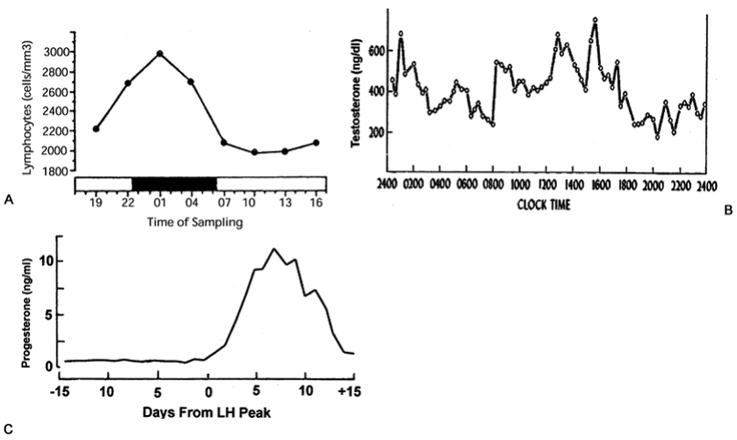

FIGURE 4.2. Biological rhythms in laboratory test results. **A:** The circadian rhythm of the lymphocyte count in whole blood shows a peak (acrophase) at midnight, a trough at 8 AM, and has a period of approximately 24 hours. (From Kanabrocki EL, Sothern RB, Scheving LE, et al. Reference values for circadian rhythms of 98 variables in clinically healthy men in the fifth decade of life. *Chronobiol Int* 1990;7:445, with permission.) **B:** An ultradian rhythm in the serum testosterone concentration is shown in a young adult man who was sampled at 20-minute intervals over the course of 24 hours. (From Griffin JE, Wilson JD. The testis. In: Bondy PK, Rosenberg LE, eds. *Metabolic control and disease*, 8th ed. Philadelphia: WB Saunders, 1980:1535, with permission.) **C:** An infradian rhythm in serum progesterone as demonstrated in a group of cycling women who were sampled daily over the course of their menstrual cycles. (From Thorneycroft IH, Mishell DR, Stone SC, et al. The relation of serum 17-hydroxy progesterone and estradiol-17B levels during the human menstrual cycle. *Am J Obstet Gynecol* 1971;111:947, with permission.)

TABLE 4.2. CIRCADIAN RHYTHMS IN SELECTED ANALYTES

	Analyte[a]	Time of Peak Concentration[b]	% Change[c]
Serum			
	Sodium	1300	2

[a] All analytes demonstrated statistically significant circadian rhythms in healthy middle-aged male subjects (11).
[b] Peak times are given as local clock times.
[c] Percentage of changes in analyte concentration are calculated as [(peak concentration – trough concentration)/daily mean concentration)] × 100.
Data from Kanabrocki EL, Sothern RB, Scheving LE, et al. Reference values for circadian rhythms of 98 variables in clinically health men in the fifth decade of life. *Chronobiol Int* 1990;7:445.

The numbers of different types of blood cells in the circulation and their functional activities show biological rhythms of several frequencies of which the circadian rhythms are the best described (12). Some of these rhythms show large enough amplitudes to be clinically important, especially if consecutive samples from the same patient are to be evaluated. Circadian rhythms in the aggregability and adhesiveness of platelets contribute to a transient hypercoagulability during the morning hours, and this particular rhythm correlates with the peak incidence

of myocardial and cerebral infarctions and sudden cardiac deaths in the morning. One important positive consequence of biological rhythms in the function and activity of the hematopoietic and immune systems is that this rhythmicity provides an opportunity for improving the effectiveness of drug therapies and other treatments by changing the times at which they are delivered.

Ultradian Rhythms

A second type of biological rhythm is ultradian rhythm. This rhythm, which has a period of less than a day, is commonly observed for analytes that are released into the bloodstream intermittently or in pulses. Ultradian rhythms are frequently observed in the blood levels of various glandular secretions. Although the ultradian rhythm for a particular analyte may show some person-to-person uniformity in pulse frequency or duration, the clock times at which pulses occur and the pulse amplitudes can show wide variation from day-to-day within a subject and from subject to subject within a population. The ultradian rhythm in the serum testosterone concentration in a male subject is shown in Fig. 4.2b (13). Considering that the RI for total testosterone is 250 to 900 ng/dl, a single blood sample drawn at, say 0900 would be consistent with a diagnosis of hypogonadism in this subject, whereas a single sample drawn 20 minutes later provides a result that is well within the RI for the test. Ultradian rhythms have the overall effect of widening the RI for all analytes in which they occur because each subject used to establish the test's RVs is likely to have been sampled at a different time relative to his or her own unique pulsatile pattern. Consequently, single test results for analytes that demonstrate ultradian rhythms are often of limited value in the diagnosis and monitoring of disease. In fact, the poor predictive values of single measurements of many blood hormones that are owing in part to their pulsatile patterns of release have led to an emphasis on the use of stimulation and suppression tests in diagnostic endocrine testing. Indeed, the daily rhythms of many blood hormone levels demonstrate both circadian and ultradian components.

Infradian Rhythms

Infradian rhythms have cycle times of greater than 24 hours. The most common example of an infradian rhythm that affects laboratory test results is the menstrual cycle, which is associated with marked rhythmic changes in the levels of many constituents in blood and body fluids including the pituitary gonadotropins and the ovarian hormones (Fig. 4.2c) (14). Substantial clinical and epidemiologic data showing seasonal differences in the incidence of viral disease, depression, malignancy, and suicide suggest the existence of many other infradian rhythms in humans (8). The significance of these other rhythms to the interpretation of laboratory test results remains to be demonstrated. In view of the previous discussion, it is always prudent to consider subject-to-subject differences in biological rhythms that are not accounted for by a test's RVs as a possible cause of an unusual or unexpected result.

Constitutional Factors

Gender (4,6)

Statistically significant gender-related differences in test results have been described for many laboratory parameters; however, most of the male–female differences in test results are not clinically significant and do not require the use of gender-specific RVs. Even for analytes for which gender-related differences eventually develop, test results tend to be similar in males and females until after the age of puberty. The most important general mechanism of male/female differences in test results in adults is sex hormone–dependent physiologic processes. For example, males undergo an androgen-dependent increase in muscle mass compared with females and thus demonstrate increased serum levels of muscle constituents (e.g., creatine kinase) and muscle metabolites (e.g., creatinine). Blood loss during the menses is one basis for gender-related differences in laboratory parameters related to the red cell mass (e.g., red blood cells, hemoglobin, ferritin). The menstrual cycle is also associated with marked changes in the circulating levels of ovarian steroids, which, in turn, influence many physiologic processes. For example, plasma corticosterone concentrations are increased as much as 1.5-fold in the luteal phase compared with the follicular phase. In addition, there are preovulatory increases in plasma renin and aldosterone, and the plasma fibrinogen concentration, as well as the serum concentrations of phosphate and iron, decrease during menstruation.

Age

To consider the effects of age on laboratory test results, it is necessary to divide the population into groups. However, one problem with any categorization scheme based on chronological age is that the biological age of a subject does not necessarily correspond to his or her chronological age. Thus, simple predictions of expected values based on age alone can be problematic. Nevertheless, for the purpose of the following discussion, four groups are considered: infants (younger than 1 year), children (1 to 17 years), adults (18 to 65 years), and the elderly (65 years and older).

The composition of the blood of a newborn varies considerably with the maturity of the infant at birth and changes substantially over the first 24 hours of life (15). Premature infants have lower levels of many tissue enzyme systems, less protein binding, hyperbilirubinemia, and reduced renal function compared with full-term infants. Important changes in the body fat and body water contents occur within the first hours and days after birth. Newborns experience shifts of fluid from the intravascular to the extracellular space followed by a loss of extracellular fluids leading to a decrease in body water content from an initial value in the range of 70% to 75% to the adult value of 50% to 55%. As a result of these fluid shifts, the plasma concentrations of macromolecules, of protein-bound low molecular weight constituents, and of blood cells all increase. The interpretation of laboratory test results in this age group is further complicated by a combination of rapid physiologic changes, the possibility of significant analytical interference by hemolysis and bilirubin, and a general lack of method-specific, age-dependent RVs. Several

excellent compendiums of neonatal RVs are available (16); however, the transferability of published values to analytical methods other than the ones used for their original estimation cannot be taken for granted.

The composition of body fluids changes gradually between infancy and puberty (6). During this interval, the plasma protein concentration increases and the plasma concentrations of enzymes decrease. The onset of sexual development is characterized by progressive increases in plasma levels of gonadal hormones. With the exception of the sex hormones, age-specific RVs usually have little impact on test interpretation in this age group. One significant and rapid change that occurs as children approach the age of puberty is a marked decrease in the activity of the hepatic drug-metabolizing enzyme systems (17). The chronological age at which this change occurs varies from child to child. One consequence of this change is that a previously effective dose of a therapeutic drug (such as phenytoin) may produce toxic drug levels after the rate of drug metabolism abruptly decreases.

Laboratory values remain relatively constant up until menopause in women and middle age in men. The physiologic changes that accompany menopause, which typically occurs between the ages of 40 and 62, are driven by a progressive decline in the ovarian estrogen output, which, in turn, leads to postmenopausal changes in related laboratory parameters including the pituitary gonadotropins and the serum and urine constituents that reflect bone resorption. Although aging per se does not appear to be a major factor in influencing laboratory values in healthy adults, the susceptibility to chronic and debilitating diseases increases during adulthood, and the laboratory values that are found to be characteristic of this age group may not necessarily be consistent with a state of good health. For example, the 95th percentiles for serum cholesterol of 255 mg/dl and 270 mg/dl, which were observed in large samples of healthy middle-aged women and men, respectively, in the Lipid Research Clinics North American Prevalence Study (18) in the early 1980s was far different than the value (200 mg/dl or more) that is now considered to be desirable for all adults. The original sample of healthy subjects apparently included many individuals who were not recognized to be at an increased risk of cardiovascular disease at the time of sampling. Unless the subjects used to establish RVs for adult populations are carefully screened for the presence of subclinical or intercurrent diseases, the RVs may be biased—possibly to the point of being insensitive to the detection of pathological changes in individual subjects.

The elderly constitute the fastest growing age group in our population. These subjects experience a number of physiologic changes that result from aging per se as well as changes that are owing to age-related differences in nutrition and the presence of intercurrent disease. The accurate interpretation of many laboratory tests in this group requires the use of age-specific RVs that have been derived from carefully screened reference subjects (19). A recent study (20) in which investigators measured 47 different laboratory parameters in young adults and healthy individuals in the 60- to 90-year age range and 93 parameters in young adults and healthy centenarians concluded that the RVs for the following analytes showed little or no change with age: urine protein excretion, the serum concentrations of sodium, potassium, chloride, carbon dioxide, pH, total calcium, most serum proteins, liver enzymes, total bilirubin, and magnesium. RVs for the following analytes showed age-related increases both in men and women: serum concentrations of ionized calcium, parathyroid hormone, glucose insulin, C-peptide, luteinizing hormone, follicle-stimulating hormone, γ-glutamyltransferase, urea nitrogen, immunoglobulin (Ig) A, high-density lipoprotein cholesterol, cholesterol, triglycerides, thyroid-stimulating hormone, copper, microsomal antibodies, antithyroglobulin antibodies, lactate dehydrogenase 5, and gastrin. RVs for the following analytes showed age-related decreases: phosphate (men only), IgM, IgD, zinc, T_3, T_4, free and total testosterone (men only), estrone and estradiol (women only), androstenedione, progesterone, hemoglobin, hematocrit, erythrocytes, leukocytes, platelets, and serum iron.

For all age groups, it is important to identify specific analytes for which the accuracy of test interpretation might be improved by the use of age-specific reference limits. However, as described in the section on RVs, it is also important to recognize that such an improvement will only be realized if the interage differences are large enough to result in significant differences in the means and variances of the age-stratified groups.

Genetic Heterogeneity

Genetic heterogeneity within a population leads to person-to-person phenotypic differences that can contribute to the variability in laboratory test results. Racial differences in laboratory values have been described among many populations in various parts of the world. However, in many instances, such differences are not easily verified because it is often difficult to separate effects of race per se from those of other factors. In the U.S. population, African Americans tend to have an increased muscle mass and a more marked skeletal development than their Caucasian counterparts, leading to racial differences in serum levels of creatine kinase and lactate dehydrogenase in adults and in serum alkaline phosphatase in children. African Americans also tend to have higher serum total protein levels and higher serum levels of gamma globulins, α-globulins, ß-globulins, IgG, and IgA than Caucasians (4,6). A more subtle, but perhaps a more significant consequence of genetic heterogeneity are person-to-person differences in the structures of biological macromolecules. Genetic heterogeneity at the molecular level can lead to differences in the reactivity of a subject's DNA, proteins, or cells toward the nucleic acid probes and antibodies that are used as reagents in many diagnostic tests. This type of genetic heterogeneity can result in false-negative findings in molecular biology tests, inaccuracy in immunoassay results, and poor clinical correlation of analyte levels with disease incidence and/or severity. For example, the laboratory determination of mutations within the *BRCA1*gene can identify individuals at risk for a certain heritable form of breast cancer. However, the finding that more than 450 different mutations are associated with this type of cancer makes it practically impossible to exclude the presence of a clinically significant mutation by laboratory testing with currently available techniques (21). Recently, differences with respect to a subject's secretor status and Lewis genotype have been shown to affect the interpretation of serum levels of the tumor

marker CA 19-9 in that Lewis-negative individuals appear to have undetectable CA 19-9 levels even in the presence of substantial tumor burdens (22). A final example is the genetic size polymorphism in apoprotein a, which causes differences in the immunoreactivity of lipoprotein a [Lp(a)] toward analytical assays in which the epitope recognized by the antibody reagent includes a particular variable domain of the apoprotein (23). It now appears that the lack of correlation of Lp(a) levels with cardiovascular risk in some racial groups may be owing, in part, to genotype-dependent inaccuracy in the Lp(a) assay rather than to physiologic differences. As the field of laboratory medicine moves more toward the use of highly specific probes and antibodies in analytical methods, genetic variability will become an increasingly more important consideration in the design and development of test methods and in the interpretation of test results.

Extrinsic Factors

Posture

A subject's posture before and during blood collection affects the concentration of many plasma constituents. A change in posture from supine to standing is accompanied by an increase in the hydrostatic pressure within the vasculature and an efflux of water and small, freely diffusible molecules from the vascular compartment to the interstitial space. This fluid shift leads to a reduction in plasma volume and increases in the concentrations of nondiffusible blood constituents including cells, plasma proteins, enzymes, and protein-bound analytes (e.g., cortisol, T_4, phenytoin, cholesterol). The plasma concentrations of these constituents increase on the order of 4% to 15% within approximately 10 minutes after the posture changes from supine to standing (24). Body water shifts in the opposite direction when the posture changes from upright to supine and the above-named plasma constituents will undergo a corresponding decrease in concentration over the course of approximately 30 minutes. In addition to these nonspecific changes, more marked posture-related differences occur in the concentrations of analytes that are normally involved in the homeostasis of vascular tone. For example, plasma renin, serum aldosterone, and the catecholamines all increase by as much as twofold with a change from supine to erect posture (4,6). Thus, specimen collection procedures for these analytes often specify the posture of the subject during the blood draw as well as the level of physical activity immediately before specimen collection. Posture-related changes should always be considered as a potential cause of day-to-day variability in the plasma or serum concentrations of proteins, cells, and high molecular weight constituents such as lipids and lipoproteins, especially when a particular test result is slightly above or below a reference limit or a clinical decision threshold. The existence of postural effects also provides a rationale for using different criteria for the interpretation of test results in ambulatory and hospitalized subjects.

Exercise (4,25)

Physical exercise can cause numerous alterations in the composition of plasma and urine. Some of the mechanisms of exercise-related changes are shifts in plasma water, decreases in the glomerular filtration rate and urine production, an increased release of hormones that regulate energy metabolism, a generalized stress response, changes in lipoprotein metabolism, and a leakage of macromolecules from cells and tissues. The most marked exercise-related changes occur in the plasma concentrations of hormones such as antidiuretic hormone, catecholamines, growth hormone, glucagon, corticotropin, and cortisol, which can increase by as much as two- to fourfold. Exercise-induced increases in blood hormones typically fall to baseline levels within 1 to 2 hours after the end of the exercise period. However, the changes in aldosterone, renin, and angiotensin can persist for as long as 24 hours. Acute exercise also leads to increases in the plasma levels of pyruvate, lactate, alanine, and free fatty acids as well decreases in arterial pH and PCO_2. Exercise-induced changes in plasma and urine electrolytes and volume usually normalize within 1 hour after exercise. Vigorous exercise can also be associated with a temporary activation of blood coagulation and platelet function and increases in plasma prostaglandin levels. Coagulation factors VIII and Xa also show pronounced increases and platelet factor IV levels decrease. Brief periods of strenuous exercise lead to an increase in the urinary concentration of hemoglobin, and the urine concentration of albumin can increase by as much as 100-fold. Urine protein excretion is greatest during the first 20 to 30 minutes after the exercise period but can remain elevated for as long as 24 hours. Pronounced myoglobinuria can also occur after extreme muscle exertion and persist for as long as 24 to 48 hours. Increases in the plasma concentrations of muscle enzymes like lactate dehydrogenase, creatine kinase, aspartate aminotransferase, and aldolase can range from two- to as high as 40-fold depending on the type of exercise performed. In general, analytes that change with exercise do so to an extent that depends on the degree of strenuousness of the exercise as well as on the level of physical training of the subject. Well-trained athletes are typically more resistant to exercise-related changes than are untrained subjects.

Diet (4,6,26)

The consumption of a standard test meal is followed by increases in the serum concentrations of triglycerides (1.5-fold), aspartate aminotransferase (1.2-fold), bilirubin (1.15-fold), and glucose (1.15-fold). In some cases, meal-related increases are relatively long lasting. For example, ingestion of a protein-rich meal in the evening leads to increases in the blood urea nitrogen, phosphorus, and uric acid that can persist for as long as 12 hours. After a large meal, the serum levels of cholesterol and growth hormone are increased for approximately 1 hour, whereas the postprandial elevation in serum triglycerides can persist for as long as 8 hours. Consumption of diets stressing a particular constituent can cause small changes in some test results. For example, high-fat diets are associated with increases in the serum levels of total cholesterol (1.28-fold) and high-density lipoprotein cholesterol (1.14-fold); high-fiber diets are associated with decreases in serum cholesterol (5%), serum estradiol (15%), and the urinary excretion of albumin (25%); high-protein diets are associated with increases in plasma ammonia, urea nitrogen, and uric acid and an increase in the glomerular filtration rate (1.1-fold).

Prolonged fasting or starvation also affects many test results. For example, the serum concentrations of ß-hydroxybutyrate, acetone, and acetoacetate increase within 14 hours of the start of fasting. After 48 hours of fasting, ß-hydroxybutyrate is increased as much as 30-fold. At this time, free fatty acids and glucagon concentrations are also increased, the serum insulin concentration is decreased, and metabolic acidosis develops. Starvation of 4 weeks' duration is accompanied by 50% decreases in the concentrations of blood urea nitrogen, triglycerides, and γ-glutamyltransferase and 20% to 40% increases in the serum levels of uric acid, creatinine, and aspartate aminotransferase. The recommended duration of fasting before specimen collection is typically 12 hours, and the above data show why deviations from this standard in either direction can interfere with test interpretation.

Caffeine (6)

Of the many dietary constituents that have been shown to affect laboratory values, caffeine is of special importance because of its presence in beverages that are often consumed in large quantities. Caffeine has many physiological actions including the stimulation of the adrenal medulla and the adrenal cortex. Caffeine also has marked effects on lipid metabolism leading to increases in plasma free fatty acids, glycerol, and lipoproteins. Caffeine significantly increases serum gastrin and has powerful diuretic effects that lead to increases in urinary concentrations of erythrocytes, renal tubular cells, calcium, magnesium, sodium, and potassium.

Drugs

It is not uncommon for subjects that are undergoing laboratory tests to be taking one or more prescription drugs. Therapeutic drugs can affect laboratory test results by either interfering with the specific analytical method used for the test (analytical interference) or by causing physiologic changes in the biosynthesis, release, tissue distribution, metabolism, or excretion of the analyte that is being measured. In the former case, the potential for the drug to cause an error in test interpretation will be method specific. In the latter case, an error in interpretation might result from the inability to differentiate a drug-induced physiologic change from a pathologic change. It is the laboratory's responsibility to identify potential sources of analytical and physiologic interference for each test that is offered and to inform clinicians of cases in which relatively common drugs might cause significant errors in interpretation. It is the clinician's responsibility to determine whether and when interfering medications can be withdrawn before specimen collection and to instruct the patient accordingly. Information concerning drug interference with laboratory test results can be found in the manufacturer's package inserts that are supplied with analyzers and test kits, the *Physicians' Desk Reference*, articles from the medical literature, and reference works on the subject of drug interference (7). Drug interference is best avoided by recognizing its potential for occurrence, withdrawing medications before sampling whenever possible, and evaluating any suspicious results in light of a subject's medication history.

Alcohol Use

Alcohol use, both acute and chronic, are important causes of drug-related changes in test values. Some of the more prominent interactions and their magnitudes are summarized in Table 4.3 (4,26).

TABLE 4.3. ACUTE AND CHRONIC EFFECTS OF ALCOHOL ON SELECTED LABORATORY RESULTS

	Test	-Fold Change[a]
Acute (within 2–4 h)		
	Aldosterone	1.5
	Triglycerides	1.3
	Prolactin	0.5
	Cortisol	0.5
	Cholesterol	0.9
	Osmolality	inc
	Glucose	1.0 to 1.5
	Testosterone	dec
	Luteinizing hormone	inc
	Catecholamines	inc
Chronic		
	γ-Glutamyltransferase	10.0
	Aspartate aminotransferase	2.5
	Alanine aminotransferase	1.6
	Estradiol	1.6
	Cortisol	1.6
	Triglycerides	1.3
	Cholesterol	1.1
	Mean cell volume	1.1
	High-density lipoprotein cholesterol	1.2
	Iron	1.8

[a] Alcohol-related changes in serum chemistry results and in the mean cell volume are expressed as -fold changes compared with control subjects. Values <1.0 indicate alcohol-related decreases; values > 1.0 indicate increases.
inc, increase of unspecified magnitude; dec, decrease of unspecified magnitude.
Data from refs. 4, 6, and 26.

Oral Contraceptives (27)

The oral contraceptive preparations that are used clinically contain different combinations of estrogens and progestins or progestins alone. These preparations can influence the results of many laboratory tests. For example, estrogen-containing oral contraceptive preparations affect hepatic protein biosynthesis leading to increases in the plasma concentrations of fibrinogen, and several of the serum proteins that are involved in hormone transport including the binding globulins for cortisol, thyroxine, and sex hormones, and many of the clotting factors including VII, VIII, IX, and X. Many of these drug-related changes have physiologic significance. For example, increased amounts of coumarin derivatives are required to prolong the prothrombin time of subjects taking oral contraceptives, and the platelet aggregation response to catecholamines in these individuals is also increased. The magnitude of the effects of a particular oral contraceptive preparation on particular laboratory tests is often proportional to the estrogen content of the preparation. A sample of the more than 200 interactions of oral contraceptives with laboratory tests that have been reported in Young's reviews (4,7) are presented in Table 4.4.

TABLE 4.4. EFFECTS OF ORAL CONTRACEPTIVES ON SELECTED SERUM ANALYTES

Analyte	-Fold Change
Apoprotein A 1	1.1
Apoprotein B	1.2
Cholesterol	1.1
High-density lipoprotein cholesterol	1.1
DHEA-S	0.7
Luteinizing hormone	0.1-0.2
Prednisolone clearance	0.5
Protein S	0.75
SHBG	2.5-3.0
Testosterone	0.7-0.8
Transcortin	2.0
Triglycerides	1.5
Ferritin	1.6
Follicle-stimulating hormone	0.7
Iron	1.2

Oral-contraceptive-related changes in serum chemistry results and in the mean cell volume are expressed as-fold changes compared with control subjects.
Data from refs. 4 and 7.

Pregnancy

The major physiologic adaptations of normal pregnancy including expansions of plasma volume and erythrocyte mass, an altered distribution of cardiac output, an increase in plasma protein synthesis, hyperventilation, and marked endocrinologic changes lead to significant changes in many laboratory values compared with the nonpregnant state (28). Consequently, the accurate interpretation of test results during pregnancy often requires the use of RVs derived from a population of healthy pregnant women at defined stages of gestation. Pregnancy-related differences in some of the more commonly ordered laboratory tests that were selected from Young's review (4) are shown in Table 4.5. Several sources of pregnancy-specific RVs are presented in ref. 28.

TABLE 4.5. CHANGES IN SELECTED LABORATORY VALUES DURING NORMAL PREGNANCY

	Laboratory Value	-Fold Change
Serum		
	Albumin	0.75
	α_1-Acid glycoprotein	0.66
	Alkaline phosphatase	2.0–3.0
	CA 125	2.0
	Creatinine	0.7
	1,25 dihydroxy vitamin D	2.0
	Erythropoietin	2.0
	Estradiol	10.0
	Free fatty acids	1.7
	Ferritin	0.25
	Iron	0.65
	Sex hormone binding globulin	6.0–10.0
	Thyroxine-binding globulin	2.0–3.0
	Transferrin	1.7
Blood		
	Red blood cells	0.9
	Factors II, V, VII, VIII, IX, X	inc
	Erythrocyte sedimentation rate	inc
	Fibrin split products	inc
	D-dimer	3.5

	Estriol	inc
	Hyaline casts	inc
	Albumin	1.6
	Alanine	2.0

Pregnancy-related changes in serum chemistry results and in the mean cell volume are expressed as-fold changes compared with control subjects.
Data from refs. 4, 24, and 28.

Intercurrent Illness

Specific medical conditions such as shock, malnutrition, fever, thermal burns, trauma, recent transfusions, and component therapies all have distinct effects on the composition of blood and body fluids and can confound the interpretation of disease-related changes in laboratory values when one of these medical conditions is present along with a primary disease. The specific effects of these relatively common conditions on test values are beyond the scope of this chapter. Interested readers can find more information in one of the comprehensive reviews on the subject (5,6).

THE ESTABLISHMENT AND VERIFICATION OF RVs

Part of "4 - The Interpretation of Laboratory Tests"

The diagnosis and management of disease are accomplished through the evaluation of information gained from many sources including the history and physical examination, various imaging and endoscopic techniques, histopathologic examinations, and clinical laboratory tests. Regardless of the diagnostic modality, the medical significance of the result observed in an individual under investigation is usually determined by comparison with some control or RV. The process of interpretation through comparison has led to the emergence of a more objective and scientific basis for the process of medical decision making and is the foundation for future advances in the field of evidence-based medicine. Although the use of RVs in laboratory medicine would appear to be well established and relatively straightforward, several challenges and controversies still remain in this important area of laboratory practice. This section, portions of which have been previously published (29), is intended to provide a brief overview of some of the major philosophical and practical aspects of establishing and using RVs in the clinical pathology laboratory. More detailed treatments of the subjects presented here can be found among the references, which include several authoritative reviews (30,31,32,33 and 34).

Development of Standardized Terminology

In the early days of laboratory medicine, the standard of comparison for a test result was the “normal” value or the “normal” range. In this context, the word normal was intended to indicate that the values were the usual, customary, or typical ones that were associated with good health. Unfortunately, this terminology had several drawbacks. Of relatively minor importance was the fact that the word normal might be taken to imply that the laboratory value under discussion was normally distributed (i.e.,

gaussian) in the population. A more significant limitation of the terminology was that terms like normal range, normal value, and upper limit of normal implied that there was some clear-cut value that could effectively discriminate between health and disease. Although most health care workers will agree that there is rarely a stark dividing line between health and disease, there is still a tendency to interpret laboratory results in a binary fashion as signifying either health or disease using the normal value as the cut point. The previous terminology, which fostered this illogical binary approach to interpretation, also had the negative consequence of causing unnecessary alarm and anxiety to a subject whose laboratory result was found to be abnormal.

In the past decade, there has been increasing support to replace the older terminology with a nomenclature that permits the unambiguous description and discussion of the subject. The new terminology, which is now endorsed by the World Health Organization, the International Federation of Clinical Chemistry, and the National Committee for Clinical Laboratory Standards (NCCLS), is based on the fundamental definition of a RV as: A value (test result) obtained by the observation or measurement of a particular type of quantity in an individual selected on the basis of well-defined criteria.

This definition is part of a larger framework of standardized terms (Fig. 4.3) that apply to all phases of the process by which RVs are established and used (32).

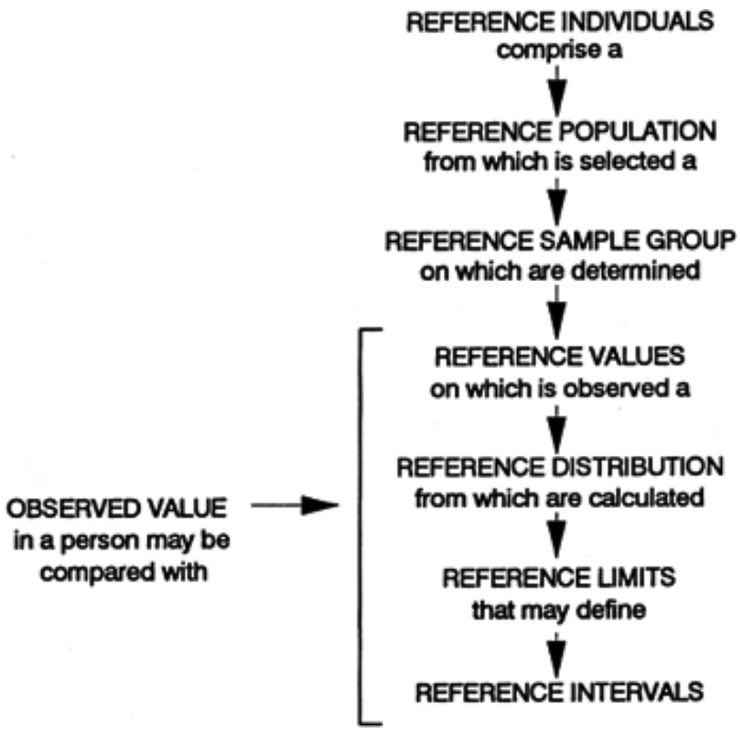

FIGURE 4.3. Standard terminology for the description and discussion of reference values. These terms, which refer to various aspects of the establishment and use of reference values, were proposed by the International Federation of Clinical Chemistry and the International Council for Standardization in Hematology and are endorsed by the World Health Organization and other organizations worldwide. [Redrawn from National Committee for Clinical Laboratory Standards. *How to define and determine reference intervals in the clinical laboratory; approved guideline C28-A*. Villanova, PA: NCCLS, 1995.]

Types of RVs Currently in Use

The RV that is used most frequently in contemporary laboratory medicine is the RI, which is bounded by upper and lower reference limits that are usually chosen to enclose 95% of the values observed in nondiseased subjects. Population-based, health-associated RVs of this type are useful in the process of medical decision making in particular settings, for example, when screening for the presence of a disease in a population in which affected individuals do not present with any obvious symptoms (35). However, only a small percentage of the laboratory tests performed are ordered for this purpose, the majority being used to monitor the progress of a disease process or the effectiveness of a treatment. In the latter situations, other types of RVs are typically more informative. Therefore, the laboratory must consider the possibility that disease-associated RVs, subject-based RVs, multivariate RVs, and clinical decision limits might all have a place among the RVs that it presents to its clients. The ultimate goal is to provide the RV that best supports the medical decision at hand.

Accreditation Requirements

Determining which type of RV is most efficient for a particular test or for a particular clinical setting is the task and responsibility of the laboratory director. Among the guidelines that influence the director's activities are the standards set by the federal government and by voluntary accreditation agencies like the Joint Commission for the Accreditation of Healthcare Organizations (JCAHO) and the College of American Pathologists (CAP). The Clinical Laboratory Improvement Act of 1988 (CLIA) regulations contain three standards related to reference values (36). The first (§493.1109) requires that pertinent reference or normal ranges as determined by the laboratory performing the tests must be available to the authorized person who ordered the tests. The second standard (§493.1211) requires that reference ranges or normal values must be included in the laboratory procedure manual. The third standard (§493.1213) requires that before reporting patient results, the laboratory must establish for each method, the specifications for a number of performance characteristics including the reference range(s). Further definitions in this subpart of the standard state that in cases in which a manufacturer's reference range can be used, the laboratory that uses it must verify that the range is appropriate for its patient population. Furthermore, for methods developed in-house, modifications of a manufacturer's test procedure, or a manufacturer's procedure not cleared by the U.S. Food and Drug Administration (FDA) as meeting CLIA requirements, the laboratory must verify or establish reference ranges. Finally, the laboratory is required to have documentation of the verification or establishment of all applicable test performance specifications including the RVs.

The CAP standards related to RVs (37) include a requirement that reference ranges be verified or established and documented as a part of the performance specifications for moderate complexity tests introduced after July 31, 1998, and high complexity tests introduced after July 1, 1992 (01.4208, Phase II). A note appended to the standard specifies that, when reasonable, RVs must be developed for each analyte and specimen type and acknowledges that for many analytes, literature references or information from a manufacturer's package insert may be appropriate. A second standard (01.4211, Phase II) requires that the laboratory periodically evaluates the appropriateness of its RIs and takes corrective action if necessary. A note appended to this

standard specifies that there should be a reevaluation of RVs whenever a laboratory changes an analytical methodology. Finally, a third standard (01.4120, Phase II) requires that RVs be reported with the test result. Under some circumstances, this last standard might be satisfied by distributing a list of RVs to all users and sites where laboratory reports are received.

JCAHO (38) requires that RIs or normal ranges for each test be included in the clinical record as part of the laboratory report or by including a current list of values that are approved by the laboratory director (IM.7.7). This standard emphasizes the possibility of variation in RVs from laboratory to laboratory or with different methodologies or age groups, requires that the units of concentration or activity are included in reports, emphasizes that RVs should be updated as methods change, specifies that RIs be furnished for referred test, requires that documentation is available in the laboratory to show the basis for the reference ranges and is available to the clinical staff on request, and requires that reference ranges are appropriate to the population served by the laboratory.

Generally, these federal regulations and voluntary standards give the laboratory director the flexibility to define the types of RVs that will be used and the procedures by which the values will be defined and determined. However, the various standards do require three major activities on the part of the laboratory: the RVs must be established or verified by the laboratory that uses them, the RVs must be presented to the users of the laboratory along with patient results, and the RVs and the details of their establishment must be documented. The standards do not necessarily require that a laboratory establish its own RVs *de novo*. Instead they imply that the verification and transfer of an existing RV (from a manufacturer or from the literature) is an acceptable alternative. In this case, it is important to consider the types of activities that comprise the process of verification. Fortunately, recently published NCCLS guidelines (32), which are presented later in the chapter, recommend three possible methods for verification. Although there may be some room for debate, it would appear that verification must include the testing of a sample from the laboratory's own reference population to comply with the CAP standards.

Principles for the Establishment of RVs

Specifications

It is important to consider that a RV has little meaning unless it is accompanied by a complete set of specifications that describe precisely how it was derived. A comprehensive definition of the RV serves as documentation for users of the laboratory and for accreditation purposes and also provides the information that another laboratory would require to evaluate the acceptability of a transfer. The following details should be specified to define completely a RV: the characteristics of the reference population and the way in which the reference sample group was selected; the physiologic and environmental conditions under which the specimens were obtained; the techniques and timing of specimen collection, transport, preparation, and storage; a description of the analytical method used including its accuracy, precision, and quality control procedures; the original results obtained for the reference sample; the statistical methods that were applied to the data; and finally, the RVs that were derived (39).

Literature Review

The first step in any reference range study should be a comprehensive review of the literature with the intent of identifying any factors that might affect the observed value of the analyte of interest. Such factors must be known at the very outset of the study to guide the development of exclusion and partition criteria and to develop procedures for patient preparation, specimen collection, and specimen storage. In cases in which an entirely new analyte or analytical method is being addressed, this step might even require the investigation of the potentially significant factors by experimentation.

Exclusion and Partition Criteria

Exclusion (or selection) criteria are used to reduce the heterogeneity of a reference sample by excluding subjects that might have unusual analyte values because of the presence of disease or some unique constitutional or extrinsic factor. The most common criteria are the sources of biological variability listed in Table 4.1. Of course, the criteria used in any given study will depend on the analyte under investigation and the objectives of the study. Partitioning criteria are used to divide the reference population into subclasses that, for one reason or another, are expected to have different and distinct distributions of the analyte of interest. Again, reference populations are often subdivided based on constitutional and extrinsic factors like those presented in Table 4.1. Note that once the decision to partition a reference population is made, each subclass is henceforth treated separately and independently, thus multiplying the resources required to complete the study. Therefore, as emphasized in the first part of the chapter, it is important to partition only if subclass-specific RVs provide a significant improvement in the diagnostic attributes of the test. Although this is often a difficult judgment to make at the outset of a study, it can be assessed after some data are collected by comparing the means and standard deviations of the proposed subclasses. If the ratio of the standard deviations of two proposed subclasses is less than 1.5 (or if an *F* test on their variances is not significant) and if there is no significant difference in the subclass means by the standard normal deviate test (or the *t* test), then a single RV should be determined for the combined group (32,34).

Once appropriate selection and partition criteria have been chosen, a mechanism for applying them to the selection process must be devised. The most effective way to implement the criteria is to evaluate the population by means of a well-designed questionnaire. Guidelines for the preparation and administration of a questionnaire and an example of an effective format are presented in a recent NCCLS document (32). Before evaluating any patients, the laboratory should consult with its institutional review board to determine whether it is necessary to obtain informed consent from the reference subjects. The consent form, the questionnaire, and the reference study itself may require prior approval by this board.

Selecting the Reference Sample

The sampling of individuals from the reference population is one of the most critical aspects of the RV study. The major considerations during this step are the selection of a random sample, whether the subjects will be selected prospectively or retrospectively, and the minimum number of subjects required. Ideally, the reference sample should be randomly drawn from the population. This means that every member of the defined population should have same chance of being included in the reference sample. Unfortunately, it is practically impossible to obtain a completely random sample. Usually, the closest approximation is to randomly select subjects from the reference population and then to isolate from this group those subjects who meet the selection criteria for the study (34). Although it is generally assumed that this compromise is not likely to seriously influence the results, the possibility of obtaining biased RVs increases with more serious violations of the principle of random sampling.

Reference individuals can be selected in either a prospective or a retrospective fashion (33), and when properly performed, both approaches will provide reliable results. The critical aspect of the selection process is that individuals are selected based on defined criteria that are independent of the value of the analyte for which the RVs are being determined. Both of these methods of sampling are considered direct methods because it is the individuals or subjects who are selected and not their laboratory results. In the retrospective mode, direct sampling is possible only when the subjects are selected from a database that contains analytical results and sufficient clinical and demographic data so that appropriate exclusion and partitioning criteria can be used to select a reference sample corresponding to a defined population.

Over the years, there has been considerable debate concerning the use of indirect approaches to the selection of reference samples. In the indirect methods, RVs are established from laboratory results (not subjects) that have been selected from a database. The database typically consists of all the results reported by the laboratory or all the results observed on preadmission tests, and various statistical techniques are used to extract the normal values from the total distribution (40). However elegant the statistical approach, the RVs derived by this method can be used for little more than deciding whether a future patient result is extreme or unusual relative to those of the patient population served by the laboratory. The contribution of such information to the process of medical decision making seems questionable. Indirect sampling is not widely accepted as a valid technique for establishing RVs. However, this method might serve as a quality control monitor for the detection of changes in analytical accuracy over time.

What is the minimum number of reference subjects required to estimate population-based RVs for a new analyte or method? The values recommended in the literature range from 30 to 700 subjects (32,41,42)! This wide range is owing in part to the fact that the precision in estimating population values depends not only on the sample size but also on the interindividual variability of the analyte, the skewness of the distribution of the analyte values in the population and on the statistical method used to estimate the population percentiles (30,34,41). The minimum number of reference subjects required to estimate a 95% RI by the nonparametric technique (see Nonparametric Method section) is 39; however, at this low value, the smallest and largest observations represent the 2.5th and 97.5th percentiles, and it is not possible to calculate confidence intervals (CIs) for the reference limits. The International Federation of Clinical Chemistry and Laboratory Medicine and NCCLS now recommend a minimum sample size of 119 for estimation of RVs by the nonparametric technique (32). This is the smallest value of *N* that permits the estimation of 90% CIs around the upper and lower reference limits. A sample size of 119 has been shown to be reasonable when the distribution of analyte value is symmetrical, but it may be inadequate when the distribution is skewed (41). In the latter case, as many as 700 reference subjects may be required for a precise nonparametric estimate of the 95% RI. Similar calculations for parametric estimates indicate that sample sizes between 50 and 450 are required for precise parametric estimates (41). The practical approach to the issue of sample size is twofold: use the largest sample size possible and always calculate CIs for the reference limits that are estimated. A wide CI indicates poor precision and suggests that the limit may not effectively discriminate an extreme or pathologic test result from one that is just within the RI. Unacceptable precision in an estimated limit can be addressed by increasing the size of the reference sample, partitioning the reference population, or reducing preanalytical and/or analytical variability for the analyte.

Preparation of Subjects, Specimen Collection, and Sample Analysis

The preparation of the reference subjects before sampling should follow defined conditions of prior diet, physical activity, stress, length of fasting, and so forth. The specimen collection procedure must provide for consistent site preparation, posture, and environmental conditions. In addition, specimen handling must be consistent with respect to variables such as the timeliness of separation or processing and the duration and conditions of transport and storage. A consideration of these factors will serve to minimize the biological and preanalytical variability of the analyte. It is important that the conditions that are specified for the RV study are also attainable and practical for routine use in the setting in which future patient samples will be obtained.

The primary concern during the analytical phase of the study is that the test method has been fully characterized with respect to its precision, accuracy, minimum detection limit, linearity, recovery, and interference. There must also be a program in place to assure continuity of these performance characteristics into the future. It is clear that changes in analytical performance characteristics can significantly affect the validity of a previously established RV (43).

Data Analysis

There are two general statistical methods for the estimation of population-based reference limits and their CIs: nonparametric and parametric. The nonparametric method is considered to be the easiest to perform because the desired parameters are obtained by simply ranking the RVs in ascending order and choosing values corresponding to particular rank numbers. The nonparametric

method is applicable to any reference distribution regardless of its shape or symmetry, and it can be used with noncontinuous variables (i.e., titers). One disadvantage of this method is that the reference sample must consist of at least 119 subjects to estimate 90% CIs of reference limits. The nonparametric method is currently recommended by NCCLS for establishing population-based RVs (32).

The parametric method requires that the original reference distribution or some mathematical transformation thereof conforms to a gaussian (i.e., normal) distribution. This method is more complicated than the nonparametric method because the reference distribution must be tested for "normality", transformed if required, and retested for "normality" before the estimation of reference limits. If the data are not normally distributed, the use of the parametric technique will give erroneous results. However, when this condition is satisfied, the procedure for estimating reference limits is simple and straightforward. Major advantages of the parametric method are that 90% CIs can be calculated for samples of all sizes and that the precision of the estimated reference limits is generally better than that of the nonparametric method for any sample size (41). Many of the statistical software packages available for the personal computer contain programs for testing a distribution for normality, as well as the means for applying mathematical transformations to a data set. Thus, the tools required to use the parametric method are available to most laboratorians.

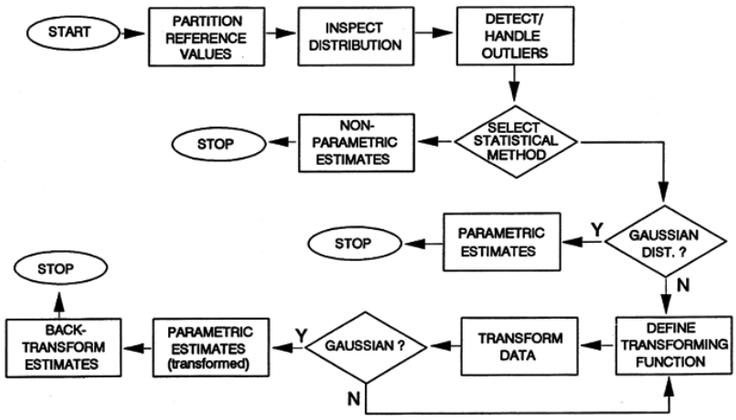

FIGURE 4.4. Statistical treatment of reference values for the estimation of population based reference intervals. (Redrawn from Solberg HE. Establishment and use of reference values. In: Burtis CA, Ashwood ER, eds. *Tietz textbook of clinical chemistry*. 2nd ed. Philadelphia: WB Saunders, 1995:454.)

Estimating Reference Limits: Some Examples

An outline of a procedure for estimating population-based RIs is presented in Fig. 4.4. As an example of the use of the different techniques, consider a set of values for the serum IgG concentration in a reference sample group of 139 subjects. A partial listing of the data arranged in order of ascending IgG concentration is presented in Table 4.6. The first step in the analysis of any set of observations is the visual inspection of a histogram of the data (Fig. 4.5). This inspection will indicate whether the distribution is unimodal or multimodal, and the shape and symmetry of the distribution will provide the first indication of whether it is normally distributed. Visual inspection will also identify observations that are extreme or atypical compared with the bulk of the data. These extreme results or *outliers* can arise as the result of an analytical error or the misclassification of a reference individual. Because both statistical methods for estimating reference limits are sensitive to the effects of the outliers, is important to have an objective means for detecting them. Among the many methods that are available, a simple test devised by Dixon is the most widely recommended (32). This test involves calculating the ratio D/R, where D is the absolute difference between the highest (or lowest) and the second highest (or lowest) value in the distribution and R is the range of all the values including the extreme

one. If D/R > 0.33, then the extreme value is considered an outlier. Visual inspection of the histogram in Fig. 4.5 suggests that the data are skewed to the right and that the highest IgG value (17.7 g/L) might be an outlier. From the data in Table 4.6, D/R = (17.7 - 15.5)/(17.7 - 5.7) = 0.18.

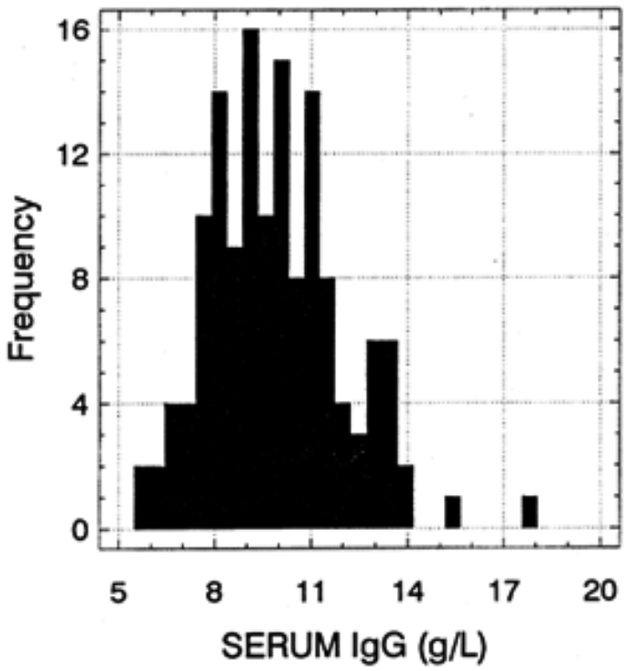

FIGURE 4.5. Reference distribution for serum immunoglobulin (IgG) G concentration. Serum IgG concentrations from 139 reference individuals are displayed in a histogram format. Visual assessment indicates that the data are skewed to the right and may contain several outliers.

TABLE 4.6. PARTIAL LISTING OF SERUM IMMUNOGLOBULIN G RESULTS FROM A REFERENCE SAMPLE OF 139 SUBJECTS

Rank	Immunoglobulin G (g/L)	Rank	Immunoglobulin G (g/L)
1	5.7	130	13.2
2	5.7	131	13.3
3	6.3	132	13.4
4	6.4	133	13.4
5	6.7	134	13.4
6	6.8	135	13.6
7	6.8	136	13.8
8	6.9	137	13.9
9	7.1	138	15.5
10	7.2	139	17.7

The immunoglobulin G results shown in the histogram in Fig. 4.5 were sorted in ascending order and assigned rank numbers of 1 to 139. The results occupying the 10 lowest and the 10 highest ranks are shown here.

Because the extreme value does not violate the one-third rule, it is retained.

Nonparametric Method

For the nonparametric estimates, the observations for the reference sample are arranged in ascending order and assigned rank numbers such that the lowest value is ranked 1 and the largest is ranked n (Table 4.6). The limits that enclose 95% of the reference population are estimated by identifying the rank numbers corresponding to the 2.5th percentile (r1) and the 97.5th percentile (r2) as follows (33):

$$r1 = 0.025(n + 1) = 0.025(140) = 3.5 \qquad (1)$$

$$r2 = 0.975(n + 1) = 0.975(140) = 136.5 \qquad (2)$$

Rank 3.5 corresponds to an IgG value midway between those that occupy ranks 3 and 4. Thus, by interpolation r1 = (6.3 + 6.4)/2 = 6.35. A similar interpolation of rank 136.5 gives a value of r2 = (13.8 + 13.9)/2 = 13.85. Thus, 6.4 and 13.9 are the estimated lower and upper reference limits, respectively. Ninety percent CIs for these limits depend on the sample size and are determined by consulting a table such as that presented in reference 34. For a sample size of 139, the CI for the 2.5th percentile is bounded by values corresponding to ranks 1 and 8 (5.7–6.9 g/L) and that for the 97.5th percentile, the values corresponding to ranks 132 and 139 (13.4–17.7 g/L).

Parametric Method

The first step in the parametric method is to test the assumption that the distribution of the RVs is normal. Simple tests for a normal distribution include the assessment of distribution shape; the comparison of the mean, median and mode of the distribution; and plotting of the data on normal probability paper (Fig. 4.6). More objective assessments include the evaluation of skewness and kurtosis and application of the chi-square test, the Kolmogorov-Smirnov test, or the Anderson-Darling test. These tests, which are available in many personal computer–based statistical software packages, are described in detail elsewhere (33,34). When the original data are normally distributed, the percentiles can be calculated directly as described below. If this is not the case, then the original data must be transformed. Transformation of many biological variables (which are often skewed

to the right) to normality can often be accomplished by taking the logarithm (y = lnx) or the square root [$y = (x)^{1/2}$] of the original results. If these simple transformations fail, more complicated single or sequential transforming functions can be applied (30,33,34). The success of any transformation must be verified by retesting using one of the graphical or statistical tests described above. The 2.5th and 97.5th percentiles are calculated from either the original or the transformed data as follows (33):

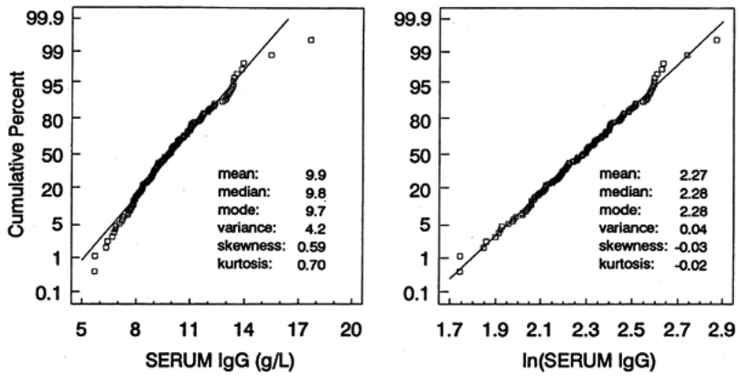

FIGURE 4.6. Evaluation of reference distributions of original and transformed data. **A:** The original reference values from Fig. 4.5 were analyzed by calculating descriptive statistics and by plotting on normal probability paper. The nonequivalence of the mean, median, and mode; the nonzero values for skewness and kurtosis; and the nonlinearity of the normal probability plot indicate a nonnormal distribution for the original data. **B:** The evaluation of the same criteria show that the reference distribution was transformed to "gaussianity" using a logarithmic transformation (y = lnx).

$$2.5\text{th percentile} = \bar{x} - 1.960(s) \qquad (3)$$

$$97.5\text{th percentile} = \bar{x} + 1.960(s) \qquad (4)$$

where [x with bar above] is the mean of the sample, s is the standard deviation, and 1.96 is the multiple for a standard normal deviate. (When n is less than 30, the t value for the 0.05 probability level at n degrees of freedom should be substituted for 1.960.) The 90% CIs for each percentile are estimated as:

$$\text{percentile} \pm 2.81[(s/(n)^{1/2}] \qquad (5)$$

In the IgG example presented above, the distribution of IgG values was nonnormal by both subjective and statistical criteria; however, the natural logs of the original data were normally distributed (Fig. 4.6). Using the mean and standard deviation of the transformed data, the percentiles and their 90% CIs are calculated as:

2.5th = 2.27 - 1.96 (0.20) = 1.87

CI = 1.87 ± 2.81 (0.20/11.78)

97.5th = 2.27 + 1.96 (0.20) = 2.67

CI = 2.67 ± 2.81 (0.20/11.78)

Back transformation by taking the exponents of each parameter gives a lower limit of 6.5 g/L (CI, 6.2 to 6.8) and an upper limit of 14.3 g/L (CI, 13.8 to 15.1).

Transference of RVs

The *de novo* establishment of RVs can be both difficult and costly, hence many laboratories have sought to adopt or transfer RVs from the literature or from the manufacturer's of instruments and reagent systems. In fact, it has been estimated that this practice may well account for the majority of RVs in use in clinical laboratories today (32). The act of transference of a RV from its originator to a receiving laboratory appears to be synonymous with the act of verification, as stated in the CLIA regulations and the CAP standards. One prerequisite for a valid transfer is that the original RV has been completely specified and that the original RV study was correctly performed. This being the case, the validity of the transfer hinges on two factors: the comparability of the analytical systems used in the original and the receiving laboratories and the similarity of the patient or client populations served by the two laboratories. If the analytical systems in the two laboratories are not identical, then the first issue should be addressed using studies and acceptance criteria such as those recommended in NCCLS document EP9-A. The second issue should be addressed by evaluating the match between the specifications of the original study and the conditions and the characteristics that prevail in the receiving laboratory and its patient population.

The minimum requirement for the verification (validation) of a transferred range is documentation showing that the pertinent factors of the original RV study have been reviewed and found to be applicable in the receiving laboratory (32). Depending on the circumstances, the receiving laboratory may either wish to or be required to further verify applicability of a transferred range by testing a small sample of reference individuals from its own population. Obviously, the small sample should be selected according to the principles described previously and its characteristics should match those of the original reference population in every significant way. Two options for sampling and statistical analysis have been recommended by NCCLS. The first involves the testing of 20 reference individuals from the receiving laboratory's subject population. These test results are examined for homogeneity, and outliers are excluded and replaced with new subject values to keep the total number of observations at 20. The transfer is considered to be verified if no more than two of the 20 values fall outside the 95% reference limits established in the original study. This critical value for rejection is derived from binomial probability theory, which holds that when the 95% RIs of the two laboratories are identical, the probability that more than two of 20 results will be outside the original RI is approximately 0.075 (30). If three or more values fall outside the limits, a second group of 20 subjects is evaluated by the same criterion. If the verification fails a second time, then the receiving laboratory should establish its own RVs in a full-scale study. The second option involves the testing of 60 reference individuals from the receiving laboratory's subject population. The criteria for verification—no significant difference in the means or variances of the original reference sample and the test sample—are the same as those recommended for evaluating the need to partition a reference sample into subclasses (44).

Recently, a novel statistical method involving Monte Carlo sampling was proposed for use in the verification of the transfer of RVs. This nonparametric method can be used to simultaneously evaluate multiple statistical parameters (e.g., means, medians, percentiles) and thus can provide for a more extensive comparison of an original and a test distribution. The theory behind this technique and examples of its application are presented in reference 45. The recently published NCCLS guidelines and the Monte Carlo method now provide several possible alternatives for evaluating objectively the acceptability of RV transfers. There is still a need for more research in this area to refine the current approaches and to develop techniques for the evaluation of more difficult cases including the transfer of RVs between different methods and different analytical systems.

Multivariate RIs

The comparison of a single laboratory result with its population-based RI is called a univariate comparison. When results from many different tests are each compared in this fashion, multiple univariate comparisons are made. Indeed, this is the way that panels of test results are usually evaluated. A major problem with this practice is that when 95% RIs are used, we expect 5% of the reference population to fall outside the interval. Therefore, when n multiple univariate comparisons are made, the probability that one or more of the results will fall outside of its univariate RI is:

$$p = (1 - 0.95^{n}) \qquad (6)$$

Thus, for five and 10 test panels, this probability would be 0.33 and 0.40, respectively. One way to solve this problem is to develop multivariate RVs that are based on the joint distribution of two or more variables in the reference population. In the bivariate case, the RI consists of a two-dimensional reference surface. In the trivariate case, the RI is a three-dimensional ellipsoid body. In the n-variate case, the RI is an n-dimensional body in hyperspace (46).

Multivariate RIs are established according to the same guidelines as univariate ones; however, the statistical analysis of the data as well as the subsequent use of the intervals requires computer programs designed for this purpose. The methods and conventions required for the establishment of multivariate RIs are discussed elsewhere (30,46). There are only a few instances in which bivariate RIs are routinely used in laboratory medicine. Our knowledge of the operating characteristics of tri- and n-variate RIs is even more limited. In general, the experience with multivariate RIs indicates that they do reduce the rate of chance positive findings among the reference population compared with the multiple univariate approach. A test battery can be highly unusual in the multivariate sense even though each of the individual test results is within its univariate RI. Conversely, the multivariate result can be within its RI even though a result for one of the variates is extremely unusual. Furthermore, multivariate RIs, which are typically population based, show the same insensitivity to significant changes in individual subjects as do univariate RIs (see Subject-Based RV's). The potential to use multivariate RIs effectively will surely increase with the data-processing capabilities of laboratory and hospital information systems; however, each potential application will require a thorough evaluation to determine whether the approach actually improves the diagnostic efficiency over that of the multiple univariate mode.

Subject-Based RVs

Individuality of Biological Variables

Although clinical laboratories devote considerable effort to the establishment and verification of population-based RVs, this type of reference system often lacks the sensitivity to detect clinically significant changes in an individual subject. This is owing to the fact that for many biological variables, the average amount of intraindividual variability over time is much less than the subject-to-subject variability (47). An example of this is shown in Fig. 4.7, in which the distribution of the means and ranges of serially measured IgG concentrations from single subjects are plotted (48). Considering that the population-based RI for this analyte is 600 to 1,200 mg/dl, it is apparent that a subject could have a serum IgG concentration that would be considered extreme relative to his or her own personal mean and yet still fall well within the population-based RI.

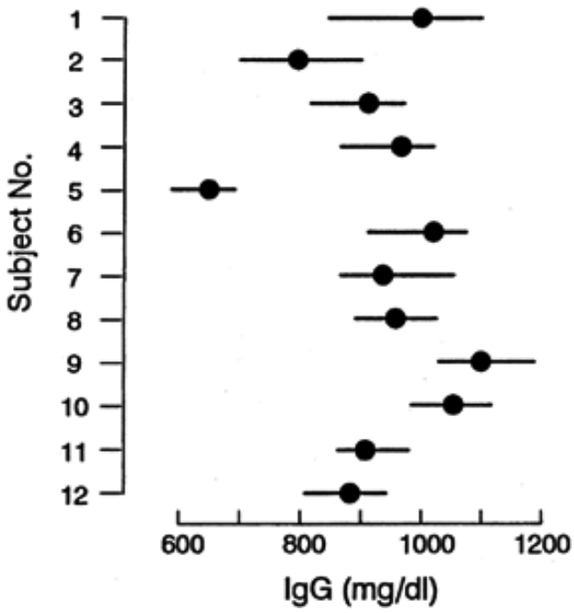

FIGURE 4.7. Intraindividual variability of serum immunoglobulin (IgG) concentration in 12 subjects. The means and ranges of serum IgG results from 12 subjects sampled on 10 occasions over a 3- to 5-month period are plotted in relation to the 95% population-based reference intervals of 600 to 1,200 mg/dl. Note that the range of values for any one individual encompasses only part of the conventional reference interval. (Redrawn from Fraser CG, Harris EK. Generation and application of data on biological variation in clinical chemistry. *Crit Rev Clin Lab Sci* 1989;27:409.)

One way to describe the degree of personal uniqueness or the individuality of a biological variable is by performing multiple determinations in individual subjects over time, calculating the different components of variance, and expressing the result as an index of individuality (II):

$$II = (CV_I^2 + CV_A^2)^{1/2}/CV_G \qquad (7)$$

where CV_I is the intraindividual coefficient of variation, CV_A is the analytical coefficient of variation, and CV_G is the within-group (subject-to-subject) coefficient of variation (31,48). Analytes with low indices demonstrate a high degree of individuality and vice versa. Harris (47) showed that when II is less than 0.6, the population-based RI will be insensitive to significant fluctuations within a subject. In contrast, when the index is more than 1.4, the population-based RI will be a more reliable reference (at least for a person whose mean and CV_I are about average). The within- and between-subject variations for many analytes are available in the literature (49,50 and 51), thus permitting the IIs for many of laboratory tests to be readily calculated. Index values for some common tests are presented in Table 4.7. One general conclusion from the literature on this subject is that IIs more than 1.4 tend to be the exception rather than the rule! This observation has several important implications for the field of laboratory medicine: the population-based RI is often a rather weak diagnostic tool, efforts to decrease CV_G (for example, by partitioning or exclusion) will improve the utility of the RIs that are derived, and the practice of using a patient's previous result (as determined in some defined state of health) as a RV should dramatically improve the diagnostic value of many laboratory tests.

Reference Change

The effective use of subject-based RVs requires the establishment of criteria for evaluating the significance of a difference between two successive test results. Empirical criteria for some routine laboratory tests have been established based on the results of surveys in which clinicians were asked to indicate how much a result would have to change before they would take action (52). Techniques for developing more objective statistical criteria have also been presented. One such criterion, the reference change

(RC), is defined as the difference between two successive measurements that would be statistically significant ($p < 0.05$) in 95% of the subjects in the reference sample (53). The development of a RC value requires the determination of the intraindividual variation under steady-state conditions (CV_I), the distribution of CV_I across the reference sample, and the incorporation of a model that describes the statistical relationship between serial measurements within an individual (30,52). If it is assumed that the intraindividual variation is constant across the reference population and that serial test results are statistically uncorrelated, the RC, i.e., the percentage of change that is considered to be significant, can be calculated as (51):

$$RC = 2.77\ (CV_A^2 + CV_I^2)^{1/2} \qquad (8)$$

This simplified model, which has been widely used, has been criticized as being too conservative, thus leading to a high proportion of positive findings that are neither medically nor clinically significant (30,51). Using what is claimed to be a more realistic model, RC can be calculated as:

$$RC = 2.77\ [\sigma_p^2\ (1 - r)]^{1/2} \qquad (9)$$

where σ_p is the 90th percentile of the true within-subject variance and r is the average serial correlation coefficient (54). A thorough discussion of the equations for calculating RC and the relative merits of the different models can be found in the references previously cited. An increase in the development and application of subject-based RVs is likely to occur in the field of laboratory medicine over the next decade. Such a change should greatly increase the value of laboratory test results to the process of medical decision making.

Clinical Decision Limits

These RVs consist of thresholds for an observed test result above (or below) which a clinician should (would) act to make some change in the management of a patient (55). These limits are developed by first defining the various reference populations relevant to the clinical question at hand. For example, in the simplest case we might consider two populations: one healthy and one affected with a particular disease. Next, the RVs for the populations are evaluated along with other relevant scientific or medical knowledge (i.e., the consequences or costs of misclassification, the prognostic implications of a high or low result, and the natural history of the pathologic process) to establish threshold values for the interpretation of the test result. The decision limits, which may be quite distinct from the reference limits for the test, can have either a broad or a narrow focus depending on the characteristics of the reference populations considered. Clinical decision limits are particularly useful for integrating laboratory test results into algorithms and critical pathways designed for the diagnosis and the management of different clinical problems. One well-known application of this type of RV is the establishment of plasma cholesterol concentrations of 200 and 240 mg/dl as clinical decision limits for the evaluation of hyper-cholesterolemia.

Presentation of RVs

Several different conventions for presenting quantitative results and their accompanying RVs have been proposed (32,34). The typical practice of presenting an observed result along with an upper and lower limit of the RI and flagging it as either high or low has been criticized for fostering the two-verdict (pathologic/nonpathologic) approach to interpretation and for being wasteful of the information contained in the reference distribution (34). Some laboratories have addressed this issue by reporting results in terms of standard deviation intervals of the mean of the reference distribution, multiples of the median, or as fractiles

TABLE 4.7. BIOLOGICAL VARIATION OF SELECTED ANALYTES IN HEALTHY POPULATIONS

		Biological Variability (%)		
	Analyte	CV_I	CV_G	Individuality Index
Serum				
	Sodium	1.07	0.54	5.9
	Potassium	1.2	1.6	2.0
	Calcium	2.4	3.8	3.9

	Potassium (24 h)	25.8	23.7	1.09
	Creatinine (random)	41	13	3.16
	Calcium (24 h)	26.2	24.3	1.08
	Albumin (24 h)	36	58	0.62

Within-individual (CV_I) and within-group (CV_G) of variation are given as percentages. The values for individuality index (II) that are marked with + were calculated using the observed total analytical variability for the analyte in the laboratory where the study was performed. In all other cases, II was calculated assuming a value of 3.0% for CV_A. In practice, the actual value for II will be less than the value given when CV_A is >3% and greater than the value given when CV_A is 3%. II at any value of CV_A can be readily calculated using formula (7) as given in the text.
Data from refs. 48,49,50 and 51.

or percentiles of the reference distribution. The most common example of this type of presentation is the use of multiples of the median in reporting results for maternal serum α-fetoprotein, human chorionic gonadotropin, and unconjugated estriol. Although the rationale for these alternate methods of presentation is well founded, such formats are not widely used in clinical laboratories in the United States.

For RVs to accomplish their intended purpose, they must be reported to the ordering physician along with a patient's test results. Ideally, the laboratory report should contain all RVs pertaining to the interpretation of a particular result. This could entail the inclusion of an assortment of RVs for healthy and diseased populations, a patient's previous test result and the RC, appropriate clinical decision limits, and so forth. Because the laboratory is usually unaware of the precise reason that a test was ordered and of the presence of preanalytical variables that might be unique to a particular patient, this comprehensive approach would permit the clinician to choose the most appropriate RV as a standard comparison. Conversely, the laboratory must strike a balance between supplying the most useful RV(s) and obscuring the decision-making process with superfluous data. One solution to this dilemma would be to supply the single most relevant RV and to make available via a computer terminal or a workstation other RVs of potential interest to a physician or client. With the future prospect of a totally electronic medical record and the great rate of advancement in the field of medical informatics, it is not unreasonable to expect that the application of multiple RV systems to a single analytical result will soon become a routine practice.

CLINICAL PERFORMANCE CHARACTERISTICS

Part of "4 - The Interpretation of Laboratory Tests"

The ability of a laboratory test to distinguish among the various possible alternative states or conditions of a subject is one of its most basic performance characteristics. Indeed, this characteristic, which is called the clinical accuracy of the test, is the most important property with respect to a test's utility or value in the process of medical decision making (56,57).

The clinical laboratory of a large hospital is likely to perform or refer hundreds of different tests that have been ordered to evaluate or monitor a variety of different medical conditions and disease entities. These considerations raise a number of important questions. What methods are used to evaluate the clinical accuracy of laboratory tests? When multiple tests reflect the functional status of an organ system or the activity of a disease, which test will be the most informative? How can the results of laboratory tests be combined with information derived from the clinical evaluation and other diagnostic procedures? How can data from multiple sites be combined to derive the best available estimate of the clinical accuracy of a particular test?

Such questions are critical not only from the standpoint of promptly achieving the best outcome for the patient but also from the standpoint of efficiency and cost-effectiveness. Once established, clinical performance characteristics help clinicians to select the most effective tests and testing strategies and to translate laboratory results into a probability statement regarding the likelihood of a particular disease or outcome in their patient. Clinical performance characteristics help the laboratory director to focus the resources of the laboratory on tests with the highest clinical relevance. This section is intended to review the theory and methodology related to the characterization of the medical usefulness of laboratory tests.

Establishing Clinical Performance Characteristics

The data used to establish the clinical performance of a laboratory test are obtained during the phase II and phase III clinical trials that are required for a test to be approved by the FDA as a medical device. Studies of a similar design are also often performed in the field after a test has been released. In a phase II trial, test results from selected patients having the disease for which the test is indicated are compared with results from control subjects who are disease free. In a phase III trial, the clinical accuracy of the test is investigated in the target population in which the test is intended to be used in practice. Four crucial design elements are essential to the validity of the parameters derived from clinical trials (58). (i) The clinical status of the subjects in each group should be established using a reference (gold standard) method. (ii) The trial should evaluate a broad spectrum of healthy and diseased subjects, and the diseased group should include patients with a wide range of clinical presentations. (iii) CIs should be calculated for all the parameters that are estimated. (iv) When the diagnostic accuracy of a new test is being compared with that of a previously established test, a large sample of patients should be studied, the exact number being based on the sensitivity and specificity of the new test and the prevalence of the disease in the population in which the new test will be utilized. A more comprehensive discussion of the philosophical and statistical rationale pertaining to these design elements is presented elsewhere (56,58).

Sensitivity and Specificity

Two of the most widely used parameters for describing the clinical performance of a laboratory test are the clinical sensitivity (Se) and clinical specificity (Sp). (These parameters should not be confused with the *analytical* sensitivity and the *analytical* specificity of a test—both of which are properties of test methods.) Figure 4.8 shows the distribution of test results from a phase I clinical trial of a hypothetical test in samples from healthy and diseased subjects and several diagnostic thresholds or cutoff values (A–D) that might be used to discriminate between the two groups. The Se of the test is defined as the proportion of the diseased subjects that have a test result that is higher than a particular cutoff. The results for these subjects are interpreted as being positive for the presence of the disease. The Se is equivalent to the true positive (TP) rate for the test. The Sp of the test is, by definition, the proportion of disease-free subjects who have test results that are lower than a particular cutoff value. These subjects are considered negative for the presence of the disease. The Sp is equivalent to the true negative (TN) rate for the test. If there was no overlap between the distributions of results in the healthy and diseased groups, a cutoff value could be chosen to classify correctly all subjects as either healthy or diseased. The Se and Sp of the test at this particular cutoff would both be equal to 1.0 and

the clinical accuracy of the test would be perfect. In practice, however, the distributions of the test results in the healthy and diseased groups usually overlap. Thus, no matter where the cutoff value is set in the area of overlap, there will be false-positive (FP) and false-negative (FN) test results. FP results will occur in nondiseased subjects whose results exceed the cutoff, and FN results will occur in diseased subjects whose results are lower than the cutoff. It is possible, and often desirable, to use different cutoffs for a particular test in different clinical situations, but in all cases, cutoffs that improve Se will diminish Sp and vice versa.

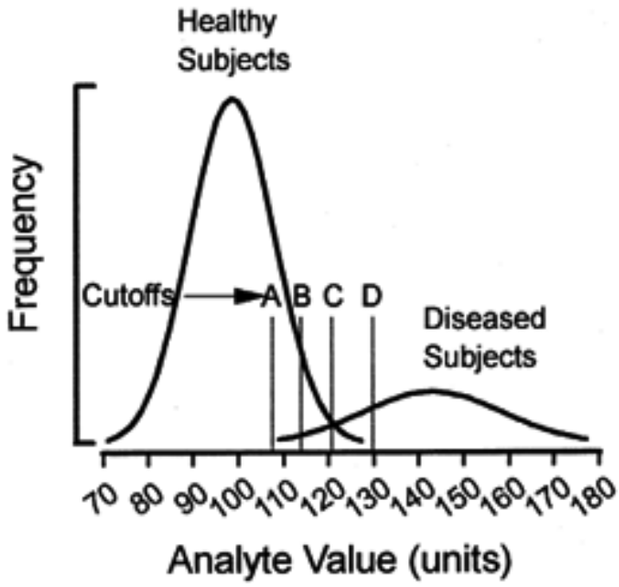

FIGURE 4.8. Frequency distributions of analyte values in healthy and diseased subjects. The values for the concentration of a hypothetical analyte were determined in a group of 200 healthy subjects and in a group of 50 diseased subjects. The raw data for each group were fitted to gaussian distributions. A through D represent possible cutoff values (or discrimination thresholds) that could be used to classify subjects based on their analyte values. See the text for details.

The calculation of Se and Sp with respect to any cutoff value is conveniently performed by arranging the test results for the healthy and diseased subjects in a two-by-two table based on the classification of each result as a TP, a FP, a TN, or a FN (Fig. 4.9) relative to the correct clinical state as determined by the gold standard method. Once the table is laid out, the parameters of interest can be quickly estimated using simple formulas.

Calculating Se and Sp

As an example of the calculation of Se and Sp, consider the hypothetical test used to determine the results presented in Fig. 4.8. The distributions of test results for 200 healthy subjects and 50 diseased subjects were obtained by gaussian fits of the original data. A tabulation of the original results relative to a cutoff value of 116 units is presented in a two-by-two format in Table 4.8. Using the formulas from Fig. 4.9, we calculate Se and Sp as:

Se = 48/(48 + 2) = 0.96

Sp = 194/(194 + 6) = 0.97

TABLE 4.8. A 2 × 2 TABULATION OF TEST RESULTS FOR 250 SUBJECTS

	Test Results		
Disease Status	**Positive**	**Negative**	**Totals**
Diseased	48	2	50
Healthy	6	194	200
Totals	54	196	250

Predictive Value and Bayes Theorem

Se and Sp are widely used for categorizing the clinical performance of a laboratory test. However, these parameters only express the probability that a diseased subject will have an abnormal result and the probability that a nondiseased patient will have a result within the RI. In practice, the clinician is usually most interested in evaluating the probability that a subject with a positive test result truly has the disease against the alternative hypothesis that the subject's test result is falsely positive (59). The proportion of total positive test results that are truly positive is called the predictive value of a positive test (PV+). Similarly, the proportion of total negative test results that are truly negative is the predictive value of a negative test (PV-). Again, calculation of these parameters can be quickly performed using the data in the two-by-two table along with the appropriate formulas. For the example presented above:

$$\begin{aligned} PV+ &= TP/(TP + FP) \\ &= 48/(48 + 6) = 0.88 \end{aligned} \qquad (10)$$

and

$$\begin{aligned} PV- &= TN/(TN + FN) \\ &= 194/(194 + 2) = 0.99 \end{aligned} \qquad (11)$$

It is important to remember that PVs determined in a clinical study are only accurate when the test is applied to populations with a disease prevalence that is similar to that of the study sample.

The dependence of PV+ on disease prevalence is expressed by Bayes theorem (60), which holds that:

$$\begin{aligned} PV+ = (Se)(prevalence)/[(Se)(prevalence) \\ + (1 - prevalence)(1 - Sp)] \end{aligned} \qquad (12)$$

When equation 12 is used to calculate PV+ in the above example in which the disease prevalence was 0.2 (i.e., 50 of the 250 subjects studied had the disease), the value of PV+ is identical to the value calculated using equation 10. However, equation 12 provides for the calculation of the expected value of PV+ at any disease prevalence. For example, if we were to use our test to screen for the presence of the disease in a population in which the prevalence was only 0.05, we can calculate that PV+ would decrease to 0.62. Thus, in this population, more than 40% of the positive results

obtained would be FPs. At a disease prevalence of 0.01, we calculate that 74% of the total positive results would be FPs. These exercises demonstrate why many a laboratory test that has looked promising when initially evaluated in a high-prevalence study population has later proved to be of limited value when applied to the general population with a lower disease prevalence.

Receiver Operating Characteristic Curves (61)

The receiver operating characteristic (ROC) curve is a graphical approach for determining the most efficient decision threshold or cutoff value for a laboratory test. The ROC curve can also be used to compare the relative clinical accuracies of different laboratory tests in a particular clinical setting. An ROC analysis is carried out by classifying the test result for each subject in a clinical trial as either positive or negative using a wide range of different cutoff values. The Se and Sp of the test at each cutoff are then calculated as described above, and the variables (1 - Sp) and Se are plotted on linear scales on the *x* and *y* axes, respectively.

The mythical “perfect” test in which Se and Sp are both 1.0 will graph as a rectangular hyperbola with its apex at the upper left-hand corner of the ROC plot (Fig. 4.10, left panel) (62). A test that does no better than a coin flip in differentiating healthy from diseased subjects will graph as a diagonal line with a slope of 1 and an intercept of zero (Fig. 4.10, right panel). Useful laboratory tests typically give plots that lie in between these two extremes (Fig. 4.10, center panel). In cases in which a single laboratory test is being evaluated, the single most efficient cutoff, i.e., the one that will maximize the number of correct classifications, is the one that plots nearest to the upper left corner of the curve.

DISEASE STATUS	TEST RESULT pos	neg	Total
DISEASED	TP	FN	TP+FN
HEALTHY	FP	TN	FP+TN
Total	TP+FP	FN+TN	TP+FP+FN+TN

FIGURE 4.9. A two-by-two table for calculating the sensitivity (Se) and specificity (Sp) of a laboratory test. A subject's test result is categorized into one of four groups based on whether it is above or below the cutoff value and the subject's true disease status as determined by independent criteria. Se and Sp are readily calculated using simple formulas. Sensitivity (Se) = TP/(TP + FN); Specificity (Sp) = TN/(TN + FP). TP, true positive test results; FP, false positive test results; TN, true negative test results; FN, false negative test results.

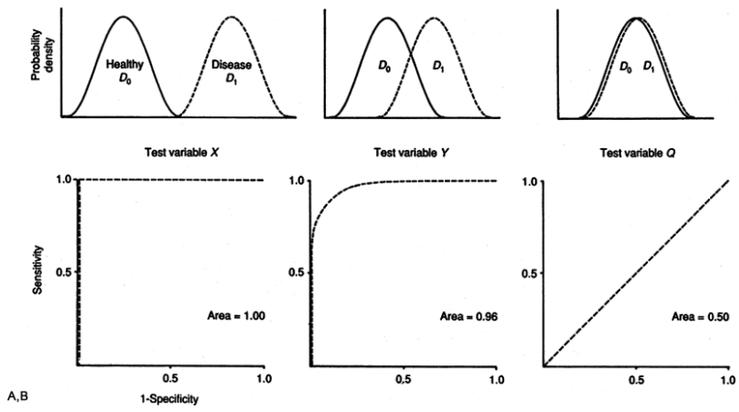

FIGURE 4.10. Receiver operating characteristic (ROC) curves for three tests of differing discriminatory power. The distribution of analyte values in healthy and diseased groups and the corresponding ROC curves are shown for a perfect test (i.e., with 100% clinical accuracy) **(a)**, a typical test that has adequate discriminatory power but will give some false positive and false negative results **(b)**, a test that does no better than chance at discriminating healthy and diseased subjects **(c)**. (Redrawn from Strike PW. *Measurement in laboratory medicine*. Oxford, UK: Butterworth-Heinemann, 1996.)

Constructing a ROC Plot

A ROC analysis of the test described in Fig. 4.8 was performed by selecting multiple cutoff points, calculating Se and Sp at each cutoff, and plotting (1 - Sp) versus Se as shown in Fig. 4.11. It is recommended that when possible, at least 10 cutoffs be evaluated in an analysis. These results show that the most efficient diagnostic threshold (i.e., the one that provides the most correct classifications of the study population) is 120 units. Keep in mind that, although this cutoff may be the most efficient overall, it might be desirable to use different cutoffs in different clinical situations. For example, if it was especially important that the test perform with 100% Se (and thus to identify correctly all diseased subjects) a cutoff value of 108 units would be the most effective. If achieving a Sp of 100% is crucial (thus avoiding the misclassification of a healthy subject), a cutoff value of 124 units might well be selected. When the relative performances of several tests are being compared, their ROC curves are plotted on the same axes (Fig. 4.11B) (58). The curve that most closely approaches the upper left corner of the plot is declared the more efficient test at the cutoff value corresponding to the upper left most point on its curve. This figure shows the comparison of serum parathyroid hormone (PTH), serum phosphate, and

serum chloride concentrations for the differentiation of patients with primary hyperthyroidism from control subjects. Serum PTH can be seen to have a higher Se and Sp than serum phosphate at all decision thresholds. Serum chloride has poor discriminatory power as demonstrated by the observation that the TP (Se) and FP rates (1 - Sp) are approximately equal at every decision threshold. Such a plot can be used to quickly determine the relative Se of the three tests at any desired level of Sp or their relative Sp at any desired level of Se.

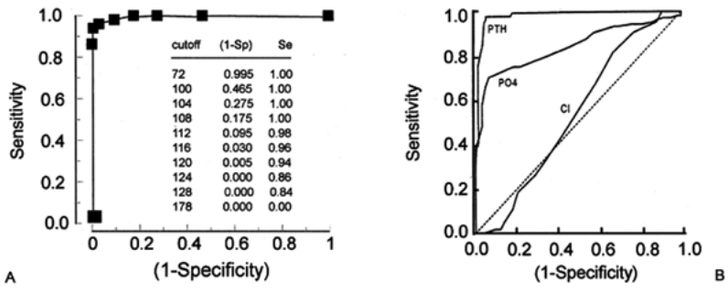

FIGURE 4.11. Construction and analysis of receiver operating characteristic (ROC) curves. **A:** A ROC curve for the hypothetical test shown in Fig. 4.8 was drawn by calculating sensitivity (Se) and specificity (1 - Sp) with respect to 10 cutoff values and plotting the results on a coordinate axis in which *X* = (1 - Sp) and *Y* = Se. **B:** A ROC analysis of the discriminatory power of serum parathyroid hormone, serum phosphorus, and serum chloride for the diagnosis of primary hyperparathyroidism. See the text for details. (Redrawn from Boyd JC. Mathematical tools for demonstrating the clinical usefulness of biochemical markers. *Scand J Clin Lab Invest* 1997;57 (suppl 277):46.)

The area under a ROC curve (AUC) can be used to express the overall clinical accuracy of a test as a single number (Fig. 4.10). By convention, the area is always in the range of 0.5 to 1.0, where 1.0 indicates that the test discriminates perfectly between the two groups, and a value of 0.5 indicates that the test does no better than a coin toss in discriminating one from the other. Unlike a point estimate, the AUC does not depend on a single region of the plot, nor does it indicate how well the test will discriminate at its single best cutoff. Rather, the AUC is a global measure of test accuracy. When the relative overall accuracies of multiple tests are compared by estimating the areas under their ROC curves, the test with the largest area is declared the most accurate. If the estimation of the areas is carried out using a computer program that calculates the CIs of the estimates, areas can be compared by statistical methods to determine the significance levels of any observed differences. For the comparison in Fig. 4.11B, the AUC for PTH, phosphate, and chloride were 0.983, 0.843, and 0.537, respectively, and the AUC for PTH was found to be significantly greater than that for the serum phosphorus test. The strength of AUC as an overall measure of performance can also be construed as a weakness because of the information that is lost when the curve is reduced to a single number. Two ROC curves with similar areas can have different shapes and if the curves cross one another, one of the tests will have a better Sp for a given Se, whereas the other will have a better Se at a given Sp (58). When the clinical accuracies of multiple tests are to be compared, it is always best if the clinical performance data for all the tests have been obtained from the same group of subjects. If this is not the case, then the statistical approach to data analysis will have to be adjusted to avoid bias in the results (58). Several commercial and public domain software programs for ROC analysis are available. These programs generally contain routines that will calculate Se and Sp, generate ROC plots, calculate AUCs, generate standard deviations and CIs for estimated parameters, and compare AUCs for multiple tests. A list of some of the more popular programs is presented in reference 61.

Summary ROC Analysis

In the emerging new field of evidence-based laboratory medicine, a composite version of the ROC curve called the summary ROC curve (sROC) is becoming more widely used for the assessment of diagnostic accuracy through metaanalysis (63,64). This approach involves extracting from the published literature clinical accuracy data from multiple independent studies and combining the results using mathematical models that account for study-to-study differences in diagnostic thresholds and sample sizes (65). By this technique, the Se and Sp determined for a laboratory test at multiple sites and involving a wide range of study subjects and clinical presentations can be combined. The composite sROC curve so derived represents, at least in theory, the best available estimate of the clinical accuracy of a diagnostic test.

Figure 4.12 shows a sROC curve for the metaanalysis of the Papanicolaou test based on the results of 62 studies involving a total of more than 20,000 subjects (65). The Se and Sp at the most effective discrimination threshold observed in each of the individual studies are plotted on the figure along with the sROC curve that was fitted from the combined data. Note that the estimates of Se for the individual studies ranged from 11% to 99% and the observed values for Sp ranged from 14% to 97%. This example shows the marked differences that can occur when clinical performance parameters are estimated at different sites and surely raises questions as to how much confidence should be placed in the results of any one published study. The sROC curve showed that the overall clinical accuracy of this test was not

high in studies performed before 1992 and that there was no cutoff point at which the test could simultaneously provide adequate Se and Sp. From the fitted curve, we can see that decision thresholds that provide a Sp in the 0.90 to 0.95 range (1 - Sp = 0.05 to 0.10) are associated with Se in the range of only 0.2 to 0.35. Metaanalysis is expected to have a significant positive impact on laboratory medicine by helping the field to establish reasonable expectations for clinical accuracy and to determine which tests provide the best information for clinical decision making.

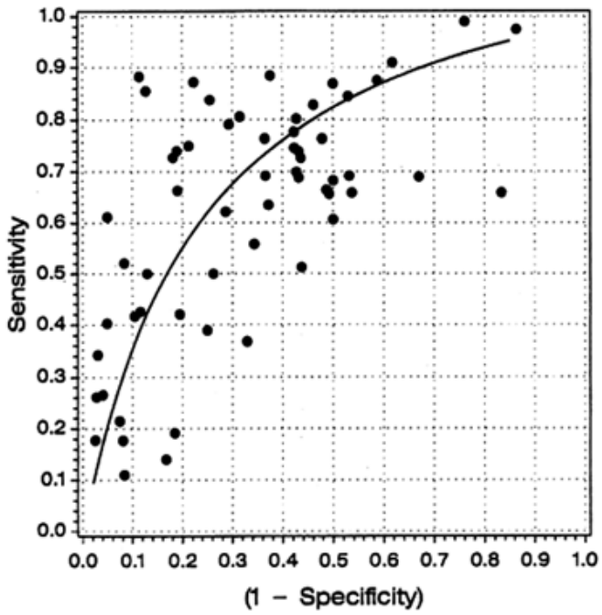

FIGURE 4.12. Estimation of clinical accuracy by metaanalysis. This summary receiver operating characteristic (sROC) curve for the Papanicolaou test is based on metaanalysis of 62 clinical studies. The sensitivity and (1 - specificity) values at the most effective discrimination threshold for each study are plotted as individual points. The combined data were used to derive a composite sROC curve. See text for details. (From Fahey MT, Irwig L, Macaskill P. Meta-analysis of pap test accuracy. *Am J Epidemiol* 1995;141:680, with permission.)

Likelihood Ratios

Another way of characterizing the clinical accuracy of laboratory tests is through the calculation of likelihood ratios (LHR) (58,59 and 60). A LHR expresses the probability that a particular outcome (e.g., test result, clinical finding) will occur in a diseased subject divided by the probability that the same outcome will occur in a nondiseased subject. For tests with only two outcomes or tests in which the results are interpreted using cutoff values that define two classes (positive and negative) of results, the LHR of a positive test (LHR+) is:

$$\begin{aligned} \text{LHR+} &= \text{Se}/(1 - \text{Sp}) \\ &= \text{TP rate}/\text{FP rate} \end{aligned} \qquad (13)$$

The LHR of a negative test (LHR-) is:

$$\begin{aligned} \text{LHR}- &= (1 - \text{Se})/\text{Sp} \\ &= \text{FN rate}/\text{TN rate} \end{aligned} \qquad (14)$$

For a continuous variable that is measured in two or more groups of subjects, the LHR+ at any cutoff value is equal to the ratio of the heights of each group's frequency distribution at the cutoff point. As is the case for Se and Sp, LHRs can be calculated for a test at a single or at multiple-decision thresholds or cutoffs. In addition, for continuous variables, LHRs can be established for different ranges of test results. In the latter case, the magnitude of a test result provides additional discriminatory power compared with the situation in which the result is merely categorized as positive or negative with regard to a cutoff.

In theory, LHRs for laboratory tests vary from 0 to infinity. A test with an LHR+ of 1 is considered to be of little or no value because in this case, an abnormal test result will be equally likely to be found in diseased and nondiseased subjects. Note that the LHR+ has the elements of a cost-benefit ratio in that the numerator in equation 13 (the TP rate) represents the benefit of testing and the denominator (the FP rate) represents the costs associated with testing (i.e., the FP results may lead to unnecessary further testing, inappropriate treatment, and anxiety among the subjects tested) (66). The discriminatory power of a test increases as its LHR+ increases above a value of 1.0. The LHR- expresses how many times less likely a normal test result is expected to occur in a diseased subject than in a healthy subject. The values of LHR- of clinical interest lie between 0 and 1, with the smallest values being associated with tests of the highest negative predictive value. The LHR- can also be interpreted in terms of cost and benefit with the numerator of equation 14 (the FN rate) representing the cost of testing and the denominator (the TN rate) representing the benefit of testing.

The greatest advantage of using LHRs to evaluate the clinical performance of laboratory tests is that when the probability of disease before testing is known (or can be estimated), the LHR+ and LHR- allow the direct estimation of the posttest probability of disease in view of the new information contributed by the test result (67). Furthermore, when serial testing strategies are used, the posttest probability after the first test is performed can be used as the pretest probability for the next test in the series. Thus, the overall impact of applying of a series of tests can be calculated. Finally, LHRs can be estimated for clinical signs and symptoms as well as for nonlaboratory diagnostic procedures (e.g., electrocardiographic findings, radiographic results), thus allowing the information from different modalities to be combined in serial diagnostic schemes or “critical pathways” for which overall predictive values can be calculated (68).

Working with LHRs

The most convenient way to work with LHRs is to convert probabilities of disease into the odds of disease and to use a simplified version of Bayes theorem:

$$\text{Pretest odds} \times \text{LHR} = \text{Post test odds} \qquad (15)$$

Odds and probabilities are interconverted using the following two formulas:

$$\text{Odds} = \frac{\text{Probability}}{(1 - \text{Probability})} \qquad (16)$$

$$\text{Probability} = \frac{\text{Odds}}{(1 + \text{Odds})} \qquad (17)$$

As an example of how to calculate and use LHRs, consider a patient who is being evaluated for the possible presence of a condition that has a prevalence of 20% in the population. The pretest odds of disease, as calculated from equation 16 are

$$\frac{(0.2)}{(1-0.2)} = \frac{0.2}{0.8} = 0.25$$

If during the physical examination the clinician were to identify a clinical sign or symptom that had previously been shown to have an LHR+ of 3.5 for the presence of the disease, the post-examination odds of disease would be raised to:

0.25 × 3.5 = 0.875

(disease probability = 0.875/1.875 or 0.47)

If this clinical assessment were then followed by the performance of a laboratory test with a LHR+ of 30, the posttest odds of disease in the presence of a positive test result would be:

0.875 × 30 = 26.25

(disease probability = 26.25/27.25 = 0.96)

Thus, the serial application of the clinical assessment and the laboratory test increased the probability of disease in this patient from 0.20 to 0.96. The LHRs for many clinical criteria, laboratory tests, and nonlaboratory diagnostic tests are now available in the literature. A sample of the range of LHR+ and LHR- values for selected clinical and laboratory evaluations is presented in Table 4.9 (59,67,68,69 and 70). Note that there are many cases in which clinical assessments have a discriminatory power that meets or exceeds that of a laboratory test that might be ordered to support a diagnosis. Also note that when multiple LHRs are established for different ranges of values for continuous variables (e.g., fasting plasma glucose), the magnitude of a disease-related change adds further discriminatory power to the test.

TABLE 4.9. LIKELIHOOD RATIOS FOR SELECTED LABORATORY AND CLINICAL EVALUATIONS

Disease	Evaluation	LHR+	LHR-
Sinusitis	Clinical	39	0.12
Deep vein thrombosis	Clinical	17	0.15
	Ultrasound	32	0.03
Streptococcal pharyngitis	Clinical	6.3	0.18
	Rapid antigen test	7.0	0.33
Bacterial infection, newborn	Band cell count > 1,000/mm^3	5.4	0.55
	White cell count ≥ 20,000 or < 5,000	1.8	0.81
	C-reactive protein > 10 mg/L	6.4	0.51
	Ear swab culture	7.5	0.33
Intermittent bacteremia	Blood culture, 1 set	129	0.26
	Blood culture, 2 sets	76	0.025
	Blood culture, 3 sets	53	0.015
Tuberculosis	Sputum smear	31	0.79
Myocardial infarction	Electrocardiogram	2.6	0.27
	CK-MB (single test)	2.8	0.75
	CK-MB (serial tests)	50.0	0
Cushing's syndrome	Central obesity	3.1	0.14
	Skull radiograph	10.6	0.49
	Plasma cortisol, 0800 h	2.5	0.16
	Plasma cortisol, 2400 h	24.0	0.04
Non-insulin-dependent diabetes mellitus	Fasting plasma glucose		
	>80 mg/dl	3.1	0.68
	>100 mg/dl	3.4	0.22
	>110 mg/dl	9.6	0.37
	>120 mg/dl	29.8	0.47
	>130 mg/dl	211	0.58
	>140 mg/dl	∞	0.69
Pheochromocytoma	Computed tomography scan	5.6	0.10
	Urinary catecholamines	16.4	0.19
Primary hypothyroidism	Serum thyroxine, decreased	6.0	0.12
	Thyroid-stimulating hormone, elevated	99	0.01
Primary hyperthyroidism	Serum thyroxine, increased	9.0	0.11
	Thyroid-stimulating hormone, suppressed	99.0	0.01
Ankylosing spondylitis	Clinical	6.3	0.18
	Human lymphocyte antigen B27 testing	11.5	0.09

Data from refs. 56,67,68,69 and 70.

One caveat that must be observed when combining LHRs for individual tests or criteria in a serial evaluation scheme is that each test or criterion in the series must be independent of all the others. In the absence of independence, the value calculated for the postseries probability of disease may be grossly erroneous. A second caveat is that LHRs, as estimates based on samples from a population, have CIs that indicate the reliability of the estimates. As was the case for reference limits, LHRs with narrow CIs are expected to give more accurate predictions of posttest probability than LHRs with wide CIs.

Nomogram for Estimating Posttest Probabilities

A posttest probability can also be directly determined from a pretest probability and a LHR using the nomogram (Fig. 4.13) originally published by Fagan (71). In addition to being convenient, this nomogram is instructive in that it demonstrates graphically the value of tests with very high or very low likelihood ratios for ruling in or excluding disease. For example, if a patient with a pretest probability of disease of 10% tests positive in a test with an LHR+ of 50, the posttest probability of disease is raised to 85%. If the same patient were to test negative on a test with an LHR- of 0.005, the posttest probability of disease would be decreased to less than 1%. Tests with LHRs near 1 are rarely effective in adding information to a clinical decision. This nomogram permits the potential information content of a test result to be rapidly evaluated.

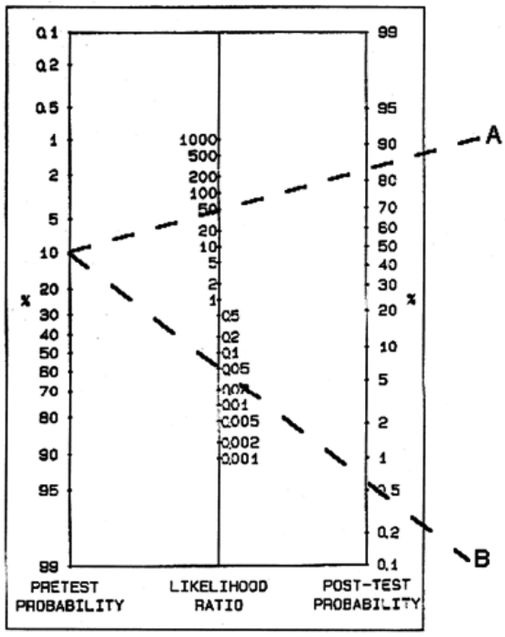

FIGURE 4.13. Nomogram for applying likelihood ratios (LHRs). This nomogram is used by drawing a line from the pretest probability on the left axis through the likelihood ratio of the test on the center axis and extending the line until it intersects the right axis. The posttest probability after application of the test is indicated at the point of intersection. The dashed lines show how positive findings for tests with LHRs of 50 (line A) or 0.005 (line B) markedly change the probability of disease from the pretest value of 10%. (Redrawn from Fagan TJ. Nomogram for Bayer theorem. *N Eng J Med* 1975;293:257.)

Estimating LHR from ROC Curves (72)

LHRs for a particular test can also be obtained directly from a ROC curve by evaluating the slopes of the curve in different regions (Fig. 4.14). If a test generates results on a continuous scale, then the slope of a tangent drawn to the ROC curve at any point is equal to the LHR for a single test result corresponding to that point on the curve. If a test generates dichotomous results (i.e., positive or negative relative to a cutoff), the slope of the curve between the origin and a point on the curve corresponding to any cutoff is equal to the LHR of a positive test when the results are classified as positive or negative according to that cutoff. If the test generates results that are classified into more than two intervals, the slope between the two points corresponding to the upper and lower bounds of the interval is equal to LHR for a test result that lies within the interval. These relationships provide a convenient means for the estimation of LHRs from ROC and sROC curves.

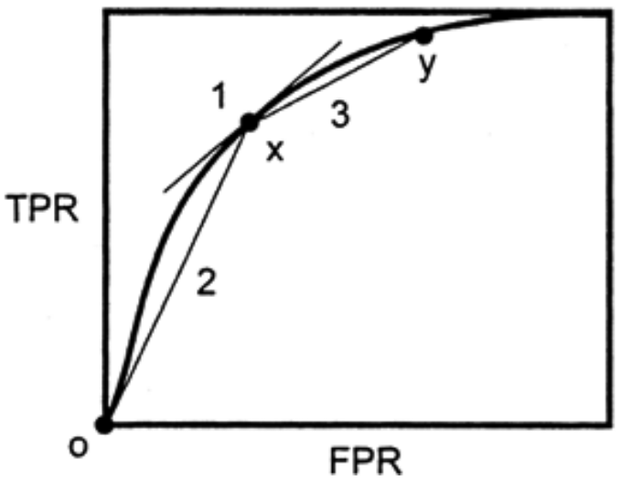

FIGURE 4.14. Estimating likelihood ratios from a receiver operating characteristic (ROC) curve. Three different slopes of an ROC curve: 1, the slope of a tangent at any point; 2, the slope of a line from the origin to any point on the curve and 3, the slope of a line connecting any two points on the curve correspond to different likelihood ratios for the test. See the text for details. (From Choi BCK. Slopes of a receiver operating characteristic curve and likelihood ratios for a diagnostic test. *Am J Epidemiol* 1998;148:1127, with permission.)

As stated previously, information obtained from the history and physical examination and from nonlaboratory diagnostic modalities is often sufficient to raise the pretest probability of disease to such a high level that additional testing may be superfluous. The clinician must ultimately decide when and when not to test based on the level of certainty that is required before applying various treatments or therapies. For example, a lesser degree of certainty might be acceptable in cases in which intervention is inexpensive and innocuous and the consequences of nonintervention are serious. Although such decisions are not always straightforward, careful consideration of the cost-benefit relationships using clinical performance characteristics can have a great impact on the economics of laboratory testing by minimizing the utilization of tests that do not make a significant contribution to diagnosis and management.

The three main topics of this chapter—biological variation, the establishment and use of RVs, and the clinical accuracy of laboratory tests—are highly interrelated, and the full appreciation of the significance of any test result requires a considerable understanding of the theoretical and practical aspects of each subject. As laboratorians, our efforts to minimize sources of error, variability, and misunderstanding in these three areas of practice will increase the value of laboratory services to our clinicians and their patients.

ACKNOWLEDGMENTS

Part of "4 - The Interpretation of Laboratory Tests"

The author thanks Ms. Debra Holmes and Ms. Decarlo Sykes for their help in preparing the manuscript. The author is especially

grateful to Edward W. Bermes, Jr., Ph.D., Professor Emeritus of Pathology, Loyola University of Chicago, for serving as a mentor, a colleague, and a friend throughout the author's career in clinical chemistry. The author also thanks his many colleagues in Pathology including the faculty, technologists, residents and administrators who were part of the dynamic and challenging practice environment from which this effort emerged.

Laboratory Information Systems

Kenneth D. Mcclatchey

Marisa Saint Martin

Information systems in pathology provide opportunities for pathologists and clinical laboratory scientists to have an impact both clinical care and modern research agendas. Not many technologies have had the implications and critical contributions to humanity as have the information technologies.

Radical changes in the health care system are creating a new role for the pathologist. This role has to do more with the management of information than with reading a slide and making the correct diagnosis. This is a new opportunity for pathologists that needs to be seen and captured in time. Business skills including marketing and management are becoming as important to success as clinical expertise. Information technology is essential as a link to all segments of integrated medical delivery systems: a tool to convert data into useful information and a source of knowledge for determining clinical efficacy versus cost. Clear communication between the pathologist and the clinician is vital for quality health care, and even though the primary mode of communication has been the pathology report, we may have to rethink the way we report in an attempt to provide the clinician (and possibly the patient) with integrated useful information for each particular patient instead of just data. The pathologist with interest in and appropriate knowledge of information systems is in a unique position to become an expert in information management.

HISTORY

Part of "5 - Laboratory Information Systems"

Digital computers became available for general use in the late 1950s. Early computers provided few user-oriented features and required considerable knowledge and skill to operate. They ran batch-oriented programs and supported single-tasking only. FORTRAN (formula-translation) and COBOL (common business-oriented language) were the only high-level languages available. Typically, mainframe computer systems were encased in rooms with glass walls and were tended by computer specialists who spoke their own language and were often far removed from normal hospital activities. This specialization and remoteness often resulted in the development of applications that were ill-suited to the workday departmental information processing needs of hospitals.

Early in the development of the field, most major computer manufacturers such as IBM, Burroughs, Honeywell, and NCR, understanding the potential for sales in the health care market, were active in their support of hospital information systems. Corporations such as Lockheed and McDonnell-Douglas, which were experienced in using computers to manage complex management tasks, also decided to offer health care computing as business ventures. For example, Lockheed supported the early development of the Technicon Hospital Information System.

The Technicon system, begun by Lockheed in the 1960s, installed at the El Camino Hospital in Mountain View, CA, became the best known and most successful patient management system of its time. The ultimate success of the system at El Camino led to the spread of this and other systems to other hospitals. The Technicon system is still being marketed today, which is unusual because many of the early software and hardware vendors have gone out of business or are no longer active in the hospital market.

In 1987, Hammond (1) listed five factors that have driven the development of hospital information systems:

1. Hardware and software technological factors: During the development period, computers evolved from single-tasking “untouchable” and unfriendly mainframe computers to highly interactive and multiuser minicomputers
2. Increasing technological expertise on the part of system developers and users
3. Economic factors: As the cost of delivering health care increased, computers seemed to offer at least the opportunity to operate in a more efficient manner
4. An increase in the amount of laboratory data generated, which necessitated more automated procedures
5. Increased influence of external organizations: Information requirements of federal and state governments and third-party payers forced hospitals to turn to automated systems for financial and patient management applications

PERSONAL COMPUTERS: HOW DO THEY WORK?

Part of "5 - Laboratory Information Systems"

A typical personal computer will have several basic components. Whatever the machine, it will have a keyboard or any other means of entering information (input device), a video monitor, printer or other means of getting information back out to the user (output device), and a method of making permanent

records of running additional software (disk drive). All these components are arranged in the system board (Fig. 5.1). The system board includes the central processing unit (CPU), which is the microprocessor that directs all the computer activities; an auxiliary CPU, a crystal quartz clock that coordinates the responses of the computer's many circuits, the ports for connecting input and output attachments, and two very important microchips for internal memory: the ROM and the RAM (Fig. 5.2).

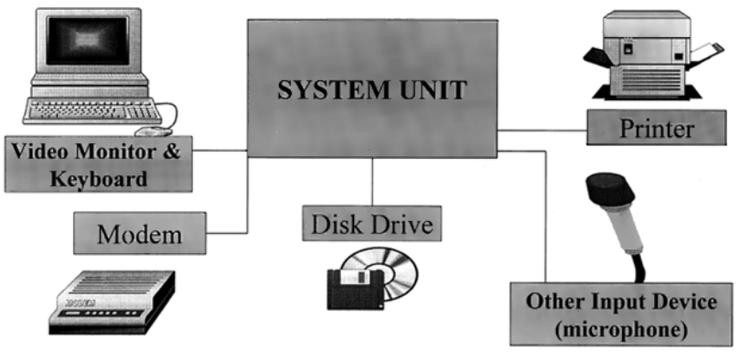

FIGURE 5.1. Components of a personal computer.

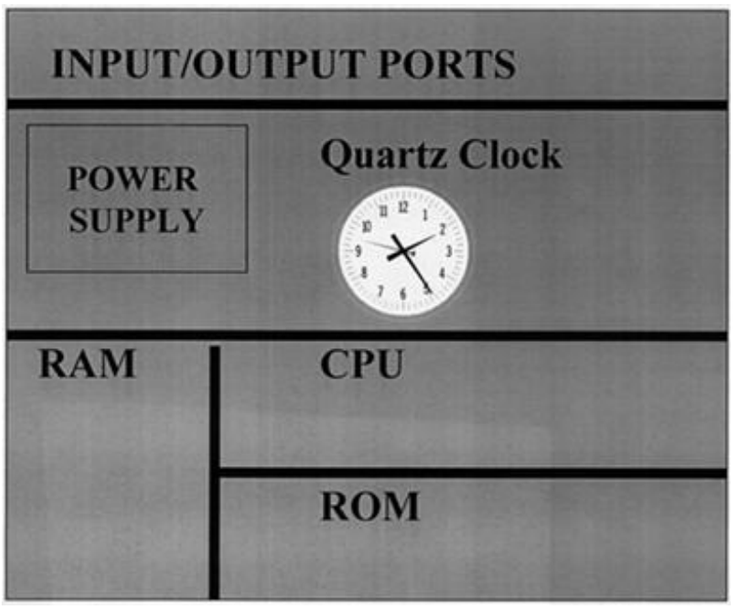

FIGURE 5.2. Components of a computer.

The ROM (read only memory) holds instructions that cannot be altered. The RAM (read and write memory or random access memory) stores programs and information only when the computer is operating. It can be changed by the user.

Computers only read or understand binary digits. Binary digits have only two components or possible states, such as 1 and 0 or true and false. Computers use a combination of 1s and 0s to create numbers and words. A bit (short for binary digit) is the smallest unit of information. A nibble is four bits, and a byte is a sequence of eight bits, treated as a storage unit. For example,

bit: 0 or 1
nibble: 0010
byte: 00100010 → this sequence equals the number 34

A megabyte (MB) is the hard disk storage capacity and represents 1,000,000 bytes. A gigabyte (GB) is 1,000 megabytes and a terabyte (TB), 10,000 megabytes.

The executed instructions of a computer are in the form of high-level machine languages such as Lobol (used for numbers), Pascal, Fortran, Mumps (for medical terms), Basic, and Java (for networks).

Computers today usually handle memory using a 32- to 64-bit (or better) architecture; they have 90 to 550 MHz (speed of replacing one image with the next one), and 28 dot per inch screen (defines sharpness). The chip in the motherboard for speed of the run of the computer has several upgrades from 286 to 386 to 486 to Pentium, Pentium II, and Pentium III.

A modem is a device that allows connection of the personal computer through telephone or fiber optic lines. It can be internal or external. The modem speed unit is called the baud.

In general, the hardware constitutes the physical parts of a computer, and software represents all the instructions that tell the computer what to do, how to act, and so on. Computer programs are examples of software. Program files are the commercial ones that can be purchased; data files are the ones the operator creates. The operating system is a combination of programs that coordinates the computer duties and manages the storage of other programs and other information. It acts as the “stage manager.” The application programs are the “stars” (e.g., word processor, games). Translator programs convert statements of higher level languages into machine language. Utilities programs perform sorting/merging of files. When a computer is turned on, a series of self-checks of internal components and functions takes place so rapidly as to seem almost simultaneous. Only seconds after, a message appears on the monitor to indicate that the computer is set for action.

DIVISION OF PATHOLOGY INFORMATICS

Part of "5 - Laboratory Information Systems"

Seventy to 80% of important medical decisions involves a laboratory test, and the formation of a pathology informatics division is imperative in this new era of health care delivery. The division would be responsible for improvement and growth of the laboratory and anatomic pathology and its interconnection with other hospital information systems. It should have an administrative component and personal computer support and should also be responsible for the academic computing of the department (Fig. 5.3). An intense collaborative process must exist between the hospital information system (HIS) and the laboratory

information system (LIS). The LIS relates to the HIS, the billing system, ancillary reporting and record keeping, and electronic record and custom reporting. When an order is placed on the floor (HIS), the information is transferred to the LIS. The LIS prints the labels and the labeled specimen is delivered to the laboratory. After the results are obtained, the information is entered into the LIS and the data are sent to HIS upon inquiry. The reports are prepared on a LIS (Fig. 5.4).

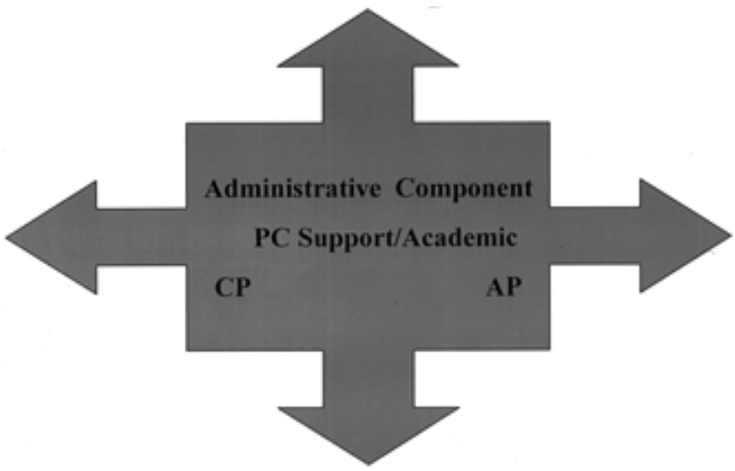

FIGURE 5.3. Division of pathology informatics.

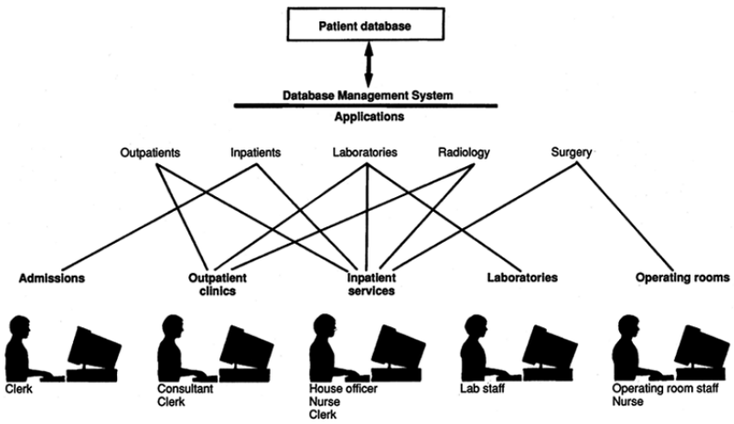

FIGURE 5.4. Applications sharing an integrated database.

Several types of interfaces are required for this process to run: ADT (admission/discharge/transfer), orders, results, billing, reference labs. HL7, (a protocol for formatting and transmitting data in the health care environment) is an example of commonly used interfaces. Transferring of the data is only one of the functions of the interfaces. Others include code translation, conversion of protocol and date, and error handling.

ANATOMIC AND CLINICAL PATHOLOGY: THE NEW ERA

Part of "5 - Laboratory Information Systems"

Indisputably, with the many economic forces influencing the medical field, the demands on the anatomic and clinical pathology laboratories continue to escalate with the increasing volume of specimens and expectations for a shorter turnaround time. Not only the laboratory, but radiology, radiation oncology, nuclear medicine, pharmacy, and home health care, among others, are part of the scope of the clinical, information systems. This clinical integration of information is developing new career opportunities for many people. Seminars, conferences, training programs for residents, students, pathologists, and fellowships in informatics are only the beginning of this fast-growing segment of medicine, which is becoming a new medical specialty.

THE LABORATORY INFORMATION SYSTEM

Part of "5 - Laboratory Information Systems"

The LIS provides different services for the laboratory itself as well as for the clinical services. Order and result entry, inquiry, inventory control, and time management are the most common laboratory services obtained from the LIS. For the clinical services, reporting and patient institutional billing are the most used services. The LIS is also extended into decision support through internal or external rule engines, hospital mergers, and outreach

to remote laboratories or physician practices. The pathologist as an information manager has become a vital link between the patient, the clinician, researchers, and other pathologists (Fig. 5.5). Considering that approximately 70% to 80% of the information regarding patient care will be generated in pathology laboratories, we have an obligation to communicate that information in a clear, timely, available, and complete manner.

FIGURE 5.5. Anatomic pathology impact. Making the diagnosis is only half of the struggle. We are only as good as the clarity, timeliness, availability, and completeness of our reports.

Reporting

Pathologist–clinician communication is vital; however, it is difficult to find the time to discuss across a microscope or a conference table. Providing a clear and complete report with integrated information including all significant diagnostic and prognostic tests will improve the clinical service that patients receive (Fig. 5.6). There is an enormous educational value in accurate/educational reporting, not only for the clinicians but also for the interested patient, who may already come to see his or her doctor with pages of information obtained from the Internet.

Integrated report example

Patient demographics	Case worker
Gross pictures	Gross description
Microscopic picture	Microscopic description or comment
Molecular or Flow cytometry studies and special procedures.	
Final Diagnosis (with integrated comment)	

FIGURE 5.6. Integrated report example.

Work Flow

With a good computer system, the work flow in the pathology lab can be improved to the limit of the imagination of the medical director or the information division chief and the system capabilities. Cytology quality assurance, tissue coding, online stain ordering, resident signout/review, and electronic sign out can all be done faster, in a more reliable manner with a state-of-the-art anatomic pathology system, for example.

Productivity

Productivity is enhanced by the use of e-mail, personal computers allowing multiple functions, transcription reengineering, training of residents/fellows, and studying material for examinations, marketing, information. Informatics can be the gateway for pathology to develop links to the community we serve.

System Selection: Purchase of a LIS

For those clinical laboratories that are already computerized, the rationale for upgrading an existing LIS is relatively simple: it would be unthinkable to return to a manual information processing system. The need to develop a rationale for purchasing a system is much more appropriate for laboratories not currently running a LIS. Despite the usual visceral reaction that modern organizations ought to be computerized, it is a useful exercise to list formally the advantages and disadvantages of a LIS. The development of a list may avoid the naive expectation that a LIS will solve all the problems of the laboratory.

Strengths

- Ability to perform the same task as many times as needed in the same way
- Speed
- Perfect memory

Weaknesses

- Stupidity (computers can do only what they are programmed to do)
- Inability to make inference
- Inability to deal with exceptions
- Inability to deal with broad constructs

Benefits with Proper Human–Machine Interface

- Laboratory professionals acquire “perfect memory”
- The computer’s ability to perform repetitive tasks relieves the laboratory staff of onerous aspects of work
- Laboratory professionals deal with exceptions
- Laboratory professionals increase their capabilities and shift their emphasis toward the tasks for which they are trained

The realization of these benefits assumes that the human–machine interface is properly designed. The basic thrust of Korpman's (2,3) reasoning is that a LIS will shift much of the drudgery of routine repetitive rote tasks to the computer, allowing laboratory personnel to exercise their intellect by dealing primarily with exceptions. This is a very praiseworthy objective.

Although Korpman is undoubtedly correct in his analysis, the pathologist seeking to justify the purchase of a LIS to hospital administrators may sometimes require a more tangible, exact list of reasons for the purchase of such an expensive item.

A number of data-handling activities must be performed manually if there is no LIS support for the clinical laboratory activities. They include the following:

1. Creation of phlebotomy drawing lists
2. Distribution of completed manual test requisitions to the individual laboratories
3. Creation of intralaboratory worksheets
4. Distribution of hard copy test results to patient care units
5. Individual response by laboratory to telephone queries for test results

To develop a cost-benefit analysis for a LIS to total costs of personnel to perform these and other functions must then be compared with the purchase and support cost of LIS hardware and software, as well as the personnel costs for the direct support of the computer. It is important not to overlook that some of the personnel costs associated with a LIS are related to individuals not directly assigned to the LIS unit, such as technologists in other clinical laboratories.

Hendricks and Langhofer (4) in 1982 evaluated the impact of the acquisition of a LIS on a community hospital. The acquisition produced a decrease in inflation-adjusted labor costs per unit of work, a decrease in inflation adjusted direct cost per unit of work, a decline in the ratio of clerical-to-technical labor force, and an increase in overall laboratory productivity. Comparison of the average College of American Pathologists' (5) *Manual for Laboratory Workload Recording Method* units per laboratory full-time equivalent for the 3 years before and 4 years after the LIS installation showed a 12% increase in productivity compared with a 5% increase in automated tests. The authors concluded that productivity in their laboratory rose by approximately 7% (overall productivity increase minus the increase in automation) as the result of computerization.

Hendricks and Langhofer (5) stress that there are several nonquantifiable effects of computerization that must be factored into any cost-benefit analysis. An example is the development of *ad hoc* reports by extraction of information from the laboratory database for quality assurance, utilization review, or risk management. With manual systems, such reports are the result of many man-hours of work.

Justifying the cost of a LIS is most interesting from the perspective of increasing the efficiency of physicians and providing a better patient outcome. Few would deny that the creating of a hard copy interim test report, organized by laboratory with a moving 4-day window of current and previous results, makes physicians more efficient. They are also made more efficient by remote stat delivery of test results to critical care units immediately after test verification. Access to a long-term on-line archive of test results becomes critical when handling and transporting the paper record is difficult.

Ultimately, the necessity to computerize the clinical laboratories in a hospital is driven by two factors: (a) high labor costs in a hospital makes the automation of manual processes attractive from a financial point of view and (b) reports and quality assurance activities, which simply cannot be provided by manual systems, are being demanded with increasing frequency in all hospitals regardless of the resource implications.

There are 13 major steps in the selection and installation of a LIS:

1. Creating a LIS project team
2. Gathering information
3. Reviewing and analyzing the information collected
4. Developing and distributing a request for a proposal
5. Evaluation vendor responses
6. Selecting a vendor
7. Negotiating with a vendor and developing a contract
8. Training and site preparation
9. Installing the hardware
10. Making parallel runs
11. Going live
12. Fully operating
13. Evaluating and monitoring

THE LIS PROJECT TEAM

Part of "5 - Laboratory Information Systems"

Once the decision has been made to purchase a LIS or to upgrade an existing system, it is necessary to assign a task force of hospital personnel to coordinate the project from its inception until the system is turned over to personnel in the LIS unit after the go-live date. The working core of the project team *must be* clinical laboratory personnel. They are the natural leaders of the project team because a successful LIS implementation is critical for them. Conversely, the participation of personnel from outside the clinical laboratories can also be critical to the success of the project, and their participation should be encouraged. For example, a clinician who can speak to the needs of the physicians in terms of test reporting formats and locations of terminals for data retrieval should be represented on the project team. Gunton describes the design process using a diagram. He explains the initial process as trying to close the information gap. Ultimately, maintenance programmers and users will attempt to close the maintenance gap throughout the life of the system (Fig. 5.7).

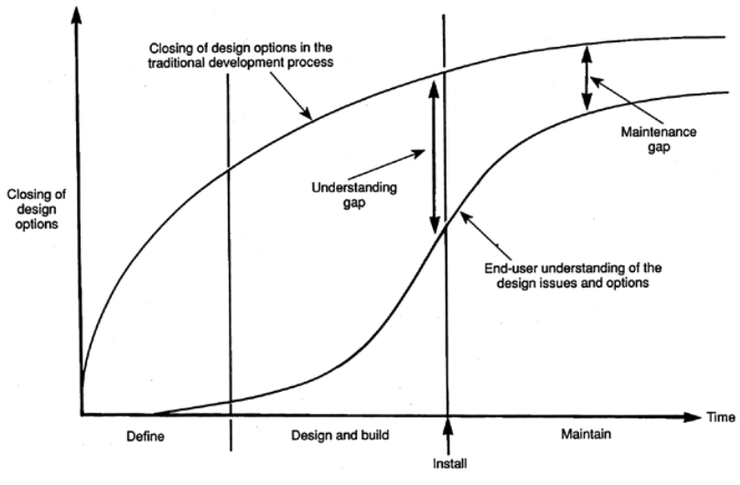

FIGURE 5.7. Laboratory information system design process and end-user learning curve.

INFORMATION GATHERING

Part of "5 - Laboratory Information Systems"

There are four general sources of information about laboratory information systems: causal conversation among professional colleagues, written publications by professional societies, vendor-generated print materials, and vendor displays at national and regional meetings. Even with written material from multiple sources at hand, it may be difficult to isolate the essential pieces of information (e.g., what language is the system written in, are all laboratory modules up and running, how many sites were installed in the past calendar year?).

In most instances, it is possible to reduce the large number of possible LIS vendors to a half dozen or fewer on the basis of the initial needs analysis of the clinical laboratories and information about the various systems gleaned from both informal discussions and formal sources. Generally, hospital personnel should not feel the need for hands-on demonstrations of systems until they have pared their list down to a small number of vendors. Under such conditions, the competing vendors will be delighted to visit the hospital and set up a formal demonstration of the system under controlled conditions.

DEVELOPING A REQUEST FOR A PROPOSAL

Part of "5 - Laboratory Information Systems"

A request for proposal (RFP) is a document developed by a LIS project team in which the information processing needs of the clinical laboratories and the hospital are delineated. This document is distributed to those LIS vendors with a reasonable chance of being successful bidders in the competition, some of whom will choose to issue a written response to the request for proposal (RFP). A successful vendor will then be chosen from the responders.

The key elements of a RFP are

- Hospital and laboratory profile
- Functional system requirements
- Technical systems requirements
- Training requirements
- Implementation requirements
- Financial considerations
- Vendor profile
- Conditions of bidding
- Evaluation criteria
- Decision timetable

The key goals during the development of a request for proposal are to:

1. Gather information about all potential LIS vendors and then develop a basis for comparison among those responding
2. Analyze current laboratory operations to assist in vendor selection and to ensure successful system installation
3. Create a long-term strategic plan for the automation of the clinical laboratories, including a prioritization among all available computer applications if funds are limited
4. Develop a justification for the purchase and configuration of the LIS to ensure current and continuing resource support
5. Build a consensus among the members of the LIS project team
6. Develop a formal plan for staffing the LIS unit and daily operations after implementation

Analysis of Current Laboratory Operations

An important first step in the development of an RFP is a systems analysis of the various clinical laboratories. There are three primary objectives for a systems analysis in the clinical laboratories as part of the RFP process: (a) to evaluate the information-handling

systems currently operating within the laboratories, (b) to document specific responsibility for “loop closure” in laboratory testing requests and recording procedures, and (c) to analyze the laboratories in terms of input, output, processing, and control. Loop closure means addressing the fundamental cause of a recurring problem rather than continuing to treat it symptomatically.

Krieg and colleagues (6) use several techniques for performing systems analysis including logic flow charts, data flow diagrams, and wall chart displays. Logic flow charts, also called system flow charts, are the most useful for planning and documenting laboratory operations, whereas data flow diagrams are especially useful for planning and documenting computer programs. The wall chart display is used to visualize forms and documents used in a particular data-processing system.

The reason for proceeding with the systems analysis step is to take a hard look at current laboratory operations and information flow. An attempt should be made to correct any problems encountered before the installation of a LIS.

The installation of a LIS often requires that certain operational changes be made in laboratory operations. Although not always the case, such changes frequently serve to enhance the efficiency of information processing within the laboratories. Veteran laboratory personnel may balk at the implementation of changes mandated by a LIS installation, preferring to continue with the “tried and true.” Such employees may be uncomfortable with change or may have instituted procedures scheduled to be discarded and therefore may have a vested interest in their continuation. Friedman (7) calls the persistence to use familiar procedures that appear to be more efficient than they actually are the “competency trap.”

Having complete a systems analysis, it becomes much easier to make informed judgments about the efficiency of current laboratory operations. Systems analysis will ultimately provide an inside look into current operations and suggest ways in which the LIS can be customized to meet the information needs of local users.

A fairly typical question that arises during the time that (a) a systems analysis is being performed on laboratory operations and (b) vendor offerings are being reviewed in a preliminary way is whether all laboratory modules should be brought up simultaneously on the “go-live” day.

The classic process has been to bring up the “numerical production” laboratories such as chemical pathology and hematology at one time, and then other laboratories with more complex applications such as microbiology and blood bank at a later time. With the sophistication of today's systems, the strategy is “all laboratories go live at the same time.” Such a method hastens the return to normality from what is perceived to be an awkward transition state.

Purchasing a LIS with Sufficient Capacity

The proper sizing of a LIS for a hospital is a complex issue with major implications for the hospital. It is important to have a sufficiently powerful central processor and disk storage with the response time of the system and the number of months of test results on-line being satisfactory to users.

To design a system of sufficient size, vendor personnel start with hospital volume statistics provided in the RFP including the (a) current laboratory workload, (b) the number of yearly inpatient discharges, (c) the number of yearly ambulatory care and emergency department visits, (d) workload measurement, and (e) the anticipated growth in laboratory activity.

Using these data plus the anticipated software configuration of the LIS, including the number of applications running and the requirements for on-line order entry and test results, the vendor will make recommendations about system size. The cost of the hardware will then be rolled up in the quotation for the system.

Vendors know that they are competing with other vendors on the basis of cost as well as system functionality. On the one hand, they will design a system with adequate capacity for near-term requirements. On the other, they will not build in excessive system capacity for the long term. LIS performance for the future will depend on the increase in the laboratory workload and increasing use of the system. Moreover, the vendor will undoubtedly release software upgrades with new features that may increase the system functionality but will also require more computer power.

In the final analysis, the sizing of a LIS depends on the following:

1. The recommendation of the vendor in the RFP
2. The hardware configuration of comparable hospitals in terms of complexity and workload, which will be analyzed during site visits
3. Some “fudge factor,” taking into consideration local hospital resources and the interest and willingness of the hospital to invest in a state-of-the-art system

Whenever possible, it is wise to buy more system capacity than will be necessary to run the LIS software on day 1 and then grow into the system.

Several questions pertaining to hardware upgrades should be addressed after vendors submit recommendations for a particular system configuration. For example, what is the relationship of the recommended system capacity to the maximum capacity of that configuration? What are the increments of growth when the recommended hardware configuration is deemed inadequate? What is the recommended hardware (and software) upgrade path from the recommended configuration, and is it smooth or is it complicated?

VENDOR SELECTION

Part of "5 - Laboratory Information Systems"

Extreme care should always be taken when selecting a vendor. The importance of this decision rests in part with the large amount of money required for the initial system purchase, as well as for continuing software and hardware support. Equally important is the fact that the installation of a LIS requires a major investment in training. Having made such an investment, laboratory professionals are generally loath to switch to another vendor at some later point. The status quo is often the path of least resistance, even when the current vendor may be providing an inferior product and service. LIS vendors understand that the

switching costs for their current clients are high and so will try to maximize them to the extent feasible. For example, one major issue in switching from one LIS vendor to another is file conversion from the old to the new system, particularly for anatomic pathology and blood bank files. The LIS vendor being abandoned will do little to facilitate this process. The new LIS vendor may also be wary of actively participating in the file conversion for fear of charges of copyright infringement by the previous vendor. The scenario goes on and on.

Criteria for Vendor Selection

Some general criteria to use in the search process are

1. Is the system designed to meet the needs in multiple settings, such as a multihospital group with laboratories in geographically distributed sites?
2. Is the company adequately capitalized and financially healthy?
3. Is the system well documented, well designed, and written in a language such that software support could be obtained in the event of vendor failure?
4. Will the vendor place and maintain, on site or in escrow, a copy of the source code and complete documentation?
5. Is the vendor investing sufficient resources in product development, as judged by the number of assigned personnel in the area and the frequency of major new product announcements?
6. Are contracted or purchased software modules clearly identified with their origin acknowledged, and do they integrate well into the total system?
7. Has the development cycle for the entire system been completed, and has it been running in test or prototype sites for at least a year?
8. Are all planned interfaces (instrument, hospital mainframe computer) running successfully at other sites?
9. Is the system, with all the desired laboratory modules and applications, running successfully in another site of equal complexity?
10. Has the vendor shown continued and steady growth, as measured by the number of clients installed per year, or is the number of installations declining, indicating decreasing acceptance in the market?
11. Does the vendor's support and training staff meet local needs, and does the staff appear to be adequate for anticipated installations?
12. Does the hardware vendor have a major position in the market and a close collaborative relationship with the LIS vendor?

The installation of a LIS commits the clinical laboratories and the LIS vendor to a long-term and close relationship. It is extremely important that the “chemistry” is right between the two organizations to foster a positive and productive relationship.

Connelly et al. (8) provide an informative discussion of both formal and informal methods for sorting through the enormous amount of data about vendors generated through the RFP process. The subjective viewpoint holds that the large number of qualitative factors inherent in the LIS selection process made rigid and elaborate procedures for quantifying differences between favored vendor impractical. Such thinking favors either the *educated guess method*, wherein in overall impression of the system is garnered by the decision makers, the *cost only method*, or the *easy way out method*, whereby most prominent vendor or the current vendor is selected.

According to Connelly and colleagues (8), there are two formal or structured approaches to vendor selection. In the first, the *elimination by aspect method*, key features that serve as mandatory requirements are identified. Systems not meeting these mandatory requirements are dropped from consideration. The approach that Connelly and colleagues favor is the *multiattribute utility model (weighted scoring model)*. This approach consists of nothing more than developing a set of major and minor attributes for the desired system and values for each. Evaluators from the LIS project team score each minor attribute for each vendor. Some simple calculations provide a performance score for each vendor. The leader of the LIS project team should review the scores of the anonymous evaluators carefully to make sure that no one is “gaming” the process by assigning highest scores to the favored vendor and zeros to all others. This could seriously skew the mean scores for the whole set of evaluators.

The Site Visit in Vendor Selection

The site visit is often omitted or given short shrift, perhaps because of the expense, coordination, and effort in transporting a large number of personnel to multiple hospitals. For either the first-time buyer or the department-switching vendors, it is necessary to view LISs in a production environment before final selection. Be sure to choose hospitals for site visits of equal size and complexity to the home institution, even though this may increase the travel costs. Vendors have a small cadre of “show” sites for visits where personnel are generally happy with the product. It may be worthwhile to attempt to schedule through the vendor a visit to a hospital other than a standard show site. Not all clients of a particular vendor will be equally satisfied with the product, so do not be surprised if some criticism is aired during site visits.

Variables that enter into the pricing equation for a laboratory information system are

- Workload
- Complexity of the system (e.g., multihospital cluster, large outreach programs)
- Number of laboratory modules installed (e.g., blood bank, blood bank donor, anatomic pathology, microbiology)
- Discretionary products installed such as *ad hoc* report generator decision-support software, or even voice dictation
- Number of instrument interfaces
- Complexity and function of the interface to the hospital mainframe computer (e.g., ADT, order entry result reporting, test status)
- Processor power
- Disk storage and archive storage requirements
- System redundancy
- Scheduled down-time requirements

Some possible reasons for a low bid from a vendor in response to a RFP are

1. A reliable company with a good product, but anxious for the hospital as a client (e.g., prestigious hospital, first hospital in a region)
2. A relatively new company anxious to develop a client list
3. A very new company that wants to use the hospital as an alpha test site
4. An established company that has already amortized the cost of its current software product and is not investing resources in research and development at present
5. An underpowered or undersized system
6. The bid is for a microcomputer-based LIS, which will always be cheaper by a substantial margin than a minicomputer-based system
7. The HIS vendor already has the hospital as a client and will bid low on the LIS software to maintain its position in the hospital

It is important to write language into the contract guaranteeing system response time under specified system load conditions. Some vendors will balk at such contract language, calling it unrealistic or unnecessary, whereas others may actually insist on the inclusion of performance criteria in the contract to protect themselves. One of the most important reasons to include specifications about system performance in the contract is to discourage a vendor from undersizing a system recommendation to underbid competitors by keeping hardware costs low.

The advantages and disadvantages (9,10) of the use of an outside consultant in the selection of a LIS are

Advantages

1. Saves work for the laboratory director and staff
2. Provides special expertise and a potentially large repertoire of solutions
3. Identifies problems that may be easier for an outsider to recognize
4. Allows the arbitration of disputes between the various hospital factions
5. Lends an air of credibility to the process

Disadvantages

1. Consulting services have cost, which may be high or perceived as high
2. Selecting an effective consultant may be difficult
3. Some organizations do not readily accept outside advice
4. Consultants are not forced to live with their bad decisions
5. Consultants may be tempted to apply a previous successful solution to all future problems
6. Frequent use of consultants may stifle the development of local expertise of local buy-in to a system
7. Consultants may be unwilling to share the decision-making process with hospital personnel

The major reasons for the failure of a LIS are

1. Poor fit between the LIS and the laboratory/hospital environment
2. Poor design of the LIS such that the replaced manual systems were actually superior
3. Lack of acceptance or sabotage of the newly installed LIS by various user groups such as medical technologists and hospital physicians
4. Unacceptable system response time
5. Inadequate leadership during a politically complex and technically challenging process
6. Inadequate training of the various user groups
7. Inadequate system support from the vendor
8. Belief that purchasing a turnkey system can create unrealistically low expectations about resources necessary to support the system
9. Because it is difficult to hire skilled personnel to run a newly installed LIS, inexperienced personnel must be rapidly trained in addition to other duties
10. Overambitious implementation schedule

MANAGING A LIS

Part of "5 - Laboratory Information Systems"

One of the most important elements for the management of a high-quality LIS is a test system, which consists of a copy of the production software and a patient test result database that can be used to simulate live runs. The basic idea of the test system is that new releases of software can be tested in the local environment before being brought up live on the production system. This is important because no software, even from the most reputable vendor, is error free. Moreover, no vendor can exactly replicate the various computing environments of all their hospital clients when writing new software.

Even though no test system can exactly mimic the production environment of the hospital, it is always preferable to run new software on the test system rather than immediately installing on the production system. If a hospital does not have a test system and new software must be immediately installed on the production system, the only alternative is to fall back to an audit approach in which the system output is monitored closely for a period of time for errors.

Routine Operation

Each LIS unit needs to develop a written set of guidelines pertaining to some important aspects of routine operations. The following issues should be addressed:

- Physical site security
- Backup and recovery
- Software and database security
- Power outages and fluctuation of current

Because the LIS plays such a critical role in laboratory operations and because it is relatively vulnerable to both vandalism and adverse changes in its operating environments, care must be taken to protect the hardware and software from harm. Many of

the systems for protecting the LIS will be put in place when the system is installed such as door locks, fire protection system, and an adequate air conditioning unit, and an uninterruptible power supply. Limiting access to the computer room and surveillance for the presence of unauthorized personnel is the best means for guarding against vandalism of the system.

Backup and Recovery

Backup and recovery are the means to restore a LIS to perfect working order after the system goes down, either on a scheduled or unscheduled basis. Of course, coming up after a scheduled downtime should present no problems in terms of restoring the systems because the system should be taken down on an orderly, regular basis. Unscheduled downs can occur on the basis of either a hardware of software problem. It is possible to build hardware redundancy into a system to minimize the risk of a hardware failure through the use of parallel processors or use of hardware architecture with more than one CPU in a cluster. Such hardware redundancy, of course, does not guard against software defects creeping into the system and corrupting the database. The insidious aspect of software failure is that the system may continue to function on an apparently normal basis. Even if shadowing is in place to protect the database with simultaneous writing of data to two drives, both copies of the files may be corrupted by a software defect.

After an unscheduled downtime, the patient database must be reconstituted assuming that an up-to-date copy of system software is readily available. There are three components of the patient database: active on-line patient files, historical on-line patient files, and purge tapes of patient data. Although backup strategies will vary from vendor to vendor, a typical approach is to write test results to both purge tapes and to the on-line historical file when they are purged from the active files. Therefore, reconstituting lost data after an unscheduled downtime will usually involve asking the individual laboratories to reenter lost test results from active files plus recovering historical patient data from purge tapes.

Reentry of results from the individual laboratories may be simple if data are maintained for a short period of time in the memory of automated laboratory instruments. Manual data entry may also be required on occasion, if results are not maintained in electronic form in the laboratories. The extent to which data are maintained in an electronic format in the laboratories in the event of an unscheduled downtime is a trade-off question, comparing the resources necessary to maintain such files versus the cost of manual data entry at the time of system failure.

System Security

For the most part, turnkey LISs will come equipped with adequate security systems. The lowest level of security, commonly assigned to hospital physicians, is the ability to read test results only. Higher levels of security involving the ability to write to files will be assigned to bench-level medical technologists. Higher levels of security would be assigned to shift supervisors or chief technologists and involves the ability to modify test methodologies and generate management reports. High-level LIS managers in larger hospitals, of course, are assigned the highest security levels.

Most LISs are run as true turnkey operations after the system is installed and stable. This means that a small number of clinical laboratory personnel are trained to supervise and troubleshoot the system, but that it frequently runs unattended. The LIS vendors respond to software problems via dial-in modems. Hardware problems are handled in two different ways. If the equipment has been purchased directly from the hardware vendor, LIS personnel will summon field engineers under contract to attend to hardware problems. If both software and hardware have been purchased from the LIS vendor, apparent hardware problems may also be routed through the LIS vendor. Larger and more complex hospitals may not be content to run LIS operations on a true turnkey basis and will establish a management structure within the clinical laboratories to provide leadership to the clinical LIS operation.

Imaging and Voice Recognition

System automation integration and implementation requires full commitment by the department leadership, fully dedicated informatics technicians, and administrative support. Modernizing the laboratory may find resistance from the conservative pathologist fearing the “change,” administrative concern about employee layoffs, and economic justification for such expense, but if the efficiency of the new system can be demonstrated and the long-term savings can be projected, success should follow. Images are the essence of anatomical pathology. They can be incorporated in the report, be published on the Internet, or be sent to outside centers for special consultation. Gross pictures can be electronically taken and printed as integral parts of the report. Long-distance education and consultation can be achieved by developing an Internet-based imaging strategy. There are some limitations to digital imaging in pathology, cost being one of the most important ones; however, new and better technologies providing faster images with better resolution and more storage capacity are being developed at a lower cost.

Telepathology can be defined as the practice of pathology through the viewing of digital images for primary diagnosis, consultation, distance education, proficiency testing, and so forth. The telepathology system can be set up utilizing a fully robotic microscope that can be controlled at a distance or using a regular microscope with accessories to control the position of the stage controlled by an operator/technician.

Static images can be stored and e-mailed or reported on web sites for consultation, mentoring, or teaching purposes.

In summary, telepathology can be classified according to the type of images (static or dynamic) and the control system of the microscope. It can also be divided according to the type of information that the images contain (general pathology versus specialty), the type of communication (Internet/Intranet), or telephone service.

Another opportunity for laboratory automation and modern departmental reengineering is provided by the acquisition and utilization of automated speech/voice recognition. From the electric typewriter to the first autospeech recognition system instituted in 1990, a tremendous evolution in providing clinicians,

other pathologists, and patients with clear and timely information has been achieved.

The generic operations in anatomic and clinical pathology demonstrate a clear stepwise progression. In anatomic pathology, the steps include accession of the specimen, dictation of the gross description, production of a working draft by the transcriptionist, pathologist review of gross dictation, review of the slides, and preparation of microscopic description (final diagnosis, transcription of final diagnosis and correction of gross description, final corrections by pathologist, and sign out). With the installation of a personal computer voice recognition system, the cycle is simplified to four or five steps including accession, pathologist gross dictation, and real time editing of the description, printing or electronic saving of working draft, issuing of microscopic description/full diagnosis with real-time editing, and signed-out report. The demand for decreased turnaround time and budget reductions for the pathology laboratory have brought up new alternatives in providing quality information. Automated voice recognition has been more easily accepted by other industries and businesses with a large number of voice transactions like telephone companies, stock transaction groups, airlines.

Speech recognition is based on the conversion of analog to digital voice signals by specialized computer hardware. Kurzweil, MedSpeak, and Broca are examples of automated voice recognition for pathologists. The software can be speaker dependent/speaker adaptive, or speaker independent.

Voice recognition implementation decreases the turnaround time, improves productivity, and gives pathologists more independence, providing the entire department with opportunities for increasing the number of specimens diagnosed without adding staff, increasing outreach programs to improve revenue, providing a better competitive outreach advantage.

Different companies are working in providing speech recognition systems with increased speed, a larger vocabulary, an error rate less then 5%, and natural language capability with total speaker independence.

Internet Reporting

We are witnessing a major communication transformation since the invention of the printing press. The Internet has changed the way we think of communication by providing a new, efficient, and effective method of interactive multidirectional transferring and obtaining of information.

The Internet is basically a “network of networks,” a network that links two or more computers. It was created as Aparnet by the U.S. Department of Defense in the 1960s to connect different networks at different sites.

The worldwide web has grown from 130 sites in June 1993 to 4,389,131 as of March 1999. On-line physician activity increased by 87% since 1997, as reported by the Healtheon Corporation (11).

The Internet functions as a virtual endless library. Distance education, telepathology, and Internet reporting are few of the opportunities provided by this technology that is affecting our lives on a scale as significant as the telephone or the television. Ideas, data, and opinions are shared all over the world by people regardless of their age, sex, race, creeds, social background, or country of origin. Strategies for publishing reports, receiving and sending images, consulting colleagues at a distant site, or diagnostic options for remote laboratories are being developed daily among different pathology departments.

The reports published on the Internet can be customized to fill the needs of other pathologists, primary care physicians, oncologists, and patients. Patients are increasingly driving the decision-making process as they become more informed. The pathologist can utilize the Internet to provide other pathologists, doctors, patients, and the general public with integrated information, enhancing the care and well-being of the community.

6
Ethics in Laboratory Medicine

Brian J. Linehan

Mohamed M. El-Nageh

Stephen Cordner

Alan Richter

Ethical practice is an integral part of quality laboratory services, as well as the practice of medicine in general. For example, in clinical laboratory medicine, an invalid or wrongly interpreted result is not only of no benefit but may also lead to actual harm for the patient, and in forensic pathology, an incorrect observation or an invalid conclusion may lead to injustice. These are illustrative of the obvious links between quality and ethics.

Pathologists and the staff of medical laboratories are bound by the values and ethics of the medical profession, the ethical codes of their national medical association, and the ethical codes of other relevant scientific and professional bodies. Those with responsibility for the services provided by medical laboratories must accept that, in common with other health professionals, they have obligations of service over and above the minimum required by law. These obligations may vary somewhat from country to country and laboratory management will need to determine what is appropriate for their own situation. The details should be incorporated in a “Laboratory Quality Manual.”

Laboratories must not engage in practices forbidden by law (except in unusual situations in which the law is contrary to generally accepted ethical practice or contrary to the dictates of individual conscience).

All staff working in a medical laboratory should endeavor to protect the human rights of patients and seek to prevent unlawful discrimination and thereby uphold the reputation of their professions.

DEFINITIONS

Part of "6 - Ethics in Laboratory Medicine"

Doctor

Doctor is used in the general sense of a registered medical practitioner. In some parts of the world the term *physician* would normally be used in this way, whereas in other places, the term physician is restricted to a specialist in internal medicine.

Medical Laboratory

Terminology varies from country to country, but the name is intended to be inclusive and cover all institutions providing a pathology service or performing tests on specimens from human beings.

A typical medical laboratory is staffed by pathologists and medical scientists as well as a variety of other staff often including nurses, administrative staff, information technology staff, and accountants. Clearly, however, the details vary with the size of the facility and local custom.

Ethical Practice

Ethical practice can be regarded as appropriate technical practice accompanied by integrity in attitudes and behavior. In deciding what has integrity, reference is often made to moral values voluntarily adhered to within the community and to standards espoused in various codes of professional practice.

WHY DO WE NEED ETHICS?

Part of "6 - Ethics in Laboratory Medicine"

Laboratory medicine, including the whole range of clinical and anatomic pathology, is an integral part of modern medical practice. It would be impossible to practice medicine at a standard considered acceptable in most countries without access to laboratory services. Even in less developed countries, access to some laboratory testing is expected. Medical laboratory services are an integral part of medical services, and there is a public expectation that the same standards and ethical principles that govern the delivery of clinical services will also apply to the delivery of laboratory services.

It may be argued that regardless of how we look at the traditional doctor--patient relationship, the relationship between a patient and the laboratory has little ethical content: the patient has an advocate in the form of the doctor and all that is required from the laboratory is a technically competent service subject to normal commercial rules. In some situations, this would appear to be how laboratory services are supplied, but the authors believe that this is not ideal and in some cases not even acceptable. It is true that the further removed the service is from direct contact with the patient, the less the requirement for the special demands arising from the traditional doctor–patient relationship. Even so, the requirements are still present. It cannot be assumed

that the patient's own doctor will always be able to select and interpret the tests to the maximum benefit of the patient. In some cases, fortunately rare, the medical laboratory may even have to act in the patients' interests to protect them from unethical exploitation by their own clinicians. With the frequency of third-party payment systems, the opportunities for unethical collusion between the treating doctor and the laboratory are common, and it therefore requires an ethical approach on the part of the laboratory, as well as the doctor, to ensure that this does not occur.

Even in reference laboratories, where direct contact with the patient is even further removed, it is still important that the laboratory operates within an overall ethical framework that establishes the patient's interests as always being the first consideration.

Many of the requirements of medical ethics are common to other professions such as accountancy and law; that is, these are common ethical issues not unique to medicine or pathology. Confidentiality is a prime example of this, and in some countries, this requirement is supported by law. However, the law cannot cover all situations. The adoption of a code of medical ethics, as applicable to medical laboratories, increases community confidence that medical laboratories are part of medicine generally and that they will operate to the high standards of ethical behavior required of the medical profession. Medical ethics exist for the protection of patients, and this protection must not be compromised.

Medical laboratories (and increasingly the hospitals of which they may be part) are frequently organized as corporate structures. Many are owned by large national or international companies. Consequently, they often act like corporations, and focus on business-oriented goals. Usually these are profit centered and technology driven, and the law in many countries requires company directors to act in such a way as to maximize wealth for their shareholders.

Unless there is a clearly defined and accepted ethical framework within which medical laboratories operate, it is likely that they will become increasingly commercially oriented with traditional medical values and the public good becoming subordinate to commercial goals.

Many would argue that the delivery of medical laboratory services (or, indeed, all health services) is the same as the delivery of any other commercial service and should be governed by the same commercial rules. This implies the concept of *caveat emptor* (“let the buyer beware”) and assumes the patient or customer is able to determine the value of the services provided. In medicine, this is generally not the case. For market forces to apply in a pure capitalist model, we need unlimited buyers, unlimited sellers, and perfect information. Although it can be argued that these conditions seldom, if ever, exist, even in the normal commercial world, they apply to a much lesser extent in medical interactions. The main reasons why medical services, including laboratory-based medical services, are different from ordinary commercial transactions are

1. *The asymmetry of information between doctor and patient*. Usually the patient is seldom able to evaluate in any meaningful way the quality of the medical information or service supplied. Although increasingly patients will question the accuracy of a medical opinion or the adequacy of a particular outcome, they are usually dependent on the opinion of another doctor in coming to their conclusion. Patients can assess some aspects of a medical service such as whether they have been kept waiting for an excessive period or whether there has been unauthorized disclosure of information. However, the ability of the patient to meaningfully evaluate the medical service is weak.
2. *The patient is often dependent on the doctor and in a weak position psychologically to assess the value of the medical service or consider alternatives*. Effectively the “seller” has a monopoly. This is obvious if the patient is, for example, unconscious, but the same factors apply to a variable extent in most medical encounters. Patients often feel that the doctor or health professional is in a position of power and many feel intimidated. Often they feel particularly dependent on the doctor, and patients recently advised of a serious diagnosis may be in a state of shock and unable to assess a medical service as they might another type of service.
3. *There is often a third-party payer such as the state*. This distorts the normal market signals and alters the normal critical evaluation a customer might make before deciding on a purchase. Again, there is an effective monopoly because the “purchaser” has no motivation (as far as price is concerned) to question the seller, and the system tends to function as if they had no choice.

For these reasons, and perhaps others, the provision of a medical service, including a laboratory medical service, is different from an ordinary commercial service, and there is a special obligation on the person providing that service to ensure that it is appropriate and reasonable for the recipient under the circumstances. This obligation exceeds those that normally apply to a seller of goods or services and is embodied in the concept of ethics.

This does not mean that health professionals or laboratories should not act in an efficient and business-like manner; in fact, they have an obligation to make optimal use of the resources available to them—but they must ensure that their overall purpose is the welfare of the patient. This is achieved by adopting ethical principles that serve as a guide for the operation and governance of the medical laboratory. If their principles are the same as those adopted by the medical profession, then the patient can have the same confidence in the laboratory as he or she has in the doctor.

PRINCIPLES OF ETHICS

Part of "6 - Ethics in Laboratory Medicine"

The essential purpose of medical ethics is to ensure that the patient's trust, and the public's confidence, in the medical profession is deserved. This is achieved by protecting patients and ensuring that they are able to obtain the maximum benefits available from medicine. At the same time, medical ethics aim to protect patients from the abuse that can occur when one person is in a position of power (in this case, based on superior medical knowledge and often status) vis-à-vis another.

Medical ethics are generally considered to be derived from the teachings of the Greek physician Hippocrates (460–377 B.C.), commonly known as the Father of Medicine. He was a man of good character and high moral standards. The ethical principles he taught survive today in the form of an oath (the Hippocratic Oath) traditionally (if not actually) taken by those entering medical practice. Although the exact wording has changed to reflect more modern thinking and practice, the essential principle remains the same: the patient's interests are paramount. The best known modern version is the Oath of Geneva, adopted by the World Medical Association (WMA) in 1948 and subsequently amended in Sydney in 1968 (Appendix 1). The International Code of Medical Ethics of the World Medical Association-1949 was adopted by the WMA at London in October 1949 and has been used as the basis for various codes of ethical practice adopted by different national medical associations (Appendix 2).

The ethical standards of those working in medical laboratories are derived from medical ethics and incorporate the same principles. Public expectations of medical laboratories will reflect, with regard to ethical standards, those expected of the medical profession generally.

For these and other reasons, it is desirable that medical laboratories should be under the overall direction and control of a medically qualified person, usually a pathologist, although it is appreciated that this is not always possible or customary. Nevertheless, any person appointed to direct or control a medical laboratory must accept that the principles of medical ethics will serve to guide the operations of the laboratory. Goals based solely on financial or technical considerations are not acceptable.

It is the responsibility of the professionals working in those institutions to ensure that these principles are practiced and that they are worthy of the same level of trust that the medical profession has come to enjoy.

In recent times, as an aid to decision making in medicine and as a starting point for discussions in medical ethics, four principles have been generally agreed as important. They are derived from the Declaration of Geneva, which in turn is derived from the Hippocratic Oath, and reflect the values and responsibilities implicit in the Oath. These are

1. Autonomy: The right of patients to make decisions on their own behalf. This right presupposes informed consent and the right to knowledge about their condition.
2. Beneficence: The duty or obligation to act in the best interests of the patient.
3. Nonmaleficence: The duty or obligation to avoid harm to the patient.
4. Justice: This embodies concepts of fairness and giving what is rightfully due. It applies not only to the individual but also in the wider medical context and incorporates notions of equity and fair distribution. This is important when medical services are distributed, as they usually are, in an environment of limited resources.

The patient's right to privacy and the correlating medical duty of confidentiality are also important to the practice of laboratory medicine. They can be regarded as subsets of autonomy and beneficence and nonmaleficence. More generally, information is gathered and records are created about the patient for his or her benefit. The patient is usually in the best position to judge whether a particular disclosure will be a benefit. This is the basis of the general rule, which is subject to exceptions, that information should not be disclosed to a third party without the patient's consent.

An ethical decision-making tool is hereby proposed to assist in methodically or systematically tackling an ethical dilemma.

Step 1: Do a stakeholder analysis. This uncovers all who have a stake in the issue and could include, among others, the patient, the patient's family, doctors, laboratory technicians, and medical service organizations.

Step 2: Gather the facts and ensure data integrity. This involves questioning all assumptions and being clear about the facts in the case.

Step 3: Apply the four principles (autonomy, beneficence, nonmaleficence, and justice) to the case. This involves testing that these principles have been upheld. Implicit in the four principles are the concepts of integrity, respect, honesty, and confidentiality. It is also imperative that the case be viewed through the lens of culture, should this be appropriate, because respect, for example, can be expressed very differently across cultures, and these differences must be considered within the boundaries of ethics.

Step 4: Once a decision has been reached, apply the newspaper (or mother/parent) test before acting. This involves conjecturing how a proposed action would be reported in a respected newspaper or what your mother or parent might say to you when told of your action. It is a simple “gut test” to see whether what you plan to do passes your conscience.

GENERAL APPLICATION OF ETHICAL PRINCIPLES TO LABORATORY MEDICINE

Part of "6 - Ethics in Laboratory Medicine"

Responsibilities

Based on a stakeholder analysis, medical laboratories have responsibilities to three main groups:

1. *The patient*. Medical laboratory professionals are accountable for the quality and integrity of the services they provide. This obligation includes maintaining individual competence and endeavoring to protect the patient from incompetent or illegal practices by others.
2. *Colleagues and the profession*. Medical laboratory professionals should strive to uphold the dignity and respect of their professions and maintain a reputation for honesty, integrity, and reliability. They should aim to contribute to the advancement of the profession by improving the body of scientific knowledge, promoting high standards of education and practice, and collaborating with colleagues and other health professionals where practicable.
3. *Society*. Professionals working in a medical laboratory also have a responsibility to contribute to the general well-being of society. This may be within their sphere of professional competence or simply as members of the community.

Medical professionals should comply with relevant laws and regulations pertaining to their professional activities. The medical

profession is committed to a high standard of care and practice, and professionals should endeavor, to a reasonable extent, to influence those that do not meet this standard.

Collection of Information

Laboratories must collect sufficient information to identify adequately patients and specimens. They also should collect sufficient information for other legitimate purposes, but unnecessary information should not be collected. If possible, there should be sufficient clinical information to enable the test to be correctly interpreted. Legitimate concerns may also involve information relevant to the safety of other patients and staff as well as information required for billing purposes and resource management including utilization reviews. The patient should be aware of the information collected and the purpose for which it is collected.

Collection of Specimens

All procedures carried out on competent patients require their informed consent. Where the patient is incompetent by reason, for example, of age or mental state, consent may be given by the parents or a properly authorized person. In exceptional circumstances when this is not possible, necessity may justify the procedure when it is clearly in the best interests of the patient that the procedure be performed. For most routine laboratory procedures, consent can be inferred when the patient presents at a laboratory and willingly submits to the usual collecting procedures, e.g., venepuncture. However, certain procedures, especially the more invasive procedures (e.g., bone marrow aspiration) will require a more detailed explanation of their risks before consent being given. Some tests, e.g., certain genetic testing will require special pretest counseling to ensure that the patient fully understands the implications of the test result.

Adequate privacy for the patient must be made available. It should be appropriate for the type of specimens (or information) being collected and be sensitive to the cultural expectations of the patient and the resources available.

Performance of the Test

All tests will be carried out to an appropriate standard that should be determined in detail by professional organizations or regulatory authorities. Accreditation programs designed to promote standards and ensure compliance are to be encouraged. Where no such guidance is available, the patient's interests will prevail. In some situations, this may mean that a laboratory should refuse to attempt a test rather than produce an unreliable result that could result in harm being done to the patient. All laboratory work will be carried out with the high level of skill and competence expected of the medical, scientific, and allied health professions.

Reporting of Results

Test results are confidential unless disclosure is authorized. They will normally be reported to the clinician who requested the tests and may be reported to other parties with the patient's consent or as required by law. Decisions concerning implied consent for the reporting of results to other involved practitioners (e.g., consultant practitioners to whom the patient has been referred) should be made carefully, taking into account local customs. The laboratory should have written procedures detailing how various requests are handled, and this information should be made available to patients on request. The laboratory is also responsible for taking all reasonable precautions to ensure that the method of transmitting results to requesting clinicians or other authorized persons is secure and reliable. This applies whether the method used is by courier, public post, or electronic means. The laboratory also has a responsibility to ensure that the turnaround time for results is reasonable taking into account the type of test and the patient's condition. There should be the facility to report urgent results as soon as they are available.

In addition to the accurate and timely reporting of test results, the laboratory has an additional responsibility to ensure that, as far as possible, the results are correctly interpreted and applied in the patient's best interests. Care must be given to the construction and format of the report to facilitate correct interpretation and diagnosis. When appropriate, a pathologist or some other competent professional should be available to discuss results. Consultation with regard to the selection and interpretation of tests is part of a medical laboratory service.

Storage and Retention of Medical Records

The laboratory must ensure that information is stored so that there are reasonable safeguards against loss, unauthorized access, tampering, or other misuse. Test results must never be altered or corrected, except by properly authorized persons in accordance with established procedures. The retention of medical records may be defined by various statutory requirements and these need to be considered together with any guidelines issued by relevant professional bodies. Laboratories should develop their own protocols indicating the length of time different results, specimens, and slides will be kept. Test results should be physically readily available for authorized access. When the time comes for medical records to be destroyed, this should be carried out in a way that minimizes the risk of unintentional disclosure.

Access to Medical Records

Access to medical laboratory records should normally be available to the following:

1. the clinician requesting the test,
2. the patient,
3. laboratory and hospital staff if required for the management of the patient,
4. other authorized individuals.

Incompetent patients such as children and intellectually impaired individuals have the same right of access as competent adults, although this right may often be expressed through their parents or authorized agent. Parents, on the other hand, do not always have automatic right of access to their children's medical information, and different countries have different laws and customs in this respect. The laboratory should develop protocols on how to handle different requests with consideration of local laws

and customs. In exceptional circumstances, the withholding of health information from individuals normally authorized to receive it may be justified. An example of such a circumstance is when disclosure may be contrary to the patient's best interests.

When a request is made for access to test results by an authorized person, the laboratory must first satisfy itself as to the identity of the person making the request. The way in which this is done and the degree of certainty associated with the process will vary with different situations.

Different methods may exist in the same laboratory for different tests. For example, a degree of certainty associated with the identity of an authorized person seeking an human immunodeficiency virus result may be much greater than that required of one asking for the results of a routine hemoglobin. Laboratories need to establish appropriate procedures for each situation.

Financial Arrangements and Organizational Matters

Irrespective of ownership, medical laboratories should be under the operational control of a suitably qualified person (normally a pathologist) who takes professional responsibility for the operation of the laboratory, including ethical matters, and the quality of the test results.

Medical laboratories must be able to function with professional independence to avoid conflicts of interest, which is another key ethical principle that medicine has in common with all other professional services. They should not be subject to nonmedical control where this has the potential to interfere with their ability to act freely in the best interests of the patient. They may not enter into financial arrangements with referring practitioners or funding agencies where that arrangement acts as an inducement or an impediment for the referral of tests or patients or interferes with the doctor's independent assessment of what is best for the patient. This assessment, however, will usually be made in an environment of limited resources and so excessive application of these resources to any one individual may not be acceptable, particularly if it results in a failure to deliver a fair share of required services to another individual.

Private laboratory collecting rooms should be completely separate and independent from the referring practitioner's rooms, but when this is not practicable, financial arrangements must be of a normal commercial nature and not include any element of inducement.

Laboratories should also be aware of situations that could give rise to conflicts of interest and take particular care. Such situations may arise when pathologists in private practice can self-refer work. Any such self-referred work must be justifiable.

The medical laboratory has a difficult ethical responsibility when operating in an environment of limited resources provided by a third party such as the state. On the one hand, there is the obligation to ensure that patients receive all the necessary services to which they are entitled, but, on the other hand, there is the obligation to see that resources are not wasted so that other patients are consequentially deprived of their fair share nor the taxpayer (or other funding agent) unreasonably burdened. The practical implications of this will vary in different situations and particularly from country to country. There will also be different pressures on a laboratory depending on whether funding is on a budget or a fee-for-service basis and the extent to which those resources are under the control of the requesting clinician rather than the laboratory. Nevertheless, there is a responsibility on the laboratory to be involved to the extent that is reasonable and practicable in the equitable allocation of resources.

This requirement is based on the principle of justice.

SOME SPECIAL APPLICATIONS

Part of "6 - Ethics in Laboratory Medicine"

Autopsies

Generally speaking, there are two types of autopsy: the hospital autopsy, which requires the voluntary consent of a properly authorized person (usually the senior next of kin) and the forensic autopsy performed at the request or direction of a coroner or other authority to meet statutory death investigation requirements. This section deals with the former.

An autopsy is the postmortem examination of a body to provide information of medical or scientific use including the cause of death or for other relevant purposes such as the resolution of legal issues. The autopsy is an investigation that can have sig-nificant public and private consequences. The pathologist is obligated to ensure the examination is sufficiently thorough to make sure that all the potential benefits are realized.

It can be difficult for families to cope with issues related to autopsies at the time of a bereavement. Hospitals and forensic pathology institutions should have adequate facilities to advise, counsel, and support bereaved relatives. Sudden or traumatic circumstances leading to death are recognized as leading to much psychological stress, and the pathologist, and other staff, should not add to this by insensitivity. The body of the deceased person must at all times be handled with respect and the relatives must be able to rely on this occurring.

Consent for Autopsies

It is recognized that many religions and cultures do not accept the need for, or the desirability of, autopsies, and this must be accepted. Procedures relating to consent for autopsies will usually be governed by law, and these must be followed meticulously. In most countries, the nonforensic or hospital autopsy requires prior consent from the next of kin. This means that the nature and outcomes of the autopsy have been properly and sensitively explained. This will include an explanation of any necessity to retain tissues for the purpose of the autopsy and allow next of kin the opportunity to consider donating tissues that may be used for research or teaching purposes. In some cultures, the removal of the brain and/or the heart, especially if they are retained after the rest of the body is released for burial, is particularly sensitive. The interaction with the next of kin should be conducted in a manner that promotes discussion and encourages them to ask questions. The laboratory should have a clear understanding of the procedures for authorizing an autopsy in the absence of any next of kin or if they cannot be contacted.

Histopathology and Cytology

In the course of a histopathologic or cytologic examination, particular observations may be made, e.g., the presence of spermatozoa, which are not related to the purpose of the examination. Careful thought should be given as to whether such observations should be reported as there could be significant social implications. As in clinical pathology, the seriousness of tissue diagnosis is such that clear information must be provided to assist the treating doctor in properly advising the patient about the diagnosis and its consequences. The pathologist must consider the patient's best interests at all times.

Reproductive Technology

Issues raised by discussions of reproductive technology touch on deeply held convictions and religious beliefs, as well as perceptions about what constitutes a human being or a person, about identity, about the family, and about the sense of one's own characteristics living on in some form after death. Just as these convictions and perceptions vary, so does the way in which different societies, cultures, and religions treat these issues. Consequently, it is not possible to arrive at a universally accepted ethical view on this subject. The different and strongly held views on abortion, artificial insemination by donor, in vitro fertilization, gamete intrafallopian transfer, and other procedures and techniques are examples of this concern. Detailed discussion of these important areas is beyond the scope of this chapter. A laboratory will need to develop its own policies based on local laws and customs.

Clinical Pathology (Clinical Chemistry, Hematology, Microbiology, Immunology)

As with histopathology and cytology, the results of tests in these areas can have a life-altering impact on patients. Information provided about the results, and the manner of its provision, must assist the treating doctor in properly advising the patient about the diagnosis and its consequences.

Transfusion Medicine

The Code of Ethics for Blood Donation and Transfusion adopted by the International Society of Blood Transfusion is given in Appendix 3. The League of Red Cross and Red Crescent Societies adopted the Statement on the Ethics of Voluntary, Non-Remunerated Blood Donation, which is given in Appendix 4.

Voluntary Donation

Blood donors should give their blood voluntarily and without expectation of payment. No pressure should be exerted on a potential donor. Volunteer blood donors give blood of their own free will and without coercion. This is in line with the right to self-determination and rights to protection of physical integrity and privacy.

Protection of the Donor

No coercion or pressure should be exerted on potential donors, who should be provided with adequate information about the process to properly consent to the donation. Blood should be collected under the overall supervision of a physician. Confidentiality concerning all personal donor details, including laboratory results, should be ensured. The donor has the right to know about results of tests on their blood and the use to which their blood is put.

Protection of Recipient

The patient in need of a blood transfusion should, where clinically possible, be provided with reliable information of the risks, benefits, and any available alternatives to blood transfusion.

A proper application of the principle of autonomy means that the patient needing blood (provided she/he retains the capacity to understand and assess the information provided) is free to accept or refuse blood transfusion.

Measures to ensure quality are paramount throughout all the stages of blood transfusion starting with the detailed criteria for donor selection and deferral. This also includes the complete range of management and operational systems needed to ensure the safety of blood and blood components or products to prevent adverse reactions and transfusion-transmitted infections.

Acknowledgment

This chapter is based substantially on El-Nageh M, Linehan B, Cordnev S, et al. *Ethical practice in laboratory medicine and forensic pathology*. Alexandria, Egypt: World Health Organization Regional Office for the Eastern Mediterranean, 1999.

APPENDICES

APPENDIX 1 - Oath of Geneva

Adopted by the General Assembly of the WMA at Geneva in 1948 and amended by the 22nd World Medical Assembly at Sydney in 1968, the Declaration of Geneva was one of the first and most important actions of the Association. It is a declaration of physicians' dedication to the humanitarian goals of medicine, a declaration that was particularly important in view of the medical crimes that had recently been committed in Nazi Germany. The Declaration of Geneva was intended to update the Hippocratic Oath, which was no longer applied to modern conditions.

At the time of being admitted as a member of the medical profession:

I solemnly pledge myself to consecrate my life to the service of humanity;

I will give to my teachers the respect and gratitude which is their due;

I will practice my profession with conscience and dignity;

The health of my patient will be my first consideration;

I will respect the secrets which are confided in me, even after the patient has died

I will maintain by all the means in my power, the honor and the noble traditions of the medical profession;

My colleagues will be my brothers;

I will not permit considerations of religion, nationality, race, party politics or social standing to intervene between my duty and my patient;

I will maintain the utmost respect for human life from the

time of conception; even under threat, I will not use my medical knowledge contrary to the laws of humanity.

I make these promises solemnly, freely and upon my honor.

APPENDIX 2 - International Code of Medical Ethics of the WMA–1949

Adopted by the Third General Assembly of the WMA in London in October 1949.

Duties of Doctors in General

A doctor must always maintain the highest standards of professional conduct.

A doctor must practice his profession uninfluenced by motives of profit.

The following practices are deemed unethical:

1. Any self advertisement except such as is expressly authorized by the national code of medical ethics.
2. Collaborate in any form of medical service in which the doctor does not have professional independence.
3. Receiving any money in connection with services rendered to a patient other than a proper professional fee, even with the knowledge of the patient.

Any act, or advice which could weaken physical or mental resistance of a human being may be used only in his interest.

A doctor is advised to use great caution in divulging discoveries or new techniques of treatment.

A doctor should certify or testify only to that which he has personally verified.

Duties of Doctors to the Sick

A doctor must always bear in mind the obligation of preserving human life from conception. Therapeutic abortion may only be performed if the conscience of the doctors and the national laws permit.

A doctor owes to his patient complete loyalty and all the resources of his science. Whenever an examination or treatment is beyond his capacity he should summon another doctor who has the necessary ability.

A doctor shall preserve absolute secrecy on all he knows about his patient because of the confidence entrusted in him.

A doctor must give emergency care as a humanitarian duty unless he is assured that others are willing and able to give such care.

Duties of Doctors to Each Other

A doctor ought to behave to his colleagues as he would have them behave to him.

A doctor must not entice patients from his colleagues.

A doctor must observe the principles of “The Declaration of Geneva” approved by the World Medical Association.

APPENDIX 3 - Code of Ethics for Blood Donation and Transfusion*

International Society of Blood Transfusion

The preamble to the above Code, which was unanimously approved by the General Assembly of the International Society of Blood Transfusion, held during the Society's 16th Congress (Montreal, 16–22 August 1980), states that its purpose is to “define the principles and rules to be observed in the field of blood transfusion; these should form the basis of national legislation or regulations.” The text of the Code (which was approved by the League of Red Cross Societies) reads as follows:

The Donor

1. Blood donation shall in all circumstances, be voluntary, no pressure of any kind must be brought to bear upon the donor.
2. The donor should be advised of the risks connected with the procedure; the donor's health and safety must be a constant concern.
3. Financial profit must never be a motive either for the donor or for those responsible for collecting the donation. Voluntary non-remunerated donors should always be encouraged.
4. Anonymity between donor and recipient must be respected except in special cases.
5. Blood donation must not entail discrimination of any kind, either of race, nationality or religion.
6. Blood must be collected under the responsibility of a physician.
7. The frequency of donations and the total volume of the blood collected according to the sex and weight of the individual, as well as the upper and lower age limits for blood donation, should be defined by regulations.
8. Suitable testing of each donor and blood donation must be performed in an attempt to detect any abnormalities:
    a. that would make the donation dangerous for the donor.
    b. that would be likely to be harmful to the recipient.
9. Donation by plasmapheresis should be the subject of special regulations that would specify:
    a. the nature of additional tests to be carried out on the donor,
    b. the maximum volume of plasma to be taken during one session,
    c. the minimum time interval between two consecutive sessions,
    d. the maximum volume of plasma to be taken in one year.
10. Donations of leucocytes or platelets by cytapheresis should be the subject of special regulations that specify:
    a. the information to be given to the donor about any drugs injected and about the risks connected with the procedure,

b. the nature of any additional tests to be carried out on the donor,
c. the number of sessions within a given time frame.

11. Deliberate immunization of donors by any foreign antigen with the aim of obtaining products with a specific diagnostic or therapeutic activity should be the subject of special regulations that would specify:
    a. the information to be given to the donor about the substance injected and the risks involved,
    b. the nature of any additional tests which have to be carried out on the donor.

    N.B. The purpose of the special regulations in items 9, 10, and 11 above is to safeguard the donor. After being told about the nature of the operation and the risks involved, a statement of informed consent must be signed by the donor. For donors immunized against red cell antigens, a special card should indicate the antibodies and specific details as to the appropriate blood to be used in case the donors need to be transfused.

12. The donor must be protected by adequate insurance against the risks inherent in the donation of blood, plasma or cells, as well as the risks of immunization.

The Recipient

13. The object of transfusion is to ensure for the recipient the most efficient therapy compatible with maximum safety.
14. Before any transfusion of blood or blood products, a written request, signed by a physician or issued under his responsibility must be made, which specifies the identity of the recipient and the nature and quantity of the substances to be administered.
15. Except for the emergency use of type O blood or red blood cells, every red cell transfusion necessitates preliminary blood grouping tests on the recipient, and compatibility tests between the donor and the recipient.
16. Before administration, one must verify that blood and blood products are correctly identified and that the expiry date has not been passed. The recipient's identity must be verified.
17. The actual transfusion must be given under the responsibility of a physician.
18. In case of a reaction during or after the injection of blood or blood products, appropriate investigations may be required to ascertain the origin of the reaction and to prevent its recurrence. A reaction may require the interruption of the transfusion.
19. Blood and blood products must not be given unless there is a genuine therapeutic need. There must be no financial motivation on the part of either the prescriber or of the establishment where the patient is treated.
20. Whatever their financial resources, all patients must be able to benefit from the administration of human blood or blood products, subject only to their availability.
21. As far as possible the patient should receive only that particular component (cells, plasma, or plasma derivatives) that is needed. To transfuse whole blood into a patient who requires only part of it may deprive other patients of necessary components, and may carry some additional risks to the recipient.
22. Owing to the human origin of blood and to the limited quantities available, it is important to safeguard the interests of both recipient and donor by avoiding abuse or waste.
23. The optimal use of blood and blood products requires regular contact between the physicians who prescribe and those who work in blood transfusion centres.

The Controls

24. Appropriate controls should be required by the Health Authorities to verify that blood transfusion practices meet internationally accepted standards and that the guidelines or regulations issued in accordance with this code are effectively respected.
25. The following should be regularly checked:
    a. the proficiency of the staff,
    b. the adequacy of the equipment and premises,
    c. the quality of methods and reagents, source material and finished products.

Footnote

*The text of this Code (accompanied by an editorial describing its development) was originally published in the *ISBT Newslett* 1980;9 and in *Transfusion Int* 1981;26. It is reproduced here with the kind permission of the International Society of Blood Transfusion.

APPENDIX 4 - Statement on Ethics of Voluntary, Non-Remunerated Blood Donation: League of Red Cross and Red Crescent Societies

The following statement was adopted at the Third International Colloquium on Recruitment of Voluntary Blood Donors, held in Hanover on 22–24 August 1990; it was thereafter endorsed by the International Group of Red Cross Blood Transfusion Experts at its 19th Meeting, held in Los Angeles, CA, on 9 November 1990:

> The League of Red Cross and Red Crescent Societies, in keeping with its humanitarian principles, has always maintained uncompromising support for the concept of voluntary, non-remunerated blood donation.

The XXIVth International Conference of the Red Cross in Manila in 1981 reaffirmed the movement's commitment to voluntary nonremunerated blood donation, and in this context approved the Code of Ethics developed by the International Society of Blood Transfusion as consistent with the principles of the movement. The rapid changes of the last decade have thrown new light on the ethical aspects of blood donation.

Voluntary nonremunerated blood donation is considered among the safest kind of blood donation in terms of security to the recipient as the blood donor does not benefit from the transaction. The donor is expected to communicate without hesitation any contraindication that could have potential harmful effects on a recipient. In recent years, this responsibility has become more onerous, and the questions asked by the transfusion services have become of necessity more personal and more detailed than before.

For these reasons, there are increased ethical responsibilities, some old, some new, placed on transfusion services that collect

blood from voluntary nonremunerated donors. They include the following:

1. No coercion or pressure should be brought to bear on a potential donor to donate.
2. Every transfusion service should have current detailed criteria for donor selection and deferral, and these should be explained to the donor when an occasion for deferral arises.
3. Staff and volunteer who have donor contact should be carefully selected and trained to ensure that donors are handled sensitively and thoughtfully.
4. Donors should be made aware of the ethical responsibilities that they have toward the recipient(s) of their donation.
5. Donors should be assured by every available means that his or her donation is being utilized for patients in need without financial gain for any intermediate party.
6. Donors should be assured that blood and blood products made available through voluntary nonremunerated donation are being used optimally within hospitals for patients in need.
7. Donors should be assured that the transfusion service will treat in a confidential manner all personal donor details, including the results of all laboratory tests.

The Red Cross and Red Crescent Movement continues to support, as consistent with its principles, the ethical implications of voluntary, nonremunerated blood donation.

Section 2 Molecular Pathology

Molecular Pathology - Introduction

Serhan Alkan

Section Chief

7. Introduction to Molecular Diagnostics
8. Molecular Biology of Inherited Diseases
9. Molecular Biology of Solid Tumors
10. Molecular Biology of Infectious Disease
11. Clinical Applications of Molecular Biology Hematopoietic Disorders

The diagnosis and characterization of genetic diseases and of malignancy are increasingly dependent on analysis of specific genetic sequences that determine the pathologic processes in such disorders. This type of molecular genetic analysis is technology intensive; as with other, more established diagnostic methods, proper design and interpretation of these new diagnostic approaches requires understanding of the concepts behind the techniques and of the biological processes and molecular structures that are being examined. Chapter 7 addresses these issues by first providing fundamental information about the organization of genes. This chapter includes discussion of techniques used to detect specific gene sequences, their RNA products, and to determine abnormalities involving overall structure and sequences. This is followed by Chapter 8, a discussion of molecular biology of the commonly seen hereditary disorders.

Chapter 9 outlines the clinical and molecular pathogenesis of solid tumors, several illustrations for applications of molecular methods in the analysis of solid neoplasms in which mutational events are considered to be pathogenic and in some cases used for proper histologic classification.

Microbiology is one of the disciplines most dramatically affected by molecular techniques and Chapter 10 illustrates some of the examples of molecular diagnostic techniques used in clinical practice. Some of these topics particularly utilization of these assays are also covered in the microbiology section. Chapter 11 describes molecular techniques that are used to detect genetic abnormalities associated with hematopoietic malignancies and to characterize common abnormalities associated with coagulative disorders. Molecular characterization of lymphoid and myeloid malignancies represents a major focus of this chapter, as it is increasingly clear that this type of analysis is providing important therapeutic and prognostic information.

7

Introduction to Molecular Diagnostics

Andrea Ferreira-Gonzalez

David S. Wilkinson

Carleton T. Garrett

During the past decade, we have acquired a vast amount of knowledge about genes and their proteins. This new information directly impacts the way we view diseases and is beginning to have a significant impact on many areas of laboratory medicine. The well-defined boundaries that earlier separated medical specialties are disappearing rapidly. Nucleic acid probe technology provides information for diagnosis, determining prognosis, selecting therapeutic modalities, and monitoring disease progression. Examples abound for the application of this technology in microbiology, immunology, forensic science, genetics, and oncology (1, 2, 3, 4, 5, 6, 7, 8, 9, 10 and 11). Following chapters will discuss current and future clinical applications of nucleic acid probe technology in laboratory medicine. This chapter will provide a framework for understanding the molecular techniques used to detect sequence changes in nucleic acids and the biological processes that such sequence changes can affect. This understanding is important for the meaningful evaluation and interpretation of results.

REVIEW OF NUCLEIC ACID BIOCHEMISTRY

Part of "7 - Introduction to Molecular Diagnostics"

Nucleic Acid Structure

Deoriboxynucleic acid (DNA) contains genetic information that is unique to the particular organism from which it is isolated. DNA consists of a chemically linked sequence of nucleotides. Each nucleotide consists of a nitrogenous base, a pentose sugar (2-deoxyribose) and phosphate. There are four separate bases: adenine (a) and guanine (G), which are purines; and thymine (T) and cytosine (C), which are pyrimidines (Fig. 7.1). The nucleotides are arranged along the strands of DNA sequentially, like beads on a string. In most DNA molecules, there are two DNA strands that wrap around each other in a highly ordered fashion such that a T on one strand always pairs with an A on the other strand and a C always pairs with a G. This pairing of A to T and C to G, referred to as base-pairing, is the basis for nearly all detection systems used to measure differences between fragments of DNA (Fig. 7.1). The resulting double-stranded, helical structure has the DNA bases in the interior connected to each other through hydrogen bonds, while the sugar-phosphate backbone groups lies on the outside (12). Nucleotides contain a phosphate group on the number 5′ carbon atom of the deoxypentose (5′ end), and a hydroxyl group on the number 3′ carbon atom (3′ end). Two or more nucleotides can be joined together through phosphodiester bonds, which link the 5′ carbon atom of the 2-deoxy-pentose from one nucleotide with the 3′ carbon atom of the 2-deoxy-pentose of the other nucleotide. The resulting chain of 2-deoxy-pentose sugars linked together by phosphodiester bonds forms the backbone of the DNA molecule orienting the bases towards the center of the DNA. Because the A:T and G:C pairs have an identical width, the pairing of A:T and C:G creates regularity to the width of the DNA double helix. The base pairs lie 3.4Å apart, and the helical turn repeats approximately every 34Å. The two strands of DNA are complementary to each other rather than identical. That is, for every A on one strand there is a corresponding T on the opposite strand, and a similar ‘complementary relationship’ exists for C and G. The two strands of nucleotides comprising the double helix also are oriented in an antiparallel fashion. That is, the nucleotide at one end of the double helix that contains a free hydroxyl group on the 5′ prime carbon atom (the 5′ end) pairs with a nucleotide that has a free hydroxyl group on the 3′ carbon atom of its 2-deoxy-pentose (the 3′ end) (12).

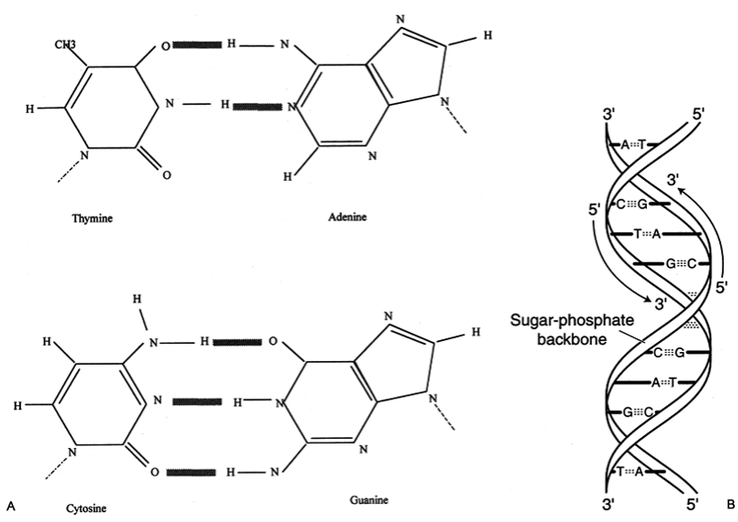

FIGURE 7.1. (**A**) Purine and pyrimidines. The shaded bars correspond to the hydrogen bonds formed between complementary bases. (**B**) DNA double helix. Solid bars correspond to bases and dotted bars correspond to hydrogen bonds between paired bases.

Genome Structure and Replication

In eukaryotic cells, almost all the genetic material is located in the nucleus. Each DNA molecule is organized into discrete units called chromosomes. The total genetic information stored in chromosomes is referred as the genome of the organism. The human genome contains approximately 3×10^9 nucleotide base pairs that are packaged into 23 chromosomes pairs. Twenty-two chromosome pairs are independent of whether the sex is male or female and are called autosomes. The remaining chromosome pair determines the sex and may be either X or Y. Human cells are diploid, which means that they contain 44 autosomes and 2 sex chromosomes, XX for females and XY for males (13). The structure of DNA facilitates its replication. First, the two nucleotide strands of the DNA double helix must separate (14). Separation is accomplished by breaking the hydrogen bonds that hold complementary bases together. The helix is unwound

through enzymatic action. Next, a second enzyme, called helicase, breaks the hydrogen bonds between base pairs, using the energy derived from its ATPase activity causing strand separation (15). The junction between the separated strands and the hydrogen-bounded strands is called the replication fork. Once both strands are separated, each strand can act as a template for replication. Ribonucleic acid (RNA) polymerase ads short nucleotide sequences of RNA (primer) to the separated strands. These primers bind to the DNA strands and provide sites for subsequent addition of complementary nucleotides by DNA polymerase (16). During DNA replication, both DNA strands are copied. The addition of bases occurs in a 5′ to 3′ direction. As noted above, the original strands of DNA are antiparallel. Thus, for one parent strand, the replicating complementary copy grows in the direction that the parent DNA molecule is unwinding and hence can be copied without interruption. This strand is called the leading strand. The remaining strand (lagging strand) must be copied in short pieces, which then are joined together. For the lagging strand, DNA polymerase excises the RNA primers that served as initiation sites for earlier DNA segments and fills in the nucleotide gaps left after their excision. DNA ligase then joins the separately created DNA segments. Because copying of the 3′ to 5′ oriented lagging strand takes place in interrupted fragments, DNA replication is said to be semidiscontinuous (12, 16, 17). Another step during the replication process, associated with the generation of the 3′ to 5′ strand, is proofreading of the newly created nucleotide sequence. If a base added to the chain is not complementary, a 3′, 5′ exonuclease excises the mismatched base and replaces it with the complementary base. Replication is terminated by the addition of characteristic sequences at the 3′ ends of the strands in the presence of the enzyme telomerase. The extraordinary fidelity of DNA replication is necessary to maintain the accuracy of the genetic information from one generation to another (16, 17).

Gene, Gene Structure, and Gene Expression

A gene is the smallest functional unit of genetic information. A gene consists of a sequence of bases that encodes a functional product, either RNA or protein (12, 18). The vast majority of eukaryotic genes contain nucleotide sequences called exons that code for proteins. In addition, there are sequences that are interspersed among the coding sequences called introns, which do not code for proteins (Fig. 7.2). A codon consists of a triplet of nucleotides that specifies one amino acid. There are 64 possible codons. Sixty-one triplets code for different 20 amino acids. One triplet specifies the beginning of a polypeptide, and three codons provide signals for the end of the coding sequence. The process of gene expression consists of transcribing the DNA by RNA polymerase into messenger RNA (mRNA) and translating this mRNA into protein. Codons are read in the 5′-to-3′ direction, however, genes are not transcribed indiscriminately by RNA

polymerase. Other proteins determine whether a particular gene is to be copied into mRNA (12). In addition to the exons and introns, there are regulatory sequences called promoters that govern transcription of a gene (12, 19). The promoters for the genes transcribed by the RNA polymerase I and II usually are upstream of the start point of the gene, while the promoter for RNA polymerase III lies downstream of the start point of the gene. An example of a prototypic eukaryotic protein-coding gene is shown in Figure 7.2. The most common promoter sequence is called the TATA box. It usually is located 25 base pairs (bp) upstream of the start point and it occurs in almost all eukaryotes. Its 8 bp consensus sequence consists of A:T base pairs ATATAA. The TATA box tends to be surrounded by CG-rich sequences, which may be important for function. The role of the TATA box could be to align the RNA polymerase via interactions with nuclear proteins called transcription factors, so that RNA polymerase initiates transcription at the proper site. Another promoter is called the CAAT box (19). The CAAT box (GGCCAATCT) often is located at approximately 80 bp upstream of the starting point. However, it can function at distances from the start point that vary considerably. It also may work in either orientation. Mutational analysis shows that this is one of the strongest promoter elements. The GC box promoter region contains the sequence GGGCGG and multiple copies may be present in the region of the promoter (12).

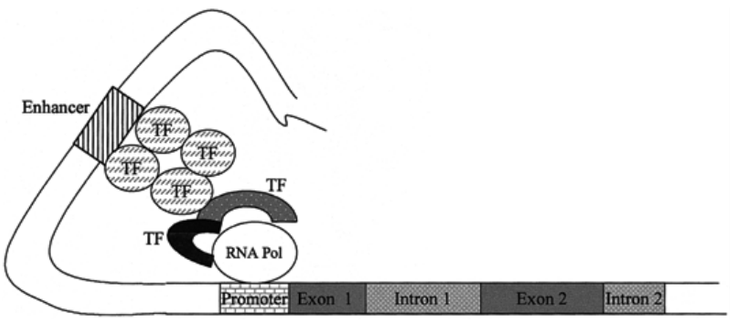

FIGURE 7.2. Gene structure and transcription initiation complex.

Enhancers are another category of regulatory sequences, distinct from promoters, which can increase the rate of transcription (12, 20). Their distance from the promoter can be variable, and their function is independent of orientation. The enhancers of immunoglobulin gene expression have been studied extensively. They are located within the transcription unit. These enhancers only are active in B lymphocytes; thus, enhancers may be part of the mechanism of tissue-specific gene regulation (12). All cells within a higher eukaryotic organism contain the same sequence of DNA, but there are profound phenotypic differences between cells (i.e., liver cell, kidney cell, etc). The phenotype of different cells is a result of differential gene expression within these cells. Complex mechanisms govern regulation of gene expression within each cell type. They cause constitutive expression of some genes, rapid fluctuations in expression of other genes in response to environmental or endogenous stimuli or cell injury, and permanent inactivation of yet other genes (18).

RNA polymerase cannot properly initiate transcription unless it is aided by a number of general transcription factors (20). These transcription factors are protein molecules that are required for transcription but are not part of RNA polymerase. They may bind directly to DNA, to other factors, or to RNA polymerase. Transcription factors provide recognition and specificity for minimal promoter and enhancer sequences. RNA polymerase II promoters have binding sites for transcription factors about 100 bp upstream of the start site. Distances between binding sites can be similar for different genes, but some are specific for a particular gene. Transcription factors bind to specific sequences and form a complex to which RNA polymerase then binds. Initiation of transcription follows formation of this complex (20).

There are two types of transcription factors. One type binds to RNA polymerase when the latter forms the transcription initiation complex (20). These factors are general transcription factors needed for mRNA initiation or termination. Other factors bind specific DNA sequences in the target promoter region. These factors can be general transcription factors or specific to a certain class of promoters. In addition, there are protein transcription factors that bind enhancer regions after recognizing a specific sequence present in the enhancer element. These enhancer regions may act as docking sites for regulatory proteins that move to the vicinity of the gene because of their affinity for the enhancer sequence (21). Once bound to the enhancer sequence, these proteins participate in the assembly of the transcription initiation complex at the promoter possibly by bending the DNA into a loop (Fig. 7.2). Typically, transcription factors contain a helical shaped region that lies adjacent to a cluster of positively charged amino-acid residues. This domain binds specifically to short sequences of double-stranded DNA present in promoters and in enhancer regions (22). Transcription factors do not act in isolation. They form regulatory networks through interactions with each other and by binding to different regions of the DNA to regulate gene transcription. A physically different domain within the transcription factor, called the trans-activator domain, mediates these cooperative associations. These transcription factors can be classified according to certain structural motifs of the DNA-binding domain. Most of the transcription factors contain one of four motifs. These are called the helix-turn-helix, zinc finger, leucine finger, and helix-loop-helix (22).

Gene expression involves the transcription of only one DNA strand (antisense strand). The first nucleotide of the newly created mRNA strand contains a free triphosphate group at its 5′ end, and subsequent nucleotides are linked together through the formation of the 3′ to 5′ phosphodiester bonds. The strand grows in a 5′ to 3′ direction through the addition of nucleotides that are complementary to the antisense strand until a termination signal is reached. The mRNA strand then is freed from the DNA template. The mRNA molecule has the same sequence as the sense strand of the DNA but uracil replaces thymine and ribose replaces 2-deoxyribose (12).

The newly synthesized mRNA molecule, also called immature or heterogeneous RNA (hnRNA), is first processed within the nucleus and then migrates to the cytoplasm where protein synthesis will occur (23). During processing, the hnRNA undergoes a series of post-transcriptional modification steps that result in a mature mRNA. The first post-transcriptional modification is the addition of a special nucleotide sequence at the 5′ end called a cap, which increases the efficiency of gene expression by helping the 40S ribosomal subunit to find and bind to the mRNA in the cytoplasm. At the 3′ end of the molecule, a nuclease recognizes a specific sequence in the hnRNA (AAUAAA) in the noncoding portion of the transcript and cleaves approximately 20 bases from the 3′ end of the molecule. A second enzyme, adenosine terminal transferase, adds a polyadenylate (polyA) tail of at least 200 adenylate nucleotides (23).

Although the entire gene is initially transcribed into hnRNA, it is not all used in assembling the final protein. The introns present in the hnRNA must be removed before translation of the mRNA in order for the appropriate polypeptide to be synthesized. The removal of the introns occurs through a process called splicing (24). Splicing is a highly regulated process and occurs with the help of protein-RNA structures called spliceosomes. Excision of the intron proceeds through a lariat mechanism. In this process, the intron forms a loop (lariat) that enlarges until the 5′ end of one adjacent exon is juxtaposed to the 3′ end of the other adjacent exon. At this point, the two exons form a link via a phosphodiester bond and discard the intron. Small nuclear RNAs participate in this process (25, 26). The splicing process requires absolute precision because deletion or addition of any bases during this process will throw the coding sequence out of frame (26).

Protein Synthesis

Spliced mRNA molecule produced through the preceding process carries the instructions from the gene for the synthesis of proteins (12). The process by which the mRNA is decoded into protein is called translation. Translation occurs in the cytoplasm and requires the involvement of two additional kinds of RNA molecule, transfer RNA (tRNA) and ribosomal RNA (rRNA) (27). The mRNA leaves the nucleus after transcription and enters the cytoplasm where it attaches to the 40S ribosomal subunit. The latter is composed of ribosomal proteins and 18S rRNA. This occurs through a complex series of interactions with proteins called initiation factors (IF), which form the translation initiation complex. As a result of these interactions, all key components are brought together and translation of the mRNA can start. In order for translation to begin, the 40S ribosomal subunit scans through the mRNA from the cap until it finds the correct in-frame start codon, usually AUG. Following this event, binding of the larger 60S ribosomal subunit occurs to form the 80S ribosomal initiation complex. After assembly of the complex, protein synthesis begins. The correct aminoacetyl-tRNA is brought to the ribosomal-mRNA complex by a recognition factor. Following peptide bond formation, translocation of the ribosome relative to the mRNA brings the next codon into position. When the termination codon is reached, the polypeptide chain is released and the ribosome detaches from the mRNA (28, 29).

Genomic Integrity

The double-helical structure of DNA and the complementary base pairing between the purine and pyrimidine bases maintain fidelity of the DNA sequence during its replication and its transcription into mRNA. Translation of mRNA via tRNA into a peptide sequence of amino acids depends upon the accurate reading of the template DNA. Despite safeguards present in the biological system, errors may occur (30). Misreading of the DNA template can occur if a base is not in its usual configuration, i.e., if tautomerization has occurred. Deamination of the bases also can result in erroneous base-pairing (31). If a base is inadvertently deleted, a frame shift mutation may result unless compensatory additions or deletions balance the loss (30). The change of a single base, rather than its loss, represents a point mutation. Mutations may result from chemical or radiation exposure (32). Certain types of DNA damage can be repaired directly by the intervention of endogenous enzymes. DNA photolyase, for example, splits pyrimidine dimers formed by ultraviolet radiation, and 6-O-methylguanine methyl transferase repairs methylated DNA. Less-specific avenues of repair also are available. These include DNA glycosylase, which excises a base from the phosphodiester backbone, 5′->3′ nuclease, which causes chain scission in a DNA strand next to the site of DNA glycosylase activity (incision), and 3′->5′ exonuclease, which excises an offending nucleotide from a strand of DNA (30). Other types of genetic damage, less amenable to repair, include translocation of entire DNA sequences from one chromosome to another, deletion of an entire chromosome (monosomy), or addition of a chromosome (trisomy) (12). Consideration of the mechanisms for these latter changes is beyond the scope of this chapter.

The uniqueness of the base sequence of an organism's genome makes it a highly specific marker for that organism. Moreover, it is becoming increasingly apparent that many disorders are a direct consequence of errors in DNA replication and genetic polymorphisms. These facts, coupled with the elegant simplicity of copying the nucleotide strands, have provided the impetus and current capabilities of molecular diagnostic techniques.

NUCLEIC ACID PROBE TECHNOLOGY

Part of "7 - Introduction to Molecular Diagnostics"

Nucleic acid probe technology represents a collection of techniques and reagents that have as their objective the detection of

a specific sequence of DNA and/or RNA. One of the major advantages of nucleic acid probe technology is that it makes use of nature's most specific marker for all living organisms, which is the sequence of nucleotides comprising the organism's genome. The order of the nucleotides comprising the DNA of one species differs from that in another species. The ability to distinguish the DNA of one person from another has obvious implications in the fields of transplantation and forensic sciences (33, 34). Moreover, because changes in DNA sequences are the cause of genetic and malignant diseases, the ability to measure nucleotide sequence changes in DNA reliably has significant implications for the diagnosis and management of human disease (35, 36). Until 1975, however, practical laboratory methods of detecting differences in nucleotide sequences had not been perfected. In the subsequent years, this situation has changed substantially.

Nucleic Acid Hybridization

Nucleic acid probe technology primarily is based on the simple concept of complementary base pairing between two strands of nucleic acid. Double-stranded DNA (dsDNA) can be denatured into two complementary single strands by simply applying heat, alkali, or other double-helix destabilizing agents, such as formamide. When incubated under the appropriate conditions, the complementary strands can reassociate to reform the duplex double helical structure. The term hybridization refers to this reformation of a sequence-specific, base-paired duplex. Hybridization also can occur between two complementary RNA molecules or complementary RNA and DNA molecules. The temperature at which a specific dsDNA sequence denatures is called the melting temperature or Tm. Thus, the Tm reflects the thermal stability of a double-stranded nucleic acid hybrid. The factors that affect the stability of a double-stranded nucleic acid helix have been studied carefully. The three major factors affecting the melting temperature are the ionic strength of the solution, the presence of specific denaturing agents, and the base composition of the particular nucleic acid sequence. The contributions of all these factors are combined to produce the following relationship:

$$Tm = 81.5 + 16.6 (\log M) + 0.41(\% G + C) - 0.61 (\%form) - 500/L$$

Where: Tm = melting temperature (C°); M = molarity of monovalent cations; %G + C is the percentage of guanine and cytosine present in the DNA; (%form) refers to the percentage of formamide in the solution; and L is the base pair length of the DNA.

Hybridization of two complementary nucleic acid sequences starts with the formation of a short duplex region between the correctly base-paired complementary sequences (nucleation) and this event is followed by a rapid base pairing of the remaining nucleotides on either side of the nucleation sequence (zippering up). The rate of hybridization is significantly dependent upon the rate at which nucleation occurs. The maximum rates of hybridization occur at temperatures approximately 20 to 25°C below the Tm of the nucleic acid duplex. At lower temperatures, the hybridization is slow and cross-hybridization between noncomplementary sequences tends to occur more frequently, because the mismatched duplexes are stable at the lower temperatures. On the other hand, at temperatures approaching the Tm of the duplex, hybridization also tends to be slow because perfectly matched duplexes tend to dissociate at a frequency that approaches the frequency at which nucleation is occurring. Other factors can profoundly affect the rate of hybridization. Low rate of hybridization occurs with hybridization solutions that contain low-salt concentration (low ionic strength) and high viscosity. DNA hybridizes at a higher rate in the presence of inert polymers like dextran sulfate and polyethylene glycol. Formamide often is added to the hybridization solutions to lower the Tm of the duplexes and enable hybridization to occur at lower temperatures. Other parameters that can affect hybridization are the base composition, the pH of the hybridization solution, and the length and concentration of the probe present in the hybridization solution (37).

Isolation of Nucleic Acid

The first task that must be accomplished in order to perform a molecular assay is the isolation of nucleic acid. A number of different procedures have been applied to the isolation of nucleic acid, whether DNA or RNA. Three factors that determine the isolation procedure to be used are the purity, integrity, and amount of nucleic acid that is required to successfully perform the assay. The greater the need to maximize any one or all of these factors, the more labor-intensive and complex must be the procedure utilized to extract the DNA or RNA.

The common starting point for all nucleic acid extraction procedures is the lysis of cells (38). A DNA extraction procedure is facilitated greatly by the use of Proteinase K, detergents, and chelating agents. The detergents dissolve cell membranes and denature proteins present in the cell. Proteinase K is a potent enzyme that degrades proteins. Chelating agents inhibit nucleases that degrade DNA by binding divalent cation ions that are necessary cofactors for the nucleases. After digestion with ribonuclease (RNAse), purification of the DNA from this mixture can be achieved by using organic extraction with phenol, chloroform, and isoamyl alcohol. Lipid contaminants and hydrophobic denatured proteins separate into the organic phase or interface. Nucleic acids partition into the aqueous phase and can be concentrated by precipitation with the addition of salt and alcohol. Organic extraction procedures produce a high yield of highly purified DNA with a molecular weight suitable for use in procedures that require high-molecular-weight DNA. As might be expected, however, the method is extremely labor intensive and uses hazardous chemicals (39).

There are a number of DNA extraction procedures that do not involve the use organic reagents. One method that is widely used is the salting out procedure for isolation of high molecular weight DNA. This procedure is based on the use of a saturated sodium chloride solution that dehydrates and precipitates the partially digested proteins from the Proteinase K treated whole cell lysate. This procedure has the advantage of using nontoxic reagents and is less time consuming compared to organic extraction. The method also allows for extraction of a larger number of cells at one time. One disadvantage is that in a small number of cases, the procedure fails to remove contaminants that subsequently can interfere with molecular testing (39).

More recently, several rapid extraction procedures have been described that can dramatically reduce the time and effort necessary for isolation of DNA (40). Some of these procedures are based on the use of chaotropic reagents to disrupt cellular components and at the same time inhibit exonucleases without causing major DNA shearing. Purification of the nucleic acid is achieved by using spin columns that contain a silica-based gel that can bind DNA in the presence of high salt. The DNA is eluted from the column with deionized water or a low-salt buffer after washing with buffers of decreasing salt concentration. The major advantage of these rapid procedures is minimal time and labor involved for the DNA extraction from a variety of specimens producing good-quality DNA. The trade-off is the small sample size that can be processed at one time, limiting the amount of nucleic acid that can be recovered (41).

Isolation of RNA is more challenging than isolation of DNA. A significant problem encountered during RNA extraction is the degradation of RNA by RNAses. RNAses are very difficult to inactivate and even resist boiling. In addition to their presence within the cells of the tissue being extracted, these enzymes can be introduced easily during laboratory manipulation from a variety of sources including sneezing, hair, dandruff, and fingerprints. Chaotropic agents such as guanidinium isothiocyanate generally are used in the purification of RNA (42). These agents are capable of dissolving cellular membranes, causing nucleoproteins to dissociate from nucleic acid and inactivating ribonucleases. Purification of RNA can be achieved by organic or nonorganic procedures (42, 43). The organic and nonorganic procedures for isolating RNA are similar to the ones already described for DNA. As a final step in purification, RNA should be stored in a solution containing 1 unit/μL of Rnasin.

Southern Hybridization and Restriction Fragment Length Polymorphism Analysis

One of the first nucleic acid probe assays used in the clinical molecular laboratory was the study of hematological and inherited diseases using restriction fragment length polymorphism (RFLP) analysis (44). An important concept for understanding RFLP analysis is that of polymorphism. Polymorphism refers to a variation in the nucleotide sequence at a specific locus in the DNA of two closely related organisms. The term frequently is restricted to nucleotide sequence variations that occur at a relatively fixed frequency and that are present in normal individuals. However, the term also has come to be used to indicate differences in DNA sequences that arise through mutation and through gene rearrangements (12). Restriction endonucleases are a class of enzymes that recognize specific sequences in DNA and cause chain scission of the DNA at or close to the recognition sequence (Fig. 7.3). The recognition sequences usually are 4 to 6 nucleotides in length (12). Recognition sequences for many different restriction endonucleases are present throughout the entire length of the DNA of any given organism. However, because the DNA from one cell is essentially identical to the DNA from every other cell of that same organism, the location of the recognition sites for a given restriction endonuclease essentially is the same in all the DNA molecules isolated from that organism. There are no predetermined rules governing how far apart restriction sites must be located. Thus, over some stretches of the DNA molecule, there will be only a few scattered sites, while over other portions the sites will be closer together. Therefore, when a DNA molecule as large as that present in humans is cut by a restriction endonuclease, fragments ranging in size from a few thousand base pairs (a few kilobases) to 30,000 or more base pairs in length are generated. These can be fractionated by size on an agarose gel. An important point is that the intervening sequence of nucleotides between any two restriction sites for a given fragment from any single cell should be the same as that for the same fragment from any other cell, because the recognition sites are located at identical positions in the DNA from each cell. If following digestion of DNA with *MstII*, the gene for ß-globin is found on a 1.2 Kb fragment of DNA from one cell then it will be on a 1.2 Kb fragment from every other cell. As shown in Figure 7.4, if one extracts DNA from a tissue, digests it with *MstII*, and separates the fragments on an agarose gel, the fragments of DNA with the ß-globin gene accumulate or concentrate at the location on the gel to which 1.2 Kb-long fragments of DNA migrate. This process of concentrating fragments of DNA that possess a specific nucleotide sequence at a specific location on an agarose gel raises their concentration to the level that they can be detected by DNA hybridization (45). Restriction endonucleases are used together with the techniques of gel electrophoresis, DNA transfer, and DNA hybridization to identify a restriction fragment length polymorphism (Fig. 7.4) (46). During gel electrophoresis, the negatively charged DNA or RNA migrates through an inert porous solid medium (i.e., agarose, acrylamide,

etc.) from the negative to the positive electrode. The degree of migration is inversely related to the length of the nucleic acid restriction fragment. Determination of the molecular weight of the nucleic acid fragments is achieved by analyzing controls consisting of fragments of nucleic acid of known molecular weight. These nucleic acid standards are called DNA or RNA ladders. By comparing the rate of migration of the unknown sample to the rate of migration of the ladder, one can determine the size of the nucleic acid fragment in question (45). When the DNA fragments are separated on an agarose gel, the pieces containing the sequence of interest come to lie at the same location on the gel. The DNA then is denatured and transferred out of the gel by gentle convection onto a filter where it becomes irreversibly bound. Denaturation is necessary both to assist the DNA in binding to the filter during transfer, and to enable the DNA on the filter to be recognized subsequently by a DNA probe. The process of transferring the DNA out of the gel and binding it to the filter is called Southern blotting (45). The process of transferring RNA out of the gel onto a filter is called Northern blotting, and transferring protein out of a gel onto a filter is called Western blotting (46). The location of the desired nucleic acid sequence on the filter is determined using a labeled probe by the process of hybridization. The probe usually is 1,000 to 6,000 nucleotides long (1 to 6 Kb) and is labeled with some reporter group, such as a radioactive isotope or by nonisotopic means. It is hybridized with the filter-bound nucleic acid and the target sequence detected by exposing the filter to x-ray film or by development of a colorimetric signal (Fig. 7.4).

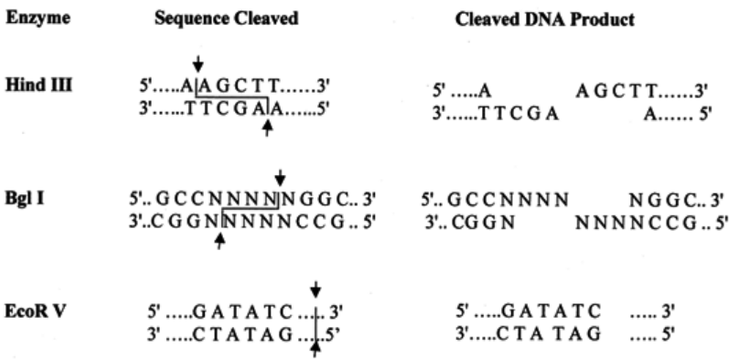

FIGURE 7.3. Restriction Endonucleases. Examples of DNA restriction endonucleases and sequence recognized by them (N represents any base).

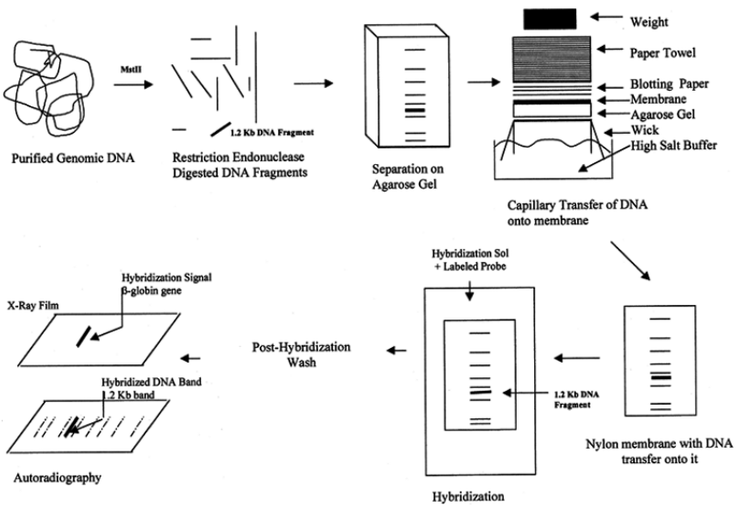

FIGURE 7.4. Representation of Southern Blot Hybridization Analysis. The essential steps for the procedure are represented. Purified genomic DNA is digested with restriction endonucleases and separated in an agarose gel. The DNA is fragmented into smaller pieces by depurination with HCl and the double-stranded DNA is denatured with alkali (NaOH). The denatured DNA in the gel is transferred out of the gel into a nylon membrane by capillary action in the presence of high salt. The nylon membrane is treated with blocking agents and hybridized with a solution containing a single-stranded DNA probe labeled with a radioisotope. After washing nonspecific hybridization products, the nylon filter is exposed to an x-ray film and exposed for autoradiography.

TABLE 7.1. NUCLEIC ACID AMPLIFICATION TECHNIQUES

	Technique	Target	Patent Holder
Target amplification	Polymerase chain reaction (PCR)	DNA	Hoffman-LaRoche
	Ligase chain reaction (LCR)	DNA	Abbott Laboratories
	Transcription mediated amplification (TMA)	RNA	Gen-Probe
	Nucleic acid sequence based amplification (NASBA)	RNA	Organon Tecknica
	Strand displacement (SD)	DNA	Becton-Dickinson
Probe amplification	Invader	DNA	Third Wave Technology
Signal amplification	Branched DNA (bDNA)	DNA	Chiron/Johnson & Johnson
	Hybrid capture	DNA	Digene

Based on the previous discussion, it might be concluded that a DNA probe to a specific target sequence should identify one and only one restriction fragment when hybridized to DNA isolated from the tissue of a single person. In fact, however, each human cell actually contains two complete copies of the human genome, as reflected by the presence of two sets of chromosomes. While one copy of the human genome is very similar to every other copy, the sequences at some loci vary because of the presence of a polymorphism at that specific location. If a variation in the DNA sequence occurs at a recognition site for a restriction endonuclease, the site usually will be eliminated. The restriction enzyme then will have to cut the DNA at a recognition site further from the target sequence in order to create a restriction fragment that contains the target. A second mechanism that can lead to restriction fragments of different lengths is the presence of a sequence consisting of a variable number of tandem repeats (VNTR) that occurs between two restriction endonuclease recognition sites (47). These VNTR sequences consist of a core sequence from eight to ten, to more than 50 nucleotides in length that is repeated from a few to many times. For a given

copy of the human genome, the size of the VNTR sequence is fixed. However, it can vary between different copies of the genome. Thus, because all human tissues except sperm and ova are diploid, examination of a single individual's DNA using a probe to a VNTR sequence may detect two fragments.

If a probe detects a target sequence that can exist in multiple-sized DNA fragments, the probe is said to detect a restriction fragment length polymorphism (RFLP) (48). An individual with two different-sized fragments is said to be heterozygous for that RFLP. Because each single copy of DNA (each set of chromosomes) was inherited from a different parent, this RFLP can be used to aid in paternity testing and for human identity testing. If a neoplastic or genetic disease alters the size of a restriction fragment, the target sequence of the nondiseased tissue may lie at a different location on the filter as compared to that of the diseased tissue. The disease then is said to induce a restriction fragment length polymorphism. Chromosomal rearrangements or deletions and point mutations involving a restriction endonuclease site can all produce RFLPs. RFLPs also can be used to help identify genes that carry mutations and are responsible for inherited diseases through a process called linkage analysis. The latter process relies on the fact that when an RFLP is found to be tightly associated with the development of an inherited disorder, the target sequence must lie relatively close to the gene causing the inherited disease (44, 47).

A number of practical considerations limit the usefulness of RFLP studies in clinical work. First, the methodology is cumbersome and labor-intensive, usually requiring 7 to 10 days to obtain a result. In addition, this methodology sometimes requires large quantities of highly purified DNA of high molecular weight. Second, for many purposes such as detecting point mutations or small deletions or insertions, this method is not sufficiently sensitive unless the mutation alters a known restriction endonuclease site. Even with these limitations, however, for certain disease and disorders, RFLP Southern hybridization analysis is still the method of choice.

In vitro Nucleic Acid Amplification Methods

The Polymerase Chain Reaction (PCR) was the first *in vitro* nucleic acid amplification method developed and it revolutionized life sciences (49). As the result of its development, advances have been made in defining the molecular pathogenesis of many diseases. In the last decade, we have seen development of additional methods of *in vitro* nucleic acid amplification and associated clinical applications. In this section, we will review the basic concepts underlying several of these *in vitro* amplification methodologies. A list of common *in vitro* nucleic acid amplification methods is given in Table 7.1.

Target Amplification Methods

Polymerase Chain Reaction

The PCR causes the *in vitro* amplification of a target DNA sequence by 100,000 to over one-million fold greatly enhancing the ability to detect low levels of target nucleic acid (50). The technique utilizes a set of oligonucleotides called primers (checkered black boxes Fig. 7.5). The primers generally are 19 to 21 nucleotides long and each primer is complementary to a sequence at the 5′ and 3′ ends of the target sequence, respectively. PCR utilizes repeated cycles of DNA polymerase activity to achieve amplification. For PCR to work, the DNA must be denatured. Denaturation is accomplished through use of high temperatures that break the hydrogen bonds that hold the two strands of DNA together. Next, the primers hybridize (anneal) to complementary sequences present at either end of the target sequence. After hybridization of the primers, DNA polymerase extends the primers by adding complementary deoxyribonucleotides beginning at the first base adjacent to the 3′ end of each primer. Through this process, the DNA polymerase creates two new strands of DNA, which are complementary to the target sequence (51). Following the first cycle of denaturation, primer annealing, and primer extension, four strands of DNA exist where initially there were only two. After two cycles, the four strands are converted to eight strands of target sequence. During the third cycle, the eight strands are converted into 16 strands. This geometric increase of the DNA continues for as many cycles as the reaction runs, resulting after ten cycles in about a thousand-fold increase, after 20 cycles in a million-fold increase, and after 30 cycles in a billion-fold increase (Fig. 7.5).

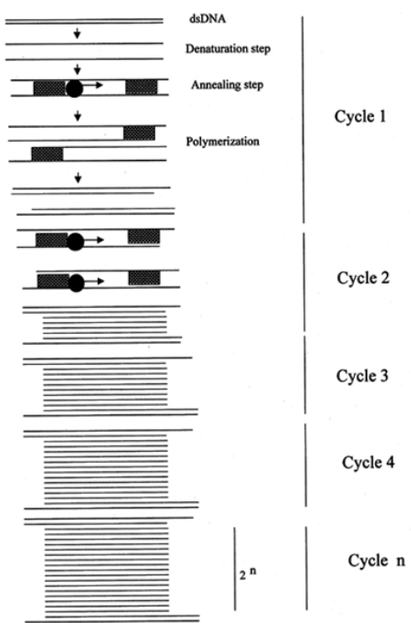

FIGURE 7.5. Polymerase Chain Reaction (PCR). Each cycle of the PCR is composed of denaturation of double-stranded DNA by heat, followed by annealing of primers (checker boxes) to the complementary target sequence. Annealing is favored by lowering the temperature of the reaction below the melting temperature (Tm) of the primer pair. The last step in the cycle is extension by a thermostable DNA polymerase. After one cycle, the number of target copies is doubled. After two cycles, the number of copies of the target sequence is quadruplicated. After 20 cycles, the number of target copies could reach one million.

Major advantages are derived from the enhanced sensitivity of *in vitro* amplification. By increasing the copy number of the target sequence, PCR allows the use of less sensitive detection systems that facilitate use of nonradioactive isotopic detection methods. Another advantage is that the amount of target nucleic acid required for each assay is reduced. The purity of the target sequence generally is less critical because as long as a few target sequences are able to bind the primers, the target can be amplified to a level where it ultimately can be detected. DNA extraction can thus be reduced to a simple, one-step incubation procedure. Detection of small mutations also is greatly simplified. One can amplify a portion of a gene by PCR and then directly

sequence the DNA product without ever having to purify the DNA fragment through cloning. If cloning of the gene is desired, then it is a simple matter to insert the amplified fragment into a vector (52). Sequencing is expected to soon become a standard of practice in the treatment of human immunodeficiency virus (HIV). Mutations in the *pol* gene of HIV-1 may predict resistance of the organism to treatment with zidovudine (AZT) and other therapeutic agents (53). As with any methodology, there are limitations for PCR. The sequence of the target gene must be known so that primers can be prepared to amplify a portion of it. A related problem in microbiology is that the genome of most microorganisms changes over time as a result of mutations. If the mutation occurs in the region of a primer, this mutation may prevent the primer from binding properly to the template and, thus, may inhibit the PCR.

Another limitation of PCR is the potential contamination of negative samples by amplified product (amplicon) (54). Amplified fragments of DNA, called amplicons, may be aerosolized easily into the work environment when sample tubes are opened following amplification; therefore, special precautions must be observed because contamination of a negative sample by even one of these small DNA fragments can cause a false-positive result. Pipetman and other similar pipets, gloves, fingers, clothing, equipment, reagents, “virtually everything with which you might work” can spread amplicon easily (55). Physical and chemical approaches have been introduced to avoid amplicon contamination. Physical separation of pre-PCR and post-PCR work areas is a basic requirement. Use of hydrophobic filtered tips or positive displacement pipettes is another standard. All reagent and sample preparation and handling of patient material should be confined to one area designed as the preamplification area. The sample then should be transported to a separate area, the postamplification area, in which the PCR technique and detection procedures are performed (56, 57). Contamination also can occur from a high background level of template DNA (58). This “high level” is, however, actually so low that its existence may go undetected until one begins to prepare samples for PCR in the contaminated area. This problem arises most often when samples are prepared in an environment where there has been biological amplification through culture or cloning of a target organism or sequence.

Chemical approaches to reduce amplicon contamination have been developed. The most common chemical method is the combined use of the enzyme Uracyl-N-Glycosylase (UNG) and the nucleotide dUTP (59). Inclusion of dUTP in the PCR reaction results in incorporation of dUMP in place of dTMP into the amplicon. The decontamination process consists of treating a sample with UNG prior to PCR. If amplicon containing dUMP contaminates the sample, this dUMP containing amplicon will be destroyed by the action of UNG. UNG will not destroy “true” DNA template in the sample because the latter does not contain any dUMP. The advantage of this system is that there is no need to manipulate the PCR product after amplification and analysis. Even though this approach seems ideal, it has been shown to have limitations with regard to eliminating the effects of amplicon contamination (60). The greater the size of the amplicon and the greater the number of copies of contaminating amplicon, the less likely it will be that the UNG-dUTP procedure will control for contamination.

Another chemical approach is the addition of psoralen compounds to the PCR reaction mixture before amplification. After amplification, the PCR product is treated with ultraviolet light to activate the psoralen compounds, which in turn bind and form adducts with the pyrimidines present in the PCR product. One major disadvantage of this system is that because the psoralins cross-link double stranded DNA irreversibly, the use of probes for PCR product detection no longer is feasible (61).

Reverse Transcriptase PCR

In order to use PCR technology with an RNA target, it is first necessary to use reverse transcriptase (RT) to create a complementary DNA (cDNA) copy of the RNA molecule (62). With this modification, RT-PCR provides an important tool to study gene expression, particularly low copy number mRNA. The first step in RT-PCR is to copy the mRNA into cDNA by RT. A primer is annealed to the mRNA providing a segment of double-stranded

nucleic acid with a free 3′ OH end that can be used for extension by the RT. The RT enzyme then extends the primer by adding complementary nucleotides in a 5′ to 3′ direction. The primer used for this process could be the downstream primer that subsequently will be used in the PCR reaction, or oligo (dT), or random hexamers. The action of the RT causes the formation of an RNA/DNA hybrid molecule. The cDNA strand of this hybrid then can serve as the DNA target molecule in a standard PCR assay. During the initial denaturation step, the RNA is removed and a second DNA strand is created by DNA polymerase from the single-stranded cDNA using the upstream primer. Subsequent PCR cycles then will generate more copies of the double-stranded cDNA target molecule (63, 64, 65). A potential problem that can arise with RT-PCR is that the reaction will amplify genomic DNA that may be contaminating the RNA sample. Even very small amounts of genomic DNA can produce a positive amplification signal in an RT-PCR reaction. One way to distinguish amplification signals of genomic DNA versus mRNA derived cDNA is to design primers that span an exon-exon junction in the cDNA. The presence of an intron in the genomic DNA template will yield a larger fragment than the one from the intronless cDNA template. Unfortunately, this approach cannot always be used, because the necessary information to design primers is not known for a particular gene, or because some functional genes lack introns, as do all processed pseudogenes present in genomic DNA. The use of a well-characterized internal control in the PCR amplification procedure provides a standard by which sample-to-sample comparisons can be made. By using this type of control, meaningful information regarding gene expression can be obtained by RT-PCR (66).

Nucleic Acid Sequence Base Amplification and Transcription Mediated Amplification

A different approach to nucleic acid amplification uses RNA as the target nucleic acid and isothermal amplification (67). One of these procedures is called Nucleic Acid Sequence Based Amplification (NASBA) (Fig. 7.6) (68). This method reverse-transcribes an RNA target into cDNA using a reverse transcriptase enzyme Avian Myeloblastosis Leukemia Virus Reverse Transcriptase (AMLV-RT). A second enzyme, DNA-dependent RNA polymerase subsequently uses this cDNA as a template for RNA synthesis resulting in approximately 100 copies of RNA from one molecule of the original target RNA. The addition of an RNAse H1 enzyme allows degradation of the RNA template thus liberating the cDNA for transcription of RNA. Organon Technika, the holder of the patent for this methodology, has developed a quantitative approach to this method by introducing a series of synthetic RNA molecules of known concentration during nucleic acid extraction (69). Quantitation of target RNA is performed on magnetic beads coated with a specific probe for each RNA control and the RNA target sequence. These probes are labeled with ruthenium, which following excitation by electrical current, causes the emission of light that is proportional to the amount of amplified product bound to the magnetic bead. Transcription mediated amplification (TMA) is a second nucleic acid amplification technique that uses RNA as a target and is isothermal (70, 71). It is very similar to NASBA in its method of amplification.

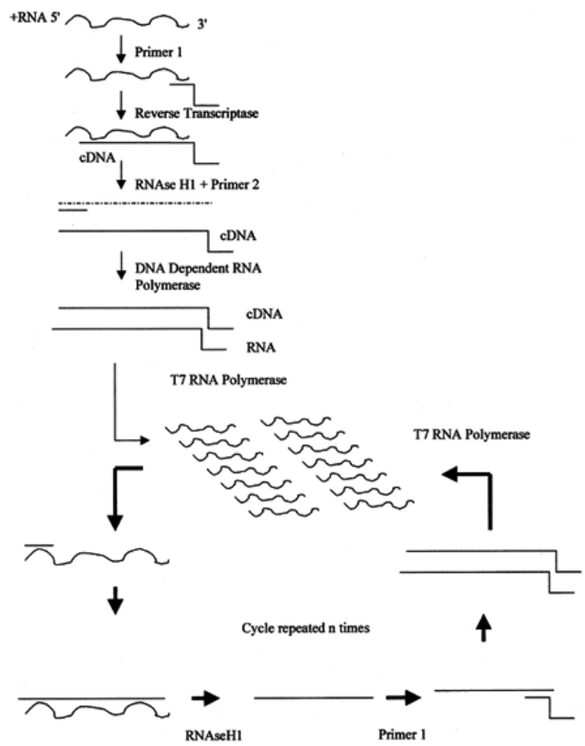

FIGURE 7.6. Nucleic Acid Sequence Based Amplification (NASBA). A ribonucleic acid (RNA) target is reverse transcribed to complementary DNA (cDNA) using Avian Myeloblastosis Leukemia Virus Reverse Transcriptase (AMLV-RT). Ribonuclease (RNAse) H1 degrades the RNA template so the cDNA can be transcribed to RNA. A second enzyme uses the cDNA for RNA synthesis.

Ligase Chain Reaction

The Ligase Chain Reaction (LCR) is an amplification method that first was developed for the detection of point mutations in genetic disease and cancer (Fig. 7.7) (72). Four primers are used in the procedure. Two primers are located adjacent to each other and are complementary to the opposite strand of the target sequence. Under these circumstances, ligase enzymatic activity will join the 3′ end of one primer to the 5′ end of the adjacent downstream primer in both sets of primers. The temperature of the reaction then is raised leading to denaturation and separation of the ligated primer pairs from the target molecule. When the reaction temperature is reduced, nonligated primers can anneal to both the target nucleic acid and the previously ligated primers. These primer pairs then are covalently linked through the action of the thermostable ligase. Because ligated primers subsequently can serve as a target for the complementary set of primers in the next reaction cycle, exponential amplification occurs. If there is a mismatch at the 3′ end of the upstream primers, ligation will not take place (73). More recently, a modification of the LCR was described called the gap LCR. This modification uses four oligonucleotide primers but the two primers in each set are separated by a gap of one or more bases when they are hybridized to the target nucleic acid sequence. After hybridization of the oligonucleotide primers, a thermostable DNA polymerase fills in

the gap followed by ligation of the extended primers by the thermostable ligase (74).

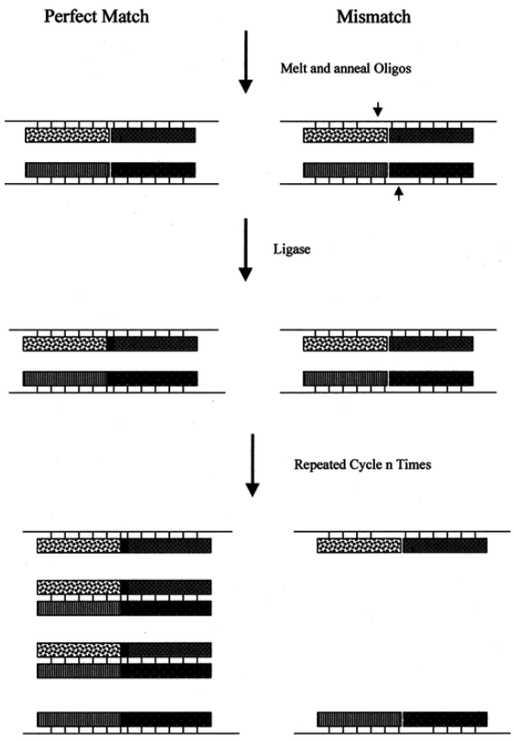

FIGURE 7.7. Ligase Chain Reaction (LCR). The shaded boxes represent primers. The ligase will ligate adjacent primers only if the primer sequence is exactly the same as the genomic DNA sequence at the junction of the primers.

NUCLEIC ACID PROBE SIGNAL AMPLIFICATION TECHNOLOGY

Part of "7 - Introduction to Molecular Diagnostics"

An alternative to target amplification for increasing the sensitivity of nucleic-acid-based testing is to increase the strength of the detection signal that occurs following binding of the probe to the target sequence. Branched DNA technology (b-DNA) uses this strategy called signal amplification (75). b-DNA technology detects and quantitifies the presence of a target nucleic acid sequence through hybridization of multiple probes to the target sequence. The first step in the b-DNA assay is to bind the target nucleic acid sequence to the well of a microtiter plate. This process uses capture probes that hybridize to the target and are themselves covalently attached to the base of the microtiter well. After this step, a series of oligonucleotide probes containing a region that is complementary to the target sequence are added and hybridized to the trapped target. These probes hybridize to sequences located in the target that do not contain any complementarity to the capture probes. In addition, these oligonucleotide probes contain sequences that are designed to anneal to a specially modified b-DNA molecule that produces the detection signal for the system. This branched DNA molecule contains up to 45 sites for oligonucleotides that have been linked covalently to alkaline phosphatase molecules. When this signal amplification system becomes fully saturated, the result is that as many as 1,700 enzyme molecules can become bound to the target sequence. After addition of alkaline phosphatase substrate, the presence of the target sequence is detected by light emission. Detection and quantitation of the target sequence is achieved by measuring the amount of light emitted from the sample compared to the amount of light generated by control samples (76).

Another signal amplification system is the hybrid capture technology. This method uses RNA probes for the detection of a DNA target sequence. In this procedure, one or more RNA probes are hybridized to the DNA target. The RNA/DNA hybrids then are captured in the wells of a microtiter plate using either monoclonal antibody to RNA/DNA hybrids that are attached to the walls of the well or oligonucleotides that are bound

to wells and are complementary to regions of the target. Next, monoclonal antibodies against RNA:DNA hybrids labeled with alkaline phosphatase molecules are added. A chemiluminescent substrate then is added and light emission is measured (77, 78).

Methods for Detecting Amplified Nucleic Acid Sequences

A variety of methods is utilized to determine whether the desired DNA sequence is present after *in vitro* amplification in the clinical sample. These methods are: (a) direct detection of amplicon by gel electrophoresis; (b) solid-phase hybridization; and (c) liquid-phase hybridization.

The simplest and most direct method to detect the presence of a target sequence in amplified product is by direct visualization after gel electrophoresis. Because the sequence of the gene chosen for amplification by PCR usually is known, so is the size of the DNA fragment that will be generated by the PCR reaction. To measure fragment size, the PCR product is placed on an acrylamide or agarose gel and after electrophoresis, the presence of the fragment is detected directly by immersing the gel in a solution of ethidium bromide, which binds preferentially to double-stranded DNA fragments. Direct visualization of the PCR product is achieved by exposing the stained gel to ultraviolet light. If radioactive nucleotides or fluorescently labeled primers have been incorporated into the PCR product, the PCR product can be detected by autoradiography or with a fluorescence scanner. Direct incorporation of radiolabeled nucleotides into the PCR product increases sensitivity and permits detection of DNA fragments on the order of 1/1000 of those detectable by ethidium bromide. Use of direct incorporation of radiolabeled nucleotides or fluorescently labeled primers has the disadvantage that the PCR sometimes can amplify fragments other than the desired target sequence. This method can be made more specific if a restriction endonuclease recognition site is present in the DNA fragment. In the latter case, the PCR product is subjected to restriction digestion. The digested PCR products then are put on a gel and examined to verify that the predicted restriction site is present in the fragment and that it is located appropriately based on the size of the restriction-digested products (46).

In the solid-phase and liquid-phase hybridization procedures, the detection of amplified product is achieved by hybridization of the amplified product with a specific probe, generally an oligonucleotide probe. This approach, when used in combination with gel electrophoresis, has the potential to provide information on both fragment size and homology. In performing hybridization studies with oligonucleotide probes, one must be aware that the melting temperature of the probe, and hence the optimum hybridization temperature for the reaction, is highly sensitive to changes in the base composition and the length of the probe.

In the solid phase hybridization, either the amplified DNA fragments or probes to the amplified target are bound to a solid phase support. A number of different solid supports have been used. Among these are nitrocellulose, nylon, chemically activated papers and, more recently, polystyrene surfaces like microtiter plates. In the past, the most widely used solid support was nitrocellulose, which binds high-molecular-weight DNA with high efficiency but retains nucleic acid fragments below 500 base pair with poor efficiency. In addition, nitrocellulose membranes are fragile and can become brittle. The introduction of nylon membranes as a solid support media for hybridization overcomes some of these problems. Nylon membranes can bind nucleic acid smaller than 500 base pairs with high efficiency. Recently, polystyrene surfaces have been used with good success as solid support media. However, the process of binding target or probe to polystyrene is more complicated than to nitrocellulose or nylon membrane. Polystyrene is the material from which microwell titer plates are constructed. Use of formats incorporating microwell titer plates has become very popular. This format can be automated easily, decreasing the usage of reagents (46).

Solid support hybridization methods include spot-blot, slot-blot, dot-blot and reverse dot-blot formats. In spot-blot, the PCR-amplified fragments are simply spotted onto a nitrocellulose or nylon filter. In the slot-blot and the dot-blot procedures, the PCR-amplified fragments are placed in a small well and then drawn under vacuum through the membrane filter. During this process, the DNA fragments bind to the filter. The filters then are treated either with heat under vacuum or by ultraviolet light to bind the DNA irreversibly to the membrane. Next, the filters are placed in a hybridization solution with a labeled probe. Another commonly used solid hybridization method is the reverse dot-blot hybridization procedure. In this procedure, the oligo probe is bound to the solid phase support and the denatured amplified product is hybridized to the bound oligo probe. In cases where agarose gel electrophoresis of the PCR product has been performed, one can transfer the PCR product onto a nylon membrane using a Southern blot procedure. The membrane then is hybridized with a labeled oligonucleotide probe. The combination of gel electrophoresis and hybridization with an oligonucleotide probe permits two independent means of verifying the identity of the product because one is able to measure the size of the product as well as judge complementarity to the probe.

One approach to detecting small genetic changes is through the use of short oligonucleotide probes called allele-specific oligomers (ASOs). These probes usually are about 16 to 21 nucleotides long. The main characteristic that determines the ability of an oligonucleotide probe to detect very small genetic changes is its size. When a DNA probe anneals to its complementary sequence during DNA hybridization, the energy that holds the two strands together comes from the number of bases that are in proper register with each other. With a very short (oligo) probe, however, all bases must match the target sequence, or the destabilization from one mismatched base is sufficient to prevent a stable hybrid from forming (46).

One method that has been developed to reduce signals resulting from nonspecific hybridization signals generated by the presence of nonspecific hybridization between probe and nontarget sequences is the sandwich hybridization technique (79, 80). In sandwich hybridization, a portion of the amplified product is hybridized to a probe that has been bound previously to a solid support. After the first hybridization, the amplified material that has been bound by the first probe is hybridized to a second probe that is labeled with radioactive nucleotide or other reporter molecule. This approach only can generate positive signal

if there is an appropriate sandwich between immobilized target probe and the labeled probe. The second probe could be labeled with a biotin molecule at the 5′ end. Detection of amplicon then is performed by adding streptavidin conjugated to an enzymelike horse radish peroxidase. After adding the substrate for the specific enzyme, color development occurs that can be measured in a colorimetric reader (80).

In the liquid hybridization system, a portion of the PCR-amplified fragments is mixed directly with a labeled probe. Following hybridization, the samples are placed on an agarose or acrylamide gel and the labeled nucleotides separated from the hybridized fragments via electrophoresis. The hybrids generally are detected by direct autoradiography of the gel (46). Recently, another way of performing liquid hybridization has been described. This method, called the 5′ nuclease assay, detects the accumulation of PCR product as it is being produced in the PCR reaction tube (detection real time) (Fig. 7.8). PCR product is detected through the hybridization of a fluorescently labeled probe and the target sequence. The probes actually are labeled with 2 fluorescent dyes, a 5′ fluorescent dye that acts as a reporter dye, and a 3′ fluorescent dye that acts as a quencher. The probes are 25 to 30 nucleotides in length. When the reported dye is excited, fluorescence emission is blocked by the quencher. During amplification, the probe containing the reporter and quencher dyes binds to the target sequence if the latter is present in the sample. During the extension step of the PCR cycle the polymerase encounters the probe as it extends the primer and cleaves the probe through use of its 5′ exonuclease activity. Following hydrolysis of the probe, the quencher is separated from the reporter dye leading to an increase in the fluorescence intensity from the reporter dye. Because the probe is removed during the extension step, PCR is not interrupted and polymerization can continue to the end of the target sequence. With each cycle more probe binds to the ever-increasing amount of amplified target sequence and subsequent cleavage of the probe results in increased fluorescence. The greater the initial amount of the target sequence in a sample, the more rapid will be the accumulation of fluorescent signal. Because fluorescence is being monitored during each cycle, the point at which a fluorescent signal is greater than the background is a measure of the initial quantity of the target sequence. Thus, the higher the starting copy number for a particular target sequence, the lower will be the number of cycles that the PCR reaction must execute before product is first detected. This is in contrast to traditional detection of PCR product, which is performed at the end of thermal cycling (end point analysis). Real-time analysis of PCR product has two major advantages over end point analysis. First, it eliminates the need for post-PCR manipulation reducing the risk of amplicon contamination; and, second, it increases sample throughput by reducing the time required for product detection (81).

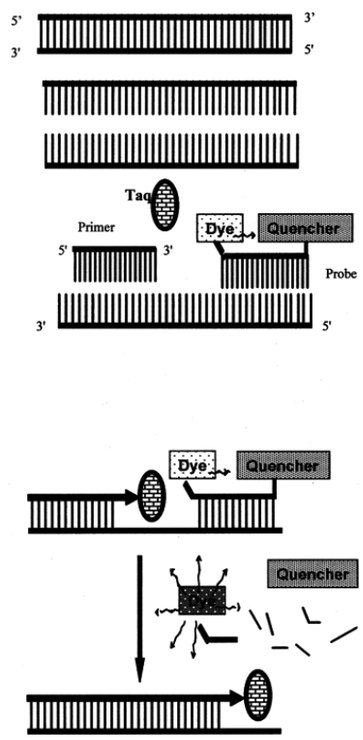

FIGURE 7.8. 5′ Exonuclease Assay (Real time PCR). PCR product is detected from the displacement of a fluorescent labeled probe. The probe is labeled with two fluorescent dyes, a 5′ dye acts as a reporter and a 3′ dye as a quencher resulting in no fluorescence emission from the reporter dye. During PCR amplification, the probe binds the target sequence and is hydrolyzed by the DNA polymerase. In the extension step, DNA polymerase extends the DNA until it finds the probe. The DNA polymerase contains a 5′ ->3′ exonuclease activity and hydrolyzes the probe. In the presence of target sequence, the quencher dye is separated form the reporter dye leading to an increase in fluorescence.

Detection of PCR product generally is facilitated by linking probe or product to some form of reporter molecule. Reporter molecules fall into two broad categories: radioactive and nonradioactive. Nucleotides that have been labeled with radioisotopes such as phosphorus 32 or 33, and sulfur 35 are the most common reporter molecules for research assays and clinical assays developed in house. The detection of this type of label following hybridization is performed commonly either by radioautography, by scintillation counter, or with phosphoimagers (42). The second category of reporter molecules are nucleotides that are covalently linked to one or more hapten molecules such as biotin, a fluorescent dye, or a reporter enzyme. These labels generally are nontoxic and safer than radioactive labels. Biotin-labeled probes generally are detected by using color development with streptavidin-conjugated peroxidases or alkaline phosphatase in the presence of the appropriate substrate. The fluorescent and chemiluminescent products are analyzed by fluorometry, auto-radiography, or luminometry (79).

Peptide Nucleic Acid Probes

Since the discovery in 1991, peptide nucleic acid (PNA) probes have attracted considerable interest as a tool for the analysis of nucleic acids. PNA oligomers are formed from repeating units of 2 amino-ethyl-glycine to which the purine or pyrimidine bases are attached via acetyl linkages. Despite radical differences in the chemical structure between nucleic acid and PNA, hybridization between PNAs and nucleic acids exhibit increased affinity and specificity compared to corresponding oligonucleotides. PNAs of approximately 20 bases are synthesized by manual or automated means. These PNA oligo-probes can be labeled with several different reporters like biotin, fluorescein, rhodamine, or acridine. PNAs can form stable hybrids with complementary DNA and RNA over a broad range of salt concentrations (82).

Direct DNA-Sequencing Procedures

There are several approaches to nucleic acid sequencing. The first method developed by Maxxan and Gilbert used chemical cleavage with four different chemical reactions of DNA strands that previously had been labeled with a radioactive nucleotide. Cleavage occurs at a particular base and reagents are adjusted such that each molecule is cleaved only once. This creates a set of nested DNA fragments that have a common starting point but each successive fragment is one base longer than the preceding fragment. The fragments are analyzed by polyacrylamide gel electrophoresis and autoradiography using gels capable of differentiating fragment sizes down to one base difference (83).

The most commonly used method of DNA sequencing is that of Sanger (84). This method uses four different enzymatic reactions that synthesize a complementary strand to the template DNA by using a primer and DNA polymerase. First, the single-stranded DNA is combined with primer, radioactive nucleotides and DNA polymerase. The polymerase extends the primer along the single-stranded template incorporating four to five labeled nucleotides. The sample of DNA and primers then are divided into four aliquots and each aliquot is combined with a second set of nucleotides that contains three deoxynucleotides and one dideoxynucleotide. The dideoxynucleotide differs from the normal deoxynucleotide in that it does not possess a 3′ hydroxyl group on the pentose sugar. For this reason, when it is incorporated into the extending DNA strand, the polymerase is not able to continue to add additional nucleotides to the growing strand. Termination of the DNA strand therefore occurs at the site of incorporation of the adenine, cytosine, guanine, or thymidine dideoxynucleotide. This procedure results in a series of single-stranded fragments of varying lengths. In the case of strands generated in the presence of dideoxythymidine, all of the strands will terminate with a thymidine. Because the incorporation of the dideoxynucleotide is random, some strands will have terminated after extending nearly to the end of the template while others will terminate very early during the extension process. When each of the four dideoxynucleotide reaction mixtures is subjected to electrophoretic separation on a denaturing acrylamide gel, the autoradiogram of these four mixtures results in what is called a sequencing ladder. By examining the autoradiogram either directly or with the aid of a image analyzing system, the sequence of the target DNA can be directly determined.

The Sanger sequencing method formerly required that the target sequence first be purified from all other possible contaminating sequences through a process termed cloning. This latter procedure could require weeks to months to accomplish and was highly labor-intensive. This made using DNA-sequencing for clinical purposes essentially unrealistic. However, through the use of PCR, the lengthy cloning procedures required to perform DNA-sequencing now can be circumvented through the process of direct amplification of the desired sequence from the DNA in the patient's specimen (85, 86, 87, 88). Once the amplified fragment has been obtained using PCR, it is subjected to further rounds of denaturation, primer annealing, and extension in which only one primer (sequencing primer) is used in conjunction with appropriate dideoxynucleotides. This procedure is called cycle sequencing and results in the generation of many single-stranded copies of the target sequence that can be examined on sequencing gels.

An additional improvement in the technology of this field has been the development of automated DNA-sequencing devices (84). Some improvements in the methodology have been introduced but the most important has been the introduction of robotic workstations to set up all reactions and automate loading of DNA-sequencing devices. A number of these devices use fluorescent-labeled primers or labeled dideoxynucleotides to tag the newly synthesized DNA fragments. Two formats have been used. One format utilizes a sequencing primer that is used in all four reactions and that is labeled with the same fluorescent dye. After the reactions are completed, each sequencing reaction is analyzed in a separate lane on the sequencing gel. The other format uses four fluorescent-labeled primers where the primer in each sequencing reaction has a unique dye. After the reactions are completed, the four different reactions are combined and resolved in a single lane in a sequencing system. In both approaches, DNA is detected using laser-activated fluorescence during the separation process. The automated laser fluorescent DNA sequencer from Pharmacia (Piscataway, NJ) uses a single dye labeled primer and the four-lane separation approach. In this instrument, a fixed red helium neon laser beam is located at the bottom of the sequencing gel and emits light through the entire width of the gel. As the sequencing reactions are electrophoresed in a sequencing gel, the tagged DNA strands pass through the laser beam and emit fluorescent light. The fluorescent light is then captured by 40 photodiode detectors. These detectors, placed at a right angle to the beam at the face of the gel, capture the signal and send it to a computer where the sequences are determined. Since four sequencing reactions are required per sample and the sequencing gel contains 40 lanes, a maximum of ten samples can be analyzed at one time.

Another sequencing device is the Model 377 ABI Prism Automatic DNA Sequencer from Applied Biosystems Division of Perkin-Elmer (Foster City, CA) (Fig. 7.9). This sequencing device uses the four-dye, single-lane approach previously described. An argon laser scans back and forth along the bottom of 36 lanes of the sequencing gel. Recent updates to the system include the capability of gels with 96 lanes. When the tagged DNA reaches the area where the laser is located, it emits light that passes through a prism. The prism separates the light emitted from each dye, which then is sent to a photomultiplier tube that subsequently

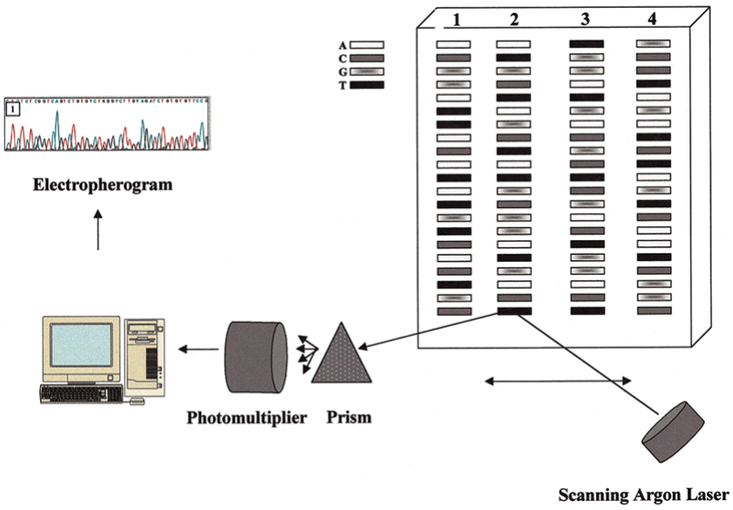

FIGURE 7.9. Automatic DNA Sequencing. Single-lane automatic DNA sequence analysis. The 377 ABI Prism automatic DNA sequencer uses four fluorescent labeled primers or four fluorescent labeled dideoxynucleotides to tag the newly synthesized DNA fragments. The four reactions are combined into a single tube and are separated by electrophoresis in a single lane. When the tagged DNA reaches the area where the laser is located, it emits a light that passes through a prism. The prism divides the light emitted from the dyes and sends it to a photo-multiplier and subsequently to a computer where the sequence is determined. The order of the colors as they pass through the laser reflects the DNA sequence.

sends the appropriate signal to a computer where the sequence is determined. The 310 ABI Prism Automatic DNA Sequencer uses the same detection method as the 377 model, but separates the sequencing reaction by capillary electrophoresis (89, 90). After the sequencing reactions are finished, they are placed in a sample tray and almost all subsequent aspects of analysis are automated. This device uses preformulated polymers that are injected automatically into capillaries. This eliminates the time consuming need to pour slab gels. An electrokinetic injection system is used to load each sample into the capillary for electrophoresis. The automatic loading system ensures consistent and reproducible handling of samples. The 310 Genetic Analyzer simultaneously detects four different fluorescent dyes in a single capillary with the ability to operate unattended for 48 hours.

Even though the devices described above are major improvements over manual sequencing, these systems still have a limited throughput. Alternative approaches are being developed to produce sequence results faster and more economically than currently possible. One novel approach is sequencing by hybridization (SBH) on chips, also called “DNA chips.” These DNA chips are composed of a large number of oligonucleotides of known sequence arranged on a solid support. The location of each specific sequence on the chip is mapped and known. A labeled DNA fragment is applied to the solid support and hybridizes to some of the oligonucleotide sequences. Based on the location of the hybridized DNA fragments, a computer program deduces its sequence (91, 92, 93). In order for SBH to be practical, miniaturization of the solid support is necessary. Several different approaches to SBH have been developed using micro-arrays. One of these approaches called the GeneChip (Affymatrix, Santa Clara, CA) contains a high-density array of oligonucleotide probes placed on a miniature silicon solid support. By combining photolithography technology used in semiconductors and solid phase chemical synthesis, light-directed oligonucleotide synthesis can be carried out on the surface of the silicon chip. The efficiency of synthesis is approximately 95%, which limits the length of the oligonucleotide that can be synthesized currently to 30 nucleotides in length.

At present, the Affymatrix chip contains 400,000 different probe regions. Because DNA is comprised of four bases, the different oligonucleotides are arranged in clusters of four for each base position. The labeled target hybridizes to the oligonucleotides that contain a sequence complementary to portions of the target molecule. By using laser confocal microscopy and computer-assisted analysis, the location and thus the sequence of the hybridized fragments can be deduced (90, 92).

The challenges facing SBH are common to a number of nucleic acid probe technologies. These include probe selection, target preparation, and probe immobilization as well as expensive equipment used to make and analyze this type of micro-array. Another approach developed by Nanogen, Inc. (San Diego, CA) captures prefabricated oligonucleotides onto electro-active spots on silicon wafers that are controlled independently. Each of these independent locations has a unique oligonucleotide attached to the surface where the electric potential can be controlled independently. By applying an electrical potential to each location of the micro-array, the target DNA is pulled toward the spot and hybridization can occur in minutes instead of hours. DNA chip technology appears extraordinarily promising, but it is far from becoming a routine tool for use in the molecular diagnostics laboratory at this juncture (91, 93).

AUTOMATION AND TECHNOLOGICAL ADVANCES IN MOLECULAR DIAGNOSTICS

Part of "7 - Introduction to Molecular Diagnostics"

Utilization of molecular testing has steadily increased in all areas of the laboratory and this phenomenon shows no signs abating. A number of molecular tests have become standard of practice (e.g., HIV-1 viral load, DNA tests for cystic fibrosis, and other inherited disorders). This has led to an increase in test volume and consequently to the need for more automation, better detection systems, and more standardization of current manual procedures. In the past, radioactivity has been the most popular method for labeling and detecting nucleic acid probes. Radioactivity is inexpensive and sensitive, but disposal of radioactive material is expensive and hazardous. Recently, new reporter molecules have been introduced that are sensitive and nonhazardous. Some of these have come into routine use for a number of molecular assays. Fluorescence now is the basis of almost all DNA chip-based technology and luminescence also has become more widely used because of the wide range of its linear response. Use of these reporter methods has facilitated automation of the detection of *in vitro* amplified product.

Automation of other aspects of molecular testing is likewise increasing (94). Thermocyclers are an example of an automated, single-function instrument that is in common use. Automatic nucleic acid extractors are another example of single-function instruments. A number of automatic nucleic acid extractors are commercially available using different extraction principles.

More recently, multifunction devices that are capable of performing more than one step of the testing process have become available. An example of one such device is the Roche Cobas Amplicor instrument. This device contains thermocyclers for performing multiplex PCR and reflex testing in addition to a three-axis cartesian robotic pipeting station for automated processing, detecting, and quantifying of amplicon present in each sample. Full-function molecular diagnostics automated devices that perform extraction, amplification, and detection are limited at present. One such device from Roche Molecular Systems is composed of a sample preparation unit (Ampliprep) coupled to a completely enclosed amplification, detection, and quantification system.

The development of micro-array devices is expected to have a major impact on automation in molecular diagnostic testing. The applications of DNA chip technology focus on the study of genomic structure and the study of gene expression. High throughput studies of genomic structure are expected to become important as single nucleotide polymorphisms (SNPs) are identified that relate to the metabolism of therapeutic agents and that predict our susceptibility to develop a host of common diseases (95, 96). The other application for micro-arrays is to determine gene expression profiles for cells and tissues. Gene expression arrays hold great promise for the characterization of the cancer cells for diagnostic, prognostic, and even therapeutic purposes (97, 98, 99). Cancer cells usually contain a number of genetic alterations that may be more easily detected at the level of gene expression than through direct examination of the cell's genome.

Microfluidics and chip technology likely will contribute substantially

to the automation of molecular testing. The concept of lab-on-a-chip has been proposed in which the chip would perform a large number of the processes currently performed by laboratory personnel (100). These chips would begin with whole blood and perform nucleic acid extraction, restriction enzyme digestion, gel electrophoresis, hybridization, and detection without the need for human intervention at any step. An early application of this concept has been incorporated by Clinical Microsensors (Pasadena, CA) into a hand-held, point-of-care instrument. At the core of their technology is the bioelectronic detection of nucleic acid, either DNA or RNA in a variety of different samples. They use microchips that contain a number of electronically active “pads” coated with specific DNA capture probes. The specific probes on the microchip surface directly capture complementary target DNA sequences. A signal probe labeled with ferrocene is added and hybridized to the target sequence. The ferrocene molecule acts as an electron donor. When a slight voltage is applied to the sample following hybridization, the electrons of the ferrocene molecules rapidly tunnel through the double-stranded DNA yielding an electronic signal that can be detected through the microelectrode.

Finally, another technology that holds promise to facilitate automation is matrix-assisted laser desorption and ionization mass spectrometry (MALDIMS) (101). In this technique, the target is immobilized as a spot, and simultaneously probed with oligonucleotides that are labeled with a unique mass marker. A laser beam is used to vaporize and ionize a small amount of material, which in turn is analyzed by a mass spectrophotometer (102). The methodology combines the potential for high sensitivity, specificity, and fast turn-around time, but the complexity and the cost of the instrumentation make it impractical for clinical laboratory use at this juncture.

Molecular Biology of Inherited Diseases

Jeffrey A. Kant

Genetic diseases are passed in simple and complex patterns from parents to children — except for perhaps ‘insanity.’ We now understand the simple patterns well, including underlying molecular genetic defects that cause many disorders. Inherited conditions that exhibit more complex patterns, to include multifactorial disorders, behavioral traits, and perhaps even variant expressions of well-understood single gene disorders still await resolution at the molecular level. This chapter will concentrate on disorders with simple patterns transmitted through the germline of parents. *Somatic disorders* associated with mutations that arise in cells after conception and are not transmitted reproductively will be discussed under oncologic disorders. The full elucidation of the human genome sequence through the Human Genome Project and other efforts, combined with information from sequencing projects directed at other genomes such as the mouse, promise a veritable explosion of additional clinical applications over the next decade for simple, and ultimately complex, inherited disorders.

TERMINOLOGY

Part of "8 - Molecular Biology of Inherited Diseases"

There are a number of important terms to understand in a discussion of inherited diseases. Important terms or concepts are highlighted in *italics* throughout this chapter.

The medical manifestation(s) of a disease are referred to as the disease *phenotype*. A patient with cystic fibrosis (CF) may demonstrate symptoms of pulmonary infection resulting from inspissated secretions and failure of normal respiratory tract clearance mechanisms or maldigestion and failure to thrive because of loss of pancreatic exocrine function. There also may be characteristic laboratory or cellular abnormalities associated with the basic defect in the disease, such as improper chloride transport in CF that results in an elevated sweat chloride level.

The specific molecular alterations that lead to absence of or defects in a functional gene product in a patient are referred to as the disease *genotype*. CF patients who have inherited the three base pair deletion mutation in the cystic fibrosis transmembrane conductance regulator (CFTR) known as ΔF508 from each parent generally display pulmonary and digestive disease in early childhood. Conversely, male patients whose genotype consists of a single ΔF508 mutation paired with a missense arginine to histidine change at CFTR residue 117 (R117H) frequently do not exhibit severe manifestations of CF but may have isolated abnormalities of the genitourinary tract such as bilateral or unilateral absence of the vas deferens that are undetected until adulthood — or not at all. For reasons that are only partially understood, two patients with the same genotype may display different phenotypes or timing in demonstrating a particular phenotype.

Physicians often are confused by the terms *penetrance* and *variable expressivity*. Penetrance refers to whether manifestations that permit a diagnosis of the inherited condition are present during the lifetime of a patient who has inherited a genotype that generally leads to disease. Variable expressivity refers to phenotypic variability in a disorder in a family where patients generally possess the same genotype.

The term *mutation* is semantically tricky. This term connotes a genotypic change that produces an adverse phenotypic effect, either by itself in dominantly transmitted disorders or in combination with another mutation in recessively transmitted disorders, which will be discussed below. The human genome constantly undergoes processes that produce and enhance genetic diversity. These include gross events such as crossovers between sister chromatids in meiosis as well as changes involving the deletion, insertion, or substitution of one or a few nucleotides on all chromosomes. If molecular changes do not lead to an adverse phenotypic effect, such changes are best termed genetic *polymorphisms* (or variants) and not mutations. Another commonly used term is *allele*, which refers to a gene or chromosomal site with known genetic variants, whether polymorphic or mutant.

Homozygous is a term used to describe the genotype of individuals who carry identical sequences on both autosomes (or both X chromosomes) at the site of a known disorder; of course, most people are homozygous for a nonmutant sequence, commonly referred to as ‘normal’ or ‘wild type.’ *Heterozygous* refers to individuals who carry one mutant and one normal autosome or X chromosome. Depending on whether the disorder is dominant or recessive, heterozygous individuals may or may not demonstrate a disease phenotype. A *compound heterozygote* is an individual bearing different mutations in the same gene on the respective autosomes or X chromosomes. *Hemizygous* refers to genotypes of the X and Y chromosomes in males, where there generally is not an opportunity for a diploid gene dosage.

PATTERNS OF INHERITED DISEASES

Part of "8 - Molecular Biology of Inherited Diseases"

Recognized simple patterns of inherited diseases include *autosomal recessive*, *autosomal dominant*, *X-linked*, and *mitochondrial* forms (Table 8.1). Almost all cases of such disorders are a result of molecular defects affecting single genes. By way of background, autosomes constitute chromosome pairs 1–22; X-linked disorders involve genes on the X chromosome that generally are present in two copies in females and a single copy in males. Mitochondria have been known for some time to carry their own discrete and separately replicating circular deoriboxynucleic acid (DNA), which contains genes whose mutation can lead to mild or severe disorders. Figure 8.1 provides representative family pedigrees for each of these patterns.

TABLE 8.1. SOME COMMON INHERITED DISORDERS BY PATTERN OF INHERITANCE

Inheritance Pattern	Disorder	Gene(s)
Autosomal recessive	α thalassemia	α-globin
	ß thalassemia	ß-globin
	Cystic fibrosis	CFTR
	Gaucher disease	Glucocerebrosidase
	Hereditary hemochromatosis	HFE
	Spinal muscular atrophy (autosomal recessive)	SMN-telomeric (? Others)
	Tay-Sachs disease	Hexosaminidase A
Autosomal dominant	Charcot-Marie Tooth disease, type 1A	Peripheral myelin protein 22
	Hereditary nonpolyposis colon cancer (HNPCC)	MSH-2, MLH-1, PMS-1, PMS-2
	Hereditary pancreatitis	Cationic trypsinogen
	Hereditary breast cancer	BRCA1/BRCA2
	Huntington disease	Huntingtin
	Marfan syndrome	Fibrillin
	Myotonic dystrophy	Myotonin kinase
	Neurofibromatosis, type I	Neurofibromin
	Neurofibromatosis, type II	MERLIN
	Osteogenesis imperfecta (OI, Types I and II)	Type I Collagen, α1 or α2
X-linked recessive	Duchenne/Becker muscular dystrophy	Dystrophin
	Fragile X syndrome	FMR-I
	Glucose 6-phosphate dehydrogenase deficiency	G6PD
	Hemophilia A	Factor VIII
	Hemophilia B	Factor IX
X-linked dominant	Hypophosphatemic rickets	PHEX
Mitochondrial	Leber's hereditary optic neuropathy (LHON) MERFF, MELAS, NARP, KSS	Many to few mutations in tRNA or other genes, mitochondrial rearrangements, etc.

CFTR, cystic fibrosis transmembrane conductance regulator
MERFF, Mitochondrial enchephalopathy with ragged red muscle fibers
MELAS, Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes
NARP, Neurogenic muscle weakness, ataxia, and retinitis pigmentosa
KSS, Kearn's-Sayre Syndrome

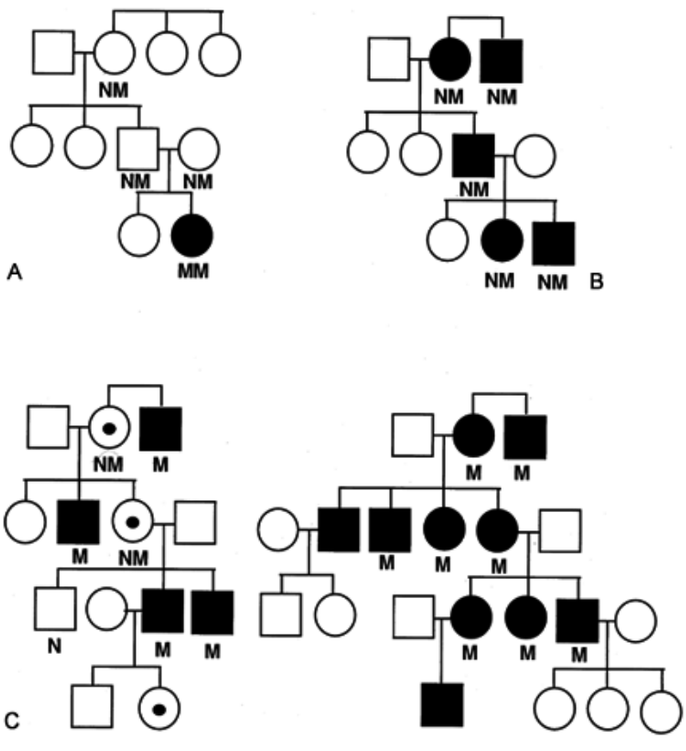

FIGURE 8.1. Major patterns of inheritance for molecular genetic disorders. (**A**), Autosomal recessive; (**B**), Autosomal dominant; (**C**), X-linked recessive; (**D**), Mitochondrial.

Autosomal recessive disorders frequently appear without warning in children of normal couples; neither parent exhibits signs of disease, and in many cases neither may be able to identify close or even distant family members with the disease that afflicts their child. This is because disease only is seen when an individual has inherited a mutant copy of the same gene from each parent (Fig. 8.1A). The presence of a single normal gene copy, as is the case for each parent, provides a sufficient level of the essential gene product to prevent the manifestations of disease. Individuals with one normal and one mutant gene copy are termed *carriers* for the particular autosomal recessive disease. The likelihood two carriers will each transmit an autosome carrying a mutant gene to conceive an affected offspring is 25% (1 in 2 from father × 1 in 2 from mother). In general, autosomal recessive disorders are

close to 100% penetrant and may show mild to modest phenotypic variability for identical genotypes.

In contrast to autosomal recessive disorders, *autosomal dominant disorders* (at least those that do not result in the death of affected individuals before they are able to reproduce) generally are seen in each generation of a family and affect both sexes (Fig. 8.1B). Both sexes also transmit the disease to offspring, an important difference from mitochondrially transmitted disorders. Because the disorder is dominant, the likelihood offspring will be affected is 50% with each pregnancy. The dominant nature of these disorders reflects a molecular mechanism in which the presence of a single mutant gene product is either sufficient to produce disease in the presence of a normal gene copy (as in a number of connective tissue disorders) or the loss of the normal gene product is sufficiently likely (as in hereditary breast cancer because of BRCA1/2 gene mutations) that the preexisting loss of a normal autosomal gene dramatically increases the patient's risk of developing cancer.

X-linked recessive disorders, a result of mutations affecting genes on the unequally distributed X chromosome, affect males but rarely affect females (Fig. 8.1C) because a normal gene on the second X chromosome is protective. Females therefore are similar to carriers of an autosomal recessive disorder, except that 50% of their male offspring demonstrate disease. Cytogenetic disorders (e.g., Turner's syndrome) that remove entire X chromosomes or portions may give rise to X-linked disorders in females, as can a marked skew in the mandatory X chromosome inactivation that occurs in each cell with more than one X chromosome. If an affected male reproduces, a mutant X chromosome may be transmitted to a daughter, but never to sons. An interesting feature of lethal X-linked recessive disorders in populations at equilibrium for the disorder is a high germline mutation rate of 33% (*Haldane's hypothesis*). A woman whose first male child demonstrates such an X-linked disorder has only a two in three risk of being a somatic carrier. Most X-linked disorders are recessive, but rare *X-linked dominant disorders* (e.g., hypophosphatemic rickets) exist with expected patterns of inheritance. Male-to-male transmission does not occur. 50% of children born to affected females are affected by disease. Affected hemizygous males show a more consistent and severe disease course, and heterozygous affected females demonstrate greater phenotypic variability.

Mitochondrially inherited disorders are from mutations associated with the 37 genes found on the 16.5 kb circular mitochondrial chromosome that include transfer and ribosomal ribonucleic acid (RNA) genes as well as several proteins involved as subunits in enzymes associated with oxidative phosphorylation. Not surprisingly, mitochondrial DNA mutations are associated with encephalopathies and myopathies; diseases of organs which show a greater dependence on oxidative phosphorylation. Because sperm contribute few mitochondria to a fertilized ovum, mitochondrial disorders are transmitted only by females but affect all offspring of both sexes (Fig. 8.1D). Mitochondria replicate their DNA independent of nuclear replication and segregate independently to daughter cells in mitosis. As a result, the percentage of mitochondria carrying a specific mitochondrial DNA mutation may vary between somatic cells and organs, a phenomenon known as *heteroplasmy*. Heteroplasmy can lead to interesting threshold effects and variabilities of disease expression in mitochondrially inherited disorders.

Occasionally, inheritance defies expected Mendelian patterns, as when two or more affected children are born in a family without prior history of an autosomal-dominant or X-linked recessive disorder. Such phenomena have been shown in many cases to arise from *germline mosaicism* where a spontaneous mutation presumably arose early enough in gametogenesis that it is present in a modest percentage of an individual's germ cells. The ability to predict risk to subsequent pregnancies in such situations is difficult to estimate, and generally is based on empiric experience, which may not be extensive.

Estimation of Simple Genetic Risks

The prospect of having an initial (or subsequent) affected child naturally is of concern in families with a history of a genetic disorder. Physicians caring for affected patients and genetic counselors frequently are asked to provide information on the risk of an individual being a disease carrier or a couple conceiving an affected child. Needless to say, risk assessment is most desirable before pregnancy occurs to aid in reproductive planning and, as we will discuss below, the opportunity for molecular genetic testing to provide improved risk information can be extremely helpful to this process.

The risk of conceiving an affected child in a nuclear family with one of the four major types of Mendelian inheritance has been discussed above, and extension of these principles to close relatives is relatively straightforward. For example, the likelihood of inheriting a mutation-bearing autosome from either parent or a mutation-bearing X chromosome from a known carrier mother is one in two. Thus, the risk of a fully penetrant autosomal dominant disorder is 50% to all children, similar to that for an X-linked recessive disorder to male children. For autosomal recessive disorders, two carrier parents have a one in four risk of conceiving an affected child. Several additional examples of simple risk assessment with explanation are provided in Figure 8.2.

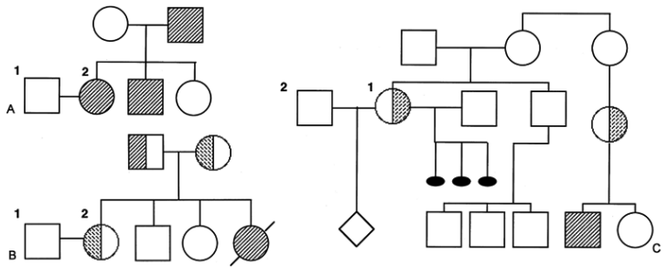

FIGURE 8.2. Estimation of simplex genetic risks. (**A**), What is the risk the couple (individuals 1 and 2) will have a child affected by the fully penetrant autosomal-dominant disorder affecting this family? The risk is 50%. The likelihood the affected mother will transmit a mutant autosome is one in two. The father contributes little or no risk because he is unaffected clinically, and the likelihood of a new mutation in his germline is much less than the genetic risk of transmission from the mother. (**B**), What is the risk the couple (individuals 1 and 2) will have a CF-affected child? Individual 2 is a known CF carrier by DNA testing. Her husband, who is of Northern European origin, has not been tested. The mixed white population carrier frequency for CF is ˜1 in 25. The wife's carrier risk is known to be 100% from prior testing. 1/25 × 1 = 1/25 is the likelihood both are CF carriers. 1/2 × 1/2 = 1/4 is the likelihood each will contribute a mutant CF chromosome if both are CF carriers. 1/25 × 1/4 = 1/100. This risk could be lowered further by molecular testing of the husband. A negative result from a molecular screening assay that has 90% sensitivity of detecting CF mutations in this population would reduce his *a priori* carrier risk from 1 in 25 to 1 in ˜240. (**C**), What is the risk that the fetus of individuals 1 and 2 will be affected by CF? The *a priori* carrier risk of individual 2 is 1 in 25. The *a priori* carrier risk of individual 1 is 1 in 8. The risk her aunt is a carrier is 1 in 2. The risk her mother is a carrier is 1 in 4. Therefore her risk is 1 in 8; because the father's carrier risk is sufficiently lower (1 in 25) than the mother's 1 in 4 it is 'ignored.' The risk individuals 1 and 2 are both CF carriers is 1 in 200 (1/8 × 1/25). If both were carriers, the risk of both transmitting a mutant CF chromosome is 1 in 4, and the risk the fetus will be CF-affected is 1 in 800 (1/200 × 1/4). Obviously, direct molecular testing would be useful in this family. In fact, individual 1 was demonstrated to be a ΔF508 mutation carrier, but despite this because individual 2 was negative, the final risk to the fetus was 1 in ˜960 (see 2B above).

Because individuals being considered for genetic risk analyses in reality do or do not carry a mutation of concern, prior reproductive experience or laboratory tests may be helpful as *conditional parameters* in modifying the basic genetic risk of having an affected child or of being a carrier for a disorder. Risk calculations that incorporate such conditional probabilities are termed *Bayesian calculations*, from Bayes theorem. Table 8.2A and Table 8.2B demonstrate risk modification calculations in X-linked recessive inheritance to assess the carrier likelihood for a woman who has two clinically unaffected sons; her mother and sister are obligate carriers for Duchenne muscular dystrophy (DMD) (Fig. 8.3). This woman's *a priori* carrier risk of 50% is lowered significantly to less than 10% by her 'favorable' birth experience with male children to date (Table 8.2A) and normal serum levels of creatine kinase, an enzyme elevated in two thirds of obligate DMD carriers but uncommonly elevated in noncarriers (Table 8.2B).

MOLECULAR DIAGNOSTICS OF INHERITED DISORDERS—GENERAL APPROACHES

TABLE 8.2. BAYESIAN RISK ANALYSIS (based on pedigree shown in Figure 8.3)

A. LIKELIHOOD WOMAN IS OR IS NOT A CARRIER FOR DMD BASED ON A *PRIORI* GENETIC RISK AND BIRTH HISTORY

Probability Term	Carrier for DMD	Not a Carrier for DMD
Prior probability (genetic) 50% risk of inheriting mutant X chromosome from mother-obligate carrier	1/2	1/2
Conditional probability	1/2 × 1/2 = 1/4	1 × 1 = 1 (100%)
Likelihood of 2 unaffected males		
Joint probability (prior × conditional)	1/2 × 1/4 = 1/8	1/2 × 1 = 1/2
Posterior probability	(1/8)/(1/8 + 1/2) = 1/5	(1/2)/(1/8 + 1/2) = 4/5
Individual probability/total		
Risk (likelihood) = posterior probability	20%	80%

B. LIKELIHOOD WOMAN IS OR IS NOT A CARRIER FOR DMD BASED ON GENETIC RISK, BIRTH HISTORY, AND SERUM CREATINE KINASE LEVELS (SEE PRIOR RISK CALCULATIONS)

Probability Term	Carrier for DMD	Not a Carrier for DMD
Prior probability (genetic risk + birth history), from Table 8.2A	1/5	4/5
Conditional probability	1/3	19/20 (95%)
Normal serum creatine kinase × 2		
Joint probability (prior × conditional)	1/5 × 1/3 = 1/15	4/5 × 19/20 = 76/100
Posterior probability	(1/15)/(1/15 + 76/100)	(76/100)/(1/15 + 76/100)
Individual probability/total		
Risk (likelihood) = posterior probability	8%	92%

Molecular Changes in Genes: Naming Conventions

Common conventions for naming mutations and polymorphisms are discussed below and additional examples are provided in Table 8.3, using examples from the CFTR protein. Most of these focus on single nucleotide changes and small insertions or deletions rather than large-scale deletion or duplication of exons or whole genes. Proteins are composed of amino acids numbered 1 to N from the amino terminus. A glossary of single-letter amino acid codes is used in conjunction with the numerical position of an altered amino acid to describe point mutations resulting from single nucleotide substitutions; for example, R117H indicates substitution of histidine (H) for the normally occurring arginine (R) at amino acid 117 of CFTR. Mutations where nucleotide substitution generates a translation stop codon are coded as 'X,' for example, G542X–STOP for glycine at amino acid 542. Mutations in introns, which generally occur at exon-intron junctions and compromise normal messenger RNA (mRNA) splicing, are designated by a minus (-) or plus (+) sign to indicate the number of nucleotides the mutation follows or precedes the exon-intron junction, which is indicated by the number of the nucleotide in mature mRNA that starts or ends the exon, for example, 621+1G>T describes a substitution of the invariant first guanine of intron 4 of CFTR by thymidine. The term Δ (delta) indicates loss (deletion) of an amino acid, hence ΔF508 means the loss of the amino acid phenylalanine at residue 508 of CFTR from a three nucleotide deletion in the gene and subsequent mRNA.

TABLE 8.3. A RANGE OF MUTATION TYPES IN THE CFTR GENE

Mutation	Type	Description
R117H, G551D	Point (missense)	Amino acid codon to new amino acid codon in exons 4 and 11; R117H is phenotypically mild, G551D severe
G542X, W1282X	Point (nonsense)	Amino acid codon to stop codon in exons 11 and 20
ΔF508	Deletion (non-frameshift)	Loss of amino acid phenylalanine at CFTR residue 508
3659del C*	Deletion (frameshift)	Amino acid codon to frameshift in exon 19
3100insA*	Insertion (frameshift)	Amino acid codon to frameshift in exon 16
621+ 1 G > T*	Splice junction	G > T at first nucleotide of intron 4
3849+ 10kbG > T*	Splice junction	Mutation at considerable distance (10 kb) from splice junction activates cryptic splicing in intron 19
CF50kbdel#1	Large deletion	Complex deletion involving exons 4–7 and 11–18.

* For these mutations, the numbers used are nucleotides numbered from the 5′ end of mature mRNA, not amino acid numbers; 'silent' nucleotide polymorphisms that do not lead to a change of amino acid are also numbered using nucleotide numbers.
CFTR, cystic fibrosis transmembrane conductance regulator.

Techniques for the Study and Clinical Diagnosis of Inherited Diseases

Refer to the introductory chapter in this section for additional information on specific molecular techniques. The major molecular biologic technique employed today in clinical testing for inherited diseases is polymerase chain reaction (PCR) amplification, commonly followed by analysis on electrophoretic gels with or without prior restriction endonuclease digestion. However, different approaches to amplification of sample DNA or methods that do not involve amplification of the target sequence, as in PCR, are being used increasingly in the clinical laboratory. Southern blot hybridization also is useful for the analysis of certain genetic disorders, generally where larger regions of DNA are being interrogated. Although time-consuming and technically demanding, direct nucleic acid sequencing following PCR is being used more often in the clinical laboratory for inherited diseases.

Inherited disorders are studied for the most part using two approaches: an indirect approach known as *linkage analysis*, which has become less common as the molecular pathology of various disorders is elucidated, and *direct identification* of specific molecular changes associated with disease. Direct identification has a number of advantages over linkage analysis, particularly the ability to conduct definitive testing (within the sensitivity limitations of the test) on individual adult and prenatal samples usually without the need for samples from other family members. The ability to directly identify common mutations in common disorders also has opened up the possibility of widespread population-based genetic screening.

Linkage Analysis and Polymorphisms

The term polymorphism used earlier in this chapter is an essential element of linkage analysis. A polymorphism is a chromosomal site that shows variability among individuals, usually an alteration of one to a few nucleotides. With assays that detect that variability, it is possible to track individual chromosomes through a family pedigree. A requirement for useful tracking is that polymorphisms be reasonably 'near' (or linked with) a disease locus on the chromosome so they are unlikely to be affected by crossover between sister chromatids.

Restriction fragment length polymorphisms (*RFLPs*) were the first molecular polymorphisms identified. Nucleotide changes in the genome were found to either abolish or create recognition sequences for restriction endonucleases, enzymes that cut double-stranded DNA at precise nucleotide sequences, usually four to six nucleotides in length. In fact, as we shall see, RFLP analysis also is a useful assay for disease-causing mutations. A problem with RFLPs is they are relatively uninformative, rarely allowing distinction of chromosomes in more than 50% of individuals in a population, and often far fewer.

Di-, tri- and tetranucleotide repeat polymorphisms are particularly useful and have largely supplanted RFLPs for linkage analysis. These typically are termed *microsatellite* polymorphisms, and are scattered about the genome, often in introns, with size variations resulting from the number of repeating motifs (e.g., $CA_{(n)}$ in the case of dinucleotide repeats). These markers are far more variable, and thus informative, than RFLPs, frequently demonstrating a dozen or more distinct alleles. A third type of polymorphism, based on *variable numbers of tandem nucleotide repeats* (*VNTR*) of larger size, also is highly informative but less common than microsatellite polymorphisms. Highly informative polymorphisms with large numbers of alleles have wide applications today in identifying relationships among individuals or in linking individuals to criminal evidence in forensics.

Figure 8.4 demonstrates the use of microsatellite polymorphic markers to track the normal and mutation-bearing chromosomes in an autosomal recessive disorder spinal muscular atrophy (SMA). Here there are polymorphic markers on both the centromeric and telomeric sides in this disease locus, an important advantage if informative because recombination can be identified except in rare instances of double recombination. The likelihood a patient carries a disease-causing chromosome, or an affected individual carries two, can be calculated based on whether there are informative markers, their distance from the disease locus, and whether informative markers are present on both sides of the disease locus. A low or high likelihood usually can be intuited from the inheritance pattern; precise risk calculations are best performed by computer programs or qualified genetics professionals.

Polymorphic markers, within and outside the gene, also can be useful secondary analysis tools in diseases where the causative gene and specific mutations have been identified, when direct identification of 100% of mutations is not possible. This includes many patients with Duchenne muscular dystrophy, hemophilia A and B, neurofibromatosis-1, and other disorders.

Direct Mutation Identification

Most inherited disorders now can be examined, at least in a primary mode, for specific molecular alterations that are characteristic of a disease. In some cases, specific mutations are associated with specific effects (genotype-phenotype correlation) although mutations more often convey a general (e.g., severe versus mild) impact on phenotype.

Many different types of mutations have been delineated. Single '*point*' mutations (usually in exons, but sometimes in introns or regulatory/other control regions) are most common. Other types include small *insertions* or *deletions* of one to several nucleotides that shift the 'reading frame' for protein translation, and larger-scale deletions (or insertions) involving portions of, or even whole, genes. An interesting class of mutations responsible for a variety of neurodegenerative disorders is expansions of microsatellite *trinucleotide repeats* within or near certain genes. Another interesting group are disorders of *imprinted genes* in which mutation of a locus normally active only on the chromosome inherited from mother or father can have significant phenotypic effects if inherited from the 'wrong' parent. Table 8.4 presents an overview of the common types of mutations and some disorders associated with them, several of which are discussed in greater detail below. The reader will notice that some disorders (e.g., DMD, hemophilia A) have multiple types of mutations, and more than one type of laboratory assay may need to be employed to screen for the full spectrum of mutations.

TABLE 8.4. COMMON DISORDERS ASSOCIATED WITH DIFFERENT TYPES OF GENETIC MUTATIONS

Type of Mutation	Disease	Genes Affected
'Point' mutations (to include small insertions or deletions of one or more nucleotides)	α thalassemia	α-globin
	ß thalassemia	ß-globin
	Cystic fibrosis	CFTR
	Duchenne/Becker muscular dystrophy	Dystrophin
	Gaucher disease	Glucocerebrosidase
	Hemophillia A	Factor VIII
	Hereditary hemochromatosis	HFE
	Hypercoagulability – factor V Leiden	Factor V
	Hypercoagulability – factor II	Prothrombin (Factor II)
	Neurofibromatosis, type I	Neurofibromin
	Sickle cell anemia	ß-globin
Splice junction mutations	ß thalassemia	ß-globin
	Cystic fibrosis	CFTR
Intragenic inversion	Hemophilia A	Factor VIII
Partial or full gene deletion	α thalassemia	α-globin
	ß thalassemia	ß-globin
	AR spinal muscular atrophy (SMA)	Survival motor neuron (SMN)-telomeric
	Duchenne/Becker muscular dystrophy	Dystrophin
	Hemophilia A	Factor VIII
	Neurofibromatosis, type I	Neurofibromin
Partial or full gene duplication	Charcot-Marie Tooth disease, type 1A	Peripheral myelin protein 22 (PMP22)
	Duchenne/Becker muscular dystrophy	Dystrophin
Trinucleotide repeat expansion	Dentatorubro-pallidoluysian atrophy (DRPLA)	Atrophin (CAG)**
	Fragile X syndrome	FMR-I (CGG)
	Friedreich's ataxia	Frataxin (GAA)
	Huntington disease	Huntingtin (CAG)
	Myotonic dystrophy	Myotonin kinase (CTG)
	Spinocerebellar ataxia, type I	Ataxin (CAG)
	X-linked SMA (Kennedy's disease)	Androgen receptor (CAG)
Hybrid genes due to chromosomal crossover	ß thalassemia	ß and γ globin
Imprinted genes*	Prader-Willi syndrome (PWS), Maternal imprint	? several
	Angelman's syndrome (AS), Paternal imprint	? several
	Beckwith-Wiedmann syndrome	unknown

* Imprinting is believed to be associated with methylation and lack of expression of a critical gene(s); loss of a functional paternal (PWS) or maternal gene (AS) by deletion, uniparental disomy, abnormal methylation, or possibly point mutation, leads to disease.
** Repeated trinucleotide given in parentheses
AR, autosomal recessive
CFTR, cystic fibrosis transmembrane conductance regulator

Because molecular abnormalities can generally be assayed precisely, assays for individual mutations usually show 100% sensitivity and specificity. However, for disorders with many mutations, clinical laboratory assays must select a subset of mutations; thus, the detection sensitivity of the overall assay will be less than 100%. Apart from procedural errors in assays such as a specimen switch, incorrect assay conditions, or reagents, there are few reasons for false negative or false positive results in molecular assays. Unknown polymorphisms that alter nucleotides at the 3′ end of PCR amplification primers may lead to poor or absent amplification of an allele with loss of information about that allele. In theory, contamination by amplicons from another positive sample

could lead to a false-positive result. Prenatal samples, particularly chorionic villus samples, must be dissected free of maternal tissue, lest a chimeric genotype be obtained, which can be catastrophic for proper interpretation.

MOLECULAR DIAGNOSTICS OF INHERITED DISORDERS—SPECIFIC DISORDERS

Part of "8 - Molecular Biology of Inherited Diseases"

The current application of molecular approaches to specific disorders is presented; most applications involve direct mutation detection.

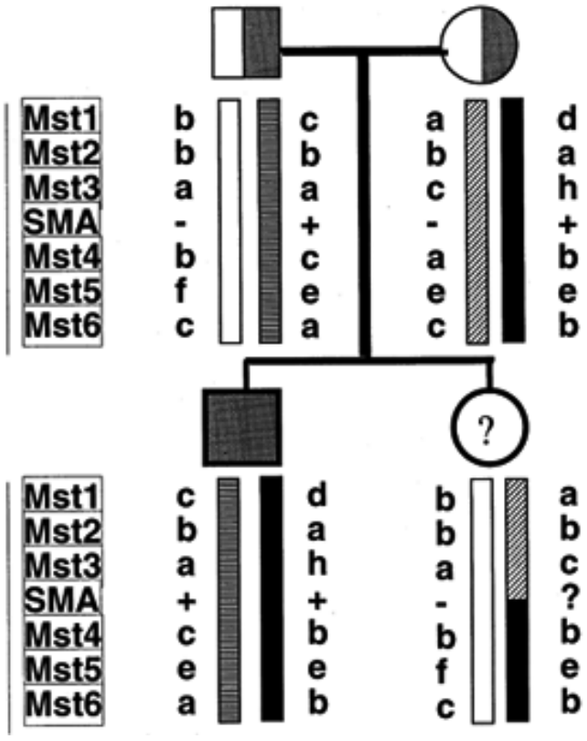

FIGURE 8.4. Linkage analysis using microsatellite polymorphism markers. Linkage analysis was performed in this family with autosomal recessive spinal muscular atrophy (SMA) to determine if the fetus (a daughter) of 16 weeks gestation has the same chromosomal pattern as the affected son. A list of six microsatellite polymorphisms in the region of the SMA locus is indicated; SMA indicates the locus on chromosome 5q responsible for this disorder; Mst1 is furthest away from SMA on the centromeric side, Mst6 furthest on the telomeric side. Alleles a through h are indicated based on relative size for each Mst locus and arranged in haplotypes corresponding with the mutant (+) and nonmutant (-) SMA chromosomes. Linkage analysis was performed for this family before more specific direct analysis for SMA became available. The fetus has inherited a recombinant chromosome from her mother. Whether this chromosome carries a mutant locus cannot be determined because recombination occurred between Mst3 and Mst4, which encompasses the disease-causing region. Fortunately, the fetus has inherited the nonmutant chromosome from her father, and has low likelihood of demonstrating SMA.

Cystic Fibrosis

Cystic fibrosis (CF) is a prototypical autosomal-recessive disease with a carrier frequency of ˜1 in 25 to 30 for mixed whites, but rarer in Hispanics, African-Americans, and Asians. Roughly one in 2,500 births are children affected with CF. A three nucleotide deletion that removes sequences encoding a phenylalanine residue at position 508 of the CFTR protein, known as the ΔF508 mutation, comprises ˜70% of mutant CF chromosomes in the United States. Unfortunately, there are over 700 other CF mutations, none more than 5% prevalent in the general U.S. population, although certain mutations are more common in certain ethnic groups, such as the W1282X, which comprises ˜40% of CF mutations in individuals of Ashkenazic Jewish background. The number of mutations screened currently in clinical assays ranges as high as 90, but many laboratories test for a core of 15 to 30 mutations that yield assay sensitivity in the low 90% range for individuals of mixed Caucasian origin. A proposed uniform panel of ˜35 mutations soon will be recommended for population-based screening in the United States. Panels of 90% sensitivity should identify mutations in both individuals from slightly more than 80% of couples who present for screening. For families in whom only one of two causative

mutations can be identified, a variety of flanking and intragenic polymorphisms are useful.

Duchenne/Becker Muscular Dystrophy (DMD/BMD)

Approximately two thirds of all Duchenne/Becker Muscular Dystrophy (DMD/BMD) patients show deletion (usually) or duplication of a moderately large region (thousands to millions of nucleotides) of the dystrophin gene on the short arm of the X chromosome. The other one third appear to have mutations involving one or a few nucleotides that are extremely difficult to find in the dystrophin gene, the largest of all human genes with 79 exons spanning two megabases of DNA. Mutations produce two clinical phenotypes: a severe illness in which patients are wheelchair-bound early in life (DMD) and a milder form where there is much less muscle weakness (BMD). Partial gene deletions or duplications that cause DMD juxtapose exons in a way that disrupts the normal translation reading frame of dystrophin mRNA while deletions or duplications causing BMD, even though they may be quite extensive, retain the reading frame (Figure 8.5).

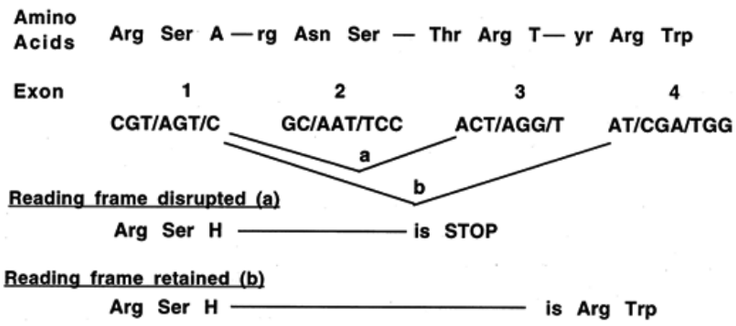

FIGURE 8.5. Effects of partial gene deletion on gene product produced. Four exons (1–4) are shown for a short hypothetical gene. Two examples of partial gene deletion are shown, one (a) that deletes exon 2, and the other (b) that deletes exons 2 and 3. Amino acids coded by the full-length mRNA from exons 1–4 are given above the nucleotide sequence. Amino acids encoded by the mRNAs resulting from partial gene deletions (a) and (b) are given below. Note that deletion (a) disrupts the normal translation reading frame by juxtaposing the final nucleotide of exon 1 (the first in a codon) next to the first nucleotide of exon 3 (also the first in a codon); this quickly leads to a translation STOP codon. Deletion (b), by contrast, which juxtaposes the final nucleotide of exon 1 next to the first of exon 4 (the 2nd in a codon) maintains the translation reading frame, resulting in a protein missing several amino acids and with one new amino acid (His) but otherwise identical in sequence to the normal protein.

Diagnostic approaches to DMD/BMD generally first look for partial gene deletion by screening genomic DNA in males for the presence or absence of specific regions of the dystrophin gene. A demanding but commonly used assay combines two groups of nine pairs of PCR primers in multiplex assays for 18 regions of the dystrophin gene. The loss of regional signals in males confirms partial dystrophin gene deletion and a diagnosis of DMD/BMD. Linkage analysis usually is used next for families in which gene deletion cannot be demonstrated or affected males are deceased. Finally, Southern blot analysis using complimentary DNA (cDNA) probes from the dystrophin gene may be employed to look for deficiencies or excesses of exon dosage to identify individuals with duplications as well as to identify carrier females in families with known (and sometimes unknown) deletions.

Disorders Associated with Trinucleotide Repeat Expansions

Expansions of trinucleotide microsatellite sequences, usually in the nucleotide format CXG, where X is any nucleotide, are unique from single nucleotide changes or gene deletions that predominate in many genetic disorders. Although these mutations are transmitted through the germline, they may undergo further expansion (and rarely contraction) in somatic or germ cells postfertilization. Trinucleotide repeat disorders for the most part reflect large-scale or small-scale expansions.

A good example of a large-scale trinucleotide expansion is *myotonic dystrophy* (DM), which affects young to middle-aged adults. The disease is autosomal dominant with variable expressivity, and within individual families exhibits a phenomenon termed *anticipation*, where the age of onset decreases and disease severity increases in successive generations. The molecular cause of DM and the basis for anticipation involves variable expansion of a CTG repeat in the 3′ untranslated region of the myotonin kinase gene on chromosome 19. Normal individuals show 5 to 30 CTG repeats, while adult DM patients exhibit several hundred to over one thousand repeats. Children of affected adults who exhibit the severe congenital form of DM have CTG repeats of 2,000 or more. Transmitting parents of adult patients generally show a small expansion of this region, usually 40 to 150 repeats, called a premutation. These individuals demonstrate few or no symptoms and require electromyographic studies to disclose myotonia.

A similar defect involving variable amplification of a CGG triplet region just 5′ of the FMR gene on the long arm of the X chromosome characterizes the *fragile X syndrome*, a common cause of inherited mental retardation in males. Normal individuals show up to ˜50 repeats. Affected patients demonstrate several hundred to several thousand repeats, with disease severity correlating roughly to repeat size. The chromosomal region surrounding the FMR gene becomes highly methylated in affected males, presumably silencing expression of the FMR gene. Males with mild symptoms but expansions expected to cause disease may demonstrate lower degrees of methylation. As in DM, unaffected females and clinically unaffected males may transmit the disease through premutations with small to modest CGG expansions of 50 to 200 repeats. The likelihood that a premutation allele will expand increases significantly in relation to size in the range from 60 to 100 CGG repeats. A few point mutations of the FMR gene also have been identified to cause the fragile X syndrome.

Several other disorders exhibit trinucleotide repeat expansions of a more limited size (Table 8.5). These disorders usually

are inherited in a dominant fashion for autosomal loci, and recessively for X-linked loci. As an example, in Huntington disease, there is expansion of a CAG triplet in the 1st exon of the Huntingtin gene on the short arm of chromosome 4. The CAG region encodes a polyglutamine stretch in the resultant Huntingtin protein, which, when expanded, is thought to have a toxic effect on neurons. Affected individuals demonstrate 36 to as many as 100 or more repeats. The number of repeats correlates with age of onset as well as disease severity. For many of these disorders, there still is uncertainty about the phenotypic effects or likelihood of expansion in transmission to offspring of rare alleles that fall between documented normal or expanded ranges.

TABLE 8.5. REPRESENTATIVE TRINUCLEOTIDE REPEAT DISORDERS

Disorder	Repeat	Normal^	Premutation^#	Affected^
DRPLA	CAG	<34	N/A	48–83
Huntington Disease	CAG	<35	N/A	36–125
Spinocerebellar ataxia, type 1	CAG	<36	37–44#	>45
Spinocerebellar ataxia, type 2	CAG	<37	32–34#	>35
Spinocerebellar ataxia, type 3	CAG	<36	37–60#	>61
Spinocerebellar ataxia, type 6	CAG	<16	17–20#	>21
Spinocerebellar ataxia, type 7	CAG	<17	18–37#	>38
X-linked SMA**	CAG	<30	N/A	36–62
Fragile X syndrome	CGG	<50	50–200	>200
Myotonic dystrophy	CTG	<37	40–150	>150
Spinocerebellar ataxia, type 8	CTG	<91	N/A	100–160
Freidrich's ataxia	GAA	<33	N/A	>66

** Dentato-rubro-pallidoluysian atrophy
* Also known as Kennedy's disease
# , Inconclusive range
N/A, Not applicable or uncertain
^ , Ranges may shift slightly as more information is collected; ranges given are intended to be representative

Hereditary Cancer Syndromes

It is clear that some portion of a number of malignant neoplasms are caused by hereditary alterations in specific genes. These include hereditary breast cancer (BRCA1, BRCA2, and ATM genes) malignant melanoma (p16 gene), hereditary colon cancer (APC as well as several DNA mismatch repair genes), retinoblastoma (rb gene), and more complex combinations such as the Li-Fraumeni syndrome (p53 tumor suppressor gene) with tumors of multiple organ systems.

About 5% of breast cancer in the United States is attributed to autosomal dominant inheritance of two genes: BRCA1 on chromosome 17 and BRCA2 on chromosome 13. Both are complex with >20 exons, large mRNAs, and many point mutations scattered the entire length of each gene. For a laboratory to offer ‘full service’ BRCA1/2 testing DNA sequencing is required, although some partial gene deletions will not be identified. Because of patent limitations (see below), full sequencing of BRCA1/2 is an option only through a single provider. However, laboratories may screen (with a license) for selected groups of BRCA1/2 mutations. Most commonly, a group (del185AG and 5382insC in BRCA1; 6174delT in BRCA2) is screened in individuals of Ashkenazic Jewish background, where the cumulative carrier frequency for these is approximately 1 woman in 40.

The interpretation of DNA sequencing results of BRCA1/2 offers an excellent example of the need to assemble databases associating nucleotide changes with disease for hereditary cancers. In addition to many disease-associated mutations, many clear-cut or likely polymorphisms also have been identified in BRCA1/2. An instructive example is a STOP change found at the 3′ end of the BRCA2 gene, which nevertheless turns out to be a polymorphism; presumably it occurs sufficiently carboxy in the BRCA2 polypeptide that it does not adversely affect protein function. An extremely important aspect of counseling patients in breast cancer families is to make sure that women who appear to have *not* inherited a mutant BRCA1/2 locus understand they still have the general population risk (˜10%) of developing breast cancer from other causes.

Studies of the APC gene in hereditary polyposis patients as well as several DNA mismatch repair genes (usually MSH2 and MLH1) associated with hereditary nonpolyposis colonic cancer (HNPPC) also have revealed multiple disease-causing mutations. By contrast, the c-ret oncogene associated with familial multiple endocrine neoplasia, type 2 syndromes with cancers of the thyroid and other organs shows a more restricted range of mutations confined to several exons.

Hereditary Hemochromatosis

Hereditary hemochromatosis (HH) is the most common autosomal recessive disorder in whites with a carrier frequency of 1 in 8 to 1 in 10. Affected individuals demonstrate significant iron overload with deposition in a number of organs leading to dysfunction and failure, particularly in the cardiac and endocrine systems. Two genetic variations of the HFE gene, which is closely linked to the HLA locus on chromosome 6, are most commonly associated with the molecular basis of this disorder.

The first is a single nucleotide change altering residue 282 from cysteine to tyrosine (C282Y), which interferes with the binding of HFE to transferrin receptors usually leading to increased iron uptake. This mutation is found in the homozygous state in 65% to 100% of affected individuals depending on the study. HH appears to be partially penetrant; a modest number of 282Y homozygotes do not have clinical or biochemical evidence

of disease, so there are almost certainly other (likely genetic) factors that affect iron metabolism.

The second variation is a point mutation that changes histidine to aspartic acid at HFE residue 63 (H63D). This change is in linkage disequilibrium with the 282Y mutation — they are not associated. An interesting feature of compound heterozygotes (one copy each) for the 282Y and 63D variants is an increase in serum iron concentration and an excess of HH disease over that seen with other combinations of alleles including heterozygous carriers of 282Y.

The heterozygous state of HH may not be entirely benign, as studies have suggested an increased risk of cardiac and cerebrovascular disease in individuals heterozygous for the C282Y mutation including acute myocardial infarcts and cerebrovascular disease. There also are familial forms clearly unlinked to HFE, so the genetics of iron overload appears to be subject to a variety of influences.

Mutations Associated with Thrombosis

Defects in the protein C anticoagulant pathway account for most currently known genetic risk factors for venous thrombosis including deficiencies in protein C or S. A poor anticoagulant response to activated protein C (APC), termed APC resistance, is detected in 20% to 60% of venous thrombosis patients. The genetic basis of APC resistance usually is a point mutation in the gene for coagulation factor V, which results in the substitution of glutamine for arginine (R506Q), also known as Factor V Leiden. The mutation reduces the ability of APC to inactivate Factor V, resulting in a more thrombophilic state.

The Factor V R506Q mutation can be assayed using a variety of techniques to detect point mutations and may be present in heterozygous or homozygous states. The heterozygous state is relatively common (3% to 5% of the U.S. population) and is associated with a 5- to 10-fold increased risk of venous thrombosis. Approximately 20% of individuals presenting with a first deep venous thrombosis, and 60% of patients with recurrent venous thromboses or thromboembolic events, are Factor V Leiden heterozygotes. Heterozygous women using oral contraceptives have a 20- to 30-fold risk of thrombosis compared to women with normal genotypes who are not taking contraceptives. Moreover, women who experience second trimester spontaneous abortions, young women with myocardial infarcts, and women with complications of pregnancy such as preeclampsia, all appear to carry Factor V Leiden at a rate above the background population frequency. One half of offspring of heterozygous carriers would be expected to share an increased thrombosis risk. Thus, testing raises genetic counseling issues for tested individuals and their close relatives. The homozygous state is uncommon but associated with a much increased relative risk of venous thrombosis.

Direct mutation assays to determine Factor V Leiden genotype offer several advantages over the functional APC resistance assay: they are not compromised by anticoagulant therapy, are unaffected by lupus anticoagulants, can differentiate between heterozygous and homozygous individuals, and are unambiguous without significance thresholds as may occur with APC resistance assays. Of individuals classified as activated protein C resistant, approximately 94% are Factor V Leiden heterozygotes.

A G>A nucleotide change in the 3′-untranslated region of the prothrombin gene may result in elevated prothrombin levels and a several-fold increase in risk of venous thrombosis. 1% to 2% of the general population appears to be heterozygous for this mutation. Like Factor V Leiden, the prothrombin mutation appears to carry additional risk of venous thrombosis in women in states mimicking pregnancy, and thrombosis risk is additive for individuals heterozygous for both Factor V Leiden and prothombin 20210A.

Finally, a missense C>T change at nucleotide 677 of the methylene tetrahydrofolate reductase gene (MTHFR) can lead to decreased levels of MTHFR and increased serum homocysteine in individuals homozygous for the thermolabile 677T variant. Increased serum homocysteine has been shown by several studies to be a risk factor for coronary artery disease, and because the MTHFR 677T variant is found in 5% of the population, this could be an underlying genetic contributor to cardiovascular disease, one that may be manageable by diet because folate therapy often is helpful in suppressing serum homocysteine.

Genetic Alleles Associated with Risk for Specific Diseases

This is an expanding group of disorders, likely to grow significantly as the genetics of more complex disorders are better understood. An increased risk for developing a variety of diseases has been associated with histocompatibility genes on chromosome 6; these include ankylosing spondylitis (B27) and juvenile diabetes mellitus (DR3, DR4). Because many of these disorders involve immune-mediated mechanisms, such associations are understandable.

Individuals heterozygous or homozygous for the e4 allele of the apolipoprotein E gene show ˜3- and 8-fold increased risks of developing adult-onset Alzheimer's disease compared to individuals without this allele, while the presence of an e2 allele may be protective. While this is not useful to clinically unaffected individuals, the sensitivity and specificity of testing for the ApoEe4 allele in patients with early memory loss and features of Alzheimer's disease appears to be a useful diagnostic adjunct.

Applications of Genes to Confirm Individual Identity

As previously discussed, highly polymorphic loci, particularly when used in combination, serve as excellent individual identifiers to suggest a high probability of relatedness or definitive nonrelatedness when two sources of DNA are compared. Common uses include exclusion or inclusion for paternity or criminal investigation, familial association for immigration, and resolution of potential sample mix-ups in pathology laboratories. Identifying alleles also are essential in selecting optimal donors for bone marrow or other transplants where superiority of molecular over serologic typing methods clearly is established, as well as in the measurement of engraftment and relapse in allogeneic bone marrow transplants. A variety of approaches including sequence-specific amplification, dot blots, reverse dot blots, and direct DNA sequencing are employed.

BUSINESS, REGULATORY, AND ETHICAL ISSUES ASSOCIATED WITH TESTING FOR INHERITED DISORDERS

Patents

The granting of *patents* by the United States Patent and Trademark Office for molecular alterations that cause inherited diseases as well as methods to detect them, and the licensing and use of these patents has affected the way diagnostic services are offered for a number of these disorders. The broadest example is the patent for PCR, which is licensed broadly for clinical use; most laboratories pay a minimum 9% royalty on revenue collected for tests using this technique. Ironically, many patents for specific genetic disorders are owned by university medical centers that may license the patent exclusively to a single (generally commercial) laboratory thereby preventing other academic laboratories from developing testing. Examples of tests for which patents have been enforced include: Charcot-Marie-Tooth disease, type 1A; hereditary hemochromatosis, several of the spinocerebellar ataxias, Friedrich's ataxia, and hereditary breast cancer genes BRCA1 and BRCA2.

Regulation of Genetic Testing

The longer-term status of *regulatory oversight of genetic testing* is unclear at the moment. Virtually all molecular genetics tests currently are regulated by the Food and Drug Administration (FDA) under their lowest level of scrutiny (class I), which is applied to ‘home-brew’ tests developed and validated in individual laboratories. Some have called for stratification of genetics tests into several categories as well as prospective evaluation and validation of individual tests for inherited disorders by the FDA (or designates) to establish clinical utility before tests can be performed for reimbursement by Medicare and other third-party payors.

Informed Consent, Genetic Counseling, and Genetic Discrimination

It is common for laboratory physicians to provide information before and after testing about assays for inherited disorders including limitations. This is important information for physicians or other health-care personnel who obtain informed consent from the patient for testing by explaining the laboratory testing, the genetics of the disorder, its natural history including possible variable expressivity, treatments available for affected individuals, physical and psychological effects others have experienced in caring for a patient with a disorder, and other risks such as discrimination based on genetic information. Health-care professionals also communicate the results to patients following testing. The entire consent and disclosure process is complicated with pitfalls for the uninitiated. Issues such as nondirective counseling of the patient and other family members, addressing possible revelation of nonpaternity, and privacy issues can be mismanaged by those with little experience, and the use of a genetics counselor or medical geneticist sometimes may need to be strongly recommended by the laboratory physician. The definition of a ‘genetic test’ has been somewhat controversial, and there is wide variability currently in whether formal informed consent is obtained and for which disorders. Patients undergoing presymptomatic testing for Huntington's disease are invariably consented, whereas it is uncommon to see informed consent obtained for mutations associated with hypercoagulable states (Factor V Leiden, Prothrombin 20210A, and thermolabile MTHFR). It is likely in the future that laboratories performing genetic testing will be required to demonstrate that informed consent has been obtained, in at least an agreed-upon subset of genetic disorders.

Requests for certain genetic tests also may place laboratory directors in conflict with clinicians or parents. It is generally agreed that *testing of children for genetic disorders* is not indicated unless a therapeutic intervention is anticipated. If information is not essential to the child's health, it is argued the individual at risk should choose to know or not know this information (with informed consent) after becoming of legal age. There also is concern that children may become stigmatized by parents or others if a result is positive. A host of other difficult ethical issues may be encountered, and the involvement of a genetics professional or bioethicist may be warranted.

At this time, there is not universal statutory protection from discrimination in provision of health insurance or employment based on genetic information, although bills have been discussed in Congress for several years, and there are limited protections that have been enacted for individuals in certain types of health plans. Several states have passed more comprehensive bills. Although there are a few horrific anecdotes, the few studies that have looked recently at the issue of *discrimination based on genetic information* have not indicated this is happening to any significant degree. Genetic testing enjoys the same privacy and confidentiality afforded other types of medical information in the United States, including the expansions required under recently enacted Health Insurance Portability Assurance Act (HIPAA).

Molecular Biology of Solid Tumors

Andrea Ferreira-Gonzalez

Arlene Buller

Mary E. Barcus

David S. Wilkinson

Carleton T. Garrett

Our understanding of the molecular changes responsible for malignant transformation has increased significantly over the past decade. As yet, however, the direct impact of this information on the diagnosis and management of patients with solid tumor neoplasia has been rather limited. Over the next decade, however, three factors are poised to alter this situation dramatically. First is the exponential increase in our knowledge of the human. Second is the dramatic increase in high throughput technology for detection and analysis of molecular changes in human tumors. Technology such as real-time polymerase chain reaction (PCR) and deoriboxynucleic acid (DNA) chips (1) are increasing the possibility that molecular testing can be performed with the turn-around times and the degree of reliability needed for performance in a clinical laboratory. Third is the enormous investment of private and public funds to identify potential molecular targets for new cancer therapies. This chapter will review some of the molecular changes that have been reported to contribute neoplastic transformation and tumor aggressiveness in solid neoplasms. These in turn will serve as potential targets and opportunities for future diagnostic, prognostic, and therapeutic interventions in solid tumors as well as provide some rationale for why a particular molecular change potentially may be important in each or all of these three areas (2).

MOLECULAR PATHOGENESIS OF NEOPLASTIC TRANSFORMATION

Part of "9 - Molecular Biology of Solid Tumors"

The central hypothesis underlying our current view of the mechanism of neoplastic transformation is that this process reflects a progressive adaptive change in cell regulation that is a result of progressive accumulation of changes in the DNA comprising the genome of the cell (3). These genetic changes result in activation of genes called *oncogenes* whose normal function is to induce growth or inhibit cell death (apoptosis); and, inactivation of genes called *tumor suppressor genes* whose normal functions are to suppress cell replication, induce cell death, and safeguard the integrity of the cellular genome (4). Beginning in the 1980s it became possible to transform nonneoplastic rodent and avian cells into tumor cells by introducing mutant and/or overexpressed versions of oncogenes into these cells in culture by noninfectious means (5, 6). Recently, nonneoplastic human cells were transformed to neoplastic cells through transfection of the cells with telomerase (hTERT), SV-40 large T antigen and mutant H-ras.[7] These studies implicate activation of telomerase and ras as well as inactivation of p53 and the retinoblastoma (RB) protein, as a minimum set of genetic changes for neoplastic transformation of some types of human cells (7). However, other molecular changes may be required for other types of human cells (8).

Oncogene Activation

Oncogenes originally were identified as genes that were present in acutely transforming retroviruses and were required for the virus to cause transformation of the infected cell in tissue culture (9). It subsequently was determined that these genes were derived from the host cell's DNA and that the genes had become incorporated into the retroviral genome through some recombinational event (10). Moreover, these genes were found frequently to play a role in normal cell replication and development in the absence of any retroviral involvement (11). Later, following development of methods to transfer noninfectious DNA obtained from primary tumors into susceptible eukaryotic cells, additional genes capable of inducing neoplastic transformation were identified including HER2/neu (12). Other nonretroviral oncogenes such as N-myc have been identified by virtue of their homology to retroviral-associated oncogenes as well as being amplified in certain human tumors (13).

Oncogenes have been found to cause transformation via two general mechanisms. The first is by inducing or facilitating cell replication and the second is by inhibiting apoptosis (Table 9.1). Facilitating cell replication can come about through stimulation of ‘upstream’ events beginning with binding of growth factors to growth factor receptors and extending through activation of transcription factors that turn on genes required for cell replication (14). Alternatively, some oncoproteins induce cell replication by directly interacting with the ‘downstream’ proteins that directly control the cell cycle (15). For a cell to divide, coordinated

replication of all of its various components together with the segregation of chromosomes into two daughter cells must occur. This complex process is controlled by the progressive phosphorylation and degradation of a group of molecules called cyclins through oligomerization between the cyclins and cyclin-dependent kinases (16). Over expression of these cyclins can cause the cell to enter into cellular division and promote the development of cancer (15, 16).

TABLE 9.1. CLASSIFICATION OF ONCOGENES

Class	Type	Examples
1	Growth factors	Sis, α-TGF,
2	Growth factor receptors	Erb (EGFR), HER2/neu,
3	Cytoplasmic signal Transduction modulators	H-, K-, N-ras, src, raf,
4	Nuclear transcription factors	N-, c-, L-myc, c-jun, fos
5	Cell cycle enhancers	PRAD1 (cyclin D)
6	Inhibitors of apoptosis	bcl-2, bcl-X

Apoptosis and programmed cell death refer to a process in which a cell causes its own death. It is an essential process for normal organ development and for the development of the immune system (17). Stimuli that induce apoptosis include the binding of specific ligands to certain types of receptors (18), the absence of certain growth factors in cells that have been stimulated to undergo cell division (19), and the inability of a cell to repair damaged DNA (20). Apoptosis is regulated by a series of competing proteins, some of which promote cell death and others of which inhibit it (21). Loss of apoptosis contributes directly to tumor development as well as tumor resistance to treatment with radiation and chemotherapy (22).

Inappropriate expression or over expression of oncogenes may occur through several mechanisms. At the genetic level, the oncogene may undergo mutations that enhance or constituitively activate the protein as is the case for the members of the ras gene family (23). Alternatively, the gene may become activated through gene rearrangement where it or an active portion of it is translocated into a region of the cell's genome that normally is up-regulated in that tissue (24). In the case of Ewing's sarcoma, a portion of the EWS gene, which is responsible for its oncogenic activity, joins to the FLI-1 gene as a result of a translocation between chromosomes 11 and 22 (25). A third mechanism of oncogene activation is demonstrated by c-erbB-2 and N-myc, which becomes over expressed in some breast cancers and neuroblastomas respectively through amplification of the oncogene (26, 27). Not all cases of over expression or inappropriate expression of an oncogene are associated with detectable mutations of the oncogene. However, in those cases where this is the case, the mutation represents a potential tumor marker of high specificity because it will be present in the tumor cells but not normal cells.

Genes Involved in Tissue Invasion, Metastases, and Angiogenesis

Malignant solid tumors derive most of their potential to destroy their host, not through direct expansion of the lesion, but through their ability to extend either by direct invasion or metastasis into other regions of the host's body. A second important feature of malignant tumors is their ability to induce the development of a new blood supply to the tumor cells (28). The ability of cancer cells to invade adjacent normal tissue and stimulate angiogenesis is in part because of their expression and secretion of extracellular proteinases (29). One group of extracellular matrix degrading enzymes that have been studied for their role in metastasis of tumor cells are the matrix metalloproteinases (MMPs). These include MMP-1, MMP-2 (72 kd type IV collagenase), MMP-3 (stromelysin), MMP-7 (pump-1, PUMP, matrilysin), MMP-9 (92 kd type IV collagenase) and MMP-10 (stromelysin-2). Induction of metalloproteinases has been demonstrated in several normal cells under normal physiological states such as invading trophoblasts (30), developing human mononuclear cells (31) and in normally cycling endometrium (32). Expression has been observed in some normal cells following stimulation by growth factors (33, 34). MMPs have been detected in both cancer cells and cancer cell stroma (35, 36) as have their naturally occurring inhibitors [tissue inhibitors of metallo-proteinases (TIMPs)] and tumor invasion has been regarded by some to result from an imbalance between MMPs and TIMPs (37, 38). A second family of proteinases, the serine proteases and in particular the plasminogen activator/plasmin system, also has been implicated in tumor cell invasion and metastases (39). Expression of the urokinase-type plasminogen activator (uPA) often is increased in malignant tumors (40). Extracellular proteinases appear to play an important role in both the stimulation and inhibition of angiogenesis (41).

Tumor Suppressor Genes

Based on studies that examined the phenotype of cells created from the fusion of malignant and benign cells, it has been recognized that certain genes can suppress the malignant or neoplastic phenotype and that these genes are, in fact, dominant in their biological behavior (42, 43). The first tumor suppressor gene to actually be isolated and its mechanism of action defined was the retinoblastoma gene (44) and its isolation served as a model for isolation of many subsequent tumor suppressor genes. The key to isolating the retinoblastoma gene was the observation that it appeared in familial cases to be transmitted in association with markers on chromosome 13 (44). Subsequent studies narrowed the region to a single gene on 13q14. This gene was shown to possess mutations in patients who developed retinoblastoma while family members who inherited the wild type, that is, normal retinoblastoma gene, did not develop tumors. It subsequently was demonstrated that the tumors arising in these individuals tended to retain the mutant gene but to lose the normal gene presumably through abnormal chromosomal segregation during mitosis (45). This process involving the physical loss of one of the alleles of a tumor suppressor gene during the course of neoplastic transformation is known as loss of heterozygosity (LOH). The process fits with an earlier prediction by Knudson regarding the mechanism for transmission of genetic cancers (46). It now is used as the major experimental approach to identifying new tumor suppressor genes (47).

Tumor suppressor genes appear to exert their antitumorigenesis activity by three basic mechanisms: (i) suppression of cellular

and DNA replication; (ii) promotion of apoptosis; and, (iii) maintenance of genomic integrity through DNA repair and chromosome stability. The terms ‘Gatekeepers’ and ‘Caretakers’ have been proposed to classify the effect of a tumor suppressor gene's activity (4, 48) though not specifying the mechanism through which this phenotypic effect is achieved. Thus, ‘Gatekeepers’ are genes that prevent cell replication when the cell's genomic integrity has been compromised while ‘Caretakers’ act to ensure genomic integrity through maintenance of chromosome stability and repair of DNA damage (4). In general, genes that appear to suppress tumorgenicity through molecular mechanisms one and two fall into the category of ‘Gatekeepers’ while those that utilize primarily mechanism three belong to the ‘Caretaker’ genes.

The overall result of the effects of all tumor suppressor genes appears to be to contribute to the maintenance of the integrity of the cellular genome. Genomic instability appears to be expressed in two forms. The first form might be characterized by ‘subtle’ instability in which changes in DNA such as point mutations and small deletions and insertions occur but where the number of chromosomes and general integrity of the genome remains unperturbed. This type of instability arises from either inactivation of genes in the nucleotide excision repair (NER) pathway, which result in the clinical syndrome of *xeroderma pigmentosa*; or inactivation of one of the DNA mismatch repair (MMR) genes, which have been implicated in the development of cases of colon cancer arising in hereditary nonpolyposis coli (4). This form of genomic instability is referred to as either nuclear excision repair instability (NIN) or mismatch repair instability (MIN) and cell lines with these genetic disorders show an expected increased mutation rate when compared to normal cells (4, 49).

TABLE 9.2. CLASSIFICATION OF TUMOR SUPPRESSOR GENES

Class	Type	Examples	Tumors	Ref
1	Suppressors of cell cycle	p16, p21	p16 (many solid tumor malignancies)	54
2	Enhancers of apoptosis	bax, FHIT	NSCLC (FHIT)	55
3	Protectors of genomic stability*			
	Mediators of DNA integrity			
	Nucleotide excision repair	Xeroderma pigmentosa DNA repair enzymes	UV induced skin cancer	56
	Mismatch repair	hMSH2, hMLH1, BRCA1, BRCA2	Colon cancer	57,58
	Mediators of chromosome stability			
	Number of chromosomes			
	Spindle check point proteins	hMAD2	Breast cancer, T-cell leukemia	59 60
		hBUB1, hBUBR1	Colorectal cancer	61,62
	DNA-damage check point proteins	ATM, ATR,		63,64
		BRCA1, BRCA2,		65
		p53		66
	Proteins modulating centrisome number	Aurora2/STK15	Small cell lung cancer	67
	Protect against translocations			
	DNA-damage check point proteins	(see above)		
	Normal recombination proteins	RAG1, RAG2		68
	Protect against amplification			
	DNA-damage check point proteins	p53		69

* Based on reference 4
Abbreviations:
ATM, ataxia telangiectasia mutated
ATR, ataxia and rad-related
BRCA1, breast cancer 1
BRCA2, breast cancer 2
FHIT, fragile histidine triad
hMSH2, human Mut 5 homolog 2
NSCLC, non-small cell lung cancer
RAG1, recombination activating gene 1
RAG2, recombination activating gene 2
UV, ultraviolet

The second form of genomic instability is identified by the presence of chromosomal instability (CIN). The CIN phenotype is characterized by a gain or loss of chromosomes (aneuploidy) and losses in heterozygosity even in cases where two alleles for a particular gene exist (4). This type of instability occurs in the majority of solid tumors and is more common than NIN or MIN (4, 47, 50, 51 and 52). Two characteristics of tumors that express the CIN phenotype are of interest. First is the fact that this phenotype appears to be dominant. Fusion of cells demonstrating CIN with those demonstrating MIN result in cells in which the mismatch repair deficiency is corrected but chromosomal instability still is present (4, 53). This suggests that only a single hit may be needed to induce the CIN phenotype. The second important characteristic of this phenotype is that a surprisingly large number of genes appear to be potentially involved in the creation of this phenotype [Table 9.2 (54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68 and 69)]. The CIN phenotype is postulated to arise as a result of a loss of function of ‘Gatekeeper’ genes that act as check points for each of the many processes that are involved in replication of the genome during cell division (Table 9.2). Disruption of these checkpoints presumably

permits development of the broad range of mutations (Table 9.2) that inevitably permit tumor cells to develop and express the malignant phenotype.

CLINICAL SIGNIFICANCE OF MOLECULAR CHANGES IN SOLID TUMORS

Part of "9 - Molecular Biology of Solid Tumors"

Use of Microsatellite and Other Molecular Changes in Tumor Diagnosis

The current standard approach for establishing a diagnosis of cancer is to obtain a tissue biopsy or cytologic sample of the suspected lesion and determine on the basis of morphological criteria whether it is benign or malignant. However, samples characterized by scanty atypical cells or subtle morphological differences between benign and malignant lesions can prove to be diagnostic dilemmas. For these reasons, the spectrum of somatic mutations associated with neoplastic transformation is being evaluated as markers of the neoplastic cells. In general, for solid tumors, detection of changes in microsatellites, point mutations, and viral nucleic acids appear to be promising as new targets for detecting and identifying tumors [Table 9.3 (25, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, and 84)].

TABLE 9.3. MOLECULAR CHANGES OF POTENTIAL USE IN TUMOR DIAGNOSIS

Molecular Marker	Examples	Reference
Microsatellite analysis		
LOH and MSI	Bladder cancer cytology	70,71 and 72
Oncogenes or TSGs mutations		
Ha-ras mutation	Bladder cancer cytology	73
Ki-ras mutation	Bronchopulmonary cytology	74,75
Oncogene translocations		
EWS-FLI-1 [t(11;22)]	Ewings sarcoma	25,76
EWS-ERG [t(21;22)]	Ewings sarcoma, pPNETS	77
PAX3-FKHR [t(2;13)]	Alveolar rhabdomyosarcoma	78
EWS-WT1 [t(11;22)]	Desmoplastic small round cell tumor	79
SYT-SSX [t(X;18)]	Synovial sarcoma	80,81
Oncogene expression		
Telomerase	Bladder cancer cytology	82
Detection of viral targets		
HPV	Endocervical neoplasia cytology	83,84

LOH, loss of heterozygosity
MSI, microsatellite instability
TSG, tumor suppressor gene
pPNETS, peripheral primitive neuroectodermal tumors of childhood

Microsatellites potentially are one of the most useful molecular markers for use in diagnosing cancer. They consist of regions of DNA that are composed of a ‘core’ sequence of from two to five nucleotides that are repeated sequentially from two to greater than 50 times. Thousands of microsatellites have been identified within the human genome and their locations mapped throughout the 22 autosomes and the two sex chromosomes. Microsatellites are the usual marker for studying loss of heterozygosity. They also may become mutated when there is inactivation within a tumor of one or both of the DNA mismatch repair genes. These mutations are expressed as new microsatellite alleles that differ from the normal germline alleles through an increased or decreased number of repeats. Such a finding is called microsatellite instability.

Alterations of microsatellites have been compared with conventional cytology for the diagnosis of both primary and recurrent transitional cell carcinoma (TCC) of the bladder (70, 71 and 72). Molecular examination showed increased sensitivity compared to cytologic evaluation, identifying microsatellite changes in 95% vs 50% of those individuals with bladder cancer. Two similar studies by Mourah et al. and Steiner et al. detected recurrent TCC in 83% and 91% of patients evaluated by microsatellite analysis (71, 72). This technique appears to represent a sensitive and noninvasive diagnostic modality that may supplement routine screening for this neoplasm. Alterations in microsatellites also have been proposed as aids in the evaluation of cytologic specimens from the head, neck, and lungs.

Detection of mutant oncogenes or mutant tumor suppressor genes also may prove useful in identifying tumor cells. In a study by Fitzgerald et al., H-ras mutations were observed in nearly half of patients evaluated with bladder tumors (73). In addition, molecular testing for H-ras mutations appeared to confer increased sensitivity as a screening method, detecting a significantly greater proportion of low-grade tumors than cytologic screening alone.

K-ras mutations have been identified in a number of tumors including lung adenocarcinomas. Evaluation of cytologic specimens such as sputum and bronchoalveolar lavage fluid by PCR-based molecular assays has shown promising results, identifying 50% to 80% of mutations shown to be present in resected material (74, 75). Such studies may prove to be a valuable complement to conventional cytologic examination in screening for neoplasia.

In addition to the detection of mutations as delineated above, characteristic translocations have been reported in some solid tumors, most notably sarcomas such as Ewings sarcoma, rhabdomyosarcoma, and synovial sarcoma (25, 76, 77, 78, 79, 80 and 81). Demonstration of these translocations by RT-PCR or cytogenetic studies may elucidate diagnoses of these challenging lesions and facilitate the detection of residual or recurrent disease. As with other ancillary techniques, a negative finding must be interpreted in conjunction with other clinical and morphologic data and does not invariably exclude a given lesion.

Finally, molecular methods may be employed in the detection of viral oncogenes known to be associated with malignancies. For example, with the use of techniques such as *in situ* hybridization, human papillomavirus (HPV) has been identified as a potential etiologic agent associated with cervical cancer. While the implementation of screening for cervical dysplasia by the Papanicolaou (PAP) smear has dramatically reduced the incidence of cervical cancer, the PAP smear carries a known risk of false negatives. Furthermore, because of the inability to predict, based upon morphology alone, which lesions will behave most aggressively and progress to carcinoma, inconclusive and abnormal results necessitate close follow-up. Some studies suggest that HPV testing may detect a subset of patients with high-grade cervical dysplasia not detected by conventional screening by PAP smear (83). In addition, HPV testing may serve to distinguish a subset of patients at greatest risk for progression of cervical dysplasia to carcinoma (84).

USE OF MOLECULAR CHANGES IN DETERMINING TUMOR PROGNOSIS

Part of "9 - Molecular Biology of Solid Tumors"

The prognosis of a patient following the diagnosis and treatment of malignancy traditionally has been based on the clinical and pathologic stage of disease and histological grade of the tumor. This analysis enables some estimation of disease outcome and stratification of patients into treatment regimens but it remains imperfect when attempting to apply the criteria to an individual patient. Molecular pathology has the potential to improve the assessment of tumor outcome through more precise staging (molecular staging) of the extent of disease and through identification of molecular changes that are associated with adverse clinical outcome.

Microsatellite and mutational analyses have demonstrated utility as prognostic indicators as illustrated in Table 9.4 (85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109 and 110). LOH at particular loci in carcinomas of the cervix, gastrointestinal tract, head, neck, and lung appears to denote a subset of high-grade tumors or a poor prognosis. Lee et al. have reported a three-fold increased risk of death in patients with head and neck squamous cell carcinomas (HNSCC) that demonstrate LOH of 14q (99). In a separate study of HNSCC, LOH at 17p appeared to correlate with poor response to chemotherapy (101).

TABLE 9.4. ASSOCIATIONS BETWEEN MOLECULAR CHANGES AND PROGNOSIS

Tumor	Alteration	Association	References
Bladder cancer	LOH RB	High grade/muscle invasion	86
	Genomic alterations 2q-, 5p+, 5q-, 6q-, 8p-, 10q-, 18q-, 20q+	Higher grade	87
Breast cancer	Plasma DNA similar to tumor DNA	Poor prognosis	88
	Allelic loss at 1p22–p31	Lymph node metastasis, tumor size 2 cm	89
Cervical carcinoma	LOH on chromosome 1	Advanced stage	90
Colorectal cancer	LOH at 18q21	Recurrence/poor survival (Dukes B & C)	91,92
	p53 expression	Recurrence/poor survival (Dukes A)	92
	MI and K-*ras* mutations in normal-appearing colonic mucosa micrometastases	Predictive of colorectal cancer	93
		Decreased survival (50 vs. 91%)	94
	P16-hypermethylation	Shorter survival in T3N0M0 tumors	95
Gastric cancer	LOH p53	Invasive potential	96
	LOH of 7q (D7S95)	Poor prognosis	97
Gliomas	Chromosome 22q loss	Astrocytoma progression	98
HNSCC	LOH of 14q	Poor outcome	99
	LOH on 2q	Poor prognosis	100
	LOH at 17p	Chemoresistance	101
Melanoma	LOH in plasma	Advanced stage/tumor progression	102
Neuroblastoma	N-*myc* amplification	Poor prognosis	103
	TRK-A expression	Good prognosis	103
Neuroblastomas, 4s	N-*myc* amplification, 1p deletion,17q gains, elevated telomerase activity	Poor outcome (*not independent*)	104
NSCLC	Allelic imbalances on 9p	Poor prognosis	105
	Reduced Fhit protein expression	Poor prognosis (stage I)	106
	LOH 11p13	Poor prognosis	107
PNET	LOH of 17p	Metastatic disease	108
	c-*myc* amplification	Poor prognosis	108
Prostate cancer	LOH on 13q	Advanced stage	109
Retinoblastoma	LOH at RB1 locus	Tumoral differentiation, absence of choroidal invasion	110

(a) Modified from Table 1 in reference 85
Abbreviations: HNSCC, head and neck squamous cell carcinoma
LOH, loss of heterozygosity
NSCLC, non-small cell lung cancer
PNET, primitive neuroectodermal tumor
RB, retinoblastoma gene

Amplification of several oncogenes appears to have prognostic relevance in certain tumors. In neuroblastoma, N-*myc* amplification has been shown to be predictive of poor prognosis (103). Brinkschmidt et al. have also reported poor outcomes in stage 4s patients with deletions of 1p, gains on 17q, and elevated telomerase activity (104). In contrast, TRK-A expression appears to

confer a favorable prognosis (103). Another well-studied example of where oncogene amplification may have clinical relevance is the amplification of the c-*erb*B-2 or HER-2/*neu* proto-oncogene. This oncogene encodes a growth factor receptor with tyrosine kinase activity (27). Amplification of this oncogene has been identified in neoplasms of the breast, stomach, endometrium, ovary, and lung (27). c-erbB-2 amplification appears to correlate with poor prognosis and chemoresistance in some neoplasms (111).

Molecular staging is another approach to evaluating the prognosis in patients with solid tumors (94, 112, 113 and 114). This technique frequently is referred to as examination for minimal residual disease when applied to the study of hematological malignancies. The standard approach uses RT-PCR to detect the presence of tumor cells in lymph nodes or bone marrow that cannot be identified by standard histologic or immunohistochemical evaluation. Shivers et al. (112) and Bostick et al. (113) have reported the detection of micrometastases by RT-PCR in melanoma patients and have demonstrated a statistically significant increased rate of recurrence in those individuals positive by the molecular assay.

In a comparable study by Liefers et al. (94), RT-PCR for carcinoembryonic antigen (CEA) identified occult lymph node metastases in approximately 50% of stage II colorectal carcinoma patients (node-negative by histology). The presence of micrometastases correlated with poor prognosis, identifying a subset of patients with 50% 5-year survival compared to 91% in those individuals negative for metastases by both histology and RT-PCR. In addition, RT-PCR for CEA has been employed for the detection of metastatic esophageal cancer in histologically negative lymph nodes (114).

Increased telomerase activity appears to represent a promising molecular marker of neoplasia and is useful as a marker in molecular staging. For example, Soria et al. reportedly have measured telomerase activity as a means to identify circulating tumor cells in the peripheral blood of breast cancer patients with metastatic disease (115). Following the extraction of epithelial cells from blood using immunomagnetic beads coated with antibodies specific to epithelial cells (BerEP4), telomerase activity was assayed using PCR and ELISA methodology. Eighty-four percent of stage IV breast cancer patients had detectable telomerase activity in the isolated epithelial cells compared to none of the tested control cases. Telomerase activity as determined by the telomeric repeat amplification protocol (TRAP) also has been shown to be predictive of poor prognosis in neuroblastoma (104).

Therapeutic Implications of Molecular Changes

The identification of the multitude of genomic alterations that characterize neoplasms invites the development of new molecular therapies for solid tumors. Current approaches to gene therapy include the use of “suicide gene” to activate drugs at the tumor, transfer of tumor suppressor genes, and the inhibition of activated or amplified oncogenes with the use of antisense oligonucleotides and monoclonal antibodies (116). In addition, the development of microarrays, which enable a rapid assessment of presumed therapy response based upon genetic make-up, has the potential to allow more individualized treatment of oncology patients, conferring optimal response yet minimizing drug toxicity (117). While still in their infancy, the fields of gene therapy and pharmacogenomics undoubtedly will make significant contributions to the management of neoplastic disease over the next decade.

Perhaps the most recognized example of a new therapy based on the presence of a molecular change is the use of Herceptin (Genentech, Inc., San Francisco, California) in the treatment of breast cancer (118, 119, 120, 121 and 122). This recombinant humanized monoclonal antibody to the Her2 receptor protein has shown efficacy in clinical trials for use in women with metastatic breast cancers that overexpress the protein. Studies have demonstrated a survival benefit when administered either independently or in combination with conventional chemotherapeutic agents (121, 122). Antisense oligodeoxynucleotides (ODNs) also are being examined as potential antitumor agents that, by virtue of sequence, could be targeted specifically to induce decreased oncogene expression through binding and degradation of RNA. Initial investigations of HER2/neu antisense ODNs by Roh et al. reveal increased tumor response to chemotherapy in the presence of these agents (123).

Therapy directed at the restoration of tumor suppressor gene function through transfer of wild-type genes is another potential avenue for therapies based on identification of specific molecular lesions. Various studies have focused on the delivery of p53, p16, and PTEN to tumor cells, although the optimal vector for gene import remains undetermined (124, 125, 126 and 127). For example, adenovirus-mediated transfer of p16INK4A protein expression has demonstrated a significant therapeutic effect against HNSCC in cell lines and mouse studies (125). Studies evaluating p53 gene transfer in patients with advanced NSCLC have shown stabilization of disease in 64% of subjects and partial response in 8% of subjects receiving multiple intratumoral doses (126). Preliminary results of clinical trials evaluating adenovirus-mediated transfer of p53 in advanced head and neck tumors also reveal promising results (127).

SPECIAL CONSIDERATIONS IN HEREDITARY CANCER SYNDROMES

Part of "9 - Molecular Biology of Solid Tumors"

Although the majority of cancer is sporadic, clustering of cases often is observed within families. In recent years, an increasing number of cancer-predisposing genes segregating in families have been isolated. Accounting for approximately 5% of all cancer, familial cancer syndromes most commonly result from mutations in tumor suppressor and DNA repair genes. A person carrying a germline mutation in a cancer-susceptibility gene generally is predisposed, but not mandated, to develop cancer. Although all cells in the body contain the mutation, only a fraction of cells in specific tissues may develop cancer. Moreover, some individuals with the mutation will remain disease free. Multiple factors, some not yet understood, control disease development. Complicating factors include variability in the penetrance, or the likelihood that a mutation in a gene will be expressed, and the expressivity of the disease, which includes the severity and age of onset. Penetrance and expressivity are dependent

on the type of mutation, cell type, effects of modifier genes, and environmental effects such as diet and carcinogen exposure. Variable expressivity and penetrance are hallmarks of all of the known familial cancer syndromes defined thus far, and have a direct effect on how the physician will manage the patient and the patient's family (128).

Genetic testing is available for inherited predisposition to a number of common as well as unusual types of cancer. A list of inherited cancers and their cancer predisposition genes is shown in Table 9.5 (128, 129, 130, 131, 132, 133, 134, 135, 136 and 137). Inherited breast and ovarian cancer syndrome provides a detailed illustration of the important features of genetic predisposition to malignancy. Five to 10% of breast and ovarian cancer have been linked to mutations in the BRCA1/2 tumor suppressor genes on chromosomes 17 and 13, respectively. Most families with multiple cases of breast and ovarian cancers and approximately half of the early-onset breast cancer families have mutations in BRCA1 (128, 138, 139). Colon and prostate cancers also are observed at a higher frequency than in the general population (128, 139, 140). Mutations in BRCA2 are responsible for approximately one third of inherited breast cancer cases and are associated with breast cancer in males (141). Testing for mutations in these genes is offered only to individuals with a family history suggestive of inherited breast/ovarian cancer syndrome. When a genetic alteration is identified in an individual, several factors are taken into account in assessing the risk of actually being affected with cancer. First of all, is the genetic change indeed a deleterious mutation? It is always desirable to test an affected member of the family first to determine whether a particular genetic change is responsible for the disease. Hundreds of genetic changes have been identified in BRCA1/2, many of which are harmless polymorphisms that do not affect the function of the genes. If the mutation is present only in the affected person's DNA and not in healthy members of the family, then it can be presumed that the mutation is responsible for the disease. If it is not possible to test an affected member of the family, then any genetic changes that are detected must be compared to a genetic database to attempt to determine whether the change is the causative mutation. Once a mutation is confirmed, then a person's risk is calculated based on the number of affected relatives, the occurrence of bilateral versus unilateral breast cancer, the presence of ovarian cancer, and the age of onset. Penetrance and expressivity are variable.

TABLE 9.5. GENES ASSOCIATED WITH INHERITED CANCER SYNDROMES

Condition	Gene(s)	Gene Classification	Location/Type of Tumors	References
Breast and/or ovarian cancer	BRCA1 and BRCA2	Tumor suppressor	Breast*, ovary*, colon, prostate,	128
Familial adenomatous polyposis (FAP)	APC	Tumor suppressor	Colon*, small bowel, stomach, bone, CNS, soft tissue	128,129 and 130
Hereditary nonpolyposis colorectal cancer (HNPCC)	hMSH2, hMLH1, PMS1, PMS2, hMSH3, hMSH6	Mismatch repair	Right side of colon*, endometrium*, stomach, ovary, small bowel, transitional cell, sebaceous, CNS	128,129 and 130
Renal cancer	VHL	Tumor suppressor	Kidney*, hemangioblastoma, phaeochromocytoma	128
Neurofibromatosis types I/II	NF1, NF2	Tumor suppressor	CNS*, myeloid leukemia	128
Nevoid basal cell carcinoma	PTC	Development and cellular proliferation	Skin*, CNS	128
Inherited prostate cancer	BRCA1, HPC1, others	Tumor suppressor	Prostate*	128,131
Familial melanoma	MLM1, CDKN2A, CDK4	Cell cycle regulator, oncogene (CDK4)	Skin*, pancreas	128,132
Multiple endocrine neoplasia (MEN2A/B)	RET	Oncogene	Thyroid* and adrenal glands	128,133,134
Li-Fraumeni syndrome	P53	Tumor suppressor	Bone, soft tissue, breast, brain, adrenal gland, leukemia	128,135,136
Tuberous sclerosis	TSC1, TSC2	Tumor suppressor	Hamartomas of skin, CNS, heart, kidney	128
Retinoblastoma	RB1	Tumor suppressor	Eye*, bone, soft tissue, brain, skin	128
Rhabdoid predisposition	HSNF5/INI1	Tumor suppressor	CNS, kidney	137
Xeroderma pigmentosum	XP	DNA repair	Skin	128
Bloom's syndrome	BLM	Helicase (DNA ligation)	Leukemia, GI carcinoma	128
Ataxia telangiectasia	ATM	Cell cycle regulator	Leukemia, lymphoma, GI carcinoma	128

* Most common location of tumors

Determining that a person carries a cancer-predisposing mutation can greatly affect his/her medical management. There is significant controversy in the literature regarding this issue for inherited breast/ovarian syndrome (142). Due to the variable

penetrance of mutations in BRCA1/2, there exists the possibility some individuals with a positive test result will never develop the disease. Therefore, carriers of BRCA1/2 mutations should be familiarized thoroughly with the advantages and disadvantages of each treatment option.

Genetic testing has been well-documented to offer treatment alternatives in the medical care of at-risk individuals. Prophylactic colectomy is the treatment of choice for individuals at risk for familial adenomatous polyposis (FAP) because mutations in the adenomatous polyposis coli (APC) tumor suppressor gene have a high penetrance (129). Therefore, a negative genetic test result will prevent such drastic measures from being necessary. In hereditary nonpolyposis colon cancer (HNPCC), carriers of mutations in one of several DNA repair genes (MLH1, MSH2, MSH6, PMS1 and PMS2) are at an 80% lifetime risk of colorectal cancer, and are advised to undergo surveillance by colonoscopy every 1 to 3 years, or prophylactic colectomy (130). Studies have indicated that increased surveillance in HNPCC mutation carriers increases life expectancy by seven years compared to no surveillance (129).

In multiple endocrine neoplasia type 2 families (MEN2), individuals with a 50% risk of inheriting mutations in the RET proto-oncogene must undergo prophylactic thyroidectomy and/or annual biochemical screening at an early age because medullary thyroid carcinoma (MTC) can develop as early as 6 years of age (134). Genetic testing can determine at an early age those individuals who require increased surveillance and/or thyroidectomy, while sparing those individuals who have not inherited a causative mutation.

The era of genetic testing has unveiled a plethora of ethical dilemmas, not the least of which is the use of archival material for DNA studies. Requiring informed consent for the use of archival materials in genetic research serves to protect both the researcher and the source of the samples from legal, social, and psychological sequelae. A balance must be developed in which the potential benefits of the use of stored tissues for genetic research are weighed against the rights of the individual not to have his/her genetic material scrutinized unknowingly. Although it is mandated by federal regulations that informed consent must be obtained when an identifiable sample is used for genetic studies, unidentifiable samples are exempt from this requirement (143). A question arises regarding stored tissues as to whether consent obtained at the time of sample collection is valid for further studies at a later date. There is consensus that all identifiable stored samples require an informed consent before use in a research protocol (143, 144). For samples that will be anonymized, the recommendations for obtaining consent vary with the protocol to be used (143). Guidelines regarding informed consent are in the process of development and certainly will be an important issue in the future.

CONCLUSIONS

Part of "9 - Molecular Biology of Solid Tumors"

While recent findings in molecular biology have greatly increased our understanding of the molecular mechanisms responsible for expression of the malignant phenotype, no single molecular change group of molecular changes has been identified to date that permits a clinician to diagnose, predict the behavior, or treat all or even most cancers. This hardly is surprising given the complexity of the molecular changes observed to occur with neoplastic transformation. Perhaps because of this complexity, molecular information will not be of practical value to the clinical management of solid tumors until technology evolves to a point where very small samples of tumor cells can be simultaneously and rapidly evaluated for 50 to 100 or more genetic changes. However, this may be an exaggeration of the degree of genetic information needed for clinical utility. For example, identification of a single clonal mutation that is present in an individual's tumor cells offers itself as potential marker for distinguishing normal from neoplastic cells in that individual. Moreover, some mutations such as loss of heterozygosity on 17p and 9p are present in a significant fraction of the more common solid tumors and thus offer themselves as potential tumor markers. Whether one or a limited small number of genetic mutations will prove to be independently useful in predicting prognosis of individual tumors is less clear although some encouraging findings have been observed with regard to N-myc amplification in neuroblastomas and c-erbB-2 (HER2/neu) over expression in breast cancers. Information is likely only to increase as sequencing of the human genome is completed and the genes associated with malignancy further defined. Advances in technology in the form of microfluidics and high density DNA and complementary DNA (cDNA) arrays will provide platforms that potentially will allow the complex changes present in individual tumors to be evaluated in real time. The time frame for all of this to become integrated into routine clinical laboratory practice is unclear but the rate of discovery of new information as well as development of new technology continues to accelerate.

Molecular Biology of Infectious Diseases

Ramon L. Sandin

Within the field of diagnostic pathology, the areas of clinical microbiology and clinical virology were the first to be strongly influenced by the use of DNA probes and amplification techniques. Numerous reports have been published on the detection of pathogens of different types by DNA probes and amplification techniques, and several examples are provided in Table 10.1, along with references.

TABLE 10.1. SELECTED EXAMPLES OF MICROBES DETECTED WITH THE USE OF DNA PROBES AND AMPLIFICATION TECHNIQUES

Type	Examples (References)
Bacteria	*Legionella spp.* (103,104)
	Group A streptococci (2)
'Higher' bacteria	*Nocardia spp.* (105)
Mycobacteria	*Mycobacterium tuberculosis* (37,106)
	Mycobacterium avium (6)
	Mycobacterium intracellulare (6)
Fastidious or noncultivable organisms	*Coxiella burnetii* (107)
Fungi	*Aspergillus spp.* (108)
	Histoplasma capsulatum (109)
	Blastomyces dermatitidis (110)
	Pneumocystis carinii (111)
	Cryptococcus neoformans (108)
Viruses	*Herpes simplex* (112)
	Human Immunodeficiency Virus (93,94)
	Human Cytomegalovirus (64,65,93)
Parasites	*Toxoplasma gondii* (113)

Prior to the development of synthetic amplification techniques such as the polymerase chain reaction (PCR), DNA probes were prepared either "in-house" or commercially and were used directly on clinical specimens for microbial detection (1, 2). The advent of nucleic acid probe technology offered the promise of speedy and specific direct microbial detection in a clinical specimen that may obviate culture. However, laboratory studies showed that if the number of target molecules in a clinical sample is low, the sensitivity of either "in-house" ("home-brew") or of commercially available nucleic acid probes may be unacceptably low (3). It became clear to those working in the field of nucleic acid probe technology that in order to increase the sensitivity of the methods used for detecting the presence of infectious agents in a clinical specimen, "amplification" of a detectable "entity" may have to occur (4). "Amplification" means making many entities from a few. Such entities may be whole microbes. Amplification of intact microbes via culture has been used in microbiology laboratories for a long period of time. Nucleic acid probes have been used for several years to confirm the nature of a culture-amplified isolate (5). For mycobacterial species, the only commercialized probe assay system today is the AccuProbe System (Gen-Probe Inc., San Diego, California), which is based on detection of ribosomal ribonucleic acid (rRNA) (6) by way of hybridization to single-stranded DNA probes. Instead of the Iodine125-labeled probes used by the earlier Gen-Probe system, AccuProbe uses a chemiluminescent, acridinium ester-labeled probe detected with a luminometer, with a sensitivity of greater or equal to 95% (6). Gen-Probe probes for culture confirmation (7) are available for *Mycobacterium avium* complex, *Mycobacterium tuberculosis* (MTB) complex, *Mycobacterium gordonae*, *Mycobacterium kansasii*, fungi, and bacteria. Probes also are available for direct detection of group A streptococci (2), *Chlamydia trachomatis* (Pace 2 System, Gen-Probe) (8), and *Neisseria gonorrhoeae*. Unfortunately, culture confirmation requires prior growth of the organism in culture either in solid media or in the faster automated broth media (9), where growth still may entail a lengthy period of time, such as several weeks as in MTB, which may not be practical.

TABLE 10.2. CLINICAL SCENARIOS IN INFECTIOUS DISEASES WHERE THE USE OF PCR AND OTHER AMPLIFICATION TECHNIQUES MAY BE ADVANTAGEOUS

Clinical Scenario	Example(s)
Detection of slow-growing organisms	*Mycobacterium tuberculosis*, agents of deep mycoses
Detection of organisms that are highly infectious or dangerous to culture	HIV, *Coxiella burnetii, Coccidioides immitis*
Detection of agents involved in encephalitis where a rapid and sensitive diagnosis may obviate obtaining a brain biopsy	Herpes simplex virus, enterovirus
Detection of microbes for which routine, commercially available culture methods are lacking in diagnostic laboratories	*Treponema pallidum*, 37°C phase of *Coccidioides immitis, Toxoplasma gondii, Pneumocystis carinii*
Detection in asymptomatic newborns where serology may be misleading	Congenital HIV infection
Detection of viruses in invasive specimens (CSF, peripheral blood, bone marrow aspirates, etc.) from patients undergoing bone marrow or solid organ transplantation where greater sensitivity is advantageous	Parvovirus, enterovirus or CMV
Determination of the load of virus or other pathogen for prognostic purposes or for monitoring therapeutic drug effectiveness	HIV quantitation
Determination of the level of expression (i.e., transcription) of a pathogen's DNA by direct measurement of RNA	RT-PCR for CMV, HSV
Detection of antimicrobial resistance genes by amplification of sequences known to mediate such resistance	Isoniazid resistance in *M. tuberculosis*
Reclassification of previously uncultured organisms into the correct position in their genealogical tree	Sequencing of amplified 16s rRNA by RT-PCR or 16s rDNA targets by PCR
Determination of the safety or infectivity of blood products	Presence of HIV or HTLV I/II in blood products

Adapted with permission from Sandin RL, Greene JN. Diagnostic molecular pathology and infectious disease. *Cancer Control*. 1995; 2: 250
Abbreviations: CMV, cytomegalovirus; CSF, cerebrospinal fluid; HIV, Human Immunodeficiency Virus; HSV, herpes simplex virus; HTLV I/II, human T-lymphotropic virus type I and type II; PCR, Polymerase chain reaction; RT, reverse transcription.

If the amplified "entity" is a submicrobial chemical molecule such as DNA or ribonucleic acid (RNA), it may lend itself to a more rapid synthetic amplification process than culture (4). Thus, when the PCR and other non-PCR amplification techniques were discovered and developed, the world of microbiology was boosted even further into a new flurry of activity. Thousands of papers have been published documenting the use of PCR and non-PCR amplification techniques for detection of all types of microorganisms. The extreme sensitivity of these techniques may not be necessary for detection of many of the myriad of organisms on which these techniques have been tested, however. Selected clinical scenarios do exist in clinical microbiology and virology where the use of PCR or non-PCR amplification techniques may be so advantageous that application of such techniques will become the standard-of-care (10). Such is the case already with determination of human immunodeficiency virus

(HIV) viral loads in plasma specimens of acquired immunodeficiency syndrome (AIDS) patients for determination of prognosis and therapeutic drug effectiveness. Table 10.2 summarizes the clinical scenarios where amplification techniques may become indispensable within infectious diseases in the near future.

As technologies such as nucleic acid probes for culture confirmation and direct nucleic acid amplification techniques become more widely used, it becomes easier for agencies such as the Centers for Disease Control and Prevention (CDC) to issue new recommendations about improved turn-around time of cultures and stains, which routine diagnostic laboratories can aspire to fulfill. For example, the CDC recommends that a laboratory deliver results of acid-fast bacilli (AFB) smears within 24 hours of specimen collection, and that growth and identification of MTB in clinical specimens be completed, on the average, within 21 days of specimen collection (11, 12). In those laboratories where such recommendations are met, advanced technologies such as probes and amplification undoubtedly are in use.

AMPLIFICATION TECHNIQUES AT VARIOUS STAGES OF DEVELOPMENT, FDA-APPROVAL STATUS OF VARIOUS COMMERCIAL ASSAYS IN INFECTIOUS DISEASES, AND ASSAYS UNDERGOING DEVELOPMENT

Part of "10 - Molecular Biology of Infectious Diseases"

The amplifiable entities most commonly used in synthetic amplification assays include the following: target DNA as in the PCR; target RNA as in reverse transcriptase PCR (RT-PCR); amplification of a signal or reporter molecule as in the Branched DNA Signal Amplification Assay (Chiron Corporation, Emeryville, California); the ligation product of two or more probes as in the gapped ligase chain reaction (LCR, Abbott Laboratories, Abbott Park, Illinois); target RNA via a transcription-mediated system as in the Gen-Probe TMA systems (Gen-Probe, San Diego, California), and several others. Simplified reviews of these techniques can be found in Wolcott (13) and Sandin (4, 14).

TABLE 10.3. LIST OF SEVERAL COMMERCIAL PCR AND NON-PCR AMPLIFICATION SYSTEMS AT DIFFERENT STAGES OF DEVELOPMENT

Target Amplification Systems

- PCR by Roche under the name Amplicor series (Roche Diagnostic Systems, Branchburg, New Jersey)
- Transcription-mediated amplification systems
  —Examples
  -
    - Gen-Probe rRNA isothermal amplification system (Gen-Probe, San Diego, California) and VIDAS (VITEK, St. Louis, Missouri) adaptation (VIDAS PROBE)
    - NASBA (Nucleic acid sequence-based amplification) isothermal target amplification system by Organon-Teknika (Durham, North Carolina)
    - Strand Displacement Amplification (BDProbe Tec ET) (Becton-Dickinson Diagnostic Instrument Systems, Sparks, Maryland)

Signal Amplification Systems

- Branched DNA Signal Amplification System by Chiron Corporation (Emeryville, California)
- Hybrid Capture System by DiGene Diagnostics, Inc. (Silver Spring, Maryland)

Probe Amplification Systems

- Ligase Chain Reaction by Abbott Corporation (Abbott Park, Illinois)
- Cycling Probe Technology by ID Biomedical (Vancouver, Canada)
- Q-beta Replicase, formerly by Gene-Trak, Inc. (Framingham, Massachusetts)

Several other techniques undergoing research and development

Adapted with permission from Sandin RL. The ABC's of molecular amplification. *Infect Med* 1999; 16:98 and Sandin RL. Polymerase chain reaction and other amplification techniques in mycobacteriology. In, Heifitz, L. *Clinics in Laboratory Medicine. Clinical Mycobacteriology*. Philadelphia, PA: WB Saunders CO; 1996:617

TABLE 10.4. FDA-APPROVED ASSAYS IN INFECTIOUS DISEASES UTILIZING MOLECULAR AMPLIFICATION TECHNIQUES (updated as of July 1, 1999)

Roche Molecular Systems
A) HIV-1

- Amplicor HIV-1 Monitor 1.0, 400 copies detection limit, microwell plate format (MWP)
- Amplicor HIV-1 Monitor 1.0, Ultrasensitive, 50 copies detection limit, MWP

B) *Mycobacterium*

- Amplicor *Mycobacterium tuberculosis*, MWP

C) *Chlamydia trachomatis*

- Amplicor *C. trachomatis*, MWP format
- COBAS Automated system for *C. trachomatis*

Gen-Probe Transcription-Mediated Amplification Systems (TMAs)
A) *Mycobacterium*

- AMTDT-1 (Amplified *M. tuberculosis* Direct Test, version 1)
- AMTDT-2 (enhanced AMTDT or E-MTD)

B) *Chlamydia trachomatis*

- Amplified *C. trachomatis* Direct Test

Digene Diagnostics Hybrid Capture Systems
A) Human Cytomegalovirus

- CMV Hybrid Capture 1 (tube format), version 1– 5,000 copies/mL of whole blood detection limit, qualitative
- CMV Hybrid Capture I version 2–700 copies/mL of whole blood detection limit, qualitative

B) Human Papillomavirus

- HPV Hybrid Capture I (tube format)
- HPV Hybrid Capture II (MWP)

Abbott Corporation (Ligase Chain Reaction or LCx) Systems
A) *Chlamydia trachomatis*

- LCx *C. trachomatis*, male and female urine and genital swabs

B) *Neisseria gonorrhoeae*

- LCx *N. gonorrhoeae*, male and female urine and genital swabs

Target, probe, and signal amplification systems have undergone intense research and development efforts in the last several years. Table 10.3 offers a list of several commercial PCR and non-PCR amplification systems at different stages of development. Table 10.4 offers a list of Food and Drug Administration (FDA)-approved assays in infectious diseases utilizing several of these molecular amplification techniques, and Table 10.5 offers a list of molecular amplification assays in infectious diseases undergoing research and development efforts by the various manufacturers at the time of this writing. It is expected that many more assays will undergo research and development efforts in the near future. The most widely used synthetic amplification technique is the target amplification system known as PCR. Most in-house or home-brew PCR assays have been developed by academic scientists at their respective institutions. Commercial PCR-based assays by the Roche Molecular Diagnostic Systems (Branchburg, New Jersey) have appeared in the market and will continue to do so in the future. In contrast, most of the research and development on alternate non-PCR amplification techniques that are now becoming available commercially has resided predominantly or exclusively

within industry and companies. Some of these signal, probe, and non-PCR target techniques promise to have some potential advantages over in-house testing by PCR, namely (i) less prone to carryover contamination; (ii) more amenable to quantification; (iii) high specificity; and (iv) an increased ease of automation. The advent of technologies other than in-house PCR testing should allow for strong competition between these techniques to occur in an attempt by companies to secure a place within the diagnostic repertoires of clinical laboratories.

TABLE 10.5. MOLECULAR AMPLIFICATION ASSAYS IN INFECTIOUS DISEASES NOT YET FDA-APPROVED IN THE UNITED STATES, BUT UNDERGOING RESEARCH AND DEVELOPMENT; AVAILABLE FOR USE OUTSIDE THE UNITED STATES ONLY; OR AVAILABLE IN THE UNITED STATES FOR RESEARCH PURPOSES ONLY (I.E., IN CLINICAL TRIALS, OR SUBMITTED TO THE FDA BUT NOT YET APPROVED) (updated as of July 1, 1999)

Roche Molecular Systems

A) HIV-1

- Amplicor HIV-1 Monitor 1.5, with expanded subtype detection capability, MWP
- Amplicor HIV-1 Monitor 1.5, Ultrasensitive
- COBAS automated system for HIV-1
- Qualitative MWP format for HIV-1 DNA amplification

B) *Mycobacterium*

- Amplicor *Mycobacterium avium-complex* (MAC), MWP format
- Amplicor *Mycobacterium* genus-specific system, MWP format
- COBAS automated system for mycobacterial amplification

C) *Chlamydia trachomatis*

- Amplicor *C. trachomatis*/*Neisseria gonorrhoeae*, COBAS and MWP formats

D) Hepatitis C

- Amplicor Hepatitis C, MWP format, qualitative and quantitative
- COBAS automated system for Hepatitis C

E) Others

- Amplicor HTLV I/II, MWP format
- Amplicor CMV, qualitative, MWP format
- COBAS automated system for CMV, quantitative (CMV Monitor)
- Ampli-Prep automated sample preparation system
- Real-time quantitative fluorescent amplification and detection system (TaqMan probes and instrument)

Gen-Probe Transcription-Mediated Amplification Systems (TMAs)

A) *Chlamydia trachomatis*/*Neisseria gonorrhoeae*

- Amplified *C. trachomatis*/*N. gonorrhoeae* Direct test

B) HIV-1

- Amplified HIV-1 Direct test, quantitative

C) Hepatitis C

- Amplified Hepatitis C Direct test, quantitative

D) HIV-1/HCV

- Multiplex amplification of HIV-1 and Hepatitis C, for Blood Bank use ONLY

E) Hepatitis B

- Amplified Hepatitis B Direct test

F) VIDAS PROBE (adaptation of amplification and detection steps of TMA to the VIDAS instrument from Bio-Merieux VITEK)

- *M. tuberculosis*
- *C. trachomatis*
- *C. trachomatis*/*N. gonorrhoeae*
- *N. gonorrhoeae*
- HIV-1 RNA, quantitative

G) TIGRIS Instrument for automation of extraction, amplification and detection steps

H) Atypical pneumonia panel

I) Biochip Technology (Microparticle arrays) adaptation of the TMA technology, in conjunction with Affymetrix, a biochip company.

Digene Diagnostics Hybrid Capture Systems

A) Human Cytomegalovirus

- CMV Hybrid Capture 1 version 2, Quantitative application

B) *Chlamydia trachomatis* and *Neisseria gonorrhoeae*

- *C. trachomatis* Hybrid Capture assay
- *N. gonorrhoeae* Hybrid Capture assay
- *C. trachomatis*/*N. gonorrhoeae* Hybrid Capture assay

C) Other viral assays

- Hepatitis B Hybrid Capture assay
- Herpes simplex virus I/II Hybrid Capture assay
- HIV-1 RNA Hybrid Capture assay
- HIV-1 DNA (provirus) Hybrid Capture assay

Abbott Corporation (Ligase Chain Reaction or LCx) Systems

A) HIV-1

- LCx HIV-1 viral load, quantitative

B) *Mycobacterium*

- LCx *Mycobacterium tuberculosis*, qualitative

C) Other assays

- LCx Hepatitis B assay, quantitative

Organon-Teknika (NASBA) Systems

A) HIV-1

- NucliSens HIV-1 QT assay, quantitative, 400 copies/mL detection limit with 1 mL of plasma, and 4,000 copies/mL detection limit with 100 uL of plasma

B) Human Cytomegalovirus

- NucliSens CMV pp67 mRNA assay

C) Other assays or instruments

- NucliSens Extractor, automated nucleic acid extraction instrument
- NucliSens Isolation kit
- Detection kit for in-house amplification products

Becton-Dickinson Strand Displacement Amplification (BD Probe Tec ET) Systems

A) *Chlamydia trachomatis* and *Neisseria gonorrhoeae*

- BD Probe Tec ET *C. trachomatis*, direct detection from urine and urethral swabs, 510(k) submitted to FDA on 12/98
- BD Probe Tec ET *C. trachomatis* and *N. gonorrhoeae*, differential direct detection from urine and urethral swabs, 510(k) submitted to FDA on 12/98

B) *Mycobacterium*
- BD Probe Tec ET *M. tuberculosis*, direct detection from respiratory specimens, in clinical trials
- BD Probe Tec ET *M. tuberculosis*, for culture confirmation, in clinical trials
- BD Probe Tec ET *M. kansasii*, for culture confirmation, in clinical trials
- BD Probe Tec ET *Mycobacterium avium* complex (MAC), for culture confirmation, in clinical trials

C) Other assays
- Several viral detection and quantification kits

Bayer Diagnostics Branched DNA Signal Amplification Systems (bDNA formerly by Chiron Corporation)

A) HIV-1
- Quantiplex bDNA HIV-1 viral load 1.0 (10,000 copies detection limit)
- Quantiplex bDNA HIV-1 viral load 2.0 (500 copies detection limit)
- Quantiplex bDNA HIV-1 viral load 3.0 (50 copies detection limit)

B) Hepatitis B
- Quantiplex bDNA Hepatitis B viral load 1.0

C) Hepatitis C
- Quantiplex bDNA Hepatitis C viral load 1.0
- Quantiplex bDNA Hepatitis C viral load 2.0
- Quantiplex bDNA Hepatitis C viral load 3.0
- HCV qualitative assay using Gen-Probe TMA technology

PCR is the best studied, the most frequently used, and the most widely published amplification technique, almost certainly because it was the first technique developed, and all original PCR assays followed in-house or home-brew protocols. Thus, the specific technical considerations, definitions, and workings of in-house PCR will be presented first in this chapter. Because abundant work has been published on in-house PCR and on stereotypical commercial applications of PCR and non-PCR techniques for detection of MTB in clinical specimens, MTB has been chosen as the prototype organism with which to describe such particulars in this chapter. Another microorganism that also has been the subject of innumerable studies in the development, validation, and availability of commercial amplification techniques, both PCR and non-PCR, is HIV. Unfortunately, given space constraints, all discussion on progress, technical considerations, and results of large studies of the various PCR and non-PCR amplification techniques will be focused on MTB. Because this chapter resides in the Molecular Pathology section of this book, it was intentionally written to provide abundant technical detail on the actual workings and steps involved in “running” a diagnostic molecular assay, and so can serve as a technical manual. *Chlamydia*/*Neisseria*, CMV, and hepatitis C and B also have been the subject of tremendous research and development efforts as documented in the published literature. Various aspects of these and other organisms will be considered as part of Table 10.1, Table 10.2, Table 10.3, Table 10.4, and Table 10.5, and Table 10.18

MYCOBACTERIUM TUBERCULOSIS

Part of "10 - Molecular Biology of Infectious Diseases"

MTB will be used to illustrate the “growing pains” that the field of PCR amplification technology has experienced in developing effective assays, the attendant evolution in procedures, and the problems associated with sensitivity and specificity of first-generation home-brew as well as commercial assays. The importance of this bacillus to our present world cannot be underappreciated. It is estimated that as much as one third of the world's population has been infected with MTB, and there are approximately eight million new cases of tuberculosis annually (15). The incidence of tuberculosis is constantly increasing, and strains of MTB resistant to chemotherapeutic agents have been recovered with increasing frequency. It is for that reason that amplification techniques that can expedite the diagnosis of tuberculosis in clinical specimens are of such crucial importance to clinical medicine.

TABLE 10.18. CPT CODES (1998) INTENDED FOR USE WITH MOLECULAR DIAGNOSTIC TECHNIQUES FOR ANALYSIS OF NUCLEIC ACIDS, WITH EMPHASIS ON THE FIVE INFECTIOUS AGENTS MOST FREQUENTLY AMPLIFIED FROM CLINICAL SPECIMENS

CPT Code	Description
Specific codes for Infectious Disease Identification

Polymerase Chain Reaction, In-House (Home-Brew) Assays, Technical Considerations

Definition and Crucial Steps

PCR can be defined simply as a synthetic method of creating many copies of discrete fragments of DNA present in a clinical specimen, thus facilitating detection of nucleic acids present initially only in very small quantities (i.e., picograms or femtograms) (16, 17). A technical definition of the method would be that it is a semi-automated amplification of DNA *in vitro* by a series of successive incubation steps at different temperatures using a heat-stable DNA-dependent DNA polymerase. There are three steps to amplification by PCR: (i) denaturation; (ii) primer annealing; and (iii) extension. These can be carried out using three different temperatures or the assay may be set up so that two temperatures are used. In step one, the denaturation step, double-stranded DNA is melted or denatured by heating at a high temperature, such as 94°C for a finite period of time, such as 1 minute. In step two, the primer annealing step, primers are allowed to bind to the single-stranded DNA at a lower temperature, such as 52°C for 2 minutes. Primers are crucial to the specificity of the assay because they are small fragments of DNA that flank or delimit the target sequence that is to be amplified and subsequently detected. In step three, the extension step, a new strand is synthesized by the polymerase using single nucleotides as building blocks, starting out at the site of the primer, and "filling in the gap" that exists between the target sequence strand and the primer. An intermediate temperature usually is chosen for step three such as 72°C for a period such as 3 minutes. Steps one to three are called a "cycle." Repetition of cycles yields amplification of the target DNA. Under optimal conditions,10 cycles would lead to approximately 1,000 copies of the target regions and 20 cycles to approximately one million copies. The amplified product subsequently is detected by using the more traditional and common methods for detection, or by resorting to one of the novel ones; both approaches are reviewed later.

Thermocyclers commonly used for PCR utilize metal blocks or water for thermal equilibration, and samples are contained in plastic microcentrifuge tubes or microtiter wells. Average temperature transition rates for heat block thermocyclers are about 1°C per second (18). Thus, a considerable amount of time is spent heating and cooling the sample. A new alternative is the use of a rapid air thermal cycler (Air Thermal Cycler (ATC), Idaho Technology, Idaho Falls, Idaho) (18, 19). It uses high velocity air for heating and cooling. Samples are contained in microcapillary tubes with a high surface area-to-volume ratio. Comparison of air vs. heat block thermal cyclers for smear-positive MTB culture positive specimens showed high sensitivity for both types of thermal cyclers (18); additionally, the air thermal cyclers helped reduce overall cost and total assay time (18, 19).

There are four crucial steps in performing in-house PCR: lysis or extraction of the nucleic acids which one aims to amplify in order to make them accessible to the polymerase; choice of the most appropriate target area of the genome to be amplified; choice of the most appropriate amplification scheme to be used during the process; and determination of the most appropriate method of detection of the amplified product as regards the size and complexity of the laboratory where the work is being performed. Each of these crucial steps now will be examined as it regards MTB. It will become obvious to the reader that because of the enormous variety of methods and schemes available to the user for amplifying this or any other microorganism, comparing results from various studies to one another may be akin to comparing apples to oranges.

Methods of Cell Lysis, Extraction or Purification of Nucleic Acids

The majority of the early studies used the "traditional" and more laborious methods of cell lysis, extraction, and purification of nucleic acids before amplification. This was particularly true in studies through 1992. Since then, more novel and simpler adaptations have been reported in subsequent studies with varying results. The basics of the more traditional method of extraction of nucleic acids in mycobacteriology involves the following steps. Sputum samples are treated with NaOH and N-acetyl-L-cysteine (NALC) for digestion-decontamination. Cell lysis is accomplished by treatment with sodium dodecyl sulfate (SDS) or NaOH, which is followed by several extractions with phenol-chloroform-isoamyl alcohol. The extract may be dialyzed for purity in water and then concentrated by ethanol precipitation followed by dilution in water or buffer prior to being used for amplification by PCR (20, 21, 22).

An early successful and widely used adaptation of this basic traditional method is that of Eisenach et al. (23). In this method, cell lysis occurs by incubation with lysozyme for 2 hours, followed by treatment with SDS, NaOH, and NaCL. The nucleic acid subsequently is purified by passage through powdered glass or by spin column chromatography. Newer, simpler methods have been reported that are expected to challenge the traditional ones in terms of sensitivity, specificity, and speed. Some results are conflicting, however, as will be presented.

TABLE 10.6. MOST COMMON METHODS OF CELL LYSIS, EXTRACTION AND PURIFICATION OF MYCOBACTERIAL NUCLEIC ACIDS FOR "IN-HOUSE" PCR AMPLIFICATION

Method	References

Table 10.6 summarizes some of the most common extraction and purification methods for PCR amplification of mycobacteria, with references. Buck et al. (24) evaluated several simple

methods against the more traditional and laborious extraction method. Included among these variations was the use of nonionic detergents and proteinase K for lysis and extraction; boiling samples with nonionic detergents without the use of proteinase K; submitting the samples to eight freeze-thaw cycles; and sonication by flotation of specimens on a dish in water next to a sonicator probe (Sonics and Materials, Danbury, Connecticut) for 30 minutes followed by boiling. These authors report that sonication produced the best results, compared well with the reference method, and was able to allow detection of as little as 10 to 100 organisms. In contrast, Folgueira et al. (25) compared sonication with the use of nonionic detergents and proteinase K and found conflicting results. They found that enzymatic detergent treatment yielded better results than sonication. Clarridge et al. (26) used Triton X-100, a detergent solution, and heat (100°C) without further DNA extraction in treating samples received in a very busy diagnostic laboratory with good results. Kocagoz et al. (27) boiled clinical specimens for 10 minutes and used them directly without further processing. They report a sensitivity of 10 organisms. Stronger bands were obtained after boiling than with the use of lysozyme-proteinase K-SDS lysis followed by phenol-chloroform-ethanol extraction. Victor et al. (28) reported on a simple procedure for the mass screening of sputa. It entailed decontamination of sputa and purification from inhibitors by passing the specimen through a 50% sterile sucrose solution via a 5-minute centrifugation step. They used the pellet straight for PCR with acceptable results. Wilson et al. (29) used guanidinium thiocyanate, a chaotrope, to solubilize specimens and captured the released DNA with silica particles. The DNA was then eluted with water. Sensitivity of PCR with this method was 75%.

Thus, results are very variable and, at times, contradictory. The lack of standardization in extraction methodology for in-house assays may be the culprit. It is recommended that the scientist try one or several of the reported methods, adapt them to his or her particular needs, and perhaps simplify them to suit the constraints of a given laboratory. The author has tried several of the methods and has found modifications of the Eisenach et al. method (23, 30) to be useful. A particular laboratory must evaluate several methods and decide which works best at a particular institution (31).

Most Common Gene Targets for Amplification

A target may be a gene sequence that is present as a single copy in the MTB genome, or one that is present as a repeated sequence. Decisions as to which target to use for amplification carry with it implications regarding the sensitivity of the assay. One also must decide how broad a specificity is desired (i.e., amplification of all mycobacteria, of only organisms within the MTB-complex, or more specifically of only MTB). Table 10.7 summarizes these choices regarding types of targets for amplification and provides various references.

TABLE 10.7. GENE TARGETS FOR PCR AMPLIFICATION OF MYCOBACTERIUM TUBERCULOSIS

Targets	References
A) In terms of copy number	
1. Single copy DNA gene sequences	20, 22, 32, 33
2. Repeated DNA sequences	21, 23, 35, 36, 39, 114
3. Ribosomal RNA sequences via RT-PCR	47, 48
B) In terms of specificity	
1. Specific for the entire genus *Mycobacterium*	22, 50, 51, 60, 68, 115, 116, 117
2. Specific for the MTB-complex (MTB, *M. bovis, M. bovis* BCG strain, *M. microtii*, and *M. africanum*)	23, 34, 35, 36, 51, 52,68, 118
3. Specific for the species *M. tuberculosis*	34, 42, 51, 53, 54, 55,56, 58
4. Specific for the *M. bovis* BCG vaccine strain	61

Adapted and updated, with permission, from Sandin RL. Polymerase Chain reaction and other amplification techniques in mycobacteriology. In: Heifitz, L. *Clinics in Laboratory Medicine. Clinical Mycobacteriology*. Philadelphia, PA: WB Saunders Co; 1996: 617

The use of single-copy genes as targets is more risky than the use of targets that constitute repeated DNA or RNA sequences because the sensitivity of the assay is innately reduced in the former when compared with amplification of targets that are preamplified in the organism. Additionally, a mutation in the single-copy target gene may lead to false-negative results. Brisson-Noel et al. (20) used a single-copy sequence as the target in their assay, the gene coding for a part of the 65 kd antigen present in organisms of the MTB-complex (22). Because the sensitivity of this assay was not very high, this same group subsequently improved it by using a two-step nested PCR approach, an approach to amplification, which will be discussed in a subsequent section. These authors used 50 cycles of amplification for each of the two rounds of amplification. Hermans et al. (32) used a 158 base pair single-copy fragment located near a repetitive sequence. Five of 34 isolates of MTB from cultures appeared not to have the target copy and did not amplify, thus producing false negatives. Miyazaki et al. (33) showed increased sensitivity by using a nested PCR approach for amplification of a single-copy gene from the 38-kd protein gene of mycobacteria.

A more common approach is the use of repeated DNA or RNA sequences (34). Eisenach et al. (23, 35) and Thierry et al. (36) have used the IS6110 sequence as a target for amplification. This is a repetitive DNA sequence of 1361 base pairs in length that has been described, albeit with controversy, to be specific for the MTB-complex and present in high copy number in MTB (10 to 20 copies) but in low copy number in *M. bovis* (1 to 5 copies). Because there are several copies of this sequence per organism, it serves as a “preamplified” sequence, thus increasing the sensitivity of a PCR assay (34). An additional advantage of using repeated sequences is that deletion or mutation of one of the sequences should still allow for others to be intact for amplification. The IS6110 has been perhaps the favorite, or at least the most frequently utilized, target sequence for in-house amplification of MTB in reports to date in the world literature (34, 37, 38). However, it must be mentioned that von Soolingen et al. (39) reported on one strain of MTB that was exceptional in that it lacked the IS6110 sequence. This is felt to be rare but suggested to the authors that the widely accepted practice of using this element for amplification may have to be revisited. Yet

others have challenged the specificity of this sequence and the notion that it is found solely in the MTB-complex organisms (40, 41, 42). The heated debate that has ensued has produced a flurry of recent publications where groups of investigators have challenged one another's assertions (38, 40, 41, 42, 43, 44 and 45). It now appears that there are selected regions of the IS6110 that are MTB-complex-specific targets (38, 43), while others may not be, and that care must be taken in choosing which regions to use for amplification assays. Homology to other species outside of the MTB-complex may be restricted to the central 181-base pair region of IS6110 (43). The use of nucleotides 762 to 865 and 970 to 1026 of IS6110 has been reported as specific to the MTB-complex (38, 43). Table 10.8 summarizes the disadvantages raised in the literature as it regards the use of IS6110 for PCR amplification of mycobacteria.

TABLE 10.8. DISADVANTAGES RECENTLY RAISED AGAINST THE USE OF THE REPEATED SEQUENCE IS6110

Disadvantage	References
Producing possible false negative results	
• Rare MTB strains (originally from South East Asia and India) may lack IS6110	39, 119
• A few strains have only one copy of IS6110	120
Producing possible false positive results	
• Homology has been reported to exist with mycobacteria other than MTB	40, 41, 42, 44, 45

Abbreviations: MTB, *Mycobacterium tuberculosis*

Investigators also have resorted to the use of ribosomal RNA sequences as targets that can be amplified via the RT-PCR. There are advantages to the use of RNA as a target. 16S rRNA sequences are found in large copy numbers (1,000 to 10,000 molecules/cell) in MTB and thus would serve as a preamplified target for PCR amplification. Some stretches of rRNA are highly variable among species and would serve for the delineation of species-specific amplification schemes, whereas other stretches are conserved and would serve as targets for genus-specific amplification (46). rRNA sequences also serve as a yardstick for the evolutionary stage of a particular microorganism regarding other organisms and can be used for such studies. Thus, Boddinghaus et al. (47) amplified conserved regions of mycobacterial nucleic acids via RT-PCR and then determined the specific species amplified with the use of probes to species-specific variable regions. A similar approach was used by Patel et al. (46), but amplification was of the 16S rRNA gene (i.e., 16S rDNA) via PCR, rather than 16S rRNA via RT-PCR. Kirschner et al. (48) followed amplification with sequencing of the amplified product to determine which species was amplified. Messenger RNA (mRNA) is extremely short-lived, averaging only a few minutes, and has been used in RT-PCR formats to detect viable mycobacteria (49), whereas DNA targets do not distinguish between viable and nonviable organisms.

Primers also can be designed to suit the desired degree or breadth of specificity of a given investigator. Some workers have set out to amplify any organism within the genus *Mycobacterium* present in a clinical sample, while others set out to amplify only those within the MTB-complex, whereas still others have designed primers only for MTB. Targets such as the DNA J gene are genus specific (22, 50) and must be followed by species-specific probes. Sequences such as the IS6110 (23, 35, 36, 51) and others (52) are repeated sequences reported to be specific to the MTB-complex. One group from South America (53) emphasized their need to distinguish between human tuberculosis of bovine origin (i.e., as a result of *M. bovis*) from tuberculosis resulting from MTB. This group designed primers homologous to sequences within the mtp40 region (53), which is reported to be specific for MTB, and helps distinguish this species from other closely related species within the MTB-complex (53 to 56) (see Table 10.7). It is part of the mpcA gene, which encodes a phospholipase C protein (57). A rapid method of differentiating MTB from *M. bovis* would be helpful clinically because of the intrinsic resistance of *M. bovis* to pyrazinamide, and epidemiologically because risk factors for *M. bovis* infection may be different from those for MTB infections (58). Thus, the discovery of the usefulness of the mtp40 gene sequences for such purposes was welcome. Unfortunately, the mtp40 region is yet another sequence that has been the subject of controversy, this time as it regards its sensitivity. The mtp40 gene is not present in all strains of MTB and, hence, may not be useful for differentiating MTB from *M. bovis* in all cases of interest (57, 58). A different scheme recently suggested for the differentiation of MTB from *M. bovis* is an oxyR allele-specific amplification method (59).

Additional recent studies continue to shed light on the availability of mycobacterial sequences of various specificities to suit the needs of those using amplification schemes. The 32-kD protein gene described recently is found in all mycobacterial species, contains diversity between different species, and only some intraspecies variability has been detected (60). Thus, it has been suggested as a good target for identification of mycobacteria by PCR-based sequencing. Other recent studies have shed light on sequences specific for *M. bovis* and for the vaccine strain *M. bovis* Bacillus Calmette-Guerin (BCG), which can be used in PCR-based assays (61). The BCG is an attenuated derivative of a virulent strain of *M. bovis*. BCG has been used as a vaccine against MTB, as cancer immunotherapy, and as a recombinant vehicle for multivalent vaccines against other infectious diseases (61). BCG can cause disease in humans, especially those with cellular immunodeficiencies (62). Therefore, the ability to rapidly and specifically identify BCG is clinically important. The genomic region designated RD1 was found to be present in all virulent *M. bovis* and MTB strains tested, but deleted from all BCG strains evaluated (61). A multiplex PCR with primers to the MTB complex and to the RD1 region would be useful in identifying sequences from the *M. bovis* BCG strain present in a clinical specimen. A comprehensive table of sequences available for PCR amplification of mycobacterial organisms can be found in reference 51.

TABLE 10.9. ADVANTAGES AND DISADVANTAGES OF THE TRADITIONAL OR "STRAIGHT" PCR APPROACH IN AMPLIFICATION

Advantages	
	Simple
	Cheaper than more laborious approaches
	Fast
	Routinely accepted
	Has less contamination risks than when amplicon transfer is required for amplification
Disadvantages	
	Less sensitive than approaches using a second round of amplification
	Possible nonspecific banding ("dirty background") after 40–50 cycles if hot-start is not used (see text)

Reproduced with permission from Sandin RL. Polymerase chain reaction and other amplification techniques in mycobacteriology. In: Heifitz, L. *Clinics in Laboratory Medicine. Clinical Mycobacteriology*. Philadelphia, PA: WB Saunders Co; 1996: 617
Abbreviations: PCR, Polymerase chain reaction

Technical Approaches or Schemes Used for Amplification ("Straight" PCR, Nested PCR, RT-PCR)

Most published studies have used the traditional or "straight" PCR (SP) approach to amplification for 30 to 40 cycles to amplify MTB. Table 10.9 summarizes the advantages and

disadvantages of this approach. This most popular and simple approach entails the addition of amplification reagents to PCR tubes from the start and the placement of tubes in the temperature cycling heating blocks for amplification to occur.

In order to increase the sensitivity of assays, particularly those that use single-copy target sequences, other investigators have resorted to the use of one or more of the following alternate modalities: two-step (two-tube) nested PCR (TSNP) (63, 64, 65 and 66); one-step (one-tube) nested PCR (OSNP) (29, 30); reamplification with the same primer pair (67); or RT-PCR (47, 48 and 49). Multiplex PCR (5, 68), or the addition of several primer pairs concurrently, is yet another choice to consider when amplification of more than one mycobacterial species is desired, as in cases of mixed infections. The advantages and disadvantages of TSNP are summarized in Table 10.10, and of the OSNP in Table 10.11.

TABLE 10.10. ADVANTAGES AND DISADVANTAGES OF THE TWO-TUBE OR TWO-STEP NESTED PCR (TSNP)

Advantages	
	Increased sensitivity
	Addition of new enzyme and reagents allows for longer maintenance of the reaction in the “exponential” phase
	Target DNA used in nested (second) step is the amplicon from the first round, which is many fold greater in number than original target in clinical sample
	Smaller size of final amplicon produced by second round of amplification increases efficiency of reaction
	Inhibitors of PCR in clinical sample are decreased during second round due to dilution as new reagents are added during the second step
	Increased specificity
	Decrease in nonspecific banding (“dirty background”) over traditional PCR following 40 or more cycles of amplification. These bands are a result of coamplification of genomic sequences (reference 63)
	Decreased false positives from concatenation of fragmented DNA (reference 64)
Disadvantages	
	Greater expense than straight PCR as twice as much enzyme and reagents are used
	Extra manipulations and length of the assay as cycling blocks cannot be programmed for all cycles from the start
	Increased risk of contamination unless three rooms are used for setup instead of two (pre-PCR, PCR, and Internest transfer rooms)

Adapted and updated, with permission, from Sandin RL. Polymerase chain reaction and other amplification techniques in mycobacteriology. In: Heifitz, L. *Clinics in Laboratory Medicine. Clinical Mycobacteriology*. Philadelphia, PA: WB Saunders Co; 1996: 617
Abbreviations: PCR, Polymerase chain reaction

TABLE 10.11. ADVANTAGES AND DISADVANTAGES OF THE ONE-STEP (ONE-TUBE) NESTED PCR (OSNP)

Advantages	
	Less expensive than TSNP
	Faster than TSNP as there is no internest transfer step and instrument can be programmed from the start
	Less contamination risks than TSNP and less manipulations
	Addition of twice the amount of enzyme from the start may help approximate the level of sensitivity of the TSNP
Disadvantages	
	No added advantages of diluting out inhibitors
	May never approximate the extreme sensitivity of the TSNP

Reproduced with permission from Sandin RL. Polymerase chain reaction and other amplification techniques in mycobacteriology. In: Heifitz, L. *Clinics in Laboratory Medicine. Clinical Mycobacteriology*. Philadelphia, PA: WB Saunders Co; 1996: 617

In the TSNP approach, tubes are kept in the cycling heating blocks for 20 or 30 cycles and the reaction then is stopped. An aliquot of the “amplicon” (amplified sequence) then is transferred to a new tube to which are added new enzyme and reagents and a new primer pair that is different from the outer primer pair used during the first round. This inner (nested) primer pair will code for a shorter amplicon during the second round of amplification, and this shorter amplicon is contained within the stretch of DNA amplified during the first round and thus, “nested” within it. Reaction tubes are placed on the cycling heating blocks and allowed to proceed for an additional 20 or 30 cycles, after which detection of the amplified product occurs. Because of the reasons stated in Table 10.10, the sensitivity of this assay tends to be higher than that of SP. A major disadvantage of this system is that there is an increased risk of contamination from the added step of transferring amplicon before the second round of amplification, and most diagnostic laboratories do not like to use this approach. An additional room is required for transfer of amplicon between steps (69).

The OSNP approach is a compromise between SP and TSNP. It entails the addition of two primer pairs (i.e., outer and inner primer pairs) to tubes from the start. There is no need to transfer aliquots before a second round of amplification, thus decreasing the potential for amplicon carryover contamination as with the TSNP approach. Primer pairs have to be designed carefully such that the optimum annealing temperature of the inner primers is different from that of the outer primers. During the first 20 or 30 cycles of amplification, inner primers are functionally inactive at annealing temperatures that are optimal for the outer primers. Inner primers come into play once the reaction parameters change at the end of the first round of amplification. The cycling heating blocks are programmed so that the switch occurs automatically during the last of the 20 or 30 cycles of amplification, and thus the instrument can operate uninterrupted during the night or while the technologist is performing other duties.

Using the enclosed tables that summarize the advantages and disadvantages of each of these three amplification schemes (Table 10.9, Table 10.10 and Table 10.11) the laboratorian may decide which system is optimal to perform in-house PCR for MTB. The use of RT-PCR as an additional and useful technical approach to amplification was discussed in an earlier section.

Methods of Detection of the Amplified Product

Some of the most popular techniques used to mediate detection of mycobacterial nucleic acids amplified by in-house PCR assays include use of ethidium bromide for size fractionation; hybridization with probes via Southern hybridization, in solution hybridization, or dot blotting; and sequencing of the amplicon. More novel methods include use of digoxigenin, chemiluminescence, and colorimetry. A comprehensive list with several references is included as Table 10.12. Some of the earlier studies, and subsequent studies using repeated sequences as targets, relied only on ethidium bromide for detection of the amplified product (70). Ethidium bromide is a dye that makes nucleic acids detectable by fluorescence upon intercalation between the bases of the nucleotides. It allows for size fractionation of the amplicon (i.e., determination of the size of the amplified nucleic acid compared with controls of known size). The sensitivity of an assay may be increased by using a nucleic acid probe for detection of the amplicon instead of, or in addition to, the use of ethidium bromide. Nucleic acid probes traditionally have been labeled radioactively with p32 that has served as the “reporter” molecule in many early studies. The use of such a second method of detection also enhances assay specificity. Binding or hybridization of such as probe to the amplicon may be performed via a dot blot format, a Southern hybridization format (20), or an in-solution hybridization format (65).

TABLE 10.12. METHODS OF DETECTION OF AMPLIFIED MYCOBACTERIAL NUCLEIC ACIDS

Method	References
Ethidium bromide for size fractionation	70,88

The use of digoxigenin as part of the scheme of detection is becoming more popular (32, 71). Fiss et al. (71) used digoxigenin-labeled probes in a reverse dot blot format with good results. In the last step of the reaction, an antidigoxigenin antibody was added that was linked to alkaline phosphatase. Upon the addition of a substrate for this enzyme that chemiluminesces, detection of the original amplicon can be mediated via chemiluminescence. This group consistently detected 100 mycobacterial colony forming units (CFUs). Wilson et al. (29) used digoxigenin- and biotin-labeled primers in a colorimetric enzyme immunoassay format. Following a first round of amplification with unlabeled outer primers, inner (nested) primers that were labeled with digoxigenin and biotin, respectively, were added for a second round of amplification. Thus, the amplified product contained both digoxigenin and biotin. Microtiter wells coated with avidin served for attachment of the amplicon via the biotin moiety whereas an antibody/alkaline phosphatase conjugate reacted with the digoxigenin moiety of the amplicon. Addition of substrate allowed for colorimetric detection and quantification of the amplified product.

Kirschner et al. (48) amplified 16S rRNA sequences, sequenced the amplicon, and was able to discriminate among species of mycobacteria based on hypervariable regions within the amplified gene. Others have treated the amplicon with restriction endonucleases and evaluated the resulting restriction fragment length polymorphism (RFLP) patterns (72, 73). The greatest advancements in detection methods entail the use of nonradioactive techniques, automation, and systems that allow detection of amplicons from multiple samples at the same time (ie., microtiter plates), such as are becoming common in the commercially available amplification kits.

Commercial software programs exist that computerize the analysis of restriction fragment length polymorphisms (74). One such package is the GelCompar (Applied Maths, Kortryk, Belgium) and sold in the United States as Molecular Analyst Fingerprinting Plus (Bio-Rad Laboratories, Hercules, California). Another is the BioImage System (BioImage Corporation, Ann Arbor, Michigan). Both systems were compared (74) and found useful, however, they both require the user to make critical decisions in the analysis, to check that artifacts are not being detected and to visually verify that the system is finding all bands in each lane. Commercial sequencing software packages also exist. One such system sequences amplicons from the 16S rRNA gene (Micro Seq 16S rRNA Gene kit, Perkin-Elmer Applied Biosystems, Foster City, California).

Another aspect of the PCR procedure that has hampered its potential for an even wider range of applications, but which also appears to be under evaluation for commercialization, is the need for standardized, quality-controlled frozen or refrigerated ingredients. The availability of ready-to-use freeze-dried PCR mixes of proven quality would greatly facilitate implementation in laboratories with relatively limited facilities and who choose to use home-brew PCR. The development of one such stabilized, freeze-dried PCR mix for detection of mycobacteria was recently described by Klatser et al. (75). Reaction mixes that were off-the-shelf,

preoptimized, premixed, predispensed and freeze-dried were stable for 1 year at 20°C and for up to 3 months at 37°C. All that was required was reconstitution of the mix and addition of the template DNA. Recently, a commercial freeze-dried basic PCR mix became available (Ready-to-Go PCR beads, Pharmacia Biotech) (75). Likewise, frozen standards for use as controls are being evaluated at the present time by commercial companies.

Sensitivity and Specificity of Published Assays, and Results of Large Published Studies on In-House PCR for MTB

Most published studies show proof of the capacity of in-house systems to detect between five and 100 CFUs of mycobacteria in sensitivity studies performed using dilutions of cultural isolates. There is variability between published studies, however, because the laboratories reporting such results differ in terms of target sequences, schemes of amplification, and detection methods used in their in-house PCR amplification assays. The highest sensitivity has been reported using schemes where the target sequence is either a repeated sequence, involves nested PCR, or the assay entails the use of amplification of preamplified rRNA via RT-PCR. One group that reported detection of three to 60 mycobacteria (22) improved the sensitivity of their assay with a nested PCR scheme using the same single copy gene target sequence (i.e., the 65 kd-antigen) (67). Other groups have reported detection of fewer than 10 organisms using a repetitive sequence as target (52), of 1 fg of DNA from culture using ethidium bromide only and 40 cycles of non-nested PCR (70), and of 1 fg of DNA using a repetitive insertion sequence (35) and 30 cycles of PCR from culture. Miyazaki et al. (33) increased the sensitivity of their assay 1,000-fold by a nested PCR approach, 35 cycles per run, down to detection of 10 fg of DNA, and Boddinghaus et al. (47) reported detection down to 0.1 fg of purified nucleic acid from cultures using RT-PCR of rRNA and a p32-labeled probe. This overwhelming variability in detection of amplified products by these investigators must be attributed to the enormous diversity in methodology used by each of the reporting laboratories.

In general, however, when actual clinical specimens are run and the results are compared with those of culture from the same specimens, the sensitivities of assays are usually lower than when dilutions from culture isolates are prepared and subsequently amplified (76). That is not surprising given that there are several known, as well as many uncharacterized, inhibitors of the Taq polymerase. These include, among others, hemoglobin (77), phenol, SDS, anticoagulants such as heparin and EDTA (77), and polyanetholsulfonate (77). In one study of amplification for *Mycoplasma pneumoniae* (78), PCR inhibition was observed in throat swabs submitted in routine bacteriological transport media, where it was the agar that was shown to be inhibitory. In other studies, inhibition was noted by calcium alginate and aluminum swab shafts (79), and by mucolytic agents (80). PCR application to fecal specimens has been very limited because of the presence of abundant and unknown inhibitors in such specimens. Recent manipulations, treatments, and columns have yielded significant improvements in this arena (81). Some of the measures reported to nullify the presence of inhibitors in clinical samples are included in Table 10.13. Some measures also have been reported to help increase the specificity of the assays by decreasing the rate of false positives, and some of these include: probe confirmation of the amplicon and use of “hot start” techniques to reduce mispriming at low temperatures. Measures are also known that will decrease or prevent the rate of PCR carry-over contamination of aerosolized amplicons from one clinical sample to another, and a comprehensive list is included in Table 10.14. Some of these interventions, such as the d-UNG, would have been helpful in the earliest studies in the literature reporting on the use of actual clinical specimens, such as that of Shankar et al. (76). This group reported on the use of PCR to diagnose meningitis as a result of MTB in cerebrospinal fluid. Although PCR was found to be more sensitive than culture in highly probable cases (15 of 20 versus 4 of 20, respectively), they reported on the possibility of cross-contamination of some of their negative controls and carryover abrogation techniques were not available at the time of that study.

TABLE 10.13. SEVERAL MEASURES USED TO NULLIFY OR DETECT THE PRESENCE OF INHIBITORS OF PCR AMPLIFICATION THAT MAY BE PRESENT IN CLINICAL SPECIMENS

Measure	Reference
Centrifugation through a sucrose gradient	28
Use of guanidinium thiocyanate/silica particles as the lysis and capture methods	29
Two-step nested PCR	65
Sample dilution	31
Use of internal control primers for myosin, actin, etc.	30
Use as internal control of a sequence that coamplifies with the target sequence, but with a product of different size	23
Column chromatography	23,30
SDS-NaOH as lysis pretreatment	125

TABLE 10.14. SEVERAL PRECAUTIONS AND MEASURES KNOWN TO DECREASE OR PREVENT PCR CARRYOVER CONTAMINATION OF AEROSOLIZED AMPLICONS FROM ONE CLINICAL SAMPLE TO ANOTHER

Preparation and use of master mixes, separate pipettes and rooms for pre- and post-PCR work, single use frozen reagent aliquots
Use of cotton-plugged pipette tips
Use of commercially available enzyme systems to inactivate prior contaminating amplicons d-UNG (uracyl DNA-N-glycosylase enzyme) with dUTP nucleotides
Photochemical modification of contaminating DNA with psoralen or isopsoralen
Treating the reaction mixture with multiple restriction enzymes, DNAase, bleach or hydroxylamine
Autoclaving
Exposing the reaction mixture to ultraviolet light

Abbreviations: PCR, polymerase chain reaction

Several large studies have been published using in-house PCR assays for detection of MTB in actual clinical specimens. The great majority use respiratory specimens, especially sputa, for the evaluation. Of note are studies conducted by Clarridge et al. (26), Kirschner et al. (82), Forbes et al. (83) and Nolte et al. (84). The specifics on sensitivity and specificity, as well as other important details, from each of these studies are found in Table 10.15. Although some of the earlier studies utilized culture alone as the gold standard for the study, others used an expanded gold standard (EGS), whereby culture alone was not the only criterion. Any questionable or incompatible result where there was a discrepancy between culture and amplification, was submitted to a clinical investigation consisting of chart review of the patient's history and physical examination, evaluation of roentgenogram results, as well as any other prior laboratory studies. This evaluation helped adjudicate true positivity to either culture or amplification, with results from the other method being considered falsely negative.

TABLE 10.15. SENSITIVITY AND SPECIFICITY OF LARGE PUBLISHED STUDIES UTILIZING IN-HOUSE PCR AMPLIFICATION FOR DETECTION OF MYCOBACTERIUM TUBERCULOSIS IN RESPIRATORY SPECIMENS

Reference	Total # of Specimens	# of MTB Positive Specimens	Gold Standard	PCR Sensitivity For all Specimens (%)	PCR Sensitivity For Smear Negatives (%)	PCR Specificity (%)	Smear Sensitivity (%)	Culture Sensitivity (%)	Target Used

Clarridge et al. (26) reported on the large-scale use of PCR in a routine mycobacteriology laboratory that processed over 5,000 specimens. Of 623 cultures positive for AFB, 218 were positive for MTB. PCR was positive in 181 cases (85%). They report the presence of inhibitors in 8% of clinical specimens. When compared with culture, PCR had a sensitivity of 83.5%, a specificity of 99%, and a positive predictive value of 94.2%. If results from multiple specimens on the same patient were considered, no patient who had three or more sputa tested in their laboratory was misdiagnosed, a comment echoed by several authors in the other large published studies. This group concluded that such results are encouraging for the use of PCR for the rapid identification of the most infective cases of tuberculosis. Kirschner et al. (82) offered an additional suggestion: in paucibacillary disease (i.e., where the specimens are smear-negative), do not report out a negative amplification result until three specimens have been evaluated. A summary and “take-home” figures on sensitivity and specificity from all large studies conducted using in-house PCR for MTB detection in actual clinical respiratory specimens, can be found in Table 10.16. It is obvious that it is the low sensitivities achieved while testing smear-negative specimens that will prove to be the Achilles' tendon of all molecular diagnostic mycobacteriological methods (85). It is suggested that the reader compare these figures with those to be presented later in this chapter from large studies using commercially available kits.

TABLE 10.16. SUMMARY OF RESULTS FROM LARGE PUBLISHED STUDIES ON USE OF IN-HOUSE PCR FOR DETECTION OF *MYCOBACTERIUM TUBERCULOSIS* IN CLINICAL RESPIRATORY SPECIMENS

Average Sensitivity (all specimens):	83–90%
Range of study sensitivities:	70–100%
Average Sensitivity for Smear (+):	>90%
Average Sensitivity for Smear (–):	50–80%
Average Specificity:	>90%

In-house PCR assays applied to clinical specimens other than those from the respiratory tree, such as pericardial tissue in cases of tuberculous pericarditis in HIV-positive patients, also show promise and merit further development (86). Likewise, there are published schemes on PCR detection of MTB in formalin-fixed, paraffin-embedded tissues using primer pairs that yield high sensitivities (34).

A word of caution must be raised in regards to the results from an important and somewhat discouraging report on the actual status of sensitivity and specificity of in-house studies as they have been performed in many laboratories around the world (87, 88 and 89). Noordhoek et al. (87, 88) recruited seven laboratories from different countries and continents to participate in a blinded study of 200 sputa, saliva, and water samples spiked with known numbers of *M. bovis* BCG cells or with no organisms. The IS6110 repeated sequence was used as target. Each laboratory was instructed to use its own protocol for pretreatment, extraction, detection, and amplification of samples, as they would if these were specimens coming from patients admitted to their institution. The results were surprising. As expected, there was an enormous variability in the methods used at all steps in the process, from pretreatment and lysis of specimens through detection of amplicon. The reported sensitivities ranged widely. In samples with as many as 1,000 microbes, the reports of positive results by PCR ranged from 2% to 90% of samples. In the interest of fairness, it must be mentioned that *M. bovis* BCG cells, sent to participants in lieu of MTB for safety purposes in shipping, usually contain fewer molecules of IS6110 than MTB (1 to 5, versus 10 to 20). Sensitivities with actual MTB-containing samples theoretically should have been higher than those reported in the study. However, specificities also varied widely. False-positive results ranged from 3% to 20% with one extreme value of 77%. It was concluded in this study that implementation of an effective system for monitoring the sensitivity and specificity of in-house PCR assays would be required before the technique can be used reliably. It also was suggested that more controls be added throughout the entire process, from collection of samples through detection of amplified product. This study supported the conclusion of the U.S. Public Health Service at

the time that with such a current state of technology, reliable detection of MTB still depended on conventional laboratory methods.

In 1996, a subsequent study along the same lines was undertaken once again by Noordhoek et al. (90) in order to shed light further on the reliability of nucleic acid amplification and detection of MTB in the world. This time, it was an international collaborative quality control study among 30 laboratories in 18 countries. Blinded panels of 20 sputum samples were prepared, containing zero, 100, or 1,000 mycobacterial cells. Each laboratory was asked to detect MTB by their routine method of nucleic acid amplification. This is an important difference from the earlier study where participants were asked to use the repetitive IS6110 sequence of MTB as the target for amplification. Part of the large variation in sensitivity and specificity of this earlier study may have been because of the lack of familiarity of some investigators with the use of the target IS6110. Therefore, this second study allowed participating laboratories to use their own protocol for amplification and detection of MTB without any restriction on the method or the nature of the target. Some of the laboratories used commercial amplification kits, such as those that will be discussed subsequently in this chapter. Only 20 blinded samples were provided this time, instead of 200, so as not to disrupt the routine workloads of the participating laboratories.

Only five laboratories correctly identified the presence or absence of mycobacterial DNA in all 20 samples. Seven laboratories detected mycobacterial DNA in all positive samples, and 13 laboratories correctly reported the absence of DNA in the negative samples. Lack of specificity was more of a problem than lack of sensitivity. Of interest, no two laboratories used exactly the same procedure for liquefaction and decontamination, pretreatment for lysis of MTB, DNA extraction, analysis of PCR products, or monitoring for the presence of inhibitors of the polymerase. Eight participants used commercially available kits, 19 participants used IS6110 as target. There was no correlation between correct test results and the use of any particular method. Seventeen laboratories used dUTP/dUNG to avoid contamination with amplicon, however, eight of these reported false-positive results among the BCG-negative samples.

The results of this second study show that nucleic acid amplification methods for MTB detection may be unreliable, even when laboratories use the method routinely applied in their laboratory. Even well-standardized reagents for amplification and detection such as those present in commercially available kits do not ensure reliable detection. This may be because of the fact that these kits do not include standardized procedures and reagents for liquefaction and decontamination of specimens. Pipetting, mixing, and centrifugation are critical to avoid loss of DNA and to circumvent cross-contamination. Appropriate positive and negative controls should be used in each run so that the whole procedure from sample lysis to detection undergoes monitoring. The authors recommend the use of negative sputum samples to which a known, small number of mycobacteria have been added by spiking. With controls such as these, the entire procedure from pretreatment to analysis is monitored for sensitivity. Because mycobacteria tend to clump, however, control reagents are not easy to prepare, and should only be prepared under standardized conditions and eventually should become available commercially. Internal controls to monitor for inhibition of the polymerase in the individual samples should also be used, which could consist of a modified target that is added to the sample. To conclude on this second study (90), the outcome of the study underlines the need for reference reagents and standardized operating procedures that would enable experienced technicians to perform reliable quality control assessment of amplification methods. Reference reagents should be used to monitor the performance of the whole assay, including pretreatment of clinical samples.

Notwithstanding any discouraging results gleaned from the two previous studies, a large number of reputable laboratories around the world perform in-house PCR tests for MTB with dependable results. There are many measures that can be taken to enhance the legitimacy of in-house PCR assays for MTB, beyond those stipulated on Table 10.13 and Table 10.14. At the level of one's own local hospital or institution, a laboratory must institute the regular use of high-positive, low-positive, and negative controls with each run. There should be stringent carryover abrogation techniques instituted in the laboratory. Before using an assay with patient samples, it must be validated via a sensitivity study using dilutions from culture, a specificity study using species other than MTB, a study of actual clinical samples compared with culture, and additional studies to optimize the reaction with the use of adjuncts (Table 10.17) and known abrogators of inhibitors. At the international level, the development of standardization attempts such as stereotypical protocols published by the National Committee for Clinical Laboratory Standards (NCCLS) for molecular microbiology must continue to be

encouraged. Enrollment in proficiency testing, laboratory inspections, laboratory surveys, and other policing modalities such as those performed by the College of American Pathologists is fundamental. It may well be, however, that the ever-increasing commercial availability of stereotypical PCR and non-PCR amplification kits will greatly standardize the field by allowing techniques that may be less prone to contamination with amplicon, more amenable to quantification, or more sensitive than the first-generation-in-house assays that have been reported in the literature to date. Developed countries are starting to employ such commercially available kits with great speed at present. It remains to be determined, however, if the high costs of such kits will allow the developing world access to such urgently needed technology, or if the poorest of countries may have to continue to rely only on potentially cheaper in-house PCR assays. In the worse of scenarios, some countries may be incapable of resorting to the use of amplification techniques at all.

TABLE 10.17. SEVERAL APPROACHES TAKEN TO OPTIMIZE ASSAY SENSITIVITY AND BAND INTENSITY OF AN IN-HOUSE PCR ASSAY FOR DETECTION OF MYCOBACTERIUM TUBERCULOSIS UTILIZING GELS FOR SIZE FRACTIONATION OF THE AMPLICON (REFERENCE 30)

Incorporation of 5% formamide during hybridization step
Optimization of hybridization temperature
Incorporation of 15% glycerol during the amplification step
Increase to 2X of Taq polymerase quantity
Use of thin-walled tubes for amplification
Evaluation of combinations of water and buffers from different commercial sources
Use of fresh primer aliquots

Possible Explanations for the Attainment of Less Than 100% Sensitivity in Amplification Assays, Particularly with Smear-Negative Specimens

If PCR amplification does offer the potential for detection of as little as a single organism present in a clinical specimen, why is less than 100% sensitivity attained in clinical studies? There are at least six possible explanations to this phenomenon.

Almost uniformly in the large published studies, a much greater portion of the treated sputum or clinical sample was utilized for culture of the specimen in liquid and/or solid media, and the remainder was used for PCR amplification. This is so because the gold standard for identification has been culture, and because these were actual clinical specimens, they deserved to be tested by the routinely used and accepted diagnostic methods, which must take precedence over techniques under evaluation. Thus, from a 1-mL volume of treated sputum, as much as 66% (26), 80% (82), or a greater fraction was used for culture in these studies, and left-over fractions were utilized for PCR.

It is well known that the distribution of acid-fast bacilli within a clinical specimen tends to be uneven because of clumping. This could be worse in paucibacillary specimens where clumping of very few organisms could create great specimen heterogeneity. Sampling error thus becomes a major problem with these specimens, and the testing method that is alloted the greatest amount of sample will produce the best results. Because a smaller fraction of the specimens was tested by PCR, the sensitivity of PCR may have been artefactually low. This intra-specimen variation in distribution because of clumping also could affect specimens collected on different days (i.e., inter-specimen variation), so that the same phenomenon could be occurring with all specimens tested on a given patient, with the same result: culture is favored to receive the few cultivable clumps of organisms, while PCR receives a fraction for amplification that may contain no organisms.

A fraction of the extracted or exposed mycobacterial DNA also can get lost during the extraction procedure, a factor that gains importance with paucibacillary specimens. This variable would not be expected to affect culture, as extraction of nucleic acids is not a part of cultural procedures.

Perhaps of greatest importance is the fact that there are inhibitors of PCR present in clinical samples, a phenomenon alluded to earlier in this chapter, and whose presence could endanger PCR sensitivity particularly for paucibacillary specimens. Large studies report that on average, 3% to 16% of all clinical specimens possess inhibitors of the polymerase (91). Measures such as the use of internal control sequences, or of spin columns to remove proteic inhibitors, or the use of PCR amplification of samples previously submitted to broth enrichment, may be necessary in order to get rid of amplification inhibitors and increase the sensitivity of PCR. Some of these measures will be the subject of further comment in the following section of this chapter. Internal controls are of immense utility in PCR and are sequences that are amplified either concurrently with the target sequence (i.e., in a multiplex style) or in a separate aliquot of the lysed specimen (92), and are used to evaluate the presence of inhibitory substances in the sample. These controls should always be run as part of a clinical assay. They may consist of 100 to 200 base pair sequences found within normal cellular gene sequences and expected to be present in all specimens whether or not the target (i.e., mycobacterial) sequence is present. Examples of internal controls include myosin heavy chain gene (93, 94), b-globin, and lipoprotein, as well as other genomic endogenous sequences. Such sequences help monitor the integrity of the nucleic acid target. A disadvantage of the use of endogenous sequences is that at times these may not accurately reflect amplification of the primary target because of differences in the primer sequences, size of the amplicon, and the relative amount of the two targets (95). Other internal controls that are not normal cellular gene sequences also have been described, which serve their purpose well, such as sequences within the 16S to 23S rRNA intergenic space regions of MTB (92). Alternatively, another approach consists of the use of synthetic genetically engineered internal control sequences with primer binding regions identical to those of the target sequence and which, thus, coamplify with it. The internal sequence may be similar to the target sequence in length and base composition but contains a unique probe-binding region that differentiates the internal control from amplified microbial target nucleic acid (95). Such a system has been described for use in conjunction with the Roche Cobas Amplicor, and microwell Amplicor systems (Roche Molecular Systems, Branchburg, New Jersey) (95), which will be described later. The internal control also may be made longer or shorter than the target sequence so as to render it detectable by size fractionation, if a gel system is being utilized for detection of the amplified product.

A sixth and final possible explanation for the low sensitivities attained with in-house PCR assays is offered, and becomes manifest when workers try to boost their systems by adding more lysed specimen to the amplification tubes in an attempt to increase the amount of MTB DNA placed in PCR reaction tubes. Addition of more lysed specimen will result in the addition of mostly genomic DNA, always present in much greater amounts in a specimen than mycobacterial DNA. Given the stoichiometric ratios that must be met within reaction volumes of 100µL or less, too much genomic DNA may inhibit PCR instead of boosting its sensitivity. There are attempts at enriching for specific MTB DNA and using such enriched fractions for amplification, and one such method is described next.

Trends in the Field for Increasing Sensitivity of In-House Assays, Especially for Smear-Negative Specimens.

Several trends are being followed in the field of amplification in an attempt to increase sensitivity when testing smear-negative specimens. Two such trends will be examined in this section.

MTB can be allowed to undergo cultural amplification in broth (i.e., as in the 12B bottles of the Bactec 460 system) up to a low growth index (GI), such as between 10 and 50 (91, 96). Instead of waiting until a considerably higher index is produced, with its attendant delay in diagnosis, to be followed by the use of Gen-Probe Accuprobe DNA probes for culture confirmation, an aliquot of broth preamplified to a low GI then is submitted to PCR amplification. This approach saves time over culture confirmation with probes and increases sensitivity over the use of PCR directly from the original smear-negative clinical specimen. It could be argued that this abrogates the promise from amplification techniques of allowing diagnosis while obviating the need for culture, but with sensitivities as low as those obtained with smear-negative specimens in the previously reported studies, the boost that such an approach can offer can not be dismissed. Success with a similar but expanded approach was described by Sanguinetti et al. (97). These investigators applied PCR amplification of 16S rRNA gene sequences and a subsequent reverse cross-hybridization assay with 14-C species-specific probes, to the identification of mycobacteria grown in liquid medium positive by the Bactec 460 TB and the Bactec 9000 MB systems (Becton Dickinson, Franklin Lakes, New Jersey). Commercially-available nucleic acid amplification systems are also being used to amplify MTB from positive broth cultures (77, 98, 99).

A second approach described is the enrichment and capture of MTB DNA (100, 101a) extracted from a clinical specimen and concentrated as the lysed specimen runs through a specific chromatography column, with the added benefit of removal of genomic DNA and protein inhibitors (100). Such columns can be coated internally with anti-MTB probes that specifically bind MTB DNA subsequently eluted from the column and used for PCR amplification (i.e., “Sequence-capture PCR”)(100). Although these systems do increase assay sensitivity, they are more labor intensive and require more modifications to the in-house procedure than systems without such enrichment attempts. Perhaps eventually commercial kits will include such modifications for amplification from smear-negative specimens. Alternatively, as described with studies using *M. ulcerans* (101b), immunomagnetic separation was utilized to isolate the intact organism from a heterogeneous sample, prior to lysis of the microbe's nucleic acid in preparation for PCR amplification. The technique uses monodisperse magnetic beads coated with antibodies against surface epitopes of the bacterium of interest.

CPT Codes Intended for Use with Molecular Diagnostic Techniques for Analysis of Nucleic Acids

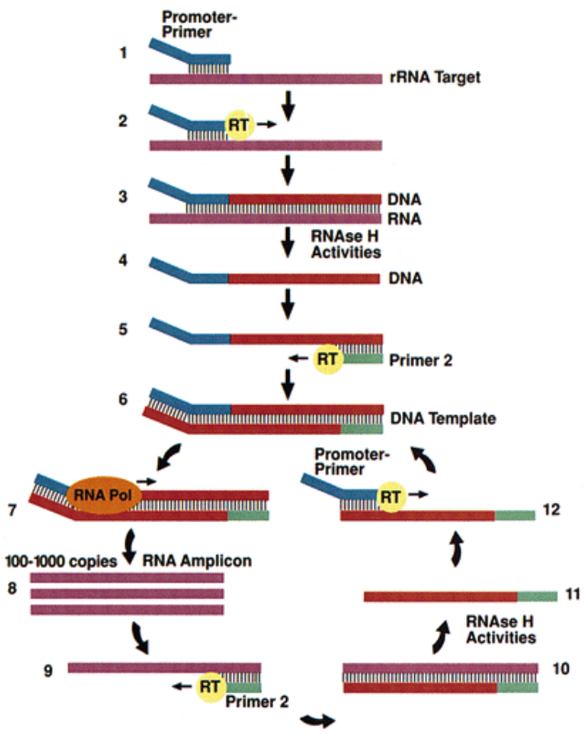

FIGURE 10.1. Steps in the transcription-mediated amplification cycle (TMA): (i) Promoter-primer binds to rRNA target; (ii) reverse transcriptase (RT) creates DNA copy of rRNA target; (iii) RNA:DNA duplex; (iv) RNAse H activities of RT degrades the rRNA; (v) primer 2 binds to the DNA and RT creates a new DNA copy; (vi) double-stranded DNA template with a promoter sequence; (vii) RNA polymerase (RP) initiates transcription of RNA from DNA template; (viii) 100 to 1,000 copies of RNA amplicon produced; (ix) primer 2 binds to each RNA amplicon and RT creates a DNA copy; (x) RNA:DNA duplex; (xi) RNAse H activities of RT degrades the rRNA; (xii) promoter-primer binds to the newly synthesized DNA. RT creates a double-stranded DNA and the autocatalytic cycle repeats resulting in a billion-fold amplification. Reproduced with permission from the Gen-Probe company.

There are several Current Procedural Terminology (CPT) codes described specifically for use whenever molecular diagnostic techniques are utilized to analyze nucleic acids. Whereas the earlier series of codes 83890 through 83912 was used for testing of infectious diseases, the CPT 1998 manual offers a new and expanded list of codes for testing of microorganisms. The specific assay run should be reported as precisely as possible by using the most specific code available. If there is no specific agent code for the particular organism being tested, then the general methodology code for infectious diseases should be used (i.e., 87797, 87798, 87799). Table 10.18 summarizes the specific codes applicable to detection by nucleic acid probes and/or amplification techniques of the five microorganisms most frequently amplified from clinical specimens (i.e., MTB, HIV, *Chlamydia*, CMV, and

hepatitis C). It also lists general codes for use when the organism in question has yet to have a specific code allotted to it, as well as other general codes that apply to any molecular diagnostic procedure. In cases where a labor-intensive in-house assay with multiple steps is used for analysis of an organism and no specific microbial code is available, then each procedure could be coded separately. For example, the steps of isolation of DNA, restriction endonuclease digestion, electrophoresis, and nucleic acid amplification could be coded as 83890, 83892, 83894, and 87798.

Gen-Probe TMA Commercially-Available System (rRNA Transcription-Mediated Amplification System) Coupled with the Hybridization-Protection Chemiluminescent Detection System for Mycobacterium Tuberculosis.

Features

The original Gen-Probe (San Diego, California) amplification system for MTB is called the AMTDT-1 (Amplified MTB Direct Test, Version 1). It was the first amplification assay for MTB to be approved by the FDA for use in the United States. It received approval in December 1995 for use with smear-positive respiratory specimens collected from previously untreated patients. Such restricted use was no doubt from the paucity of data at the time on its performance with nonrespiratory specimens such as CSF, pleural and synovial fluid, etc., to the lack of data on how long sputa from positive patients would remain amplification-positive for MTB after appropriate therapy had been instituted (12), and as will be presented later in this chapter, to the low sensitivities achieved when smear-negative specimens were tested. The test also has been marketed in Europe, Canada, Japan, Australia, and other Pacific-rim countries. Development of amplified tests for other microbes using the same technology is underway.

A transcription-mediated amplification system (TMA) differs from PCR, most notably, in the type of amplicon produced. In PCR, DNA is produced in large quantities from a DNA template. In RT-PCR, RNA templates are converted to single-stranded DNA templates that serve as substrate for the production of multiple DNA particles during amplification. In TMA, ribosomal RNA substrates are converted to single-stranded DNA substrates that are then transcribed into an RNA amplicon (Fig. 10.1). TMA is an isothermal, autocatalytic, homogeneous system. It is isothermal in that a single temperature is used during the amplification step, and homogeneous in that it does not use a solid substrate or precipitin reaction to separate the bound product (ligand-ligate) from free product; this occurs in the solution phase. Following a 2-hour incubation step at 42C, abundant RNA is produced that subsequently is detected by the Gen-Probe chemiluminescence-labeled DNA probes using the Hybridization Protection Assay (HPA) (Fig. 10.2). TMA assays provide several advantages: (i) there is abundant rRNA inside the MTB (2,000 to 5,000 molecules) so that the target is “preamplified” and thus has the potential for an increased sensitivity; (ii) a single temperature is used during the amplification step; (iii) a single-tube format is used whereby reagents are added to the tube but never removed from it, and detection occurs in the tube that minimizes the risk of carryover contamination; (iv) results are available on the same day (4 to 5 hours); (v) there is no nucleic acid purification step, just sonication; (vi) the HPA format has been well tested for several years when used for culture confirmation; (vii) RNA is more labile outside the tube than DNA, which reduces carryover risks; and (viii) system picks up MTB-complex members. A summary of the general features of AMTDT-1 can be found in Table 10.19.

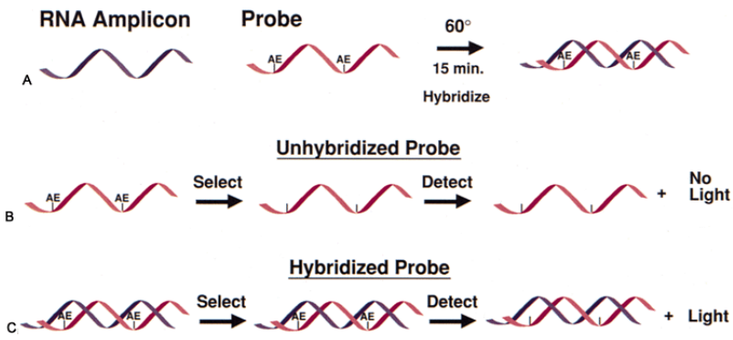

FIGURE 10.2. Detection of amplicon with DNA probes and the Hybridization Protection Assay (HPA) technique. (**A**) Acridinium ester (AE)-labeled DNA probes are added and allowed to hybridize to specific target sequences within the amplicon produced in the TMA reaction. (**B**) Separation of hybridized from unhybridized probes is done by the addition of selection reagent that hydrolyzes the AE on the unhybridized probes. No light is emitted in the luminometer from the unhybridized probes. (**C**) The AE on the hybridized probes is protected within the double helix and is not hydrolyzed by the selection reagent. Light is emitted and detected by the luminometer. Reproduced with permission from the Gen-Probe company.

TABLE 10.19. FEATURES OF THE GEN-PROBE AMTDT-1 (AMPLIFIED *MYCOBACTERIUM TUBERCULOSIS* DIRECT TEST, VERSION 1)

Type of amplification	Target
Target	16S rRNA (repeated sequences, very “preamplified”) of MTB complex
Amplification method	TMA (Transcription-mediated Amplification)
Enzymes	Reverse transcriptase, T7 RNA polymerase
Sample volume	50 µL of treated specimen, with N-acetyl-L-cysteine/NaOH suggested as liquefier
Sample lysis	Sonication and beads
Format	Single tube
Thermal conditions	Isothermal reaction
Amplified product	RNA
Detection	Chemiluminescence (Hybridization-Protection Assay)
Amplicon containment	Procedural (no removal); RNA is labile in environment
Instruments	Luminometer, heating blocks
Assay time	4–5 hours (amplification step at 42C is 2 h.)
Kit format	50 tests. Shelf-life is 12 months with unreconstituted reagent vial, and 1 month once reconstituted
Laboratory space requirements	Single room
Training	Offered by company

Abbreviations: MTB, *Mycobacterium tuberculosis*

The main steps involved with this system are enumerated in Table 10.20. Sputum samples or bronchoalveolar lavages are treated for digestion decontamination and concentration and a sample placed in lysing tubes containing glass beads. Specimen lysis is mediated via sonication, which breaks cell walls and liberates rRNA. The mycobacterial 16rRNA appears unaffected by the routine decontamination and lysis procedures used in most laboratories that entail the use of N-acetyl-L-cysteine/NaOH, as opposed to mRNA whose levels may be reduced significantly (102). Following lysis, an amplification reagent is added to each

reaction tube and overlaid with oil. Various DNA primers are included in this reagent. Aliquots from the lysed specimens then are added to the reaction tubes with the amplification reagent in it. Incubation occurs at 95°C for 15 minutes in a dry heating block and that is followed by cooling at 42°C for 5 minutes, which allows the primers to anneal to the regions that flank the target. Then, the enzyme mix is added. There are two enzymes added together: reverse transcriptase (RT) and T7 RNA polymerase (RP). Nucleotides (dNTPs and NTPs) also are included. This mixture is incubated at 42°C for 2 hours, during which time the RT will create complementary DNA (cDNA), and the RP will transcribe that to multiple RNA amplicons. Subsequently, a termination reagent is added to each tube to destroy any cDNA template.

TABLE 10.20. MAIN STEPS INVOLVED IN THE GEN-PROBE AMPLIFIED *MYCOBACTERIUM TUBERCULOSIS* DIRECT TEST, VERSION 1 (AMTDT-1)

1)Specimen lysis

2)Addition of an “amplification reagent”

3)Incubation

4)Addition of an “enzyme mix”

5)Incubation

6)Addition of a “termination reagent”

7)Detection by the Hybridization Protection Assay

Adapted and updated, with permission, from Sandin RL. Polymerase chain reaction and other amplification techniques in mycobacteriology. In: Heifitz, L. *Clinics in Laboratory Medicine. Clinical Mycobacteriology*. Philadelphia, PA: WB Saunders Co; 1996: 617

Detection occurs via hybridization with a DNA probe. Reconstituted probe reagent now is added to the reaction tubes and incubation occurs at 60°C for 15 minutes. A selection reagent then is added for 10 minutes at 60°C to allow for the selective detection of hybridized amplicon. Acridinium ester, the reporter molecule on the probe, will undergo hydrolysis only when present on unhybridized probes. This is the essence of the hybridization protection assay (HPA). Upon the formation of a hybrid between the DNA probe and the RNA amplicon complementary to it, the acridinium ester label on the probe is

protected against alkali treatment by the formation of the double-stranded hybrid (DNA-RNA helix). This selection step occurs in solution in a single phase. Chemiluminescence is achieved by excitation of the acridinium ester molecule with the addition of H2O2/OH-. Detection is accomplished by reading chemiluminescence in a luminometer. A large signal-to-noise ratio is achieved. In regards to hardware, only a sonicator, a luminometer, heating blocks, and water baths are required.

Large Published Studies

The AMTDT-1 has been evaluated in at least seven large published studies, using predominantly respiratory specimens, the majority of which were sputa (126, 127, 128, 129, 130, 131 and 132). The cutoff for positivity used in these studies was approximately 30,000 relative light units (RLUs). The specifics for each study are summarized in Table 10.21. It can be concluded from such large studies that the sensitivity of AMTDT-1 for all specimens ranges from 70% to 98% with an average of 86% to 90%, while that of smear-negative specimens ranges from 70% to 80%, with some selected lower results. Specificities were high, ranging from 97% to 100%, with an average of 98%. Once again, it is the smear-negative specimen that challenges amplification systems in their inability to detect very low levels of mycobacteria. The majority of the studies concluded once again that the use of three or more specimens per patient leads to an accurate diagnosis.

TABLE 10.21. SENSITIVITY, SPECIFICITY AND OTHER DATA FROM THE SEVEN LARGE PUBLISHED STUDIES ON THE AMTDT-1 USING PREDOMINANTLY RESPIRATORY SPECIMENS, MOSTLY SPUTA

Reference	Total # Specimens	# MTB Positive Specimens	Gold Standard	AMTDT-1 Sensitivity (%) for all Specimens	AMTDT-1 Sensitivity (%) for Smear Negatives	AMTDT-1 Specificity (%)	Smear Sensitivity (%)	Culture Sensitivity (%)
126	135	37	EGS	91.9	70	100	71.9 (K)	96.9
127	758	119	EGS	82	71.8	99	53 (A)	88
128	750	156	EGS	91	72.5	98.5	67.3 (A)	91
129	938	111	EGS	97.8	80	97.1	Not reported (A)	89
130	617	21	C	71.4	14 (1/7)	99	66.7 (A)	100[a]
131	760	175 (both hospitals, H and L)	C	H 65, L 93	48 (both hospitals)	H99, L99	H 54 (A) L 87 (A)	100
132	412	61	C	98.4	Not reported	98.9	Not reported	Not reported

[a] Only specimens positive by culture were considered true positives, so the sensitivity of culture as gold standard was 100%. Yet, 6 specimens from patients with tuberculosis and on anti-TB medication were AMTDT-1 positive/culture negative but were disregarded when calculating sensitivities.
Abbreviations: A, auramine; C, culture; EGS, expanded gold standard; K, Kinyoun; MTB, *Mycobacterium tuberculosis*.

Issues to be Addressed and Attempts at Addressing Them

The issue of potential for inhibition during amplification of clinical samples when a target amplification system such as TMA is used, is always of concern and should be addressed by the incorporation of an internal control in the system. The response thus far has been that because the amplicon in TMAs is RNA, which is very labile outside of the tube, this should not be of concern. The need for full automation of the system is being addressed in two ways (see Table 10.5): by way of the TIGRIS instrument now under development, and by a collaboration with the VITEK company (Shelton, Connecticut) to produce cartridges that allow the use of the TMA technology within the format of the VIDAS instrument (i.e., VIDAS PROBE). In terms of inoculum size, it has been suggested to the company that increasing sample inoculum from 50 to 500 µL would increase sensitivity, and the enhanced version of the kit has taken that into account, as will be described later. The kit needs adaptation to nonrespiratory samples, and the packaging format should be revisited to include kits with 50 tests or less that would allow small laboratories access to the technology before the kit shelf-life expires. Alternatively, the shelf-life of the reagent vial following reconstitution should be increased.

Bodmer et al. (133) increased the volume of decontaminated respiratory specimen used from 50 to 500 µL with an increase in sensitivity from 71.4% to 83.3%. This modification was adapted into the enhanced second version of the kit, known as the AMTDT-2. Four studies reported on the adaptation of the procedure for use with CSF and other nonrespiratory specimens, with high sensitivities (125, 134, 135 and 136), and the results are presented in Table 10.22. It is precisely the extrapulmonary presence of tuberculosis (i.e., pleuritis, lymph nodes, CSF, etc.) that requires a rapid and very sensitive laboratory diagnostic method, because the traditional techniques have well-known limitations, mainly because of the small amount of bacteria present in these specimen types. In fact, direct CSF smears in tuberculous meningitis, although virtually diagnostic if the organism is found, usually are positive in less than 10% of cases, while cultures require up to 8 weeks and also are often negative (137, 138 and 139).

TABLE 10.22. EVALUATION OF THE AMTDT-1 WITH A VARIETY OF NONRESPIRATORY SPECIMENS, INCLUDING CSF

Reference	No. of Specimens	Type of Specimens	Sensitivity (%) for all Specimens	Specificity (%) for all Specimens
134	322	Variety*	93.1	97.7
135	294	Variety*	83.9	99.6
136	224	Variety*	85.7	100
125	136	121 peripheral bloods, 15 bone marrows	94.3	100

* Variety of specimens includes CSF, urine, lymph nodes, various body fluids or aspirates, biopsy tissues, and pus.
Abbreviations: CSF, cerebrospinal fluid

Pfyffer et al. (134) increased the amount of sample to 500 µL, pretreated specimens with SDS-NaOH and increased the amplification time from 2 to 3 hours. Sensitivity increased significantly, especially for CSF where they consistently detected 100 cells per milliliter. SDS denatures potential protein inhibitors of amplification, but must be removed by sufficient washings prior to running the assay.

Ehlers (135) treated specimens with NaLC-NaOH with no

adaptations of the stereotypical procedure. Substances inhibitory to amplification were found in 7.5% of all samples, and they tried various commercial extraction columns and resins but without any consistent ability to eliminate inhibitors.

Gamboa et al. (136) also pretreated specimens with SDS-NaOH and found it to be mandatory in obtaining consistent and reproducible results. When this group increased the specimen size to 500 µL concurrent to the use of SDS, the sensitivity of the study increased to 95.6%. The same group then reported in another paper (125) the use of 10% SDS for the preparation of peripheral blood and bone marrow aspirates from AIDS patients with high sensitivities. Once again, SDS appears to abrogate inhibitors present in clinical specimens.

The enhanced version of the Gen-Probe kit for MTB recently was FDA-approved (see Table 10.4), and is called the AMTDT-2 or E-MTD for enhanced version MTD. At least one large published study and several abstracts are available on its performance (98, 140, 141).

Some changes in the kit format include: increase in sample volume size from 50 to 450 µL, reduction in incubation time of the 42°C amplification step from 2 hours to 30 minutes, and elimination of the termination reaction. The assay turn-around time is decreased from 5 hours to 3.5 hours. Gamboa et al. (140) compared AMTDT versions 1 and 2 in respiratory and nonrespiratory specimens and the summary is found in Table 10.23. All samples were pretreated with SDS-NaOH or 10% SDS. Overall results of both versions were concordant for 97% of samples. Version 2 appeared to be more sensitive with smear negative specimens, but was more susceptible to inhibitory substances. The authors suggest that internal controls incorporated into the kits by the company would increase the user's confidence in the reliability of negative results.

TABLE 10.23. COMPARISON OF AMTDT VERSIONS 1 AND 2 WITH RESPIRATORY AND NONRESPIRATORY SPECIMENS

		Version 1				Version 2			
Type of Specimen	No. of Specimens	Sensitivity (%) of all Specimens	Sensitivity of Smear Positives	Sensitivity of Smear Negatives	Specificity (%)	Sensitivity (%) of all Specimens	Sensitivity of Smear Positives	Sensitivity of Smear Negatives	Specificity (%)

Gamboa F, Fernandez G, Padilla E, et al. Comparative evaluation of initial and new versions of the Gen-Probe Amplified Mycobacterium Tuberculosis Direct Test for direct detection of MTB in respiratory and non-respiratory specimens. *J Clin Microbiol* 1998; 36: 684

VIDAS Adaptation (VIDAS PROBE)

The Gen-Probe company is in partnership with the Bio-Merieux Vitek company to adapt the amplification and detection steps of the TMA technology to the automated VIDAS, an immunoassay instrument. According to Table 10.5, assays undergoing research and development include the following targets: MTB, *C. trachomatis*, *C. trachomatis*/*N. gonorrhoeae*, *N. gonorrhoeae*, and HIV-1 quantitative. This adaptation will allow use of the TMA technology particularly by small laboratories with small specimen volumes, while the company continues to develop its TIGRIS instrument for larger laboratories with high throughput that require full automation of the extraction as well as the amplification and detection steps.

Polymerase Chain Reaction, Commercial, Roche Amplicor for M. Tuberculosis

Features

Roche has developed a series of PCR-based amplification assays under the trade name Amplicor. Those kits, which are FDA-approved, are included in Table 10.4, and the many more that are undergoing clinical trials, research and development, or awaiting FDA approval, are included in Table 10.5. The MWP format for MTB is FDA-approved, while the automated COBAS format is pending approval. Like the Gen-Probe assay, the Roche kit has been approved for use with respiratory samples, which are smear positive, from previously untreated patients.

The basic format of the Amplicor series includes a specimen collection and transport kit, specimen preparation kit, amplification kit with prepackaged components (Fig. 10.3), and a detection kit. The system includes the AmpErase (uracil-N-glycosylase) method of abrogating amplicon carryover contamination as part of the “master mix” (Fig. 10.4). dUTP is present also in the mix instead of dTTP. Amplicons from previous runs will contain dU instead of dT. AmpErase will destroy uracil-containing amplicons before thermal cycling during the first denaturation cycle, but the enzyme itself is inactivated at cycling temperatures so it cannot destroy new genuine amplicon present in an uncontaminated specimen. Thus, new amplicons are unaffected before detection. The UNG activity is limited to amplicons below a particular size and does not work for prior dT-containing contaminating amplicons. The “master mix” includes

the following reagents: Taq polymerase, AmpErase, dATP, dCTP, dGTP, dUTP, and biotinylated primers (Fig. 10.3). Because primers have biotin, the amplicon will be biotinylated and captured in microtiter wells that contain the probe. Avidin-horseradish peroxidase conjugates are added, substrates are added subsequently, color is produced, and absorbances are determined and read in an enzyme immunoassay plate reader. Thus, the format appears to be user-friendly and amenable to use for detection of amplicon from multiple clinical samples at the same time. A complete summary of the most salient features of the system is found in Table 10.24.

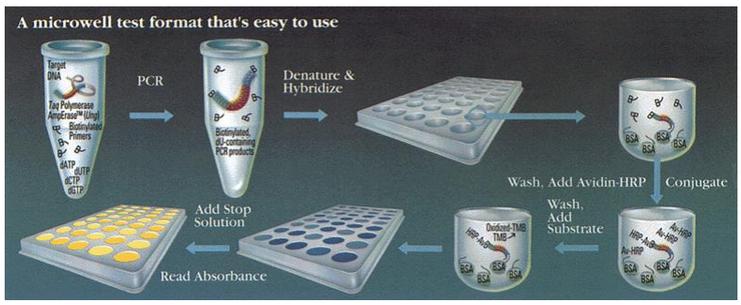

FIGURE 10.3. The microwell-plate format (MWP) of the Roche Amplicor kits allows for detection of amplicons produced by PCR from master mixed reagents provided with the kits. Reproduced with permission from Roche Diagnostics Systems, Inc.

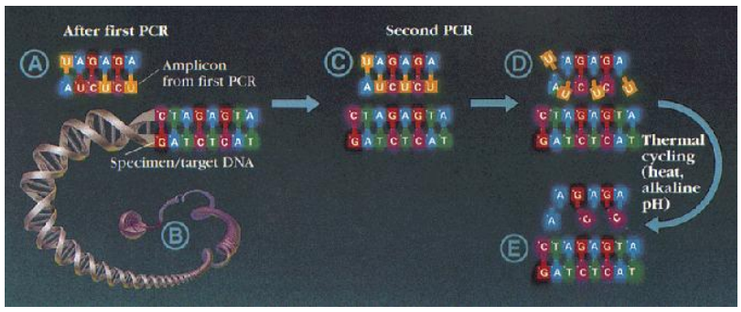

FIGURE 10.4. To control carryover contamination, the Roche kits contain AmpErase (uracil-N-glycosylase) as part of the master mix. This enzyme catalyzes the destruction of uracil-containing DNA strands prior to thermal cycling. Contaminating amplicons are broken apart during the first denaturation cycle to render them inactive, but the enzyme is itself inactivated at cycling temperatures, so newly formed amplicons are unaffected prior to detection. Reproduced with permission from Roche Diagnostic Systems, Inc.

TABLE 10.24. SUMMARY OF FEATURES OF THE ROCHE AMPLICOR MWP FORMAT FOR *MYCOBACTERIUM TUBERCULOSIS*

Type of Amplification	Target
Target	DNA (16s rRNA gene, single copy gene of MTB complex)
Amplification method	PCR
Enzymes	Taq polymerase
Sample volume	100 µL of treated specimen, with NaLC-NaOH as suggested liquefier
Sample lysis	60C, NaOH, Triton X
Format	Microtiter plates
Thermal conditions	Three-temperature setup
Amplified product	DNA
Detection	EIA
Amplicon containment	Uracyl-N-glycosylase (AmpErase)
Instruments	Thermal cycler, etc.
Assay time	6 h
Kit format	96 tests, shelf-life 3 months
Laboratory space requirements	Pre- and postamplification rooms
Training	Offered by the company

Abbreviations: EIA, enzyme immunoassay; MWP, microwell plate; PCR, polymerase chain reaction

Large Published Studies

Twelve large studies have been published that evaluate the MTB MWP kit with real clinical specimens, the majority of which are respiratory samples, mostly sputum (142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152 and 153). The specific details from each study are summarized in Table 10.25. General conclusions that can be drawn from that table are the following: the sensitivity for all specimens ranges from 58% to 95%, with the average being about 75% to 80%; specificities range from 96% to 100%, with an average of 99%; sensitivity of smear-negative specimens ranges from 50% to 70% with selected studies

showing lower values; and most studies concluded that the use of three or more positive specimens leads to an accurate diagnosis. Two studies comparing the Roche MWP MTB format with the Gen-Probe AMTDT version 1.0 (159, 160) showed similar sensitivities and specificities for both assays.

Abbreviations: A, auramine; C, culture; EGS, expanded gold standard; K, Kinyoun.
Reference 150 also evaluated nonrespiratory samples, but these were not included in the calculations presented.

Issues to be Addressed and Attempts at Addressing Them

Several issues of importance that are undergoing scrutiny by the company will be mentioned, and subsequent paragraphs will address the actions being taken by the company. The need for an Internal Control (IC) to test for potential inhibitors in clinical specimens has been addressed by the creation of an IC for use with COBAS and the newest versions of the MWP assays such as those for MTB, *C. trachomatis*, *N. gonorrhoeae*, and hepatitis C virus. The need for advanced automation of the amplification and detection steps is being addressed with the COBAS Amplicor instrument. The company may consider increasing the sample inoculum size from 100µL to 200 or 500 µL with a possible attendant increase in sensitivity. An adaptation of the MTB system for use with nonrespiratory samples is a must, and a revisiting of the packaging format to suit the needs of smaller laboratories also would be advantageous. Second- and third-generation kits most likely will address all of these issues in the future.

An article has been published describing the creation of an internal control (IC) for routine use in combination with the COBAS Amplicor MTB, *C. trachomatis*, *N. gonorrhoeae*, and hepatitis C virus (95). It contains primer-binding regions that are identical to those of the target sequence and contain a unique probe-binding region that differentiates the IC from amplified target nucleic acid. Only 20 copies of the IC are introduced into each test sample, which helps determine inhibition that may occur at the crucial limit of test sensitivity. Inhibition rates of 5% to 9% were exhibited in the COBAS assays for these four organisms, and test sensitivities were 1% to 6% greater with the use of the IC. When introduced into an unprocessed specimen, the IC can help monitor nucleic acid recovery during specimen preparation. Of note, both target and IC DNA will draw from the same limited and common pool of reagents in the master mix, during amplification. Thus, IC amplification may be suppressed because of competition in samples containing large amounts of target DNA, while it may be preferentially amplified in samples containing extremely low levels of target microbial sequences. In general, IC should be included with every specimen that is run, but alternate schemes may be envisioned, such as its selective use in specimens that test negative for the primary target, or its restricted use with specimens most likely to show inhibition such as those with traces of blood, urogenital specimens from pregnant women, etc. In the case of MTB, it may be used when the

probability of infection is high and the consequence of a false-negative result is severe. Such is the case when testing smear-positive specimens where a clinical suspicion for tuberculosis is great, yet a false-negative test result would lead the clinician to conclude that the patient has a nontuberculous mycobacterial infection (95). Commercially available ligase chain reaction and transcription-mediated amplification systems do not have such internal controls as have been described here.

The MTB MWP format was evaluated with CSF in diagnosing tuberculous meningitis (137).

The assay had a sensitivity of 60% and a specificity of 100%, which may not be great, but still the test was more sensitive than stain and culture. The kit also has been evaluated for MTB detection from Bactec 12B bottles or MGIT tubes after giving the specimen, usually a smear-negative specimen, a culture preamplification “boost” prior to submission of an aliquot to PCR amplification. Smith et al. (77) tested 12B broth cultures with a GI of 20 or more with the MTB MWP kit, while testing those broth cultures reaching a GI of 300 or more with DNA-probes. The sensitivity and specificity of PCR were 93% and 100%. The mean time from specimen inoculation to detection and identification was 16 days for PCR and 28 days for the DNA probe assay. Ichiyama et al. (99) tested positive MGIT broths (Mycobacterium Growth Indicator Tubes, Becton Dickinson) with both PCR and DNA-probes and found the sensitivities to be 98% for PCR and 77% with the probes. PCR assays specific to the entire genus *Mycobacterium* and useful in the detection of a wide range of mycobacterial species in clinical samples have been described (154). Genus-specific primers and probes amplify, capture, and detect amplicons, while products then can be hybridized to species-specific probes for more selective identification.

The automated COBAS Amplicor PCR system will automate the amplification and detection steps of the PCR reaction, providing containment of the detection components. Manual sample preparation for the DNA extraction step is still required, but perhaps will be carried out in the future by a separate instrument. COBAS allows for the simultaneous amplification of different infectious agents, given that it contains several thermal cyclers, each of which can be programmed to amplify a different target at its required parameters, and there will be coamplification with an internal control. Biotinylated amplicons are captured onto magnetic particles that are coated with specific probes, and the bound products are detected colorimetrically. The is no evidence of instrument carryover between high positive specimens and negative samples placed in tandem. There was 100% correlation between samples run by COBAS for MTB and those run with the MWP assay format (155). The amount of sediment used for MTB in COBAS is the same as with the MWP format (i.e., 100 µL of pretreated respiratory specimen). The actual hands-on time for the MTB assay has been reported to be 4.4 minutes (155).

At least four large studies have compared COBAS MTB with culture (15, 156, 157 and 158), and the comparison of all studies is included in Table 10.26. Bodmer et al. (156) tested COBAS in a population with high prevalence for tuberculosis. There was inhibition of amplification in 4.7% of samples that included several smear-positive specimens, which suggested to them that such a rate of inhibition justifies the systematic inclusion of the internal amplification control. Yuen et al. (157) compared COBAS with LCX from Abbott and found it to be more sensitive than LCX for all respiratory specimens as well as for smear-negative ones. Rajalahti et al. (15) reported an increase in sensitivity when three consecutive sputa were received per patient. Finally, Eing et al. (158) published the first report on the COBAS MTB assay applied to both respiratory and nonrespiratory specimens. With a modified protocol for DNA extraction (i.e., washing plus sonication), sensitivities with smear-negative gastric aspirates were superior to those of sputa. They also suggest that three or more smear-negative sputum specimens be tested per patient prior to accepting a negative result as a true negative.

TABLE 10.26. COMPARISON OF THE COBAS *MYCOBACTERIUM TUBERCULOSIS* ASSAY WITH CULTURE OR WITH THE MWP FORMAT FOR DETECTION OF *MYCOBACTERIUM TUBERCULOSIS* IN CLINICAL SPECIMENS

Reference	No. of Specimens	Type of Specimens	Gold Standard	Sensitivity (%) for all Specimens	Sensitivity (%) for Smear Positives	Sensitivity (%) for Smear Negatives	Specificity (%)	Culture Sensitivity	Correlation with MWP Format
155	230	respiratory	-	-	-	-	-	-	100%
156	1,012	respiratory	C	92.6	-	-	99.6	Gold standard (100%)	-
157	204	respiratory	C	84.3	-	57.9	100	Gold standard (100%)	-
15	324	respiratory	C	83	-	68	99	Gold standard (100%)	-
158	1,681	respiratory and non-respiratory	EGS	66.3	96.4	45.4	99.7	-	-

Abbreviations: C, culture; EGS, expanded gold standard (see text); MWP, microwell plate.

CONCLUSIONS ON THE MOLECULAR BIOLOGY OF INFECTIOUS DISEASES

Part of "10 - Molecular Biology of Infectious Diseases"

There should be no doubt in the reader's mind that the use of DNA probes and molecular amplification techniques in infectious

diseases has revolutionized the field and is here to stay. In-house assays are ever-present around the world, but it is the presence of the technology in stereotypical kit forms from companies that has begun to increase the accessibility of this technology to the small microbiology and virology laboratory. A look at Table 10.3, Table 10.4 and Table 10.5 should excite the reader as to what is currently available and what is upcoming in terms of robust assays in kit format.

The majority of scenarios that will require the use of amplification have been stated in Table 10.2. However, no one should think that these techniques will completely free the laboratory from establishing labor-intensive culture procedures for a myriad applications. Using an assay that detects MTB-complex as an example, all non-TB mycobacteria present in the sample would be missed, members within the MTB-complex would not be distinguished from one another, and viable organisms would still be required in culture for susceptibility testing, despite progress in the molecular understanding and rapid detection of resistance against antituberculosis agents with amplification techniques. Lastly, positive signals from amplification of dead or dying treated organisms, or of saprophytic microbes that could be present in the absence of pathology, will always require clinical correlation for an accurate interpretation, and the eventual use of amplification kits for performing the “test of cure” for several conditions will require stringent evaluation as part of large clinical trials.

Clinical Applications of Molecular Biology Hematopoietic Disorders

Serhan Alkan

Curtis A. Hanson

Advances in molecular biology of hematologic neoplasms have led to the development of diagnostic tools routinely used for detection and evaluation of treatment efficiencies. As the knowledge and use of more molecular-based diagnostic testing evolves in clinical laboratories, the technology will eventually become automated and a standard practice in diagnostic laboratories for clinical evaluation of various disorders. We are already witnessing the use of semi-automated molecular based assays for quantification and processing of complex information by microchip technology to evaluate diseases with underlying genetic causes. These changes, occurring during the last couple of years, are establishing a new standard in patient management. The molecular techniques that are particularly related to diagnostic testing have been providing laboratorians and physicians with highly sensitive, accurate, and reproducible results in a very fast and efficient manner.

These technologies are providing new molecular approaches to assess the genome at all levels, including the ability to determine the presence, or absence of individual genes, their base sequences, and structural alterations in chromosomes. As correlations between genetic anomalies and diseases are established, there will be future application of novel technologies. The development of clinical diagnostic products will provide information critical to the evaluation and management of various disorders, including lymphomas, leukemias, other cancers, as well as other genetic diseases. For example, there is emergence of microchip technology, in which either oligonucleotides or complementary deoriboxynucleic acid (cDNAs) are spotted onto solid supports and subsequently hybridized with genes obtained from patient samples. This powerful technology has the potential to design various chips for disease-specific screening tools e.g., acute leukemia microchip including common fusion genes generated by translocations. It is likely that chip technology will lead to refinements of hematologic neoplasms and help characterize molecular events associated with particular tumors (1, 2).

As molecular biologic techniques become further embedded into clinical laboratories, it is necessary for pathologists to understand both the technology and the clinical applications of these diagnostic modalities. To accomplish this, we aim to provide in this chapter information for commonly used techniques in diagnostic hematopathology including immunoglobulin (Ig) and T-cell receptor (TCR) gene rearrangement, detection of translocations that has become a diagnostically important tool in laboratory evaluation of hematopoietic neoplasms, and review common genetic abnormalities seen in various hematologic neoplasms. This section is essentially divided into several parts to review common abnormalities seen in lymphomas, leukemias, and nonneoplastic hematopoietic disorders in which the latter group includes several important recently described molecular abnormalities in diseases related to coagulation and anemias. The genetics of commonly seen anemias such as hemoglobinopathies are covered elsewhere in this book hence are not discussed here.

HEMATOLOGIC NEOPLASMS

Part of "11 - Clinical Applications of Molecular Biology Hematopoietic Disorders"

The most important and commonly used tests used in evaluation of lymphoid neoplasms include immunoglobulin and T-cell receptor gene rearrangement by using Southern blot analysis and polymerase chain reaction (PCR) amplication. Molecular gene rearrangement studies have had the biggest diagnostic impact in non-Hodgkin's lymphoma. In particular, these studies have been used in (i) identifying clonal proliferations, especially in peripheral T-cell lymphoma; (ii) confirming the cellular lineage of a lymphoproliferation; (iii) analyzing for recurrent disease; and (iv) evaluating “atypical” hyperplasias for the presence or absence of a clonal population when routine morphology or immunologic methods are equivocal.

IMMUNOGLOBULIN AND T-CELL RECEPTOR STRUCTURE AND FUNCTION

Part of "11 - Clinical Applications of Molecular Biology Hematopoietic Disorders"

Both the immunoglobulin and T-cell receptors are heterodimers composed of two distinct disulfide-linked chains. These receptors are part of the so-called immunoglobulin supergene family. This family of related genes all has a similar molecular structure and encode their genetic material through a process of DNA recombination before a functional protein can be produced. The immunoglobulin genes (heavy chain, kappa, and lambda light chain genes) and the T-cell receptor genes (alpha, beta, gamma, and delta chain genes) each are composed of three or four basic

gene regions: variable (V), diversity (d), joining (J), and constant (C) regions (Fig. 11.1). As will be discussed later, one segment from each of these regions recombines to encode for a particular immunoglobulin or T-cell receptor protein. Both receptor proteins are composed of a constant region and a variable region. The constant region confers a common characteristic structure, and the variable region is the site responsible for unique antigen recognition. The vast diversity of variable region structure is attributable to gene rearrangement, a process that is replayed uniquely in every developing B- and T-lymphocyte. To fully appreciate the diagnostic and therapeutic impact of molecular techniques in the clinical laboratory, one must first understand this gene rearrangement process.

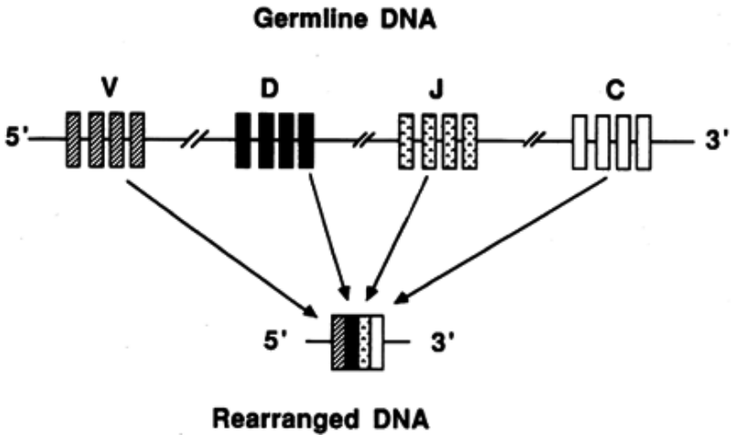

FIGURE 11.1. General structure of the immunoglobulin and T-cell receptor genes. One gene segment from each of the variable (V), diverse (d), joining (J), and constant (C) regions from the germline DNA recombine during the rearrangement process to form a unique gene sequence.

Immunoglobulin Genes

Construction of an intact immunoglobulin molecule is the result of rearrangements involving multiple regions within each of the immunoglobulin heavy and light chain genes (3, 4). Although the immunoglobulin heavy and light chain genes are located at different chromosomal loci, all undergo a similar rearrangement process of their different gene regions. The immunoglobulin heavy chain gene is located on chromosome 14q32, the kappa light chain gene on chromosome 2p12, and the lambda light chain gene on chromosome 22q11. The first rearrangement step in the early B-precursor cell begins with the heavy chain gene locus. The heavy chain gene contains greater than one hundred variable (V) region genes, approximately 30 D region genes, and six J region genes that create more than 18,000 possibilities for generations of immunoglobulin H rearrangement pattern. The nine constant (C) region genes in this locus encode the immunoglobulin constant region and correspond to the particular immunoglobulin isotype: Cμ(IgM), Cδ(IgD), Cγ1-4(IgG1-4), Cα1-2(IgA1-2), or CεIgE). Heavy chain rearrangement initially begins with one D region gene recombining with one J region gene, followed by recombination with a V region gene (Fig. 11.2). The resulting rearranged DNA is transcribed and undergoes ribonucleic acid (RNA) splicing, which involves removing any intervening intron material and splicing the V, D, J, and Cμ exons together (Fig. 11.2). The resulting messenger RNA (mRNA) product can then be translated into an immunoglobulin heavy chain molecule. If, however, the initial D-J or V-D-J rearrangement mistakenly encodes for a termination or nonsense codon, then transcription or translation of the gene becomes “non-productive.” Subsequently, the same recombination process will begin on the second heavy chain gene located on the other chromosome 14. If the second attempt at heavy chain rearrangement is unsuccessful, the B-precursor cell will die.

The next step in the rearrangement process occurs in the late stage of B-cell development is the rearrangement of one of the kappa immunoglobulin light chain genes, located on chromosome 2p12. The kappa light chain gene structure differs slightly from the heavy chain gene: first, the kappa gene lacks any known D regions, and second, there is only one C region gene (Fig. 11.3). If the initial kappa V-J rearrangement is a “productive” rearrangement, the transcription and translation process will lead to the formation of a complete immunoglobulin light chain. This light chain then will combine with the heavy chain to form an intact immunoglobulin molecule. If, however, the first V-J rearrangement is nonproductive, another V-J rearrangement is attempted on the second kappa light chain gene on the other chromosome 2p12. If both kappa rearrangements are nonproductive, the light chain gene rearrangement process begins anew with the lambda light chain gene on chromosome 22q11. Like the kappa gene, the lambda light chain gene structure lacks any known D regions. In contrast to the kappa gene, the lambda gene includes six C regions, each having a high degree of homology to one another (Fig. 11.3). If the light chain gene rearrangement process fails with both lambda genes, immunoglobulin differentiation cannot proceed and the cell is destined to die in the bone marrow. The sequential rearrangement of kappa before lambda accounts for the normal two-to-one ratio of kappa-to-lambda positive B-cells in peripheral blood. After transcription, the rearranged V-D-J or V-J segments undergo RNA splicing, juxtaposing the V-D-J or V-J segments with the C region. The Cμ gene is initially juxtaposed with the rearranged V-D-J sequence, because it is the first 5′ constant region exon. Only Cμ will be spliced into this V-D-J sequence, and the remaining constant regions will be “ignored” during transcription. Therefore, the μ heavy chain constant region, i.e., IgM, will be the initial immunoglobulin expressed by the B-lymphocyte.

Isotype Switching

The process by which B-cells acquire other surface immunoglobulin isotypes is called isotype switching. Although these cells have different heavy chain constant regions, they still maintain the same antigen binding specificity because there has been no change in the variable region of the antibody. One mechanism of isotype switching involves the transcription of a long V-D-J-Cμ-Cδ transcript; this results in the formation of a mixture of V-D-J-Cμ and V-D-J-Cδ mRNA and, consequently IgM and IgD immunoglobulin. Another mechanism of isotype switching involves deletion of intervening C regions between the V-D-J rearrangement and the C region gene of choice.

T-Cell Receptor Genes

The development of the mature T-cell begins as a bone marrow-derived thymocyte precursor, which migrates to the thymus where subsequent maturation occurs. In the thymus, T-cells that express the preferred T-cell receptors with appropriate MHC molecule are selected for further differentiation, and potential “self” reacting T-cells are removed.

All four T-cell receptor genes (alpha, beta, gamma, and delta) undergo a recombination process involving V, D, J, and C regions, similar to the immunoglobulin heavy and light chain genes. However, there are some important differences that require understanding in order to detect T-cell receptor gene rearrangement.

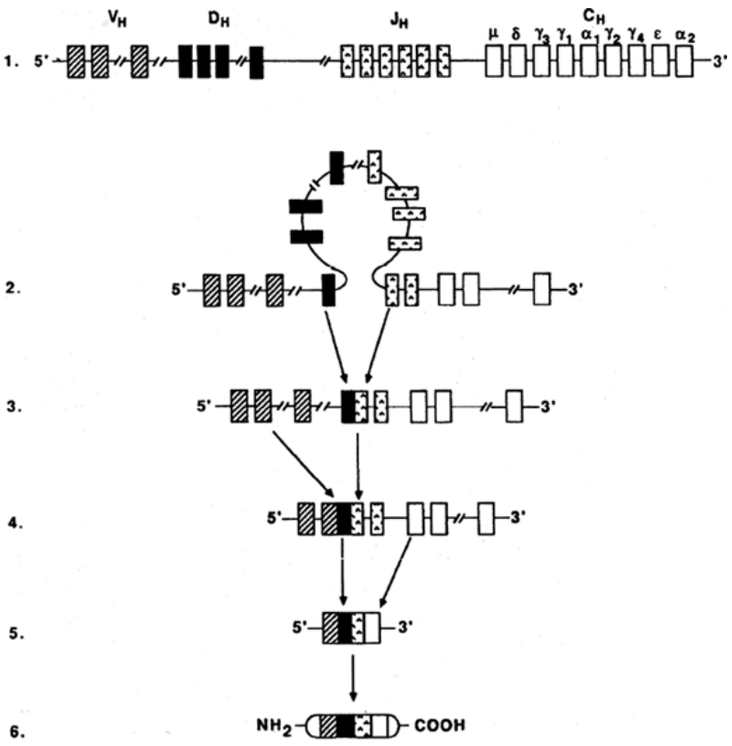

FIGURE 11.2. Rearrangement of the immunoglobulin heavy chain gene. The hatched boxes [variable (V)], solid boxes [diversity (d)], stippled boxes [joining (J)], and open boxes [constant (C)] represent the exons of the respective gene regions. 1) germline configurations; 2) the initial step in D-J rearrangement with “looping out” of intervening DNA, and 3) eventual D-J recombination; 4) V-D-J rearrangement; 5) RNA transcription and splicing step, and 6) immunoglobulin heavy chain production.

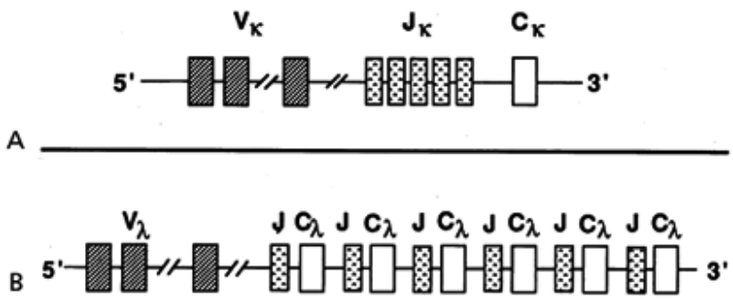

FIGURE 11.3. Structure of the immunoglobulin kappa (**A**) and lambda (**B**) light chain genes. See Figure 11.1 and Figure 11.2 for general explanation of figure characters.

There are at least two types of T-cell receptors expressed by T-lymphocytes. The most common T-cell receptor is composed of alpha (α) and beta (ß) chains, while the second type of T-cell receptor is composed of a gamma (γ)/delta(δ) heterodimer, α/ß positive T-cells predominate within the peripheral blood and lymph nodes, while γ/δ-positive T-cells predominate in epithelial and epidermal locations (5). This differential localization of the T-cell population suggests that each type of T-cell receptor serves a different role in the immune system. Both the α and δ chain genes are located on chromosome 14q11, with the δ chain gene located

entirely within the α gene. The ß chain gene is located on chromosome 7q34, and the γ chain gene is located on chromosome 7p15. The ß and δ genes consist of V, D, J, and C regions, while the α and γ genes are composed of V, J, and C regions. Each of these T-cell receptor genes undergoes recombination in a fashion similar to the immunoglobulin genes, leading to the production of an intact, heterodimeric, T-cell receptor protein (Fig. 11.4).

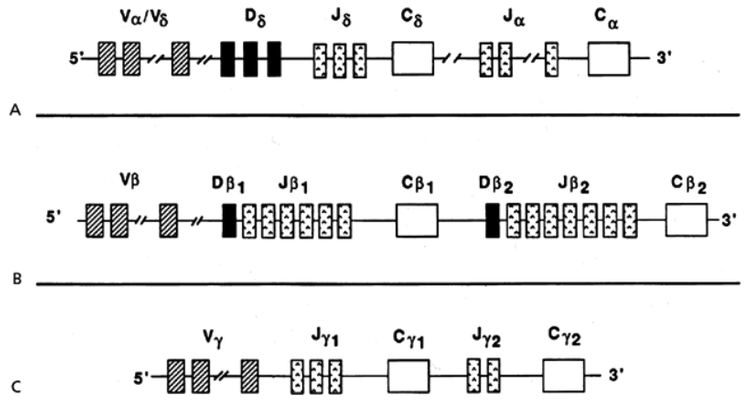

FIGURE 11.4. Structure of the T-cell receptor genes. See Figure 11.1 and Figure 11.3 for explanation of Figure characters. (**A**) shows the structure of the Tα/δ gene on chromosome 14q11. (**B**) shows the germline configuration of the Tß gene. (**C**) shows the Tγ gene structure.

T-α Gene

The α gene consists of approximately 100 V regions and over 100 J regions, which are spread over a 1,000 kb portion of chromosome 14 (Fig. 11.4). The large gene size and the numerous J regions have contributed to the difficulty in studying the α chain gene. The V-J recombination subsequently rearranges with a single α constant region, Cα, to form a complete α transcript.

T-ß Gene

In contrast to the other members of the immunoglobulin supergene family, the ß chain gene consists of two separate loci, $ß_1$ and $ß_2$, each composed of its own D, J, and C regions (Fig. 11.4). The $ß_1$ and $ß_2$ regions recombine only within their own groups, i.e., $Dß_1$-$Jß_1$-$Cß_1$ or $Dß_2$-$Jß_2$-$Cß_2$. The two constant regions, $Cß_1$ and $Cß_2$, are highly homologous, suggesting that the constant region of the ß receptor protein is functionally similar regardless of whether $Cß_1$ or $Cß_2$ is expressed. Rearrangement of Vß within the $ß_2$ locus is associated with deletion of the $Dß_1$-$Jß_1$-$Cß_1$ locus. As with the immunoglobulin family, if the initial V-D-J rearrangement of the ß chain gene is unsuccessful, an attempt will be made to rearrange the ß chain gene on the other chromosomal allele.

T-γ Gene

The γ chain gene was initially discovered in a small subset of circulating T-cells that were CD3 positive, but that lacked CD4, CD8, and the α/ß T-cell receptor. The CD3-associated T-cell receptor from this group of cells was found to have some similarities to the ß chain gene, but offered less diversity, suggesting that it was based on a more primitive recognition system. The γ gene contains 11 V regions and only two J loci, which leads to a limited diversity in this gene subset (Fig. 11.4). Thus, a polyclonal mixture of T-lymphocytes can demonstrate what appear to be oligoclonal rearrangements of the Tγ gene, as only seven or eight possible gene combinations can form. Consequently, gene rearrangement analysis of the Tγ gene must be interpreted with great caution.

T-δ Gene

The δ gene has a unique structure, as it is located entirely within the α chain gene; the V, D, and J regions of the δ locus are situated between the V and J regions of the α gene (Fig. 11.4). Similar to the γ chain gene, only 10 Vδ regions have been identified. The δ gene locus contains only one C region, which is structurally similar to Cα. As should be obvious from the genomic structure of the α/δ locus, a V-Jα rearrangement will effectively delete the entire δ gene. Thus, it would be impossible to express the δ receptor in a cell that has a functional α/ß receptor. Because of their location and similar structure, it has been hypothesized that the α gene evolved as a result of a δ gene duplication.

Clonality

Clonality is an essential concept to understand before interpreting Southern blot hybridization studies. A clonal process is defined as a proliferation of daughter cells originating from a single precursor cell, each having identical phenotypes and growth characteristics as that original precursor cell. Normal B- and T-lymphocytes are polyclonal proliferations, with each lymphocyte having its own unique structure and functional characteristics. Theoretically, each lymphocyte within an individual should have

its own unique molecular structure and, thus, be capable of responding to a different antigenic stimulation.

As stated earlier in the immunoglobulin and T-cell receptor section, there are literally millions of different potential recombinations that can occur among the V, D, and J regions in a gene. In addition to these random associations among V-D-J, N-region diversification and somatic gene mutations can occur that further add to the tremendous diversity of the system. N-region diversification is a terminal deoxynucleotidyl transferase (TdT)-dependent process that results in additions or deletions of nucleotides at the V-J or V-D-J junctions.

Laboratory Analysis of DNA

Commonly used molecular assays used for DNA extraction, restriction endonuclease digestion, and Southern blot transfer and hybridization studies previously were discussed. Two important concepts that must be thoroughly understood before interpreting gene rearrangement studies are: (i) probe structure and location, and (ii) the restriction enzyme map of the gene.

The most commonly used immunoglobulin heavy chain gene probe is complementary to the J_H and Jk region. Thus, when a clonal V-D-J rearrangement has occurred, the J_H probe will bind to the segment: the J_H probe will recognize any or all of the six J_H exons.

The T-cell receptor gene probes work in a fashion similar to their immunoglobulin gene equivalents. Both Jß and Cß probes have been used in the evaluation of the ß chain gene. Because the two Jß regions and the two Cß regions each have a high degree of homology, the Jß and Cß probes will bind to both Jß and both Cß regions, respectively.

Immunoglobulin Gene Rearrangement

A knowledge and understanding of the restriction enzyme map of the desired gene is essential before a Southern blot study can be interpreted. These maps localize various restriction enzyme sites relative to the gene of interest as well as to each other. The whole concept of gene rearrangement refers to the process by which a restriction enzyme site is “rearranged” relative to its previous location, thus changing the size and blot location of a particular hybridization fragment. For example, the immunoglobulin heavy chain gene contains a *Bam*HI restriction enzyme site, located 5′ upstream from the joining region, and another BamHI site, located 3′ downstream from the Cμ constant region. This results in a germline 17 kb fragment after digestion with *Bam*HI. During the process of D-J or V-D-J rearrangement, the recombination into the J region removes the intervening sequences 5′ to the J region area, thus eliminating the initial 5′ BamHI restriction site (Fig. 11.5). Consequently, the germline 17 kb fragment seen with *Bam*HI-cut DNA then would be rearranged to either a larger or smaller fragment, depending on where the next, random 5′ *Bam*HI site is located. Because of its different size, the rearranged fragment will migrate to a different location in the blot and is thus referred to as a rearranged immunoglobulin heavy chain gene. Southern blot analysis of clonal rearrangements of either the immunoglobulin or T-cell receptor genes is capable of detecting a clonal proliferation, if the specimen being studied contains five percent monoclonal cells.

PCR Detection of Monoclonality

As discussed earlier, diversity of the antigen receptor gene is accomplished by random selection of one of the V, D, and J region genes. Because of this random selection of the V region genes, PCR methods for amplification of immunoglobulin heavy chain genes is less sensitive in determination of clonality compared to Southern blotting because it is technically very difficult to generate primers to bind efficiently to all of the V region sequences. In contrast, PCR is more sensitive for detection of monoclonal population if primer used for the V consensus region amplification anneals successfully during the PCR amplification. To be able to increase the sensitivity by PCR amplification, multiple V region primers are designed to bind to the consensus region of immunoglobulin genes, which are referred to as framework (FR) regions. The most common targets include FR3 and FR1. The use of consensus primers allows greater sensitivity for the priming of the many V region genes. In polyclonal proliferation, PCR amplification of Ig genes using consensus sequence primers will produce no prominent band because all of the lymphocytes amplified by PCR represent different length of segments of DNA amplified using V (FR3 or FR1) and J_H primers. In the presence of a monoclonal population, however, these will be a prominent single band visualized by electrophoresis and ethidium bromide staining. There is a significant difference in evaluation of monoclonality between the agarose gel and polyacrylamide gel electrophoresis (PAGE) analysis. PAGE allows a much better separation of the monoclonal proliferation and is recommended for monoclonality assessment. Although gene rearrangement studies are quite useful for assessment of lymphoma or leukemia, there are important considerations in the utility of this assay. Gene rearrangements can be seen in acute myelogenous leukemia and myelodysplastic disorder; hence it should not be used for differential diagnosis between myeloid and lymphoid leukemic process. Also, some of the high-grade lymphoid tumors have promiscuous gene rearrangement (6, 7). Another important aspect of the PCR analysis is the consideration of clonal evolution that describes development of a separate clone in a previously established tumoral clone and giving rise to different rearrangement of the antigen receptor genes (8). This is believed to be secondary to continuous active state of recombinase, which is giving rise to new rearrangements.

T-Cell Receptor Gene Rearrangement

In the T-cell receptor gene system, a similar rearrangement process occurs. The most commonly used gene probe for T-cell receptor gene rearrangement studies are those complementary to the T-cell receptor ß chain gene. In this gene, there is a *Bam*HI restriction enzyme site 5′ of the $Jß_1$ region and 3′ of $Cß_2$: this *Bam*HI fragment, therefore, surrounds both Jß-Cß loci. Similar to that described with the immunoglobulin heavy chain gene, the 5′ upstream *Bam*H1 enzyme site is eliminated during the process of either a D-J or V-D-J rearrangement. Consequently, the germline fragment seen with *Bam*HI-cut DNA would be rearranged

to either a larger or smaller fragment. Although this enzyme would appear ideal, the large size of the germline band (23 kb) seen with *Bam*HI may be difficult to distinguish from rearranged fragments. Because of this interpretative difficulty, it is essential that multiple restriction enzymes be used when evaluating the T-ß chain gene. Most laboratories use *Bam*HI, *Eco*RI, and *Hind*III restriction enzymes when evaluating for T-cell receptor gene rearrangements.

The *Eco*RI restriction enzyme sites for the T-cell receptor ß chain gene are located 5′ of the JB_1 region, 3′ of the CB_1 region, and both 5′ and 3′ of CB_2 (Fig. 11.6A); this will yield a germline configuration of 11 kb and 4 kb bands when probed with a Tß constant region probe (Fig. 11.6B). When either a DB_1-JB_1 or Vß-DB_1-JB_1 rearrangement has occurred, the most 5ß *Eco*RI restriction site is removed, thus changing the size of the germline 11 kb band (Fig. 11.6C). The 4-kb band is not changed, as the *Eco*RI sites around (two are not disrupted following either DB_1-JB_1 or V-DB_1-JB_1 rearrangement).

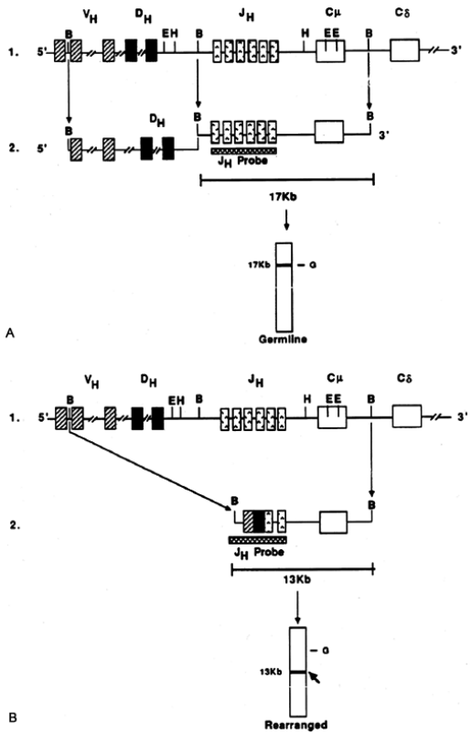

FIGURE 11.5. Restriction enzyme map of the immunoglobulin heavy chain gene. The thin vertical lines represent recognition sites for *Bam*HI (*B*), EcoRI (*E*), or *Hind*III (H). See Figure 11.1 and Figure 11.3 for an explanation of other figure characters. (**A**) The heavily stippled box represents the J_H probe. When cut with *Bam*HI, the unrearranged immunoglobulin heavy chain gene leads to a germline 17 kb band. (**B**) Following V-D-J rearrangement, the original 5′ *Bam*HI site disappears and is replaced by the next random *Bam*HI site, leading in this example to a rearranged 13 kb fragment as detected by the J_H gene probe. Other rearrangements might yield *Bam*HI fragments of smaller or larger size.

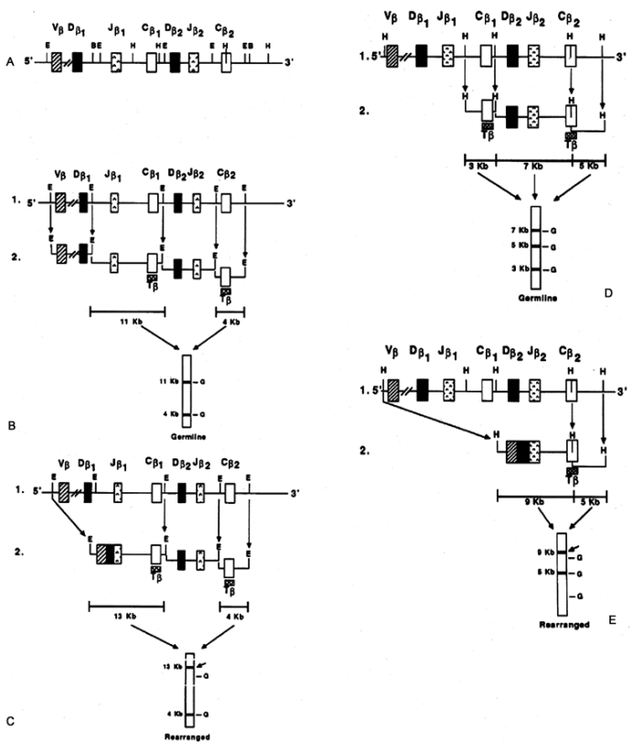

FIGURE 11.6. Tß chain rearrangement analysis (**A**) and by EcoRI (**B, C**) and HindIII (**D, E**) are shown. Restriction enzyme map of the Tß chain gene. See Figure 11.1 and Figure 11.4 for explanation of figure characters. (**B**) The heavy stippled box represents the Tß constant region probe. The germline configuration shows two bands following *Eco*RI (E) enzymatic digestion, as the probe will bind to both Cß regions. (**C**) Following Vß-DB_1-JB_1 rearrangement, the 5′ *Eco*RI site disappears and is replaced by the next random *Eco*RI site. This leads to a rearranged 13 kb fragment (arrow). The 4 kb fragment of CB_2 has not been affected by this rearrangement process. (**D**) The germline configuration shows three bands following *Hind*III (H) enzymatic digestion, as the probe will bind to both Cß regions. (**E**) Following the Vß-DB_2-JB_2 rearrangement, the HindIII site 3′ of CB_1 is deleted and is replaced by the next random *Hind*III site. This leads to a rearranged fragment of 9 kb size (arrow) and deletion of the 3-kb band. The 5-kb fragment of CB_2 has not been affected by this rearrangement process.

The limitation of using *Eco*RI for T-cell receptor ß chain analysis is its inability to detect rearrangements involving the ß2 locus. When a DB_2-JB_2 or Vß-DB_2-JB_2 rearrangement has occurred, the ß1 locus and, thus, the *Eco*RI restriction sites around the ß1 locus, is deleted, including the germline 11 kb band. However, this D-J or V-D-J rearrangement into the ß2 locus will not disrupt either of the *Eco*RI restriction sites surrounding the CB_2 region. Thus, with a ß2 rearrangement, the 4-kb band is not changed and one is left with an allelic deletion of the 11 kb band. This deletion will not be evident with rearrangement studies if the other allele remains in germline configuration or if there are significant numbers of non-T-lymphocytes in the specimen being analyzed, which could contribute to the germline band.

To overcome this limitation, *Hind*III usually is used as an additional restriction enzyme for T-cell receptor ß chain gene analysis (Fig. 11.6D). The *Hind*III restriction enzyme sites are located immediately 5′ and 3′ of Cß1, within the CB_2 segment, and 3′ of CB_2; this will yield germline bands of 3 kb, 5 kb, and

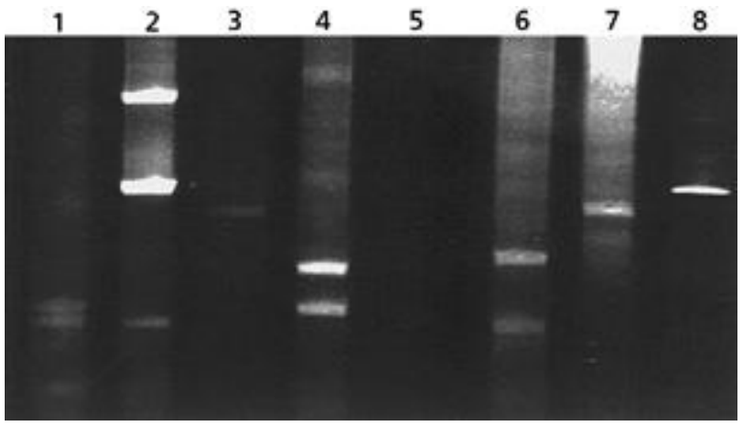

FIGURE 11.7. Temporal temperature gradient electrophoresis (TTGE) analysis of various lymphoid disorders. DNA is polymerase chain reaction (PCR) amplified by GC-clamped primers. Small aliquots of amplicons then were separated by a denaturing polyacrylamide gel and gradients of increasing temperature. Distinct bands detected under ultraviolet light demonstrate evidence for monoclonality. Sample in lane 5 is polyclonal while others are example of T-cell neoplasm.

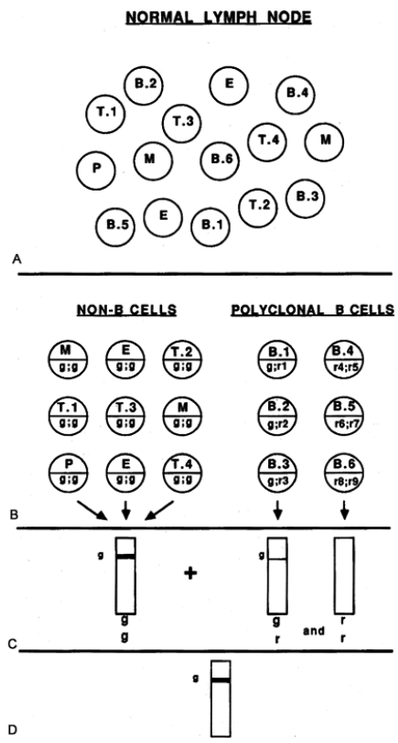

FIGURE 11.8. Schematic drawing of a normal lymph node and resulting immunoglobulin gene rearrangement studies. (A) A normal lymph node consists of a mixture of polyclonal B-cells (B.1-B.6), polyclonal T-cells (T.1-T.4), macrophage/histiocytes (M), polymorphonuclear granulocytes (P), and endothelial cells (E). (B) Schematic depiction of gene rearrangement analysis applied to cells from a normal lymph node. The non-B-lymphocytes are shown on the left-hand side and consist of T-cells, macrophages, neutrophils, and endothelial cells. These cells retain their immunoglobulin genes in germline configuration. The polyclonal B-cells, depicted on the right-hand side, consist of a mixture of B-cells (B.1-B.3) that retain one immunoglobulin gene allele in germline configuration while rearranging the other allele in a unique recombination (r1-r3). The remaining B-cells (B.4-B.6) have attempted to rearrange both immunoglobulin alleles (r4-r9), with only one allele per cell exhibiting a "productive rearrangement." (C) This schematic of a Southern blot audioradiograph shows that the non-B-cells contribute to the formation of one germline band because both alleles remain in germline configuration. Some polyclonal B-cells have one germline allele and one uniquely rearranged allele; the germline alleles will contribute to the formation of a germline band on Southern blotting, while the single-copy rearranged alleles are undetectable by this method. The remaining B-cells with two rearranged alleles also exhibit no detectable bands, as each rearrangement again is a unique recombination. (D) Final Southern blot resulting from the combination of the non-B-cell component and polyclonal B-cells, therefore, leads to a single germline configuration with no rearranged bands identified.

7 kb when probed with a TB constant region probe. If a rearrangement into the B1 locus has occurred, none of the *Hind*III restriction enzyme sites are affected, thus giving a germline configuration on Southern blot. However, rearrangement into the B2 locus will remove the *Hind*III site between CB_1 and DB_2, thus changing the size of the germline 7 kb band (Fig. 11.6E). The 3 kb band will be deleted along with the B1 locus; the 5 kb band will be unchanged as the *Hind*III sites surrounding CB_2 are unaffected by the rearrangement process.

Thus, for T-cell receptor B chain gene analysis, *Bam*HI restriction enzyme analysis will show rearrangements involving either the B1 or B2 locus. However, the large germline band seen with *Bam*HI presents its own unique problem. Analysis with *Eco*RI restriction enzyme will demonstrate rearrangements of the B1 locus, but will not show a rearranged band if the B2 locus is involved. This is in contrast to *Hind*III restriction enzyme analysis, which will demonstrate B2 loci rearrangements, but fail to demonstrate B1 rearrangements.

Although in B-cell neoplasms, clonality can be determined using surface markers such as kappa and lambda light chains, the T-cell clonality cannot be detected by these methods. Apparent loss of T-cell antigen expression is considered to be good evidence for T-cell malignancy; however, some cases may have this feature without presence of malignant process. Hence, the molecular biologic studies for the determination of T-cell clonality are essential for lesions suspicious for T-cell malignancy.

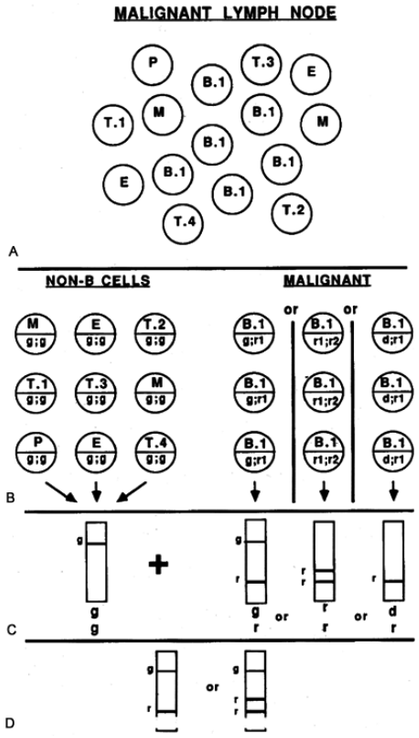

FIGURE 11.9. Schematic drawing of a malignant lymph node and resulting immunoglobulin gene rearrangement studies. (**A**) A malignant lymph node consists of a mixture of monoclonal B-cells (B.1), polyclonal T-cells (T.1–T.4), macrophage/histiocytes (M), polymorphonuclear granulocytes (P), and endothelial cells (E). (**B**) Schematic depiction of gene rearrangement analysis applied to cells from a neoplastic lymph node. The nonmalignant cells are shown on the left-hand side; these cells retain their immunoglobulin genes in germline configuration. The monoclonal B-cells depicted on the right-hand side consist of monoclonal B-cells that may be in one of three possible configurations: (i) the cells may have one rearranged immunoglobulin allele and the other allele in germline configuration; (ii) the cells may have both immunoglobulin alleles rearranged, with only one productive rearrangement; or, (iii) one allele may be deleted and the other immunoglobulin locus rearranged. (**C**) This schematic of a Southern blot audioradiograph shows that the few reactive cells contribute to the presence of a germline band. The monoclonal B-cells will have one of three possible configurations depending on the status of both immunoglobulin alleles. (**D**) Final Southern blot resulting from combination of the reactive cells and monoclonal B-cells lead to a faint germline band, contributed from the few background normal cells and possibly a germline allele in the monoclonal B-cells. The dominant band, however, appears rearranged.

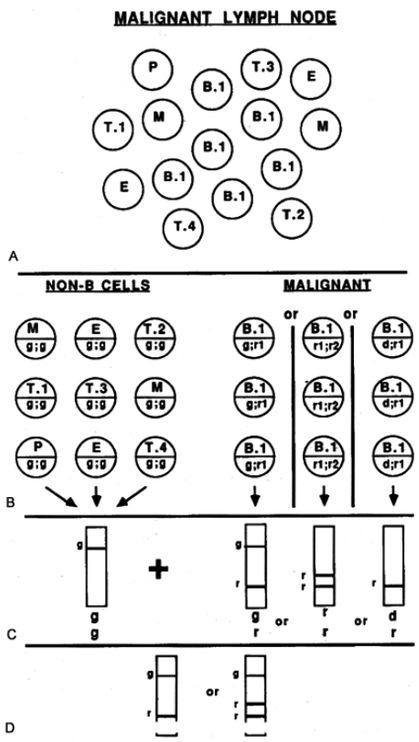

FIGURE 11.9. Schematic drawing of a malignant lymph node and resulting immunoglobulin gene rearrangement studies. (**A**) A malignant lymph node consists of a mixture of monoclonal B-cells (B.1), polyclonal T-cells (T.1–T.4), macrophage/histiocytes (M), polymorphonuclear granulocytes (P), and endothelial cells (E). (**B**) Schematic depiction of gene rearrangement analysis applied to cells from a neoplastic lymph node. The nonmalignant cells are shown on the left-hand side; these cells retain their immunoglobulin genes in germline configuration. The monoclonal B-cells depicted on the right-hand side consist of monoclonal B-cells that may be in one of three possible configurations: (i) the cells may have one rearranged immunoglobulin allele and the other allele in germline configuration; (ii) the cells may have both immunoglobulin alleles rearranged, with only one productive rearrangement; or, (iii) one allele may be deleted and the other immunoglobulin locus rearranged. (**C**) This schematic of a Southern blot audioradiograph shows that the few reactive cells contribute to the presence of a germline band. The monoclonal B-cells will have one of three possible configurations depending on the status of both immunoglobulin alleles. (**D**) Final Southern blot resulting from combination of the reactive cells and monoclonal B-cells lead to a faint germline band, contributed from the few background normal cells and possibly a germline allele in the monoclonal B-cells. The dominant band, however, appears rearranged.

Most recent amplification studies using PCR primers with GC-clamps and subsequent analysis by denaturing density gradient electrophoresis (DDGE) or temporal temperature gradient electrophoresis (TTGE) has significantly improved the TCR analysis of the TCR genes (9, 10). Assay based on the detection of PCR products of TCR genes by DDGE requires preparation of a gradient gel. Detection of a predominant monoclonal DNA fragment by TTGE relies upon the same principle in which denaturing gradient electrophoresis is based. Both TTGE and DDGE allow the separation of DNA fragments based not only on their length, but also the sequence of the fragments (Fig. 11.7). Using TTGE, the PCR fragments are electrophoresed through a denaturing gel containing urea as the denaturant. During TTGE, the temperature of the gel is increased gradually

in contrast to the DDGE in which the gel is prepared by a gradient of denaturant. Change in temperature results in a linear temperature gradient over the length of the electrophoresis run.

Both in DDGE and TTGE, the detection of similar size but different DNA fragments is based on the melting temperature of the target fragments being analyzed. In a denaturing condition of either DDGE or TTGE, double-stranded DNA fragments amplified by PCR is subjected to conditions that allow melting the fragments in discreet segments referred to as melting domains. The melting temperature (Tm) of these domains is sequence specific. Therefore, the DNA fragment partially separates (melts) when the Tm of the lowest melting domain of the fragment is reached. This partial melting causes branching in the DNA fragments, hence reduces the mobility of the fragments in a polyacrylamide gel.

Figure 11.8 and Figure 11.9 demonstrate a schematic for understanding the rearrangement process in a normal and malignant lymph node, respectively. Figure 11.10 demonstrates example of Southern blot detection of T-cell receptor gene rearrangement in a patient with peripheral T-cell lymphoma.

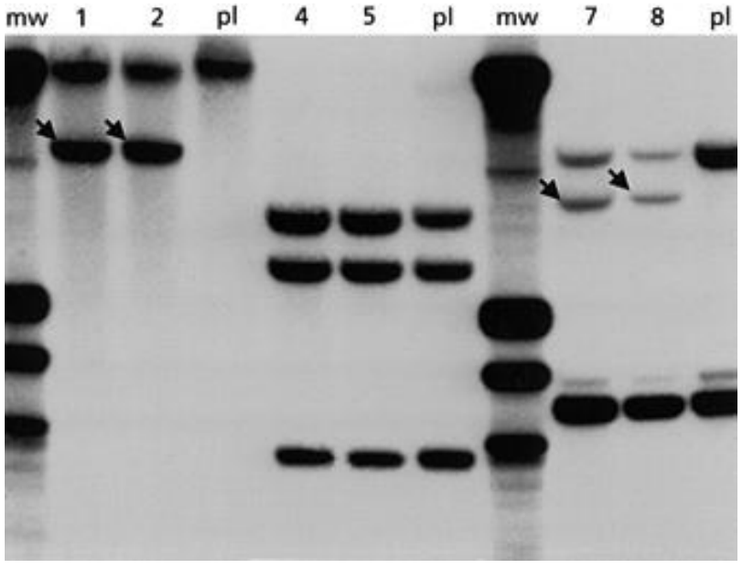

FIGURE 11.10. Southern blot detection of T-cell receptor gene rearrangement in a patient with peripheral T-cell lymphoma. Two separate lesions were investigated for evidence of a monoclonal T-cell population. Restriction digestion in the *Bam*HI (1, 2) and EcoRI (7, 8) show extra bands (arrow), which are not detected in the lane with DNA isolated from placenta (pl). Although *Hind*III digest (4, 5) shows no extra band, two rearranged bands detected by *Bam*HI and *Eco*RI are sufficient to establish clonality. Because both lesions show similar banding pattern, these lesions are considered to be clonally identical.

Non-Hodgkin's Lymphoma

The non-Hodgkin's lymphomas (NHLs) are a diverse collection of lymphoid malignancies with varied etiology, pathogenesis, and clinical course. The diversity of the NHLs is illustrated by recent classifications based primarily on morphology, immunophenotype, and chromosomal abnormalities. Significance of chromosomal abnormalities has been shown by these classifications that have taken into consideration molecular aberrations associated with specific morphologic entities (11, 12). With the currently available molecular assays, genetic abnormalities of various subtypes of lymphomas can be identified in a significant number of lesions (Table 11.1).

TABLE 11.1. COMMON RECURRING CHROMOSOMAL TRANSLOCATIONS IN NON-HODGKIN LYMPHOMA

Disease	Translocation	Oncogene Involved
Small lymphocytic lymphoma	t(14;19)(q32;q13.1)	BLC-3
Mantle cell	t(11;14)(q13;q32)	CCNDI (Cyclin D1)
Lymphoplasmacytic	t(9;14)(p13;q32)	PAX5
Marginal zone	t(11;18)(q21;q21)	Unknown
Follicle center cell	t(14;18)q32;q31)	BCL-2
Burkitt	t(8;14)(q24;q32)	C-MYC
	t(2;8)(q12;q24)	C-MYC
	t(8;22)(q24;q11)	C-MYC
Diffuse large cell	t(3;-)(q27;-)	BCL-6
Anaplastic large cell	t(2;5)(p23;q35)	NPM-ALK

The realization of association between specific chromosomal alterations, particularly chromosomal translocations, had lead to identification of dysregulated genes because of specific genetic abnormalities during the last decade. In this section, these common chromosomal and molecular abnormalities associated with NHLs are described by grouping under specific histopathologic subtypes.

Many chromosomal translocations in B-cell NHL result in juxtaposition of cellular oncogenes to the regulatory portion of immunoglobulin genes or equivalent loci. In general, coding regions of the oncogenes are not interrupted by the translocation. Therefore, the overall consequences of the translocation appear to be deregulated expression of the gene product; the gene may be expressed at inappropriate levels compared with normal lymphocytes of the equivalent stage of B-cell differentiation and/or at inappropriate times when unaffected genes usually are switched off. However, in some lymphomas, gene products involved in translocations also have been found normally in lymphoid tissues at considerable levels. Attempts have failed to demonstrate clear differences at the level of expression of a particular gene between lymphoma tissues carrying a translocation involving the relevant gene and those lacking the gene rearrangement (13). For instance, Bcl-6 protein is expressed in germinal center B cells as well as in a variety of germinal-center-derived lymphoma tissues independently of BCL6 gene rearrangement (14). This suggests that the loss of regulation also is an important factor in lymphomagenesis.

Chronic Lymphocytic Leukemia

The most frequent cytogenetic aberrations in chronic lymphocytic leukemia (CLL) are trisomy 12 and structural abnormalities involving the long arm of chromosome 13 (13q12-q32) on which retinoblastoma gene is located. Their incidence ranges 12% to 32% for trisomy 12 and 10% to 28% for 13q abnormalities. Trisomy 12 is more commonly associated with atypical morphology, higher proliferative activity, advanced disease, and short survival; however, this is not confirmed in a recent study using both karyotyping and fluorescent *in situ* hybridization (FISH) (15, 16 and 17). On the other hand, 13q deletion has been associated with typical morphology, early stage, and longer survival (18). These abnormalities have been considered as presence of single independent clones for specific subtypes of CLL. Molecular studies have demonstrated that monoallelic loss of RB1 at 13q14 band is found in about 30% of cases, but a higher incidence of deletions affecting the interval between D13S319 and the D13S25 loci also has been described (18). FISH analysis has become a more reliable assay for evaluation of these chromosomal aberrations. In fact, a recent study has demonstrated trisomy 12 in hematopoietic stem cells suggesting that the precursor cells in some of CLL patients is much earlier in development than previously considered (19, 20). It is likely that molecular-based techniques will find a higher incidence of and perhaps novel genetic abnormalities in CLL due to its low proliferation rate.

Lymphoplasmacytoid Lymphoma

Close association of t(9;14)(p13;q32) with small lymphocytic lymphoma with plasmacytoid differentiation was demonstrated in a large series of karyotypically analyzed NHL (21). Initial molecular analysis of t(9;14) suggested the PAX5 gene as the responsible gene by two independent groups (22, 23). The t(9;14) translocation involves the PAX (paired homeobox) transcription factor family which has been shown to be important for the embryonal development and organogenesis (24). PAX 5 gene shows restrictive expression in tissues mainly showing expression in the fetal brain and liver during embryogenesis, but only in the lymphocytes and testes following birth. A number of other reciprocal chromosomal fusion partners with the 9p13 breakpoint also have been described including 1q25, 3q27, 7q11, 12q13, 12q21, 10p13, and 9q13. The PAX5 gene encodes the BSAP (B-cell-specific activator protein), which is a key regulator of B-cell development and differentiation (25). Functional loss of PAX 5 causes maturation arrest in the lymphoid cells at the pro B-cell stage. In contrast, overexpression of the gene results in the proliferation of the splenic B-lymphocytes.

A high prevalence of chronic hepatitis C virus (HCV) infection recently has been shown in NHLs, most of which belong to the lymphoplasmacytoid lymphoma/immunocytoma subtype (26). The HCV also is considered to be a major etiologic factor of type II mixed cryoglobulinemia (MC), which is characterized by an underlying proliferation of monoclonal B cells (27). Type II MC frequently evolves into overt B-cell NHL, suggesting that chronic HCV infection can lead to both a benign and a malignant lymphoproliferative disorder. The pathogenesis of HCV and lymphomagenesis currently is unknown.

Mantle Cell Lymphoma

Mantle-cell lymphomas (MCL) are associated with a characteristic chromosomal translocation, t(11;14)(q13;q32). This translocation involves rearrangement of the bcl-1 proto-oncogene from chromosome 11 to the immunoglobulin heavy chain gene on chromosome 14, resulting in an overexpression of cyclin D1 mRNA (also known as bcl-1 and PRAD1) (28, 29). Cyclin D1 overexpression is considered to be directly involved with the lymphomagenesis. D-type cyclins physically associate with cyclin-dependent kinases (CDK4 and CDK6) and facilitate lymphoid proliferation. Upon cyclin-D1 activation, the retinoblastoma (RB) tumor suppressor protein (regulator of E2F transcription factor) loses its interaction with transcription factors leading to upregulation of E2F and promotion of S-phase progression and shortened G1 phase.

The bcl-1 locus is rearrangement detected in 50% to 80% of MCLs by using Southern blot or 75% to 80% by cytogenetics studies. This can be further increased using FISH. Detection of overexpression of cyclin D1 by immunohistochemical studies and molecular detection of bcl-1 translocation are very useful for the diagnosis of mantle cell lymphomas or confirmation of histologic suspicion. The breakpoints are widely scattered on chromosome 11q13; however, the majority of the breakpoints are localized to a 1-kb DNA segment known as the major translocation cluster (MTC) (30). Within the MTC, the breakpoints occur in a relatively small region on chromosome 11 and the 5′ area of one of the IgH joining (JH) regions on chromosome 14. PCR can be utilized to amplify *bcl-1* translocation; however, some of the breakpoints falling outside the MTC cannot be identified with PCR (31). PCR technique has been demonstrated to be sensitive when the MTC is present, however, because of the lack of involvement of MTC, the technique has a low sensitivity for documentation of bcl-1 translocation. It is estimated that only in 33% to 50% of patients with MCL, the breakpoints could be detected by PCR using primers in the region of the MTC. Although differential detection of cyclin D1 by quantitative RT-PCR has been reported as a diagnostic tool, this has not become a practical assay because it requires sampling of whole tissue, which also contains nonneoplastic both reactive and stromal cells. FISH-based assays have found a higher rate of *bcl-1* translocation than PCR assays, likely because of the broader-based probes that can be used (32, 33).

Follicular Lymphoma

The *bcl*-2 translocation is present in 80% to 85% of follicular lymphomas (FL) and up to 30% of diffuse B-cell lymphomas. Approximately 65% of *bcl-2*rearrangements in FL occur at the major breakpoint region (*MBR*) located in the untranslated 3′ end of the last exon and in approximately 10% to 20% of cases, the rearrangement occurs in the minor cluster region (*mcr*) located approximately 30 kb downstream of the *bcl-2*gene (Fig. 11.11) (34, 35 and 36). In a few cases, rearrangements occur at other sites such as the variant cluster region at the 5′ end of the *bcl-2* gene. Tight clustering of the breakpoints at *MBR* and *mcr*, as well as the availability of consensus sequences of the *JH* segments of the *IgH* make this a practical target for PCR amplification. In fact, it is possible to use two universal primers (one for each breakpoint) along with a primer derived from JH region to amplify the majority of the translocations at *MBR* and *mcr*, with minority of translocations failing to be amplified. The biological and clinical significance of differences in breakpoint regions in FL is unclear. However, a recent study suggested that FL patients with *MBR* or *mcr* type of translocation were less likely to show complete remission compared to patients with germline pattern (37). Expression of *Bcl-2* protein can be seen without translocation, as evidenced by its expression in a number of normal tissues, as well as a number of other lymphoproliferative disorders without a t(14;18) (13). A high level of *Bcl-2* protein confers a survival advantage on B cells by inhibiting apoptosis and more generally may block a common cell death pathway induced by chemotherapy, conferring clinical drug resistance on cells over-expressing *Bcl-2* protein. One of the hypotheses for the gene rearrangement is the presence of sequences near the *bcl-2* gene, which resembles the signal sequences recognized by the recombinase enzyme system involving excision of DNA during antigen receptor gene rearrangement. These sequences are 3′ of the *bcl-2* gene such that the gene itself is translocated as a whole functional unit in close proximity to the immunoglobulin enhancer gene regulatory region. This is believed to cause overexpression of *bcl-2* gene. Overexpression of *bcl-2* does not allow differentiation of FCL from other indolent lymphomas because they also

commonly demonstrate expression of this protein. Hence, molecular detection of *bcl-2* translocation may be required for accurate classification of some lymphomas. Fresh or frozen unfixed tissue usually is required for molecular assessment of *bcl-2* translocation with Southern blot analysis in lymphoid tissues, but detection of *bcl-2* translocation with PCR can be performed with formalin-fixed tissue embedded in paraffin (Fig. 11.11c).

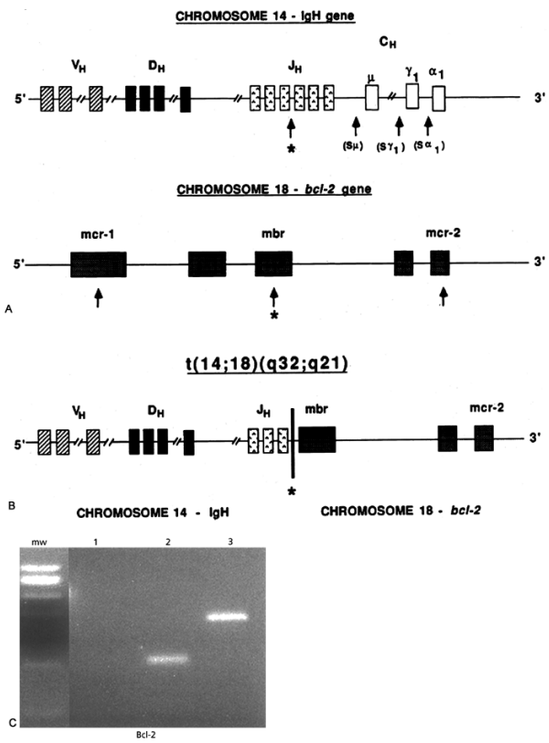

FIGURE 11.11. Molecular gene structure of chromosomes 14 and 18. See Figure 11.1, Figure 11.3, and Figure 11.17 for explanation of figure characters. (**A**) Normal gene structure of chromosomes 14 and 18. Arrows indicate locations of the most common breakpoint sites. *mcr* stands for minor cluster regions and *mbr* represents the major breakpoint region of the bcl-2 gene. *(continued)*

Initial molecular characterization of *bcl-2* significantly contributed to our understanding of apoptosis and helped in identification of other molecules involved in apoptosis regulation. *Bcl-2*, similar to *bcl-XL*, functions as inhibitor of apoptosis by protein-protein interactions with a number of homologues apoptosis regulatory proteins including death promoting protein bax. Bax heterodimerizes with *bcl-2* in homeostatic state while homodimerization (bax-bax) causes apoptosis; in contrast, overexpression of *bcl-2* favors *bcl-2-bcl-2* homodimerization, which prevents apoptosis. Hence, the ratio of *bcl-2*, as well as *bcl-XL* and bax, is very critical in determining the fate of cell. There are also additional factors such as bad and bag-1, which also influence the function of *bcl-2*. Although *bcl-2* overexpression alone is insufficient to transform B-lymphoid cells, the survival advantage provides an opportunity for genetic mutations, which will lead into lymphoma development. This was shown in the case of c-myc in which *bcl-2* was shown to complement the c-myc protein, in part by inhibiting c-myc induced apoptosis.

In addition to diagnostic usefulness of *bcl-2* translocation detection, the assessment of *bcl-2* translocation has been used for the evaluation of minimal residual disease with a sensitivity of 10^{-5} or greater. There is a good correlation between bone marrow positivity for the *bcl-2* translocation by PCR and relapse following autologous bone marrow transplantation (38, 39). However, it should be remembered that *bcl-2*-rearranged cells were documented in the normal healthy donors (40, 41).

Burkitt's Lymphoma

Burkitt's lymphoma (BL) shows two epidemiologic distribution patterns, endemic and sporadic forms. The endemic form of BL typically affects children between 5 and 10 years of age and usually presents with involvement of jaw, abdominal, and extranodal sites. In the endemic type of BLs, clonal integration of Epstein-Barr virus (EBV) is shown in 95% of the tumors, whereas EBV is seen in 15% to 20% of nonendemic sporadic form of BLs (42). The sporadic form occurs in adolescent and young adult age patients, mostly presenting with abdominal mass. Presence of EBV genome in BLs has been implicated for the neoplastic transformation.

On the basis of sequence divergence in the EBNA-2 gene, two different families of EBV, type A and type B, have been defined. Type A EBV immortalizes B cells more efficiently *in vitro* and infects immunocompetent individuals more commonly than type B EBV. However, type B EBV is seen at increasing rates in immunocompromised hosts and in lymphoid neoplasms in this setting. There is a higher level of expression of EBV lytic cycle transcripts (BZLF1, BHRF1, BLLF1, and Fp) in endemic BL tumors similar to the strain association of AIDS-related EBV-positive lymphomas. There appears to be a nearly equal mix of type-A and type-B virus in endemic BL in contrast to Hodgkin's disease (HD) and posttransplant associated lymphoproliferative disorders (PTLDs) where type-A virus predominates (43). Whether the virus type (A or B) detected in BL simply reflects the frequency

of infection in the affected population, or there is a specific virus-type tumor association in some instances remains to be determined. LMP1 is a transforming protein that interacts with tumor necrosis factor receptor (TNFR)-associated factors (TRAFs), and is involved in NFκB activation (44). LMP1 is one of the most significant gene implicated in lymphomagenesis. It resides at the carboxyl terminus (amino acids 346–355), which is a short 30-base pair segment considered to be important to the transforming ability of LMP1 protein. This segment is deleted in a variety of EBV-associated tumors and may be related to tumor pathogenesis or disease progress (45, 46). The deletion also is noted in some cases of endemic BL.

The translocation t(8;14)(q24;q32) is the characteristic chromosomal aberration of BLs. The t(8;14) juxtaposes the c-myc gene in 8q24 next to the IgH locus in 14q32, resulting in overexpression of c-Myc (Fig. 11.12). Although often used as a “characteristic” marker for BL, this translocation is not specific for BL and can be found in other large-cell lymphoma.

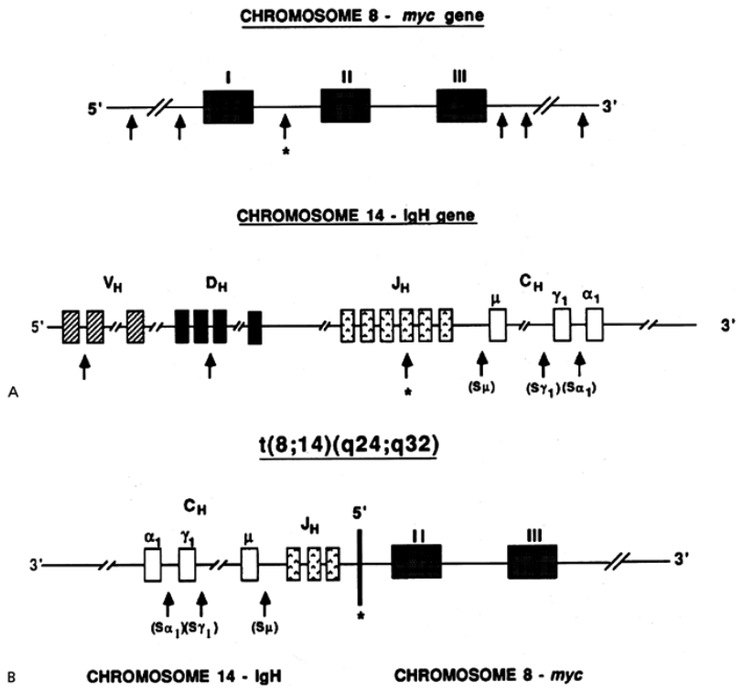

FIGURE 11.12. Molecular gene structure of chromosomes 8 and 14. (**A**) See Figure 11.1 and Figure 11.3 for explanation of figure characters. The arrows indicate preferential locations of breakpoint sites in the t(8;14) translocations. The Sμ, Sγ, and Sα represent the respective switch regions for particular constant region exons. (**B**) This is one example of a reciprocal translocation between the *myc* oncogene and the immunoglobulin heavy chain gene. The breakpoint on chromosome 8q24 has occurred between c-myc exons I and II (*). The breakpoint on chromosome 14q32 has occurred within the middle J_H region and has joined in a 5′ to 5′ fashion with the *c-myc* oncogene.

The great majority of the endemic BLs shows breakpoints far upstream of c-myc gene. In contrast, sporadic BLs almost always show breakpoints within or close to the c-myc locus. C-myc translocation causes transcriptional dysregulation as a result of juxtaposition to the immunoglobulin gene because of the enhancer elements. Mutations within the c-myc locus also may contribute to the transcription of upregulation as well as functional dysregulation of the c-myc gene, which in turn promotes cell cycle progression and inhibits differentiation. *In vitro* studies in transgenic animals have shown cellular transformation as a consequence of c-myc upregulation supporting an important role for c-myc in lymphoma development.

Mechanism of c-myc cellular transformation is not fully understood; however, it is thought to be secondary to dysregulation of transcription of genes essential for the gene regulation. One of the key regulatory functions is c-myc interaction with Helix-loop-Helix (HLH) leucine zipper protein referred to as MAX. Transcription or regulation of myc is related closely to dimer formation with MAX, MAD, and MXI, two other HLH proteins. While myc/MAX heterodimer formation causes activation of

gene expression, MAD/MAX heterodimer formation causes transrepression of target genes. In a normal homeostatic state, cells form c-myc/MAX heterodimers while MAX/MAX homodimers compete for the similar target sequences to inhibit the transcription activation. In the case of BL, overproduction of c-myc causes excessive amount of c-myc/MAX complexes, which transactivates the target genes.

Primary Effusion Lymphoma

Primary effusion lymphoma (PEL) is a recently described distinct subtype of B-cell NHL associated with infection by the human herpesvirus-8, which is also associated with Kaposi's sarcoma, multicentric Castleman's disease, angioimmunoblastic lymphadenopathy, and multiple myeloma (47, 48, 49). PEL occurs predominantly but not exclusively among HIV-infected individuals. These lymphoid neoplasms show propensity to body-cavity involvement without mass lesions. There is little or no dissemination to other solid organs. Tumor cells show usually immunoblastic morphology, late B-cell phenotype. Genotypically of PEL cells reveal clonal Ig gene rearrangement in all cases and EBV infection in most cases. There are so far no chromosomal abnormalities noted in this entity. PEL carries a clinically aggressive course and have a poor prognosis.

Hodgkin's Disease

HD shows a heterogenous morphology and classified into four histologic subgroups, including lymphocyte predominance, nodular sclerosing, mixed cellularity, and lymphocyte depleted types. In general, lymphocyte predominance is biologically considered to differ from other three categories. Reed-Sternberg cells are a characteristic feature of HD and represent only a minority of (0.1% to 1%) cells in involved tissue. The RS cells are surrounded by T lymphocytes, histiocytes, fibroblasts, eosinophils, and other nonmalignant hematopoietic cells.

The etiology of HD remains unknown. Unlike NHLs, there are no consistent structural karyotypical abnormalities associated with HD. The most frequent cytogenetic abnormalities include 1p36, 6q21-q26, 14q11, and 14q32. There have been studies looking at the bcl-2 gene rearrangement using assays similar to those used for the Ig gene analysis. These studies showed variable results; however, in general, *bcl-2* positivity is believed to be rare in HD and positivity may be related to nonneoplastic cells having rare translocation of *bcl-2* gene (50). EBV has been extensively investigated in HD in different population. In the Northwestern American and European population, approximately 50% of HD cases are EBV-positive but reaching up to 90% South American population in some endemic areas. The prevalence of EBV is higher in mixed cellularity than nodular sclerosing type and extremely rare in nodular lymphocyte predominance type (51, 52). EBV is present in clonal episomal form suggesting that the cell had been infected before the neoplastic transformation and supports a possible role in pathogenesis of HD. The EBV infection is latent and shows expression of EBNA1 and LMP-1 but no EBNA2, consistent with type II pattern (53). Despite serologic and epidemiologic studies, the precise functional role for EBV in the pathogenesis of HD remains unknown.

Because of the scarcity of RS cells in tumor tissue, it has been exceedingly difficult to use standard techniques of molecular biology on HD tumor tissues to characterize molecular events involved in neoplastic transformation. Immunoglobulin and T-cell receptor gene studies demonstrate germline pattern in the great majority of HD cases most likely because of the presence of low number of RS cells. Isolation of single cells by microdissection followed by PCR analysis has allowed molecular analysis of RS cells. Using these methods, detection of Ig gene rearrangements in single RS cells of classical HD favored for B-cell origin. In majority of the cases, Ig gene rearrangements amplified from multiple RS cells showed a clonal relationship among the RS cells supporting a clonal origin. It is believed that RS cells are derived from germinal center (GC) B cells because there are somatic mutations within the rearranged Ig genes. Based on the finding of crippling mutations in some of the cases, it was suggested that RS cells in classical HD as a rule are derived from crippled GC B cells that lost the capacity to express antigen receptor because of somatic mutations (54). The discovery that the RS cell shows an immunoglobulin gene rearrangement suggests that HD has a physiologic similarity to B cells (55, 56 and 57).

Recent studies show constitutive expression of NFκB that plays an essential role in prevention of apoptosis in various tumors (58). Studies related to activation of NFκB including cytokines, EBV, and loss of inhibitory genes appear to provide newer insight into the biology of HD (59).

Cutaneous T-Cell Lymphoma and Sezary Syndrome

Sezary syndrome is a leukemic variant of cutaneous T-cell lymphoma (CTCL) in which patients typically present with generalized erythroderma, lymphadenopathy, and abnormal T-cells (Sezary cells) in the peripheral blood (60). The Sezary cells have a characteristic morphology with cerebriform nuclei and typically show a CD4 positive, CD7 negative immunophenotype. The clonal nature of the disease also has been shown by demonstration of rearrangement of the TCR-β and TCR-γ genes. Recent modifications, especially PCR amplification of TCR-γ genes now allow monoclonality determination in small samples (61, 62). Association between mycosis fungoides (MF), its leukemic variant Sezary syndrome (SS) and the human T-cell lymphotropic virus type-I (HTLV-I) has been controversial. Previous studies demonstrated HTLV-I provirus in the skin lesions of patients with MF by PCR analysis using oligonucleotide primers directed against common genes of HTLV-I such as gag, pol, env, or tax oligonucleotide primers (63, 64). However, a recent cooperative international study investigated 127 patients from five different countries with different geographical backgrounds using PCR with primers against all regions of the HTLV-I genome and failed to demonstrate an association between MF and HTLVI (65).

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATLL) is a T-cell neoplasm characterized by cutaneous disease, lymphadenopathy, hepatosplenomegaly, and high leucocyte counts with peripheral atypical lymphocyte and hypercalcemia (66). The epidemiologic studies have shown endemic areas involving Japan, Caribbean basin, tropical islands of Pacific Ocean, and the Seychelles in the Indian Ocean. The black population in the Southeastern United States show higher incidence of ATLL. ATLL is believed to be

caused by human retrovirus HTLV-I, which binds CD4-positive cells and cause uncontrolled proliferation (67, 68). The diagnosis of ATLL is made by the characteristic clinical and histologic finding with the detection of serum antibodies to HTLV-I. Histologically, some cases may be difficult to differentiate from Sezary syndrome because both lesions are proliferation of CD4 T-lymphocytes. Monoclonal integration of HTLV-I proviral DNA in cellular DNA of ATLL cells may be needed as confirmation of clinical diagnosis ATLL.

Posttransplantation Lymphoproliferative Disorders (PTLDs). PTLDs represent a heterogeneous group of lymphoid proliferations that arise in immunosuppressed transplant recipients. Clinical course is variable. Some of these lesions regress after a reduction in immunosuppressive therapy, whereas others progress despite aggressive therapy. There are morphological, immunophenotypic, and immunogenotypic criteria developed to predict clinical outcome (69).

Molecular genetic characterization of PTLDs, including an assessment of the presence of structural alterations in some oncogenes and tumor suppressor genes, is highly informative in predicting clinical outcome. Great majority of PTLDs are associated with EBV (70, 71). PTLDs with monomorphic morphology and a strong clonal immunoglobulin gene rearrangement band on Southern blotting and a c-myc gene rearrangement are more likely to have progressive disease. There are three basic clinical presentations to predict clinical course:(i) plasmacytic hyperplasia (PH): immunoglobulin gene rearrangement is polyclonal, and EBV terminal repeat analysis is polyclonal or faint monoclonal by Southern blot analysis; (ii) polymorphic PTLD: monoclonal or oligoclonal by immunoglobulin gene rearrangement or EBV terminal repeat analysis and no other identifiable genetic alterations; and (iii) lymphoma/multiple myeloma: monoclonal with structural alterations of the N-ras, p53, and/or the c-myc genes. A single clonal band representing the joined EBV genomic termini can be detected in most monomorphic PTLDs, demonstrating the presence of a monoclonal expansion of B lymphocytes carrying EBV DNA. The polymorphic lesions lack structural alterations in most of the genes involved in other lymphoid neoplasms, including BCL-1 and BCL-2, c-myc, p53, and ras. According to this clinical classification, the PTLDs classified as PH and polymorphic PTLD are more likely to regress with a reduction in immunosuppression or to undergo resolution with more aggressive therapy than those classified as lymphoma or myeloma. Recently, an additional study looking at bcl-6 gene structure was shown to be useful to predict treatment response (72). Although BCL-6 gene shows a germline pattern, sequence analysis of BCL-6 illustrates a difference among patients. Patients with polymorphic PTLD and lymphoma/myeloma usually have a mutation in the first intron segments of the bcl-6 gene, which commonly is associated with progressive disease. In summary, complete core analysis of PTLD requires molecular assays for immunoglobulin gene rearrangement, EBV terminal repeat analysis, c-myc translocation, and bcl-6 mutation.

Anaplastic Large Cell Lymphoma

Approximately 2% to 8% of all NHLs contain a t(2; 5)(p23; q35) chromosomal rearrangement, which is found in mostly CD30-positive anaplastic large-cell lymphoma (ALCL) of T-cell or null cell phenotype. This translocation juxtaposes the nucleophosmin (*NPM*) gene at 5q35 with the anaplastic lymphoma kinase (*ALK*) gene at 2p23 (73, 74). NPM is a 38-kd protein involved in shuttling ribosomal components between the nucleus and cytoplasm (75). The fusion gene created by the (2;5) translocation encodes an 80-kd chimeric NPM-ALK kinase, in which 40% of the N-terminal of NPM is linked to the entire intracytoplasmic region of ALK. The NPM-ALK hybrid protein is thought to play a key role in lymphomagenesis by aberrant phosphorylation of intracellular substrates. It is believed that *NPM* gene promotes the expression of the ALK catalytic domain present in the chiameric NPM-ALK protein. Few cases with other partner genes with ALK have been described. It was shown that constitutive ALK activity contributes to the malignant transformation of lymphoid cells.

Although the vast majority of cases with a t(2; 5) rearrangement possess anaplastic large-cell histology, this alteration can be detected in other histologic forms of lymphomas, hence difficult to recognize. The expression of the CD30/Ki-1 antigen by NHL does not correlate strictly with the presence of NPM-ALK with approximately one half of CD30/Ki-1-positive ALCL also being *NPM-ALK*-positive and occasional CD30/Ki-1-negative ALCL being positive for the fusion gene. Despite controversy, recent studies described B-cell type ALCL among the morphological variants of diffuse large B-cell lymphoma. Reported cases with t(2;5) chromosomal translocation as well as expression of ALK protein suggests existence of B-ALCL. However, there is insufficient number of B-ALCL to analyze clinical features, including prognosis.

In the clinical setting, detection of NPM-ALK fusion transcript can be demonstrated easily by RT-PCR, FISH, and Southern blotting. Most groups failed to demonstrate t(2;5) in Hodgkin's disease; hence, NPM/ALK positivity is believed to be very characteristic of ALCL. Recent studies have shown a better prognosis for the ALCL; nevertheless, 20% to 30% of these patients eventually succumb to their disease despite aggressive therapeutic intervention. Extensive immunohistochemical studies now have been performed using antibody developed against ALK protein, and new information has emerged based on pathologic and clinical features of ALK-positive lymphomas. Based on these studies, ALK-positive ALCL was shown to have a better prognosis (76, 77). It has been proposed to distinguish these tumors from the heterogeneous group of lymphomas covered by the term ALCL.

Majority of cutaneous ALCL, some possibly including lymphomatoid papulosis, are also reported to have a good prognosis. Several studies have shown the absence of t(2;5) in majority CD30+ cutaneous lymphoproliferations, as opposed to its presence in CD30+ systemic ALCLs. Great majority of cutaneous ALCLs also are negative for ALK expression.

Leukemias

Improvements in cytogenetic techniques have provided significant insight as to the importance of molecular abnormalities in the pathophysiology and prognosis of hematologic malignancies. Of all neoplasms, leukemias have been by far the most intensively investigated and account for the great majority of chromosomal

aberrations documented in human neoplasms. The majority of cases of acute lymphocytic leukemias demonstrate an abnormal karyotype, either in chromosome number or as structural changes such as translocations, inversions, or deletions (Table 11.2). Although leukemias currently are classified according to morphology and cell lineage as determined by immunological methods, it has become apparent that leukemias with a certain lineage comprise a heterogenous disease mostly because of the characteristic of molecular abnormalities associated with certain cytogenetic changes. Despite the fundamental importance of the underlying molecular abnormalities both in acute myeloid and lymphoid leukemias, there has not been an acute leukemia classification that systematically incorporates the results of such alterations. In this section, the most common translocations (see Table 11.2) found in leukemias with an emphasis on the pathophysiological and clinical implications will be discussed.

TABLE 11.2. COMMON RECURRING CHROMOSOMAL TRANSLOCATIONS ENCOUNTERED IN ACUTE LEUKEMIAS

Disease	Translocation	Genes Involved
AML	t(6;9)(p23;q34)	DEK-CAN
AML-M2	t(8;21)(q22;q22)	AML1-ETO
AML-M3	t(15;17)(q22;q21)	PML-RARα
AML-M4Eo	inv(16)(p13;q22)	CBFß-MYH
AML-M4/M5, biphenotypic	t(11;19)(q23;p13)	MLL-ENL
AML-M5, biphenotypic	t(9;11)(p21;q23)	MLL-AF9
CML	t(9;22)(q34;q11)	BCR-ABL
Precursor B-ALL	t(12;21)(p13;q22)	ETV6-AML1
	t(9;22)(q34;q11)	BCR-ABL
	t(4;11)(q21;q23)	MLL-AF4
Pre-B-ALL	t(1;19)(q23;p13)	E2A-PBX1
B-ALL	t(8;14)(q24;q32)	MYC-IgH

AMI, Acute myelogenous leukemia
ALI, acute lymphoblastic leukemia

Acute Myelogenous Leukemias AML1/ETO [t(8;21)(q22;q22)

The (8;21)(q22;q22) translocation is one of the most frequent karyotypic abnormalities detected in acute myelogenous leukemia (AML), accounting for approximately 40% of de novo AML cases that have M2 morphology in the French-American-British (FAB) classification. This karyotypic abnormality is associated with a good clinical response to chemotherapy and a high remission rate with a long-term disease free survival. As a result of this translocation, the gene encoding the *AML1* (*CBFA2*) transcription factor from chromosome 21 is fused to the "eight-twenty-one gene" (ETO, also known as MTG8 and *CBFA2T1*) on chromosome 8 (78). This fusion gene encodes a chimeric AML1-ETO protein consisting of the N-terminus of AML1 fused in frame to the C-terminus of ETO. The chimeric protein is believed to induce leukemogenesis by its abnormal activation of both myeloid and lymphoid target genes through the AML1/CBFB transcription factor complex (79). One of the targets of this translocation, AML1, is the DNA-binding subunit of the AML1/CBF transcription factor complex and binds the enhancer core motif, TGT/cGGT. DNA-binding affinity of AML1 is increased through heterodimerization with CBF, and both its DNA-binding and interaction with CBF are mediated through a central domain with high homology to the *Drosophila* segmentation gene, *runt*. The AML1-ETO chimeric product retains this domain and therefore also binds the core enhancer sequence and interacts with CBF.

Transcriptional regulation by AML1 through the enhancer core motif has been shown to be important for the tissue-specific expression of a number of hematopoietic-specific genes including interleukin-3 (IL-3), granulocyte-macrophage colony-stimulating factor (GM-CSF), the receptor for CSF-1 (CSF-1R), myeloperoxidase, and subunits of the T-cell antigen receptor (TCR).

The t(8;21) can be detected by molecular studies using Southern blotting or RT-PCR. One of the important caveats for the molecular detection by PCR is that despite clinical remission with long duration patients remain PCR positive for the AML1/ETO transcript without clinical progression (80). In fact, some patients reported to be positive as long as 10 years after complete morphologic and cytogenetic remission. This data suggests that RT-PCR analysis for the minimal residual disease for this patient population should be interpreted with a caution. In addition, RT-PCR studies also have shown that AML1/ETO transcripts can be detected in patients where there is no evidence of the t(8;21) at the karyotypic level indicating very low number of cells without evidence of leukemia.

Acute Promyelocytic Leukemia, t(15; 17)(q22; q21)

Acute promyelocytic leukemia (APL) is associated characteristically with the reciprocal translocation of t(15; 17)(q22; q21), leading to the formation of *PML-RARA* as well as *RARA-PML* fusion genes (81). PML-RARA, transcribed by the fusion gene, retains all the functional domains considered to be of importance in APL. PML-RARA is believed to play a key role in leukemogenesis, as demonstrated in transgenic animal model. However, the role for del(17q)-derived RARA-PML in the development of APL remains unclear, particularly because reciprocal transcripts are not detected in all of the APL patients (82). The pathogenesis of APL in cases associated with a PML-RAR *A* rearrangement is believed to be secondary to a block in myeloid differentiation that leads into abnormal proliferation of promyelocytes. This block in differentiation may be overcome by retinoids such as all-*trans* retinoic acid (ATRA) (83). RARA is a member of the steroid hormone nuclear receptor family, acting as a transcription factor mediating the effect of retinoic acid at specific response elements. There are other translocations of the RARA gene associated with APL that have been characterized at the molecular level. These include: t(11;17)(q23;q21), t(11;17) (q13;q21) and t(5;17)(q35;q21), causing fusion of RARA to nucleophosmin (NPM), promyelocytic leukemia zinc finger (PLZF), and nuclear mitotic apparatus (NuMA) genes, respectively. One of the important aspects of APL with t(11;17)(q23;q21) is the lack of clinical response to ATRA therapy (84).

There are three major breakpoints in PML gene (intron 6, bcr1; exon 6, bcr2; intron 3, bcr3) that generate two transcripts of different length by RT-PCR. These are referred to as long (L)

and short (S) forms. L includes bcr1 and bcr2 or variable (V) transcripts, which can only be distinguished by DNA sequence or specific oligonucleotide hybridization. Great majority of PML patients show bcr1 and bcr3 transcripts. Correlations between type of PML/RAR transcript and response to therapy and outcome have been investigated; however, the impact of this separation currently is unknown.

The diagnosis of APL is mainly supported by the molecular detection of PML-RARA transcripts using RT-PCR or FISH analysis to detect reciprocal translocation because cytogenetic analysis sometimes fails because of only erythroblasts entering mitosis or no microscopically detectable rearrangement is present. The molecular analysis is particularly useful in cases classified as microgranular variant of APL. In cases with morphologic features of APL that lack PML-RARA transcript, they should be further investigated for the presence of other cytogenetic abnormalities mentioned above. In addition, most of the studies indicate that a positive PML/RARA by PCR after consolidation is a strong predictor of subsequent hematologic relapse, whereas repeatedly negative results are associated with long-term survival in the majority of patients.

Inversion 16

The pericentric inv(16)(p13q22) and related t(16;16)(p13;q22) cytogenetic abnormalities are observed in approximately 10% of *de novo* acute myeloid leukemia (AML) cases and typically associated with M4 with eosinophilia (M4EO) FAB subtype. However, some cases may lack AML-M4EO histology (85). This subtype of AML has been considered to have relatively favorable therapeutic outcome. The translocation results in the molecular fusion between the CBFB gene on 16q22 (encoding core binding factor-subunit [CBF]) and the MYH11 gene on 16p13 (encoding a type II smooth muscle myosin heavy chain [SMMHC]) (86). The fusion protein CBF-SMMHC disrupts normal myelopoiesis by inhibiting the function of endogenous CBF and its heterodimerizing AML1 (CBF) partners. This, in turn, alters the expression patterns of critical target genes in myelopoiesis. The large majority (>85%) of cases of inv(16)/t(16;16) AML are associated with a type A fusion transcript, corresponding to an in-frame CBFB nucleotide 495-MYH11 nucleotide 1921 junction. RT-PCR technique is advocated for detection CBFB-MYH11 fusion gene transcripts that encode a CBF-SMMHC fusion protein in cases histologically consistent with AML-M4 (86).

Philadelphia Chromosome, Chronic Myelogeneous Leukemia

Philadelphia chromosome primarily is seen in chronic myelogeneous leukemia (CML) and acute lymphocytic leukemia. It results from a reciprocal translocation between the long arm of chromosomes 9 and 22, transposing the c-abl gene from chromosome 9 to the bcr gene on chromosome 22, causing a hybrid BCR-ABL gene (87) (Fig. 11.13). The breakpoints in the ABL gene occupy a large segment of an intron sizing 300 kb and referred as major breakpoint cluster region (M-bcr) and minor cluster region (m-bcr). The great majority of the CML cases show translocation into M-bcr that is spanned between exons 12 and 16. This region historically has been named exons b1 through b5. Majority of bcr-abl translocation causes a fusion transcript involving the exon b2 or b3 of the M-bcr region and a2 of the ABL gene generating transcripts b2-a2 and b3-a2 (Fig. 11.14) (88).

The incidence of the BCR-ABL fusion gene in CML patients is underestimated by traditional karyotypic studies. Other molecular assays, like Southern blot analysis, FISH, PCR, and pulsed-field gel electrophoresis to complement cytogenetic analysis now are used commonly in clinical evaluation of CML patients. Although Southern blot analysis had played an important role in early description of molecular structure of BCR-ABL, this assay currently is considered to be inferior as a single diagnostic tool.

Cytogenetic analysis is essential to diagnose and follow the course of CML and for identifying karyotypic changes, but it has a limited utility for minimal residual disease evaluation of CML patients because of its lower sensitivity (1% to 5%). Therefore, more sensitive clinical assays for the molecular diagnosis and follow-up of residual disease now are being used. FISH and its variants, interphase and hypermetaphase FISH, allow analysis of a larger number of cells (>500) in a timely and efficient manner, with the added benefit that interphase FISH can be applied to nondividing, low proliferative fraction of cells.

In many centers, molecular-based assays, such as PCR and FISH, are becoming the techniques of choice for detecting residual disease on a molecular level. Particularly, the real-time quantitative PCR method appears to be a very reliable assay for detection of residual disease (89). Depending on the method used, i.e., nonnested or nested, PCR allows identification of a single Ph-positive cell among 10^4 to 10^8 normal cells, a sensitivity unparalleled by any other available method. This level of sensitivity provided opportunities to look at minimal residual disease (MRD) following eradication of leukemia based on morphologic evaluation. Parameters considered to be critical for the interpretation of MRD studies include (i) treatment protocol; (ii) time of sampling in respect to treatment; (iii) controls for housekeeping (e.g., actin, hemoglobin) and target genes; (iv) sensitivity of the PCR assay; (v) inter-laboratory standardization; (vi) duration of study; (vii) retrospective or prospective nature of the study; and (viii) number of tests per patient.

In patients who are in cytogenetic remission after treatment with interferon, PCR techniques still can commonly identify BCR-ABL transcripts within the first year (90). The PCR analysis of CML patients who underwent bone marrow transplantation has been variable. Miyamura et al. (91), using nested PCR, detected no association between PCR positivity and subsequent relapse in their series of 64 patients with CML in remission after allogeneic stem cell transplantation. Interestingly, the persistence of detectable BCR-ABL transcript for up to 2 years postremission did not result in disease recurrence in some patients. In contrast, Hughes et al. (92), on the basis of nested PCR study, reported that PCR positivity within 6 months after allogeneic transplantation did not predict a worse outcome, whereas PCR positivity later than 6 months after transplantation associated with progressive disease. In another multivariate analysis, PCR-positivity at 6 to 12 months posttransplantation was identified as an independent variable for influencing subsequent relapse (93). In a quantitative PCR analysis of BCR-ABL transcripts in contrast

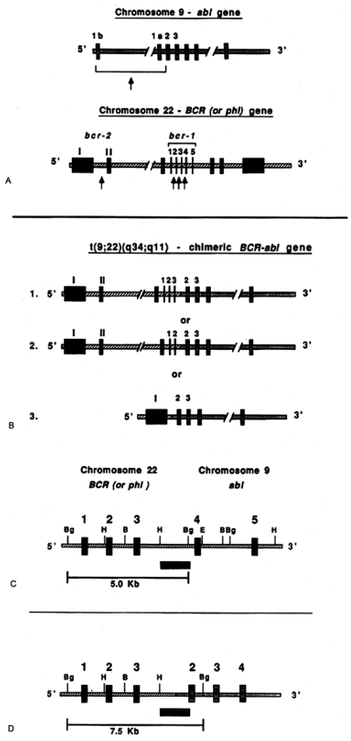

FIGURE 11.13. Molecular gene structure and schematic of the Philadelphia chromosome. The drawings do not accurately reflect distances and are drawn for schematic purposes only. (**A**) Structure of the normal chromosome 9, *c-abl* proto-oncogene, and chromosome 22, the *BCR* gene. Boxes represent exons. Arrows indicate breakpoint regions. The large bracket with the arrow at the *c-abl* gene represents a 100 kb region where virtually all translocations occur. *bcr-1* and *bcr-2* represent the breakpoint cluster regions in the *BCR* gene. Arabic numbers and roman numerals indicate the given nomenclature for the *abl* and *BCR* exons. (**B**) As a result of the reciprocal translocation between chromosome 9 and chromosome 22, a chimeric *BCR-abl* gene is formed. (1) and (2) represent over 95% of the translocations occurring in the bcr-1 region with breakpoints occurring between exons 3 and 4 or exons 2 and 3, respectively; 3) represents the reciprocal translocation of chromosome 9 into the first 5′ intron (*bcr*-2) of the *BCR* gene. (**C**) The germline configuration of the bcr-1 region (Bg = *Bgl*/II restriction enzyme) shows a 5.0-kb, *Bgl* /II fragment with the *bcr* probe. (**D**) Rearrangement of c-abl into the *bcr* region replaces the 3′ Bgl/II restriction enzyme site, leading to the formation of a larger, 7.5-kb band.

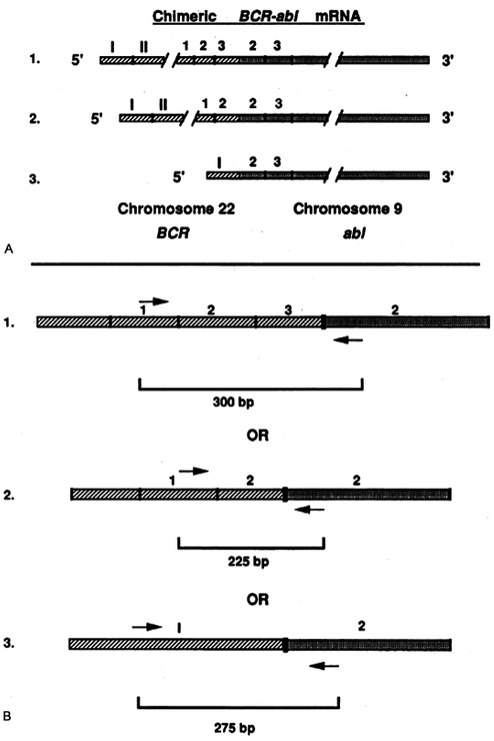

FIGURE 11.14. Gene structure of the chimeric *BCR-abl* mRNA and polymerase chain reaction (PCR) analysis. See Figure 11 for explanation of characters. (**A**) (1) and (2) represent the *bcr-abl* mRNA that is formed after translocation into *bcr*-1. (3) represents translocation of c-abl into the 5′ intron (*bcr* -2) that is associated with Philadelphia chromosome-positive ALL. (**B**) Schematic of PCR analysis for *BCR-abl* mRNA. The horizontal arrows represent the locations for oligonucleotide primers, 1) and 2). A 300 base pair fragment is amplified if an exon 3 (*bcr-1*) rearrangement has occurred or a 225 base pair is amplified if an exon 2 (*bcr* -1) rearrangement has occurred. (3) PCR amplification of a 5′ intron (*bcr*-2)-*abl* translocation.

to qualitative PCR data, the probability of relapse was shown to be significantly increased in patients with higher versus lower levels of BCR-ABL. Some studies suggest that serial PCR measurements identify patients at high risk (i.e., BCR-ABL positivity in serial samples) and low risk of relapse (i.e., transient positivity). So far, because of different levels of PCR, sensitivity and short clinical follow-up durations make it difficult to decide the clinical utility of PCR. However, it is safe to conclude that repeated PCR-negative patients are less likely to relapse. The PCR technique, although considered a valid clinical testing procedure, should be used cautiously in this setting until sufficient data are available.

Acute Lymphoblastic Leukemia (ALL)

The cytogenetic abnormalities confer important prognostic information in ALL. Complete remission rates, remission durations, as well as disease-free-survivals were significantly affected by the karyotypic abnormalities. Translocations constitute the most common changes and there are many different nonrandomly occurring rearrangements described in acute leukemias, the most common abnormalities being listed in Table 11.2.

Philadelphia Chromosome, ALL

The t(9;22) translocation is among the most frequent abnormalities encountered in ALL. In children, Ph+ ALL has a dismal prognosis even with intensive chemotherapy programs that have improved survival in other cytogenetic subgroups. Similarly, in adult ALLs, despite high remission rates comparable to those of Ph-negative ALL, remission duration and survival times are short. Therefore, patients with Ph+ ALL are suitable candidates for innovative and intensified strategies.

As discussed in the section of chronic myelogeneous leukemia, the breakpoint in the ABL region occurs anywhere in a 300-kb intron, but usually is located 5′ of ABL exon a2 in patients

with Ph-+ ALL. Deletions of ABL exon a2 and in-frame joining at the mRNA level of 5′ BCR sequences to the ABL exon a3 also have been described (94). In 50% of adult Ph ALL and in 80% of childhood Ph+ ALL, and very rarely cases of CML or AML, the breakpoint on chromosome 22 falls 5′ of the M-bcr, within a long intron segment separating the alternative exon e2′ from e2 called the minor breakpoint cluster region (m-bcr) (95). Splicing out exons e1′ and e2′ creates an e1a2 junction in the BCR-ABL transcript, translating into a smaller BCR-ABL fusion protein referred to as p190BCR-ABL. Both p210BCR-ABL (CML type) and p190BCR-ABL (ALL type) have significantly increased tyrosine kinase activity compared to the normal human c-ABL protein, p145. *In vitro* studies showed that p190BCR-ABL has a more tyrosine kinase activity than p210BCR-ABL.

Because breakpoints on the BCR gene occur outside the M-bcr region in an area too large to be reliably recognized, Southern blotting used only detection of p210BCR-ABL but not p190BCR-ABL, which is found in 50% to 80% of Ph+ ALL. Studies investigating the clinical significance of fusion protein (p190 vs p210) showed no difference between those with an M-bcr breakpoint and those with a different breakpoint location for age, immunophenotype, or outcome (96). Common association of p190BCR-ABL with ALL and p210 BCR-ABL with CML has been argued to favor a distinction between true *de novo* ALL (m-bcr, p190BCR-ABL) and CML in lymphoid blastic phase (M-bcr, p210BCR-ABL). It has been noted that there is a difference in the frequency of expression of p190BCR-ABL between pediatric and adult ALL (80% vs. 50% of Ph+ ALL cases)(97).

Interestingly, p190BCR-ABL transcripts are not confined to primary acute leukemias. Using quantitative reverse transcription-PCR (RT-PCR) for p210BCR-ABL and p190BCR-ABL mRNA, Van Rhee et al. detected p190BCR-ABL mRNA in 88% (14 of 16) of patients with CML in chronic phase, 100% (10 of 10) of patients with CML in lymphoid blastic phase, and 100% (10 of 10) of cases with p210BCR-ABL-positive ALL (98). However, the p190BCR-ABL/p210BCR-ABL ratio was 10 times greater in ALL than CML, whereas the ratio was similar in CML at diagnosis, in chronic phase, and in lymphoid blastic phase.

RT-PCR has been used to detect and monitor the bcr-abl fusion genes associated with the t(9;22) that occurs in approximately 30% of adults with ALL. Molecular diagnosis detecting bcr-abl fusion protein by RT-PCR has been shown to be a very sensitive technique compared to standard cytogenetic analysis for identification of bcr-abl positive cells. In adult ALL patients expressing B-cell phenotype, greater than 30% of the ALL associates with bcr-abl. The great majority of these patients show p190 molecular-size protein in contrast to the p210 bcr-abl fusion protein that is present in the great majority of the patients with CML. Molecular studies have revealed that even though the complete remission following induction therapy is similar in both bcr-abl positive and negative cases, ALL with bcr-abl transcript has significantly shorter duration of remission, which is associated with shorter survival. It appears that allogeneic transplantation may provide improved long-term disease-free survival for some of the bcr-abl positive ALL patients. There is no significant clinical difference in terms of response between patients with p190 bcr-abl compared to p210 bcr-abl. RT-PCR also allows detection of minimal residual disease following bone marrow transplantation. Patients who are consistently bcr-abl negative following transplantation are not likely to relapse and may become long-term survivors. However, patients who are positive for the bcr-abl transcript following transplantation carry a high risk for relapse.

The MLL gene, the t(4;11)(q21;q23)

The MLL gene, located on 11q23 has been shown to be involved with more than 30 different translocations in both acute lymphocytic and myeloid leukemias, as well as biphenotypic leukemias. Of all the various chromosomal loci participating in 11q23 translocations, the t(4;11)(q21;q23) is by far the best characterized structural lesion, with specific biological and clinical features (99). The presence of t(4;11) has been shown to be associated with a very poor prognosis in response to conventional chemotherapy in both pediatric and adult patients. Therefore, similar to patients with Philadelphia chromosome, patients with t(4;11) are recommended for more intensive regimens.

The t(4;11)(q21;q23) is seen in 2% of the pediatric patients with ALL and in approximately 3% to 5% of adult patients with ALL (100). It is especially very high in infant acute leukemias, reaching up to 60% to 70% in incidence. The frequency of the 11q23 abnormality also is higher in patients who had been previously treated with topoisomerase II inhibitors with a frequency of up to 80%. The t(4;11), regardless of the age of the patients, shows a B-cell phenotype with expression of CD10, CD19+, CD24, and commonly myeloid-associated antigens. These patients typically show hyperleukocytosis, organomegaly, a high incidence of CNS leukemia, and carry a bad prognosis, especially in infant ALL. Leukemic transformation is considered to involve a stem cell or an early committed progenitor cell with the potential for both lymphoid and myeloid differentiation (101, 102). The translocation usually involves a gene located on chromosome 11q23 referred to as mixed lineage leukemia or myeloid lymphoid leukemia (MLL) gene, which has at least 21 exons and encodes for 431 kd protein (103). The C-terminal domain shows significant homology to *Drosophila trithorax* protein. The N-terminal region has methyltransferase domain and three AT-hook motifs. The AT-hook motifs have been implicated in binding to the minor groove of the DNA double helix containing AT-rich regions. The MLL protein is considered to be an important regulator of differentiation by its effects on other DNA-binding proteins or direct interaction with DNA. The breakpoint cluster lies within the 8.3 kb region between exons 5 and 11, allowing easy identification of the translocation by Southern blot analysis (104). The translocation can be detected by RT-PCR amplification of the fusion transcript containing MLL and AF4, the gene located on 4q21. However, there are many reciprocal translocation sites for 11q23 translocations including 4q21, 9p22, 19p13, and 1p32 that can be missed by PCR. The translocation t(11;19)(q23;p13) shows similar clinical and prognostic features as the t(4;11) translocation.

The t(1;19)(q23;p13)

The t(1;19)(q23;p13) is one of the most common recurring translocations in pediatric ALL, with a frequency of 5% to 6%

overall, and of 25% in pre-B-cell ALL. It is present in less than 5% of adult ALL cases. Clinical characteristics of pre-B-ALL with t(1;19) include presentation with high WBC counts, increased LDH levels, and a DNA index of less than 1.6, which underscores that this type of leukemia is usually associated with a pseudodiploid karyotype. It frequently occurs in black people. The majority of cases are positive for CD10, CD19, and cIg (105).

Although previously considered to be a poor prognostic factor, with the use of contemporary therapies, the implication of overall clinical significance is lost (106). This translocation involves E2A, which encodes the two transcription factors E12 and E47 via alternative splicing of precursor mRNA. E12 and E47 are ubiquitous helix-loop-helix (HLH)-containing proteins that bind to the E-box element in the light-chain DNA-enhancer region and plays an important role in lymphopoiesis and regulation of B-cell development. Breakpoints in the E2A gene involves 3.5-kb intron segment between exons 13 and 14. The breakpoint region on chromosome 1q23 is dispersed and lies within an intron of at least 50 kb in size. It disrupts the homeobox-containing “pre-B-cell leukemia” gene (PRL, also referred to as PBX1), which is transcriptionally silent in lymphoid cells. The translocation fuses the 5′ sequences of the E2A gene with 3′ sequences of PBX1 resulting in fusion transcript with the activation domain of E2A and PBX1. E2A-PBX1 appears to function as a potent transcriptional activator that can be detected by RT-PCR. However, detection of E2A-PBX1 by PCR during therapy is not useful predictor of relapse (107).

t(12;21)((p13;q22).(ALL)

One of the most significant developments in pediatric hematologic neoplasms during last couple of years has been the definition of molecular abnormality seen in ALL with t(12;21) (p13;q22) (108, 109). Based on cytogenetic studies, the t(12;21) has been considered to be rare in ALL. However, t(12;21) has been difficult to detect by routine cytogenetic studies that grossly underestimate its frequency. In several studies, the application of molecular tools such as FISH, Southern blot analysis, and RT-PCR have shown TEL-AML1 fusion in up to 27% of children with B-lineage ALL, making it the most common karyotypic-molecular abnormality in pediatric ALL (110). Pediatric B-precursor ALL with TEL-AML1 rearrangement cases carry a good clinical outcome independent of age, and WBC count at presentation (111, 112). Overall, the frequency of TEL-AML1-positive ALL is low in adult B-lineage ALL (3% to 4%), and little is known about its prognostic significance.

The exact mechanism for transformation currently is unknown. Translocation generates a fusion of 5′ end of TEL gene, which contains a helix-loop-helix (HLH)-motif enabling interaction with other proteins, to functional domain of the AML1 gene. AML1 is a heterodimer protein with α and ß units. The α unit contains DNA binding and transactivation motif referred to as “runt,” because of its homology to drosophila runt gene. Hence, the fusion protein contains both HLH domain of TEL and both DNA binding and runt domain of AML1. It is interesting to note that this translocation is the first demonstration of involvement of the AML1 gene in lymphoid neoplasm. TEL-AML1 usually is associated with loss of other TEL allele indicating that loss of TEL function also may be important in leukemic transformation. Other important factors in pathogenesis are transcriptional repression of TCR enhancer and dominant-negative inhibition of AML1.

Tumor Suppressor Genes

Tumor suppressor genes are groups of genes whose expression can block the development of a tumorigenic phenotype and, upon inactivation, lead to a malignant process. The presence of these genes has been identified in certain chromosomal locations by analyzing loss of material from specific chromosomes. Most tumor suppressor gene abnormalities are detected by molecular techniques such as Southern blot analysis, PCR, single strand conformation polymorphism (SSCP), nucleotide sequencing, pulsed-field gel electrophoresis or chemical mismatch cleavage. Although tumor suppressor genes frequently are deleted in solid tumors, they appear to be present in only a fraction of cases of human leukemias. p16INK4A, with or without codeletion of p15INK4B, is the most common gene deleted in acute leukemias (mainly T-cell-derived leukemias). The incidence of homozygous deletions of p16INK4A has been as high as 80% in some series.

The retinoblastoma (Rb) and the p53 genes are the tumor suppressor genes that have been most thoroughly investigated. The Rb gene, on chromosome 13q14, was isolated and cloned by virtue of its deletion in retinoblastoma. It binds and inhibits several transcription factors (such as E2F) and causes inhibition of cell-cycle progression at the G1-S phase. It is deleted in 12% of T-ALL patients and about 20% of patients with CD10+ early pre-B-ALL. The incidence of p53 alterations in ALL is low in both pediatric and adult ALL cases. There appears to be a correlation between p53 mutation and progressive or relapsing disease, especially in T-cell ALL (113). In B-lineage disease, p53 mutations are observed frequently with translocation t(1;19), t(8;14), and the FAB L3 morphology.

NON-NEOPLASTIC DISORDERS

Part of "11 - Clinical Applications of Molecular Biology Hematopoietic Disorders"

Fanconi Anemia

Fanconi anemia (FA) is a rare autosomal recessive disease characterized by multiple congenital abnormalities and bone marrow (BM) failure. Patients with FA shows growth retardation and skin abnormalities, upper extremity defects, kidneys and gastrointestinal system abnormalities, and a higher susceptibility to develop cancer. The diagnosis of FA is usually established by demonstration of increased spontaneous chromosomal breakage that is amplified by the addition of the cross-linking agents such as diepoxybutane or mitomycin C (114). Although this clinical assay is highly sensitive and specific test for FA, it does not distinguish FA carriers from the general population. Furthermore, this assay is limited due to false-negative results, particularly in patients with cellular mosaicism (115).

Molecular studies revealed that FA is a genetically heterogenous disorder, unlike the congenital syndromes such as ataxia-telangiectasia (AT) and Bloom's syndrome, which arise from mutations in single genes. To establish molecular defect, somatic cell fusion studies, and complementation analysis were used which so far lead to identification of at least eight molecular abnormalities

(*FANC A-H*) in FA patients and four different genes (FANCA, FANCC, FANCD and *FANCG*). Localization of the major FA gene, *FANCA*, was facilitated by linkage analysis in families assigned to the FA-A complementation group. Mutations in the FANCA is found in 60-70% of patients (116).

There are a relatively small number of characteristic mutations, associated with specific ancestral backgrounds. A splice site mutation in intron 4 (IVS4+4 A > T mutation) is found in patients of Ashkenazi-Jewish ancestry and accounts for greater than 80% of FA in this population (117). Patients homozygous for this mutation show more severe FA, with multiple congenital abnormalities and early onset of hematological disease. Less common mutations include 322delG and O13X in exon 1, R185X in exon 6, R548X and L554P in exon 14. Patients with the 322delG mutation have a comparatively mild FA, with fewer congenital abnormalities and later onset of hematological disease (118). Additional pathogenic mutations identified that includes mutations in exon 1, exon 6, and exon14. Most of these mutations result in either truncation or internal deletion of the FAC protein. Only one pathogenic missense mutation (L554P) has been described.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired disorder of the hematopoietic stem cell characterized by clonal hematopoietic cells. Clinical manifestations are mainly due to intravascular hemolysis, venous thrombosis, and deficient hema-topoiesis. PNH often arises in patients with aplastic anemia (AA), accompanied by a marked improvement in their hematological indices, and it has been shown that some patients with PNH develop bone marrow suppression ultimately leading into aplastic anemia. There is a defective biosynthesis of glycosylphosphatidyl-inositol (GPI). The GPI deficiency causes defective surface expressions of at least twenty proteins that are normally anchored to the cell membrane via GPI. Deficiencies of GPI-anchored complement regulatory proteins, such as decay accelerating factor (DAF) and CD59, cause red blood cells to be very sensitive to complement resulting in complement-mediated hemolysis and hemoglobinuria. Somatic mutation in the X-linked gene PIG-A that is essential for the first step in GPI biosynthesis accounts for GPI deficiency in all patients with PNH characterized to date. Approximately, 10 or more genes are involved in biosynthesis of the GPI anchor. Although mutation in any one of these genes could result in GPI-anchor deficiency, the *PIG-A* gene is the cause of mutation in almost all PNH patients. The majority of mutations in *PIG-A* gene is a frameshift mutation of the coding region; however, there are also missense and nonsense mutations, abnormal splicing, and rarely cases with amino acid deletions have been reported. The mutations are distributed widely and heterogeneously in the coding regions and splice sites. It appears that there is no apparent clustering or a hot spot within the *PIG-A* gene.

Hereditary Hemochromatosis

Hereditary hemochromatosis (HH) is a common autosomal recessive genetic disorder of iron metabolism. It is very common among whites, with mutation affecting 1 in 300 individuals. (119, 120). It is characterized by increased iron absorption and storage that results in systemic organ damage. The clinical complications due to iron overload can be prevented by early diagnosis and treatment. Recent identification of the genetic abnormalities allowed development of a reliable genetic-based test that is expected to provide more effective preventive treatment. By positional cloning in 1996, the *HFE* gene was identified as the gene responsible for hemochromatosis. The *HFE* gene encodes an HLA class I-like protein that, in association with 2-microglobulin, has an expression pattern correlated with the localization of iron absorption. HFE seems to play a role in iron uptake by interacting with the transferrin receptor, leading to its decreased affinity for transferrin.

Two common missense mutations have been described: C282Y, accounting for 80% to 90% of HH chromosomes, and H63D, which is associated with a milder form of the disease representing 40% to 70% of non-C282Y HH chromosomes. Minority of HH patients show 193AT substitution with S65C missense substitution which accounts for 8% of HH not related to C282Y or H63D (121).

The HFE gene encodes an HLA class I-like protein that has an expression pattern correlating with the localization of iron absorption. Clinical studies have demonstrated that genetic studies requires further clinical assays since there are a number of cases within hemochromatosis families with C282Y mutation showing no iron overload. This may represent incomplete penetrance, which has not been systematically analyzed in the general population. Currently, the molecular testing is considered to be useful in a patient who is clinically suspected of having hemochromatosis or shows elevation of transferrin saturation or serum ferritin. Other clinical use is the investigation of siblings and other family members of a homozygote.

GENETIC FACTORS ASSOCIATED WITH COAGULATION DISORDERS

Part of "11 - Clinical Applications of Molecular Biology Hematopoietic Disorders"

Factor V Leiden and Prothrombin II Mutation

During the last couple of years, specific etiology of many hereditary causes of venous thromboembolism has been established. One of the most common known inherited causes of venous thrombosis include Activated Protein C Resistance (APCR) and deficiencies of the natural anticoagulants including Protein C, Protein S, antithrombin, and prothrombin. It currently is believed that the great majority of young patients with idiopathic venous thrombosis carry mutation in factor V (Factor V Leiden) or factor II genes. Molecular studies looking for genetic risk factors usually are included in the diagnostic work-up of a young patient with venous thrombosis to search for factor V and prothrombin gene mutation.

Factor V Leiden was found to be most common cause of APC resistance(122, 123). This is because of a common mutation within the Factor V gene involving a single point mutation that causes a change in aminoacid arginine (Arg) at position 506 to glutamine (Gln) in the Factor V protein (FVA-Arg 506-Gln). Only a minority of patients has been shown to have abnormality involving other portions of the Factor V gene. The FVA-Arg 506-Gln is the site at which APC cleaves factor Va; hence mutation causes resistance to proteolytic cleavage and functional activation

(Fig. 11.15). Most patients with APC resistance are identified as heterozygous for the factor V Leiden mutation; however, some individuals are homozygous who have markedly increased risk for thrombotic events compared to the heterozygotes (124). In a retrospective case-controlled study of healthy individuals over age 40, heterozygosity for the factor V Leiden was found in 12% of patients with an episode of thromboembolic event and 6% of normal individuals (125). In patients older than 60 and with an episode of venous thrombosis, heterozygosity was demonstrated in 26% of individuals. The risk for the thromboembolic disease in heterozygous individuals was reported to be considerably higher during pregnancy and oral contraceptive use. However, there appears to be no association between factor V Leiden and myocardial infarction in young women (126). A minority of individuals with APC show mutations at the arginine-306 of factor V, Factor V Cambridge, which is also reported to be associated with APC resistance (127).

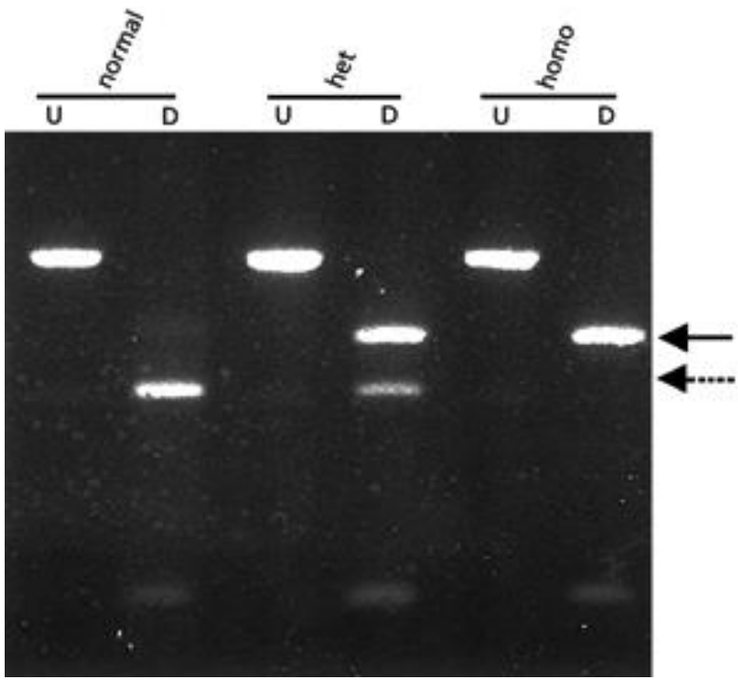

FIGURE 11.15. Detection of factor V Leiden. Exon 10 of Factor V gene is PCR amplified and cut with (d) resection enzyme *Mnl*I. DNA from normal (N) individuals contains MnlI, recognition site (GAGG), which is lost in individuals carrying mutation. Undigested DNA in normal (N) individuals shows 267 bp (upper bands) DNA fragment. After resection enzyme treatment, normal individuals show 163 bp fragment (dashed arrow). In homozygous (Hom) patients, digestion shows 200 bp fragment (solid arrow). In heterozygous (Het) patients, both 163 bp and 200 bp fragments are seen. Internal control of 67 bp in digested samples are seen in the bottom (Abbreviations: U = undigested; D = digested).

Prothrombin Gene Mutation

Mutations in the prothrombin gene cause substitution of glutamine for arginine at position 20210 in the 3′ untranslated region of the prothrombin gene (128). This mutation is associated with a 2.8-fold increase in risk for development of venous thrombosis (129, 130). In arterial thrombosis, the presence of prothrombin 20210A is considered to carry a markedly increased risk factor for the development of myocardial infarction in women, particularly with patients carrying high risk for myocardial infarction. Mutation also has been shown to carry high risk for early stroke development. Individuals with factor II 20210A show an increased level of plasma prothrombin levels; however, clinical utility is limited because of wide variability in the normal range of prothrombin assay. Thus, the DNA-based studies currently are utilized for determination of mutation. Testing for these mutations usually is done by PCR amplification of DNA isolated from peripheral blood mononuclear cells and using restriction enzyme targeted to the DNA sequences containing the mutation (Fig. 11.16).

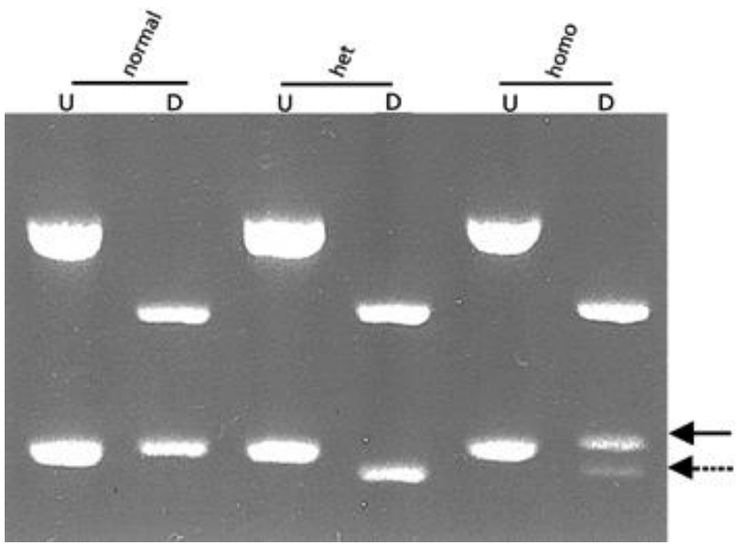

FIGURE 11.16. Detection of prothrombin gene G to A transition (20210). 3′ untranslated region of prothrombin gene, containing a G to A transition at nucleotide position 20210, was amplified and digested with HindIII restriction enzyme. Band of 345 bp (dashed arrow) after *Hind*III digestion shows a same size as undigested fragment while in homozygous (Hom) patient, digestion creates a faster moving band (322bp) (solid arrow). Heterozygous (Het) individual shows both 345 and 322 bp fragments. Most upper band is internal control for *Hind*III digestion to assure that restriction enzyme is functional. (Abbreviations: U = undigested; D = digested).

Von Willebrand Disease

Von Willebrand disease (vWD) is the most common inherited bleeding disorder. Several distinct clinical subtypes have been described with a high degree of heterogeneity and divided into two major categories depending on the presence of quantitative or qualitative defects. The quantitative deficiencies in plasma Von Willebrand factor (vWF) include types 1 and 3 vWD and qualitative abnormalities affecting vWF functions include type 2 vWD. The diagnosis usually is based on clinical findings and measurements of plasma and platelet vWF, the ability of vWF to interact with its platelet receptor, and the analysis of the multimeric composition of vWF. Because of the heterogeneity of vWF defects, a correct diagnosis of types and subtypes sometimes may be difficult but is very important for an appropriate treatment of patients with vWD.

Von Willebrand factor (vWF) is a high-molecular-weight (HMW) multimeric glycoprotein with two main functions in hemostasis: (i) stabilization and protection of factor VIII, and (ii) binding of platelets to the subendothelium at sites of vascular injury. It is synthesized in endothelial cells and megakaryocytes by a mRNA resulting from a 180-kb gene of 52 exons. There also is a partial pseudogene (exons 23–34) present which interferes with the analysis of the vWF gene. vWF is synthesized from a 9-kb mRNA exclusively in vascular endothelial cells and megakaryocytes. The prepropeptide (763 aa) and the mature

subunit (2050 aa) of vWF are composed of four repeating regions designated A, B, C, and D that are arranged as D1-D2-D′-D3-A1-A2-A3-D4-B1-B2-B3-C1-C2. Before its release, the VWF protein undergoes posttranslational modifications. It circulates, in plasma, as HMW multimers, which range in size from 500 to more than 100,000 kd. Molecular studies demonstrated that vWD shows an extensive genetic heterogeneity. Therefore, the role of molecular assays is limited in the diagnosis of this disorder.

Whereas various abnormalities (total, partial, or point deletions, point insertions, nonsense mutations) already have been identified in type 3, the molecular basis of type 1, most common type, is still unresolved in most cases.

Type 2A is the most common qualitative form of the vWD. Several causative missense mutations associated with type 2A have been identified, most of them clustered in the A2 domain (exon 28)(131). These patients show heterozygous missense mutations involving the A2 domain and they can be diagnosed by PCR (132). A novel mutation Gly 1671 Arg in type 2A and a homozygous mutation in type 2B von Willebrand disease also was described.

Section 3 Clinical Chemistry

Clinical Chemistry - Introduction

Kent Lewandrowski

Section Chief

Elizabeth Lee-Lewandrowski

Section Chief

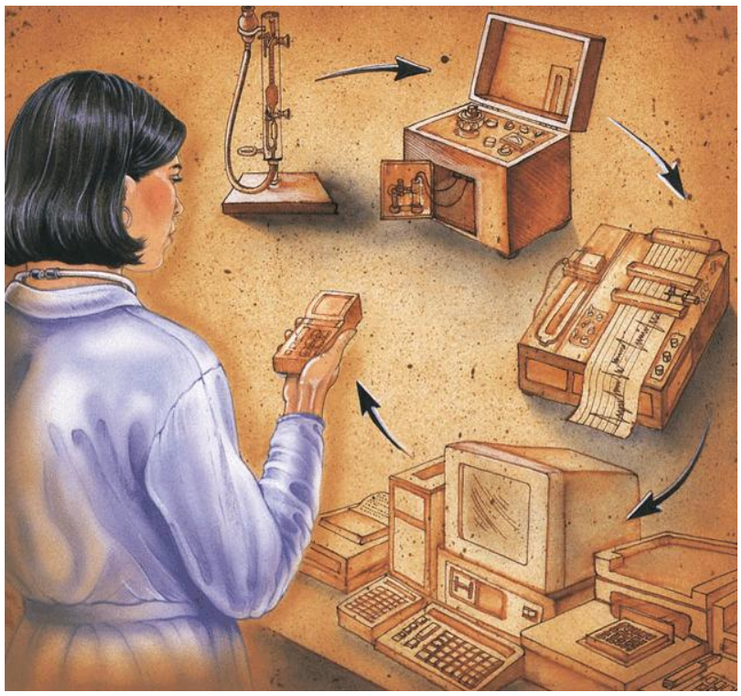

Figure.

Most illnesses either have a primary biochemical origin or result in a secondary disturbance to the intricate biochemical equilibria that characterize the healthy human organism. It follows that careful measurement of selected analytes in blood or other body fluids can provide information useful in diagnosis, and such measurements also are useful in monitoring disease progression and the response to therapy.

Although clinical chemistry sometimes is viewed as a narrow subspecialty, it is in fact a very broad field encompassing a large variety of quantitative and qualitative analytical techniques. Analytes range from simple ionic species and small organic molecules to protein, hormones, and drugs. The range of concentration of the various species of interest spans more than nine orders of magnitude. Methodologies range from difficult and labor-intensive manual methods to highly automated instrument methods.

This section is intended to cover the most important analytes of interest in clinical chemistry. When applicable, chapters include normal biochemistry and physiology, an outline of laboratory techniques for measuring the analyte, and the clinical relevance of the laboratory results. It is hoped that this section will serve as a reference for the most commonly used information about clinical chemistry, as well as an introduction to the more detailed discussion found in specialized textbooks and journal articles.

12
Immunochemical Methods

Robert E. Moore

Immunoassay, as a diagnostic tool, originates with the much older clinical discipline of serology. Approximately 100 years ago, it was demonstrated that certain types of bacteria could be agglutinated by antiserum. It was reasoned that this could be an aid in the diagnosis of typhoid fever, and the procedure was named the Grüber-Widal test. From this modest beginning, immunoassay developed into the fastest-growing methodology, at that time, in the clinical laboratory. The transition, however, was not easy. Numerous advances have allowed immunoassay to achieve its present popularity. The first of these came in the late 1950s when Drs. Berson and Yalow published a series of studies on ^{131}I-labeled insulin to detect antibodies to insulin and later to measure the insulin itself. These studies demonstrated beyond any doubt that a new analytical technique with exquisite sensitivity and specificity was possible. The principle was proven but there were practical problems that kept the technique from being adopted for general use. First, the technique was a radioactive procedure and the additional training, equipment, and regulatory issues were deterrents. Second, antibodies primarily were responsible for the specificity and to a lesser extent the sensitivity of the assay. These reagent antibodies were not commonly available, and investigators had to produce and characterize their own antibodies for each analyte that was measured. Antibody production was not a technique common to the clinical laboratory, and laboratories that were capable of undertaking antibody production found it to be a labor-intensive effort. Third, these early assays were based on competitive binding, a technique that depends on a labeled antigen competing equivalently with the natural antigen for a fixed number of sites, which meant most antigens had to be labeled in the laboratory. The short half-life of ^{131}I, and the difficulty in controlling the organic reactions required to attach this radioactive atom to the analyte, made this a very inefficient and expensive procedure. The instability of the labeled compounds required this labeling procedure to be done just before performing the analysis. Generally, these radioimmunoassay (RIA) methods were long and tedious and if the results were unacceptable, the process had to be repeated, including the labeling procedure.

It was apparent that the analytical potential of the immunoassay with a radioactive label was virtually unlimited and had allowed the quantitation of hormones and peptides for the first time. It also was evident that this potential would be sufficient to stimulate commercial vendors to begin supplying assay materials in a more convenient form, thereby giving smaller laboratories access to this technology. By the late 1960s and early 1970s, commercial preparation of antibodies was common. Investigators could pick from an ever-increasing menu of prepared antibodies and prelabeled antigens. It was a small step from antibody and antigen availability to the appearance of kit packaging. These kits contained all the reagents that the researcher would need to perform a specific assay, and this made immunoassays available to significantly more laboratories. With this proliferation of immunoassay procedures, the users demanded higher quality and standardized reagents.

A parallel development occurred with small organic molecules such as steroids, thyroid hormones, and drugs. These molecules had been synthesized for some time with tritium or ^{14}C atoms at specific structural sites. Antibodies for these materials were not available. One problem with this type of molecule is that it is not immunogenic by itself. That is, these compounds will bind with antibodies but are not capable of evoking an immunologic response in an animal to produce an antibody. This was an additional problem that was not encountered with the larger peptide hormones or proteins. The solution to this problem was to **attach, through covalent linkages**, these small molecules to much larger immunogenic molecules. As investigators began to couple these haptens to proteins, it became apparent that the stereochemistry of the coupling reactions was extremely important. Because there is a great deal of homology among steroids, drugs, and thyroid hormones, judicious choice of coupling site was required to improve the specificity of antibodies. As with the peptide hormones, it soon became apparent that the commercial manufacturers would take a leading role in supplying antibodies and prepackaged reagent systems for these assays.

As more investigators became interested in the RIA technique, it was inevitable that some effort would be invested in finding alternatives to radioactive methods. Because the specificity of these reactions is a result of the antibody, and the sensitivity is mainly because of the amplification system (i.e., multiple radioactive atoms per molecule of analyte), any chemical method that had amplification potential became a candidate to replace the radioactive label. The only limitation seems to be the imagination as multiple types of labels are combined with detection systems to produce the wide spectrum of immunoassays currently available.

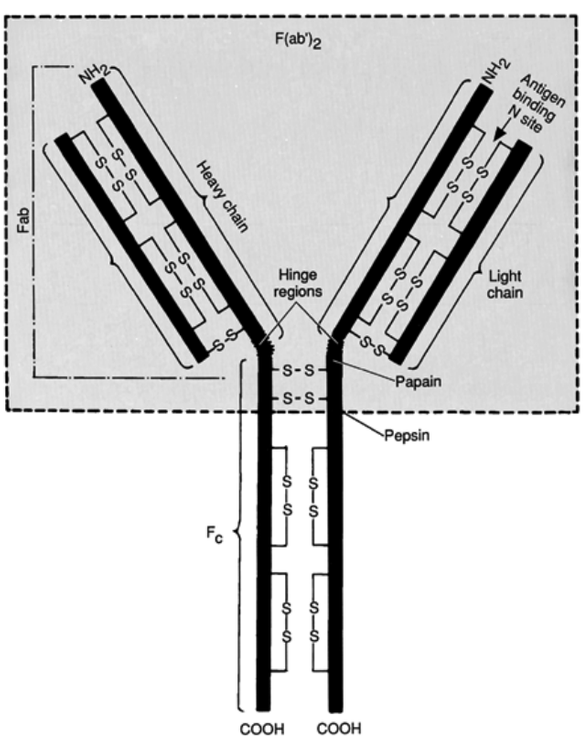

FIGURE 12.1. Schematic representation of IgG antibody. Papain digestion releases two Fab fragments and one Fc fragment. Pepsin digestion releases one $F(ab')_2$ fragment. Both enzyme digestions conserve antigen-binding sites.

All immunoassays share one common feature. They use one or more antibodies to effect the analytic measurement. They owe their specificity and to some extent their sensitivity to the quality of the antibody used in the assay.

ANTIGENS

Part of "12 - Immunochemical Methods"

To try to define antigen in a chapter on immunoassay is problematic. Immunologists and practitioners of the immunologic sciences have struggled, with limited success, to provide a precise and all-inclusive meaning for antigen. For purposes of this discussion, the following functional definition will be used: antigens are substances capable of binding to an antibody. This is in contrast to immunogens, which are substances capable of eliciting a humoral antibody response when presented to a host. The definitions in this chapter are not refined, but they are attempts to minimize confusion.

IMMUNOGENS

Part of "12 - Immunochemical Methods"

Immunogens have several qualities that have been determined empirically. Good immunogens usually are large, complex molecules that differ significantly from normal molecular species found in the host. Although the term large is difficult to describe, molecules with molecular weights greater than 10,000 are usually good immunogens, while, conversely, molecules with molecular weights below 10,000 are poorer.

Molecular size is not the only requirement. Structure is a significant characteristic in determining the efficacy of the immunogen. If the overall structure has incorporated in it lipids, glycoproteins, polysaccharides, or nucleic acids, these will generate a better antibody response in the host than will synthetic peptides composed of one or two simple amino acids. In addition to primary structure, there also is a relationship between immunogenicity and tertiary structure. The more complex spatial relationships found in biomolecules tend to be more immunogenic than less-complex synthetic linear peptides and proteins.

The quality of the immune response of the host improves dramatically as the host is able to identify the immunogen as a foreign substance. When the host animal is challenged, there is an attempt to categorize the material as self or nonself. For obvious reasons, materials that are identified as nonself elicit a much more vigorous response. If the origin of the nonself material is from an evolutionary divergent species, the immune response is expected to be far greater than if the nonself is from a closely related or same species.

Finally, not all immunogens are equal in their ability to elicit antibody formation. The immunogen can be administered as a simple solution or it can be suspended with an adjuvant that will help in amplifying the host response. Administration of the immunogen usually is by injection and the site is one of personal preference. In any case, the host should not become incapacitated (footpad, or splenic injections) because of the administration. Convenient and effective routes commonly are employed.

For biomolecules of clinical interest that are not immunogenic in and of themselves (e.g., steroids, thyroid hormones, drugs, and small peptides), they can be made effective immunogens by covalently coupling them to a much larger protein backbone. Multiple moles of a small molecule can be covalently linked per mole of large protein to produce a very effective immunogen. Molecules that require coupling to other molecules to produce immunogenicity are referred to as haptens. Because many of these small molecules share similar structure, as in the case of steroids, it is possible to select the organic coupling reaction so that the common portion of the structure is used for attachment to the protein backbone, while the unique portion of the structure is left exposed to the environment. This process increases the probability that antibodies will be generated against this unique structure.

ANTIBODIES

Part of "12 - Immunochemical Methods"

Once the immunogen has been presented to an appropriate host, a type of lymphocyte called a “B cell” will begin to produce antibodies against the immunogen. These antibodies are immunoglobulin class proteins predominantly of the IgG and IgM type, with the IgG making up most of the analytic antibodies in use today. As shown in Figure 12.1, IgG is composed of two identical heavy and two identical light chains held together by a series of interdisulfide and intradisulfide bonds. The heavy chains are designated (H) and the light chains (L). The specific heavy chain associated with IgG is designated as a γ chain, while the light chains are either κ or λ, but both do not occur on the same molecule. There are two binding sites on each IgG molecule, and these are located at the ends of the “arms” at the juncture of the heavy and light chains.

Enzymatic digestion of the IgG molecule yields some interesting structural characteristics. Pepsin digestion cleaves the two arms of the “Y” from the body of the molecule, and these arms remain attached to each other and retain the divalent antibody-binding characteristics. The body of the IgG is digested into small fragments. If papain is used to digest the IgG molecule, three fragments are obtained. The two arms are cleaved as independent fragments, each with its antibody-binding characteristic, and the third fragment is the body of the IgG molecule, which remains intact. When the two antibody fragments remain together, as in the case of pepsin digestion, it is referred to as a Fab'_2 fragment, indicating that the two antibody fragments remain together. In the case of papain, the antibody fragments are designated as Fab, because they have been cleaved into single binding sites by the enzyme. The third fragment, the body of the IgG, is the Fc fragment. The c here stands for crystallizable, referring to a characteristic of that fragment after papain digestion. The actual binding site on the IgG molecule is at the amino end, with one binding site in each of the arms.

It is possible to generate analytic antibodies in one of two ways. The historical method is to challenge an animal species with an immunogen to elicit an immune response. Each B cell or lymphocyte that is stimulated to produce antibody to the immunogen ultimately will produce one antibody with specific binding characteristics. This “clonal theory” was introduced in 1957 by Burnet (1). The large number of lymphocytes stimulated each with a single antibody response, gives rise to a broad

spectrum of antibodies that recognize different antigenic determinants over the entire structure of the immunogen. These antibodies differ in quantity and quality as to their ability to identify the specific immunogen presented, but with some luck and considerable effort in purifying and characterizing these antibodies, the result can yield very high-quality reagents for *in vitro* use. These polyclonal antibodies have been used for years in analytical methods.

The second and more recent approach is to generate monoclonal antibodies. Kühler and Milstein exploited the fact that each lymphocyte clone would produce only one type antibody. They developed a technique for continuous production of a selected antibody from cultured lymphocytes (2). This method produces very specific antibodies that recognize a single antigenic determinant on a given molecule, and the clone can be cultured virtually forever. The procedure requires inoculating mice, taking the spleen cells from responsive animals, and fusing them with a myeloma cell line. The fusion products are cultured and screened for the clone that generates the desired antibody. In theory, this approach should have produced the ideal analytic antibody. Practice has demonstrated that monoclonal antibodies (MAbs) have some deficiencies. The affinity of MAbs often is less than that required for analytic procedures resulting in low limits of detection, and the specificity for small molecules is difficult to achieve (3). Some of these drawbacks can be overcome by combining multiple clones from a given fusion, in essence producing a polyclonal serum from several MAb sources, but this is not effective for every application. For large analytes, the combination of MAbs with differing affinities for different epitopes has improved the overall avidity. This effect has not been observed with haptens (4).

Antigen-Antibody Interactions

Immunoassays can be designed to measure either the formation of an antigen-antibody complex or the inhibition of that complex

formation. Individual investigators and commercial suppliers design immunoassays to take advantage of a particular detection system or to maximize analytical sensitivity, if that is critical. It is necessary, therefore, to understand the basic qualities of the antigen-antibody complex that yield good analytic assays. As equations 12.1 and 12.2 demonstrate, the antigen-antibody reaction is a reversible reaction that can be rearranged in conventional form to yield an expression for the association constant, K_a, in terms of the reactant and product concentrations.

$$A_g + A_b \underset{k_2}{\overset{k_1}{\rightleftharpoons}} A_g \cdot A_b \qquad (12.1)$$

where

- A_g = antigen
- A_b = antibody
- $A_g \cdot A_b$ = antigen-antibody complex
- k_1 = forward reaction rate
- k_2 = reverse reaction rate

$$\frac{[A_g \cdot A_b]}{[A_g]\,[A_b]} = k_1 / k_2 = K_a \text{ association constant} \qquad (12.2A)$$

$$\frac{[A_g]\,[A_b]}{[A_g \cdot A_b]} = k_2 / k_1 = K_d \text{ dissociation constant} \qquad (12.2B)$$

Good antibodies, and consequently good assays, are characterized by large K_a values. The interpretation of this is that the equilibrium reaction lies far to the right and there is minimal dissociation of the antigen-antibody complex once it has formed. A small dissociation constant (K_d) is interpreted to mean the antibody is bound very tightly to the specific antigen. In other words, the fit between the antigen and the antibody is optimal and the binding forces have been maximized; therefore, the dissociation rate constant, k_2, is minimized. The practical implication of this is that assays designed around antigen-antibody complexes of this quality are called “robust” and tend to be less sensitive to minor changes in assay conditions such as pH, reaction time, temperature, and ionic strength. If the K_a were small, then the dissociation of the complex would become appreciable and the assay would be insensitive because of a low concentration of complexes at any given time.

The forces that determine the antigen-antibody complex all are intermolecular forces with the exception of covalent bonding. Ionic bonds, hydrogen bonds, van der Walls' forces, and hydrophobic-hydrophilic repulsion constitute the forces that are responsible for maintaining the integrity of the complex. These forces act over short molecular distances. As the fit between the antigen and the antibody improves, more and more of these noncovalent bonds are formed and the rate of dissociation of the complex is reduced. This property is called antibody affinity for a single site, for complexes that are formed using multiple antibodies on multiple antigenic sites; the sum of these forces is referred to as antibody avidity. It is an interesting property of these bonds that the total adhesive force in the complex exceeds the sum of the individual forces (5).

The stoichiometry of the antigen-antibody reaction plays a critical role in assays that are dependent on maximum precipitation. As Figure 12.2 illustrates, when a polyvalent antibody reacts with an antigen with multiple determinants, the precipitation increases gradually to a maximum and then begins to decrease. Initially, there is excess antibody for the antigen in the solution. In this situation, each antigen molecule has the maximum number of antibodies bound, but a different antibody binds each epitope on the antigen. With excess antibody available, there is little opportunity for the cross-linking of antigens and the subsequent formation of large molecular complexes. As the concentration of antigen increases, a point is reached where the antigen and antibody concentrations are balanced so that a macromolecular lattice can be formed. These lattice structures are so large that precipitation is at a maximum. The point at which maximum precipitation occurs is called the equivalence point. At this point, if one were to analyze the solution after precipitation of the antigen-antibody complex, there would be very little antigen or antibody remaining. If antigen continues to increase to a concentration where it is in excess, then each antibody becomes saturated with antigen molecules. Using IgG as an example, two antigen molecules are bound per antibody molecule. Similar to the case of antibody excess, antigen excess results in different antigens binding to the antibody, again limiting the possibility for cross-linking. The complexes formed under conditions of antigen excess are not large enough to affect total precipitation, and so considerable complex is left in solution. Note also that the *x*-axis is calibrated in concentration and the y-axis calibrated for a response to complex formation. The resulting curve, due to its symmetry, has a low and a high concentration that will yield the same response. Assays that depend on measuring complex formation, particularly if they are fully automated assays, must consider this effect and be prepared to test for antigen excess conditions.

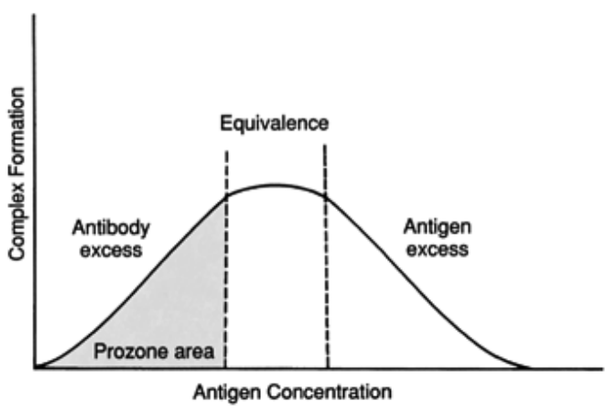

FIGURE 12.2. Titration curve for a constant quantity of antibody. In antibody excess (prozone region) there are insufficient antigen molecules to produce maximum complex formation. At equivalence, the complex formation is optimized. If the complexes are separated from the liquid phase, no free antigen or antibody is detected in the remaining solution. In antigen excess, each antibody is saturated with antigen, and complex formation is reduced.

PRECIPITATION TECHNIQUES

Immunodiffusion: Liquid Systems

The formation of precipitates between antigens and antibodies in liquid media are the simplest and oldest precipitation reactions conducted in the laboratory. This approach takes advantage of the diffusive property of molecules and the precipitation of antigen-antibody complexes. The reaction is carried out in small test tubes, small-diameter capillary tubes, or microtiter wells. A mixture of antigen and antibody is allowed to incubate for several hours. At the end of this time a precipitant will have formed and settled to the bottom of the reaction vessel. If this reaction is carried out with a constant amount of antigen and varying dilutions of antibody, a qualitative assessment of the equivalence point can be determined by evaluating the amount of precipitate that has formed in each of the tubes. The equivalence point will be equal to the concentration that formed the greatest amount of precipitant.

Another way to perform this reaction is to add the antibody solution to the tube and then very carefully layer the antigen solution on top, trying to avoid actual mixing of the solutions. As the antigen-antibody complex is formed at the interface, a ring will be visible.

In each of the aforementioned cases, the antigen and antibody were soluble and multivalent so that a macromolecular species could form that would eventually precipitate out of solution. Techniques have been developed for small antigens that do not have multiple binding sites and therefore tend to form complexes that remain soluble. One approach is to coat larger particles with the antigen before exposing it to the specific antibody. Typical supports are sheep erythrocytes or latex particles coated with the antigen of interest. Once these large support particles contain many antigens, multiple antibodies will bind and the particles will become aggregated in solution. The term aggregation generally applies to reactions in which the antigen or antibody is coated on the surface of a cell or synthetic particle used as a support medium. In this reaction, the aggregation of particles indicates the presence of the analyte. When these reactions are carried out in a series of increasing dilutions, a qualitative assessment of the concentration of analyte can be determined.

A variation on the aggregation reaction is the aggregation inhibition reaction. Like the aggregation reaction, antigens or antibodies are coated on a support such as animal erythrocytes or latex beads. The first step of the reaction is to incubate the solution to be analyzed with free antibody. This reaction proceeds to form soluble antigen-antibody complexes. At the end of this initial incubation period, the support particles with the antigens coated on the surface are incubated with the preformed soluble antigen-antibody complexes. The quantity of antigen in the test solution will determine the number of free antibodies available for agglutinating the support particles. In this case, the concentration of analyte is inversely proportional to the amount of agglutination. If a series of standard solutions is analyzed concurrently, the concentration of the antigen in the unknown can be estimated. Both the agglutination and the agglutination inhibition assays have been used in the past as slide tests for screening procedures to detect infectious diseases, pregnancy, and several red cell surface antigens.

All of the reactions described so far in liquid medium require a precalibration of the antigen and antibody solution so that precipitation or agglutination will take place. Most clinical specimens that are encountered in the laboratory fall within a relatively narrow range of concentrations. Assay optimization can thus be done for the anticipated concentrations. For the few specimens that have concentrations outside the expected range, concentration or dilution can adjust those samples so the analytes will be within the analytical range of the assay. It is important to check the analytic reagents periodically, especially as new lots of reagent are incorporated into the procedure, to confirm the analytic range.

GEL SYSTEMS

Part of "12 - Immunochemical Methods"

These reactions are carried out in a gel support, usually an agar or agarose gel, that has been heated to liquid state and then poured onto a solid support and allowed to solidify. This solid support can be glass, acetate sheets, plastic, or any appropriate transparent material. It is important that the seal between the gel and the solid support is intact to prevent the solutions from wicking along the interface. As shown in Figure 12.3, two wells are cut into the gel. An antigen solution is placed in one and an antibody solution in the other. The solutions are allowed to incubate at room temperature, during which time the solutions diffuse through the gel in a radial fashion. The rate of diffusion is dependent on several conditions: the concentration of the respective solutions, the molecular size of the antigens and antibody, and the lattice structure of the gel. As these solutions diffuse, their fronts will meet and at a point where the antigen and antibody are in equivalence, a precipitation line will be formed.

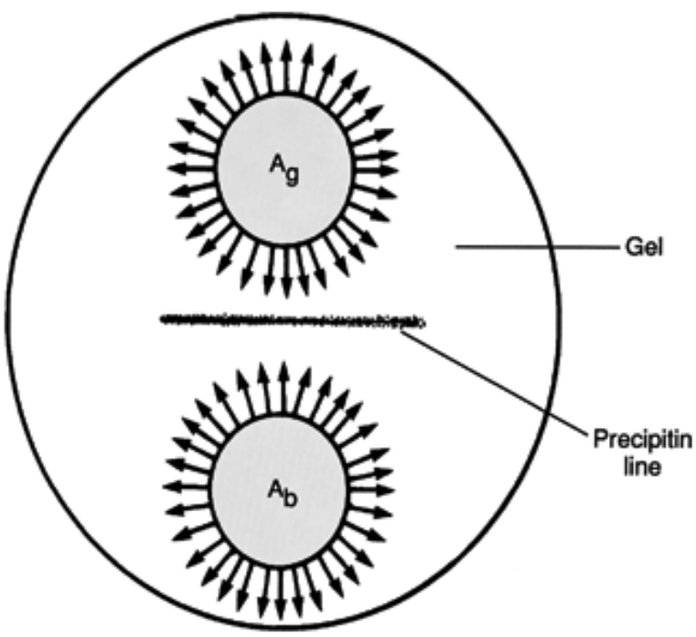

FIGURE 12.3. Immunodiffusion. Two wells are created with a gel punch in a gel slab. Antigen (*Ag*) is placed in one well and antibody (*Ab*) is placed in the other. As the solutions diffuse through the gel, antigen-antibody complexes form and a precipitin line results. If antigen and antibody are not pure, a precipitin line will form for each antigen-antibody pair of complexes generated.

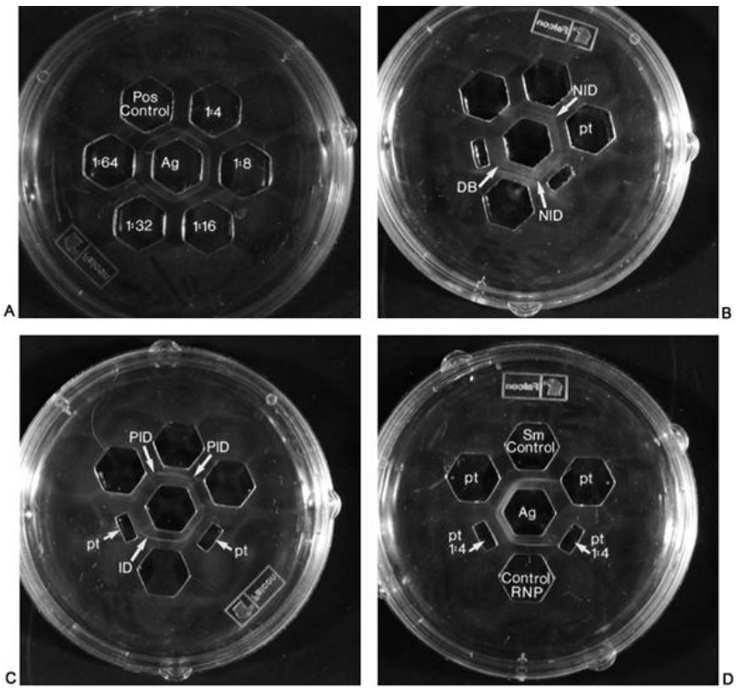

FIGURE 12.4. (**A**), Radial immunodiffusion plate. Antigen (Ag) is placed in the center well. Positive control for antigen is placed in the well marked *Pos Control*. Patient serum dilutions are made clockwise from 1:4 to 1:64. Notice that the precipitin line migrates closer to the patient wells that contain the more dilute specimen. The precipitin line forms a circle with positive control and no "spurs" or cross lines are observed. These are arcs of identity. (**B**) Immunodiffusion plate with arc of nonidentity (NID). Precipitin lines cross at the point of the *arrow*. Also visible is a double precipitin line (*DB*). This occurs when multiple antigens and antibodies are present in the sample and reagents. (**C**) Radial immunodiffusion plate with lines of partial identity (PID) and identity (*ID*). PID lines have a "spur" at the *arrows* unlike the smooth arc of identity. The precipitin line moves closer to the wells with higher dilution of specimen. (**D**) Immunodiffusion plate showing multiple precipitin lines. Patient sample (*pt*) on the left demonstrates antibodies for both Sm control and RNP control. The small rectangular well contains patient serum equivalent to 1:4 dilution.

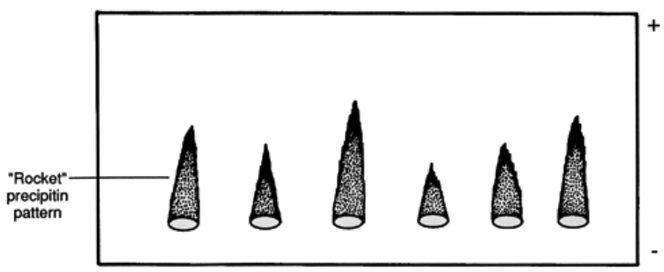

FIGURE 12.5. Laurell rocket electrophoresis. Antibody is mixed with gel and allowed to cool on a plate, forming a conductive surface. Small wells are punched at the cathode (-) side of the gel. The antigen forms, dissolves, and reforms the complexes at the electrophoresis front until the patterns are stabilized. The triangular shape of the precipitation front gives rise to the name rocket immunoelectrophoresis.

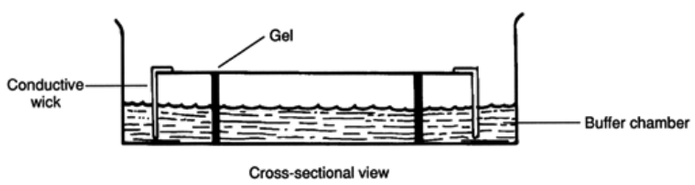

Some characteristics of the precipitin line are quite useful in the interpretation. First, the solution of higher concentration will diffuse more rapidly, and so the precipitin arc will be closer to the lower-concentration solution. Larger molecules will diffuse more slowly than smaller molecules, and if the antibody molecular weight is known, the molecular weight of the antigen can be approximated, assuming the two concentrations are similar. If there are multiple antigens or multiple antibodies, a separate line will be formed for each antigen-antibody pair. When this technique is set up in a circular fashion with multiple wells so that the antibody solution is in the center well and the circumference has several wells with different antigen solutions, the precipitin lines can be quite telling about the antigen-antibody complexes formed. As seen in Figure 12.4A, if the antigen is similar in two adjacent wells, the precipitin line is a continuous arc. If the antigens in adjacent wells are dissimilar, there are two separate arcs that cross (Fig. 12.4B), and if the antigens are similar but not identical, the precipitin line will have a single spur on one of the arcs (Fig. 12.4C). The terminology applied to these precipitin lines is "arc of identity," "arc of nonidentity," and "arc of partial identity,"

respectively. This is known as the Ouchterlony technique. Figure 12.4D demonstrates a real case with multiple precipitin lines showing positivity for the antibody controls, with additional unknown precipitin lines.

This procedure is reasonably simple and inexpensive but lacks sensitivity for quantitative applications. It is useful for applications that identify an antigen or antibody or determine their relative purities. Some experimentation has to be done to ensure that there is a reasonable relationship between the concentration of antigen and the concentration of antibody, or no precipitin line will form. If the starting protein solutions must be adjusted for concentration, adjustment of the final ionic strength and pH also may be required.

Another common diffusion technique is referred to as the Mancini technique. This procedure incorporates antibody into the agarose gel. The gel is heated to 50° to 55°C and the antibody is dispersed in this liquefied gel. If the temperature of the gel is allowed to exceed 55°C, significant antibody denaturation will take place. The gel then is poured onto a solid support and allowed to solidify, at which time small wells are cut into the gel. Each of these wells will hold a solution to be analyzed, and on a single slide a range of standard solutions as well as unknown samples can be assayed. The antigen in the well diffuses radially and precipitates as it encounters antibody in the gel. The antigen creates a concentration gradient as it diffuses from the well, and at the diffusion front when the antigen and antibody are at equivalence, a precipitate forms. As more antigen flows to the front, this precipitate redissolves because of antigen excess, and a precipitate forms farther away from the well. After several hours of incubation, this process stabilizes. Quantitative results can be obtained by plotting the diameter of the ring formed around the antigen well versus the concentration of the standards. Unknown concentrations then can be extrapolated from the curve by finding the diameter of the ring and reading the corresponding concentration.

This technique is dependent on a well-characterized monospecific antibody and reasonably simple antibody solutions. The formation of multiple rings generally means that the antibody is recognizing more than one antigen in the antigen solution, while the formation of asymmetrical rings usually is traced to a defect in the gel formation. With a little practice, this can be a moderately sensitive, simple, and cost-effective approach to analyzing some clinically important antigenic proteins.

ELECTROPHORESIS

Part of "12 - Immunochemical Methods"

The previously described diffusion methods are quite adequate for solutions that have relatively few components. In situations where the solution being analyzed is complex because of the number of components, or if it has multiple components of very similar chemical character, diffusion methods are less acceptable. An alternative to diffusion is electrophoresis. With this method, the components of a solution are separated based on size and charge in an electric field, and efficient separations can be effected on very similar molecules. Once the components of the solution have been separated, immunotechniques can be combined with the electrophoretic results to produce a quantitative analytical method.

Laurell Rocket Immunoelectrophoresis

This particular technique is named for the originator of the procedure, C. B. Laurell, and the rocket or triangular shape that the antigen-antibody complexes form at the end of the analysis (6). In this method, the antibody is dispersed in the agarose gel and the pH of the gel is adjusted to 8.6. This is an approximate isoelectric point for most IgG immunoglobulins, meaning that in the electrophoresis phase of the analysis, the antibodies will not migrate through the gel. When the gel is cool, wells are cut out at the bottom of the gel and filled with the antigen solution to be analyzed. Electrode wicks are carefully applied to the top and bottom of the gel plate as illustrated in Figure 12.5. The wicks must be attached carefully to the gel so that there is a constant current per cross-sectional areas of the gel. It is preferable to have a cooling device to keep the gel cool during the electrophoresis so there is no “drying and cooking” of the gel. As the antigens are electrophoresed from the well, they encounter the antibody that has been dispersed through the gel and the antigen-antibody complex forms at the electrophoresis front. As the antigen concentration changes, the complex dissolves and reforms, resulting in a triangular or rocket-shaped pattern at the end of the electrophoresis run. The area inside these triangular patterns is directly proportional to the concentration of antigen in the well. If the triangular shapes are symmetrical, peak height can be substituted for the area in determining the concentration of unknowns.

This technique is particularly sensitive to antigen-antibody concentrations and electric field strengths. It is important to use as low an antibody concentration as possible in the gel, and one indication of too high an antibody concentration would be the formation of excessive precipitant within the outline of the rocket.

Crossed Immunoelectrophoresis

This variation on rocket immunoelectrophoresis also is referred to as double-crossed immunoelectrophoresis or two-dimensional immunoelectrophoresis. The technique starts by electrophoresing the antigen solution on standard agarose gel under any set of electrophoretic conditions that will effect the separation of the antigens of interest. Once these antigens are separated, the gel is sliced so that the separated antigens are contained in a long thin strip of agarose. This gel strip of separated antigens is placed in or up against a second gel that has antibody dispersed through it. A second electrophoresis is conducted with the field at right angles to the original separation. From this point, the procedure is very similar to rocket immunoelectrophoresis in that, as the antigens enter and migrate through the antibody-containing gel, a precipitant forms, dissolves, and reforms, ultimately yielding triangular or triangular-like patterns of precipitation. Because several antigens can be analyzed at the same time, this technique is quite useful for metabolic studies, enzyme studies, and kinetic studies where there is interconversion of initial reactant and product.

The technique is susceptible to the same errors as Laurell rocket immunoelectrophoresis. The same conditions of low antibody concentration and low electric field strength should be observed.

Immunoelectrophoresis

One of the more common techniques used in the clinical laboratory is immunoelectrophoresis (IEP). This technique is straightforward, cost-effective, and amenable to processing large numbers of specimens as well as potentially being automated. The technique finds its primary application in the identification of serum proteins, and particularly in identifying pathological conditions such as monoclonal gammopathies, light chains, and general protein deficiencies.

The technique consists of preparing or purchasing a special gel plate for electrophoresis of the specimen containing the antigens. The special preparation of the plate requires cutting a trough in the gel and punching two small wells on either side of the trough. This is accomplished easily by using a commercially available template and gel punch or by purchasing the prepared gel from one of several manufacturers. The antigen solutions are placed in the small punched-out wells and electrophoresed long enough to separate the components of the antigen solution. On completion of the electrophoresis, antiserum is placed in the trough and allowed to diffuse into the gel. Either this antiserum can be directed against numerous proteins, as in the case of antiserum directed against human serum, or it can be specific for a single protein. In any case, precipitin arcs form where the antiserum and antigen meet and are at equivalence. These plates are read by looking at the opacity because of the precipitation of the antigen-antibody complexes, or the gel can be stained with one of the commercially available blue, red, or black protein stains. The arcs in the specimen are compared to controls and an interpretation is made as to the presence or absence of proteins and the presence of any unusual or pathological forms. Figure 12.6A depicts the gel plate with the trough and wells properly positioned and demonstrates the stained protein bands on a normal serum specimen. Figure 12.6B is an IgG myeloma.

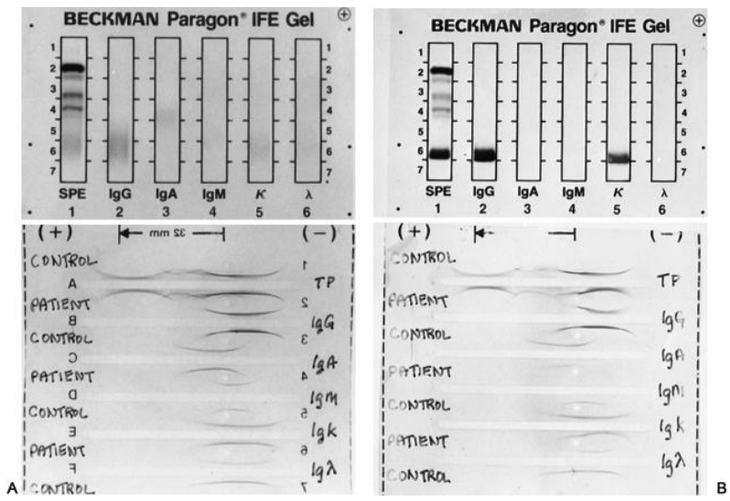

FIGURE 12.6. (**A**) Normal immunofixation electrophoresis (IFE) (top) and the same serum on immunoelectrophoresis (IEP) (bottom). Dark bands on IFE indicate the presence of a serum protein precipitated with antibody. Diffuse bands are indicative of polyclonal production of protein. IEP develops serum proteins as arcs with antibody. Control and patient sera are alternated in the gel wells so arcs can be compared directly. Antiserum is placed in the trough between the wells. (**B**), Monoclonal gammopathies of the IgG κ type. Dark bands in the serum lane and the IgG lane indicate increased concentration of IgG. The sharp band in the κ lane indicates a monoclonal increase in IgG with a κ light chain. This also is observed in the IEP (bottom) with a broad, thickened arc above the IgG trough. The arc below the κ trough demonstrates a nonsmooth arc resembling a spoon shape. All other arcs compare well with the normal control serum.

Immunofixation Electrophoresis

A modification of the immunoelectrophoresis technique first was described in the early 1960s by Alfonso and later refined by Alper and Johnson (7). The technique, known as immunofixation electrophoresis (IFE), has the advantages of rapidity and ease of interpretation over immunoelectrophoresis but suffers the disadvantages of being technique-dependent and a more costly procedure. Commercial materials are available, and the need for investigators to pour and generate their own electrophoresis plates no longer is necessary. Figure 12.6A depicts a normal serum specimen on an IFE plate with six lanes labeled

serum proteins, IgG, IgA, IgM, κ and λ. The clinical specimen, be it serum, cerebral spinal fluid, or urine, is placed at the indicated origin on each side of the lanes. Total sample volume is approximately 5 µl. The specimens are electrophoresed to separate the individual proteins in the sample. At the end of the electrophoresis time, a template is placed over the gel and pressed gently but firmly into the gel to create a seal around each of the lanes. For the lane marked serum protein, a protein fixative is added to denature and immobilize the serum proteins. For each of the other lanes, a specific antiserum is placed over the lane. The plate is covered and allowed to incubate for approximately 30 minutes. At the end of this time, the plate is washed in saline several times to remove all the proteins that have not been complexed or fixed. Therefore, the only proteins remaining in the individual lanes are those that were denatured with the fixative or those that formed complexes with the specific antiserum placed on the lane. Once the plate has been washed thoroughly, it is stained with a standard protein stain and the bands are visualized. Lanes marked G, A, and M indicate G, A, and M antisera and the presence of the respective immunoglobulin band. A diffuse area of stain is indicative of polyclonal proteins complexing with the antisera. A sharp, well-defined, darkly stained band indicates the presence of a monoclonal protein. The lanes marked κ and λ will indicate the type of light chain associated with the heavy-chain globulin or will indicate the presence of free light chains. A more detailed discussion of immunoglobulin gammopathies and protein band interpretation is available elsewhere in this edition. The main advantage of IFE is that the individual globulins and the light chains can be compared directly to the band staining of the whole sample serum proteins. If there are unusual intensities or the presence of abnormal bands in the whole serum sample, they can be compared directly to bands that are generated with specific antisera on the same plate. Figure 12.6B is an IgG monoclonal gammopathy of the κ light chain type.

INSTRUMENTAL METHODS

Part of "12 - Immunochemical Methods"

As immunoassays began to develop, there was an evolution from early qualitative precipitation techniques to procedures that separated the antigen and antibody, isolated the complex on a gel,

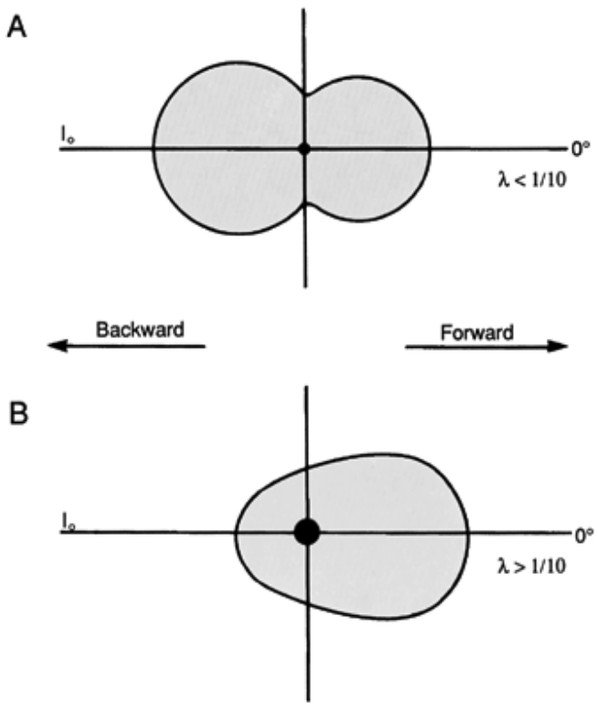

FIGURE 12.7. Light scattering as a function of particle size and angle. (**A**) Small particles (particle size less than one-tenth wavelength) scatter in a symmetrical envelope about the center of the particle. (**B**) Large particles (greater than one-tenth λ) scatter asymmetrically about the particle center, with greater intensity in the forward direction. The light source is unpolarized in both diagrams.

stained it, and quantified the stain densitometrically. The work by Drs. Berson and Yalow opened the door to a new era of instrumental techniques that had the requisite precision and sensitivity to make immunoassays a more controllable and routine analytical technique in the clinical laboratory (8). The original work of these investigators used a labeled technique whereby a molecule with a different physical characteristic was linked to the antigen-antibody reaction so a quantitative measurement could be made. From this, investigators began to pursue alternative methods. One approach took advantage of the formation of the antigen-antibody complexes without the introduction of additional molecules or atoms. In another method, investigators sought alternative labels that would have the same characteristics as the radioactive label but not share some of the disadvantages. The next sections describe these instrumental techniques. They have been arbitrarily divided into those that do not employ a label or marker for the measurement of the antigen-antibody complex and those that do.

Non-Labeled Methods

Light Scattering

Light scattering is the result of the interaction of electromagnetic radiation on particles as it passes through a sample. Light, being electromagnetic radiation, has both an electric field and a magnetic field component. As the particles in solution come under the influence of the electric field, the electrons move in one direction and the nuclei in the other, causing a relative separation. Because the electric field is sinusoidal in nature, the particle oscillates or resonates in synchrony with the electric component. This oscillation results in the reemission of energy with the same frequency as the incidence light. This reemission phenomenon is spherical in nature; that is, with reference to the specimen it can be measured in all directions. There are several characteristics of both the incident light and the particles that will affect the nature of the scattered signal. Among these are the wavelength of the incident light, whether or not the incident light is polarized, the size of the particle, the molecular weight, the concentration of particles, and the distance at which the observation or measurement is made.

Particle size generally is divided into two categories: one in which the particle is less than one tenth the wavelength of the incident light, and the other in which the particles are greater than one tenth the wavelength of light. In the first instance, the particle is small enough to be totally within the influence of the electric field. In this case, all portions of the particle see the field strength equally and become a point source of reradiation of the incident light. This phenomenon was first described by Lord Rayleigh and is described by the Rayleigh equation for small particle scattering.

$$I_s = I_i[16\pi^2 a \sin^2\xi/\lambda^4 r^2] \qquad (12.3)$$

In this expression, I_s is the intensity of the scattered light; I_i is the intensity of the incident light; a is the polarizability of the small molecule (i.e., the ability of the electric field to separate the electronic and the nuclear components of the particle); ξ is the angle of observation measured from the line of the incident light; λ is the wavelength of the incident light; and r is the distance of the observation. Although several important relationships can be taken from this equation, it is important to remember that this was derived for particles suspended in a gaseous medium and requires some corrections for solutions. The main characteristics of this expression are:

- The intensity of the scattered light is a function of the fourth power of the wavelength of the incident light; that is, short wavelengths will scatter more intensely than longer wavelengths.
- The intensity of the scattered light will be reduced in relation to the square of the distance of the obstruction. Therefore, the collectors or the measurement device should be as close to the source of scatter as is physically possible.
- As this equation is written, the right-hand side has essentially two components. The first is the intensity of the incident light, and the second is the combination of factors and constants that describe a given system. Therefore, for any given system, the scattered intensity will increase directly as the intensity of the incident light is increased. This is the rationale for the use of high-intensity sources such as lasers to yield higher scatter intensities.

The corresponding equation for liquid systems with particles in suspension and a nonpolarized source of incident radiation is given below:

$$I_s = I_i\,[4\pi^2\,(^{dn}/_{dc})^2\,Mc\,(1+\cos\xi)\,/\,N\lambda^4 r^2] \qquad (12.4)$$

The symbols remain the same as in the previous equation, with the addition of the dn/dc, a correction factor for the incremental change in refractive index of the solution with an incremental change in the concentration of particles; M is the molecular weight of the particles in question; c is the concentration; N is Avogadro's number. This expression now relates the concentration and the molecular weight of particles to the intensity of the scattered light. This is the more useful form for solution chemistry and the one that is utilized in immunoassay systems.

There are other considerations in using light scattering for immunoassay. Among these is whether the source is polarized. Other sections in this text give a detailed description of the difference between polarized and nonpolarized light. For the nonpolarized source, the scattering intensity generally is greater. Looking at the scattering intensity diagram associated with small molecules, one realizes that the scattering envelope is symmetrical about a 90° axis to the particle. The scattering envelope has a remote resemblance to the figure eight. This is in contrast to the scattering envelope of large molecules, which is asymmetrical with the greatest intensity in the forward direction and minimal intensity in the backward direction. Figure 12.7 depicts these differences. By comparing these two diagrams, it is clear that, when using scattered intensity as a measure of the presence of small molecules in a sample composed of both large and small molecules, it would be most advantageous to measure the backward scatter, because this would be least affected by large particles.

Large-particle scattering differs from small-particle scattering in that the particle generally is considered larger than one tenth the wavelength of incident light. This larger particle size means

that as the electric fields impinge on the particle, different portions of the particle will respond to differences in the electric field strength. Therefore, a large molecule can have several points of oscillation and reemission. These will constructively or destructively interfere with each other. The net result of multiple points of scattering is that the strongest intensity is in the forward direction and the weakest in the backward direction.

The molecular weight characteristic that is measured in light scattering is a weight average molecular weight. In immunoassay measurements, this means any reaction that takes place must increase the average molecular weight of the particles in solution. The greater this average molecular weight change, the greater the changes in intensity of the scattered signal. This last point is one of the reasons that light scattering techniques have not enjoyed the popularity that was initially expected. The principle of light scattering should allow the direct measurement of the complex formation. There is no requirement for additional labels or secondary indicator molecules. The problem arises when one tries to measure steroids, drugs, or other low-molecular–weight compounds in moderate to low concentrations in a matrix made up of serum proteins and lipids. The combination of an antibody to these monovalent antigens does not shift the average molecular weight sufficiently to generate a strong signal above background. Many things have been done to decrease the background signal and improve the scattered signal from the solution being investigated, but once additional steps are required, light scattering methodologies begin to have practical limitations. When an immunoassay system is set up to measure high-molecular–weight proteins in moderate to large concentrations, light-scattering is very effective. If the concentration of large molecules is too high, the macromolecular complexes that form begin to take on the appearance of aggregates. Aggregate formation does one of several things. First, the *number* of molecules present in the solution changes. Aggregates are seen as a single particle, thereby effectively reducing the number of particles in solution. Second, the average molecular weight changes by a very significant amount. Third, the physical size of these complexes exceeds the limitations of the Rayleigh-Debye scattering theory. A much more complex physical-chemical model must be employed to describe the scattering phenomenon as associated with aggregates in solution. Because of these multiple changes in solution, the results are nonlinear. Fortunately, this nonlinearity of the response can be handled by the conventional data handling techniques employed in other immunoassay procedures. These are discussed under Data Reduction.

Turbidimetry and Nephelometry

Light scattering is measured in the laboratory by one of two methods, turbidimetry or nephelometry. The difference is in the angle at which the analytic signal is measured. For turbidimetry, the detector is in line with the incident source and usually is referred to as either zero angle or 180°. For nephelometry, any other angle is used to measure the scattered signal. Turbidimetry measures a decrease in signal because of to the scattering of incident light by particles in the solution. This means that you are measuring a small difference between large numbers. Nephelometry, on the other hand, measures scattered signal against no signal because it is out of line from the incident radiation. The sophistication of modern spectrophotometers is such that turbidimetric measurements are adequate for many laboratory procedures when the antigen or antibody of interest is in moderate to high concentration. Nephelometry, however, is suited to making those measurements when the antibody or antigen is in low concentration. The much smaller signal generated by these molecules will be more easily detected against a very low background.

The sample preparation for light scattering measurements is the same whether one uses a turbidimetric or a nephelometric approach. Samples must be free of any material that is capable of scattering light such as chylomycra, dust, or other particulate introduced from the collection and preparation process. It also is important that the wavelength of light used to measure the scattering is chosen so that it is not in a transition band of a component in the solution. This means that radiating a specimen with a wavelength of light that will be absorbed by any of the components in the serum will reduce the emitted light. Turbidimetric measurements will interpret this as high scattering as a result of a high concentration of analyte, while nephelometric measurements will be made with an extremely weak signal. Interference from phosphorescence and fluorescence can be controlled with good optic design or by using polarizing filters. A potential problem for scattering and all methods that measure antigen-antibody

reactions is that of antigen excess. Instrumentation that relies on endpoint determination, that is, takes a measurement at the beginning of the reaction and one at a later time, must be capable of detecting antigen excess. This becomes less of a problem in automated instruments that use a kinetic approach, because algorithms are available for the microprocessor to determine whether the kinetics are taking place in the antigen-deficient, the equivalent, or the antigen excess zone of the curve.

Several instruments currently are on the market that are capable of doing turbidimetric or nephelometric measurements in either an endpoint or kinetic mode or both. The computer processing power within these instruments is significant, and most have complex data handling routines that allow analysis of complex curves.

Labeled Methods

It is obvious from the previous sections that there is no single immunoassay system that is suited for all the analytic measurements in the clinical laboratory. To increase the sensitivity of immunoassays, labels or markers were introduced. The first of these was the radioactive label, but that has been followed by enzymes; fluorescent, luminescent, and phosphorescent compounds, as well as metals and particle labels. The objective in using labels in immunoassay is to improve the sensitivity so that heretofore-unmeasurable analytes can be quantitated. A second objective, particularly of more recent labels, is to make the methodology simple and straightforward so increasing numbers of laboratorians would have access to the technology using standard clinical laboratory equipment. The second objective has been amended because newer labels employ technologies that are quite complex, rely on equipment that has not historically been in the clinical laboratory, and necessitate the use of powerful on-board computers for data reduction. Most of this complexity has been hidden from the technologists with the “black box” design. In addition, although the objectives are universal, the types, methods, and approaches to labeling are diverse. Labels have been linked covalently to antigens and antibodies, both the primary antibody used to detect an analyte, and secondary antibodies used for the detection of the antigen-antibody complex. Also, molecules such as enzyme inhibitors, cofactors, and fluorescent quenchers have been used as the covalently linked molecule but are there to affect the action of another molecule that is monitored for analyte quantitation. The current laboratory and research literature is replete with methods and variations on methods dealing with new labels, the chemistry of label analyte attachment, and system design. Although the details of these methods differ, they can be grouped into broad classifications based on conceptual similarities.

Labeled Antigen

There are several points to consider when selecting labels to be covalently attached to an antigen. One is the size of the antigen. For small antigens such as drugs, vitamins, and steroids, the antigenic binding site may comprise a significant portion of the molecule. If a very large label, such as an enzyme, were to be linked to this antigen, it must be done in a manner that will not sterically block the epitope on the antigen. Small labels such as isotopes, spin labels, and fluorophores must be attached in such a way as to not sterically hinder binding or change the electronic environment of the binding site. In all cases, the label must be attached so that it remains an efficient monitor of the antigen-antibody interaction but must not destabilize or significantly alter that antigen-antibody interaction.

Some successful approaches to these problems have been the use of carbon spacer arms, that is, long carbon chains that attach the antigen on one end and the label on the other. This spatially separates the label and the antigen so that steric and electronic interference is minimized. Synthesizing the antigen with ^{14}C or tritium atoms, so that it is radioactive, has the advantage of providing a true label that is structurally indistinguishable from the natural antigen. If the antigen is large, such as proteins, then the labels can be added much more easily and with less probability of interfering with the antigen-antibody interaction. Fortunately, except for research and very specialized applications, the antigens of clinical interest have been prepared with various types of labels and are commercially available. If an investigator elected to label his or her own antigen, a first approach would be to investigate using derivatives of carbodiimide, succinimide, isothiocyanate, or other organic reactions that would be appropriate for the reactive groups available on the antigen.

Antibody labeling is similar to labeling peptide or protein antigens. Most of the antibodies used in clinical chemistry are commercially available with a wide selection of labels.

Assay Design

Once the reagents have been assembled, there are several possible configurations for the ultimate assay system. These include competitive, noncompetitive, homogeneous, and heterogeneous systems. Each of these has its specific advantages and disadvantages. The choice of an essay system is generally a function of the type and quality of label and antibody available.

Competitive Assay

In this type of assay, the labeled antigen and native antigen compete directly for a limited number of binding sites in the reaction mixture. These binding sites are usually present as a fixed concentration of primary antibody. The reaction follows the law of mass action. Equations 12.1 and 12.2 illustrate the relationship between labeled and unlabeled antigen in the final antigen-antibody complex. To achieve maximum sensitivity in this assay system, it is imperative that the labeled antigen has the same binding characteristics to the antibody as the unlabeled antigen. Labels that are very large compared with the native antigen or that significantly alter the electronic environment of the antigen can alter the binding characteristics of the antigen with the antibody. This would make one of the antigens a favored binding partner, and, although the assay may work, it could have several technical difficulties, including a lack of sensitivity. The favored binding partner here is not always the native antigen.

When the antibodies are generated against an antigen with a covalently linked carrier, one of the epitopes recognized by the antibody is the organic linkage. When the antigen is labeled, if

that same organic linkage is used, the antibody could bind most strongly to that epitope. In this case, the native antigen would have difficulty in displacing the labeled antigen, and a serious reduction in sensitivity would result. These competitive designs are sometimes referred to as limited reagent systems because the concentration of antibody is held constant at a level that is insufficient to bind all antigens present. This was the predominant assay design of the original RIA methodologies.

Noncompetitive Assay

In noncompetitive methods, there is sufficient reagent to bind the antigen present in the specimen. One very popular approach to this technique is to fix an antibody to a solid support. That support can be a microtiter well, test tube, bead, or other appropriate solid support. Sample containing the antigen is added with the appropriate buffer to the solid support and allowed to incubate. During the incubation time, the antigen binds to the fixed antibody. The support material is then washed and incubated with a second antibody, which may be labeled. This second antibody then binds to a different epitope on the antigen and forms what is commonly referred to as a "sandwich." The support is washed a second time to remove all the unbound antibody, and, if the second antibody had been labeled, the measurement is made. If the second antibody is not labeled, a third antibody that will recognize the second antibody is added. This third antibody carries the label. The requisite reactants are added, and the measurement is made.

HETEROGENEOUS AND HOMOGENEOUS ASSAY SYSTEMS

Part of "12 - Immunochemical Methods"

In heterogeneous assay systems the physical characteristic of the label is unchanged by the binding process. The label that indicates the presence of the antigen-antibody complex must be separated from the extraneous label to make the quantitative measurement. An obvious example would be the radioimmunoassay system, in which the bound radioactive label emits the same signal as the unbound radioactive label. Techniques have been developed that will allow the separation of these two forms of label, allowing the measurement of either fraction. Separation techniques such as precipitation with other antibodies or chemicals, adsorption onto solid surfaces, chromatography, electrophoresis, and some innovative approaches such as coated magnetic particles, have all been successfully employed. The choice of the separation technique used in a heterogeneous assay is primarily dependent on the label used and the clinical application. For example, if the application were one that requires processing large numbers of specimens in a short period of time, then a precipitation, adsorption, or decanting technique would be most appropriate. Conversely, in some research applications, one may be able to process small numbers of specimens by using chromatographic or electrophoretic separation.

In homogeneous assays, the physical characteristic of the label changes upon binding; therefore no separation technique is required. If enzymes are used as labels, the enzymatic activity can either increase or decrease when the antigen-antibody complex formation takes place. Likewise, fluorophores can be either activated or quenched upon formation of the complex. These assay methods are generally thought to be simpler and more straightforward because the analytic measurement can be made in the presence of all the reactants.

Immunoassays designed around any of these techniques require a significant number of controls. It is important to monitor antibody characteristics, background signals, nonspecific signals, and potential interference.

SPECIFIC ASSAY TYPES

Part of "12 - Immunochemical Methods"

Radioimmunoassay

Radioimmunoassays take advantage of a radioactive atom being incorporated into one of the reactants as a label. The most common clinical atoms used are ^{125}I, ^{57}Co, ^{3}H, and ^{14}C. The γ-emitting nuclides ^{125}I and ^{57}Co can be incorporated directly into the structure of the antigen, as in the case of the thyroid hormones (^{125}I) and vitamin B_{12} (^{57}Co). The ^{125}I also can be inserted through organic reactions into the ring structure of the amino acids of peptides and proteins. These γ emitters decay at a rate that is characteristic of the atom itself. This decay is unaffected by the environment of the immunoassay reaction and can be counted with reasonable efficiency with standard γ-counting instrumentation.

The ß emitters ^{14}C and tritium generally are reserved for small molecules such as drugs and steroids and are usually substituted for "cold" atoms in the structure. As with the γ emitters, the physical decay of ß emitters is unaffected by the environment of the assay. However, the energy of the ß emission is such that it is easily absorbed by many naturally occurring compounds, making it impossible to measure ß emission directly. In order to detect ß emission, the samples are counted in a scintillation cocktail. This cocktail contains a carefully chosen solvent and organic flurophore that absorb the ß energy and reemit it as a flash of light. This flash then is counted in a scintillation counter that detects these flashes as individual events. Because energy transfer is involved, the efficiency of the detection of events is much lower than with γ emitters.

Because of the characteristics of radioactive labels, all RIAs are heterogeneous assays. The separation step in RIA generally is designed to fit the type of label employed. For labels that are small, like drugs and steroids, an adsorbent such as activated charcoal can be used to adsorb out the unbound label. This is a carefully timed process so that the charcoal does not strip away the label from the antibody, thus destroying the antigen-antibody complex. At the end of the incubation time, the samples are centrifuged and the supernatant is decanted into a second tube. The investigator has the choice of counting the supernatant that contains the bound complexes, the charcoal precipitant that contains free label, or both fractions so that a total and percent bound can be calculated on each specimen. This is older technology that has generally been replaced by simpler methods.

Another procedure is to precipitate the antigen-antibody complex with agents such as ammonium sulfate, polyethylene glycol, or additional antibodies that recognize the first antibody

used to form the antigen-antibody complex. Here the second antibody is used to make a large lattice of the antigen-antibody complex in solution. All of these methods require centrifugation to pellet the precipitant. The supernatant is decanted, and the pelleted material can be counted as the antigen-antibody complex.

Other methods use a first antibody that is fixed to a solid surface. The solutions containing the antigen and the label are added, and at the end of the incubation time, the solution is decanted. The bound antigen being fixed to the surface of the reaction vessel is then counted directly.

RIAs are capable of precise and accurate quantitation of antigen-antibody complexes if sufficient controls are included in each assay. Obviously, standard concentrations of unlabeled antigen must be used to construct a dose-response or standard curve. In addition, controls must be added to monitor the total amount of radiation added to each tube, the nonspecific binding of the radioactive label to other proteins and surfaces in the reaction medium, and, in the case of ß emitters, quench controls that monitor the energy transfer process in the specimen matrix under investigation. It is not unusual in an RIA to find a large percentage of the samples being processed to be control or calibration specimens.

The advantages of RIA are its exquisite sensitivity and the ease with which multiple specimens can be processed. With a little experience, a laboratorian can batch-process 100 or more specimens in duplicate with all the requisite controls. This makes it an attractive technology for the medium to large clinical laboratory.

The disadvantages of RIA are the short shelf-life of the labeled reagents because of the short half-life of the radioactive nuclides themselves and the damage that the nuclides do to the proteins in the reagent. In addition, there is a requirement for strict record keeping and personnel monitoring. This makes RIA somewhat more costly than other immunoassay methods, although in recent years, competition from nonisotopic methods has forced the price of prepackaged materials to a more affordable level.

Enzyme Immunoassay

Enzyme immunoassay (EIA) is a generic term that encompasses all assays that fulfill the following criteria. First, they employ immunologic elements to detect the analyte of interest, and second, enzyme activity is used to quantitate the analyte. It will become obvious that although these two criteria are relatively straightforward, some of the chemistry and assay designs are not. Many reasons can account for this. There is the general attractiveness of monitoring immunoassays with enzymes. Enzyme reactions are well-defined, familiar measurements that have been made in the clinical laboratory for decades. The enzymes themselves have been isolated, purified, and characterized and are made available by commercial suppliers at relatively low cost. The enzyme preparations are stable with long shelf lives, and they represent a minimal hazard to the laboratorian. Theoretical sensitivities range from 10^{-14} to 10^{-16} mol/liter, giving these assays the sensitivity required for many clinical assays (9, 10). Measurements either can be made on standard spectrophotometers or can be automated on high-throughput instrumentation. In addition, unlike the RIAs, EIAs require no extra licensing, record keeping, or expensive disposal procedures that ultimately contribute to the cost of laboratory analysis.

When laboratorians and researchers are left to their own devices, they tend to “tinker.” This inherent inquisitiveness, coupled with the almost unlimited number of combinations and permutations of reactions that can be put together, has led to some very ingenious and complicated assay systems. Obviously, only the most reliable and useful of these techniques will find their way to the clinical laboratory for routine use.

The function of the enzyme in the EIA is to act as an amplifier. Each enzyme linked to the antigen-antibody complex will operate on the substrate and produce products that can be measured to quantitate the formation of the antigen-antibody complex. Enzymes will continue to turn over substrate, so a few bound enzymes will result in multiple moles of product formed, resulting in an amplified signal. The assay can be designed so that there is maximum activity when no free analyte is present or there can be maximum activity when maximum free analyte is present. The following sections provide the basic requirements of the enzyme and the substrate that must be considered when designing an assay.

Enzyme Availability

Enzymes can be of plant or animal origin as long as they are abundant and isolated without difficulty. The enzymes should be robust in the sense that they can be subjected to mild organic reactions without losing appreciable activity, and they should have significant activity in the environment in which they will ultimately be used to make analytic measurements. Enzyme activity can be defined as the quantity (micromole, nanomole, picomole) of product formed (or substrate consumed) per unit time under a given set of reaction conditions. The more product formed per unit time, the greater the potential sensitivity of the assay. The enzymes should be inexpensive and available in virtually unlimited quantity. These criteria have essentially limited commercial assays to the use of horseradish peroxidase and animal source alkaline phosphatase.

Substrate

The substrate should share some of the characteristics of the preferred enzymes in that it should be available at reasonable cost in a purified form. There should be a significant difference in the measured characteristic of the substrate compared with the products formed in the enzyme reaction. This means that if the substrate is colorless, the generated product should be colored or fluorescent or should possess any other characteristic that allows confident measurement of the products in the presence of the substrate and other potential interferents. The substrate should also be stable so that it undergoes minimal nonenzymatic conversion to products. As with other reagents, biological hazards should be minimized.

One very popular type of EIA, known as the enzyme-multiplied immunoassay technique (EMIT) assay, has been developed commercially. This is a homogeneous-type assay in which the

enzyme has been conjugated to the analyte in such a way that the enzyme retains its activity in the absence of analyte-binding antibody. When free analyte is added as either a control or a specimen with a fixed amount of antianalyte antibody, the free analyte and the enzyme conjugated analyte compete for the limited number of binding sites on the antibody. When the antibody binds with an analyte that has been conjugated to an enzyme, the enzyme activity is inhibited. Consequently, the inhibition of the enzyme activity is directly proportional to the concentration of free analyte in the solution. This approach has been used very successfully in the therapeutic drug monitoring area. This is a particularly good example of a homogeneous assay because no separation step is required to measure enzyme activity. The final activity measurement can be made in the presence of all the components in the reaction.

A second type of EIA that has been popularized by researchers and commercial vendors is the enzyme-linked immunosorbent assay (ELISA). Although the term ELISA is used interchangeably with EIA, it is more appropriately applied to assays of the heterogeneous solid-phase type. Any solid material can be a candidate for the support component in an ELISA as long as it is capable of irreversibly adsorbing protein to its surface, or the surface can react chemically to covalently bond protein to the surface. Materials that have been used successfully in the past include membranes, microtiter plates, plastic test tubes, plastic beads, various polymers, and coated metal particles. These solid surfaces all perform the same function in the ELISA—to fix one of the components so that the bound enzyme can be separated from the free enzyme. In this assay, the enzyme usually retains its activity independent of its bound or free state.

In the competitive ELISA, controlled quantities of the analytic antibody are fixed to the solid phase. Then, the analyte from the specimen is mixed with the enzyme and conjugated analyte, and these are allowed to compete for the limited number of antibody-binding sites on the solid surface. After a sufficient incubation time, substrate is added, and the amount of conjugated analyte bound to the fixed antibody will generate measurable product. The concentration of the substrate product is inversely proportional to the concentration of free analyte in the test specimen.

Another approach to an ELISA system is the “sandwich” or capture design. In this procedure, an analytic antibody is fixed to the solid phase. The analyte from the test specimen standard or control is added and allowed to react with the antibody on the fixed surface. After a sufficient incubation period, the surface is washed and a second analytic antibody conjugated to an enzyme is added and allowed to incubate. The second antibody recognized a different epitope on the antigen; therefore, this system works best with analytes or antigens that are large enough to have epitopes separated on the molecule so that the two antibodies can bind freely. After the second enzyme-conjugated antibody has incubated, the surface is washed and substrate is added. The generated product is directly proportional to the concentration of analyte in the test specimens.

ELISAs also may be designed to determine antibody concentrations. Applications to screen cultures for antibody production or to measure antibody in the serum of patients suffering from various autoimmune diseases have been used in the clinical laboratory. In these assays, the antigen is fixed to the solid surface and the test specimen is added so that the antibody will bind to the fixed antigen. The surfaces are washed, as in the other assays, and a second antibody-directed against the IgG of the species generating the first antibody, e.g., human IgG in the case of autoimmune disease, which has been conjugated to an enzyme, is added. After incubation, the surfaces are washed, the substrate is added, and the concentration of the generated chromogen is directly proportional to the antibody concentration in the test specimen.

It should be obvious that there are numerous combinations of antigen-antibody, enzyme, cofactor, and substrate that can be combined in various ways to detect antigen-antibody interaction. The more complex the assay design and the more steps involved, the more difficult it will be to maintain a consistent and reproducible assay over a long period. In the simplest of these assays, one still has to be concerned about maintaining an optimum environment for both the antigen-antibody binding and the enzyme activity. As more steps are added, the potential for poisoning the enzyme, reducing the antigen-antibody interaction, or just generally increasing the background signal, becomes greater. Some of the more common enzyme reactions are listed in Table 12.1.

TABLE 12.1. ENZYMES COMMONLY USED IN EIA

Enzyme	Some Substrates
Alkaline phosphatase	4-Methylumbelliferone phosphate *p*-nitrophenyl phosphate
Glucose-6-phosphate dehydrogenase	Glucose-6-phosphate + $NADP^+$
Glucose oxidase	Glucose
Peroxidase	H_2O_2
ß-Galactosidase	ß-Galactosides

Fluorescent Immunoassay

Fluorescence is a phenomenon exhibited by molecules that have the ability to absorb light energy and then dissipate that energy, with some of its being re-emitted as light of a longer wavelength. Fluorescence lifetimes are on the order of 10^{-9} to 10^{-5} seconds, which means there is a delay between the absorption of the exciting light and the emission of the fluorescent light (11). Figure 12.8 depicts the relationship between the wavelength of the absorbed light and the wavelength of the emitted light. The difference between these two wavelengths is referred to as Stokes' shift. Fluorometers have been designed to take advantage of both of these characteristics. Excitation sources can be pulsed, i.e., turned on and off very quickly, so that measurement of the emitted light is less encumbered with the more intense exciting light. The delay between absorption and emission makes this possible. This can be combined with detectors chosen to be more sensitive to the emitted light than the exciting light for increased performance. In addition, fluorescence is emitted in all directions, so detectors can be placed anywhere around the sample and are not in direct line with the exciting light, as is the case in most adsorption spectrophotometers.

Molecules that fluoresce generally have some common characteristics.

First, they are usually ring compounds that exhibit extensive conjugation. The greater the number of alternating single and double bonds the greater the stability of the excited molecule, which leads to enhanced fluorescence. It is also observed that the greater the molecular planarity and the molecular rigidity, the greater the tendency to fluoresce. Some molecules, particularly chelaters, can be made strong fluorophores by adding the metal ion for chelation (11). It also is known that concentration, temperature, pH, and ionic strength among other things have a significant effect on the fluorescent efficiency of a molecule.

Fluorescent efficiency is termed quantum yield and is a number between 0 and 1 that expresses the amount of emitted light compared with the amount of absorbed light. Any condition that will allow an excited molecule to dissipate its excess energy through processes other than light emission will decrease the quantum yield. Conditions that are commonly encountered allowing a molecule to dissipate its energy are intermolecular collisions caused by high concentrations of fluorophore, elevated temperatures of reaction mixtures, and destabilization of resident structures by other components in the reaction mixture.

Very dilute solutions of fluorophores, in the range of micromolar to picomolar concentrations, generally are used at room temperature or cooler. Fluorescence can be measured with common clinical laboratory instrumentation and present relatively inexpensive, nonhazardous methodologies. It should be noted that fluorescence is a complex process usually dealt with in advanced chemistry and physics textbooks. The observations outlined here are presented as broad concepts so the reader has an appreciation for the requirements of a usable fluorescent immunoassay.

Assay designs in fluoroimmunoassay are very similar to the EIA designs. A fluorescent molecule can be conjugated to an antibody or an analyte and the reaction can be monitored by the presence or absence of fluorescence. The concentration of analyte in the specimen is determined by comparison to standards. The assays can be designed to be heterogeneous, homogeneous, competitive, or any other design that satisfies basic analytical principles. The more interesting uses of fluorescence are in the techniques of fluorescence polarization and time-resolved fluorescence.

Fluorescence Polarization

Fluorescence and fluorescence polarization measurements take advantage of three of the characteristics of fluorescent molecules. These are quantum yield, the time differential between adsorption and emission, and emitted light of a different wavelength than exciting light. The specific nature of the interaction of electromagnetic radiation and matter can be found elsewhere in this book and in other texts. Suffice it to say that a molecule must have a specific orientation in relation to the exciting light for the molecule to absorb energy and be elevated to an excited state. Normal light has a mixture of orientations of electric and magnetic fields. If a polarizing filter were placed between the light source and the sample, the sample would see only one orientation of the electric and magnetic component. Samples with the appropriate orientation would then absorb this light and be elevated to an excited state. If this system were frozen in time, the fluorescence emission would have the same orientation as the exciting light. However, due to the molecular rotation and the length of time required for a molecule to go from exited state to ground state, the resulting fluorescence is a mixture of electric and magnetic orientations. By imposing another polarizing filter between the sample and the detector, only the fluorescent light with the appropriate orientation will be detected. Therefore, the intensity of the polarized fluorescent signal is related to molecular orientation. Conceptually, this means if something can be done to decrease the rotational velocity of the fluorescent molecules so they retain their original orientation until they fluoresce, the intensity of the fluorescence signal will increase. In fluorescent immunoassays employing polarized signals, the rationale is that the analyte is labeled with a small fluorophore and it will rotate rapidly. In addition, relatively few molecules will emit the appropriate plain polarized light for detection. Once these analyte molecules are bound to an antibody, however, their hydrodynamic radius increases significantly. This reduces the rotational velocity, increasing the number of molecules that have the appropriate orientation. The fluorescent signal is thus increased. Under these conditions, a competitive fluorescent immunoassay (FIA) may be set up so that maximum fluorescence signal is obtained in the absence of any unlabeled analyte. When unlabeled analyte is added, competition between the labeled and unlabeled species will reduce the fluorescent signal. The concentration of analyte is inversely proportional to the fluorescent signal. Quantitation is achieved by comparison to a standard response curve.

It was mentioned earlier that the quantum yield is also taken advantage of by fluorescent and fluorescent polarization methodologies. Remembering that quantum yield is defined as the number of photons emitted divided by the number of photons absorbed, and using the Beer-Lambert equation, a series of substitutions and algebraic rearrangements can be made to show that the intensity of the fluorescent signal is directly proportional to the intensity of the exciting signal. That means for a given system, if the intensity of the exciting light is increased (i.e.,

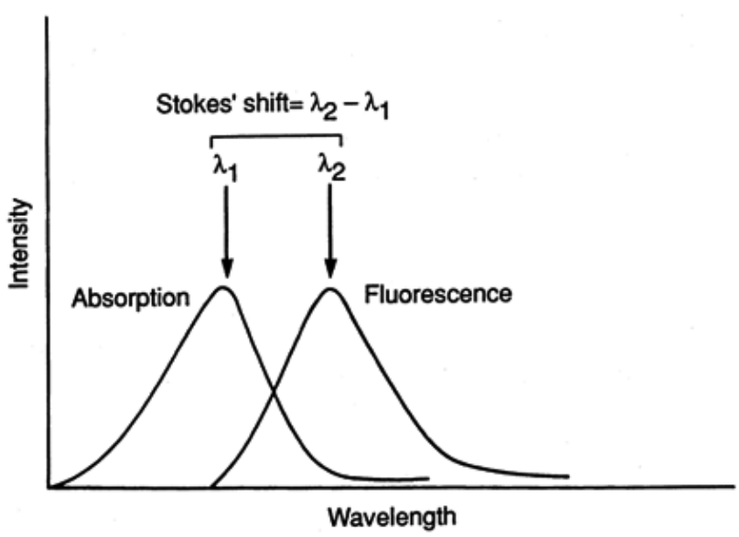

FIGURE 12.8. Relationship of absorption spectrum to emission spectrum of fluorescent molecule. Peak absorption is indicated by λ, and peak emission by λ_2. Stokes' shift is the difference between the wavelengths at the spectral peaks.

through high-intensity lamps and/or lasers), the intensity of the fluorescent signal can be increased. This is one of the reasons that fluorescence measurements are intrinsically more sensitive than absorbance measurements. Absorbance is dependent on the concentration of absorbing species and independent of incident light. Fluorescence is dependent on the intensity of the exciting signal, which can be changed in any given system. High-intensity sources coupled with polarization techniques and photon counting detectors give fluorescence immunoassay a sensitivity that is adequate for many assays. The best fluorescent polarization assays appear to be those dealing with small to medium-sized analytes.

Time-Resolved Fluorescence

Another innovative technique employing fluorescence is time-resolved fluorescence. Again, the basic design of the immunoassay is similar to the other immunoassay designs discussed. The unique feature about time-resolved fluorescence is the selection of a fluorophore that has a large Stokes' shift and an extended decay time. The large Stokes' shift means that the emitted light is separated from the exciting light, reducing the contributions from the excitation source in analyzing the signal. It is, however, from the time-resolved feature of this system that significant advantages are realized.

When a fluorophore has an extended decay time, it means that the fluorescence from a single excitation is extended over a long period. One of the characteristics of the lanthanide chelate complexes is that the fluorescence decay extends into the microsecond range, compared with nanoseconds for conventional fluorophores (11). For assays employing this type of fluorescent detection, the instrumentation excites the fluorophore with a high-intensity pulsed excitation. There is a short delay to allow the background and nonspecific fluorescence to decay before a measurement of the analytic fluorescence due to the lanthanide chelate complex is made. If this process is repeated several times over the course of a few seconds, a significant number of measurements can be made, and a statistically reliable value can be generated for the complex being measured. Because all of the background and nonspecific fluorescence is separated (resolved) from the specific analytic measurement based on time, the process is called time-resolved fluorescence. The analytic measurement is separated from the non-analytic measurements by the passage of time. Coupled with the fact that there is a large Stokes' shift, and the emission wavelength is very sharp, only a very small correction has to be made for the nonspecific signal of the lanthanide chelate complex. In principle, this methodology can potentially have sensitivity equal to or beyond that of radioimmunoassays. At least two commercial systems that take advantage of lanthanide chelate, time-resolved fluorescence.

All fluorescent techniques suffer from several limiting factors. First, fluorescence is sensitive to temperature and viscosity. Reaction conditions must accordingly be held within very narrow tolerances. In addition, most biological specimens contain materials that have natural fluorescence. In the serum or plasma specimen commonly found in the clinical laboratory, serum proteins and molecules such as bilirubin contribute to a significant background fluorescence signal. In these cases, extensive controls or corrections must be applied to separate the analytic measurement from the background signal. Time-resolved fluorescence tends to minimize these problems but does not do away with them totally. Additional interference can be a result of the internal filter effect. This internal filtering occurs when there are molecules in the measurement system that absorb light of the same wavelength as the light being emitted by the fluorescing molecules. One can try to minimize these internal filter effects by choosing fluorescent labels that emit at longer wavelengths. Biological specimens absorb the shorter visible wavelengths more often than the longer wavelengths of light.

Bioluminescence and Chemiluminescence

Chemiluminescent and bioluminescent reactions are similar to fluorescent reactions in that the measured signal is emitted light generated by the relaxation of an excited molecule. The difference between fluorescence and chemiluminescent or bioluminescent reactions is the method by which the molecule becomes excited. In fluorescence, adsorbed light energy raises the molecules to the excited state. In chemiluminescent and bioluminescent reactions, the energy is supplied by a chemical reaction. If the reaction occurs *in vivo*, it is classified as a bioluminescent reaction. Reactions that require reactants or conditions not found in biological systems are referred to as chemiluminescent reactions.

Although many organisms produce bioluminescent reactions, probably the best known is the firefly reaction. In that reaction, the substrate firefly luciferin is oxidized by the enzyme luciferase in the presence of magnesium ion and oxygen ATP, yielding a photon. This is an extremely sensitive reaction and can be used to measure ATP at the femtomole level. The quantum efficiency of this reaction approaches unity because each molecule will emit one photon of light for each photon absorbed. This and other bioluminescent reactions have found limited applicability in the immunoassay field because the reagents are expensive and the reaction works best with small molecules.

Chemiluminescent reactions have been far more successful in immunoassay applications because they are less expensive and easier to work with in assay systems. Chemiluminescent reactions never approach the efficiency of the firefly reaction, but modern photon counting equipment has been able to compensate for this deficiency. The most commonly used chemiluminescent molecules are the luminals, acridinium esters, and dioxetanes.

Luminal

Luminal, its isomer, and derivatives belong to the class of compounds known as aromatic hydrazides. When these compounds are oxidized, they emit light. This reaction usually is carried out with a catalytic agent such as peroxidase in an alkaline medium. When luminal is conjugated to one of the reactants in the immunoassay, the efficiency of the light production decreases significantly. Therefore, one of the more successful designs has been to conjugate the peroxidase to one of the reagents and then use luminal as an indicator of the peroxidase. Competitive and noncompetitive solid-phase systems are the most commonly employed designs using luminal.

Acridinium Esters

Acridinium esters are perhaps the most common of the chemiluminescent labels in use today. These compounds can be oxidized without the requirement of a catalyst. The efficiency of this reaction is greater than that of luminal. For these reasons, acridinium esters form the basis of many of today's automated immunoassay systems. Acridinium esters can be conjugated to large or small molecules without significant loss of light-emitting efficiency. They work equally well in most assay system designs; thus, instrument considerations usually dictate the type of assay system.

Dioxetanes

Dioxetanes are thermally unstable molecules that stabilize by thermal cleavage with the emission of light. These compounds can be made stable by adding a phosphate group to the phenyl ring. Under these conditions, an immunoassay can be designed that uses alkaline phosphatase conjugated to one of the reactants. Then, the phosphorylated dioxetane can be added as an indicator. Once the phosphate group is removed from the dioxetane by the alkaline phosphatase, the compound reverts to its thermally unstable condition and will emit light. Enhancers, which are essentially carefully chosen inner filters, can be used to lengthen the time that the light is emitted from the reaction.

The instrumentation required for chemiluminescence is a photometer with special adaptations. Generally, the instrument is equipped with a reagent injection system so reagents can be added while the reaction cuvette is in front of the detector. The detector is usually a high-efficiency photomultiplier tube that counts photons for a prescribed time and then employs some type of averaging algorithm to quantitate the signal. If enhancers or other types of chemistry are used to extend the light emission, less stringent requirements are placed on the photomultiplier tube.

Data Reduction

In the early days of radioimmunoassay, data reduction was a do-it-yourself project. Investigators did what they thought was appropriate to calibrate an assay and in turn to calculate results on unknown specimens. In addition, an effort was made to glean appropriate quality control indicators from these numerical procedures. The literature was replete with reviews of data reduction schemes, exploring the strengths and weaknesses of the proposed systems. The evolution of both immunoassays and data reduction systems has evolved to a point where there is more agreement on the approaches that should be used as well as significant improvement in instrumentation, desktop computers, and software. That is not to say, however, that the procedure for data reduction and quality control should be accepted from the vendor without a thorough understanding of the procedures and approaches used. All data reduction packages share a similar objective, which is to make an accurate and precise estimate of the concentration of an analyte in a given solution. Some of the more common approaches to achieving this objective are described below.

One of the first questions asked about a new assay is, “What is its limit of detection or sensitivity?” Because of the number of steps in most assays and the imprecision associated with any physical measurement process; there is a degree of uncertainty associated with each calculated result. The appropriate way to determine the limit of detection is to evaluate a zero concentration sample, calculate the statistical mean and standard deviation, and use this information to determine the analyte concentration indistinguishable from zero. A simple and practical approach to accomplishing this is to make multiple measurements on several concentrations of analyte within the range of interest, calculate the mean and standard deviations for each of these concentrations, and plot the standard deviations versus the concentration. Extrapolation of this line to zero concentration gives an appreciation for the smallest detectable analyte concentration that differs from zero (Fig. 12.9). This plot, also referred to as a precision profile, can be informative in terms of the working range of the assay. An effective approach is to plot CV percentage versus several analyte concentrations. Then decide on the maximum allowable CV the procedure can tolerate. Draw a line parallel to the x-axis at this point. The intersection with the original plot yields the working range. By evaluating the precision profile, an investigator can determine if at any concentration the standard deviation of the measurement exceeds an acceptable limit.

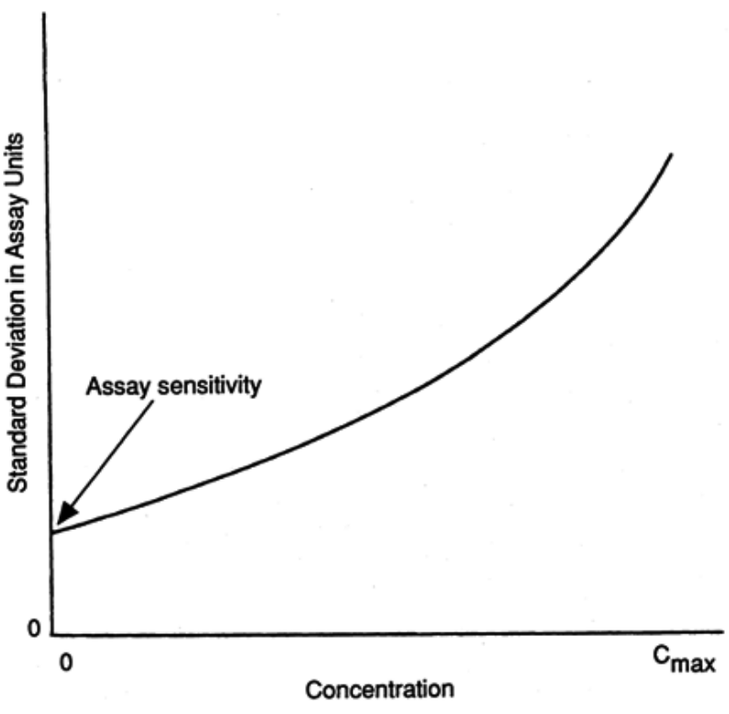

FIGURE 12.9. Precision profile diagrams. The standard deviation for several analyte concentrations has been plotted versus the analyte concentration. The units are the same as the analyte units. The line is extrapolated to zero analyte concentration and yields the level of analyte that does not differ from zero concentration in the assay. If 1 SD is used for the plot, the actual sensitivity will be two or three times the intercept value, depending on the level of confidence required.

Once a series of measurements has been made under the assay conditions, the investigator is faced with the dilemma of

selecting the best approach for using this information to calculate the concentration of analyte in other specimens. This calculation procedure generally is a part of automated methodologies, most of which present the user with a menu of data reduction choices. Manual calculations and plotting of data for the purposes of calculating the concentration of analyte in specimens is less common in the modern laboratory than it was at the time of the original radioimmunoassay. Manual plotting of data and the subsequent extrapolation of concentration for unknowns is an error-prone process. Each individual will connect the points in a slightly different manner and will read the resultant concentrations for unknowns the same way. In addition, manual data reduction is a slow and expensive process that is more important as a teaching procedure than as a daily analytic procedure.

Data reduction methods can be grossly divided into two types. The first are the point-to-point methods in which an attempt is made to draw a smooth line through the data points progressing from one point to the next. Approaches that utilize this method are point-to-point, spline, and polynomial interpolative methods. Computers can be programmed to generate these lines very quickly, but the computer does not correct the underlying weakness of these approaches. That weakness is that there are errors inherent in the values assigned to each concentration and the assumption that all concentrations throughout the working range behave identically. Once a line has been generated through these concentration points, it is assumed that the intervening concentrations, which have not been measured, will fall on that line. One cautionary note when using the polynomial or spline-fit procedures. If the data are “noisy,” the line fitting algorithms will generate a line that has so-called “hooks” because the computer has generated multiple inflection points to go through all of the data. If this situation is severe enough, a single response on an unknown can generate multiple potential concentrations from the curve. If this type of plot is used, it is essential that the curve be visualized to ensure that the standard concentrations are following an anticipated response line. Figure 12.10 illustrates a spline fit to actual assay data.

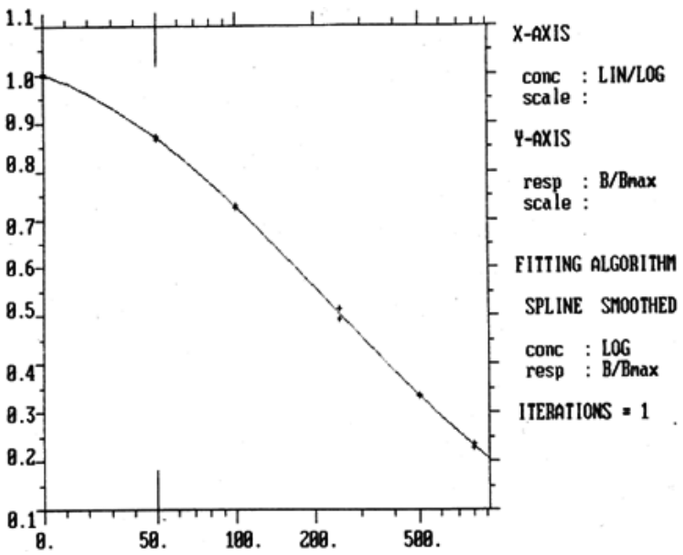

FIGURE 12.10. Spline fit to assay data. The data represent a spline fit to actual laboratory data. The x-axis is Lin/Log because of a zero concentration of analyte that does not have a log value. The response plotted on the y-axis is percent of maximum response. In this example, the spline fit required one iteration to develop an acceptable curve.

Regression methods are the other approach to data reduction. Regression methods fit a line through the data points in such a way that each data point is a minimum distance from the line. In other words, if you were to measure the distance from each data point to the line, that would be a minimum compared with any other line that could be drawn in relation to those data points. The potential problem with this approach is that it treats every data point equally. Therefore, if the method has greater imprecision at the ends of the curve or if there are outliers, the standard regression analysis fails to recognize this and treats all points equally. The method most software packages use to overcome this weakness is that of weighting. In a weighted regression, each point is adjusted by a weighting factor in accordance with its reliability. The points in a region of the curve where the error is greater and the reliability of the measurement is lower are given less influence in the calculation than those points that lie in regions of the curve where the certainty of the measurement is greater. These weighting factors can be determined by calculating the variance of multiple measurements or can be generated from mathematical models if there is sufficient information known about the behavior of the curve under study. Figure 12.11 shows a regression and a weighted regression.

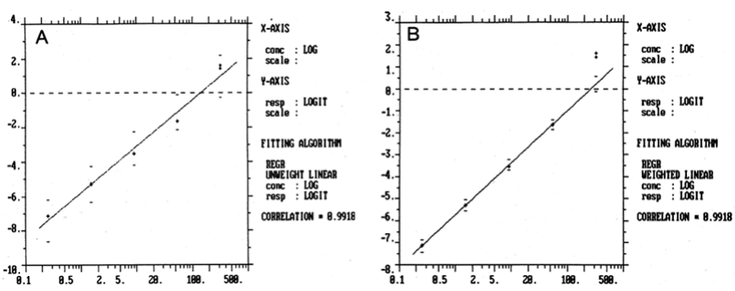

FIGURE 12.11. The figure presents an unweighted (**A**) and a weighted (**B**) linear regression. The x-axis is in log of concentration, and the y-axis is in log of the response. Notice the relative error around the line is smaller in the weighted regression, and the point at a concentration of 200 units has less effect on the line because of the unreliability of the measurement at that concentration.

A popular family of algorithms for fitting data is the logistic fit equations. These are derived from statistical functions that have been adapted to immunoassay data. Equation 12.5 shows several parameters that are related to the analyte concentration, represented by *x*, and the response measured, represented by *y*.

$$y = \frac{a - d}{1 + (x/c)^b} + d \qquad (12.5)$$

The four parameters *a*, *b*, *c*, and *d* have interesting interpretation in terms of the curve generated. Parameter *a* is the predicted response at zero analyte concentration; *d* is the predicted response at infinite analyte concentration; *c* is the inflection point on the sigmoidal curve; and *b* is the slope at that inflection point. Using this equation places no demand on any of the equation parameters. Only the concentration of the solutions and the response associated with those concentrations are required. The computer then assigns a first estimate to the value of the parameters and begins solving the equation in an iterative process. This means that the computer solves the equation, evaluates the results, makes a small change in the parameters, and continues this process until successive solutions begin to converge on the same line through the data points. This is a very effective approach to fitting a curve to experimental data, and in principle, there should be only one best-fit line that goes through a given set of data points. Because of the differences in assumptions, approaches, and software programs, it is possible to have variations from program to program. However, once it has been determined that a four-parameter logistic fit procedure is appropriate, this approach yields some additional advantages. First, there are the four parameters that can be used as quality control points for

the long-term performance of the assay. Significant changes in endpoints or slopes indicate that the assay should be reviewed. In addition, concentrations can be read from the curve at 20%, 50%, and 80% as another quality control monitor. The one precaution that should be kept in mind when employing four-parameter logistic fit equations is that you are at high risk once you exceed your calibrating solutions. That is, to extrapolate the concentration of an analyte in an unknown solution beyond the highest or lowest concentration of a calibrator leaves the analysis vulnerable to significant error. The reason for this is the four-parameter logistic fit sacrifices the ends of the curves, where the variance or error may be considerable.

Even in this day of computerized calculations, it is critical that the operator know the algorithm and assumptions used to calculate calibration curves. This information should not only be logical but should employ basic statistical concepts wherever possible. Once this information is known to the researchers, they should process their laboratory data, control specimens, and previous assays and evaluate the quality of the calculation in their hands. There are numerous software packages, both stand-alone and incorporated into instrumentation that will calculate results for any given immunoassay. The process of choosing the correct software is primarily one of evaluating the candidate products and being comfortable with the assumptions and procedures used.

Automation in Immunoassay

As might be expected, immunoassay is following a course close to classic clinical chemistry; that is, initially there were laborious manual methods designed to measure one analyte at a time in batch fashion. This was followed by assisted manual procedures in which dilutors, pumps, and spectrophotometers took over some of the steps in the assay system. Nevertheless, it remained essentially a manual procedure. Next came automation wherein specimens were prepared and presented to the system at one end and completed results were returned at the other, with relatively little hands-on intervention. In the past several years, immunoassay has reached the point of full automation. Several companies are now marketing instrumentation that takes advantage of the nonisotopic methodologies. These instruments are complete with bar-code readers, reagent monitors, and total software packages for calculating results, monitoring quality control, and generating management reports. In addition, most have the capability of being interfaced with the main laboratory computer for bidirectional communication. Companies such as Ciba Corning, Cirrus Diagnostics, Becton Dickinson, Technicon, Boehringer Mannheim, Biotrol, Abbott, and Baxter, along with several others, have marketed instruments described as automated immunoassay systems. Each of these instruments takes advantage of a slightly different technique and solves a particular problem. Several of these same companies are now integrating immunoassays on “conventional” chemistry instrumentation or have research projects to combine clinical chemistry and immunoassay into one instrument (12).

In fact, before automated immunoassays have fully matured, research and development is well established in the field of miniaturization. These techniques will define the future of laboratory methods and testing, including immunoassays (13, 14, 15). Several authors have speculated that microchips will be capable of measuring hundreds or thousands of analytes at a time on volumes in the microliter to nanoliter range (12, 13, 14). The advent of such technology will change the approach to point-of-care testing, outpatient testing, laboratory structure and size and the cost structure of laboratory medicine.

APPENDIX GLOSSARY

GLOSSARY

Affinity

Describes the strength of binding of a single binding site on an antigen with its corresponding antibody. For well-defined

systems, this can be equated to the association constant of the reaction.

Antibody

An immunoglobulin class protein that is produced by a special class of lymphocyte in response to its stimulation by foreign material.

Antigen

Any material capable of reacting with an antibody to produce an antibody-antigen complex.

Avidity

Describes the stability of antigen-antibody complexes. It is the net of all the forces of all the binding sites on an antigen and generally is greater than the simple sum of these forces.

Bioluminescence

A special category of chemiluminescence that takes place in living organisms. Photons are emitted as a result of biologically mediated reactions. Characteristically, these reactions have very high quantum yields.

Chemiluminescence

A reaction in which the product molecules are in an excited state as a result of the energy released by the reaction. Relaxation of these excited molecules results in the emission of a photon. Generally, quantum yields are low.

Detection limit

The smallest amount of analyte that is measurable above zero. Usually arrived at by measuring a zero response and taking the mean of that response plus three standard deviations.

Fluorescence

The emission of a photon from a molecule that was raised to an excited state by external radiation.

Hapten

A small organic molecule that represents a single antigenic determinant. Usually is not capable of generating an immune response by itself.

Heterogeneous assay

Assay that requires the separation of bound and free species before the analytic measurement is made.

Homogeneous assay

Assay that is designed to have the analytic measurement made in the presence of both bound and free species.

Immunogen

Any substance capable of stimulating lymphocytes to produce antibodies.

Nephelometry

A technique that measures the amount of scattered light from a sample at angles other than 0°.

Sensitivity

Synonymous with detection limit.

Specificity

A characteristic of antibodies that denotes the antibody's ability to recognize a specific antigenic determinant in the presence of similar structures. The greater the specificity the less cross-reactivity.

Turbidimetry

A technique that measures the reduction in incident light after the incident light passes through a sample. Angle of measurement is 0°.

13

The Plasma Proteins

Alexander Kratz

Elizabeth Lee-Lewandrowski

Kent B. Lewandrowski

The plasma proteins are a diverse group of molecules that perform a variety of functions. More than 500 plasma proteins have been identified, and new ones continue to be discovered. Some plasma proteins such as albumin and transferrin are routinely measured in the clinical laboratory, whereas others are of interest only in specialized situations. While it is assumed that all proteins perform some function in the body, in many cases the precise role has not been defined. With the growth of more sophisticated and sensitive methods to study these molecules (1), new applications for protein analysis in clinical practice will surely arise.

Some of the plasma proteins can be conveniently grouped as related molecules that collectively carry out a specific function. Examples include the immunoglobulins, the complement proteins, the coagulation cascade, lipoproteins, and a variety of protein hormones and hormone-binding globulins. These are covered in other chapters and are mentioned only briefly here. This chapter is concerned with the physiology, pathology, and laboratory assessment of the remaining plasma proteins with an emphasis on those that are important in clinical medicine.

True plasma proteins should be distinguished from proteins that occur only incidentally in the blood. For example, a number of enzymes may be released from damaged cells and appear in plasma but perform no known function outside of the cell. Other proteins are found in plasma only during certain pathological states. In contrast, true plasma proteins are specifically synthesized for release into the blood, where they carry out their respective functions.

Despite their name, most of the plasma proteins are not confined to the vascular compartment (2). In the capillary vessels, proteins escape from the blood either by active transport mechanisms or by diffusion through the junctions between endothelial cells. In some cases, the extravascular fraction exceeds the amount in the intravascular pool. Many of these proteins carry out part of their function in the interstitial space, ultimately returning to the vascular compartment by the lymphatics. Some plasma proteins cross the blood–brain barrier and thus enter the cerebrospinal fluid (CSF). Small amounts are found in virtually all other extracellular fluids.

Several systems have been used to classify the plasma proteins. Historically, albumin was distinguished from the globulins (nonalbumin proteins) based on its greater solubility in water (2). However, this distinction is not absolute because some other proteins are also soluble in low ionic-strength solutions. Alternatively, proteins may be classified according to function (Table 13.1). For example, some proteins perform mainly transport functions for metals (transferrin), lipids (lipoproteins), or hormones (thyroid-binding globulin). Others are involved in the clotting cascade (fibrinogen) or function as enzyme inhibitors [α_1-antitrypsin (AAT)]. Some proteins perform more than one function. Albumin, for example, serves as a carrier protein for bilirubin, some hormones, and inorganic ions. It also provides a protein source for cells and contributes the major portion of the plasma colloid oncotic pressure (COP), which is essential for normal hemodynamics.

TABLE 13.1. FUNCTIONAL CLASSIFICATION OF SELECTED PLASMA PROTEINS

Proteinase inhibitors
α-Antitrypsin
Antithrombin III
α-Antichymotrypsin
α_2-Macroglobulin
Antiplasmin
Inter-α-trypsin inhibitor
Carrier/transport proteins
Retinol binding protein
Gc-globulin (vitamin D binding protein)
Lipoproteins
Hormone binding globulins
Prealbumin
Iron transport and metabolism
Transferrin
Haptoglobin
Hemopexin
Mixed function proteins
Albumin
Immune function and host defense
Immunoglobulins
Complement proteins
C-Reactive protein
Blood clotting
Clotting factors
Fibrinogen
Fetal proteins
α-Fetoprotein
Carcinoembryonic antigen
Unknown or controversial
Ceruloplasmin
α-Acid glycoprotein (orosomucoid)
β_2-Microglobulin

Plasma proteins are often classified based on their electrophoretic mobility on cellulose acetate or agarose gel. Electrophoresis separates proteins into five regions designated albumin α_1, α_2, β, and γ (Fig. 13.1). Individual proteins characteristically migrate in one of these regions (Table 13.2). The albumin band is relatively homogeneous, while the remaining regions contain many different proteins and are simply groups of proteins with similar mobilities.

With some exceptions (e.g., immunoglobulins, protein hormones, and some clotting factors), most of the plasma proteins are synthesized in the liver. The liver is also the major site of plasma protein catabolism. Most of the plasma proteins are synthesized on the rough endoplasmic reticulum of the liver hepatocytes. After assembly of the amino acid backbone, a variety of posttranslational modifications may occur, including proteolytic removal of proprotein fragments, phosphorylation, and the addition of sugars and other prosthetic groups. Ultimately, the proteins pass through the Golgi apparatus and are packed into secretory vesicles for release into the blood. Further details of protein structure and synthesis may be found in standard biochemistry textbooks.

Hepatocytes are capable of synthesizing more than one protein simultaneously. The balance between synthesis and degradation maintains the level of plasma proteins within a relatively narrow range. Most proteins are regulated independently of the others. The level of the individual protein in plasma serves as the signal for regulation, and the rates of synthesis and catabolism are the mechanism for modulating its concentration (2). Details of the regulatory steps for specific proteins are provided under separate headings later in this chapter.

Given the diversity of the plasma proteins, it is not surprising that a variety of diseases and physiological alterations may affect protein levels. Plasma protein abnormalities arise from one or more of the following:

- Congenital abnormalities affecting a specific protein (e.g., analbuminemia, AAT deficiency)
- Acquired abnormalities affecting a specific protein (e.g., transferrin in anemia, haptoglobin in hemolysis)
- Alterations affecting multiple proteins reflecting variations in the physiologic state (e.g., age, race, gender, and pregnancy)
- Alterations affecting multiple proteins secondary to disease (e.g., cirrhosis, acute-phase response, and protein-losing syndromes)

In this chapter, we begin with a discussion of the total plasma protein followed by a description of the acute-phase response. Then the individual plasma proteins are considered. In the final section of the chapter, several methods for protein separation, identification, and quantitation are described. Assays of specific proteins are described under individual headings.

TOTAL PROTEIN

Part of "13 - The Plasma Proteins"

The total serum protein concentration is one of the more common measurements in the clinical laboratory. Several factors affect the protein concentration, including alterations in fluid balance, changes in synthesis or catabolism, and protein losses.

TABLE 13.2. CLASSIFICATION OF SELECTED MAJOR[a] AND MINOR PLASMA PROTEINS BY ELECTROPHORETIC MOBILITY

Albumin zone
Albumin
Prealbumin
α Zone

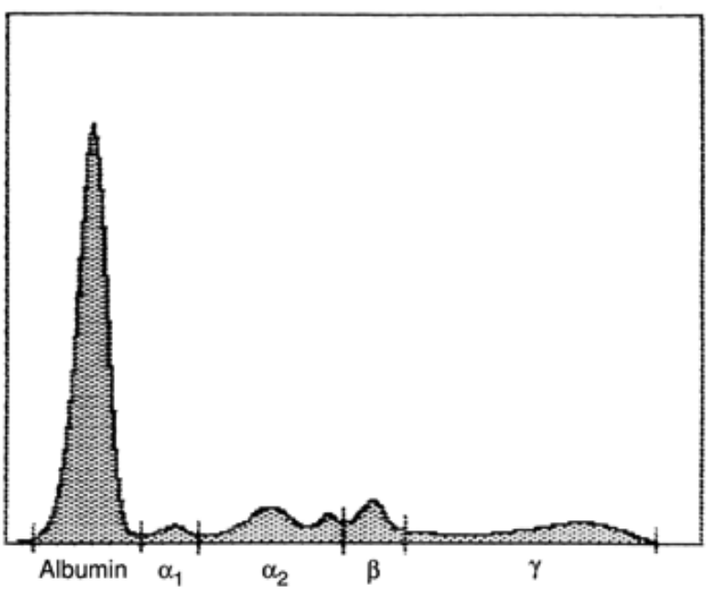

FIGURE 13.1. Densitometric scan of a normal serum protein electrophoresis pattern showing the relative position of the albumin, α_1, α_2, β, and γ regions.

Measurement of total protein is therefore a relatively sensitive but nonspecific screening test of overall health status.

The total protein may be measured on either serum or plasma. Serum samples are generally preferred because they are more convenient to use on automated equipment (3). If plasma is used, the total protein is 3% to 5% higher owing to the contribution of fibrinogen. Several preanalytic errors may alter the serum protein value (3). Prolonged tourniquet application during venipuncture results in hemoconcentration, which can increase the total protein by as much as 5 g/L. Values in recumbent subjects may be 10% lower than in ambulatory individuals. There is also a normal diurnal variation of 4 g/L and a seasonal fluctuation with peak levels in November and lowest values in June. Exercise increases the serum protein concentration by as much as 10%, but this effect is transient.

The total serum protein includes both albumin (60%) and the globulins (40%). All contribute some fraction to the COP of plasma, which is essential for normal hemodynamics. Unlike sodium salts and glucose, the movement of proteins from plasma to interstitial fluid is limited (4). The contribution of proteins to the plasma osmotic pressure tends to retain water in the vascular space. The osmotic pressure generated by the plasma proteins is called the COP, or simply oncotic pressure. Because of its abundance and small size, albumin is responsible for 80% of the total COP.

The movement of fluid from the capillaries to the interstitial space is governed by the balance between four forces. The plasma oncotic pressure acts to hold fluid in the vascular space. This force is counterbalanced by the capillary hydrostatic (hydraulic) pressure, which tends to force water out of the vascular compartment. The interstitial oncotic pressure is derived from the proteins and proteoglycans of the interstitial space and acts to draw fluid out of the capillary vessels. The small interstitial hydrostatic pressure is usually negative, and thus it also pulls fluid out of the vascular compartment. The sum of these four forces varies in different tissues (4), and water may move either into or out of the plasma compartment depending on the balance between the forces. Ordinarily the net effect is a 0.3- to 0.5-mm Hg gradient favoring movement out of the capillaries. Conversely, in the postcapillary venules, the forces normally allow return of some of the water to the circulation. The remainder is returned to the vascular space by the lymphatics. A decrease in the total protein concentration will decrease the plasma COP, which may result in edema. However, because hypoproteinemia will also decrease the amount of protein in the interstitial space, the decrease in plasma oncotic pressure will be partially offset by a decrease in the interstitial oncotic pressure. In general, hypoproteinemia must be severe to result in edema.

The total protein concentration may be altered by changes in fluid balance (plasma water). Dehydration causes a proportional increase in all the serum proteins. This occurs with decreased water intake or with increased water losses such as excessive sweating, diarrhea, vomiting, salt-losing syndromes, and osmotic or drug-induced diuresis. Conversely, volume expansion causes a proportional decrease in serum proteins. Examples include the administration of volume expanders (such as dextran), excessive administration of intravenous fluids, pregnancy, and salt-retention syndromes. These changes do not affect the actual body pools of serum proteins, and correction of the underlying fluid imbalance will correct the total protein concentration.

Changes in the amounts of plasma proteins may result from alterations in synthesis or catabolism or from protein losses. Increased synthesis of some proteins is seen in the acute-phase response to infection or tissue injury, but this is offset to some degree by a concomitant decrease in albumin synthesis. The use of steroids, including oral contraceptives, will increase protein synthesis and may increase the total protein concentration (3). Marked hyperproteinemia in the absence of dehydration usually reflects increased synthesis of γ-globulins. Hyperproteinemia owing to increased albumin synthesis is quite rare if it occurs at all.

Hypoproteinemia can be caused by decreased protein synthesis and is seen in malnutrition and in chronic liver disease. Protein calorie malnutrition deprives the liver of the necessary substrates to make plasma proteins and is a common problem in hospitalized patients (5). In chronic liver disease, the protein synthetic machinery is disturbed, which also results in hypoproteinemia. However, this is often accompanied by increased (extrahepatic) synthesis of γ-globulins, which may normalize or occasionally even increase the total protein value. Increased protein catabolism is seen in a variety of inflammatory and neoplastic conditions.

Excessive protein losses can occur through the kidney, the gastrointestinal tract, or the skin. Examples include the nephrotic syndrome, inflammatory bowel disease, extensive burns, and any severe exudative process. The most severe losses are seen in the nephrotic syndrome, in which a number of plasma proteins, especially albumin, are passed through the glomerulus into the urine. In severe cases of nephrotic syndrome, the serum albumin level may fall to less than 5 g/L (3).

Changes in the total serum protein may result from changes in albumin, globulins, or both. As mentioned earlier, a change in one protein may be offset by a change in the opposite direction of another. For this reason, it may be useful to determine the ratio of the albumin concentration to the globulin concentration (A:G ratio). The ratio may be markedly abnormal despite a normal total protein, such as in the acute-phase response, in which increased globulins are associated with a decreased albumin concentration.

Methods for measuring the total protein are discussed at the end of this chapter.

ACUTE-PHASE REACTANTS

Part of "13 - The Plasma Proteins"

The acute-phase reactants (APRs) are a group of proteins whose plasma concentration changes in response to a variety of inflammatory states including infection, surgery, trauma, myocardial infarction, malignancy, and any condition associated with tissue necrosis. Collectively, the changes in plasma proteins are referred to as the acute-phase response, even though they may accompany both acute and chronic inflammatory disorders (6). Some of these proteins are called positive APRs, meaning that their plasma levels increase, while others are designated negative APRs

to indicate that their levels decrease (Table 13.3). The acute-phase response is regulated by cytokines. Interleukin-6 (IL-6) is the major stimulator of most acute-phase proteins; other cytokines produced during inflammation, like interleukin-1ß(IL-1ß), tumor necrosis factor-α (TNF-α), interferon gamma (IFN-γ), and transforming growth factor ß (TGF-ß), upregu-late subgroups of the APRs (6). The major sources of these cytokines are macrophages and monocytes at sites of inflammation.

TABLE 13.3. MAJOR ACUTE PHASE REACTANTS

Positive	Negative
α_1-Antitrypsin	Albumin
α-Antichymotrypsin	Prealbumin
Haptoglobin	Retinol binding protein
Ceruloplasmin	Transferrin (rises in late acute phase)
Fibrinogen	
C3	
C-Reactive protein	
Hemopexin	
Serum amyloid A protein	

Measurement of APRs, especially C-reactive protein (CRP), may be useful to detect and follow patients with acute inflammatory

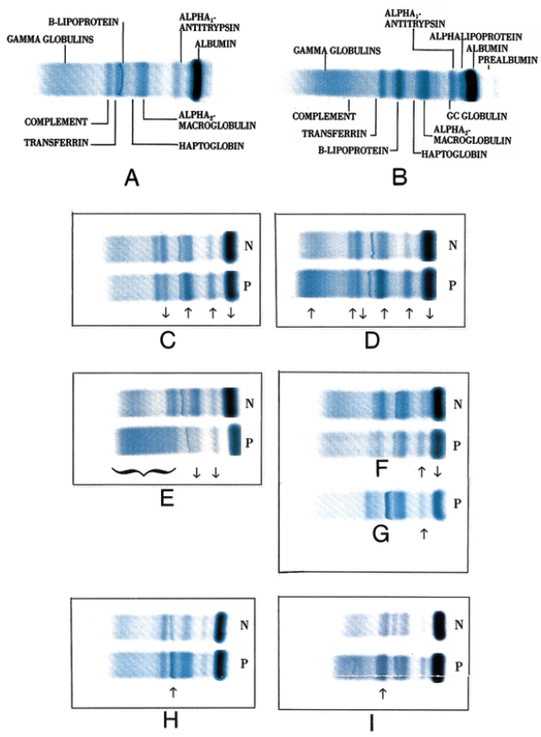

FIGURE 13.2. Representative patterns of serum proteins seen on serum protein electrophoresis. **A**, normal pattern; **B**, normal pattern on high-resolution electrophoresis; **C**, acute inflammatory pattern; **D**, chronic inflammatory pattern;**E**, cirrhotic pattern; **F**, Nonselective protein loss. **G**, nephrotic syndrome; **H**, hyperbetalipoproteinemic pattern; **I**, iron deficiency anemia. disorders. However, these changes are nonspecific and provide no information on the cause or source of the inflammation. Elevations in the white blood cell count and erythrocyte sedimentation rate (ESR) provide similar information and have been considered more practical because they are easier to measure and are more readily available. However, it should be noted that the increase in the ESR seen in inflammatory states directly results from changes in the APRs, most notably an increase in fibrinogen.

The advent of more sensitive assays for CRP has aroused new interest in the potential applications of APRs to clinical practice. Some reports suggest that assay of CRP may be superior to the ESR in a variety of clinical situations (7). Serial measurements may provide an index of disease activity and are useful to assess the response to therapy. Potential applications of APRs include monitoring postoperative patients for infectious complications, detection of occult infections, monitoring disease activity in patients with rheumatic diseases and inflammatory bowel disease, and detecting renal allograft transplant rejection. Further studies are needed to define more fully the role of APRs in clinical practice.

The changes in plasma proteins seen during the acute-phase response potentially serve a variety of functions. Among the positive APRs are the protease inhibitors AAT and α_1-antichymotrypsin. These proteins protect the body from indiscriminate proteolysis by proteases released from leukocytes and macrophages at sites of tissue injury and repair. Other proteins such as haptoglobin and hemopexin protect against reactive oxygen species (6). CRP appears to function as an immunomodulator by activating the complement system as well as neutrophils and monocyte-macrophages (7). Conversely, transferrin is a late APR, its level rising in plasma only after the other APRs have reached their maximum. It is thought that the elevation in transferrin is probably a secondary event brought about by the decrease in plasma iron associated with inflammation. Wound healing is affected by the increase in fibrinogen, which causes endothelial cell adhesion, spreading, and proliferation (6). The function of some APRs such as α_1-acid glycoprotein is not known. The role of the negative APRs is more difficult to conceptualize. The decrease in albumin during the acute-phase response may serve to divert the protein synthetic machinery of the liver away from production of this nonessential protein. In theory, this would facilitate the synthesis of critical elements needed for the inflammatory response.

The individual APRs respond at different rates, and the factor by which their concentration changes in plasma varies. Within hours, CRP and α_1-antichymotrypsin rise. Soon thereafter, α_1-acid glycoprotein increases, followed by AAT, haptoglobin, C4, and fibrinogen. Later C3, ceruloplasmin (CER), and transferrin become elevated. Within 2 to 5 days, most of the APRs have reached their maximum (8). Quantitatively, the most striking elevation is seen with CRP, which may increase by a factor of 3,000. The other APRs generally show much more modest increases (factors of 2 to 4). The early rise in CRP together with the large factor by which it increases makes it the most useful APR to measure in the clinical laboratory.

Although APRs may be measured individually, the overall pattern of the acute-phase response is most easily appreciated on serum protein electrophoresis (SPE) (Fig. 13.2C and Fig. 13.2D). The total protein is usually normal, owing to a decrease in albumin with a concomitant marked increase in the α_1 and α_2 globulins. CRP may appear as a distinct band in the slow γ to mid-ß region. The γ-globulin fraction is often normal during the early acute phase. In the course of an infectious process, oligoclonal bands may be seen, followed later by a diffuse polyclonal increase in the γ-globulins.

Patients with severe liver disease, malnutrition, or protein-losing syndromes often show an absent or blunted acute-phase response. Individuals with congenital protein deficiencies may fail to increase a specific protein or may exhibit only a partial response. This can have the effect of normalizing the level of the deficient protein and masking the underlying congenital defect.

INDIVIDUAL PROTEINS AND DISEASE STATES

Part of "13 - The Plasma Proteins"

Prealbumin and Retinol-Binding Protein

Prealbumin (MW 55,000) is a tryptophan-rich tetrameric non-glycosylated protein named for its anodal migration relative to albumin on protein electrophoresis. Synonyms for prealbumin include transthyretin and thyroid-binding prealbumin. The only known function of prealbumin is as a carrier protein for thyroid hormone and, together with retinol binding protein (RBP), for vitamin A. Prealbumin binds approximately 20% of the plasma thyroxine (T_4) and lesser amounts of triiodothyronine (T_3). However, its role in thyroid-hormone transport is relatively minor because most T_4 and T_3 are bound to thyroid-binding globulin, which has a much greater affinity for these hormones. A genetic variant of prealbumin has been described with higher than normal affinity for T_4. This causes an elevation in total T_4, but the patients are clinically euthyroid.

Prealbumin forms a 1:1 stoichiometric complex with the vitamin A carrier protein RBP (MW 21,000). This interaction stabilizes the RBP-vitamin A complex and prevents urinary losses of the vitamin (because free RBP is filtered by the glomerulus).

More than 50 variants in the prealbumin gene have been described. Most of these variants are associated with tissue deposition of amyloid fibrils, especially in heart and neurons (9).

Prealbumin and RBP are synthesized by the liver. Together with albumin and transferrin, these proteins can be used to assess protein status in patients with protein-calorie malnutrition. Both prealbumin and RBP have short half-lives (1.9 days and less than 12 hours, respectively). In addition, the body pool of these two proteins is small compared with albumin. Consequently, a deficiency in protein intake will produce a noticeable fall in prealbumin and RBP levels long before albumin and transferrin are affected. Although albumin and transferrin have traditionally been used to assess protein status, measurement of prealbumin and RBP may provide a better index of acute changes. For this reason, they are also useful in monitoring the adequacy of protein replacement therapy (5,10).

Prealbumin levels are significantly decreased in several liver diseases owing to impaired synthesis. Unlike serum enzymes, which primarily indicate hepatocellular damage, prealbumin levels reflect hepatic synthesis and can serve as an index of liver

function (11). However, prealbumin is also a negative APR and is thus not a specific indicator of liver function.

Prealbumin may be increased in patients receiving steroids, in pregnancy, in chronic renal failure, and in Hodgkin's disease.

Because of the low level of prealbumin in serum, its detection by serum electrophoresis constitutes a quality criterion for serum electrophoresis (9). Prealbumin is a compact molecule that can cross the blood–brain barrier and may also be synthesized by cells of the choroid plexus. This results in a 10- to 40-fold increase in the prealbumin-to-albumin ratio in CSF. Consequently, on CSF electrophoresis, prealbumin appears as a distinct band slightly anodal to albumin. Prealbumin can be measured by a variety of immunoassays, including radial immunodiffusion and nephelometry. The normal reference range is somewhat method dependent but is approximately 195 to 358 mg/L (12).

Albumin

Albumin (MW 60,000) is the most abundant protein in plasma, comprising approximately 60% of the total protein concentration. Although most of the plasma proteins are glycoproteins, albumin contains no carbohydrate and is therefore classified as a simple protein.

Albumin consists of a single peptide chain of 580 amino acids with a molecular mass of 66.3 kDa (13). Amino acid analysis has revealed a high content of glutamic acid, aspartic acid, and lysine, which collectively impart a large number of negatively charged groups to the molecule, rendering it highly soluble at physiologic pH. Additionally, the tryptophan content is low, a feature that has been exploited in some albumin assays. Albumin also contains a high content of cysteine residues, which help maintain the tertiary structure of the molecule through 17 intramolecular disulfide bonds. These bonds support a structure containing nine loops which form a compact elliptical molecule. On storage, albumin may form intermolecular disulfide bonds, giving rise to dimers that may appear as an extra band on SPE.

Albumin is synthesized almost exclusively by the liver, appearing first in the cytoplasm of the hepatocytes as a precursor called proalbumin. Immunoperoxidase studies have demonstrated that only 10% to 35% of the hepatocytes contain albumin at any one time, suggesting that synthesis is either restricted to a limited population of cells or occurs in a cyclical fashion throughout the liver (14). Fasting decreases the rate of synthesis by as much as 60%, whereas refeeding results in a prompt increase in synthesis. Regulation of synthesis is mainly by a negative feedback effect exerted on the hepatocytes by the plasma COP (13). Some cytokines suppress synthesis. The biological half-life of albumin is approximately 19 days.

Albumin has several important and diverse functions, including contributing nearly 80% of the plasma COP. Albumin serves as an amino acid source to a variety of cells and functions as a major transport protein because the large number of negatively charged groups on the molecule are potential binding sites. Bilirubin binds to albumin, and this is the major mechanism for sequestering and transporting bilirubin to the liver from sites of hemoglobin catabolism. Albumin is intimately involved in lipid metabolism, accepting free fatty acids from lipoprotein lipase and transporting them between the liver and peripheral tissues. Several hormones bind to albumin, including T_4, T_3, cortisol, aldosterone, estradiol, and progesterone. Because these hormones preferentially bind to their respective hormone-binding globulins, albumin serves mainly as a high-capacity, low-affinity overflow reservoir (14). Many drugs bind to albumin, including warfarin (97%), phenylbutazone (99%), salicylate (40%), penicillin (65%), and chlorothiazide (89%), among many others. Significant amounts of calcium and lesser quantities of magnesium are also bound.

Only 40% of total body albumin is in the plasma at any one time. The remaining 60% is distributed among virtually every other body fluid compartment, forming an exchangeable pool with plasma (14). Hyperalbuminemia generally results from dehydration. Artifactual increases may occur after prolonged tourniquet application during venipuncture. Conversely, hypoalbuminemia is common. Decreased albumin levels may result from a variety of mechanisms, including impaired synthesis (liver disease), increased catabolism, excessive losses (nephrotic syndrome), or “third spacing” (ascites, effusions). The most severe states of hypoalbuminemia occur in protein-losing syndromes such as the nephrotic syndrome or protein-losing enteropathy. Excessive losses may also occur in hemorrhage, burns, or exudative processes, especially of the skin and gastrointestinal tract. In the acute-phase response, albumin levels are decreased by at least five mechanisms: hemodilution, increased leakage into the extravascular space, increased catabolism, suppression of synthesis directly by cytokines, and, indirectly, by increased osmotic pressure secondary to the synthesis of the positive APRs (13). Increases in immunoglobulin levels also lead to lower albumin levels. In chronic wasting diseases such as tuberculosis and malignancy, both increased catabolism and decreased synthesis are contributing factors. Malnutrition results in decreased synthesis by denying the liver the necessary amino acid substrates needed to make albumin but may also impair liver function by other mechanisms. Malabsorption syndromes produce hypoalbuminemia by mechanisms similar to those in malnutrition. Chronic liver disease of any cause impairs albumin synthesis, although in alcoholic patients this is often accompanied by poor nutritional status. Hypoalbuminemia is also a common finding in pregnancy.

Whatever the cause, hypoalbuminemia decreases the plasma COP. Severe decreases may result in edema. In addition, the binding and transport of a number of substances are correspondingly impaired. Herrman and co-workers (15) reported that patients with low albumin levels at the time of admission exhibited increased mortality, had longer hospital stays, and were readmitted sooner and more frequently than patients with normal albumin levels.

More than 80 genetic variants of albumin have been described (13). These are all inherited in autosomal codominant fashion. The most common type is called albumin A. Variant albumins may result in a wide albumin band on SPE or may give rise to two distinct bands (bisalbuminemia) (8); binding of drugs and metabolites may also change albumin's electrophoretic pattern (13). None of these variants has yet been associated with human disease, although one variant has an increased affinity for T_4 (16). In the rare syndrome analbuminemia, there is a congenital absence of albumin. These patients may have mild edema but are otherwise spared the hemodynamic consequences of severe hypoalbuminemia

owing to compensatory mechanisms, including an increase in plasma globulins, which take over some of the functions of albumin. The major biochemical problem in these patients is a disturbance in lipid metabolism including hypercholesterolemia, increased plasma phospholipids, and lipoproteins (17).

Several methods are available to measure albumin, including electrophoretic, immunochemical, and dye-binding techniques. Albumin may be estimated indirectly by subtracting the measured total globulins from the total protein value. This method exploits the fact that plasma globulins contain substantially more tryptophan residues per gram of protein than does albumin. To estimate albumin, the total protein is first measured by standard methods. Then the globulins are assayed by reaction of their tryptophan residues with glycoxylic acid, forming a purple color, which is measured spectrophotometrically. The value for the globulins is then subtracted from the total protein.

Albumin may also be estimated by quantitative densitometric scanning of the albumin band on SPE. The scan is integrated to provide an estimate of albumin as a percentage of the total electrophoretic protein. Separate measurement of the total serum protein permits the estimate to be converted to mass units. Specificity can be improved by using immunochemical techniques, including radial immunoassay, nephelometry, enzyme-linked immunoassay, and radioimmunoassay, although these methods are relatively expensive to perform (8).

Several dye-binding methods are available to measure albumin (18), and these methods have been widely used. The assays are based on the ability of albumin to bind a number of organic anionic dyes. Binding results in a shift in the absorption maximum of the dye, which can be quantitated spectrophotometrically despite the presence of unbound excess dye. Plasma globulins either do not bind the dyes or do so only slowly. The two most popular dyes are bromocresol green and bromocresol purple. Bromocresol green is not specific for albumin and binds also to globulins, but this occurs slowly and is not a problem if the sample is assayed promptly. Conversely, bromocresol purple does not bind to globulins.

Urine or CSF samples may contain only small amounts of albumin. Traditionally these samples were therefore concentrated before measurement, but some of the newer assays are sufficiently sensitive to permit elimination of the concentration step. Urinary albumin may also be estimated by a screening dipstick method (Albustix Reagent Strips; Bayer Corp., Mishawaka, IN, U.S.A.) that exploits the change in visible color of bromophenol blue from yellow to green to blue with increasing albumin concentration (18). This method is relatively nonspecific, and it does not detect the low levels of albumin seen in microalbuminuria (13).

The reference range for serum albumin varies slightly with age, gender, posture, and the method of assay. Values may be 5 g/L greater in supine versus recumbent patients and are slightly higher in adults than in children. The adult reference range is 31 to 43 g/L (12).

α_1-Antitrypsin

AAT is one of the major plasma proteins, comprising nearly 90% of the α_1 globulin region on SPE. Deficiency of AAT has been associated with pulmonary emphysema and hepatic cirrhosis. The molecule consists of a glycoprotein (MW 52,000) that is synthesized by the liver and released into the plasma. It is also found in a number of other body fluids, including tears, lymph, bile, semen, and amniotic fluid (19). AAT is one of the APRs. Plasma levels may double in states of acute and chronic inflammation, in malignancy, after trauma or surgery, and during pregnancy or estrogen therapy.

AAT belongs to a family of serum proteins collectively known as serpins (*ser*ine *p*roteinase *in*hibitors). Other proteins in this group include α_1-antichymotrypsin, antithrombin, α_2-antiplasmin, C1 inhibitor, and a variety of lesser known proteins. Although 90% of the serum antitrypsin activity is attributable to AAT, significant amounts of trypsin are not found in plasma. Consequently, AAT functions mainly to inhibit nontrypsin proteinases, especially elastase and collagenase, in tissues and body fluids. These enzymes are released by leukocytes and macrophages at sites of inflammation. Thus, AAT is an important component of the body's mechanism to control endogenous proteolysis. Left unchecked, these enzymes would ultimately destroy normal tissues.

AAT exerts its effect by forming a covalent complex with serine-type proteinases. Complex formation inhibits the enzyme, and the complex is subsequently removed by the reticuloendothelial system, primarily in the liver. The genes encoding the AAT protein comprise an autosomal allelic system containing at least 75 codominant genes (20) inherited on a single locus called Pi for *p*roteinase *i*nhibitor. The resultant AAT variant proteins are immunologically similar but can be distinguished based on their electrophoretic mobility (19). Most of these alleles give rise to functionally normal variants of AAT, while some produce abnormal molecules and are associated with AAT deficiency. The most common normal allele is PiM, which encodes for the M protein variant of AAT. In the United States, 95% of the population has the homozygous PiMM genotype. The alleles PiZ and PiS are also relatively common in white populations and produce an abnormal AAT protein (21). The rare null allele Pi produces no protein product. Non-PiM alleles are rare in African Americans (19).

The PiZ allele is the most common variant associated with AAT deficiency. The heterozygote gene frequency of PiZ in the United States is 2% to 3%, while homozygotes comprise one in 3,630 individuals. In homozygous PiZZ subjects, the plasma AAT level is reduced to 10% to 15% of normal, while heterozygotes with the PiMZ phenotype are reduced to 60% of normal. The phenotypes PiSS and PiMS have levels of 63% and 83% of normal, respectively (21).

Deficiency of AAT may be congenital or acquired. Acquired decreases are seen in protein-losing syndromes, malnutrition, severe liver damage, and some respiratory diseases, including neonatal respiratory distress syndrome. Congenital deficiency is associated with pulmonary emphysema and with hepatic cirrhosis. Nearly 70% to 80% of homozygous PiZZ individuals develop chronic obstructive pulmonary disease (COPD) (22), often by the age of 20 to 30 years. The spectrum of COPD in AAT deficiency includes patients with chronic bronchitis and bronchiectasis in addition to those with emphysema. Cigarette smoking rapidly accelerates the progression of pulmonary disease

in homozygous PiZZ individuals and appears also to increase the risk of heterozygotes. Heterozygote PiZM individuals who do not smoke appear to have little if any increased risk of COPD (23). Not all subjects with severe AAT deficiency develop lung disease, and most patients with COPD are not AAT deficient. Possibly as few as 1% of patients with emphysema has AAT deficiency (22).

The phenotypes PiZZ, MZ, and SZ have also been associated with liver disease (24). Fifty percent of homozygous PiZZ patients exhibits intermittent abnormalities in liver function tests, and 10% to 20% develop permanent abnormalities. Nonetheless, most patients with AAT deficiency do not develop chronic liver disease. Patients may present during the neonatal period with jaundice or with neonatal hepatitis. The latter entity may appear similar clinically and morphologically to viral hepatitis or chronic active hepatitis. AAT deficiency should be considered in all infants with jaundice and all children with liver disease (24). Some patients with AAT deficiency develop cirrhosis by 2 to 3 years of age, while in others the onset is delayed until adult-hood.

Homozygous PiZZ AAT deficiency can usually be detected on SPE by noting a marked decrease in the α_1 region. This region is never completely empty because 10% of the α_1 zone is composed of other proteins. Heterozygotes often have a normal-appearing α_1 zone. A semiquantitative estimate of AAT may be obtained by densitometric scanning of the serum electrophoretogram. Traditionally, AAT activity was assessed in a functional assay that measured its ability to inhibit the catalytic activity of trypsin on certain synthetic substrates (trypsin inhibitory activity). These assays were not specific for AAT and have been replaced by immunochemical methods including nephelometric assays (8).

Quantitative assays are useful to detect patients with AAT deficiency but do not provide information about the Pi phenotype. The normal reference range of AAT is 76 to 189 mg/dL (12). Because proteases released from leukocytes or bacteria can form complexes with AAT and interfere with quantification, serum should be separated from the clot as soon as possible and stored aseptically (8). Caution should be exercised in interpreting AAT levels during pregnancy, in patients on estrogen or steroid therapy, and in patients exhibiting an acute-phase response because heterozygotes and some homozygotes can increase their AAT level in these situations. In patients with M protein levels below 50 mg/dL, AAT phenotyping should be performed (8). Methods for phenotyping include isoelectric focusing, starch gel electrophoresis, and two-dimensional immunoelectrophoresis. Polymerase chain reaction–based methods utilizing amniocytes or chorionic villi are available for prenatal diagnosis. For an excellent overview of AAT deficiency, the reader is referred to the recent review by Cox (23).

α_2-Macroglobulin

α_2-Macroglobulin (AMG), haptoglobin, and CER together make up the α_2 region on SPE. AMG consists of four identical subunits and is one of the largest serum proteins (MW 720,000). Because of its large size, it does not diffuse out of the blood vessels and can only be found in the intravascular space. Several functions have been ascribed to AMG. In addition to its long-known function as an inhibitor of endogenous and exogenous proteinases, AMG may also function as a binding, carrier, and targeting protein for cytokines and growth factors (25).

AMG is synthesized by the liver with a half-life in serum of 5 days. The half-life of AMG–proteinase complexes is approximately 8 minutes (26). Owing to the wide spectrum of activity of AMG against a variety of proteinases, it has been difficult to ascribe a specific function to this protein. Although it appears important in defense against proteolytic enzymes, AMG is present in plasma at only one tenth the concentration (on a molar basis) of AAT.

Several endopeptidases, including serine proteinases (trypsin, plasmin, elastase, collagenase), thiol proteases, metal proteases, and the carboxy protease cathepsin D, are inhibited by AMG. Unlike AAT, in which inhibition occurs by formation of a covalent bond with the active site of the proteinase, AMG irreversibly binds proteinases without affecting the active center of the enzyme (1). Once bound, the AMG-proteinase complex is rapidly cleared from the circulation by binding to a receptor expressed on macrophages, hepatocytes, and fibroblasts (27).

The biological significance of AMG as a transport protein is still the focus of ongoing research. AMG can also bind numerous growth factors, hormones, and cytokines. These include TGF-ß1 and TGF-ß2, IL-1ß, IL-6, basic fibroblast growth factor (bFGF), platelet-derived growth factor (PDGF), epidermal growth factor (EGF), nerve growth factor-ß (NGF-ß), TNF-α, insulin, vascular endothelin growth factor (VEGF), placental lactogen, and the inhibin/activin family (27,28). At least three different mechanisms have been described for the binding of these molecules to AMG. The binding of these factors to AMG might play a role in the transport and targeting of these messenger molecules; however, the biological significance of this phenomenon is still the subject of investigation (27).

AMG levels are greatly increased in the nephrotic syndrome and may attain levels greater than 1,000 mg/dL. This occurs because the large size of AMG prevents its loss in the urine through the damaged glomeruli, while the smaller plasma proteins are selectively lost. AMG may also be increased by as much as 70% in cirrhosis despite significant loss of the liver cell mass. This finding is opposite that of most other plasma proteins, although the immunoglobulins may also be elevated in liver disease. Minor increases are seen in diabetes mellitus. Unlike AAT, which behaves as an APR, AMG levels are not altered in states of inflammation. No human deficiency of AMG has been reported, and no disease has yet been identified in which measurement of AMG is of clinical value, although nephelometric and immunochemical assays exist. The reference range is 125 to 215 mg/dL. Values are slightly higher in women and are age dependent.

Ceruloplasmin

CER (MW 132,000) is a glycoprotein synthesized by the liver as a single polypeptide chain to which six to eight copper atoms are attached (29). CER migrates as an α_2 globulin on protein electrophoresis but is not normally visible on routine gels except in situations in which it is significantly increased. The pure protein is blue because of its high copper content. Increased levels may impart a green tinge to plasma samples.

While copper is an essential nutrient, it is also highly toxic to cells. Consequently, efficient means of maintaining copper homeostasis are required. After absorption in the intestine, dietary copper is bound to albumin and transcuprein and is taken up by the liver and to a lesser extent by all cells. The liver functions as a storage site. Copper is incorporated into the CER apoprotein in the liver and is released into the plasma. The majority of plasma copper is bound to CER; the remainder is bound to albumin and transcuprein. A small fraction is bound to small peptides and amino acids (8). The principal route of copper excretion is through the biliary tract, with a small amount being excreted in the urine. Copper homeostasis reflects the balance between intestinal absorption and biliary excretion. The liver is the main recipient of dietary copper and the primary route of excretion.

The principal importance of CER in laboratory medicine is in the diagnosis of Wilson's disease (hepatolenticular degeneration), which typically is associated with low plasma CER levels. Despite intensive investigation, the function of this protein remains controversial. Historically it was thought that CER played a central role in copper transport because CER-bound copper normally constitutes the majority of the total plasma copper. However, radioisotope studies have shown a negligible turnover of CER-bound copper, indicating that copper is neither lost nor gained from the molecule in the circulation (8). Furthermore, the protein deficiency state of hypoceruloplasminemia produces no symptoms of copper overload (30). It is now thought that CER may play a role in copper metabolism by acting as a donor of copper to some key copper-containing enzymes. This is accomplished through uptake and degradation of CER by a number of cells but does not involve transfer of copper from intact CER molecules. However, the primary role of CER appears to be in plasma redox reactions. CER oxidizes Fe^{2+} to Fe^{3+} and thereby allows the incorporation of iron into transferrin without the formation of toxic iron products (8). CER also plays a role in preventing lipid oxidation and free radical formation, both of which are damaging to cells.

Wilson's disease is an autosomal recessive disorder associated with toxic accumulation of copper, particularly in the liver and brain. Although the incidence is low (one in 50,000 to 100,000), it may be the most common cause of chronic liver disease in childhood. It was once believed that Wilson's disease resulted from an inherited defect in CER, but this concept has subsequently been refuted (29). It has been shown that the gene responsible for Wilson's disease resides on chromosome 13, while the gene for CER is on chromosome 3. The Wilson's disease gene is a P-type ATPase; a defect in this gene prevents incorporation of copper into CER and leads to impairment of biliary copper excretion. These defects cause a progressive accumulation of copper in the liver, resulting in chronic liver disease. Ultimately, copper may overflow from the liver and deposit in other tissues, most notably in the basal ganglia of the brain (lenticular degeneration) and in the cornea of the eye. Deposition in the brain causes neurological symptoms, including dysarthria and loss of coordination of voluntary movements. Corneal deposits produce the classic appearance known as Kayser-Fleischer rings. Copper deposition in other tissues may result in renal tubular damage, kidney stones, osteoporosis, arthropathy, cardiomyopathy, and hypoparathyroidism (29).

Hepatic involvement in Wilson's disease produces variable degrees of liver dysfunction. Some patients exhibit only minor impairment in liver function, while others develop severe liver damage as early as 8 years of age. The onset of hepatic failure may be abrupt or may result from progressive cirrhosis over many years. Fortunately, patients with Wilson's disease can be effectively treated with penicillamine, which chelates body copper and promotes its excretion in the urine. If patients are diagnosed before the onset of cirrhosis and neurological symptoms, a normal life span can be expected. For this reason, early diagnosis and treatment are essential, as is the evaluation of the patient's siblings who have a 1-in-4 chance of developing the disease. However, the majority of cases go undetected and ultimately present with advanced disease (8). Consequently, Wilson's disease should be considered in all patients with chronic liver disease and in all patients older than 12 years of age with relevant neurological findings (31). Heterozygotes for the Wilson's disease gene do not develop manifestations of the disease. For siblings of patients with Wilson's disease, DNA linkage analysis can be used to make a diagnosis before the onset of clinical symptoms (32).

The majority (90% to 95%) of patients with Wilson's disease exhibit decreased levels of plasma CER (less than 10 mg/dL) with a concomitant decrease in the total serum copper concentration. However, the non-CER copper is increased, with a resultant increase in urinary copper excretion. Administration of penicillamine augments urinary copper excretion and may be helpful in establishing the diagnosis. While all patients with neurological disease exhibit the classic laboratory findings in addition to the Kayser-Fleischer rings, perhaps as many as 20% of patients with disease limited to hepatic involvement have normal CER levels. Liver biopsy with measurement of the hepatic copper content by atomic absorption is a fairly reliable test for Wilson's disease when the level is greater than 300 mg/g dry weight. However, the hepatic copper content may also be increased in some other types of liver disease. The best test for the diagnosis of Wilson's disease is the demonstration of a negligible incorporation of radioactive copper into CER. In this test, either ^{64}Cu or ^{67}Cu is administered intravenously and the plasma radioactivity counted periodically for 48 hours. Because free radiolabeled copper is rapidly assimilated by the liver, the residual plasma radioactivity reflects copper incorporation into CER (31).

Low levels of plasma CER are not specific for Wilson's disease. Any condition associated with severe liver dysfunction will impair CER synthesis. Decreased levels are also seen in malnutrition and protein-losing states (8). Conversely, plasma CER levels are increased in pregnancy, with oral contraceptive use, and in the acute-phase response. This increase in inflammation is thought to be related to the need for scavenging oxygen radicals released at the site of inflammation by immune cells (29). Biliary tract obstruction, especially primary biliary cirrhosis, may also result in elevated plasma CER.

The reference range for CER varies with age, being highest in young children and somewhat lower in both infants and adults. Values less than 10 mg/dL are suggestive of Wilson's disease, but normal levels do not exclude the diagnosis. The adult range varies with the method of assay but is approximately 27 to 50 mg/dL (12). Most CER assays are based on immunochemical

methods, including nephelometry and radial immunodiffusion (RID). Alternatively, the oxidase activity of CER can be measured using the substrate p-phenylenediamine in a colorimetric assay.

Haptoglobin

Haptoglobin is a glycoprotein synthesized by the liver that migrates as an α_2 globulin. In addition to its well-known function in the binding of free hemoglobin, this APR might also play an important role in the control of local inflammation (8,33,34).

Haptoglobin binds free hemoglobin released by intravascular red blood cell destruction, thus conserving body iron and preventing renal filtration of potentially nephrotoxic hemoglobin. Free hemoglobin dissociates into α-ß dimers that are bound by haptoglobin. The complexes are subsequently removed by the reticuloendothelial system, which degrades the heme groups to iron and bilirubin. Complex formation occurs through the α chain of the hemoglobin dimers. Consequently, haptoglobin can bind hemoglobin types A, F, S, and D but not hemoglobin types that lack an α chain. Methemoglobin and free heme moieties do not bind haptoglobin. The total plasma binding capacity of haptoglobin is approximately 3 g of hemoglobin.

Normally, intravascular destruction accounts for less than 10% of the total red cell turnover. Continued synthesis of haptoglobin by the liver prevents it from being depleted under normal circumstances. In states of accelerated intravascular hemolysis, haptoglobin may become depleted, resulting in free hemoglobin dimers, which are filtered by the kidney. Once filtered, free hemoglobin is degraded by the renal tubular epithelial cells, with heme-iron ultimately being converted to hemosiderin. The kidney can process as much as 5 g of hemoglobin per day, but above this level, free hemoglobin appears in the urine. Free hemoglobin that has not been bound by haptoglobin or processed by the kidneys is oxidized in the plasma to methemoglobin and the heme groups are subsequently released. The free heme groups are taken up by another binding protein, hemopexin, which carries them to the liver, where they are degraded. Like haptoglobin, hemopexin may also become depleted in states of accelerated hemolysis.

The role of haptoglobin in the control of local inflammation is the focus of intensive investigation. Haptoglobin might protect against heme-stimulated oxygen radical damage (33). It also inhibits cathepsin B released by phagocytes (34). Recently, Ghamati and co-workers (35) showed that haptoglobin binds to the CD11b/CD18 receptor, a member of the integrin family. This receptor mediates the adherence and extravasation of phagocytes at sites of inflammation. This suggests a role for haptoglobin in the regulation of chemotaxis.

Three distinct phenotypes of haptoglobin have been identified by electrophoresis and designated Hp1-1 (MW 85,000), Hp1-2 (MW 120,000), and Hp2-2 (MW 160,000). These phenotypes have not been associated with human disease, but they may lead to slightly differing haptoglobin levels (36). Because of the genetic heterogeneity of haptoglobin, it has been widely used in paternity testing and forensic medicine (37). As many as 4% of blacks have congenital anhaptoglobinemia with no detectable haptoglobin in the plasma (37).

Haptoglobin is an APR and may therefore be elevated in the acute-phase response. Therefore, normal haptoglobin levels in patients with an inflammatory process do not rule out hemolysis. Elevated haptoglobin levels are also seen in the nephrotic syndrome in which other proteins are preferentially lost and in patients with increased estrogen levels.

Haptoglobin is decreased in diseases associated with intra-vascular hemolysis, including hemolytic anemias, hemoglobin-opathies, hemolytic transfusion reactions, extensive burns, malaria, disseminated intravascular coagulation, and exercise-induced hemolysis. In severe acute hemolysis, haptoglobin may be totally depleted within 6 to 12 hours, requiring as long as 1 week to return to normal. In chronic hemolytic states such as are seen with mechanical heart valves or hemoglobinopathies, there may be a steady decline in haptoglobin. In these conditions, serial measurements are a better index of ongoing hemolysis than single haptoglobin values. Haptoglobin may also be depressed in ineffective erythropoiesis associated with intramarrow red cell destruction (e.g., vitamin B_{12} and folic acid deficiency) and in liver disease owing to decreased synthesis. Haptoglobin levels in neonates are virtually zero; adult levels are only reached by the age of 4 months (38).

The complex formed by the binding of hemoglobin to haptoglobin shows a slower migration on SPE than haptoglobin alone. The presence of these complexes can indicate acute hemolysis or poor specimen handling (38).

Determination of haptoglobin levels are useful to distinguish hemoglobinuria from myoglobinuria: As long as detectable haptoglobin levels are present in the plasma, a positive dipstick test is consistent with myoglobinuria.

Historically, haptoglobin was measured by determining the hemoglobin-binding capacity of serum. In this assay, a patient sample is first saturated with hemoglobin followed by electrophoretic separation of the free from the bound hemoglobin. The haptoglobin–hemoglobin complex is then quantified by its reaction with benzidine and expressed as milligrams of hemoglobin-binding capacity per deciliter of serum. This cumbersome procedure has now been replaced by immunochemical methods, including nephelometry and RID. The reference range is 16 to 199 mg/dL (12).

Transferrin

Transferrin (siderophilin) appears as a distinct band on SPE and constitutes the major component of the ß-globulin fraction. It functions as the principal plasma protein responsible for the transport of iron. Transferrin is a glycoprotein (MW 79,550) containing two iron binding sites on a single polypeptide chain. Most of the transferrin in plasma is synthesized by the liver, although small amounts are made in a variety of other sites, including the reticuloendothelial system, the gonads, and the submaxillary gland (39). Transferrin binds ferric iron in a reversible ionic bond accompanied by the uptake of one bicarbonate anion per atom of iron. The complex is stable at physiological pH, but dissociation occurs in acidic solution. Transferrin is also capable of loosely binding several other metal ions, including copper, zinc, cobalt, and calcium, but, with the exception of copper, this is not of physiological significance (39).

The body contains approximately 3 to 5 g of iron, but only 3 to 5 mg of iron is found in plasma. Almost all this iron is bound to transferrin, with a small amount bound to other proteins such as albumin. The level of free iron is very low (less than 1 µg/dL). Consequently, the serum iron concentration refers mainly to iron bound to transferrin, whereas the total iron-binding capacity (TIBC), which is also commonly measured, is simply an approximation of the transferrin concentration. Normally only approximately 33% of the iron binding sites on transferrin are occupied. This is sometimes reported as the percentage of saturation of transferrin.

Transferrin is responsible for the transport of iron from its site of absorption in the intestine (or from sites of hemoglobin catabolism) to red cell precursors in the bone marrow or to sites of iron storage in the reticuloendothelial system of the bone marrow, liver, and spleen. The transferrin–iron complex binds to receptors expressed by these cells and is internalized into endosomes. The lower pH in these organelles leads to a dissociation of iron from transferrin. After unloading its iron, transferrin returns to the plasma and is recycled. Radiolabel tracer studies have demonstrated a biological half-life of approximately 8 days. In addition to its transport function, transferrin minimizes the level of free iron in plasma, thus reducing urinary iron losses and preventing the potentially toxic effects of high free iron levels.

The transferrin protein exhibits extensive genetic polymorphism arising from amino acid substitutions in the peptide chain and variations in the carbohydrate chains and in iron content (8). Several variants have been identified on protein electrophoresis. They are named according to their relative electrophoretic mobility when compared with the most common transferrin type, known as transferrin C. For example, transferrin D was the first variant protein discovered. Transferrin D is found in some American blacks and Australian aborigines. Although none of the electrophoretic variants has been associated with human disease, they will occasionally masquerade as M components on serum electrophoresis. Heterozygotes exhibit two transferrin bands, one with a normal mobility and reduced concentration (C protein) and the second migrating either above or below the normal band. Immunofixation techniques will distinguish these variants from true M components. Rarely, congenital atransferrinemia results in very low levels of plasma transferrin in association with iron overload and severe anemia owing to the inability to mobilize the body's iron stores (8). In patients with a history of alcohol abuse, transferrin contains less sialic acid than in control populations. A high-performance liquid chromatography–based method for the quantitation of such carbohydrate-deficient transferrin was described recently by Jeppsson et al. (40). This method appears to be a highly specific and sensitive assay for alcohol abuse.

Decreased levels of serum transferrin may be seen in liver disease and in protein-losing disorders such as the nephrotic syndrome and protein-losing enteropathy. Transferrin levels are depressed in starvation and are a useful marker of protein malnutrition in hospitalized patients (5). Like albumin and ß-lipoprotein, transferrin behaves as a negative APR (8). Consequently, low levels are seen in a variety of acute and chronic inflammatory states and in malignancy. This might serve to deprive bacteria and tumor cells of iron (41). Transferrin levels may rise during the late stages of the acute-phase response (see APRs).

Assay of serum transferrin is most commonly performed in the evaluation of anemia. In iron deficiency anemia, the transferrin level is elevated but the percentage of saturation is low. In the anemia of chronic disease, transferrin is decreased and the percentage of saturation is decreased. Transferrin levels may be increased in the early stages of acute hepatitis, in pregnancy, and with estrogen administration. In idiopathic hemochromatosis and in hemosiderosis owing to excessive blood transfusions, the serum transferrin is normal but the percentage of saturation is markedly elevated (as high as 90%).

The normal serum transferrin level is 191 to 365 mg/dL (1.91 to 3.65 g/L) (12). Increases or decreases in transferrin may be detected on SPE, and marked increases may simulate a paraprotein band.

Several immunochemical assays are available, including RID and rate nephelometry, and transferrin may also be estimated indirectly by determination of the TIBC. The TIBC (in milligrams per deciliter) is then multiplied by 0.70 to give an estimated transferrin value in milligrams per deciliter (8).

ß-Lipoprotein

Lipoproteins constitute a family of molecules composed of lipids and proteins whose function is to transport cholesterol, triglycerides, and phospholipids in the blood. Lipoproteins have been subclassified into four categories designated chylomicrons, very low density lipoproteins (VLDL), low-density lipoproteins (LDL) and high-density lipoproteins (HDL).

On SPE, HDL migrate between the albumin zone and the α region (α-lipoproteins), forming a diffuse background pattern that is not readily discernible. Likewise, the VLDLs migrate in the pre-ß region but are not resolved from other proteins. However, the ß-lipoproteins (LDL) appear in the slow α_2 or ß region as a wavy, broad band with a sharp leading edge and a trailing anodal tail.

Increases or decreases in the ß-lipoproteins can often be recognized on SPE. Elevations may occur in the nephrotic syndrome, hepatobiliary disease, hypothyroidism, diabetes mellitus, and some of the familial hyperlipidemia syndromes.

An increase produces a high-intensity band that may be cathodally displaced; this finding should prompt further investigation. Decreased ß-lipoproteins are associated with a faint band of faster mobility (42).

$ß_2$-Microglobulin

$ß_2$-Microglobulin ($ß_2M$) is a small protein (MW 11,818) comprising the common light chain of the class I major histocompatibility complex antigen on the surfaces of all nucleated cells (43). It consists of a single polypeptide chain that is noncovalently linked to the human lymphocyte antigen (HLA) heavy chain. $ß_2M$ may be necessary for insertion of the HLA molecule into the cell membrane, and its presence appears to stabilize the HLA heavy chain. It also plays a role (currently poorly defined) in the regulation of some lymphocyte functions.

A small amount of $ß_2M$ is normally present in the plasma,

urine, and CSF, presumably because the protein is shed from cell surfaces into the blood (8). Its function in these fluids, if any, is unknown.

Because of its small size, β_2M is filtered by the renal glomerulus, but most is resorbed and degraded by the renal tubular epithelial cells. The plasma level of β_2M is a good index of the glomerular filtration rate. Only trace amounts of the protein are normally present in urine. Elevated levels of urinary β_2M may be seen in patients with renal tubulointerstitial disorders, including heavy metal toxicity, anticancer drug toxicity, aminoglycoside toxicity, upper urinary tract infections, and renal allograft rejection. In contrast, patients with renal failure based on glomerular dysfunction typically show elevated plasma β_2M levels. Plasma β_2M may also be increased in a number of inflammatory diseases [e.g., hepatitis, rheumatoid arthritis, systemic lupus erythematosus, acquired immune deficiency syndrome (AIDS), and sarcoidosis] and in patients with leukemia, lymphoma, and some solid tumors. In some of these disorders, the elevation in the plasma β_2M may reflect increased lymphocyte turnover.

Several reports have indicated that β_2M levels might be an extremely useful prognostic marker for some types of lymphoproliferative disorders. Durie and colleagues (44) reported that serum β_2M is the best available predictor of survival duration in patients with multiple myeloma. Similarly, Kantarjian et al. (45) found that monitoring serum β_2M levels may provide significant prognostic information in patients with adult acute lymphocytic leukemia. Measurement of β_2M also adds relevant prognostic information to CD4 counts in predicting the progression to AIDS in human immunodeficiency virus (HIV)–infected individuals (46,47). β_2M may sometimes be seen on high-resolution electrophoresis. However, because of its low concentration, it is usually measured by immunoassay. The normal upper reference limit is 2.8 mg/L in serum and 0.2 mg/L in urine (12).

C-Reactive Protein

CRP (MW 118,000 Da) was first identified in 1930 as a substance present in the sera of patients with pneumococcal pneumonia that could bind to C-polysaccharide isolated from *Streptococcus pneumoniae*, producing a flocculation reaction. Subsequently, it was found that CRP is elevated in a variety of other acute inflammatory diseases. Thus, CRP was the first recognized APR. It rises rapidly (24 to 48 hours) after the inflammatory stimulus and shows a large increase (as high as 1,000-fold) and a short half-life of 19 hours (48). The rapid, high rise and early return to normal levels after successful therapy make CRP the APR best suited for diagnostic purposes.

CRP is synthesized by the liver and released into the plasma. Small amounts are also made by a subset of peripheral lymphocytes, but this remains bound to the surface of the cells (49). The intact molecule is a nonglycosylated, pentameric protein with five identical subunits arranged in a doughnut-shaped polymer. Each subunit consists of 206 amino acids.

Several functions have been ascribed to CRP, including initiation of opsonization and phagocytosis (8) and activation of complement, neutrophils, and monocyte-macrophages (7). Collectively, these properties imply an important role for CRP in the recognition of microbial organisms and as an immunomodulator in host defense. CRP may also be important to the recognition of necrotic tissues. It can bind to a number of molecules, including phosphate esters, lipids, polyanions (DNA, polylysine), polycations (histones, protamine), and various polysaccharides (8,49).

Small amounts of CRP are normally found in plasma at levels less than 0.8 mg/dL. The majority of CRP values for normal healthy individuals fall below the detection limit of most routinely used methods (48). Levels may increase markedly during the acute-phase response. Although CRP is not ordinarily seen on SPE, it may appear as a distinct band in the mid-β to slow γ region when levels are elevated. This can be confused with a monoclonal M component.

Traditional methods for measuring CRP included precipitation and agglutination assays. These had low sensitivity and provided only qualitative results. The lack of a satisfactory assay caused a loss in popularity of CRP testing in favor of the ESR for detecting patients with inflammatory diseases. Recently, highly specific antibodies to CRP have become available. These antibodies permit the development of rapid, specific, and very sensitive assays for this protein. These newer immunoassays include laser nephelometry (the most popular method), radioimmunoassay, and enzyme immunoassays (7) and have created a renewed interest in CRP testing in various clinical settings. CRP is a more sensitive, rapidly responding indicator of inflammation than the ESR and may someday replace it. Because infections with bacteria lead to higher CRP levels than viral diseases, CRP levels may be helpful to distinguish between these diagnostic possibilities. CRP levels are also used to follow patients with autoimmune diseases.

METHODS OF PROTEIN ANALYSIS

Part of "13 - The Plasma Proteins"

Measurement of Total Protein

Several methods are available to measure the total protein in serum or plasma. Most methods are based on the assumption that protein molecules are pure polypeptides and that different proteins react with chemical reagents in the same way (8). Neither of these assumptions is strictly true. For example, many proteins contain carbohydrate substituents that may constitute a significant part of the molecule but might not be included in the total protein value as measured by standard methods. In addition, the reactivity of different proteins depends on the structure and amino acid composition of the molecule, which are not the same for all proteins. The fact that biological fluids are composed of mixtures of proteins in varying proportions complicates the quantification of proteins in serum, urine, and CSF.

Historically, the Kjeldahl procedure for measuring total nitrogen has been considered a reference method against which other methods for protein could be compared. In this procedure, the sample is first subjected to acid hydrolysis, which converts protein nitrogen to ammonium ions. The ammonia nitrogen is then determined by titration or by nesslerization. Because nitrogen contained in nonprotein compounds is also detected by this procedure, a deproteinized sample must be tested in parallel and the value subtracted from the total nitrogen content of the original specimen. The nitrogen content of proteins varies between

15.1% and 16.8% (3), which imparts a slight error when different proteins or protein mixtures of varying proportions are analyzed. The Kjeldahl procedure is too time-consuming and complex for routine use.

The biuret method is the most widely used procedure for the measurement of total protein in the clinical laboratory. It is both simple and easily automated but lacks sufficient sensitivity for use on low-concentration samples such as CSF or urine. The method is based on the reaction of peptide bonds with copper ions (Cu^{2+}) in alkaline solution, forming a pink to violet complex that is measured spectrophotometrically at 540 nm. The intensity of the color is proportional to the protein concentration. A similar reaction occurs between copper ions and the organic compound biuret from which this method derives its name (8). The biuret reaction will occur with any peptide with three or more amino acids. Common causes of interference are lipemia, hemolysis, bilirubinemia, and turbidity, all of which may contribute to the total absorbance at 540 nm. The appropriate use of serum blanks will correct for these sources of interference.

The Lowry method employs a two-stage reaction sequence and is one of the most sensitive (but not specific) procedures for the measurement of total protein. Proteins are first allowed to undergo the biuret reaction. This is followed by reaction of the tryptophan and tyrosine residues with the Folin-Ciocalteu reagent (phosphotungstic-phosphomolybdic acid), yielding a blue color. Histidine and cysteine residues also react but produce weaker chromogens. The combined absorbance of the copper-peptide bond complexes and the reduced Folin-Ciocalteu chromogens is measured at 650 to 750 nm. The copper-peptide bond complexes account for most of the absorbance.

The Lowry method has not been widely used in clinical laboratories for several reasons. First, a variety of nonprotein compounds and drugs react, causing a positive interference. Second, the tyrosine and tryptophan content of proteins varies widely, which complicates the analysis of mixed protein samples. For example, albumin contains only 0.2% tryptophan by weight, whereas the tryptophan content of the globulins is generally between 2% and 3% (8). The method is best for measuring pure proteins of known composition. The major advantage of the Lowry method is that it is nearly 100 times more sensitive than the biuret reaction. It has been used extensively in research to measure samples of low protein concentration.

The absorption of ultraviolet light by proteins at either 280 nm or at 200 to 225 nm provides a simple method to estimate the concentration of proteins in solution. The absorbance at 280 nm is caused mainly by the aromatic rings of tyrosine and tryptophan. The content of these amino acids varies in different proteins, and free tryptophan and tyrosine cause a positive interference. The peptide bonds of proteins are largely responsible for the absorbance at 200 to 225 nm, but measurements this low in the ultraviolet region are also subject to a number of interferences. Again, the problem of poor specificity limits the usefulness of methods based on ultraviolet light absorption.

A very rapid estimate of the total protein in serum may be obtained by refractometry. This method is based on the principle that dissolved solutes increase the refractive index of water. Although serum contains a number of nonprotein compounds, these normally contribute very little to the refractive index of serum. The total protein value is simply read from a precalibrated scale on the refractometer. A positive interference is seen with azotemia, hyperglycemia, hyperbilirubinemia, and lipemia.

A number of dye-binding procedures are available to measure the total protein in clinical specimens. The principle of these assays is similar to the dye-binding methods used for albumin. The most widely used dyes are Coomassie brilliant blue and amido black. Dye-binding methods are limited by the fact that different proteins exhibit different dye-binding characteristics.

Finally, a number of turbidimetric and nephelometric methods are available for measuring proteins in serum or other fluids. These involve precipitation of the proteins with sulfosalicylic acid or trichloracetic acid. The resulting precipitate will scatter a beam of incident light, which forms the basis of the assay.

The normal reference range for serum proteins is 60 to 80 g/L (6.0 to 8.0 g/dL) (12). The level in infants is somewhat lower than in adults, with adult levels being achieved by 3 years of age. Values in women may be slightly lower than in men.

The measurement of protein in urine or CSF is more difficult than in serum because protein is present in much lower concentrations in these fluids. The most commonly used procedures employ modifications of turbidimetric and dye-binding assays. Among the latter group, Coomassie brilliant blue and Ponceau S are currently popular. Several immunoassays are also available. All methods have the types of problems described previously, and no assay is totally satisfactory.

Serum Protein Electrophoresis

SPE is a common laboratory screening test that may be used to evaluate a variety of disease processes. The most common indication for SPE is the detection of monoclonal paraproteins, although the technique has value in a number of other clinical situations. Electrophoretic methods have also been applied to the analysis of isoenzymes, lipoproteins, and hemoglobinopathies and to the detection of genetic variants of various proteins.

Principles of Electrophoresis

Electrophoresis is a method of separating charged molecules based on their relative mobilities in an electric field. A number of different support media may be used as the stationary phase (e.g., paper, agarose gel, cellulose acetate), while the mobile phase is composed of buffer ions moving under the influence of an electric field. When an electric field is applied, the negatively charged species migrate toward the anode (positive electrode), and positively charged species toward the cathode (negative electrode). Proteins contain both carboxylic acid groups (COOH), which can deprotonate to form negative charges, and amino groups ($-NH_2$), which can accept protons to form positive charges. The net charge on the protein molecule thus depends on its amino acid composition, the presence of charged substituent groups such as carbohydrates, and the pH of the electrophoresis buffer.

The direction of migration of a protein in an electric field depends on the pH of the buffer and the isoelectric point of the protein. The isoelectric point (PI) is defined as the pH at which the sum of all positive and negative charges on the molecule add

up to zero. Thus, a protein at its isoelectric point has no net charge and will not migrate in an electric field. At a pH below the isoelectric point, the protein has a net positive charge and the protein will therefore migrate toward the cathode. At a pH above the isoelectric point, the protein will migrate toward the anode.

Other factors that influence the migration of proteins in an electric field are the size and shape of the molecule, the strength of the electric field, the temperature, the effects of convection and diffusion, and the ionic and pore properties of the electrophoresis medium (50).

The first electrophoresis system was described by Tiselius in 1937. This method used a U-shaped tube filled with an electrolyte solution. The sample was then placed at the bottom of the tube. When a current was run through the system, the proteins were separated into four fractions designated albumin, α, ß, and γ. The fractions could be identified by observing a change in the refractive index of the electrolyte at the boundaries between the fractions. The Tiselius procedure has been called the moving-boundary method.

Several technical innovations have occurred since the original description of Tiselius. Modern electrophoresis methods use a solid supporting medium such as cellulose acetate, agarose gel, or polyacrylamide that is saturated with buffer. The supporting medium is connected to two electrodes by wicks that are also saturated with buffer. A power supply capable of delivering a constant voltage or current is connected to the electrodes. When a protein mixture is placed on the supporting medium, it migrates through the electric field and separates into individual components. Methods that use a solid supporting medium are referred to as zone electrophoresis.

The choice of electrophoresis buffer is one of the most important factors affecting the resolution of the system. The buffer defines the pH, which determines the net charge on the protein. This influences both the speed and direction of movement. In addition, the ionic strength of the buffer affects the rate of protein migration. Increasing the ionic strength increases the ionic association between buffer ions and exposed charge groups on the protein molecule. This has the effect of slowing the rate of movement of the protein through the support medium, producing sharper bands on the electrophoretogram. However, as the ionic strength is increased, so too are the current and heat generated during electrophoresis. This effect may denature heat-labile proteins and cause evaporation of buffer from the support medium. The effects of heating can be minimized by incorporating a cooling unit into the electrophoresis apparatus and by performing the procedure in a closed chamber to reduce evaporation.

Several support media are available for protein electrophoresis. These can be divided into two types. One type separates proteins solely based on net molecular charge. Examples of this type include paper, cellulose acetate, and agarose gel. The second type separates proteins based on both charge and molecular size. The use of two parameters to separate proteins greatly increases the resolution of the system. Examples of the latter category are starch gel and polyacrylamide (51). Both of these media contain minute pores through which the proteins must travel when migrating under the influence of the electric field. Small molecules traverse the pores more easily than larger ones, producing a molecular sieve effect. The rate of migration of proteins through these media is therefore inversely proportional to their molecular size. Proteins of different sizes but with similar size to charge ratios are not separated on cellulose acetate or agarose, whereas separation may be achieved on starch gel and polyacrylamide.

Some electrophoretic support media adsorb hydroxyl ions from the buffer, creating fixed negative charges. This property is responsible for an effect called electroendosmosis. The fixed charges are surrounded by a cloud of mobile positive ions in the buffer. When a current is applied to the system, the ionic cloud is free to move toward the cathode, whereas the fixed negative charges are immobilized on the support medium. The migrating positive ions are hydrated and therefore carry a shell of solvent molecules with them. The movement of positive ions and solvent toward the cathode creates the endosmotic effect. Proteins migrating toward the anode must move against this force. At the usual pH of electrophoretic buffers, most proteins contain enough negative charges to overcome electroendosmosis. However, proteins that bear relatively few negative charges, such as the γ-globulins, may remain still during electrophoresis or be swept backward toward the cathode by the force of endosmosis. This is the reason that most of the γ-globulins are found cathodal to the origin on standard electrophoretograms. Endosmosis is most pronounced with support media containing a large number of fixed negative charges (paper, cellulose acetate, and conventional agarose) but is less important with systems using polyacrylamide or purified agarose gels.

SPE on paper was once popular but has been largely replaced by methods using cellulose acetate or agarose gels. Polyacrylamide and starch gel electrophoresis provide the greatest resolution of protein bands but are generally used only in specialized situations or in research where high resolution is desirable.

Some laboratories are using an improved method for SPE known as high-resolution electrophoresis (HRE). HRE separates serum into 13 zones instead of the usual five. In addition, several protein bands are detected on HRE that are not well resolved by conventional SPE. HRE may be particularly useful to detect faint monoclonal paraproteins but is of limited benefit for analyzing other serum protein patterns.

Agarose Gel Electrophoresis

Both cellulose acetate and agarose have been widely used in the clinical laboratory. The use of agarose gels for SPE is becoming increasingly popular. A comparison of the two methods was reported by Aguzzi et al. (52). The remainder of this section is devoted to a discussion of agarose gel electrophoresis.

A distinction should be made between agar and agarose. Agar contains both agarose and agaropectin. Agaropectin is a highly charged substance with both carboxylic and acid sulfate groups, which create a significant endosmotic effect. In addition, agar tends to retain protein stains, which decreases the clarity of the electrophoresis pattern. Agarose is a purified form of agar in which most of the agaropectin has been removed. Partially purified agarose preparations showing moderate endosmosis are commercially available and provide a virtually transparent gel. This facilitates visualization and quantitation of the protein bands.

A standard method for serum protein agarose gel electrophoresis was described as a proposed selected method in 1979 (42). Several variations of this procedure have been used. Electrophoresis kits containing premade gels, staining solutions, and all the necessary apparatus are available from several suppliers. Most systems use a 0.5% to 1.0% gel with either a barbital or tris-boric acid-ethylenediaminetetraacetic acid buffer at pH 8.6. Fully automated electrophoresis systems have been developed that eliminate many of the manual manipulations normally required in the procedure.

For a detailed description of a standard agarose gel electrophoresis method, the reader is referred to Jeppsson et al. (42). In this method, a serum sample is first spotted on the surface of the agarose support medium and allowed to absorb into the gel. The gel is then connected to two electrodes by filter paper wicks saturated with buffer. The electrodes are attached to a constant-voltage power supply. A current is then passed through the gel to separate the proteins. When electrophoresis is complete, the gel is removed from the electrode apparatus and placed in a bath of fixing solution. The fixing solution usually contains acetic acid, which denatures the proteins and immobilizes them in the gel. This prevents diffusion of the protein bands in the support medium. Proteins in an agarose gel are invisible. Therefore, a staining solution is needed to visualize the bands. A variety of stains have been used, including Coomassie brilliant blue, amido black, and Ponceau S, which differ in their protein-binding affinities, sensitivity, and absorbance spectra. Coomassie brilliant blue is the most sensitive of the commonly used stains. Highly sensitive silver staining methods are available but are seldom necessary in routine practice. After the proteins have been stained, the gel is placed in a destaining solution (usually a mixture of methanol, acetic acid, and water) that clears the excess stain from the gel, producing sharp protein bands on a transparent background. The finished gel is quite fragile and is not suitable as a permanent record. However, the gel may be dried on a sheet of clear plastic, creating a durable record that can be stored for subsequent review.

Standard agarose gel electrophoresis systems separate serum into five zones designated albumin, α_1, α_2, ß, and γ (Fig. 13.2). The albumin band is relatively homogeneous, whereas the other zones are composed of mixtures of different proteins. Interpretation of electrophoretograms requires practice and a thorough understanding of the disease processes that may affect the protein pattern. The most useful information is obtained by careful visual inspection of the stained gel. In addition, the individual fractions can be quantitated by scanning the electrophoretogram with a densitometer. Most commercial kits are equipped with a scanning densitometer that produces a two-dimensional tracing of the electrophoresis pattern (Fig. 13.1). An integrator is used to calculate the area under each of the zones, which can then be expressed as a percentage of the total area under the tracing. If the total protein concentration is known, the results can be converted into grams per liter because the area under each zone is proportional to its concentration. The reference range for each of the five zones depends on the electrophoresis method and also varies somewhat with the age, gender, and race of the reference population and various other minor factors. A typical reference range is shown in Table 13.4.

TABLE 13.4. TYPICAL SERUM PROTEIN ELECTROPHORESIS REFERENCE PATTERN

Zone	Percentage of Total Protein (mean)
Albumin	45.8–68.2 (57.0)
α	2.1–6.1 (4.1)
α_2	8.8–18.0 (13.4)
ß	7.8–13.0 (10.4)
γ	7.8–22.6 (15.2)

Quantitative densitometric scanning provides a good measurement of the total serum albumin and a crude estimate of the γ-globulin fraction. It is not reliable for measuring other serum proteins because each zone is composed of a mixture of proteins that are not easily resolved by the densitometer. For this reason, densitometric scanning is of limited value. Most laboratories rely primarily on visual interpretation of the overall electrophoresis pattern.

The proteins that make up each of the five electrophoretic zones are listed in Table 13.2. Most of these were discussed in the preceding sections.

Albumin migrates to the far anodal region of the gel. The mobility of the albumin band may be affected by both congenital and acquired alterations in the molecule. Individuals who are heterozygotes for genetic albumin variants may show a widening of the band, or it may be split into two separate bands (bisalbuminemia). Hyperbilirubinemia, bound fatty acids, and some drugs (aspirin, penicillin) may increase the mobility of albumin (43). The significance of increases and decreases in the serum albumin was discussed previously. Sometimes a faint prealbumin band may be seen anodal to albumin.

The α_1 zone contains mostly AAT with minor contributions from several other proteins (Table 13.2). Although AAT cannot be reliably quantitated on serum electrophoretograms, a marked decrease in the AAT band or a band with altered mobility may suggest AAT deficiency and prompt further investigation.

The principal components of the α_2 zone are AMG and haptoglobin. The ß-lipoprotein band (LDL) may be found in the α_2 region on some systems but more commonly appears in the ß zone. AMG and haptoglobin usually merge into a composite fraction but are sometimes resolved into two separate bands. In patients with hemolytic anemia, haptoglobin may be noticeably decreased.

The major components of the ß zone are transferrin, the third component of complement (C3), and the ß-lipoproteins. In iron deficiency anemia, the transferrin band may be increased, although this finding is not specific. The C3 band is quite labile and is often absent unless fresh serum is used. The conversion product of C3 (C3c) sometimes appears in the fast ß region. A true decrease in C3 may occur in a variety of inflammatory disorders, including systemic lupus erythematosus. The ß-lipoproteins appear as a wavy band with a sharp leading edge and a smudgy tail. Increases in this band are seen in various conditions, including liver diseases, the nephrotic syndrome, malnutrition, and some familial hyperlipidemia syndromes.

The immunoglobulins are found in the γ region. This heterogeneous group of proteins is distributed throughout the entire

region, and they do not ordinarily produce discrete bands. The finding of a band in the γ-region should alert the observer to the possibility of a monoclonal paraprotein. Other proteins including CRP, lysozyme, and traces of fibrinogen may also produce bands in this zone. Normally, fibrinogen is not seen on SPE, but occasionally a faint band appears in patients receiving anticoagulant therapy. Marked elevations in CRP occur in the acute-phase response, which may produce a faint band in the γ region.

The most important use of SPE is for the detection of monoclonal paraproteins. The analysis of paraproteins is discussed in detail in Chapter 44, Chronic Lymphoproliferative Disorders.

In addition to the abnormalities in the individual aforementioned proteins, certain diseases produce alterations in more than one protein, which affect the overall electrophoretic pattern. These patterns may be recognized on visual examination of the electrophoretogram (Fig. 13.2) or by quantitative densitometric scanning.

The acute inflammatory pattern produces predictable changes based on the behavior of the positive and negative APRs. The albumin band is normal or decreased, while the α_1 and α_2 globulins show a marked increase. The transferrin band is usually decreased, and the γ-globulins, at least initially, appear normal. The acute-phase response may in time evolve into a chronic inflammatory pattern. Albumin continues to be decreased, and the α-globulins remain elevated. In addition, a diffuse polyclonal increase in γ-globulins appears, reflecting increased antibody synthesis. This feature serves to distinguish the acute from the chronic inflammatory pattern.

Cirrhosis produces a decrease in both albumin and the α-globulins owing to defective hepatocellular synthesis. This is associated with an increase in the β-lipoprotein band and a polyclonal hypergammaglobulinemia. The increase in γ-globulins may result in fusion of the β- and γ-globulin zones, which has been called β-γ bridging.

The electrophoretic pattern in patients with acute liver disease is quite variable. The most common pattern is a decrease in albumin with increases in the α- and γ-globulins. However, other patterns may be seen, including an isolated decrease in albumin, diffuse hypergammaglobulinemia, or a normal pattern.

Patients with nonselective protein-losing syndromes such as burns or exudative disorders of the skin, lung, and gastrointestinal tract may have decreases in all the serum proteins. This pattern may be superimposed on acute or chronic inflammatory changes, which cause an increase in some bands in the α and γ regions. Malnutrition and malabsorption result in generalized hypoproteinemia.

In the nephrotic syndrome, there is a selective protein loss. The α_2 region is often noticeably increased because of the increase in AMG. The β-lipoprotein band may be prominent, reflecting the hyperlipidemia seen in nephrotic syndrome. However, albumin is markedly decreased, as are most of the other fractions. The large increase in AMG differentiates this pattern from that seen with nonselective protein losses.

An alteration in the electrophoretic pattern is often seen in pregnancy and in some patients taking oral contraceptives. Pregnancy is associated with an increase in the plasma volume, which causes a dilutional decrease in albumin. In late pregnancy, an increase in α_1-glycoprotein may elevate the α_1 globulins, while the α_2 and β-globulins are elevated by increases in CER, β-lipoprotein, and transferrin. The γ-globulins may also be slightly elevated.

Capillary Electrophoresis

In capillary electrophoresis, electrophoretic separation of analytes is carried out in fused-silica capillaries with an inner diameter of 50 μm (range, 20 to 200 μm), an outer diameter of 375 μm, and an effective length of approximately 50 cm (range, 7 to 100 cm) (53). The high surface-to-volume ratio leads to fast dissipation of heat generated by the electric current. This allows the use of electric fields at least 50-fold more powerful than with traditional slab gels and therefore the rapid separation of proteins. Separation times of 5 to 15 minutes can be achieved. The small size of the capillary also allows sample sizes in the nanoliter range (54). Detection methods used for capillary electrophoresis include ultraviolet absorbance, fluorescence, and conductivity (53). The method can be fully automated, and commercial systems equipped with automated sample loading and data analysis are available (8). In a comparison of this method with conventional electrophoresis, it was found to be a reliable and reproducible technique with the advantages of high separation efficiency, on-line data analysis, quick separation, and ease of automation (55).

Other Methods

Various methods are available for the study of proteins. These include methods that separate proteins based on molecular size (ultrafiltration, density gradient centrifugation, molecular exclusion chromatography), solubility (isoelectric precipitation, salt precipitation, solvent fractionation), electric charge (electrophoresis, isoelectric focusing, ion exchange chromatography), and selective adsorption (affinity chromatography). Several of these methods have been used extensively in research. For further details, the reader is referred to standard biochemistry texts. Only a few of these techniques are used with any frequency in the clinical laboratory and are described briefly in the following sections.

Ion Exchange Chromatography

All forms of chromatography contain a stationary phase and a mobile phase. The mobile phase provides the driving force to separate molecules, while the stationary phase may partially or completely retard their movement, thus permitting separation. Molecules that differ in their size, charge, or other physical parameters can be resolved by selecting appropriate stationary and mobile phases.

Ion exchange chromatography uses a charged supporting medium to separate molecules based on their acid-base properties. The supporting medium consists of minute particles (“beads”) to which fixed charges are attached. The beads are loaded in a plastic or glass column. The sample is then placed on top of the column and allowed to percolate through the medium. Some molecules bind tightly to the fixed charges, some

bind only weakly, and others do not bind at all. Those that do not bind pass unhindered through the column and are collected in a fraction tube. Molecules that remain bound to the beads are then sequentially eluted with buffers of increasing ionic strength or varying pH, which displace the bound molecules from the column.

Ion exchange resins are often derivatives of cellulose. Carboxymethylcellulose contains fixed negative charges at pH 7.0 and thus is called a cation exchange resin because cationic molecules bind by exchanging for sodium ions bound to the negative charges on the resin. In contrast, diethylaminocellulose contains fixed positive charges at neutral pH and is used as an anion exchange resin. By selecting an appropriate resin, sample pH, and elution buffers (pH and ionic strength), complex protein mixtures can be separated for further study.

Ion exchange methods have been used to separate isoenzymes, glycosylated hemoglobins, and genetic variants of some proteins. Minicolumns for separating certain proteins are available in kit form.

Affinity Chromatography

Affinity chromatography is based on the principle that some proteins will bind by noncovalent forces to specific ligands. Examples of protein ligand combinations include hormone-receptor pairs, enzyme-coenzyme pairs, and antigen-antibody pairs. Because the ligand may be highly specific to a particular protein, affinity chromatography permits a high degree of purification of the protein, often in a single step.

The method of affinity chromatography is similar to other column methods. The ligand is first immobilized to an inert supporting medium. This is then loaded into a column and the sample added to the top of the column. As the sample percolates through, the protein binds to its specific ligand. Other proteins flow through the column and are collected in a fraction tube. Then an eluting buffer is added to the top of the column. The eluting buffer may be a high ionic-strength salt solution or a solution containing a high concentration of some other compound that competes with the bound protein for the ligand. The protein is thus displaced from its ligand-binding site and is eluted from the column.

Affinity chromatography is one of the most powerful techniques used to purify proteins but to date has been used only on a limited basis in the clinical laboratory.

Isoelectric Focusing

Isoelectric focusing (IEF) or electrofusing is a type of electrophoresis that separates proteins based on their isoelectric point (PI) (see earlier discussion). A protein at its isoelectric point will not migrate in an electric field, and this feature has been exploited in IEF. IEF is performed in a glass tube filled with a gel supporting medium that contains a pH gradient extending from the top to the bottom of the tube. The sample is loaded on the top of the column and a current is applied to the apparatus. The proteins in the sample migrate through the pH gradient until they reach their isoelectric point, where they stop (focus). Because the isoelectric point of proteins changes with even minor changes in amino acid composition, complex mixtures of proteins can be separated by IEF.

Like affinity chromatography, IEF is a powerful method to separate proteins. However, its use in the clinical laboratory is currently restricted to specialized situations (such as detecting AAT variants), and most laboratories are not equipped to perform this technique.

Diagnostic Enzymology and Other Biochemical Markers of Organ Damage

Alan H. B. Wu

Enzymes play a vital role in catalyzing the biochemical reactions necessary for normal human growth, maturation, and reproduction. Diagnostic enzymology involves the measurement of enzymes in body fluids for the diagnosis of disease. In most cases, serum or blood levels are the most useful, although urine, cerebrospinal, and extracellular fluid levels are sometimes important.

This chapter focuses on the analytical aspects and clinical significance of important enzymes that are measured for diagnostic purposes. The major emphasis is on the use of these enzymes for the diagnosis of diseases involving the liver, myocardium, skeletal muscle, pancreas, and bone. In the case of myocardial infarction and skeletal muscle injury, nonenzyme markers such as myoglobin and troponin are also discussed.

BASIC CONCEPTS FOR DIAGNOSTIC ENZYMOLOGY

Part of "14 - Diagnostic Enzymology and Other Biochemical Markers of Organ Damage"

Pathologic Role of Enzymes in Blood

Most enzymes that are used for diagnostic purposes have no direct physiologic role in the blood. Their presence under normal circumstances is the result of natural aging and turnover of cells. Enzymes released into the blood are usually cleared from the circulation by metabolism within the reticuloendothelial system, although some are cleared by the kidneys (e.g., amylase). The normal level of activity of these enzymes in the serum is a function of the rate of release and clearance. The half-lives of these enzymes vary greatly from an estimated 2 hours for the BB isoenzyme of creatine kinase (CK) to 170 hours for placental alkaline phosphatase (ALP).

High levels of enzymes in the blood can indicate increased cellular turnover and tissue necrosis caused by disease. This was first demonstrated by LaDue et al. (1) in 1954, when they observed that aspartate aminotransferase activity increased after acute myocardial infarction (AMI). In subsequent studies using carbon tetrachloride–induced liver injury in rats, these investigators showed that high serum enzyme levels were caused by leakage from the damaged hepatocytes. Once released from cells, enzymes can either pass directly into the blood (if the tissue is highly vascular and there is no obstruction to flow) or reach the bloodstream through slower lymphatic drainage. The subcellular origin plays a role in how readily an enzyme will appear in the blood. Soluble cytoplasmic enzymes pass through one set of membranes, whereas mitochondrial enzymes must also pass through a second set of membranes.

An equally important and largely overlooked cause of high enzyme levels in blood is tissue synthesis of new enzymes that occurs in response to disease, induction by various drugs, and carcinogenesis (2). For example, in obstructive liver disease, hepatic ALP is increased largely because of increased synthesis owing to abnormal intracanalicular pressure. Phenobarbital and several other drugs induce microsomal enzyme production that leads to increased synthesis of γ-glutamyltransferase (GGT). In addition, enzymes normally absent in serum can appear as the result of a neoplastic process.

FACTORS IN ENZYME ASSAY DEVELOPMENT

Part of "14 - Diagnostic Enzymology and Other Biochemical Markers of Organ Damage"

Enzyme Kinetics and Substrate Concentration

Enzymes (E) are biological catalysts that combine with substrates (s) to form intermediate complexes (ES) leading to the formation of product (P) and restoration of the original enzyme (3). Reactions involving one substrate exhibit the following kinetics:

$S + E \rightarrow [ES] \rightarrow P + E$

Amylase and lipase are examples of enzymes of this scheme, but most other enzymes catalyze more complex reactions in which there are two or more substrates that form multiple products.

The reaction rate is a function of several factors, including substrate and enzyme concentration, temperature, pH, and the presence of cofactors, coenzymes, activators, and inhibitors. The rate equations for enzyme-catalyzed reactions were first developed by Michaelis and Menten in 1913 after the empirical observation that reaction velocity is proportional to substrate concentration at relatively low values (3). At high concentrations, the reaction rate is maximized. This behavior is shown in Fig. 14.1. In the region where reaction velocity is directly proportional

to substrate concentration, the reaction is termed first order with respect to substrate. At a high substrate concentration, the velocity is independent of substrate concentration, and the reaction is termed zero order with respect to substrate. The Michaelis-Menten constant K_m is defined as the substrate concentration that corresponds to one half of the maximum reaction rate.

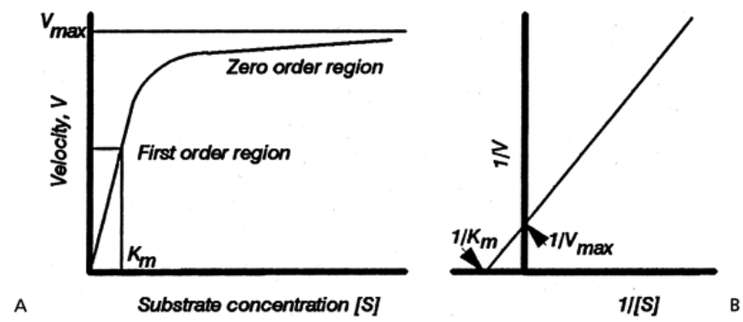

FIGURE 14.1. A: General form of the relationship between substrate concentration and the velocity of an enzyme-catalyzed reaction. V_{max} denotes maximum velocity and K_m denotes the Michaelis-Menten constant (see text). **B:** Reciprocal plots of substrate versus velocity (Lineweaver-Burke plots).

In diagnostic enzymology, the goal is the measurement of the activity or concentration of the enzyme itself. Therefore, test conditions are chosen such that the reaction rate will depend only on the amount of enzyme present in the sample to be measured. The substrate concentration should be in the zero-order region, and all other factors that influence the reaction rate should be optimized and controlled.

Selection of Other Reaction Conditions

Many parameters must be considered when developing a reagent formulation for measuring enzymes. Most enzymes operate optimally within a narrow pH range. Values above or below this range can inactivate enzymes by altering the tertiary structure of the active site or by denaturing the protein. The pH can also influence the direction of the reaction, such as for lactate dehydrogenase (LDH) for which the conversion of lactate to pyruvate is favored at alkaline pH, whereas the reverse reaction is favored at physiologic pH. The specific buffer chosen to maintain pH can also be important, as some buffers participate in the reaction and increase its rate. For example, for ALP, the reagent 2-amino-2-methyl-1-propanol (AMP) acts both as a buffer and as a phosphate group acceptor.

Cofactors and coenzymes not present in the sample or supplied by the buffer must also be added to the reaction mixture to ensure optimal activity. Pyridoxal phosphate is a necessary coenzyme for both aspartate aminotransferase (AST) and alanine aminotransferase (ALT), whereas magnesium is a cofactor needed for ALP. Other substances that are needed to enhance activity are called activators and are also added to the reaction mixture. For example, *N*-acetyl-L-cysteine is used to activate CK.

The temperature used for the reaction must be tightly controlled because reaction rates generally double with every 10°C that the temperature increases. High temperatures can denature many proteins and enzymes. By convention, most enzymes are assayed at 37°C. Although this choice is somewhat arbitrary, having a standard temperature facilitates the comparison of test results from one laboratory to another.

Inhibitors

Inhibitors are substances that can decrease the rate of enzyme-catalyzed reaction. They interact with the enzyme in a number of ways. *Competitive* inhibitors compete with substrate for binding to the active site on the enzyme. The effect of a competitive inhibitor is to increase K_m while not affecting the maximum velocity (V_{max}). Increasing the substrate concentration counteracts the effect of a competitive inhibitor. *Noncompetitive* inhibitors decrease the reaction rate by interacting with the enzyme without directly affecting the enzyme-substrate binding. V_{max} is decreased with no effect on K_m. In this case, the effect cannot be counteracted by increasing the substrate concentration. *Uncompetitive* inhibitors interact with the enzyme-substrate complex, prohibiting the formation of product. Both V_{max} and K_m are altered.

Inhibitors play an important role in diagnostic enzymology. Inhibitors are used to selectively eliminate activity from specific isoenzymes, providing a means for detecting other isoenzymes. Tartrate, for example, is used to inhibit some acid phosphatase isoenzymes, whereas dibucaine is used to detect the presence of genetic variants of serum cholinesterase.

ENZYME ASSAY PROCEDURES

Part of "14 - Diagnostic Enzymology and Other Biochemical Markers of Organ Damage"

Enzyme measurements have traditionally used kinetic assays to determine activity. Newer assays have been developed, however, that measure protein (mass) concentrations. Both types of assay are discussed in this section.

Single-Reagent Kinetic Assays

Figure 14.2 illustrates a typical enzyme-catalyzed reaction for a single-reagent kinetic assay. The reaction is monitored at a wavelength at which the reaction product absorbs light. The initial lag phase is caused by the time necessary for the enzyme to be fully

activated by cofactors and coenzymes added to the reagent. A delay of 30 to 120 seconds is usually necessary before absorbance readings become meaningful. After the lag phase, the reaction begins the linear phase, characterized by a constant rate of change in absorbance. The reaction is monitored by taking readings at regular intervals for 2 to 5 minutes after the lag phase.

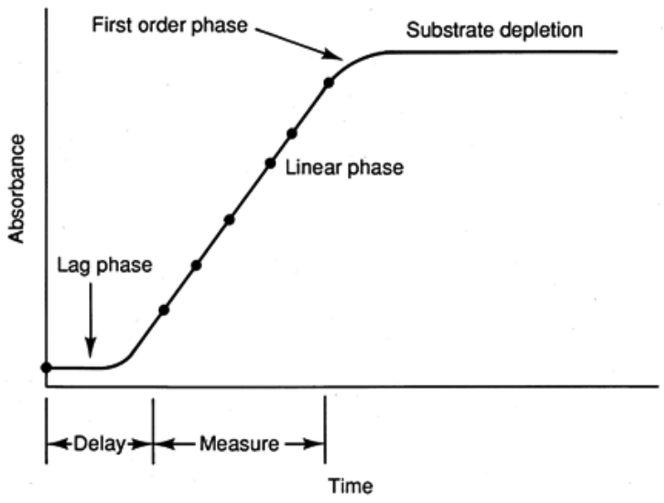

FIGURE 14.2. Absorbance versus time curve for a single-reagent assay system. The lag phase is the time necessary for activation of the enzyme. The linear phase (zero-order kinetics) is where the reaction rate is proportional to enzyme activity. The end of the first-order phase is where the substrate is depleted and the reaction ends.

If the reaction proceeds long enough, the substrate concentration becomes limiting, and the reaction enters a first-order phase. When the substrate is used up, the reaction stops. Samples with very high enzyme activity can deplete the substrate even before the first analytical reading is taken. In this case, falsely low results may be obtained (Fig. 14.3A), and the sample may appear the same as one with little or no enzyme activity (Fig. 14.3B). Enzyme analyzers must be able to detect samples with high enzyme activity. As shown in Fig. 14.3, a large difference in absorbance between the zero time point and the first reading may be used to detect the presence of a sample that has depleted the substrate. When this has occurred, the enzyme activity in these samples is obtained by dilution.

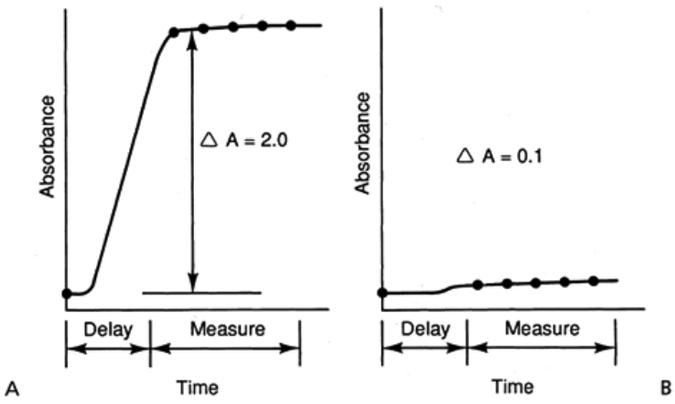

FIGURE 14.3. Absorbance versus time curves for samples with very high (**A**) and very low (**B**) enzyme activity. Because the measurement window is fixed, both samples appear to have low activity. Calculation of the difference in absorbance between the baseline and the first reading permits the distinction between samples with high enzyme activity (curve A) and those with low activity (curve B).

Start Reagent Activity Assays

Certain enzyme assay designs require the sequential addition of two reagents. The first includes the serum sample, which contains all reagents except one of the substrates. Incubation of this reagent allows both the activation of the enzyme and substrate-independent side reactions to occur, which, when present, erroneously contribute to the apparent activity of the enzyme. The analytical reaction of interest is triggered by the addition of the substrate (sometimes termed the *start reagent*) after an appropriate incubation period, usually 5 minutes. Figure 14.4 illustrates the reaction rate versus time profile for a start reagent assay. The analysis of ALT, for example, is improved by using the start reagent system, because high concentrations of pyruvate (which may occur in some serum specimens) will produce an apparent consumption of nicotinamide adenine dinucleotide (NADH) that is not dependent on ALT activity. Note that in Fig. 14.4, absorbance is shown decreasing as the reaction proceeds, indicating that the rate of consumption of a reactant is being followed.

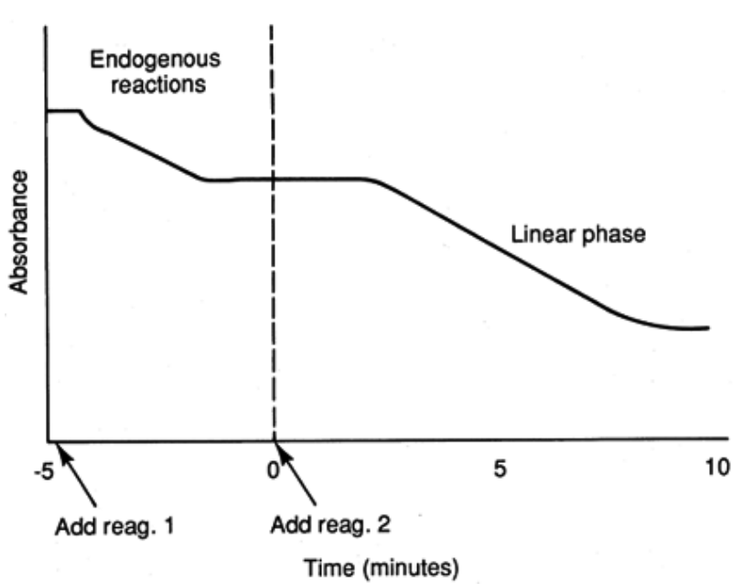

FIGURE 14.4. Absorbance versus time curve for the two-addition reagent assay system. The first reagent contains all reagents minus the substrate. The second reagent, the start or trigger reagent, initiates the reaction of interest, which is measured after a delay period.

Enzyme Activity Calculations

Enzyme activity can be expressed in either units per liter or nanokatals per liter. An International Unit is defined as the amount of enzyme necessary to catalyze the conversion of one micromole of substrate per minute. The corresponding SI unit is the amount of enzyme that will catalyze the conversion of one nanomole of substrate per second (nanokatal). Because Beer's law states that concentration is proportional to absorbance, enzyme activity can be determined from the change in absorbance per unit of time. The rate of change in absorbance is multiplied by factors to account for the molar absorptivity of the product or

substrate that is being monitored, the cell path length, and the dilution of the sample by the reagents in the reaction mixture:

$$\text{activity (U/L)} = \frac{\text{A/min} \times \text{TV}}{\epsilon \times \text{b} \times \text{SV}} \times 1{,}000$$

where A/min is the change in absorbance versus time, TV is the total volume (in microliters), SV is the sample volume (in microliters), ε is the micromolar absorptivity (in liters per millimoles · centimeters), and b is the path length (in centimeters). As an example, if an enzyme produces NADH (millimolar absorptivity = 6.3) with a ΔA/min of 0.046, and if the total and sample volumes are 300 and 5 µL, respectively, and a 1-cm path length is used, the activity (in U/L) is calculated as:

$$\text{activity} = \frac{0.046 \times 300}{6.3 \times 1 \times 5} \times 1{,}000 = 438 \text{ U/L}$$

Mass Measurements

The development of immunoassays has permitted the measurement of enzyme concentration rather than activity. These assays are particularly useful for isoenzyme analysis, as antisera can be directed toward specific isoenzymes, isoforms, or subunits. Studies have shown that for the detection of diseases, enzymes do not need to be present in an active form in blood, and mass measurements are equivalent to enzyme activity assays in diagnostic efficiency and are sometimes preferred. The enzyme concentration is determined from a calibration curve. Mass measurements are also used to measure the concentration of protein markers (e.g., myoglobin) that do not possess enzymatic activities. Specific immunoassays for enzymes and proteins are discussed in more detail under specific examples.

LIVER DISEASES

Part of "14 - Diagnostic Enzymology and Other Biochemical Markers of Organ Damage"

The enzymes ALT and AST, ALP, LDH, GGT, and (to a lesser extent) 5′-nucleotidase (5′NT) are commonly measured for the assessment of liver function. The first four of these are typically included in comprehensive chemistry profiles. None of these markers is specific for any single liver disorder. This section covers liver dysfunction, describes individual liver enzymes and their laboratory measurement, and explains how patterns of liver enzyme data can be used to aid in the diagnosis of liver diseases.

Acute Hepatocellular Injury

Viral Hepatitis

Acute viral hepatitis is a common cause of hepatocellular injury. The isolation and characterization of specific viral agents in recent years, coupled with the development of specific serologic markers, have resulted in the definitive diagnosis of these infections. A more complete description of the virology, etiology, epidemiology, and relevant serology of hepatitis types A, B, C, and D can be found in Chapter 59. Also described in this section are the other viral causes of hepatitis such as Epstein-Barr virus, herpesviruses, cytomegalovirus, and coxsackieviruses, which generally produce milder forms of hepatocellular necrosis. The features of acute viral hepatic inflammation include infiltration of monocytes and hyperplasia of parenchymal hepatocytes, often described as ballooning degeneration. There is active hepatocellular destruction and cell damage, leading to a variable degree of biliary obstruction. The liver has considerable reserve capacity for bilirubin metabolism, however, and patients are often only mildly jaundiced. The acute phase of the disease typically lasts 3 to 6 months. The enzyme markers that are the most useful for acute hepatocellular necrosis are AST and ALT.

Acute Liver Failure

Acute liver failure is characterized by extensive hepatocellular necrosis and a very high mortality; it has several etiologies. One is the progression to fulminant hepatitis, most frequently seen with hepatitis B. Toxic hepatitis is also a major cause. Table 14.1 lists various substances that can produce acute liver failure. Clinical manifestations include metabolic dysfunctions such as encephalopathy and water and electrolyte imbalance, coagulation abnormalities, hypoglycemia, respiratory failure, and renal failure.

TABLE 14.1. CAUSES OF TOXIC HEPATITIS

Solvents	Carbon tetrachloride
	Trichloroethylene
Mushrooms	*Amanita phalloides*
Metals	Yellow phosphorus
Drugs	Acetaminophen
	Halothane
	Isoniazid
	Rifampicin
Metabolic	Reye's syndrome
	Wilson's disease
	Galactosemia
	α_1-Antitrypsin deficiency

Acetaminophen overdose is another cause of acute hepatic failure. With therapeutic uses of acetaminophen, the drug is conjugated within the liver to inactive metabolites and excreted into the urine. Accidental or intentional overdose results in a saturation of the hepatic conjugation capability. As a result, highly reactive neutrophilic intermediates form that bind to hepatocytes, causing liver damage over the ensuing 2 to 3 days. Management of acetaminophen overdoses begins with the recognition of the problem. Initially, results for liver function tests are normal. Nevertheless, acute overdoses should be treated by restoring glutathione stores with administration of *N*-acetyl-L-cysteine to prevent liver damage. If fulminant hepatic failure does develop, liver transplantation is the only curative measure. Measurement of acetaminophen involves hydrolysis with an aryl acylamidase to produce *p*-aminophenol and acetate. The *p*-aminophenol is converted to indophenol with *o*-cresol. As with hepatocellular disease, acute liver failure is characterized by large increases in serum AST and ALT.

Cholestatic Liver Diseases

Cholestasis is suppression of bile flow and can be either extrahepatic or intrahepatic in origin. Delineation between these

types is not possible solely based on enzyme testing, although some patterns of enzyme activities favor one form over the other. Morphologically, the presence of bile pigments in hepatocytes defines this condition. Serum levels of liver enzymes and bilirubin are abnormal in cholestasis. Because of the reserve capacity of the liver for metabolism and excretion, however, these enzymes and salts increase in the serum only when more than 80% of the hepatocellular functional capacity has become impaired. Chapter 21 describes the role of conjugated and unconjugated bilirubin in cholestatic disease. Enzyme markers of obstruction include ALP, GGT, 5′-NT, and leucine aminopeptidase.

Intrahepatic Obstruction

Intrahepatic cholestasis often results from cirrhosis or hepatitis, but administration of some drugs such as chlorpromazine, estrogens, and anabolic steroids can also induce cholestasis. The mechanism may include the precipitation of bile salts, which impairs the flow of bile. Idiopathic familial intrahepatic jaundice is also seen in the third trimester of some otherwise uncomplicated pregnancies. This condition is relatively benign but may recur in future pregnancies. Other congenital disorders associated with intrahepatic obstruction include Dubin-Johnson syndrome and Rotor's syndrome.

Extrahepatic Obstruction

Extrahepatic cholestasis is usually the result of mechanical obstruction of the common bile duct or hepatic duct. Common etiologies of this disorder include cholelithiasis and carcinoma of the tip of the pancreas, papilla of Vater, or common bile duct. These processes lead to dilation of the ductal tree immediately above the obstruction. Inflammatory processes such as pancreatitis, and bile duct lesions seen in sclerosing cholangitis can also produce extrahepatic cholestasis.

Chronic Liver Diseases

Chronic Hepatitis

Chronic hepatitis is a disease with diverse etiologies, including viral, autoimmune, and lupoid causes. In viral causes, some 5% to 10% of hepatitis B patients and as many as 50% of hepatitis C patients develop this recurring disease. The active form is characterized by monocyte infiltration and hepatic necrosis. Chronic active hepatitis commonly leads to disruption of lobular architecture and fibrosis and can progress to liver cirrhosis. In contrast, chronic persistent hepatitis is a milder disorder that rarely progresses to cirrhosis and fibrosis. The liver enzyme results tend to be more elevated in the active form; however, differentiation is best made by performing a liver biopsy.

Liver Cancer

Primary hepatocellular and cholangiocellular carcinomas often occur in patients with longstanding hepatitis B infections and liver cirrhosis. The diagnosis is aided by computed tomography, ultrasonography, nuclear scans, and α-fetoprotein levels in blood. Primary liver cancer is especially prevalent among Oriental and black African males. Metastatic liver disease is very common in the United States, particularly from tumors that originate in the colon, lung, breast, and skin. Enzyme levels in primary and secondary cancer are usually elevated; this is caused by the destruction of surrounding normal tissue and obstruction of normal architecture by these space-occupying tumors.

Alcoholic Liver Disease

Alcoholic liver disease is associated with acute and chronic alcoholism. There are three recognized entities associated with excess use of ethanol (defined by some as a daily intake of 80 g/d): fatty liver, alcoholic hepatitis, and cirrhosis. These entities may coexist with the same patient, or occur independently. The diseases do not necessarily follow a pathophysiologic sequence.

Fatty Liver

Alcoholic fatty liver is characterized by hepatomegaly, in which the liver contains large triglyceride-containing vacuoles. The accumulation of triglycerides results from the inhibition of ß-fatty acid oxidation within the mitochondria. In addition to alcoholism, fatty liver can also occur in nutritional imbalances and metabolic disease and during pregnancy. The concentrations of traditional liver enzymes are typically within the normal range. Definitive diagnosis is made by a liver biopsy. The disease is considered benign and can be effectively reversed by immediate abstinence from ethanol intake.

Alcoholic Hepatitis

Alcoholic hepatitis is characterized by irreversible hepatocellular injury and degeneration. The major feature is hepatic infiltration by neutrophils and lymphocytes causing acute inflammation. The diagnosis is made by liver biopsy. The finding of Mallory bodies is suggestive of alcoholic hepatitis. The disease is chronic and progressive and can be fatal. Gastrointestinal bleeding and hepatic encephalopathy can occur in severe forms of the disease. Alcoholic hepatitis is considered the precursor to cirrhosis in many cases. In addition to abstinence from alcohol, treatment with corticosteroids can be beneficial. Liver enzyme concentrations are increased, notably AST and ALT, commensurate roughly with the degree of acute hepatocellular injury.

Cirrhosis

Chronic liver disease that leads to an increase in diffuse fibrosis and progression toward a nodular architecture defines cirrhosis. Some of the etiologic factors for cirrhosis are liver damage secondary to drug use, chronic hepatitis infections, biliary obstruction, and metabolic disease (such as Wilson's disease, hemochromatosis, and α_1-antitrypsin deficiency). Alcoholic cirrhosis is very prevalent in the United States and western Europe, whereas cirrhosis owing to chronic active hepatitis B infections is more common in Asia and Africa. Liver enzyme levels in cirrhosis are variably elevated and can be normal during the terminal stages of the disease.

Primary biliary cirrhosis is characterized by impairment of bile excretion and has been linked to an autoimmune process. It affects women more often than men. Inflammation and destruction of bile ducts are observed in this disorder. Elevations in ALP and aminotransferases are expected along with high titers of antimitochondrial antibody.

MARKERS OF LIVER DISEASES

Part of "14 - Diagnostic Enzymology and Other Biochemical Markers of Organ Damage"

Alkaline Phosphatase (ALP) (EC 3.1.3.1)

The phosphatases are a collection of sialoproteins located mostly within the cell membrane. They function to transport inorganic phosphate from donor to receptor molecules. Phosphatases with catalytic activity at a pH of 10.0 and higher make up the collection of ALP (orthophosphoric acid monoester phosphohydrolase).

Measurement of Total ALP Activity

Because of the heterogeneous nature of the enzyme and because a single physiologic substrate has not been identified, all analytical methods for ALP make use of synthetic substrates. The most common substrate is *p*-nitrophenylphosphate (*p*-NPP), which is converted to *p*-nitrophenoxide (*p*-NP) and inorganic phosphate:

$$p\text{-NPP} + H_2O \xrightarrow{ALP} PO_4^{-3} + p\text{-NP}$$

Because *p*-NPP is colorless, the reaction is monitored by the increasing absorbance of *p*-NP at 404 nm. The pH of the reaction is controlled at 10.3 by AMP buffer, which also acts as a phosphate acceptor to facilitate the phosphatase action of the enzyme. A magnesium salt is also part of the reagent formulation and acts as an activator of the enzyme. In other procedures, such as those recommended by the International Federation of Clinical Chemistry, zinc ions are added along with *N*-hydroxy-ethylenediaminetetraacetic acid to maintain the precise ratio of Mg^{2+}/Zn^{2+} necessary for optimal activation. The millimolar absorptivity of *p*-NP is 18.75 L/mmol · cm.

The reference range for ALP is dependent on age and relates to different stages of bone growth and demineralization during life. Figure 14.5 illustrates this dependency. Children have higher reference ranges than adults, particularly during adolescence. Older populations have increasing ALP reference ranges, reflecting increases in the incidence of osteoporosis in this population.

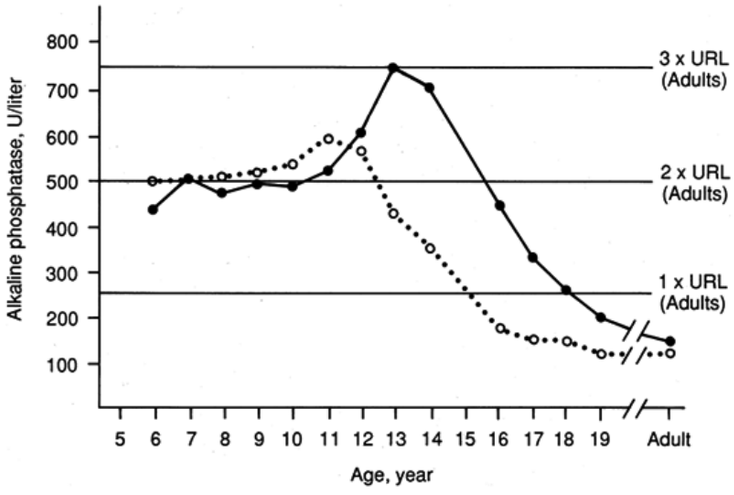

FIGURE 14.5. Plasma alkaline phosphatase activity as a function of age and sex (·--, men; o…o, women). Horizontal lines refer to multiples of the adult upper reference limit. (From McComb RB, Bowers GN Jr, Posen S. *Alkaline phosphatase*. New York: Plenum Press, 1979:532, with permission.)

ALP Isoenzymes

ALP is widely distributed throughout the tissues of the body. Among those with the highest relative activity are the adrenals, placenta, gastrointestinal tract, bone, kidney, and liver. In normal nonpregnant adults, however, most of the serum ALP originates from the bone and liver. For patients with high ALP levels, measurement of ALP isoenzymes is useful for differentiating between bone and liver sources. However, because of technical difficulties with zonal electrophoresis and the increasing use of more specific enzyme markers for hepatic obstruction, such as GGT, the clinical need for ALP isoenzymes is rare, and most laboratories do not offer routine fractionation. Analytical methods for ALP isoenzymes include selective chemical inhibition, such as with phenylalanine, heat inactivation, electrophoresis, and isoelectric focusing (IEF).

Zonal electrophoresis has been extensively studied and will produce bands for the placental, intestinal, and bone, liver, and kidney fractions. There are varying degrees of overlap between ALP isoenzymes from tissues of the last group, depending on the electrophoresis support medium. ALP isoenzymes from bone, liver, and kidney originate from a single gene expression that has been postsynthetically modified. Improvement in resolution between the bone and liver fractions is possible by treating either of the electrophoresis supports with wheat-germ lectin or by treating the samples themselves with neuraminidase. Electrophoretic studies have also demonstrated a new isoenzyme fraction migrating anodic to the liver fraction. The isoenzyme, termed the α or fast-liver fraction, is seen in hepatobiliary disorders and may be a useful marker for liver cancer. More definitive assessment of ALP isoenzymes is possible with IEF.

GGT (EC 2.3.2.2)

GGT (g-glutamyl-peptide:amino acid γ-glutamyltransferase) catalyzes the transfer of γ-glutamyl groups between donor and acceptor molecules. GGT is located in the cell membrane of nearly all human cells and tissues and functions to transport amino acids into the cell. GGT has two subunits: a light hydrophilic fraction, where the active site is located, and a heavy hydrophobic site, which anchors the enzyme to the membrane. It does not have isoenzymes as defined by separate genetically encoded forms, but there are posttranslational modifications that have been identified and measured by electrophoresis. The clinical utility of these isoforms, however, is not established (4).

Most commercial analytical methods for GGT make use of one of two synthetic substrates: γ-L-glutamyl-*p*-nitroanilide and γ-L-glutamyl-3-carboxy-4-nitroanilide. The carboxy substrate is currently preferred because of a higher solubility and because hydrolysis of the substrate does not occur spontaneously. The older unsubstituted substrate, however, is more widely used. The reactions of both are shown below:

$$\gamma\text{-glutamyl-}p\text{-nitroaniline} + \text{glycylglycine} \xrightarrow{\text{GGT}} \gamma\text{-glutamylglycylglycine} + p\text{-nitroaniline}$$

$$\gamma\text{-glutamyl-3-carboxy-4-nitroanilide} + \text{glycylglycine} \xrightarrow{\text{GGT}} p\text{-nitroaniline} + \text{5-amino-2-nitrobenzoate}$$

Either reaction can be monitored by following the increasing absorbance of the respective product at 405 nm. Tris and glycylglycine are used as buffers to maintain a pH of 8.0. Magnesium ions are added when *p*-nitroaniline is used to facilitate solubility. The millimolar absorptivities are 9.9 L/mmol · cm for *p*-nitroaniline at 405 nm and 7.9 L/mmol · cm for 5-amino-2-nitrobenzoate at 410 nm. The reference ranges at 37°C are 9 to 50 for men and 8 to 40 U/L for women. Although most of the enzyme originates from the liver, a small amount of GGT is released from the prostate, which may explain why men have slightly higher values than women.

5′-NT (EC 3.1.3.5)

5′-NT (5′-ribonucleotide phosphohydrolase) is a cytosolic membrane-bound enzyme that hydrolyzes the 5′-phosphate esters of nucleotides. Although 5′NT is found throughout the body, increased activity in the serum reflects hepatobiliary diseases. Methods for 5′NT analysis involve the use of adenosine-5′-monophosphate as a substrate:

$$\text{adenosine-5′-monophosphate} + H_2O \xrightarrow{5'\text{NT}} \text{adenosine} + \text{phosphate}$$

The reaction is monitored by measuring phosphate, using conventional methods. Because the substrate is also hydrolyzed by ALP in the serum sample, the total activity observed is the sum of 5′NT and ALP activities. The reaction is repeated with the addition of nickel ions, which selectively inhibit 5′NT, thus measuring only ALP activity. This number is then subtracted from the total to give a measure of 5′NT alone. Other inorganic ions used in the reaction mixture are manganese, to activate 5′NT, and copper, to accelerate color development.

AST (EC 2.6.1.1) and ALT (EC 2.6.1.2)

Although ALT (L-alanine:2-oxoglutarate aminotransferase) is found in a variety of human tissues, measurement of ALT is most clinically useful in the evaluation of liver diseases. ALT is found in the cytoplasm and only one isoenzyme is found in serum. Interpretations of ALT levels in these disorders are usually made in conjunction with levels of AST (L-aspartate:2-oxoglutarate aminotransferase). Unlike ALT, however, AST is also useful in the evaluation of AMI and skeletal muscle diseases. AST has cytosolic and mitochondrial isoenzymes that appear in the serum.

Analytical Measurements

ALT catalyzes the transfer of the amino group from alanine to α-ketoglutarate to form pyruvate and L-glutamate. AST catalyzes the transfer of the amino group from aspartate to α-ketoglutarate to form malate. Because none of the reactants or products of either of these reactions absorbs in the ultraviolet or visible region of the spectrum, they must be coupled to indicator reactions for analysis. ALT requires LDH, whereas AST requires malate dehydrogenase:

$$\text{L-alanine} + \alpha\text{-oxoglutarate} \xrightarrow{\text{ALT}} \text{pyruvate} + \text{L-glutamate}$$

$$\text{pyruvate} + \text{NADH} \xrightarrow{\text{LD}} \text{lactate} + \text{NAD}^+$$

$$\text{L-aspartate} + \text{-oxoglutarate} \xrightarrow{\text{AST}} \text{oxaloacetate} + \text{L-glutamate}$$

$$\text{oxaloacetate} + \text{NADH} \xrightarrow{\text{MDH}} \text{L-malate} + \text{NAD}^+$$

The reactions are monitored by following the decrease in the absorbance at 340 nm as NADH is consumed in the reaction. Pyridoxal-5′-phosphate (P5′P) is needed as a coenzyme for both the ALT and AST reactions. Normally, serum contains adequate amounts of P5′P and additional coenzyme is not necessary. However, patients with a vitamin B6 deficiency or those undergoing renal dialysis have decreased P5′P concentration, which will produce falsely low serum aminotransferase levels unless P5′P is added to the reagent formulation.

Reference Ranges

The adult reference range for both AST and ALT is roughly 10 to 40 U/L when measured at 37°C. Although men have slightly higher values than women, most laboratories use a single range for both genders.

PATTERNS OF LIVER ENZYMES AND MARKERS FOR INTERPRETATION OF DISEASE

Part of "14 - Diagnostic Enzymology and Other Biochemical Markers of Organ Damage"

Unlike some disorders such as acute pancreatitis and myocardial infarction, for which there are enzyme markers that are primarily used for one disorder and have high diagnostic efficiencies, there are no enzyme markers that are specific for any single liver

disease. When evaluating these disorders, therefore, it is appropriate to consider a panel of markers, sometimes called liver function tests (LFTs). Through common usage, this term has come to mean a group of tests that usually includes bilirubin, AST, ALT, ALP, and sometimes GGT and 5′NT. However, the term is a misnomer, because although these tests can reflect various disease processes in the liver, they do not reflect hepatic reserve for synthesis and metabolic functions. Table 14.2 lists some markers for both liver function and disease.

TABLE 14.2. MARKERS FOR LIVER FUNCTION AND DISEASE

Disease or Function	Markers
Functional evaluation	
Normal synthesis capacity	Albumin, retinol binding protein, prealbumin, prothrombin time, cholinesterase
Excretory function	Bilirubin, bile acids, rose bengal and sulfobromophthalein excretion
Metabolic function	Ammonia, amino acids, lipids, serum protein electrophoresis, globulins
Drug metabolism	Antipyrine breath and clearance test $^{14}CO_2$ breath test
Pathologic evaluation	
Hepatocellular injury	Aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase
Obstruction	Bilirubin, alkaline phosphatase, γ-glutamyltransferase, 5′-nucleotidose, bile acids
Infections	Viral and autoimmune serologies
Malignancies	Carcinoembryonic antigen, α-fetoprotein

Hepatocellular Versus Obstructive Liver Diseases

Acute Injury

The most useful enzyme markers of acute hepatocellular injury are ALT and AST. Other markers such as LDH and glutamate, isocitrate, and malate dehydrogenases exhibit elevations secondary to hepatocellular necrosis, but they are not as sensitive or as specific as the combination of AST and ALT and are therefore rarely used for diagnostic purposes.

The highest absolute levels of ALT and AST are seen after acute hepatitis, either viral or toxic. Values exceeding 1,000 U/L are commonly seen during the early phases of these diseases. In toxic hepatitis, such as with acetaminophen overdoses, levels of ALT and AST rise within a few hours after exposure and remain high for many days or weeks. Unfortunately, the extent of ALT and AST elevations do not reflect the severity of the disease, nor can they be correlated to patient prognosis. In acute hepatitis A, ALT is one of the first markers to be elevated, usually 3 to 4 weeks after infection. Levels return to normal within 8 to 12 weeks. In acute hepatitis B, the preclinical incubation phase is longer and ALT and AST may remain normal for 2 to 6 months. In acute hepatitis B, ALT and AST return to normal within 2 to 3 months, and a similar course is observed in hepatitis C. In chronic active hepatitis, enzyme levels are elevated five- to 10-fold, depending on the stage of the disease. Similar elevations are also seen in acute hepatocellular injury secondary to mononucleosis. In end-stage liver disease, enzyme levels return to normal or subnormal levels as hepatocytes become depleted of enzyme content.

In contrast, levels of ALP, GGT, and 5′NT are not as markedly elevated in these disorders. Levels of these enzymes generally do not exceed two to three times the upper limit of normal. Therefore, a disproportionate increase in ALT and AST relative to ALP and GGT favors a diagnosis of hepatocellular necrosis rather than liver obstruction. The relationship of these enzymes in hepatocellular liver disease is summarized in Fig. 14.6 (5).

Cholestasis

The best markers for intrahepatic and extrahepatic cholestasis are ALP, GGT, and 5′NT. The largest elevations (four- to 10-fold) of ALP are typically seen in obstruction owing to gallstones or malignancy and in biliary cirrhosis. The source of ALP in malignancy may be obstruction of hepatic architecture in either primary or secondary liver cancers, but other causes of ALP elevations must be ruled out. Obstructive liver disease as a cause of ALP elevations can be confirmed by measurement of either GGT or 5′NT. Increases in these enzymes are also expected in cholestasis, but these assays are more specific because although bone disease can produce elevations of ALP in the same range expected for obstructive liver disease, GGT and 5′NT are not found in the bone. Measurement of total and direct bilirubin are also important in making the diagnosis of obstructive jaundice.

Cholestasis can be readily distinguished from hepatocellular injury based on a disproportionate increase of ALP and GGT relative to AST and ALT (Fig. 14.6). The latter two enzymes are generally only slightly elevated in cholestasis, rarely more than 500 U/L.

De Ritis Ratio (AST/ALT)

Further differentiation of specific liver diseases is aided by calculating the ratio of AST to ALT levels (6). Although there is considerable overlapping of values within a given diagnosis, the de Ritis ratio can give a general indication of whether a disorder is acute or chronic and whether it is intra- or extrahepatic in origin. Values for these ratios are most useful when standard AST and ALT assays are used. When using the assays recommended by the International Federation of Clinical Chemistry, the de Ritis ratio is normally approximately 1.15. Figure 14.7 illustrates results of the de Ritis ratio from patients with various liver diseases.

Acute Versus Chronic Liver Diseases

Acute disorders of the liver, such as acute viral hepatitis and infectious mononucleosis, generally have higher values of ALT relative to AST, and the de Ritis ratio is less than 1.0. In Reye's syndrome,

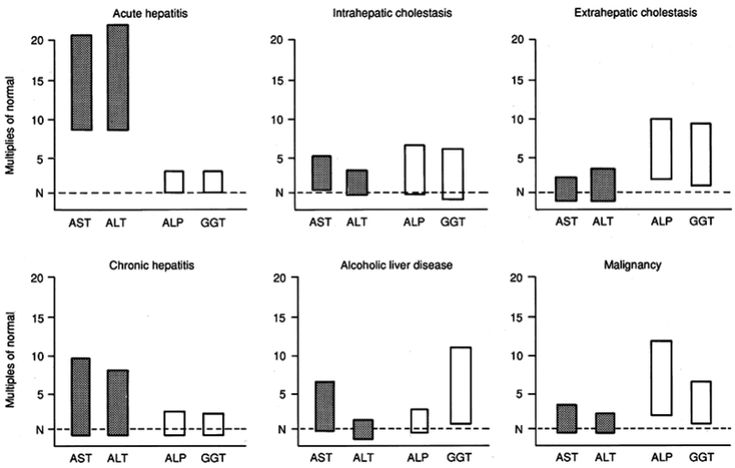

FIGURE 14.6. Relationship of alanine aminotransferase and aspartate aminotransferase to alanine phosphate and γ-glutamyltransferase in several liver diseases. (Adapted from Zimmerman HJ. Function and integrity of the liver. In: Henry JB, ed. *Clinical diagnosis and management*, 17th ed. Philadelphia: Saunders, 1984.)

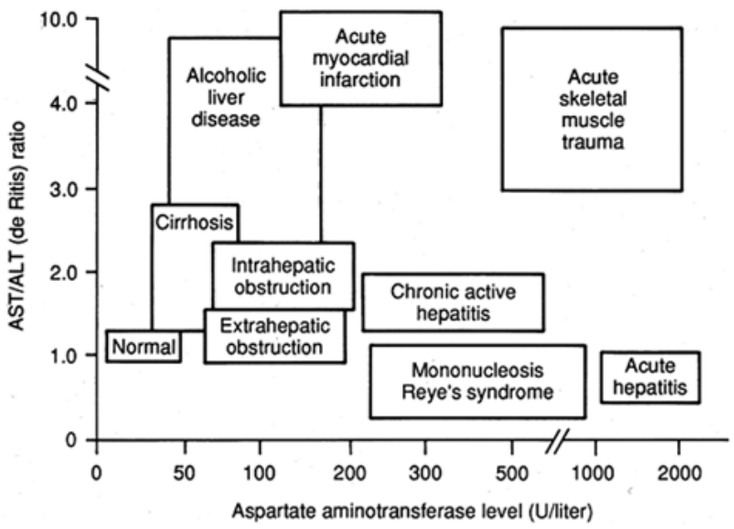

FIGURE 14.7. Ratio of aspartate aminotransferase:alanine aminotransferase versus aspartate aminotransferase levels in various liver diseases.

in which there is an acute onset of encephalopathy, the de Ritis ratio is also less than 1 in most cases. It has been postulated that elevations in ALT are seen before elevations in AST in acute liver processes because AST includes mitochondrial isoenzymes, and more time is needed for these enzymes to pass through a second set of membranes to reach the circulation. Indeed, chronic disorders such as alcoholic liver disease, postnecrotic cirrhosis, and chronic active hepatitis have de Ritis ratios greater than 1. Although this is a convenient way of remembering this relationship, the mitochondrial fraction of AST actually contributes only a small percentage of the total AST and is insufficient to significantly lower the de Ritis ratio (Fig. 14.7). Patients with chronic persistent hepatitis will have a normal or slightly elevated aminotransferase level, reflecting the mild clinical course of this disease.

Intrahepatic Versus Extrahepatic Obstruction

The de Ritis ratio may be helpful in differentiating between intra- and extrahepatic cholestasis (Fig. 14.7). Ratios of 1.5 or greater suggest intrahepatic cholestasis, whereas values less than 1.5 suggest an extrahepatic process. This difference is also consistent with the notion of acute versus chronic liver disorders. Extrahepatic obstruction is often caused by the acute passage of a stone, whereas intrahepatic causes such as biliary cirrhosis and malignancy develop over a period of time. Other laboratory test results such as high conjugated bilirubin (greater than 75%), high amylase, and the presence of occult blood in the stool favor extrahepatic rather than intrahepatic obstruction. In addition, ALP is more often elevated in extrahepatic than in intrahepatic obstruction.

Alcoholic Liver Disease

Disproportionate increases of AST relative to ALT are observed in alcoholic liver disease, and the de Ritis ratio can exceed 6.0 (Fig. 14.7). Decreased levels of ALT relative to AST are caused in part by deficiencies of dietary pyridoxal phosphate in alcoholics, a component that is more important for normal hepatic ALT synthesis than for AST.

Muscle Disease

The largest increases of AST relative to ALT are seen in myocardial and skeletal muscle diseases because of the different distribution of the enzymes in these tissues. A ratio greater than 10 can be seen in these disorders (Fig. 14.7), which are discussed more fully in the next section.

Markers of Alcohol Use

Ethanol metabolism follows zero-order kinetics, with a constant rate of clearance of approximately 20 mg/dL per hour. Ethanol is metabolized largely by alcohol dehydrogenase, with contributions from the microsomal ethanol oxidizing system, and catalase. Mildly intoxicated subjects (100 to 150 mg/dL) will have positive blood ethanol concentrations for only 5 to 8 hours after ingestion. For medical (and insurance) purposes, it is important to know whether an individual chronically consumes alcohol. The most widely used marker for alcoholism is GGT. GGT is highly sensitive to alcohol use, in part because ethanol is a potent inducer of GGT synthesis by the microsomal P-450 enzyme system. Significant elevations of GGT are also observed after prolonged drinking episodes of several months or more. Unfortunately, it is not a specific test, as other diseases and drugs can produce increases in GGT. Other markers currently being studied include carbohydrate-deficient transferrin and fatty acid ethyl esters (7). Excessive alcohol inhibits the posttranslational glycoconjugation of transferrin, leading to high concentrations of carbohydrate-deficient transferrin. This marker is thought to be a useful marker for chronic alcohol use. Fatty acid ethyl esters are produced as a metabolite of fatty acid and ethanol. Fatty acid ethyl esters may be responsible for ethanol-induced liver and pancreas damage. High concentrations may be clinically useful as an acute indicator of ethanol use within the previous 24 hours, even after serum ethanol concentrations have returned to normal.

Liver Transplantation and Markers of Rejection

The clinical indications of liver transplantation in adults includes end-stage chronic liver disease, cirrhosis (e.g., biliary, alcoholic), nonresectable hepatic tumors, and mushroom and acetaminophen poisoning. In children, liver transplantation is also performed in biliary atresia, hepatitis, Wilson's disease, tyrosinemia, and other forms of metabolic liver diseases. The suitability of the donor liver can be assessed after the infusion of lidocaine and the monitoring the rate of metabolism to monoethylglycinexylidide. High concentrations indicate a good metabolic capability and a higher rate of graft survival (8). Liver function tests such as AST, ALT, γ-GT, bilirubin, bile acids, and coagulation tests are typically used to determine the viability of the liver. Increased concentrations of these markers may indicate allograft rejection of the organ. The sensitivity of these markers, however, has not been high, and the rationale for using these tests can be questioned. Recently, new markers including glutathione S-transferase (9) and serum fructose-1-6-bisphosphatase (10) have been studied as markers for early liver transplantation rejection. These tests may become available in laboratories whose hospitals have an active liver transplantation program.

MYOCARDIAL AND SKELETAL MUSCLE DISEASE

Part of "14 - Diagnostic Enzymology and Other Biochemical Markers of Organ Damage"

Unstable Angina and AMI

The development of AMI is the result of a sequence of events that takes place over many years. The process begins with atherosclerosis, which is characterized by the narrowing of coronary arteries by formation of lipid-filled plaques. Plaques that have a thick fibrous cap overlying the lipid layer are stable and not at risk for rupturing (Fig. 14.8A). Processes such as acute inflammation and monocyte infiltration will erode the cap, making it vulnerable to rupture by shear stresses that exist within arterial vessels (Fig. 14.8B). Rupture of this plaque leads to the syndrome of unstable angina, the disease that immediately precedes an AMI. The exposure of plaque to circulating blood leads

to the aggregation of platelets and the activation of thrombin, which converts fibrinogen to an insoluble fibrin clot. Subocclusive clots (not completely blocking the artery) produce unstable angina. A classification scheme for unstable angina was established by Braunwald (11). A totally occluded clot produces AMI. Both conditions, collectively known as acute coronary syndromes, can produce chest pain at rest, lead to specific changes in the electrocardiogram, and a mild or severe release of enzymes and proteins into blood.

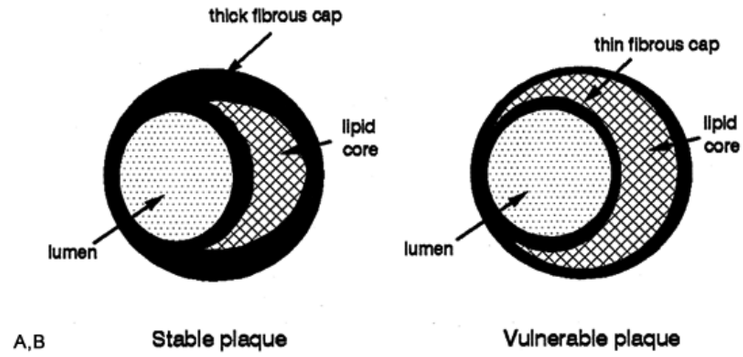

FIGURE 14.8. A: Stable coronary artery plaque not vulnerable for rupturing. **B:** Unstable plaque that is vulnerable for rupturing by shear stresses.

The most dramatic increases in biochemical markers occur in patients with an AMI. The immediate consequence is lack of oxygen delivery to the myocardium and tissue anoxia. This leads to an energy deficit and a shift toward anaerobic metabolism. Electrolytes are released into the interstitial space as the result of adenosine triphosphate (ATP)–dependent ion pump failure. If coronary circulation is restored before the onset of irreversible damage, either spontaneously or by therapeutic intervention, jeopardized myocardial tissue may be salvaged and substantial irreversible damage is avoided. Prolonged deprivation of blood flow (more than 4 hours) will cause irreversible myocardial damage, which leads to leakage of macromolecules such as enzymes and proteins. Figure 14.9 shows the temporal relationship between the release of these materials as a function of disease progression. The appearance of proteins and enzymes in the serum is prolonged because this clearance is dependent on slow drainage from the cardiac lymphatic circulation (Fig. 14.10). The presence of cardiac-specific enzymes and isoenzymes provides the basis for the biochemical diagnosis of AMI (12).

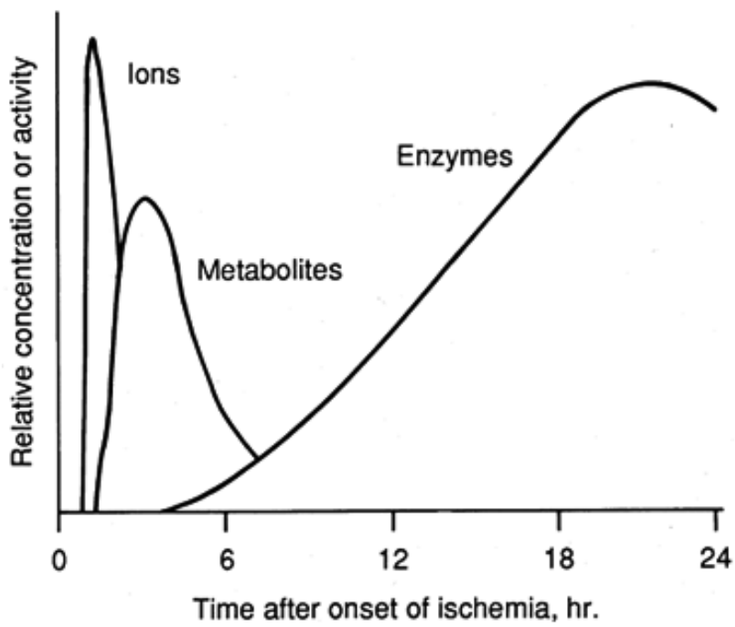

FIGURE 14.9. Release of ions, metabolites, and proteins after acute myocardial infarction. (Adapted from Hearse DJ. Cellular damage during myocardial ischaemia: metabolic changes leading to enzyme leakage. In: Hearse DJ. *Enzymes in cardiology. Diagnosis and research*. New York: John Wiley and Sons, 1979.)

Congestive Heart Failure

Heart failure is a very common disease, with more than 400,000 new cases each year in the United States. Heart failure results when the myocardium is unable to meet the blood supply demands of the tissues and organs. Failure can be classified as either acute or chronic. Primary acute failure can be caused by massive AMI or valve rupture. Chronic congestive heart failure (CHF) is seen in cardiomyopathies and valve disease. Factors that can precipitate CHF include infections, hypertension, endocarditis and myocarditis, arrhythmias, and pulmonary embolism. Physical exertion, emotional stress, and increased blood volume secondary to excessive sodium intake or discontinuation of diuretics

can also cause CHF. The New York Heart Association (NYHA) classified heart failure according to four classes based on functional capacity and on an objective assessment. Although the laboratory has played only a minor supportive role in CHF, new markers are being developed, such as brain natriuretic peptide (BNP), that might have a role in the management and monitoring of these patients. Preliminary studies have shown that there is an incremental increase in mean BNP concentrations with each progressive NHYA stage. It may be possible that BNP could be used to monitor the effects of drug therapy, such as with angiotensin-converting enzyme (ACE) inhibitors.

Skeletal Muscle Disorders

Evidence of high CK activity in the serum is useful for the diagnosis and evaluation of both acute and chronic skeletal muscle diseases. Acute release of muscle enzymes occurs in surgery, trauma, crush injuries, excessive muscular contractions (as in long-distance running or uncontrolled convulsions), hyperthermia, viral myositis, and exposure to toxins. Chronic progressive muscular fiber dystrophies include Duchenne, Becker, limb-girdle, and myotonic dystrophy. These genetic disorders generally affect young children. Inflammatory disorders of skeletal muscle include dermatomyositis and polymyositis, which are also associated with progressive muscle weakness. Neurogenic disorders of the lower motor neurons include amyotrophic lateral sclerosis and spinal muscular atrophies, whereas myasthenia gravis is caused by a disorder at the neuromuscular junction. The measurement of enzymes and isoenzymes is useful in the diagnosis of muscle disorders and, in the case of Duchenne muscular dystrophy, for detection of the carrier state in women (13).

Enzymes and Proteins Useful in Myocardial Disease

CK (EC 2.7.3.2)

The mitochondrial isoenzyme of CK (ATP:creatine *N*-phosphotransferase) functions in muscle cells to catalyze the transfer of a high-energy phosphate bond from ATP to creatine to form creatine phosphate. During active muscle contractions, cytoplasmic CK catalyzes the reverse reaction, thereby providing myocytes an immediate source of ATP. Cytoplasmic CK consists of dimeric combinations of two subunits, M and B. This enables three possible isoenzymes, MM, MB, and BB. In addition, posttranslational modifications of isoenzymes will produce three MM and two MB isoforms. Each of these forms has a combined molecular weight of approximately 80 kDa.

Measurement of Total CK Activity

Nearly all analytical methods for total CK enzyme activity make use of the formulation involving creatine phosphate and adenosine diphosphate (ADP). The product of the reverse reaction, ATP, is coupled with hexokinase and glucose-6-phosphate dehydrogenase (G6PD) to form NADH:

$$\text{creatine phosphate} + \text{ADP} \xrightarrow{\text{CK}} \text{creatine} + \text{ATP}$$

$$\text{ATP} + \text{glucose} \xrightarrow{\text{hexokinase}} \text{glucose-6-phosphate} + \text{ADP}$$

$$\text{glucose-6-phosphate} + \text{NAD}^+ \xrightarrow{\text{G6PD}} 6\text{-phosphogluconate} + \text{NADH} + \text{H}^+$$

The reaction is monitored by the increase in absorbance of NADH measured at 340 nm. A lag phase of 90 to 120 seconds is required for CK before a linear reaction rate is initiated. The pH of the reaction is maintained at 7.0 with imidazole buffer. *N*-acetyl-L-cysteine is added as an activator to maintain a supply of reduced sulfhydryl groups necessary for the complete activation of CK. The presence of adenylate kinase (AK) in the serum will produce a positive interference in this assay. AK catalyzes the production of ATP from ADP alone, which will falsely increase the apparent CK activity:

$$2\,\text{ADP} \xrightarrow{\text{AK}} \text{ATP} + \text{AMP}$$

Adenylate kinase originates from skeletal muscle, red cells, liver, and kidney. Most commercial assay systems use adenosine monophosphate and diadenosine pentaphosphate to inhibit AK activity. Alternatively, a blank can be used by measuring AK activity

Cellular damage during myocardial ischaemia: metabolic changes leading to enzyme leakage. In: Hearse DJ. *Enzymes in cardiology. Diagnosis and research*. New York: John Wiley and Sons, 1979.)

with creatine phosphate omitted. The reference range at 37°C for total CK is 38 to 174 U/L for adult men and 96 to 140 U/L for adult women.

CK Isoenzymes, Isoforms, and Variants

Isoenzyme Tissue Distribution. The clinical utility of CK isoenzyme measurements stems from the fact that skeletal and myocardial muscle tissue have different distributions of CK isoenzymes. As shown in Fig. 14.11, CK-MM is the predominant isoenzyme in both tissues (14), but in skeletal muscle, only trace levels of CK-MB are present. In contrast, the myocardium contains a much higher percentage of CK-MB. CK-BB is found throughout the brain and smooth muscle.

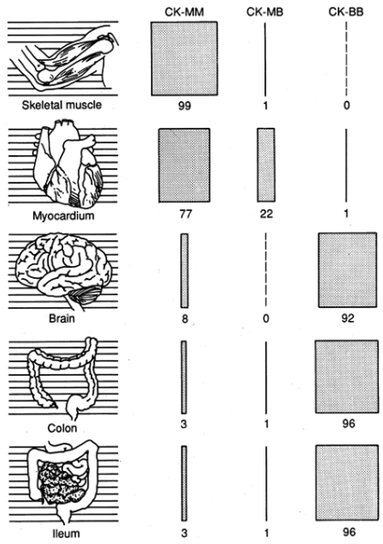

FIGURE 14.11. Tissue distribution of creatine kinase isoenzymes. (Adapted from Lott JA, Wolf PL. *Clinical enzymology. A case-oriented approach*. New York: Year Book, 1986.)

CK Isoforms. Examination of human muscle tissue isoenzymes reveals the presence of single pure gene products for CK-MM and MB. However, when released from the tissues these enzymes are slowly converted to multiple CK isoforms (MM_1, MM_2, and MB_1) through the successive cleavage of the C-terminal amino acids by serum carboxypeptidase. The isoform pattern of normal patients primarily consists of converted CK isoforms, with only trace quantities of tissue forms. High activities of the unmodified isoforms (MM_3 and MB_2) indicate the presence of an acute process.

CK Variants. In addition to the CK isoenzymes and isoforms that are present in normal sera, two atypical isoenzymes have been identified in approximately 2% of hospitalized patients. Macro CK type 1 has been identified to be CK-BB linked with an immunoglobulin (Ig). The IgG form migrates between CK-MM and MB by electrophoresis, whereas the IgA form migrates with MB. Macro CK type 2 is a polymeric aggregate of mitochondrial CK. Macro CK type 1 had no clinical significance, whereas type 2 is seen in metastatic cancer. Assays such as immunoinhibition and electrophoresis (especially with the type 1 IgA form) will produce false-positive results for CK-MB in the presence of macro CK.

Analytical Measurements. There are several analytical methods currently in use or CK isoenzyme analysis, including ion-exchange chromatography, electrophoresis, immunoinhibition, radioimmunoassay, and enzyme immunoassay (15). Electrophoresis for isoenzymes and isoforms is still used, but its popularity is diminishing. Isoenzymes are resolved on agarose gel after electrophoresis at 100 V for 20 minutes. Bands are observed fluorometrically after incubating the gels with CK reagents. The CK activity attributed to each band can be determined by scanning densitometry. Figure 14.12 illustrates the electrophoretic migration of CK isoenzymes, isoforms, and all known CK variants. Most normal samples will exhibit a single band owing to CK-MM. Patients with AMI will have high concentrations of CK-MM and MB. Increasing the electrophoresis time or the applied voltage permits the resolution and analysis of CK isoforms. Figure 14.13 illustrates the major CK-MM and MB isoforms. Electrophoresis is less sensitive than immunoassay methods, although it is the only method that permits visualization of all CK isoenzymes.

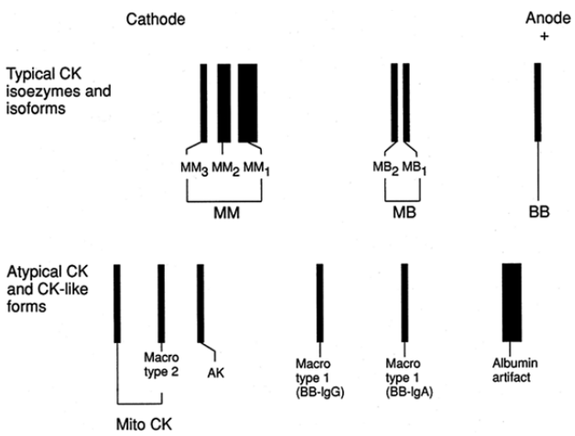

FIGURE 14.12. Electrophoretic migration of typical and atypical isoenzymes and isoforms of creatine kinase.

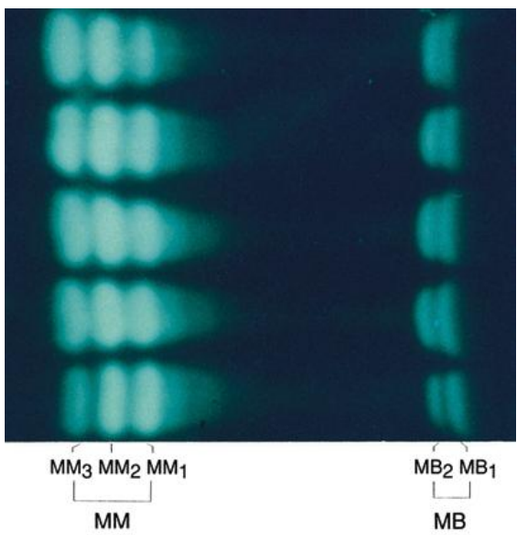

FIGURE 14.13. Creatine kinase isoforms as measured by agarose electrophoresis. (CK-isoforms, courtesy of Helena Labs., Beaumont, TX.)

In the immunoinhibition method, serum is analyzed for CK after the addition of specific antibodies. The technique, illustrated in Fig. 14.14, involves inhibiting CK-M subunit activity

with anti-M antibodies and measuring the residual B-subunit activity. If CK-BB and atypical CK forms are absent, the MB content of the sample can be determined by multiplying the B-subunit activity by 2. However, if CK-BB or macro CK is present, a usually high percentage of CK-MB/total CK will occur, and the analysis should be confirmed by a more specific CK-MB assay. The immunoinhibition technique is very useful for screening because it is inexpensive and can be linked to automated chemistry analyzers.

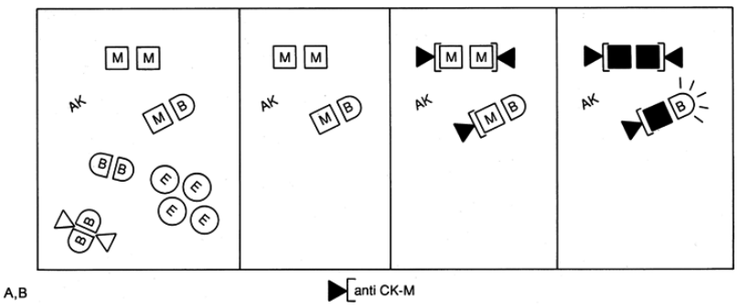

FIGURE 14.14. The immunoinhibition technique for creatine kinase (CK) B. **A:** Normal and atypical isoenzymes of CK and adenylate kinase. **B:** Only CK-MM, MB, and adenylate kinase are assumed to be present. **C:** Addition of anti-CK-M antibodies. **D:** Measurement of residual B-subunit activity after M-subunit inactivation (solid symbols). Inhibitors to adenylate kinase minimize the contribution of this interferent. The CK-MB activity is calculated by multiplying the residual activity by 2. (From Wu AHB. *Clinical chemistry*. Bethesda, MD: Health Education Resources, 1991, with permission.)

The most commonly used method for CK-MB are nonisotopic immunoassays, which measure enzyme concentration instead of activity. All commercial immunoassays make use of a two-site sandwich technique. The first antibody recognizes a particular determinant on the CK-MB molecule and is linked to a solid phase such as a tube, bead, magnetic particle, or fibrous surface. Monoclonal anti-bodies to CK-MB have been used to capture MB from the sample in this first step. The second antibody recognizes a different MB determinant and is conjugated to a label, such as an enzyme, fluorophore, or chemoluminescent tag. The concentration of CK-MB from the sample is determined from a standard curve. Figure 14.15 illustrates the Dade Stratus II method as one example. Immunoassays are very sensitive and rapid. Improvements in analytical precision and clinical performance have been reported over enzyme-activity assays, particularly when total CK levels are low.

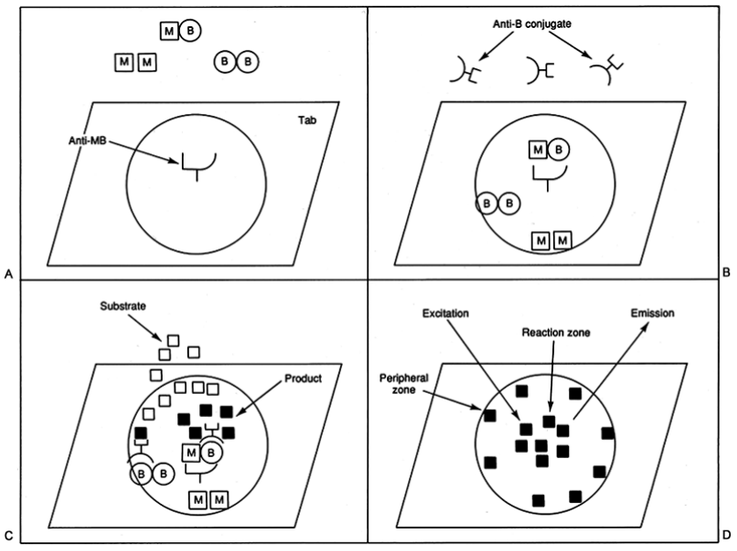

FIGURE 14.15. Radial partition immunoassay for creatine kinase (CK)-MB. **A:** A serum sample with CK isoenzymes is added to the center of a tab containing anti-CK-MB antibodies linked to glass fiber paper. The MB isoenzyme becomes immobilized. **B:** Anti-CK-B antibodies linked to alkaline phosphatase are added. These bind both to the immobilized CK-MB isoenzymes and to BB. **C:** Substrate to ALP is added to the center of the tab to produce a fluorescent product. CK-MM and BB are not bound to anti-MB and are washed outward from the reaction zone. **D:** The fluorescence intensity is proportional to (MB) measured at the center of the front surface of the tab. The fluorescence of conjugate (of CK-BB) migrating outward from the periphery of the reaction zone is not measured.

Reference Values

Reference values for CK-MB are dependent on the analytical method used and are often expressed as a fraction of total CK activity. Reference values from a healthy population should not be used as decision limits for the diagnosis of AMI, however, because there would not be adequate discrimination between the AMI and non-AMI patient (e.g., unstable angina). Cutoff values for electrophoresis and immunoinhibition are usually set around 5% of total CK or 10 U/L. For immunoassays, decision limits are expressed in mass quantities and are approximately 5 to 10 ng/mL. CK-BB is normally absent in adult serum. CK-MB and CK-BB levels are higher in children, but there are no established reference ranges, as CK isoenzyme analysis is not usually performed for this population.

There are two ways by which CK-MB results can be expressed: absolute activity (U/L) or mass concentration (ng/mL) and a percentage of total CK (relative index). The relative index is defined as:

$$\text{Relative index: } \frac{\text{CK-MB (activity or mass)}}{\text{total CK (activity)}} \times 100$$

As a rule, absolute limits are most useful when the total CK is low (e.g., less than 1,000 U/L). Because CK-MB is found in skeletal muscles, however, CK-MB levels will exceed absolute reference limits in patients with severe skeletal muscle injury or disease. In this case, a relative limit (CK-MB expressed as a percentage of total CK) is more useful when the total exceeds 1,000 U/L.

Lactose Dehydrogenase (LDH) (EC 1.1.1.27)

LDH (L-lactate:NAD^+ oxidoreductase) is a ubiquitous enzyme found in the cytoplasm of nearly all cells; it catalyzes an important step in glycolysis. LDH has a molecular weight of approximately 134 kDa and is a tetramer of H and M subunits. There are five possible isoenzyme results from these combinations. Measurement of LDH is useful for several different diseases involving the blood, liver, kidneys, skeletal muscle, and myocardium.

Measurement of Total LDH Activity

LDH catalyzes the reversible oxidation of L-lactate to pyruvate, with simultaneous reduction of NAD^+:

$$\text{lactate} + NAD^+ \xrightarrow{\text{LD}} \text{pyruvate} + NADH$$

Both the forward (lactate-to-pyruvate) and reverse (pyruvate-to-lactate) reactions are currently in use in clinical laboratories. In the United States, the forward assay is most widely used. The advantage of this method is that the reaction rate is slower and is held more constant than for the reverse assay. The reaction is monitored by measuring the absorbance of NADH at 340 nm. The optimum pH range for this reaction is 8.8 to 9.8. The reaction

rate for the reverse assay is higher than for the forward, and the precision is therefore somewhat improved. The pH range for the reverse reaction is 7.4 to 7.8. The reference interval for the forward reaction is approximately 80 to 200 U/L at 37°C, and approximately 200 to 400 U/L for the reverse reaction.

LDH Isoenzymes

Tissue Distribution. The LDH isoenzyme distribution of various tissues is shown in Fig. 14.16 (14). Requests for LDH isoenzymes are most frequently made in conjunction with the diagnosis of AMI, although measuring LDH isoenzymes can be used to determine other sources of tissue injury. Because the heart is richest in LDH_1, some analytical methods have focused on this isoenzyme alone. The decision limit most widely used is that LDH_1 activity in excess of 40% of total LDH activity supports the diagnosis of AMI. LDH isoenzyme fractionation is rarely of any value in the diagnosis of other conditions (e.g., liver disease) because there are other more specific markers available and there is overlap in the tissue distribution of LDH isoenzymes from other organs.

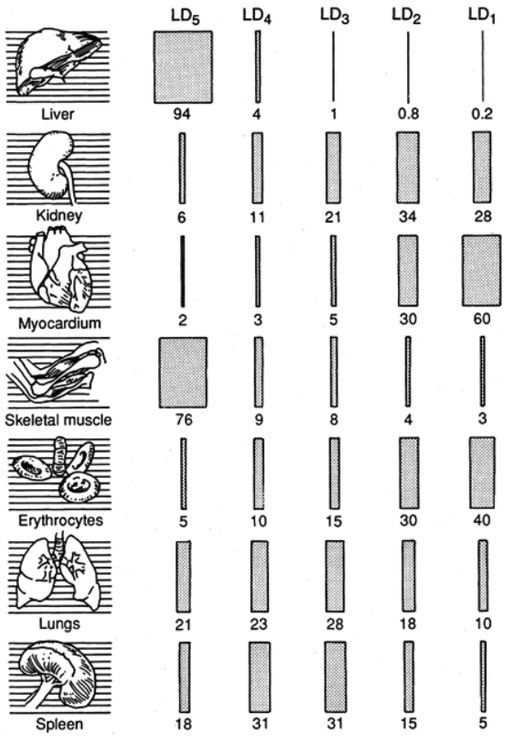

FIGURE 14.16. Tissue distribution of lactate dehydrogenase isoenzymes. (From Lott JA, Wolf PL. *Clinical enzymology. A case-oriented approach*. New York: Year Book, 1986, with permission.)

Analytical Methods. Given the decreased utilization of LDH isoenzymes, only a brief description of methods is given. The reader is referred to the first edition of *Clinical Laboratory Medicine* for details. The only routinely used procedure that allows analysis of all LDH isoenzymes is electrophoresis. Bands are visualized by densitometrically scanning the fluorescence of the NADH product or reacting NADH with a tetrazolium salt to form a colored product that can be measured at 600 nm. The serum of some patients will exhibit the presence of other LDH forms such as macro-LDH (immunoglobulin bound), but the significance of these other forms is unknown. The LDH_1 isoenzyme can also be measured directly by the Roche immunoprecipitation method. This assay uses a goat anti-LDH-M antibody LDH isoenzymes LDH_2 through LDH_5, and a second precipitating (donkey anti-goat) antibody, which recognizes and binds the first antibody. After centrifugation, only the LDH_1 isoenzyme remains, as it does not contain any M subunits. The extracted sample is then measured for residual LDH activity. A variation of this method is the use of selective chemical inhibition. The Roche LDH_1 assay makes use of guanidine thiocyanate, which acts as a competitive inhibitor for LDH_1 and a noncompetitive inhibitor for LDH_5. The degree of inhibition is greatest for LDH_5, intermediate for LDH_4, LDH_3, and LDH_2, and least for LDH_1. The reagent is formulated to optimize recovery of LDH_1 activity. The chemical inhibition method gives results that are equivalent to immunoprecipitation and has the advantage that it does not require a centrifugation step to isolate LDH_1; therefore, the assay can be automated to high-volume clinical chemistry analyzers.

Myoglobin

Myoglobin is a low-molecular weight protein (less than 18 kDa) found in all skeletal muscle and myocardial tissues. Myoglobin is an oxygen-binding protein, serves as a reserve for oxygen, and facilitates the movement of oxygen within muscle cells. Myoglobin released from the heart is indistinguishable from that released from skeletal muscle tissues. It has been known since the mid-1970s that myoglobin was an early marker for AMI (16). However, because early assays for myoglobin were based on a manual radioimmunoassay, it was not practical for a laboratory to produce stat myoglobin results for real-time management of cardiac patients. The long assay time and expense for the testing negated the advantage of early diagnosis that myoglobin had over CK-MB. In the late 1980s, nonisotopic nephelometric and turbidimetric assays were developed. This renewed the clinical interest for myoglobin as a cardiac marker. The current myoglobin assays are based on immunoassays, are available on a wide variety of automated immunoassay analyzers, and are practical for stat testing. Reference limits for serum myoglobin vary but are generally less than 100 ng/mL. Although myoglobin is filtered by the glomerulus, it is reabsorbed and catabolized by the tubules and there is little myoglobin that appears in the urine of normal individuals. Myoglobin is also increased in patients with skeletal muscle disease or injury, and in patients with acute or chronic renal failure.

Troponin

Troponin is a regulatory protein complex located on the thin filament of striated muscles and consists of three isotypes. Troponin-T

(cTnT) has a molecular weight of 38 kDa and binds the troponin complex to tropomyosin. Troponin-I (cTnI) has a molecular weight of 24 kDa and functions to inhibit actomyosin ATPase. Troponin-C has a molecular weight of 18 kDa and regulates cTnI activity by binding calcium. cTnT and cTnI are better diagnostic markers for AMI than existing enzymes such as CK-MB because cardiac isotypes are distinctly different from their corresponding skeletal muscle isotypes. Monoclonal antibodies have been developed to cardiac troponin that do not cross-react with skeletal muscle forms. There are no specificity advantages for measuring cardiac troponin C (cTnC) as the skeletal muscle forms have homology to the cardiac forms.

Point-of-Care Testing Devices

Emergency departments (ED) in the United States and worldwide are changing their patient triaging practices toward a rapid rule out of chest pain patients who do not have acute coronary syndromes. This aggressive approach involves testing blood on a more frequent basis than before, e.g., every 3 to 4 hours for the first 12 hours instead of at 8- or 12-hour intervals. After AMI has been ruled out, an exercise stress test can be performed to rule out other acute coronary diseases. Negative results for these tests enables ED physicians to discharge patients earlier than before. To meet these changing clinical demands, laboratories must perform testing for cardiac markers on a stat or as-needed basis. The National Academy of Clinical Biochemistry (NACB) has recommended a reporting turnaround time for cardiac markers of 1 hour or less (17). Many laboratories are unable to comply with this objective because of delays in receiving specimens from the ED. Hospitals that do not have an ED laboratory or pneumatic tube transport system to directly connect the ED to the laboratory must hand-deliver specimens to the laboratory. To address these problems, qualitative and quantitative point-of-care devices are now available for myoglobin, CK-MB, and cardiac cTnT and cTnI (18). These assays use whole blood and can produce results within 10 to 20 minutes. They are designed to be used at ED bedside and obviates the need for delivering the sample to the laboratory. Although the benefits for rapid turnaround time testing have been documented for EDs who have an aggressive triaging protocol, there have been no studies to determine whether bedside testing improves clinical outcomes compared with stat testing performed in a central laboratory. Point-of-care testing for cardiac markers is more expensive, and there are regulatory requirements for proficiency and quality control for the nonlaboratory personnel who perform the testing. Nevertheless, point-of-care testing is very attractive for hospitals who need rapid triage for their chest pain patients.

Use of Cardiac Markers in the Diagnosis of AMI

The diagnosis of AMI is defined by the World Health Organization (WHO), based on clinical signs and symptoms (e.g., chest pain), specific changes in electrocardiographic recordings, and the presence of elevated serum activities and concentrations of enzymes such as total CK, CK-MB, LDH, and LDH isoenzymes (19). With the development of other tests such as myoglobin, and the cardiac troponins, the WHO definition of AMI should be expanded to include enzymes and proteins because these markers are not enzymes.

The optimal use of enzyme markers for diagnosis of AMI requires careful selection of decision limits and correct timing of blood samples. Because false-positive results can occur, the best information is obtained when serial collections are analyzed to construct enzyme activity or cardiac marker concentration versus time curves.

Early Diagnosis: Myoglobin and CK Isoforms

An important factor that affects the efficiency of biochemical markers for AMI diagnosis is the sampling time from the onset of chest pain. Figure 14.17 shows the activity-time curves for cardiac enzymes and proteins after AMI. As shown, myoglobin

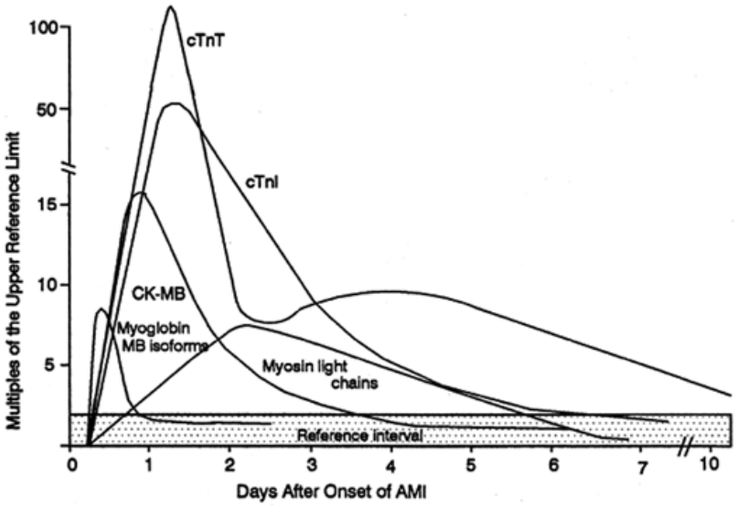

FIGURE 14.17. Activity versus time curves in serum for biochemical markers of acute myocardial infarction.

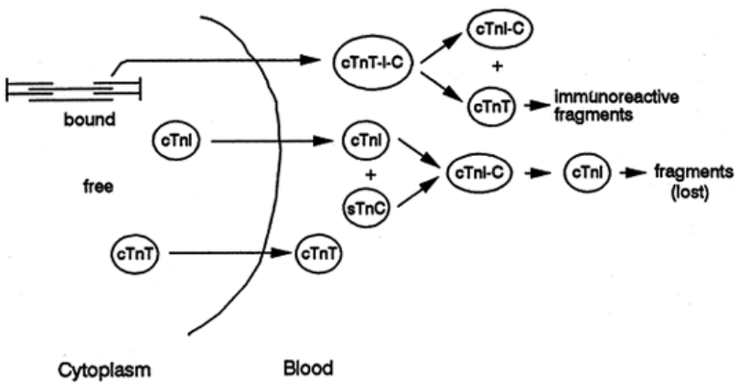

FIGURE 14.18. Release of cardiac troponin from damaged myocytes. (Modified from Wu AH. Biochemical differences between cTnT and cTnI and their significance for diagnosis of acute coronary syndromes. *Eur Heart J* 1998;19(Suppl N):25--29.

and CK-MB isoforms have the earliest diagnostic windows of the markers shown. Myoglobin is increased early after AMI because of its small size. CK isoforms appear early because serum levels normally contain only trace levels of CK isoforms, and a low cutoff can be used to detect the very earliest release of tissue isoforms after myocardial necrosis. Estimates for clinical sensitivity at various time intervals after chest pain and clinical specificity are shown in Table 14.3. Early diagnosis is important in the management of AMI, particularly if thrombolytic therapy is to be used. The clinical specificity of myoglobin is not as high as for CK-MB isoforms. Utilization of MB isoforms for routine use, however, warrants improvements in the methodology.

TABLE 14.3. ESTIMATES OF CLINICAL SENSITIVITY AND SPECIFICITY OF DiAGNOSTIC TESTS FOR ACUTE MYOCARDIAL INFARCTION

	Sensitivity				
Marker	**2–8 h**	**8–24 h**	**24–72 h**	**>72 h**	**Specificity**
Myoglobin	95	75	0	0	70
CK-MB isoforms	90	60	0	0	90
CK-MB	60	95	98	50	95
LDH_1	40	85	95	90	85
Troponin	75	95	98	98	90

CK-MB, creatine kinase-MB; LDH_1, lactate dehydrogenase 1.

Definitive Diagnosis of AMI: CK-MB and Troponin

The CK-MB isoenzyme is the most widely used enzyme for the diagnosis of AMI. Levels begin to rise 6 to 10 hours after onset, peak at 18 to 24 hours, and return to normal within 3 days (Fig. 14.17). The sensitivity of CK-MB is approximately 95% to 98% (Table 14.3). The specificity of CK-MB when sampled at the optimum time after the onset of AMI ranges from 92% to 99%. CK-MB is more specific than total CK because the total can increase in a variety of nonmyocardial diseases. False-positive results do occur when myocardial tissue is damaged by other means, such as trauma to the heart or open heart surgery. CK-MB of skeletal muscle origin can also be observed in serum with dermatomyositis, muscular dystrophies, and training for long-distance running. In each of these conditions, the skeletal muscle may contain a higher percentage of MB than normal because of increased turnover and alterations in isoenzyme expression during regeneration.

The cardiac troponins (T or I) are the most efficient markers available today for diagnosis of AMI. Because troponin has a higher tissue distribution in myocytes than CK-MB or myoglobin, the degree of increase after AMI (relative to the normal range) is much higher than for the other cytosolic markers (Fig. 14.17). The early release of cTnT and cTnI are owing to release of the free cytosolic pool of these proteins, estimated to be approximately 6% to 8% and 2.8% to 4.1%, respectively (Fig. 14.18). Because of the higher cytosolic content, cTnT may be increased slightly before cTnI after AMI. In addition, cTnT exhibits a biphasic pattern because of the significant free cytosolic cTnT component. (The second peak is owing to release of the structural elements of cTnT, as discussed in the next section.) Cardiac cTnI exhibits a largely monophasic pattern because of the lower free cTnI release and because some of the cTnI putatively binds to circulating skeletal muscle troponin C to form a binary complex (Fig. 14.18).

The specificity of troponin is also increased over CK-MB or myoglobin because false-positive results are not observed in patients with skeletal muscle disease or injury. Estimates of the clinical sensitivity and specificity for troponin are listed in Table 14.3. Because of the improved performance in clinical studies, cardiac troponin has been recommended by the NACB as the preferred marker for the definitive diagnosis of AMI, replacing CK-MB (17).

Late Diagnosis of AMI: LDH and Cardiac cTnT and cTnI

The diagnosis of AMI in patients who present to the ED with a 3- to 4-day history of chest pain may be difficult with myoglobin or CK-MB because these markers might have already returned to normal. In this situation, use of a cardiac marker that remains increased for a week or more after AMI onset is useful for making a retrospective diagnosis. Isoenzymes of LDH have classically been used for this purpose. The appearance and clearance of LDH is delayed because this enzyme is considerably larger than either myoglobin or CK.

With the development of structural markers such as cTnT and cTnI, the NACB has recommended discontinuance of

LDH isoenzymes (17). Cardiac cTnT and cTnI have a prolonged release pattern after myocardial injury owing to the slow degradation of muscle fibers by proteolytic and lysosomal enzymes. As shown in Fig. 14.17, cTnI remains increased for approximately 7 days, whereas cTnT is abnormal for as long as 10 days. The differences in the clearance rate between cTnT and cTnI is related to how the troponin complex from myocytes is released from tissues and degraded in blood and the recognition of the various troponin forms by commercial assays. Figure 14.18 shows that structurally bound troponin is released into blood as a ternary complex of cTnT-I-C, which subsequently degrades into a binary complex of cTnI-C and free cTnT. The binary complex further degrades into free subunits. Gel filtration studies have shown that the commercial assay for cTnT recognizes complexed, free, and degradative fragments of free cTnT (20). In contrast, there is not a large, free cTnI component in blood, and immunoreactive fragments of cTnI do not appear to be detectable by existing assays. A possible reason is that cTnI binds to proteins and other materials that may affect its recognition by antibodies used in commercial cTnI assays. As a result, the apparent clearance of cTnI after AMI is faster than for cTnT.

Experimental Markers for Early AMI

Cardiac troponin is gradually receiving acceptance as the standard marker for the retrospective diagnosis of AMI. Given the need by ED physicians to triage chest pain patients earlier and earlier and the sensitivity and specificity limitations of myoglobin and CK-isoforms, there is ongoing research into new early markers of AMI and acute coronary syndromes. The current research efforts are focused on using markers to identify the early pathophysiologic events that are known to occur in an evolving AMI. Table 14.4 summarizes the biochemical attributes of investigational early AMI markers. Laboratory tests for C-reactive protein and amyloid protein A can be used to indicate the presence of acute inflammation. Markers of thrombosis include soluble fibrin monomers and thrombus precursor protein. Soluble and membrane-bound P-selectins are markers of platelet aggregation, whereas glycogen phosphorylase BB is thought to be released during periods of reversible ischemia. Two markers of cellular necrosis have been proposed to augment the early diagnostic utility of myoglobin. Carbonic anhydrase III is released in patients with skeletal muscle injury, thus a normal result with a high myoglobin suggests acute cardiac injury. Fatty acid binding protein has a higher myocardial tissue content than myoglobin. The use of a ratio between the binding protein and myoglobin can be helpful in differentiating between myocardial and skeletal muscle injury, which would have a different ratio between these two markers.

TABLE 14.4. SUMMARY OF EARLY BIOCHEMICAL MARKERS FOR ACUTE CORONARY SYNDROMES

Marker	Biochemical Function	Size (kDa)	Clinical Utility
Markers of inflammation			
C-Reactive protein	Acute phase reactant	~120	Nonspecific markers of inflammation
Amyloid protein A	Acute phase reactant	12.5 (mono), 220–235 (poly)	
Coagulation factors and proteins			
Soluble fibrin monomers	Soluble protein precursor	??	Early detection of thrombus form
Thrombus precursor protein	Insoluble fibrin	??	
Platelet function			
Soluble P-selectin	Platelet activation	140	Platelet aggregation
Ischemic marker			
Glycogen phosphorylase BB	Enzyme of glycogenolysis	~200	Reversible injury
Biochemical markers			
Carbonic anhydrase III	Converts HCO_3^- to H_2CO_3	28	Skeletal muscle protein (used with myoglobin)
Fatty acid binding protein	Cytosolic fatty acid carrier	15	Nonspecific early acute myocardial infarction marker

From the National Academy of Clinical Biochemistry. *Standards of laboratory practice monograph: recommendations for the use of cardiac markers in coronary artery diseases*, 1999, with permission.

Early clinical studies showed that none of these markers by themselves has the specificity needed to be used as an early AMI marker. C-reactive protein is increased in any conditions associated with infection or inflammation. Hemostatic markers will be positive in patients with other thrombotic diseases such as stroke, pulmonary embolism, and deep vein thrombosis. Markers of reversible ischemia may be able to rule in acute coronary syndromes but cannot differentiate between AMI and unstable angina, as the reduction in coronary artery blood flow occurs in both diseases. Given these limitations, a multivariate approach may be necessary to utilize the incremental advantage that each marker might offer.

Risk Stratification of Patients with Unstable Angina

Total occlusion of a coronary artery after plaque rupture will produce large areas of myocardial necrosis and extensive release of cardiac markers. In unstable angina in which plaque rupture leads to a nonocclusive clot, minor myocardial injury can occur in subset of these patients, presumably owing to blockage of small vessels and collateral arteries. Highly sensitive cardiac markers such as cardiac cTnT or cTnI can detect the presence of minor myocardial injury, despite normal concentrations of other markers. This has been demonstrated in patients undergoing elective coronary angioplasty, in which the presence of side

branch occlusions and distal thrombi was associated with increased cTnT relative to preangioplasty values (21).

The significance of detecting minor myocardial injury in patients with unstable angina has been demonstrated by numerous investigators. Figure 14.19 shows that patients with a positive cTnT at presentation had a significantly higher short-term cardiac morbidity and mortality than patients with a normal cTnT. In a metaanalysis combining results of several outcome studies, patients with unstable angina and a positive cTnT or cTnI have an odds ratio of 5 to 1 for untoward events (22). It is possible that a slightly elevated troponin result identifies the presence of a microinfarct that might indicate a more advanced stage of the disease compared with a patient who has not yet exhibited evidence of irreversible damage. Unstable angina patients at high risk can be treated with low molecular weight heparin or a glycoprotein IIb/IIIa receptor inhibitor, each of which has been shown to reduce the incidence of future cardiac events in these patients (23). The use of cardiac troponin has the dual role of diagnosis of AMI and risk stratification in non-AMI patients who have unstable angina.

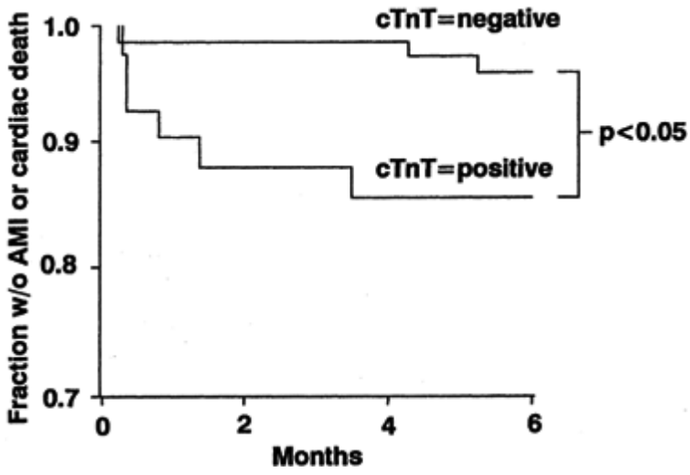

FIGURE 14.19. Kaplan-Meier survival curves for patients with unstable angina and cardiac troponin T. (Modified from Ravkilde J, Horder M, Gerhardt W, et al. Diagnostic performance and prognostic value of serum troponin T in suspected acute myocardial infarction. *Scand J Clin Lab Invest* 1993;53:677–685.)

Enzymes and Proteins in Skeletal Muscle Disease

The important enzyme markers of skeletal muscle necrosis include total CK, CK-MB, and, to a lesser extent, AST and aldolase. Elevations of total CK with a normal relative index for CK-MB indicate skeletal muscle disease, necrosis, or injury. When both total CK and CK-MB are elevated, the diagnosis of skeletal muscle injury may be difficult. Patients with muscular dystrophies can have a higher than normal proportion of CK-MB in their muscle tissue because of increased muscle turnover. In addition, individuals who run long distances can exhibit significant levels of noncardiac CK-MB in serum. Table 14.5 shows typical results of CK and CK-MB levels after a marathon race (24). In most cases, the clinical history is sufficient for differentiating acute skeletal muscle damage from acute myocardial injury. In cases of concomitant skeletal muscle injury and AMI, measurement of troponin allows differentiation between skeletal muscle injury and myocardial damage. This is because the specificity of cardiac troponin is very high, with no cross-reactivity of commercial assays to the presence of skeletal muscle troponin.

TABLE 14.5. CREATINE KINASE (CK) LEVELS BEFORE AND AFTER A MARATHON RACE

Prerace CK (U/L)	Postrace CK[a] (U/L)	Postrace MB[a] (U/L)	% MB/Total CK
202	1,293	85	6.6
322	1,654	108	6.5
232	2,261	138	6.1
340	1,768	85	4.8

[a] Values taken 24 hours after the race.
Data from ref. 24.

Extensive skeletal muscle injury, as characterized by extremely high levels of activity of total CK in serum and concentrations of myoglobin in serum and urine, is observed in patients with rhabdomyolysis. The causes of rhabdomyolysis include crush injuries, excessive muscular contractions, drugs and toxins, and immobilization accompanied by hypothermia. A serious complication of extensive skeletal muscle injury is rhabdomyolysis-induced acute renal failure. There are two theories as to the cause of renal failure: direct toxicity from the heme group of myoglobin and precipitation of myoglobin within renal tubules causing obstruction. Patients with rhabdomyolysis are treated with osmotic diuresis with mannitol to increase renal blood flow and alkalinization to stabilize the solubility of myoglobin. The complications of diuretic therapy include CHF caused by fluid overload. Not all patients with rhabdomyolysis develop renal failure.

Use of the myoglobin clearance test or the ratio of serum to urine myoglobin concentrations may be helpful in predicting which patients would progress to acute renal failure and who would benefit from interventional therapy. Figure 14.20 illustrates two patients who presented with similar histories. Both patients had very high concentrations of total CK and serum and urine myoglobin. In the first case (Fig. 14.20A), the urine myoglobin exceeded the serum myoglobin, indicating that the clearance was high, suggesting that the rate of renal removal exceeded the rate of production from necrotic skeletal muscles. Acute renal failure did not occur in this patient. In the second patient (Fig. 14.20B), the serum myoglobin was initially higher than the urine, indicating that the rate of clearance was inadequate, and acute renal failure occurred on the next day (as shown by the creatinine clearance result) (25).

Use of quantitative serum and urine myogloin tests should replace the qualitative urine myoglobin dipstick test. This latter assay is not as sensitive as an immunoassay for myoglobin and can produce false-positive results in the presence of hemoglobinuria. Furthermore, finding myoglobin in the urine alone is not predictive of acute renal failure. High urine concentrations, in fact, may indicate that the kidneys were able to excrete the high plasma myoglobin load.

PANCREATIC DISEASES

Enzymes of Pancreatic Origin

Amylase (EC 3.2.1.1)

Amylase (α-1,4-glucan,4-glucanohydrolase) catalyzes the hydrolysis of complex carbohydrates at the α-1,4 linkages of adjacent glucose residues. The amylases have a molecular weight of approximately 50 kDa and are small enough to pass through the glomerulus and are among the few serum enzymes that appear in urine. Amylase is found in the highest concentrations in the acinar cells of the pancreas, but other isoenzymes are found in the salivary gland, testis, and ovary. Each isoenzyme is encoded by a separate gene. Serum amylase consists primarily of the pancreatic and salivary isoenzymes. Macroamylase is a complex of immunoglobulin (usually IgG) with amylase (usually the salivary isoenzyme). Because of the high molecular weight of this complex, macroamylase is not cleared by the kidneys, and high amylase levels persist in the serum, often without any clinical disorder. Macroamylasemia is estimated to account for 2% to 5% of all patients with hyperamylasemia (26).

Analytical Measurements

Numerous methods have been developed for measuring serum amylase. Viscometric, nephelometric, and iodometric assays have been largely replaced with saccharogenic and chromogenic assays that are very precise and can be adapted to automated chemistry analyzers. Saccharogenic assays use small oligosaccharide substrates.

$$\text{maltopentaside} \xrightarrow{\alpha\text{-amylase}} \text{maltotrioside} + \text{maltose}$$

$$\text{maltotrioside} \xrightarrow{\alpha\text{-glucosidase}} \text{maltose}$$

$$\text{maltose} \xrightarrow{\alpha\text{-glucosidase}} \text{glucose}$$

The reaction can be monitored by following the production of glucose as conventionally measured, for example with glucose oxidase and an O_2-specific electrode, or hexokinase coupled with G6PD and NAD^+. These assays must correct for the presence of variable amounts of endogenous glucose in serum.

Chromogenic assays make use of synthetic substrates containing a chromogen that is liberated directly by amylase or after coupling with α- or ß-glucosidase. These assays eliminate the additional steps needed to measure glucose. A common chromogen is *p*-nitrophenol (PNP).

$$p\text{-nitrophenylmaltoheptaoside} \xrightarrow{\alpha\text{-amylase}} p\text{-NP-maltotetraoside} + \text{PNP-maltotrioside}$$

$$p\text{-NP-maltotrioside} + H_2O \xrightarrow{\alpha\text{-glucosidase}} \rightarrow p\text{-NP} + \text{glucose}$$

In this example, the reaction rate is monitored by measuring the absorbance of *p*-nitrophenol at 405 nm. The assay has an optimum pH of 7.0 and requires calcium and anions as cofactors. The reference interval for amylase is dependent on the type of assay and the substrate used. For the chromogenic assay, the reference interval is 20 to 160 U/L at 37°C.

Amylase Isoenzymes and Isoforms

Human serum contains two amylase isoenzymes originating from the salivary gland (S type) and pancreas (P type). Each isoenzyme exists as one of three isoforms. The pure gene product for the salivary and pancreatic isoforms are S_1 and P_2, respectively. These are converted to S_2 and S_3, and to P_3, respectively, by posttranslational deglycosidation, and deamidation of asparagine and glutamine residues. The P_1 isoform of amylase is a genetic isoenzyme variant. Isoenzyme measurements are used to differentiate the causes of hyperamylasemia, such as those of salivary and pancreatic origin, or the presence of macroamylase. Amylase isoenzymes can be measured by electrophoresis, ion-exchange chromatography, IEF, and selective inhibition and precipitation with lectins

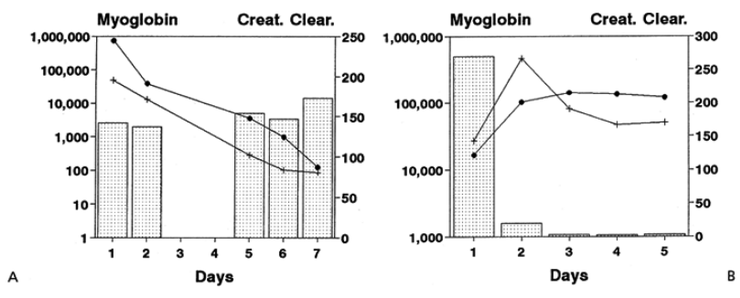

FIGURE 14.20. Use of the myoglobin clearance test to predict acute renal failure in male patients with rhabdomyolysis. Serum (+) and urine (•) myoglobin concentration (in nanograms per milliliter, left ordinate), and creatinine clearance (bars in milliliters per minute, right ordinate) plotted as a function of time after admission. Upper limit of normal in men for serum myoglobin, 0–62 ng/mL; urine, 6.8 ng/mL. Reference range for creatinine clearance, 97–137 mL/min for men. (Creatinine clearance was higher than the normal range owing to creatinine release from skeletal muscles.) **A:** Patient who did not develop acute renal failure. **B:** Patient who developed renal failure.

and monoclonal antibodies. Using electrophoresis, amylase isoenzyme bands can be made visible by use of a dyed-starch suspension (e.g., Phadebas tablets, Pharmacia Diagnostics, Piscataway, NJ, U.S.A.), which produces a color upon hydrolysis by amylase. Quantitative measurement of each band can be made scanning bands with a densitometer. In normal individuals, there are roughly equal amounts of S-type and P-type isoamylases in serum. Other methods are available to determine the total P-type amylase isoenzyme content of serum. Salivary amylase is approximately 90% inhibited by lectins from wheat germ. The estimation of pancreatic amylase is made by measuring the residual amylase activity after incubation with the lectin. Macroamylase of the S type is also inhibited by this technique. Monoclonal antibodies directed toward either salivary or pancreatic amylase can also be used to measure amylase isoenzymes in a variety of formats such as selective immunoinhibition, immunoprecipitation, immunoextraction (Fig. 14.21), or enzyme immunoassay. Immunoassays are very specific and do not cross-react with other isoamylase forms. However, they cannot be used on general chemistry analyzers, thus limiting their widespread application.

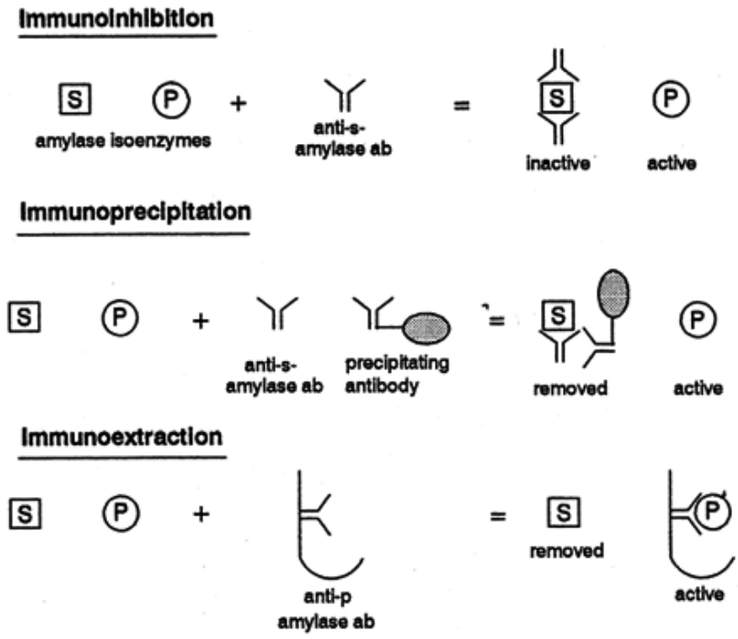

FIGURE 14.21. Analytical methods for measurement of the pancreatic amylase isoenzyme activity, using an appropriate amylase substrate. Immunoinhibition involves the inhibition of salivary isoenzymes with specific salivary (s) amylase antibodies. The residual activity is owing to pancreatic (P) amylase. The immunoprecipitation method involves the removal of salivary amylase with specific antibodies, followed by use of a precipitating antibody. The immunoextraction assay uses antibodies to pancreatic amylase to isolate it from the other forms before enzymatic analysis. (From the American Association for Clinical Chemistry, with permission.)

Lipase (EC 3.1.1.3)

Lipase (triacylglycerol acylhydrolase) catalyzes the hydrolysis of triglycerides sequentially into ß-monoglyceride and two free fatty acids. Lipase activity depends on the substrate being present as an emulsion in contrast to related enzymes such as lipoprotein lipase and other hydrolases, which are active with short fatty acid chain substrates that are water soluble. The most commonly used assay for lipase involves measuring the clearing of a substrate emulsion by the action of lipase. Measurements can be made by either nephelometry or turbidimetry:

$$\underset{\text{(cloudy emulsion)}}{\text{Triolein}} \xrightarrow{\text{lipase}} \underset{\text{(clear solution)}}{\text{glycerides + free fatty acids}}$$

The optimum pH for this reaction is 8.8. In this assay, both lipase and lipoprotein lipase are measured. However, if colipase and a bile salt such as sodium deoxycholate are included, the reaction rate and analytical sensitivity of pancreatic lipase is increased, whereas that for lipoprotein lipase is eliminated (27). Colipase, aided by the addition of bile salts, binds to lipase to form a complex. This association produces a conformational change in lipase, such that the latter can now more efficiently bind to the substrate. The mechanism of how colipase and bile salts interact with the enzyme in vivo is shown in Fig. 14.22. The reference range for lipase depends on the substrate and whether colipase is used. The upper reference limit is 200 U/L at 37°C when triolein is used as the substrate in the presence of colipase and bile salts.

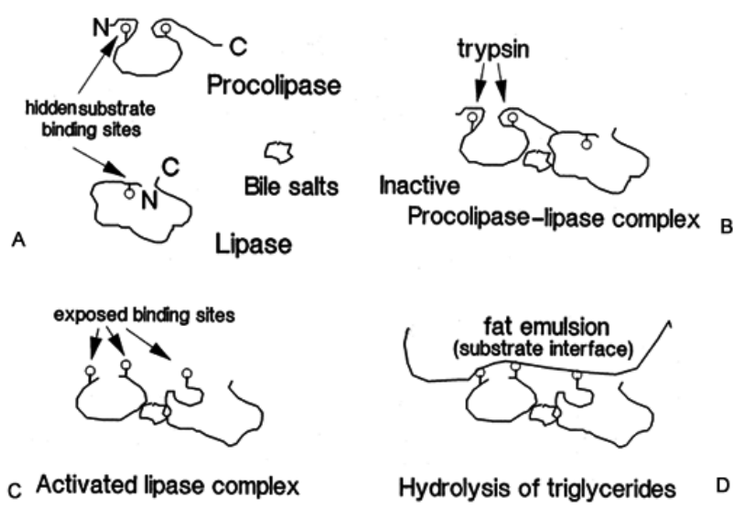

FIGURE 14.22. Mechanism for the hydrolysis of fat in the intestine by lipase–colipase. **A:** Lipase and procolipase are secreted as separate proteins from the pancreas. The binding sites for the triglyceride substrates are hidden for both enzymes. **B:** In the intestine, the two proteins associate to form an inactive complex. The binding is favored by the addition of mixed-chain bile salts. **C:** Trypsin converts procolipase to colipase by removal of the N- and C-terminal residues, exposing the substrate binding sites. This also produces a conformational change for lipase, thereby exposing its substrate binding site. **D:** The lipase-colipase can now attach to the fat particles, facilitating the hydrolysis of triglycerides. (Adapted from Borgstrom B. *Lipase*. Amsterdam: Elsevier, 1984, with permission.)

Electrophoresis of lipase reveals the presence of at least two true isoforms in serum, labeled L_1 and L_2. A third form labeled L_3 also appears on electrophoresis and is thought to be pancreatic carboxyester lipase.

Trypsin (EC 3.4.21.4)

Trypsin is a pancreatic proteolytic enzyme that specifically cleaves peptide bonds at carboxyl groups of lysine and arginine. Trypsin originates from inactive trypsinogens produced by pancreatic acinar cells. Activation of trypsin occurs in the intestinal tract by an enterokinase. Measurement of serum trypsin is seldom performed because amylase and lipase measurements are readily available and provide much the same information. However, immunoreactive trypsin from dried blood spots is being used as a neonatal screen for cystic fibrosis (28). Because of the existence of antiproteases in the blood, trypsin must be measured immunologically by using specific antisera rather than by the use of enzymatic activity.

Clinical Uses of Pancreatic Enzymes

Acute Pancreatitis

Pancreatitis results when digestive enzymes of the exopancreas find their way into the endocrine parenchyma and autodigestion of pancreatic tissue ensues. Key among these digestive enzymes is trypsin, which, together with other bile components, activates other proteolytic enzymes that are collectively responsible for pancreatic necrosis. The most consistent clinical symptom of acute pancreatitis is abdominal pain. Risk factors include excessive alcohol use, the presence of gallstones, and hyperlipidemias. The disease can take either of two forms: the edematous form, which is relatively mild and occurs in approximately 80% of all cases, and the hemorrhagic form, which is more serious and results in most of the fatalities attributed to acute pancreatitis (29).

The diagnosis of acute pancreatitis is made based on clinical presentation and medical history, in addition to radiographic and laboratory studies. Laboratory findings include an elevated serum amylase, amylase clearance, and lipase. Amylase and lipase levels rise within a few hours after onset and remain elevated for 36 to 48 hours. The extent of amylase and lipase elevations is not strongly correlated to the severity of the disease. The clinical sensitivities of serum amylase and lipase are both approximately 90% when blood is sampled in the first 36 hours, and highly sensitive assays are used. False negatives result when pancreatitis occurs in patients who have had recurrent attacks and have little or no functional pancreatic tissue remaining.

The clinical specificity for the diagnosis of acute pancreatitis is only 40% for amylase and 60% for lipase. The specificity for amylase is low because of the existence of nonpancreatic sources of the enzyme such as the salivary gland. The specificity of lipase is influenced by the design of the assay used. When serial amylase levels are measured in patients presenting with acute abdominal pain and a positive history of alcohol use or cholestatic disease, the specificity is increased. However, hyperamylasemia is observed in several other pancreatic as well as nonpancreatic disorders, and the diagnostic value of a single elevated amylase level without regard to other clinical findings is limited. Automated P-amylase isoenzyme determinations are helpful in differentiating pancreatic from salivary and macromolecular hyperamylasemia and may preclude the need for a total amylase measurement.

With improvements in methods and better standardization, a serum lipase measurement is the laboratory test of choice for acute pancreatitis. Turbidimetric assays have been adapted to automated clinical chemistry analyzers for routine and stat determinations. Further improvements in diagnostic efficiencies are obtained with the measurement of amylase and lipase isoforms. Among the markers studied, the P_3 amylase and the L_2 lipase isoforms have the highest clinical specificity for the diagnosis of acute pancreatitis. Whether the increase in clinical efficiency justifies the use of more labor-intensive electrophoretic assays remains to be determined.

The diagnosis of acute pancreatitis can be improved with the use of expert systems or decision algorithms. Rather than using the upper limit of the reference range, a flowchart makes use of higher cutoff values to increased the specificity of individual tests, whereas the use of multiple tests maintains the sensitivity. In the algorithm developed by Panteghini and Pagini (30), two times the upper reference limit for amylase was used as the entry point to the algorithm (Fig. 14.23). The diagnosis of acute pancreatitis required a fivefold increase in lipase. Using this algorithm, a diagnostic accuracy of 95.8% was produced. A neural network for use of pancreatic enzymes was also developed to improve the diagnostic efficiency for acute pancreatitis (31). This neural network produced its own algorithm based on laboratory data and final diagnoses received during the input or “training” phase. During the “test” phase, in which laboratory data but no final diagnoses were inputted, the neural network had an accuracy rate of 84%.

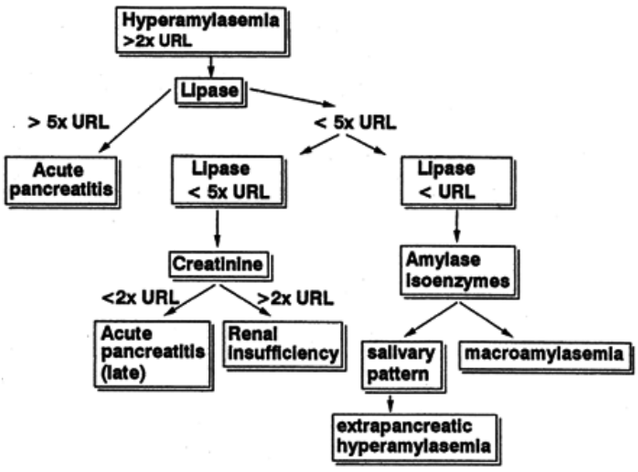

FIGURE 14.23. Algorithm for the diagnosis of acute pancreatitis from extrapancreatic hyperamylasemia, and other nonpancreatic conditions affecting results for amylase and lipase. URL, upper reference limit. (Data from Panteghini M, Pagani F. Clinical evaluation of an algorithm for the interpretation of hyperamylasemia. *Arch Pathol Lab Med* 1991;115:355—358.)

Chronic Pancreatitis

Chronic inflammation of the pancreas can be caused by either recurrent episodes of acute pancreatitis or continual subclinical pancreatic damage occurring over many months. Chronic pancreatitis often presents in patients with a history of acute pancreatitis together with diabetes in adults, and cystic fibrosis in children. Gradual degradation of exocrine function often leads to steatorrhea. Approximately 40% of chronic pancreatitis patients have vitamin B_{12} malabsorption. Examination of fecal fat and administration of the D-xylose tolerance and secretin stimulation tests are useful in determining the presence of these complications. Serum enzyme levels in chronic pancreatitis are less useful than in the acute presentation. Amylase and lipase levels are very often within normal limits and may actually be low during the end stages of the disease because of the small amount of functional pancreatic tissue. Patients with low-grade disease will also not be detectable by enzyme studies. The most useful procedure for diagnosis appears to be endoscopic retrograde choledochopancreatography, which permits direct viewing of pancreatic ducts.

Pancreatic Enzymes in Other Disorders

The optimum use of enzymes for the diagnosis of pancreatitis requires an understanding of other pancreatic and nonpancreatic causes of enzyme release. Several pancreatic injuries and diseases have the potential for releasing enzymes into the blood. These include

pancreatic trauma, abdominal surgery, carcinoma, diabetes mellitus and ketoacidosis, and injury by viruses (such as hepatitis B) and drugs (such as tetracycline, thiazides, and furosemide). Injury to or obstruction of surrounding tissue, such as a perforated ulcer or peritonitis, may also cause compression of the pancreas, resulting in enzyme release. Elevations of amylase, immunoreactive trypsin, and, to a lesser extent, lipase also occur in other nonpancreatic disorders. Because amylase and trypsin are largely cleared by glomerular filtration, high values are seen in patients with renal failure. The existence of parotid lesions and inflammation will produce salivary hyperamylasemia. Amylase isoenzyme measurements can be used to detect this form. Macroamylasemia can also cause high serum amylase values, resulting in a false-positive diagnosis for pancreatitis. Amylase isoenzyme and clearance measurements can be used to detect the presence of this form.

MISCELLANEOUS ENZYMES

Part of "14 - Diagnostic Enzymology and Other Biochemical Markers of Organ Damage"

Acid Phosphatase (EC 3.1.3.2)

The acid phosphatases (orthophosphoric-monoester phosphohydrolase) are a collection of enzymes that catalyze the hydrolysis of phosphate from a variety of natural and synthetic substrates. The optimal pH is on the acid side, usually between 5 and 6. Acid phosphatase is found in the liver, red cells, platelets, bone marrow, and prostate. Several isoenzymes of acid phosphatase can be identified in serum by electrophoresis or IEF. Measurement of acid phosphatase was primarily used for monitoring patients with prostatic cancer. However, with the development of prostate-specific antigen (PSA), assays for acid phosphastase, if used at all, are only used on rare occasions. As such, the reader is referred to the first edition of *Clinical Laboratory Medicine* for details on the enzymatic and immunoassays for acid phosphatase. Discussion of PSA in prostate cancer is discussed in Chapter 26 (Tumor Markers).

Cholinesterase

Analytical Measurement

The cholinesterases are enzymes that hydrolyze acetylcholine. True cholinesterase (acetylcholine acetylhydrolase, EC 3.1.1.7) is found in the red cells, lungs, spleen, and brain. In the serum, however, only pseudocholinesterase [(PCHE) acylcholine acylhydrolase, EC 3.1.1.8] is found. These enzymes differ in their specificity for substrates and sensitivities to inhibitors. Of particular clinical interest is the response of serum cholinesterase genetic variants to inhibition by dibucaine and fluoride.

Serum cholinesterase is measured by monitoring the hydrolysis of acetylthiocholine esters to form thiocholine:

$$\text{acetylthiocholine} + H_2O \xrightarrow{\text{PCHE}} \text{thiocholine} + \text{acetate}$$

The enzyme rate is monitored by reacting thiocholine with a disulfide agent that forms a chromogen after rearrangement and can be measured at 340 nm:

thiocholine + 4,4′-dithiopyridine → → chromogen

Clinical Significance

Serum levels of cholinesterase can be used in three different areas. Low levels of PCHE are found in patients with various forms of liver disease, including acute and chronic hepatitis, cirrhosis, and metastatic liver disease. Nonhepatic disorders, such as AMI, infections, and pulmonary embolism, have also been shown to decrease PCHE levels. Because of the existence of more specific markers for the latter disorders, serum cholinesterase is not used for detecting or monitoring these processes.

The activity of PCHE is also important in monitoring industrial and agricultural workers who use and are exposed to organophosphate insecticides. Commonly used agents such as parathion and malathion inhibit both erythrocyte and serum cholinesterase activity, leading to neurologic and neuromuscular deficits. Levels of these enzymes are useful in determining the extent of exposure to these toxic pesticides.

The third area of clinical application of cholinesterase measurements involves the use of succinylcholine (suxamethonium) as a muscle relaxant in anesthesia. Because of a genetic variant of cholinesterase, there is a substantial difference in the rate of suxamethonium clearance by PCHE in some individuals. Patients who have the atypical cholinesterase gene can experience prolonged apnea (because of extended relaxation of respiratory muscles) after administration of the drug. Recognition of these individuals is important and can be accomplished by measuring serum cholinesterase activity with and without inhibitors such as dibucaine or fluoride. Because atypical PCHE is more resistant to inhibitors than the normal PCHE, measurement of the percentage of inhibition (e.g., the “dibucaine number”) provides a measure of the amount of the atypical enzyme that is present. Normal individuals exhibit 80% to 90% inhibition. Those who are heterozygous for one of the several possible variant genes exhibit 70% to 80% inhibition, and persons with two variant genes exhibit 10% to 30% inhibition. The individuals of the latter group are most prone to breathing complications after administration of suxamethonium.

ACE (EC 3.4.15.1)

Part of "14 - Diagnostic Enzymology and Other Biochemical Markers of Organ Damage"

ACE (peptidyl-dipeptide hydrolase) is produced by the lungs and catalyzes the conversion of the decapeptide angiotensin I to the octapeptide angiotensin II. It is a vital enzyme in the control of aldosterone secretion and regulation of blood pressure. ACE can be measured by the use of synthetic peptide substrates or by immunoassay.

Although ACE is an important step in the renin-aldosterone metabolic pathway, serum measurements of ACE are not useful for studying the etiologies of hypertension. However, it has been found that ACE is elevated in approximately 50% to 80% of cases of sarcoidosis, a multisystem granulomatous disease that most commonly involves the lungs. ACE is useful for differentiation between this disease and other granulomatous disorders and between active and dormant sarcoidosis. Unfortunately, the specificity of ACE measurements is not high because several other conditions can produce elevated activities. These include Gaucher's disease, leprosy, active histoplasmosis, pulmonary embolism, Hodgkin's disease, alcoholic cirrhosis, and chronic hepatitis.

G6PD (EC 1.1.1.49)

Part of "14 - Diagnostic Enzymology and Other Biochemical Markers of Organ Damage"

G6PD is an important erythrocyte enzyme in the hexose monophosphate shunt for the utilization of glucose. The in vivo reaction of G6PD is used in its laboratory analysis:

$$\text{glucose-6-phosphate} + \text{NAD}^+ \xrightarrow{\text{G6PD}} \text{6-phosphogluconate} + \text{NADH}$$

The reaction is monitored at 340 nm by following the production of NADH. Measurements of G6PD are clinically useful for the detection of individuals who are deficient for the X-linked G6PD gene. G6PD deficiency affects black men and whites of Mediterranean descent. These individuals develop varying degrees of hemolytic anemias when exposed to particular drugs, such as sulfa drugs, aspirin, and antimalarial medications.

Lipids and Lipoproteins

György Ábel

Michael Laposata

Lipids, also known as fats, include many different compounds that have limited solubility in water. Phospholipids, triglycerides, glycolipids, and cholesterol esters have fatty acids as major building blocks. Free cholesterol is the one major lipid component that does not have a fatty acid as a component. This chapter begins with a description of the structure and metabolism of fatty acids and then the larger fatty acid containing molecules and cholesterol. The structure and metabolism of lipoproteins and a classification of lipid disorders are also included. The chapter concludes with a discussion of the laboratory measurement of various lipids and lipoproteins and the clinical significance of the most frequently encountered abnormalities.

FATTY ACIDS

Part of "15 - Lipids and Lipoproteins"

The fatty acid molecule shown in Fig. 15.1 is one of the fundamental building blocks of lipids. A long-chain fatty acid is shown with the carboxyl end to the right and the methyl end to the left. The carboxyl end of the molecule combines with other molecules when the fatty acid is esterified within more complex lipids. This figure shows palmitic acid, which has 16 carbons and no double bonds, as indicated by the nomenclature 16:0.

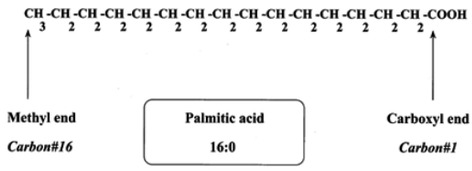

FIGURE 15.1. Molecular structure of a representative fatty acid.

Table 15.1 shows the nomenclature in more detail for several fatty acids. The number to the left of the colon indicates the number of carbon atoms in the fatty acid. The number to the right of the colon indicates the number of double bonds. For example, linoleate Δ18:2 (9,12), also known as linoleic acid, has 18 carbons and two double bonds. The numbers after Δ indicate the locations of the double bonds. In linoleate, there are two double bonds, one between the ninth and tenth carbon and one between the twelfth and thirteenth carbon. As shown in Table 15.1, the five most abundant animal fatty acids are palmitate, stearate, oleate, linoleate, and arachidonate. Many other fatty acids exist in nature.

TABLE 15.1. THE MOST ABUNDANT ANIMAL FATTY ACIDS

Familiar Name	Numerical Nomenclature
Palmitate	16 : 0
Stearate	18 : 0
Oleate	18 : 1 Δ 9
Linoleate	18 : 2 Δ 9, 12
Arachidonate	20 : 4 Δ 5, 8, 11, 14

Fatty acids that have no double bonds, such as palmitate and stearate, are known as saturated fatty acids. Fatty acids like oleate with one double bond are called monounsaturated, and polyunsaturated fatty acids are those with two or more double bonds.

Fatty acids that contain one or more double bonds can be classified as essential or nonessential, and by their omega family. Essential fatty acids are those that must be ingested because humans cannot synthesize them from precursor molecules. Nonessential fatty acids are those that can be synthesized from precursor molecules such as sugars. The designation of the omega family of the fatty acid as (n–x) or (omega–x) is established by counting the number of carbons from the methyl end to the carbon with the nearest double bond. For example, omega-6 fatty acids have the first double-bond six carbons inward from the methyl end. For omega-3 fatty acids, the first double bond from the methyl end is three carbons inward. It should be noted that although fatty acids can be metabolized into other fatty acids, they cannot change families. This means that any modification to the fatty acid does not alter the position of the last double bond.

Fatty acids can also be classified according to the stereochemical configuration of their double bonds as cis or trans. The naturally occurring form of a double bond in a fatty acid is the cis form, with the hydrogen atoms on the same side of the carbon atoms in the double bond (Fig. 15.2). Trans double bonds have the hydrogen atoms on opposite sides of the double bond. Trans fatty acids are present in significant concentration in margarine and have a straight-chain, three-dimensional structure, like saturated fatty acids. This is unlike a fatty acid with a cis double bond because the insertion of a cis double bond produces a bend in the fatty acid molecule resulting in a different three-dimensional

structure. Presumably because of their similar three-dimensional structure, trans fatty acids and saturated fatty acids both elevate serum cholesterol levels.

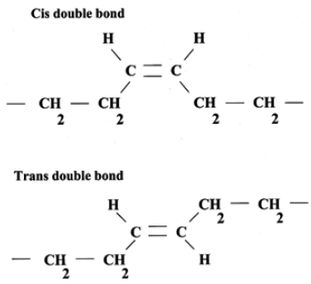

FIGURE 15.2. Stereochemical configuration of cis and trans double bonds. In the cis form, the hydrogen atoms are on the same side of the carbon atoms in the double bond, whereas trans double bonds have the hydrogen atoms on the opposite sides.

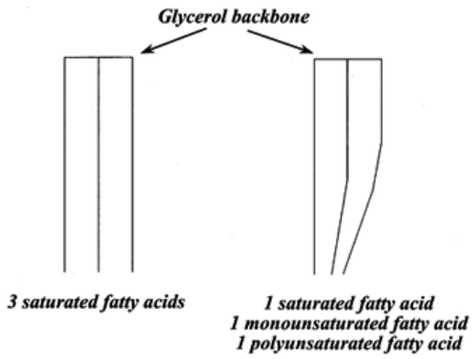

FIGURE 15.3. Structure and composition of triglycerides.

TRIGLYCERIDES

Part of "15 - Lipids and Lipoproteins"

The structure of a triglyceride is shown in Fig. 15.3. A triglyceride is three fatty acids on a glycerol backbone. On the left, a triglyceride molecule is shown with three straight chains of saturated fatty acids. On the right, a triglyceride molecule is shown with one saturated fatty acid in the left position (known as *sn*-1), a monounsaturated fatty acid in the middle (the *sn*-2 position), and a polyunsaturated fatty acid in *sn*-3.

CHOLESTEROL AND CHOLESTEROL ESTERS

Part of "15 - Lipids and Lipoproteins"

Figure 15.4 shows the structure and critical intermediates in the synthesis of cholesterol, another fundamental lipid molecule. Cholesterol contains a sterol nucleus with 27 carbons. It can be synthesized *de novo* from the progressive accumulation of two carbon units and can be ingested by eating dairy products, meat, and some fish. Cholesterol is only present in animals and animal products and cannot be derived from eating plants.

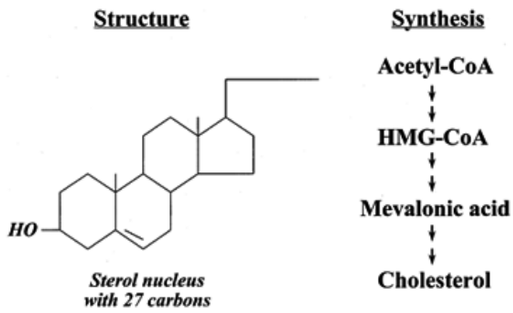

FIGURE 15.4. Molecular structure and biosynthesis of cholesterol.

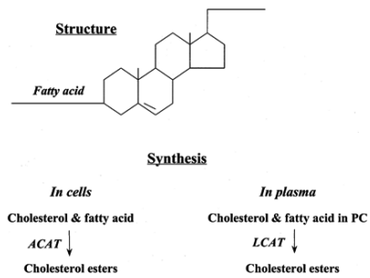

FIGURE 15.5. Structure and biosynthesis of cholesterol esters. ACAT, acyl-CoA cholesterol acyltransferase; LCAT, lecithin cholesterol acyltransferase; PC, phosphatidylcholine

Cholesterol esters are derived from cholesterol by esterification to the third carbon of the cholesterol molecule with a fatty acid (Fig. 15.5). The synthesis of cholesterol in cells is catalyzed by an enzyme, acyl-CoA acyltransferase (ACAT). In the plasma, another enzyme, lecithin cholesterol acyltransferase (LCAT), catalyzes the formation of cholesterol esters from cholesterol and one of the two fatty acids in phosphatidylcholine (PC), also known as lecithin.

PHOSPHOLIPIDS

Part of "15 - Lipids and Lipoproteins"

Phospholipids, like triglycerides, have a glycerol backbone but with only two esterified fatty acids. The third carbon is connected to a polar head group through a phosphate. The most common head groups are choline, ethanolamine, inositol, and serine (Fig. 15.6). There are many others present in much lower amounts. The polar head groups are hydrophilic and therefore water soluble. The water solubility of the head groups and the hydrophobic nature of the apolar fatty acid chains are responsible for the unique membrane-forming feature of phospholipids. It is much more common to have a polyunsaturated or monounsaturated fatty acid in the *sn*-2 position than in the *sn*-1 position.

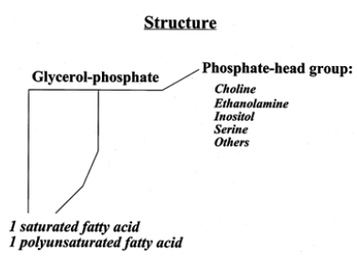

FIGURE 15.6. Structure of phospholipids.

INFLUENCE OF DIETARY FATTY ACID INTAKE ON SERUM CHOLESTEROL CONCENTRATION

Part of "15 - Lipids and Lipoproteins"

There are important clinical issues related to the amount and composition of fatty acids in the diet. Table 15.2 shows the association between serum cholesterol and the ingestion of particular dietary fatty acids. The ingestion of saturated fatty acids, usually contained within triglycerides, with 12 or 14 carbons will elevate the serum cholesterol level. The ingestion of 16:0 fatty acids will also produce an elevation in serum cholesterol. Collectively, the studies suggest that 18:0 fatty acid ingestion is either modestly detrimental or has no effect on the cholesterol level. The ingestion of polyunsaturated fatty acids, such 18:2 or 20:4, generally has a neutral to beneficial effect on the total cholesterol when ingested in modest amounts. Trans fatty acids are detrimental, like saturated fatty acids, and elevate the serum cholesterol concentration.

TABLE 15.2. EFFECT OF THE CHAIN LENGTH AND SATURATION OF DIETARY FATTY ACIDS ON SERUM CHOLESTEROL LEVELS

Fatty Acid	Effect on Serum Cholesterol
12 : 0	Very detrimental
14 : 0	Very detrimental
16 : 0	Detrimental
18 : 0	Modestly detrimental or neutral
20 : 4	Beneficial
Trans fatty acids	Detrimental

Table 15.3 shows the fatty acid composition of a variety of different food fats. Beef tallow, butter, cocoa butter, palm oil, coconut oil, and lard have high concentrations of saturated fatty acid. Coconut oil is particularly dangerous because of its very high concentration of 12:0 and 14:0 fatty acids. Oils with high concentrations of monounsaturated fatty acids include olive oil and canola oil. There are many oils rich in polyunsaturated fatty acids, such as corn oil, cottonseed oil, peanut oil, and soybean oil. Menhaden oil contains fatty acids of the omega-3 family, which have a high number of double bonds. The omega-3 fatty acids have multiple health benefits, which are discussed in a later section. There is some variability between different fish species in the amount of 20:5 n–3 and 22:6 n–3, the major omega-3 fatty acids, which depends in part on where the fish swim (Table 15.4). Fish that swim in cold water have more omega-3 fatty acids than those that swim in warm water.

22:6n-3	8.6	—	—	—	—	—	—	—	—	0.2	—

The numbers refer to the percentage of an individual species of fatty acids relative to total fatty acids in the food fat.

There are many epidemiologic data to support the inverse correlation between fish consumption and mortality from coronary heart disease. An increase in fish consumption results in a decrease in the incidence of heart attack and stroke. Early supporting evidence was provided by the finding that Greenland Eskimos consuming more than 400 g of fish per day have a very low death rate from coronary heart disease. It was subsequently shown in epidemiologic studies that Japanese on the island of Okinawa, who consume twice the amount of fish eaten by the Japanese living on the mainland, have a much lower death rate from coronary heart disease, that Japanese from fishing villages who consume 250 g or more of fish per day have significantly less coronary heart disease than Japanese from farming villages who consume no more than 90 g of fish per day, and that Dutch men consuming more than 30 g of fish per day, or on average two fish meals per week, had 50% lower mortality from coronary heart disease than men who did not eat fish.

LIPOPROTEINS

Part of "15 - Lipids and Lipoproteins"

Figure 15.7 shows the structure of a lipoprotein, with a shell composed of one layer of phospholipids with head groups directed outward, cholesterol, and apolipoproteins, and a core with very hydrophobic triglyceride and cholesterol molecules.

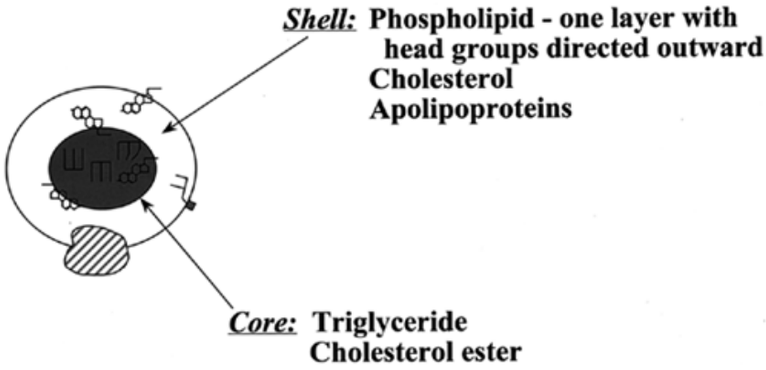

FIGURE 15.7. Schematic structure of a lipoprotein particle.

Lipoproteins are classified into four major groups based on the size of the particle and the content of the core of the lipoprotein (Fig. 15.8). Chylomicrons (CM) are very large lipoproteins formed after ingestion of dietary fat and contain mostly triglyceride in the core. An approximate ratio of triglyceride to cholesterol ester is 20:1. The predominant apolipoprotein in CM is apolipoprotein B. Very low density lipoprotein (VLDL) also has more triglyceride than cholesterol ester in its core, with a ratio of approximately five triglycerides to one cholesterol. There are many apolipoproteins associated with VLDL, with apolipoprotein C and apolipoprotein B predominating. Low-density lipoprotein (LDL) has more cholesterol ester than triglyceride in the core and contains only apolipoprotein B in the shell. High-density lipoprotein (HDL) contains mostly cholesterol ester in the core, and its predominant apolipoproteins are A-I and A-II.

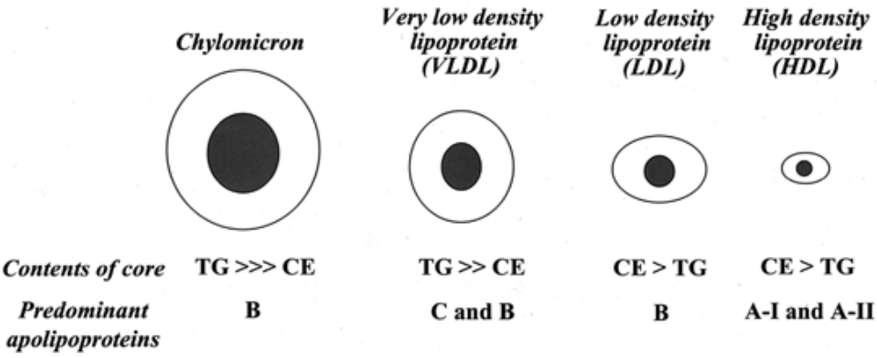

FIGURE 15.8. Comparison of size and composition of the core in the four major classes of lipoproteins. CE, cholesterol ester; TG, triglyceride; Apo, apolipoprotein.

There are multiple subtypes of the apolipoproteins, and each of the lipoprotein classes exists in a continuum of sizes and densities because of differences in the content of the core lipids. In addition, there are many apolipoproteins. Some are related to each other and have the same letter description with different numbering. For example, apolipoproteins A-I to A-IV are primarily present in HDL and CM. Apolipoprotein B-48 is synthesized in the intestines and present in CM, whereas apolipoprotein B-100 is produced by the liver and is present in VLDL, intermediate density lipoprotein (IDL), and LDL. Apoliproteins C-I, C-II, and C-III are synthesized in the liver and a component of CM, VLDL, IDL, and HDL. Apolipoprotein E has three major isoforms noted as apolipoproteins E-2, E-3, and E-4. Apolipoprotein E is produced by the liver and

peripheral tissues, and the isoforms are components of CM, VLDL, IDL and HDL.

Figure 15.9 shows the structure of a unique lipoprotein, lipoprotein (a) [Lp(a)]. This is a LDL-like lipoprotein because the apolipoprotein is apolipoprotein B and the composition of the core resembles that of an LDL particle. It is different from LDL in that apolipoprotein (a) is covalently bound to the apolipoprotein B. The apolipoprotein (a) structure is analogous to plasminogen, a precursor of plasmin, which dissolves clots.

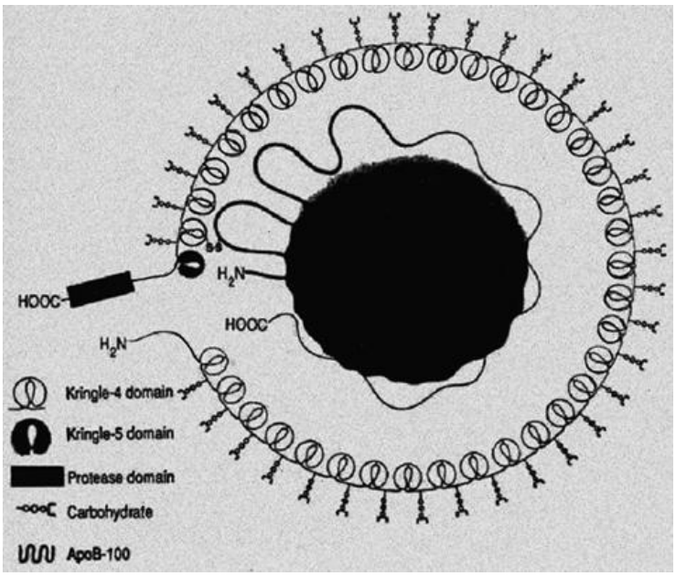

FIGURE 15.9. The unique structure of lipoprotein(a). (From Utermann G. The mysteries of lipoprotein(a). *Science* 1989;246:904–910, with permission.)

It has been demonstrated in multiple studies that an elevated Lip(a) level presents an increased risk for myocardial infarction (MI). The odds ratio for developing a MI for an individual with a Lp(a) level in the top 25% of the values from all individuals and younger than 60 years of age is on the order of two- to fourfold. The Lp(a) concentration is genetically determined and may explain the genetic predisposition to coronary heart disease in some families.

Figure 15.10 shows how LDL is incorporated into cells and the impact of LDL incorporation on cellular metabolism. LDL is shown binding to its receptor. Upon incorporation, the cholesterol in the LDL particle inhibits the synthesis of new cholesterol inside the cell and decreases the synthesis and mobilization of the receptors to the cell surface. This limits further uptake of LDL into the cell and preserves cell function.

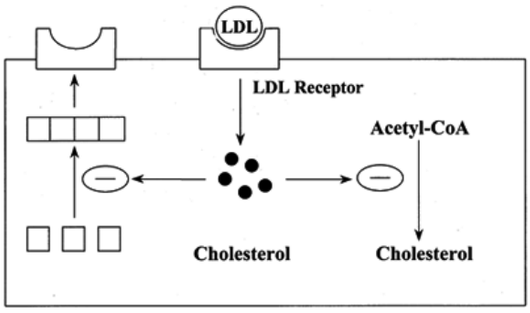

FIGURE 15.10. Low-density lipoprotein (LDL) uptake into cells and its inhibitory effect on cholesterol synthesis and LDL receptor synthesis and recycling.

Figure 15.11 illustrates the consequences of elevated LDL in the plasma, resulting from continued accumulation of LDL and decreased cellular LDL uptake. With a high concentration of LDL in the circulation, some may be oxidized, usually within the blood vessel wall. The oxidized LDL can be ingested by macrophages, which have scavenger receptors rather than LDL receptors. These cells can incorporate large amounts of oxidized LDL and may become “foam cells.”

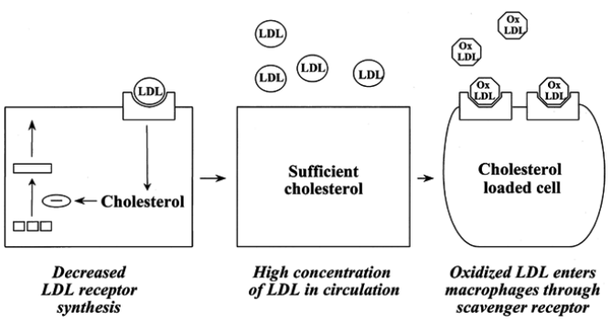

FIGURE 15.11. Pathophysiologic consequences of elevated LDL.

Blood lipid concentrations can be modified by several drugs. When bile acids are secreted into the gut from degradation of cholesterol, bile acid sequestrants bind the acids in the intestine and prevent their reuptake, creating a gradient to promote bile acid secretion into the intestine. The hydroxymethylglutaryl (HMG-CoA) reductase inhibitors (known as the statin drugs) inhibit cholesterol synthesis from precursor molecules by inhibiting the enzyme HMG-CoA reductase that converts HMG-CoA to mevalonate. Nicotinic acid, fibric acid derivatives, and other lipid-lowering drugs work by different mechanisms and alter lipoprotein metabolism in a favorable way.

Figure 15.12 shows what happens to a LDL particle when it is oxidized. At first, it is minimally modified. At this point, it can still bind to the LDL receptor. When it progresses to fully oxidized LDL, binding to the LDL receptor no longer occurs. Native LDL contains apolipoprotein B, a ligand for the LDL receptor. In the

process of oxidation, the polyunsaturated fatty acids in the lipoprotein are oxidized. The oxidized fatty acid breaks into aldehyde fragments, which bind to lysine residues in the apolipoprotein. This biochemical modification prevents the binding of the lipoprotein particle to the LDL receptor. The oxidized LDL is ingested by macrophages by way of the scavenger receptors.

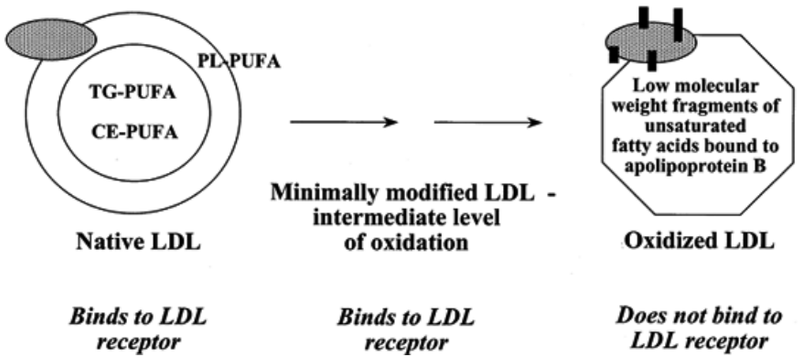

FIGURE 15.12. Effect of minimal and extensive oxidation on the fate of the low-density lipoprotein particle. PL-PUFA, phospholipids containing polyunsaturated fatty acids; TG-PUFA, triglycerides containing polyunsaturated fatty acids.

Figure 15.13 shows excess LDL moving through the circulatory system. It can take a brief detour into the vessel wall, where it can become oxidized. The oxidized LDL then promotes the adhesion of circulating monocytes to the endothelial cells, and then induces them to proliferate and differentiate into macrophages when inside the blood vessel wall. The macrophage then ingests the oxidized LDL and becomes a foam cell. There are a number of cytokines associated with this process. One is platelet-derived growth factor delivered by platelets into the blood vessel wall, which enhances the proliferation of smooth muscle cells. The accumulation of foam cells and smooth muscle cells results in the generation of the atherosclerotic plaque (Fig. 15.14). The fracture of this plaque leads to a thrombotic event, most commonly a MI from ischemia in the coronary arteries or a stroke from plaque rupture in the carotid or cerebral circulation.

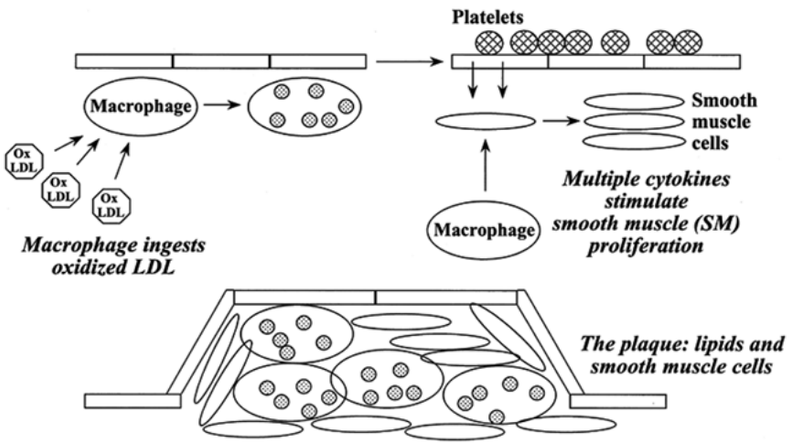

FIGURE 15.14. Mechanism of the formation of the atherosclerotic plaque.

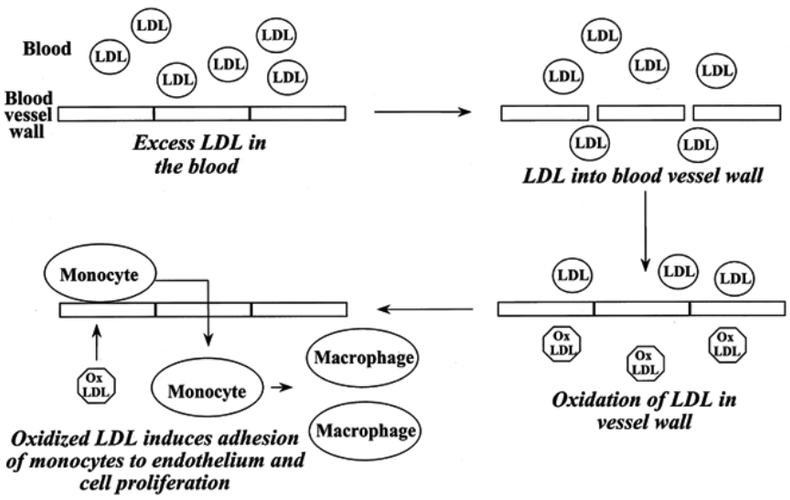

FIGURE 15.13. Events leading to the incorporation of oxidized low-density lipoprotein (LDL) into the blood vessel wall.

FAMILIAL HYPERLIPIDEMIAS

Part of "15 - Lipids and Lipoproteins"

Patients with very high cholesterol levels or other dyslipidemias may have inherited a genetic defect in lipid metabolism. Serum electrophoresis with lipid staining had been widely used for the characterization and classification of hyperlipoproteinemias. Although electrophoresis has been phased out as a diagnostic assay in most laboratories, the classification of hyperlipidemias based on the electrophoretic pattern is still in use. Six different hyperlipoproteinemia patterns have been distinguished based on the electrophoretic pattern. Type I is a severe chylomicronemia secondary to either the absence of lipoprotein lipase of apolipoprotein C-II. Type I hyperlipoproteinemia is indicated by a thick white creamy layer of CM that occupies the upper half of the tube after overnight refrigeration of serum from these patients. Type II hyperlipoproteinemia is characterized by an increase of serum LDL. This abnormality is a result of a genetic defect in lipid or lipoprotein metabolism or secondary to other diseases, such as hypothyroidism, nephrotic syndrome, and diabetes mellitus. Type II is further classified as type IIa and type IIb. In type IIa, only LDL is increased, whereas in type IIb there is an increase in both LDL and VLDL. Refrigerated serum from patients with type IIa lipoproteinemia has a deeper orange color but no significant turbidity. In type IIb, the orange color is combined with moderate turbidity. Type III hyperlipoproteinemia is also called dysbetalipoproteinemia and is characterized by an abnormal accumulation of VLDL that runs in the β region in electrophoresis, unlike the typical VLDL which has pre-β mobility. Many patients with this hyperlipidemia are homozygous for apolipoprotein E-2. The refrigerated serum from type III patients has similar appearance to the serum from type IIb individuals, except that a small creamy layer of CM is also present on the top. The type IV phenotype is characterized by an increase in VLDL. A variety of genetic defects or other diseases are responsible for this disorder. A prominent VLDL (pre-β) band on the electrophoretic pattern is characteristic, and the refrigerated serum is turbid throughout the tube. In type V hyperlipoproteinemia, both VLDL and CM are increased. These patients have defective lipolysis of triglycerides, and usually their lipoprotein lipase level is decreased. Defects in triglyceride metabolism leading to an overproduction of VLDL can occur as a result of excessive alcohol intake, obesity, or diabetes mellitus. The serum pattern shows turbidity throughout the tube with an added layer of CM on the top.

In familial hypercholesterolemia, LDL receptors are defective or deficient. Affected individuals have a cholesterol level on average approximately twice the normal level. Several genetic defects in the synthesis and expression of a LDL receptor have been identified. Patients heterozygous for a defective LDL receptor are prone to premature heart disease with a MI during the fourth or fifth decade. Tendon xanthomas on the dorsum of the hand and the Achilles tendon and corneal arcus are common and important clinical signs of this disorder. The majority of patients with moderate to severe hypercholesterolemia, however, do not have heterozygous abnormality of the LDL receptor. Several genetic factors may be responsible for the condition of these patients. However, the ingestion of too much saturated fat and cholesterol is the most common explanation for the elevation in serum LDL concentration.

LABORATORY MEASUREMENT OF LIPIDS AND LIPOPROTEINS AND THEIR CLINICAL SIGNIFICANCE

Part of "15 - Lipids and Lipoproteins"

In this section, the clinical laboratory aspects of blood lipids are discussed. A more detailed review of the methods is given at the end of this chapter. The total cholesterol value is a quantitation of all the cholesterol and cholesterol esters in all the lipoproteins taken together. HDL cholesterol can be measured in samples from which the LDL and VLDL have been removed by precipitation. The remaining cholesterol and cholesterol esters are in HDL. HDL cholesterol is measured using the same enzymatic reaction as is used for a total cholesterol quantitation. There is an insignificant amount of cholesterol in CM, and it does not influence the total or HDL cholesterol value.

For determination of the calculated LDL cholesterol, the patient must be fasting, because LDL cholesterol is calculated using an equation that includes the triglyceride level, and the serum triglyceride concentration is influenced by recent intake of dietary fat. There are also simple assays for direct LDL measurement that avoid the need to fast. The calculated LDL remains the most popular approach to LDL measurement at present. Unlike LDL cholesterol, the total cholesterol and HDL cholesterol measurements can be made on nonfasting specimens because the dietary intake of lipid is primarily triglyceride rather than cholesterol. Triglycerides are usually ingested in gram amounts, with milligram amounts of ingested cholesterol.

Calculation of LDL cholesterol is performed by subtracting from the total cholesterol the HDL cholesterol level and an approximation of VLDL cholesterol, which is the triglyceride level divided by 5. As noted earlier, in the VLDL particle, there are approximately five triglyceride molecules for every cholesterol molecule (a more detailed description is given later in the LDL cholesteral section of this chapter (p. 319). Triglycerides in excess of 400 mg/dL interfere with the determination of the LDL cholesterol level.

The analytical variability for the typical cholesterol assay in a clinical laboratory is very low, with values on the order of 3% to 5%. Thus, a repeat analysis of the same specimen will give very similar values. Importantly, however, there is a substantial biological variability when a patient is tested on different days. The biological variability ranges from 10% to 20%. Therefore, a person with a cholesterol of approximately 200 mg/dL may, not uncommonly, have values of 180 mg/dL or 220 mg/dL. For this reason, the most accurate assessment of a patient's total cholesterol is established by at least two cholesterol measurements at least 1 week apart.

The measurement of serum or plasma triglycerides is a quantitation of triglyceride in all lipoproteins taken together. This measurement is greatly affected by the ingestion of dietary fat. An accurate measurement of baseline serum triglyceride concentration can only be obtained when the patient has been fasting for 12 to 14 hours.

There are several immunoassays that can be performed for apolipoproteins. There are assays for apolipoprotein B as a measurement of the number of LDL particles; apolipoprotein A concentration reflects HDL levels. These assays have very limited clinical utility. The assay for apolipoprotein (a) as a measure of

Lp(a) is in a state of flux because there is heterogeneity in Lp(a) particles, some of which may be more atherogenic than others, and some assays for Lp(a) measure selected Lp(a) fractions rather than total Lp(a).

The National Cholesterol Education Panel has identified risk factors and developed algorithms for assessment of patients for atherosclerotic vascular disease (Table 15.5 and Table 15.6 and Fig. 15.15, Fig. 15.16 and Fig. 15.17). One risk factor is being a man 45 years or older or a woman 55 years or older in women, or premature menopause not treated with estrogen replacement therapy. Another risk factor is a positive family history of premature coronary heart disease if there is a definite MI or sudden death of the father or other first-degree male relative before the age of 55 years or before the age of 65 of the mother or other female first-degree relative. Cigarette smoking, hypertension with a blood pressure greater than 140/90 mm Hg or treatment with antihypertensives, an HDL cholesterol less than 35 mg/dL, and diabetes mellitus are also risk factors.

TABLE 15.5. RISK FACTORS FOR THE DEVELOPMENT OF ATHEROSCLEROTIC VASCULAR DISEASE

Age (y)
Men ≥45
Women ≥55 or premature menopause without estrogen replacement therapy
Current cigarette smoking
Definite myocardial infarction or sudden death before 55 years of age in father or other male first-degree relative, or before 65 years of age in mother or other female first degree relative
Hypertension
Blood pressure ≥140/90 mm Hg or taking antyhypertensive medication
Low HDL cholesterol
< 35 mg/dl (0.9 mmol/L)
Diabetes mellitus

HDL, high-density lipoprotein.

TABLE 15.6. CLASSIFICATION OF PATIENTS ACCORDING TO THEIR SERUM CHOLESTEROL LEVEL

Total Cholesterol Level	Initial Classification
<200 mg/dl (5.2 mmol/L	Desirable blood cholesterol
200–239 mg/dl (5.2–6.2 mmol/L)	Borderline-high blood cholesterol
≥240 mg/dl (6.2 mmol/L)	High blood cholesterol
<35 mg/dl (0.9 mmol/L)	Low high-density lipoprotein cholesterol

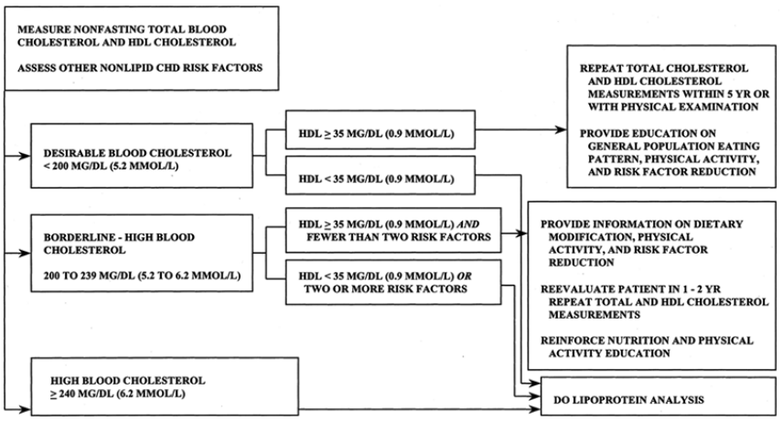

FIGURE 15.15. Algorithm for the initial evaluation of patients who never had a heart attack, stroke, angina, a transient ischemic attack, or peripheral vascular disease. [From Summary of the second report of the National Cholesterol Education Program (NCEP) Expert Panel (NCEP) on detection, evaluation, and treatment of high blood cholesterol in adults (adult treatment panel II). *JAMA* 1993;269:3015–3023, with permission.]

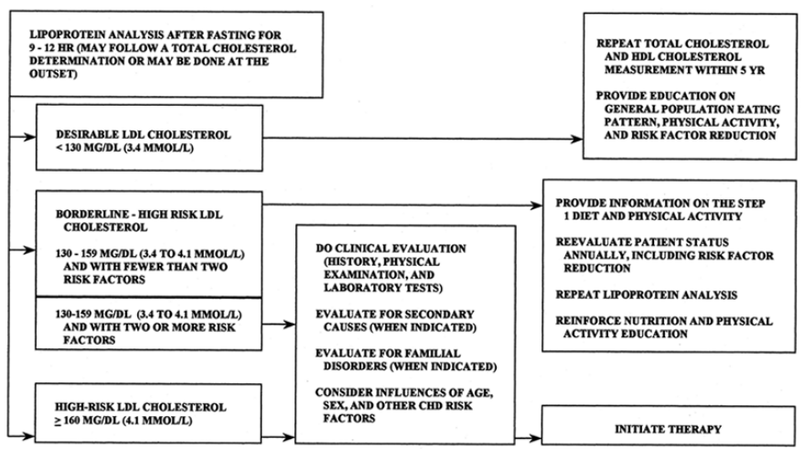

FIGURE 15.16. Algorithm for the assessment of patients without evidence of coronary heart disease. Subsequent classification is based on low-density lipoprotein cholesterol level. [From Summary of the second report of the National Cholesterol Education Program (NCEP) Expert Panel (NCEP) on detection, evaluation, and treatment of high blood cholesterol in adults (adult treatment panel II). *JAMA* 1993;269:3015–3023, with permission.]

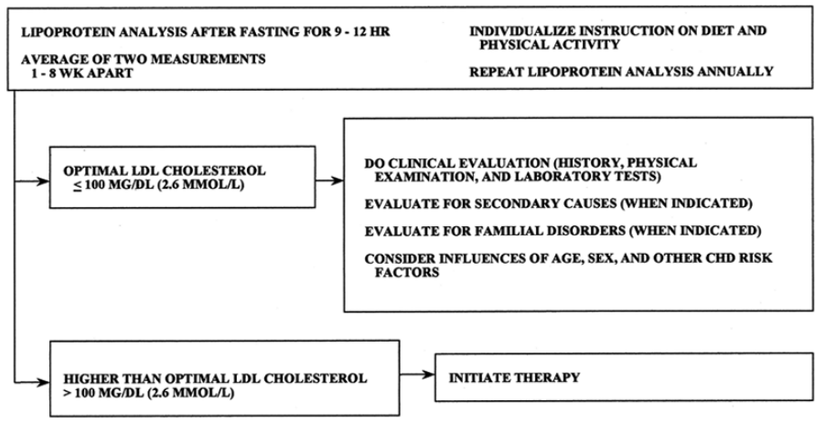

FIGURE 15.17. Algorithm for the laboratory evaluation of patients with existing coronary artery disease. [From Summary of the second report of the National Cholesterol Education Program (NCEP) Expert Panel (NCEP) on detection, evaluation, and treatment of high blood cholesterol in adults (adult treatment panel II). *JAMA* 1993;269:3015–3023, with permission.]

In the initial classification of the patient relative to total cholesterol level, values for total cholesterol less than 200 mg/dL are considered desirable. It should be noted, however, that somewhat lower values than 200 mg/dL are more desirable because they are associated with a lower risk for atherosclerotic vascular disease. Values between 200 and 239 mg/dL are considered borderline. Values in excess of 240 mg/dL are considered to be high blood cholesterol levels. An HDL cholesterol less than 35 mg/dL is considered low (Table 15.6).

There is one option to eliminate a positive risk factor and that is to have an HDL cholesterol level above 60 mg/dL. Thus, a man older than 45 years of age who has elevated HDL cholesterol, usually as a result of exercise or regular moderate alcohol intake, can eliminate the positive risk factor from his age and have a total risk factor value of zero.

Figure 15.15 shows the algorithm used for assessment of patients who have never had a heart attack, a stroke, angina, a transient ischemic attack, or peripheral arterial vascular disease. These patients are first evaluated with nonfasting total blood cholesterol and HDL cholesterol levels. The LDL cholesterol is not initially measured because it requires fasting and may not be necessary. If the total cholesterol is less than 200 mg/dL and the HDL is greater than 35 mg/dL, the patient is in the most favorable category. Conversely, the patient with a total cholesterol less than 200 mg/dL but an HDL less than 35 mg/dL is further evaluated with an LDL cholesterol. Patients with a borderline value for total cholesterol, an HDL greater than 35 mg/dL, and fewer than two risk factors are educated with regard to the benefits of a dietary modification and physical activity. The patient with a borderline total cholesterol value in the presence of an HDL less than 35 mg/dL must be further studied with an LDL cholesterol value. A blood cholesterol alone greater than 240 mg/dL necessitates an LDL cholesterol determination. Figure 15.16 shows the algorithm after LDL cholesterol quantitation. If the patient has an LDL cholesterol less than 130 mg/dL, general education about dietary fat and physical activity should be provided. If the patient has borderline LDL cholesterol of 130 to 159 mg/dL and fewer than two risk factors, the patient should receive information on diet and physical activity. However, a patient in that same LDL cholesterol range with two or more risk factors merits a thorough evaluation for the cause of the elevated lipid levels, searching for secondary causes or familial disorders to explain the lipid abnormality. A patient with an LDL cholesterol level greater than 160 mg/dL should also be thoroughly evaluated to determine the cause of the hyperlipidemia.

For patients with existing coronary heart disease or other evidence of atherosclerotic vascular disease, LDL cholesterol measurements are obtained in each laboratory evaluation (Fig. 15.17). The goal for LDL cholesterol is much lower in patients with existing disease than for those without clinically evident atherosclerotic disease. The desirable LDL cholesterol level in this group of patients is less than 100 mg/dL. Values higher than 100 mg/dL should prompt an evaluation for the cause of the dyslipidemia and possibly the initiation of lipid-lowering therapy.

Table 15.7 provides a guide for treatment decisions based on LDL cholesterol level and risk factors. For patients without clinically evident atherosclerotic disease who have fewer than two risk factors (group 1), dietary therapy should be initiated at an LDL cholesterol greater than 160 mg/dL. For those without coronary heart disease and with two or more risk factors (group 2), the LDL cholesterol target level for dietary modification is much lower at 130 mg/dL. For those with atherosclerotic vascular disease (group 3), this threshold value is 100 mg/dL for initiation of dietary therapy. Group 1 individuals should receive drug therapy to lower the lipid levels when the LDL cholesterol is greater than or equal to 190 mg/dL, group 2 individuals when the LDL cholesterol is greater than or equal to 160 mg/dL, and group 3 individuals when the LDL cholesterol level is greater than or equal to 130 mg/dL.

TABLE 15.7. GUIDE FOR TREATMENT DECISIONS BASED ON LOW-DENSITY LIPOPROTEIN CHOLESTEROL LEVELS AND RISK FACTORS

Patient Category	Initiation Level for Diet	Low-Density Lipoprotein Goal
Without CHD and with fewer than two risk factors (group 1)	≥160 mg/dl (4.1 mmol/L)	<160 mg/dl (4.1 mmol/L)
Without CHD and with two or more risk factors (group 2)	≥130 mg/dl (3.4 mmol/L)	<130 mg/dl (3.4 mmol/L)
With CHD (group 3)	100 mg/dl (2.6 mmol/L)	>100 mg/dl (2.6 mmol/L)
	For Drug Treatment	
Without CHD and with fewer than two risk factors (group 1)	≥190 mg/dl (4.9 mmol/L)	<160 mg/dl (4.1 mmol/L)
Without CHD and with two or more risk factors (group 2)	≥160 mg/dl (4.1 mmol/L)	<130 mg/dl (3.4 mmol/L)
With CHD (group 3)	≥130 mg/dl (3.4 mmol/L)	>100 mg/dl (2.6 mmol/L)

CHD, Coronary heart disease.

The dietary components of the American Heart Association

Step 1 and Step 2 diets are shown on Table 15.8. The essential features of the diets are their total amount of fat, the percentage of saturated fatty acid, and the amount of cholesterol in milligrams. The Step 1 diet requires that less than 30% of the total calories be represented by fat, that the total cholesterol intake per day is less than 300 mg, and that the total saturated fatty acid content is less than 10% of the total calories. The Step 2 diet is increased in intensity from Step 1 by decreasing the saturated fatty acid percentage to 7% of total calories and decreasing the cholesterol intake to less than 200 mg/day.

TABLE 15.8. DIETARY COMPONENTS OF THE AMERICAN HEART ASSOCIATION STEP 1 AND STEP 2 DIETS

Step 1 diet	
Total fat	<30% of total calories
Saturated fatty acids	<10% of total calories
Polyunsaturated fatty acids	Up to 10% of total calories
Monounsaturated fatty acids	10–15% of total calories
Carbohydrates	50–60% of total calories
Protein	10–20% of total calories
Cholesterol	<300 mg/day
Total calories	To achieve and maintain a desirable weight
Step 2 diet	
Total fat	<30% of total calories
Saturated fatty acids	<7% of total calories
Polyunsaturated fatty acids	Up to 10% of total calories
Monounsaturated fatty acids	10–15% of total calories
Carbohydrates	50–60% of total calories
Protein	10–20% of total calories
Cholesterol	<200 mg/day
Total calories	To achieve and maintain a desirable weight

The following sections of this chapter review the laboratory methods for the measurement of clinically important lipids and lipoproteins in the blood.

MEASUREMENT OF TRIGLYCERIDES

Part of "15 - Lipids and Lipoproteins"

In the reference method, triglycerides are first extracted from the serum with chloroform to remove water-soluble interfering substances, such as glucose and glycerol. The extract is then treated with silicic acid to remove phospholipids, and the triglycerides are hydrolyzed with potassium hydroxide (KOH) to produce glycerol and fatty acids. The glycerol is then oxidized to formaldehyde that forms a colored product with chromotropic acid. The resulting product can be measured at 570 nm.

In the more practical routine methods, triglycerides in plasma or serum are measured enzymatically. Reagents are available that contain all enzymes, buffers, and cofactors needed for the assay.

These reagents are optimized to the analytical system of the manufacturer. In all the different reagent kits, the first step is nearly always a lipase-mediated hydrolysis of triglycerides to glycerol and fatty acids:

$$1\ \text{triglyceride} + 3\ H_2O \xrightarrow{\text{lipase}} 1\ \text{glycerol} + 3\ \text{fatty acid}$$

Glycerol is then phosphorylated by glycerokinase to glycerophosphate, using 1-adenosine 5′-triphosphate. In most methods, glycerophosphate is oxidized by glycerophosphate oxidase to dihydroxyacetone and H_2O_2. The latter is then measured by standard methods, such as the blue color reaction resulting from the peroxidase-mediated condensation of *N*-ethyl-*N*-(2-hydroxy-3-sulfopropyl)-3,5-dimethoxy-4-fluoroanaline and 4-aminoantipyrine. Other methods utilize glycerophosphate dehydrogenase and nicotinamide adenine dinucleotide (NAD) to produce dihydroxyacetone phosphate and NADH (nicotinamide adenine dinucleotide, reduced form). NADH is measured by spectrophotometry at 340 nm or in a reaction catalyzed by diaphorase that produces formazan from a tetrazolium dye using NADH. Formazan can be measured at 500 nm. Enzymatic triglyceride methods do not measure phospholipids or sugars and are linear to a concentration of 700 mg/dL. The methods are very suitable for automation. Free glycerol, however, will contribute to the total amount of triglyceride measured. Glycerol concentrations in fresh serum or plasma generally do not exceed 100 mg/dL. Glycerol levels are increased 50- to 100-fold in hyperglycerolemia, a rare disorder associated with a defective or deficient glycerokinase enzyme. Free glycerol can be measured as described in the assay for triglycerides (see previously), with the omission of the initial lipase step.

MEASUREMENT OF CHOLESTEROL

Part of "15 - Lipids and Lipoproteins"

In the reference method, serum cholesterol esters are hydrolyzed by alcoholic KOH. Cholesterol is then extracted by hexane, and the extract is dried. The dry residue is treated with acetic acid, acetic acid anhydride, and sulfuric acid (Lieberman-Burchard reagent) to develop a color reaction that can be measured at 620 nm. The method has a minimal positive bias compared with the definitive method for cholesterol, which is mass spectrometry. The results can be expressed in either molar or mass concentrations:

Cholesterol concentration (mg/dL) = 38.7 × (mmol/L)

Although the reference method is very accurate, it is time-consuming and not suitable for automation. For routine diagnostic purposes, enzymatic methods have been developed. The first step is an enzymatic hydrolysis of cholesterol esters:

$$\text{Cholesterol ester} + H_2O \xrightarrow{\text{cholesterol ester hydrolase}} \text{cholesterol} + \text{fatty acid}$$

The 3-OH group on cholesterol is then oxidized by cholesterol oxidase to a ketone, with the production of H_2O_2 that can be measured in a peroxidase-catalyzed reaction forming a dye. The method is not highly specific for cholesterol. Beta-hydroxy sterols and plant sterols are also reactive, but their concentration in clinical specimens is negligible compared with that of cholesterol. The commercial reagent kits generally combine all enzymes and other required components, and the formulations vary. Manufacturers usually optimize their methods to one or more automated instruments. When a reagent calibrator-instrument system from a single manufacturer is used, cholesterol measurements should be accurate to within 1% to 3% of the reference values.

HDL CHOLESTEROL

Part of "15 - Lipids and Lipoproteins"

Ultracentrifugation to isolate lipoproteins for subsequent quantitation of lipoprotein components, such as cholesterol, has been the gold standard with which other methods are compared. In density gradient ultracentrifugation, HDL exhibit a density range of 1.063 to 1.21 g/mL. They may contain, however, some Lp(a) that has a slightly overlapping density range at 1.04 to 1.08 g/mL. Lp(a) cholesterol at high concentrations adds to the cholesterol of HDL when isolated by ultracentrifugation. For routine clinical purposes, faster and simpler methods are in common use. HDL cholesterol is usually measured in serum or plasma after the precipitation and removal of apolipoprotein B-100 containing lipoproteins, normally VLDL, IDL, LDL, Lp(a), and CM. A polyanion, reacting with the positively charged groups of lipoproteins and divalent cations that facilitate their reaction have been used for the precipitation reaction. Most of these methods use phosphotungstate, or dextran sulfate in combination with $MgCl_2$. In earlier methods, heparin sulfate and $MnCl_2$ had been widely used, but the residual Mn^{2+} ions were found to interfere with the enzymatic cholesterol methods, resulting in falsely elevated values. Thus, most laboratories avoid precipitants that require manganese. In a variation of the dextran sulfate precipitation method, the precipitating agent is coupled to magnetic particles. The lipoprotein-magnetic precipitating reagent can be rapidly removed without centrifugation, using a magnetic disk. HDL cholesterol can then be measured as described previously. Precipitation in samples with high triglyceride concentrations (>400 mg/dL) may be incomplete and result

in significant error in HDL cholesterol measurement. In these cases, the samples should be subjected to ultracentrifugation and the triglyceride-rich lipoproteins should be removed before precipitation.

An automated homogeneous assay uses sulfated α-cyclodextrin and dextran sulfate and $MgCl_2$ to reduce the availability of cholesterol in LDL, VLDL, and CM for the cholesterol esterase and cholesterol oxidase enzymes. The method eliminates the need for the time-consuming precipitation step. In addition, the cholesterol esterase and cholesterol oxidase enzymes are modified by polyethylene glycol. The modified enzymes exhibit selective catalytic activities toward different lipoprotein fraction, with a preference to react with HDL cholesterol. The resulting H_2O_2 is measured in a peroxidase reaction using 4-aminophenazone to form a purple color dye. Another direct HDL-cholesterol method utilizes antihuman lipoprotein antibodies that bind to LDL, VLDL, and CM. The antibody-antigen complexes formed block enzyme reactions with these lipoproteins, and, therefore, cholesterol esterase and cholesterol oxidase react only with HDL cholesterol. Hydrogen peroxide produced by the enzyme reactions is measured in a peroxidase condensation reaction, yielding a blue color complex. By avoiding the precipitation step and centrifugation, this method is also highly suitable for automated analyzers.

LDL CHOLESTEROL

Part of "15 - Lipids and Lipoproteins"

Methods for the measurement of LDL are based on the assumption that total cholesterol is mainly composed of cholesterol found in VLDL, LDL, and HDL. LDL cholesterol can be calculated or measured directly. To calculate LDL cholesterol, serum or plasma triglyceride, total cholesterol, and HDL cholesterol are determined, and the LDL cholesterol calculated using the equation formulated by Friedewald:

(LDL cholesterol) = (Total cholesterol) - (HDL cholesterol) - (Triglyceride)/5

when concentrations are expressed in milligrams per deciliters. Triglyceride/2.22 should be used if the results are expressed in millimoles per liter. Triglyceride/5 is an estimate of VLDL cholesterol based on the empirically established average ratio of triglyceride to cholesterol in VLDL. The Friedewald equation can be used in most cases to determine LDL cholesterol, but it should not be used for samples with triglyceride concentrations greater than 400 mg/dL. These samples usually also contain CM and CM remnants in which the triglyceride:cholesterol ratios are higher than in VLDL. A different error may occur in patients with type III hyperlipoproteinemia because of the presence of beta-VLDL. Beta-VLDL, which normally does not occur in the blood, contains significantly more cholesterol than normal VLDL and has a triglyceride:cholesterol ratio of only 3:1. Thus, using the Friedewald equation, VLDL cholesterol would be underestimated in these patients. This would also result in an overestimation of the LDL cholesterol.

LDL cholesterol also can be measured directly. The direct assays typically utilize precipitating antibodies specific for apolipoproteins in VLDL, IDL, and HDL. The concentration of LDL cholesterol is measured directly in the supernatant. In a variation of this method, the antibodies are coupled to latex. The antibodies on the beads bind VLDL and HDL, and the complexes are removed by centrifugal filtration. The bead-free filtrate ideally contains only the LDL. The concentration of LDL cholesterol is measured in the solution using an enzymatic method. In other methods, LDL is precipitated with polyvinyl sulfate or heparan sulfate. In these assays, LDL cholesterol in the precipitate is calculated as the difference between the total cholesterol concentration and the cholesterol in the supernatant. Most studies indicate that direct methods are useful and clinically accurate for the measurement of LDL cholesterol concentration, but further validation of some of these assays is needed. An additional limitation of the precipitation methods is that they cannot be used on frozen plasma or serum.

SEPARATION OF LIPOPROTEINS WITH CHOLESTEROL DETERMINATION OF ISOLATED FRACTIONS

Part of "15 - Lipids and Lipoproteins"

Total lipoprotein concentrations can be measured directly using nuclear magnetic resonance spectroscopy. This technique measures the chemical shifts of the methyl and methylene groups of fatty acids in lipoproteins from the VLDL, LDL, and HDL fractions. The results can be converted to lipoprotein cholesterol concentrations using the assumed ratios of cholesterol content in each lipoprotein class. The method is fast but requires expensive instrumentation and considerable user experience.

Ultracentrifugation in vertical rotors using density gradients and measurement of cholesterol in the fractions is another method for the measurement of total lipoprotein concentrations. This method also requires specialized instrumentation and is time-consuming and not suitable for automatization.

Gradient gel electrophoresis has also been used for the fractionation of lipoproteins. Gradient gel electrophoresis provides a better resolution than traditional agarose electrophoresis. The gels can be scanned and the areas under the peaks can be integrated. The cholesterol concentrations can be calculated using the assumed cholesterol content of each lipoprotein fraction. Insufficient resolution of the different fractions has been a major limitation of this method.

These methods have not been validated to the same degree as the ultracentrifugation-polyanion precipitation technique and the Friedewald calculation. Additional studies are required before these newer methods gain wide acceptance.

ISOLATION AND QUANTITATION OF LIPOPROTEINS

Part of "15 - Lipids and Lipoproteins"

Several methods are available to separate lipoproteins for quantitative analysis. HDL can be isolated and cholesterol can be determined using the dextran-sulfate-$MgCl_2$ or the heparin-$MnCl_2$ methods. These methods are similar to the reference methods used for HDL cholesterol measurement (refer to section on HDL cholesterol). Ultracentrifugation can be used to separate CM, VLDL, and beta-VLDL from plasma. After centrifugation

at 105,000*g* for at least 18 hours, a floating white layer composed of triglyceride-rich lipoproteins is separated. A water-clear zone precedes a colored zone near the bottom of the tube, containing lipoproteins with a density greater than 1.06 g/mL. The remaining, denser plasma proteins are located at the bottom of the tube. Lp(a) has a mobility similar to that of VLDL. Using a tube slicer and a syringe equipped with a blunt-end needle, the top and bottom lipoprotein layers can be separated and their respective cholesterol content determined.

Lipoprotein electrophoresis, now considered outdated, had been widely used. The method typically uses agarose as the separation medium. Plasma and the two main ultracentrifuge fractions can be analyzed. CM, the largest, slowest particles, remain at the origin. LDL (beta-lipoprotein) is the fastest fraction; it migrates with the ß-globulins. VLDL (pre-ß-lipoprotein) migrates with the pre-ß-globulins, whereas HDL (α-lipoprotein) with the α-globulins. Lp(a), when present in detectable amounts, migrates with VLDL.

LDL and HDL subclasses can be separated by gradient gel electrophoresis or analyzed by nuclear magnetic resonance. Although still somewhat controversial, these methods allow the identification and quantitation of the more atherogenic, small, dense LDL fraction and the various HDL fractions, which appear to have different antiatherogenic potency.

APOLIPOPROTEINS

Part of "15 - Lipids and Lipoproteins"

Apolipoproteins are measured by various immunoassays, including enzyme-linked immunoassay (ELISA), radioimmunoassay (RIA), immunonephelometry, immunoturbidimetry, and radial immunodiffusion.

Apolipoproteins A-I and B-100 are present in relatively higher concentrations and can be conveniently measured by immunoturbidimetry or immunonephelometry. Most laboratories in the United States use one of these two methods for measuring apolipoproteins A-I and B-100. Radioimmunoassay and radial immunodiffusion have not been extensively used because of the inconvenience of handling radioactive material and the relative imprecision, respectively. Apolipoprotein A-I is smaller and more soluble in water than B; there are fewer technical problems with the measurement of this apoplipoprotein A-I. Apolipoprotein A-I is present as the major protein constituent of HDL. Apolipoprotein A-I is also present, albeit in much smaller amount, in CM. In general, apolipoprotein A-I levels are parallel with the HDL levels. Apolipoprotein B-100 is present in LDL, IDL, VLDL, and Lp(a), the particles of which are considerably different in size and composition. Antibodies that are used for the measurement of apolipoprotein B-100 should equally recognize this apolipoprotein in the different lipoprotein classes. Nonionic detergents, such as Tween-80 or Tween-20, have been used to disrupt the various lipoprotein particles and unmask all antigenic determinants of the apoprotein molecules and make them available for the antibodies. The antibodies should be able to react with their respective epitope, regardless of which class was its source.

Because apolipoproteins C-I and C-II are present at lower concentrations, the more sensitive ELISA and RIA are the preferred methods for their measurement.

Lp(a) is similar to LDL in both lipid composition and the presence of lipoprotein B-100. However, it contains an additional apolipoprotein, apolipoprotein(a), which is covalently linked to apolipoprotein B-100 by a single disulfide bond and likely responsible for the characteristics attributed to the Lp(a) particle. The apolipoprotein(a)–to–B-100 ratio is approximately 1:1. Apolipoprotein(a) features a repetitive structure similar to that of plasminogen; therefore, the development of a reliable immunoassay is very difficult. Thus, there is no accepted reference method for apolipoprotein(a) at present. Monoclonal antibodies have been used for developing enzyme immunoassays. Oxidative modification of Lp(a) and removal of carbohydrate moieties have been attempted to increase specificity. In addition, sandwich assays have also been developed using anti-apolipoprotein(a) and anti-apolipoprotein-B antibodies. Because the expression of epitopes in apolipoprotein B in LDL and Lp(a) are different, the apolipoprotein-B antibodies used in this assay should be carefully selected and characterized.

SUMMARY

Part of "15 - Lipids and Lipoproteins"

This chapter reviews the structure of lipids and lipoproteins, the participation of these entities in the development of atherosclerosis, the use of lipid and lipoprotein test results in the management of patients with and without atherosclerotic vascular disease, and the clinical laboratory methods for the measurement of clinically important lipids and lipoproteins.

DEDICATION

Part of "15 - Lipids and Lipoproteins"

This work is dedicated to the memory of the first author's father, Aladír Ábel, M.D. (1927–1999), former head physician of the Clinical Laboratories, Railway Hospital, Szolnok, Hungary.

Endocrine Function and Carbohydrates

Bruce F. Bower

Robert E. Moore

Hormones are a group of diverse biomolecules that are carried by the circulation and interact with specific cells and receptors to produce a precise cellular response. These hormones may be of low molecular weight such as steroids or thyronines or they can be more structurally complex peptides such as thyroid-stimulating hormone (TSH) and growth hormone (GH). Each hormone is under the influence of stimulatory and inhibitory factors that act to provide the exquisite control of biological processes the hallmark of endocrine systems.

Recognizing the extremes in molecular size, it is not difficult to anticipate a similar extreme in physical and chemical characteristics. Because the circulation is essentially a water-based system, the insolubility of organic compounds with their extensive ring structures has been overcome by binding these small molecules to large soluble proteins called binding or transport proteins. This serves several purposes. First, the secreting cells have few limitations in terms of distance from target tissue. Second, this stabilizes the concentration of circulating hormone and is a reserve of inactive hormone that can be readily converted to the active form. The active hormone is usually an unbound or free form that is in equilibrium with the bound form. This relationship between bound and unbound hormone is under biological control. In other words, the concentration of free hormone can be rigorously controlled independent of the concentration of bound hormone.

In the case of peptides, which are generally soluble and have sufficient size to make instantaneous synthesis and secretion improbable, the existence of hormone precursors or prohormones provides the hormone reserve. In this instance, the peptide is synthesized in a form that has little, if any, biological or pharmacologic activity. The precursor hormone is stored and can subsequently undergo enzymatic alteration to be converted to the active peptide. An example of this mechanism is the conversion of proinsulin to insulin. Proinsulin has very little (approximately 10% of insulin) pharmacologic activity, but after a small peptide segment, called C-peptide, has been cleaved, the insulin portion is 100% active. Analogous to the bound-unbound state of small hormones, the active-inactive form of proteins and peptides gives rise to a point of control.

Endocrine control mechanisms take several forms. Feedback control is one of these mechanisms. Depending on the nature of the response of the controlled hormone in relation to the controlling hormone, this process is referred to as either positive or negative feedback. When the secretion of the controlled hormone is stimulated by the increased concentration of a different hormone, the effect is called positive feedback. A common example of this type of control is the observed increase in LH concentration after the increased concentration of estrogens in the late follicular phase of the menstrual cycle. This is an example of positive feedback.

Negative feedback operates in the opposite manner from positive feedback. A hormone under the influence of a stimulatory or releasing hormone will increase in concentration until it is high enough to cause the secretion of that releasing hormone to diminish or stop. Pituitary TSH will stimulate the thyroid gland to secrete thyroid hormone until the concentration of active thyroid hormone reaches physiologic levels. Then the thyroid hormone will inhibit further release of TSH from the pituitary. *In vivo*, this inhibition process can be more complex than a straight linear relationship between the two hormones. Sometimes other hormones do the actual inhibition. In the case of thyrotropin (TSH) secretion, triiodothyronine (T_3) inhibits TSH in the thyrotrope, although the thyroxine (T_4) level in the circulation correlates better with the TSH level. This is the result of an intracellular conversion of T_4 to T_3 and T_3 is the potent inhibitor.

The sequences of events that comprise the feedback system are termed loops. If the hormone acts directly on the cells secreting the hormone either itself or its releasing hormone, then the process is called a short-loop feedback system. However, if the hormone acts on the target tissue and a second hormone is released that returns through the circulation to inhibit the original hormone or its releasing hormone, the process is called long-loop feedback. These feedback loops are illustrated in Fig. 16.1.

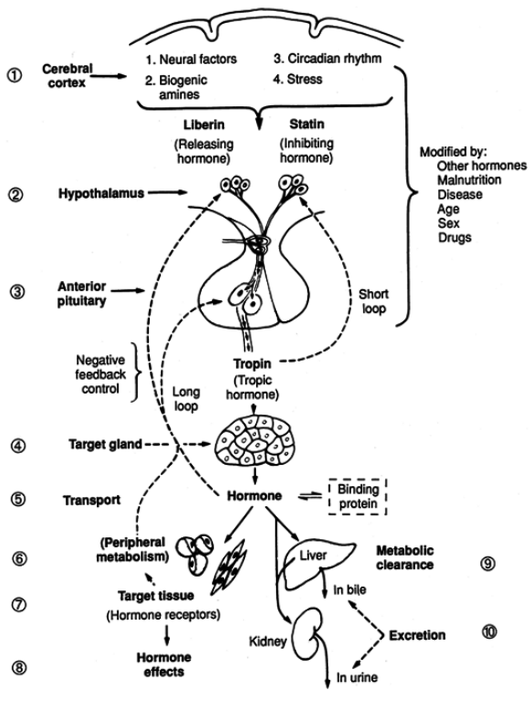

FIGURE 16.1. Stimulation, production, control, and metabolism of hormones. (1) Stimulation of the cerebral cortex resulting in (2) stimulation of the hypothalamus to release tropic hormones from the anterior pituitary (3). The hormone circulates to a target gland (4), where a second hormone can be produced. This hormone is bound to transport or binding proteins (5) and can undergo peripheral metabolism (6) or bind to receptors in target tissues (7), which results in the specific hormone effect (8). Hormones can then be cleared metabolically (9) or excreted from the system (10). If the tropin acts on the hypothalamus, this is an example of the short-loop feedback, whereas if the hormone or peripheral metabolic products circulate to act on the hypothalamus, the control is termed long-loop negative feedback. (From Gornall AG, Luxton AW. Endocrine disorders. In: Gornall AG, ed. *Applied biochemistry of clinical disorders*, 2nd ed. Philadelphia: Lippincott, 1986, with permission.)

A common and diagnostically useful characteristic of hormones is rhythmicity. Hormones are generally secreted on a periodic cycle that is referred to as circadian if the cycle is approximately 24 hours. Cycles shorter are called ultradian, and those that are longer are referred to as infradian. In addition to these cyclic secretions, there are pulsatile releases of hormones triggered by neurologic, environmental, or biochemical events. These secretion patterns can be evaluated and sometimes initiated

by the clinician under carefully controlled conditions to elucidate the underlying pathology. Often the observation that the natural rhythm of secretion has been lost is enough to direct the diagnostic workup.

The preceding description is concerned with normal physiologic events. One abnormal condition is ectopic hormone production. Ectopic production describes a disorder in which a hormone is being produced at a site or by a tissue not normally associated with the production of that hormone. These tissues are generally neoplastic and can produce hormones that can be biologically and structurally identical to, or variants of, normal hormones.

Endocrinology addresses the various clinical disorders that arise from circulating hormone concentration excesses or deficiencies, regulatory system failures, extraneous sources of hormone production, molecular variants, and receptor abnormalities. The clinical laboratory plays a crucial support role in the evaluation of the patient. The laboratory must be aware of the possible approaches to measuring hormones, their metabolites, and receptor function so a clear understanding of the biological processes can be deduced by the clinician. In the following sections, the biochemistry, physiology, laboratory measurement, and clinical interpretation of the more commonly encountered endocrine disorders are reviewed.

RECEPTORS

Part of "16 - Endocrine Function and Carbohydrates"

The circulating concentration of hormones is in the range of 10^{-7} to 10^{-12} M, and of the organs and tissues these hormones come into contact with, only a few are hormonally responsive. The mechanism of hormonal sensitivity and specificity is attributed to receptors. Receptors are cell-associated proteins that are unique in their ability to bind selected molecules, then translate that binding into subsequent cellular processes. These receptors can be located in the cellular membrane where the binding sites are on the external surface of the cell, with the remainder of the protein extending through the membrane to the cytosolic surface. These receptors are referred to as plasma membrane receptors. Plasma membrane receptors move about within the confines of the cellular membrane and interact with molecules that are unable to diffuse through the membrane. Other receptors are intracellular and bind with hormones that are able to diffuse through the plasma membrane. Binding to the intracellular receptor

allows the hormone to be translocated to the nucleus. To regulate cell function, all the elements, hormone, receptors, and the receptor-hormone complex must become activated. Receptors bind other molecules in addition to the specific hormone. The binding of these cross-reacting molecules will result in little or no physiologic response. Molecules that bind and have some activity are referred to as agonists, whereas those that bind and prevent or inhibit hormone activity are referred to as antagonists.

The physical binding of hormones to receptors is dependent on several types of weak chemical forces. These are ionic bonds, hydrogen bonds, van der Waals forces, and hydrophobic-hydrophilic repulsion. Because these forces act over relatively short molecular distances, it is not surprising that there is a stereochemical requirement to maximize the strength of binding. The better the fit between the receptor and its hormone, the greater the affinity of the hormone–receptor complex.

Experimental evidence indicates that cells contain “spare receptors,” i.e., more receptors than are required for maximal cellular response (1). Hormone-receptor binding follows the laws of mass action. Therefore, extra receptors allow the cell to be responsive to lower concentrations of hormone than if the number of receptors were limited. All the cellular receptors are functional and equivalent. At times when hormone concentration is high, these spare receptors bind hormone, but because the cell is already at maximum stimulation, no additional effect is produced. At other times when hormone concentrations are low, small changes in hormone concentration will be effective, because only a small percentage of total available receptors must be occupied to cause maximum stimulation. This is also a point of control. By regulating the number of receptors available, the cell can vary its sensitivity to the circulating concentration of hormone. This phenomenon of reducing receptors on the cell surface when hormone concentrations are high and increasing them when concentrations are low is referred to as downregulation in the first case and upregulation in the latter. The ability of cells to respond to hormone concentrations in this manner may explain the efficacy of pulsatile secretion of some hormones. In pulsatile secretion, hormone is released in short bursts over a period of time. If the receptor population on a cell were fixed, then cellular sensitivity to hormone concentration would be fixed. That is, at some critical concentration the cell would have a maximum response. Higher concentrations would not increase the response and lower concentrations might not evoke a sufficient response. By the cell modulating the receptor concentration, a maximum sensitivity is maintained without a requirement for high hormone levels. One of the unique characteristics of endocrine systems is the graded response. Another process by which the cell can control receptor-binding sites on the membrane surface is to remove the entire hormone–receptor complex. After receptor-hormone binding has taken place, the complex can be removed from the cell membrane and degraded inside the cell with either recycling of the receptor or degradation of the receptor and ligand. This internalization of hormone–receptor complexes renders them inactive and reduces the number of receptors available on the cell wall (2). Not all the mechanisms of hormone–receptor deactivation have been worked out, and there is probably more than one mechanism involved. It is thought that some of the changes in receptor number and function on cell surfaces are owing to the normal turnover of receptor protein. This description of hormone–membrane receptor interactions is generic, and each of the hormone types, e.g., steroids, thyroid hormones, peptides, and catecholamines, alters cellular function in a slightly different manner.

Steroid and thyroid hormones circulate bound to much larger proteins and are in equilibrium with a very low concentration of free hormone. Because of the hydrophobic nature of these hormones, they are able to penetrate the lipid membrane of the cell by simple diffusion. After hormone binding to a cytosolic receptor and translocation to the nucleus, there is a conformational change that permits the activated hormone–receptor complex to bind to a specific region on DNA to initiate new mRNA and ultimately new protein synthesis (3). Figure 16.2 illustrates this process.

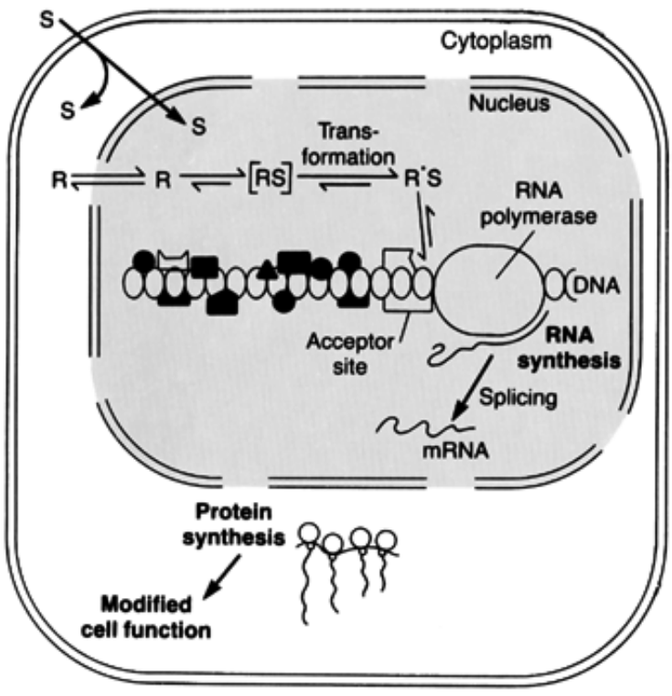

FIGURE 16.2. Steroid hormone initiation of protein synthesis. Steroid diffuses into the cell through diffusion or active transport mechanism and binds with a receptor in the nucleus to form a steroid–receptor complex. This activated complex then activates DNA, which in turn activates the RNA synthesis to eventually lead to protein synthesis and cellular response. S, steroid; R, receptor; RS, steroid-receptor complex. (From Walters MR. Steroid hormone receptors and the nucleus. *Endocrinol Rev* 1985;6:512, with permission.)

Large peptides, amine hormones, and sensory stimuli use a different mechanism for transmembrane signaling (4). There are at least three elements on or in the cell membrane that interact to affect cellular function (3,5). The first is the externally oriented receptor-binding site that binds the peptide or amine hormone (5). The second is a group of heterotrimeric guanine-nucleotide-binding proteins called G proteins. The third element is made up of the numerous effector systems that regulate cellular activity. The process starts with the binding of a hormone to a receptor and forming a receptor–hormone complex. This activated receptor–hormone complex is able to move about in the lipid bilayer of the cellular membrane and couple with a G protein. G proteins act as intramembrane signal transducers that activate cellular effectors. These protein complexes are composed

of three subunits: α, ß, and γ (5). Recent information indicates there are genes for a minimum of 16 α subunits, five ß subunits and 11 γ subunits (6). The possible combinations of heterotrimere may be more than 1,000 (6). In the inactive state the α, subunit binds a molecule of guanosine diphosphate (GDP). Immediately after binding with the activated receptor complex, the G protein exchanges a guanosine triphosphate (GTP) for the GDP and the G protein α subunit; in addition, GTP dissociates from the βγ subunit complex (7). Both the α-GTP complex and ß-γ complex can activate effector proteins (7). An activated receptor is capable of activating multiple G proteins and, in turn, the activated G protein GTP or βγ subunit can activate multiple effectors. This series of events is responsible for the amplification effect of some hormones (8). The effector protein can be an enzyme such as adenylate cyclase or phospholipase C, or it can be an ion channel regulator. This process continues until the GTP on the subunit is dephosphorylated back to GDP and the α subunit combines with the ß-γ subunit generating an inactive G protein. If the effector were adenylate cyclase, the generation of cyclic AMP would halt, and the intracellular level of cyclic AMP would be reduced by cyclic AMP phosphodiesterase. The hormone effect on the cell is terminated. Other cyclic nucleotides may be generated by analogous systems. There are other G proteins that inhibit effector proteins, giving the cell both stimulatory and inhibitory pathways activated by hormone binding to receptors (6,9).

Cyclic AMP has been referred to as a second messenger because it is the intracellular agent responsible for the direct alteration of cellular function (10). However, other intracellular ions and molecules qualify as second messengers, ionic calcium (Ca^{2+}) is an example (11). The intracellular free calcium concentration is very rigidly controlled through a series of transport processes or binding to intracellular structures (11). An important binding protein for intracellular calcium is calmodulin. The calcium–calmodulin complex represents another activated complex that can stimulate intracellular enzymes.

Calcium ion can be released in the cell through the action of a membrane-bound phosphodiesterase (phospholipase C), which generates the second messengers inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG) (4,11). IP_3 can liberate calcium from bound stores within the cell. DAG and the released calcium can activate protein kinase C, which will ultimately phosphorylate proteins. These phosphorylated proteins, generally enzymes, can either activate or inhibit further cellular processes.

Larger molecules such as insulin and epidermal growth factor (EGF) bind to the extracellular domain of a transmembrane spanning receptor, which is linked through a transmembrane sequence to an intracellular enzymatic domain often possessing tyrosine and serine kinase activity (12). Autophosphorylation of the enzymatic site leads to serine and tyrosine phosphorylation of a variety of intracellular proteins, including enzymes, which results in intracellular response.

There is an additional small group of hormones that appear to affect phosphorylation through kinases without the aid of a second messenger (10). Insulin and EGF activate receptor-localized tyrosine kinases that phosphorylate tyrosine residues on a variety of intracellular enzymes after hormone-receptor binding on the cell surface. This receptor complex spans the cell membrane, with the receptor-binding site presented to the external environment and the tyrosine kinase on the inside of the cell.

The awareness of specific tissue receptors is clinically relevant. Hormone abnormalities can arise from failures in hormone production and from failure caused by receptor abnormalities.

HYPOTHALAMIC-PITUITARY AXIS

Part of "16 - Endocrine Function and Carbohydrates"

The hypothalamic-pituitary axis can be thought of as an integrated neuroendocrine transducer in which central neural input, neuropeptide release, and both positive and negative long-loop systemic hormonal feedback regulate the production and secretion of no fewer than six anterior pituitary hormones (13). The control of anterior pituitary function by hypothalamic peptide–releasing hormones is mediated via the hypophyseal portal vascular plexus, which links the hypothalamus and the hypothalamic-releasing peptides with their corresponding anterior pituitary hormones. Table 16.1 lists these releasing peptides and their associated pituitary hormones. These central stimulating effects are modified by feedback loops from the peripheral endocrine glands in which a product hormone is secreted—adrenal gland: cortisol; thyroid: T_4 and T_3; ovary and testis: estrogen, testosterone, and the gonadal peptide inhibin; and GH: somatomedin C/insulinlike growth factor 1 (SM-C/IGF-1).

TABLE 16.1. RELEASING PEPTIDES AND HORMONES

Hypothalamic Releasing Peptides	Associated Hormone
Growth hormone–releasing hormone	Growth hormone
Somatostatin	Growth hormone
Thyrotropin-releasing hormone	Thyrotropin
Gonadotropin-releasing hormone	Follicle stimulating hormone and luteinizing hormone
Corticotropin-releasing hormone	Corticotropin

Growth hormone releasing hormone and somatostatin peptides regulate pituitary growth hormone secretion; thyrotropin releasing hormone regulates pituitary thyrotropin secretion; gonadotropin (luteinizing hormone) releasing hormone regulates both pituitary follicle-stimulating hormone and luteinizing hormone; corticotropin-releasing hormone regulates corticotropin.

An essential feature of the hypothalamic-pituitary axis is episodic secretion of hypothalamic hormones with resultant episodic secretion of pituitary hormones. Pulsatile secretion is defined by pulse, frequency, pulse amplitude, and resultant quantity of the hormone secreted. Episodic secretion complicates endocrine analysis by introducing temporal variations in the serum concentration of pituitary hormone but appears necessary to avoid downregulation of the hormone receptors through which these peptides exert their biological influence. An additional complexity is the marked diurnal variations in pituitary peptide secretion, particularly of corticotropin (ACTH) and GH, in which sleep-related nocturnal secretion predominates with resultant high early-morning values and much lower late-afternoon and evening values. Documentation of the loss of this physiologic diurnal variation may be useful clinically and requires appropriate morning and evening reference intervals for hormones such as ACTH and cortisol.

ANTERIOR PITUITARY

Part of "16 - Endocrine Function and Carbohydrates"

The pituitary gland (hypophysis) weighs approximately 0.5 g and is located in the sella turcica, a depression of the sphenoid bone. The anterior pituitary or adenohypophysis develops from ectodermal cells of the central nervous system and neuroectodermal cells from the neural crest, to eventually comprise 75% to 80% of the total pituitary mass. The anterior pituitary is further subdivided into a pars tuberalis and a pars distalis, the latter containing the cells that synthesize and secrete all the anterior pituitary hormones. The major anatomical features of the pituitary are shown in Fig. 16.3.

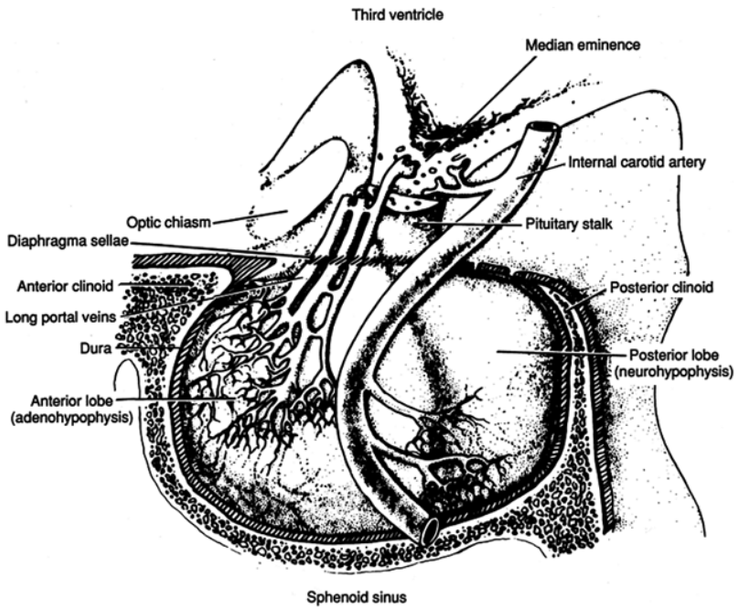

FIGURE 16.3. Major anatomical features of the pituitary gland. (From Frohman LA. *Diseases of the anterior pituitary. Endocrinology and metabolism*. New York: McGraw-Hill, 1981:151–231, with permission.)

The hypothalamus is connected to the pituitary through the pituitary stalk. Blood and hormones from the hypothalamus communicate with the anterior pituitary through the portal venous plexus. The venous circulation of the brain and the pituitary is illustrated in Fig. 16.4.

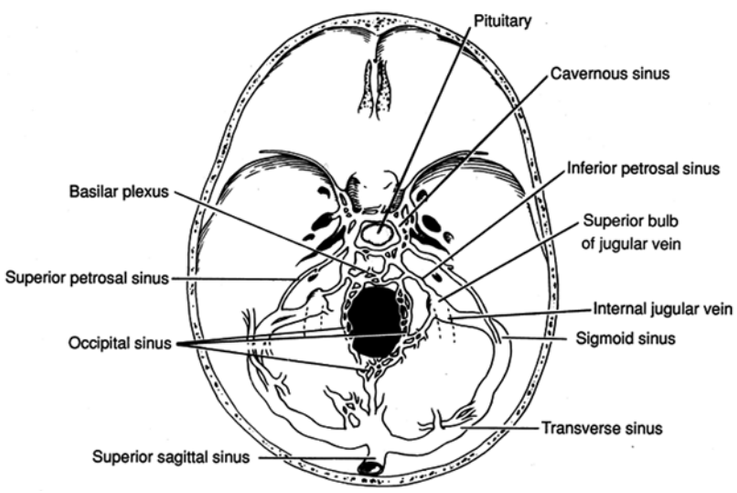

FIGURE 16.4. Venous system of the pituitary gland communicating with the systemic circulation. (From Findling JW, Aron DC, Tyrrell JB, et al. Selective venous sampling for ACTH in Cushing's syndrome: differentiation between Cushing's disease and the ectopic ACTH syndrome. *Ann Intern Med* 1981;94:647–652, with permission.)

Growth Hormone

GH, a single-chain peptide composed of 191 amino acids, is the most abundant of the anterior pituitary hormones. It is released in a pulsatile manner from the somatotropic cells and is under the direct control of two other hormones, growth hormone–releasing hormone (GHRH), which stimulates GH secretion, and somatostatin (SS), which inhibits secretion (14). GHRH and SS are controlled and secreted into the hypophyseal portal circulation by the neuropeptide cells of the hypothalamus.

The association of GH with skeletal growth has been recognized for some time. However, GH is not a true growth factor because its effect on growth is mediated through the somatomedins, a group of peptides synthesized by liver and cartilage.

SM-C, also referred to as IGF-1, is one of these somatomedins and is a true cellular growth factor acting on skeletal components to produce linear growth.

There is a general rhythmicity to the secretion of GH, with the greatest secretion taking place during deep sleep. However, this circadian character has superimposed on it evoked responses to physiologic and biochemical stresses.

Growth Hormone–Releasing Hormone

GHRH is a small peptide, present in three molecular forms having 37, 40, and 44 amino acids. All three of these molecular forms have a biologically active segment in the first 29 amino acids of the sequence. The two larger forms of GHRH are more potent than the smaller form in the human. It has been suggested that the different forms arise from a posttranslational enzyme cleavage. The active GHRH reaches the pituitary by way of the portal circulation.

Somatostatin

Somatostatin was actually observed before GHRH when an extract of hypothalamus was noted to inhibit the release of GH. Occurring as a 28-amino acid precursor that is enzymatically cleaved to the biologically active 14-amino acid form, somatostatin has an inhibitory effect on several hormones in addition to GH, including insulin, glucagon, foregut peptides, and thyrotropin. GH inhibition is considered to take place at the pituitary by the binding of somatostatin to membrane receptors, which causes both a decrease in cyclic AMP concentration and a reduction in cyclic AMP effect. Somatostatin also inhibits human TSH at the pituitary level, as well as several other hormones throughout the body.

GH Abnormalities

GH Excess

Excess GH is the cause for two pathologic conditions, each of which is associated with a particular age group. In children, excess GH leads to giantism, whereas in adults it produces acromegaly. The acromegalic has a distinctive physical appearance associated with acral growth of flat bones and large, broad features such as hands, feet, and nose. Additional facial characteristics are impressive supraorbital ridges and prognathism. The skin of these individuals is thick and oily, and physical examination will reveal enlarged organs. Laboratory findings supporting the diagnosis include an elevated and nonsuppressible serum GH and an elevated serum SM-C/IGF-1. The most convenient method to demonstrate GH nonsuppressibility is glucose administration. This is usually accomplished by giving an oral glucose load of 1.75 g/kg, to as much as 100 g, and then measuring GH levels at 30-minute intervals for as long as 2 hours. Table 16.2 lists the more common stimulation and suppression tests and their expected reference intervals.

TABLE 16.2. GROWTH HORMONE REFERENCE INTERVALS

Condition	Preparation	Collection Time	Results	Increased Levels	Decreased Levels
Normal	Fasting	Early AM		Giantism, acromegaly, ectopic secretion, stress, exercise, prolonged fasting	Growth hormone deficiency Hypopituitarism Adrenal cortical hyperfunction
Child			1–10 µg/L		
Adult					
Female			< 10 µg/L		
Male			<2 µg/L		
L-Dopa	500 mg adult	0, 30, 60, 90, 120	10 µg/L or		No response if glucose 120 mg/dl; poor response in hypopituitarism
stimulation	10 mg/kg child	180 min	5 µg/L above baseline		
Arginine	Child 0.5 g/kg	0, 30, 60 min	Fasting <5 µg/L		Hypopituitarism
stimulation	Adult 30 g/kg 30 min		Peak 10 µg/L at 30–60 min		no response
Insulin	0.1 U/kg adult	0, 15, 30, 45, 60	10 µg/L or		Poor response in hypopituitarism, hypothyroidism
stimulation	0.05 U/kg child IV	90 min	5 µg/L above baseline Glucose level ≤50% of baseline		
Exercise (vigorous)	20 min		5 µg/L		
Glucose suppression	75 g or 1.75 g/kg after fast	0, 30, 60, 90, 120 min	Decrease to <5 µg/L	None to poor suppression in acromegaly, giantism, and ectopic secretion	

GH Deficiency

GH deficiency is primarily a problem of children before they have reached normal stature. Children with short stature with decreased growth velocity who are not malnourished or genetically predisposed to short stature and who have no underlying systemic illness should be suspected for GH deficiency. Serum SM-C/IGF-1 provides a useful screening technique. Insulin-induced hypoglycemia (insulin tolerance test), arginine administration (arginine tolerance test) with blood samples drawn over a 60- to 90-minute period, and stimulation with α agonists such as dopamine and clonidine, will provide sufficient information to confirm the diagnosis. The GH should peak at levels greater than 10 mg/L in normally responsive individuals.

A literature consensus of reference values for provocative testing is summarized in Table 16.2. Although normal reference intervals are listed for fasting specimens, it is generally agreed that single random specimens for GH are neither cost-effective nor diagnostically informative.

Prolactin

Prolactin (hPrL) is a 198-amino acid protein with an approximate molecular weight of 22 kd. hPrL can occur as polymers, with the dimeric form being approximately 40 to 50 kd and a much larger form with a molecular weight in excess of 100 kd. The dimeric form is usually referred to as big hPrL, whereas the much larger aggregate is referred to as big big hPrL. When the polymeric forms are present in the circulation, they generally

constitute less than 2% of the total hPrL. In addition to being present in low concentration, these polymeric forms are significantly less active biologically and pharmacologically and do not seem to represent serious pathologic conditions.

Monomeric hPrL is secreted from the anterior pituitary and enters the general circulation. Inhibitory control of hPrL is accomplished by the neurotransmitter dopamine. Dopamine secretion is initiated by stimulation of the neurons in the median eminence in response to high concentrations of hPrL in either the general circulation or the hypophyseal portal circulation. Although dopamine is capable of suppressing the secretion of hPrL, it does not appear that dopamine concentrations are sufficient to be the only control mechanism, and it is speculated there may be other inhibitory factors. In any event, hPrL appears to be the only anterior pituitary hormone without a long-loop feedback control.

hPrL secretion is stimulated by thyrotropin-releasing hormone (TRH) and perhaps some other hPrL-releasing factor. In addition to the biochemical stimulation, hPrL secretion can be initiated by suckling, whereby stimulation of the nipple through the sucking process causes a neuroreflex of the spinal cord to the neurosecretory cells of the hypothalamus. It is thought that TRH stimulates hPrL secretion at the pituitary level, whereas drugs such as levodopa and insulin (as well as stress) stimulate at the level of the hypothalamus. Secretion of hPrL is episodic, and concentrations are generally increased during the sleep period, with the highest concentrations occurring just at the time of awakening.

Lactation

Breast development through puberty requires the presence of estrogen and progesterone in conjunction with GH, adrenal steroids, and hPrL. Although estrogen and progesterone are the most important steroids for development, all these seem to be necessary but not sufficient conditions for breast development. Development is only partial until pregnancy, at which time ducts and acini mature, but the process of lactation is inhibited. Through pregnancy, placental lactogen, estrogen, progesterone, and hPrL increase dramatically, and the breast development is completed. The roles of hPrL and placental lactogen during this time are unclear.

After parturition, estrogen and progesterone concentrations decrease and hPrL concentration remains high, stimulating the synthesis of enzymes as well as initiating milk secretion. If at weaning, hPrL concentrations decrease and milk secretion will slowly taper off and cease. It is evident from this process that hPrL is the primary hormone of lactation. Suckling, in addition to stimulating hPrL secretion, stimulates an increase in the concentration of oxytocin. Oxytocin causes constriction of the tissue around the acini, forcing the milk into the primary collection ducts. During this feeding cycle, hPrL concentration increases, with peak levels being attained between 30 and 60 minutes. The ultimate concentration is dependent on the length and intensity of the suckling taking place. This elevated concentration of hPrL then causes the synthesis of milk components that will be available for the next feeding.

Gonadotropin-releasing hormone (GnRH), inhibited by the lactation process, is responsible for depressed levels of LH and follicle-stimulating hormone (FSH), and this is probably the reason there is a contraceptive effect associated with lactation. Nonlactating women will resume normal menses with normal levels of gonadotropins two to three times sooner than women who continue to lactate after delivery.

Hyperprolactinemia

There are multiple etiologies of hyperprolactinemia, with hPrL-secreting adenomas being among the most common pituitary neoplasms (15). However, drugs such as estrogens, some anti-hypertensives, phenothiazines, tricyclic antidepressants, metoclo-pramide,

and methyldopa can all cause an increase in hPrL concentration. Hypothyroidism, renal insufficiency, and the natural states of pregnancy and lactation are also reasons for increased hPrL secretion. In cases of prolactinoma, GnRH secretion is inhibited by the elevated hPrL, which leads to inhibition of ovulation and amenorrhea. In women, the most common prolactinoma is the microadenoma measuring less than 1 cm in diameter. Microadenomas are generally slow growing and can be monitored with periodic measurement of the hPrL level, provided the patient is willing to accept the consequences of elevated hPrL such as galactorrhea and amenorrhea. In the case of macroadenoma (i.e., lesions in excess of 1 cm in diameter), the lesion is generally less common, more aggressive, associated with much higher levels of hPrL and may produce neuroanatomical symptoms such as headache and visual impairment.

Laboratory Results

Commercial immunoassays for hPrL are available that use chemiluminescent, enzymatic, fluorescent, or radioactive labels with only the radioactive methods falling into disfavor. Therefore, the choice of methodology should be the one that is the most familiar and compatible to the laboratory work flow. The patient should fast for 12 hours and should not be taking phenothiazines, estrogens, monoamine oxidase, tricyclic antidepressants, antihypertensives, or methyldopa. In addition, hypothyroidism should be ruled out and if that cannot be done with certainty by history and physical examination, then a concomitant sample for TSH analysis should be drawn. The preferred specimen is serum, which should be drawn into an appropriate container and placed immediately in the cold to clot. Blood specimens should be drawn before physical examination of the breast as breast manipulation can elevate serum hPrL concentrations. After clotting is complete, the specimen should be centrifuged in a refrigerated centrifuge, the serum separated from the cells, and the serum frozen if it is not to be processed immediately. If the specimen is to be analyzed within 4 to 6 hours, refrigeration until time of assay is acceptable. Storage for longer periods requires freezing. Reference intervals for normal as well as some selected clinical situations are given in Table 16.3.

TABLE 16.3. PROLACTIN REFERENCE INTERVALS

Condition	Patient Preparation	Specimen Collection	Results (µg/L)
Normal	Fasting 12 h	Serum early AM collection	
Male		Chilled	9.5–16.1
Female		Process in cold	12.4–18.1
Pregnancy	Same	Same	
1st trimester			<80
2nd trimester			<160
3rd trimester			<400

GONADOTROPINS

Part of "16 - Endocrine Function and Carbohydrates"

FSH and LH

LH and FSH are synthesized and released from gonadotrophs located in the anterior pituitary in response to the stimulatory effect GnRH [sometimes called LH-releasing hormone (LHRH)]. Biologically active GnRH is a decapeptide that is derived from a much larger, biologically less active propeptide of approximately 70 amino acids. The active GnRH is secreted by neurons in the median eminence, where it enters the capillaries and is carried to the anterior pituitary through the hypophysial portal system. GnRH is secreted in a pulsatile fashion and seems to be sensitive to the circulating level of estrogen in women and testosterone in men. It has been demonstrated that GnRH is synthesized early in the development of the fetus and stimulates the secretion of LH and FSH until peak concentrations are reached at approximately 20 weeks of gestation. Then from the 20th week to birth, LH and FSH, along with testosterone, decline in concentration to the levels normally associated with the newborn.

LH and FSH are glycoproteins composed of two subunits referred to as the α and ß subunits. This polypeptide character is shared with two other hormones, human chorionic gonadotropin (hCG) and TSH. The α subunit of these four hormones is identical, and experiments have shown that dissociation of the α and ß subunits and recombination of the α subunit of any one of the four hormones to a ß subunit of another hormone, will produce the hormonal activity associated with the hormone of the original ß subunit. The α subunit is a necessary component for hormone binding to receptor sites, but specificity and hormone effect are conferred by the ß subunit. In addition, these four hormones show considerable homology in the structure of the ß subunit. This was a serious problem in the early immunoassays, in which antibodies could not distinguish between hCG and LH and even had some cross-reactivity with FSH and TSH. Today, with the advent of monoclonal antibodies and a better knowledge of the structure of these ß subunits, it is possible to construct assays that are very specific and very sensitive for the individual hormones. Table 16.4 lists one set of reference

intervals for men and women. Other reference values may be found, depending on the assay and the calibrators used.

TABLE 16.4. GONADOTROPIN (LUTEINIZING HORMONE/FOLLICLE-STIMULATING HORMONE) REFERENCE INTERVALS

Condition	Patient Preparation	Collection Time	LH Results (IU/L)	FSH Results (IU/L)
Normal				
Male Female	Serum (refrigerate)	Random specimen acceptable	1–8	1–7
Follicular phase	Same	Same	1–12	1–10
Ovulatory peak			15–105	6–26
Luteal phase			1–12	1–10
Postmenopausal			15–70	30–120

LH, luteinizing hormone; FSH, follicle-stimulating hormone.

The glycoprotein character of these hormones is the result of several carbohydrate residues, of which sialic acid seems to be the most important. The sialic acid content is variable and appears to be influenced by the endocrine environment at the time of synthesis. Sialic acid residues are protective of the gonadotropin, and as the sialic acid content increases, there is an extension in the half-life and biological activity of the particular gonadotropin.

Once LH and FSH have been secreted from the gonadotrophs, they are carried through the general circulation to the gonads. In the female, FSH stimulates follicle development and receptors for LH binding, whereas LH stimulates follicular production of estradiol, ovulation, and formation of the corpus luteum. In men, FSH stimulates Sertoli cell development and LH induces testosterone secretion. It is these hormones from the gonads that can feed back through the long-loop system and control the GnRH and the gonadotropin secretion.

One of the first symptoms of pituitary insufficiency can be gonadal failure. The most direct approach to ruling out primary gonadal insufficiency from pituitary insufficiency is a direct measurement of the pituitary gonadotropins. If the pituitary hormones are depressed, that is highly suggestive of pituitary insufficiency. If, conversely, the circulating levels of LH and FSH are high, pituitary deficiency can be ruled out. In Klinefelter's syndrome, a disorder of sexual differentiation, it is common to measure elevated pituitary gonadotropins and depressed testosterone. In some individuals, this picture can be altered by the finding of a normal testosterone level. This problem arises because the assay measures total circulating testosterone, which includes the very large bound fraction. The biologically active fraction, or free testosterone, is low and can only be determined by an assay that measures free testosterone in the presence of bound testosterone.

Laboratory Methods

In the measurement of LH and FSH, as in many other polypeptides, there is no special patient preparation required. That is, fasting is not an absolute requirement because most immunoassays are tolerant of mild lipemia. Fresh serum specimens are preferred because they are the least troublesome to the laboratory, but plasma is certainly an acceptable specimen. As mentioned previously, current assays are able to measure specifically any of the glycoproteins in the presence of the others, and therefore cross-reactivity and sensitivity are no longer measurement problems. In making measurements of specimens derived from

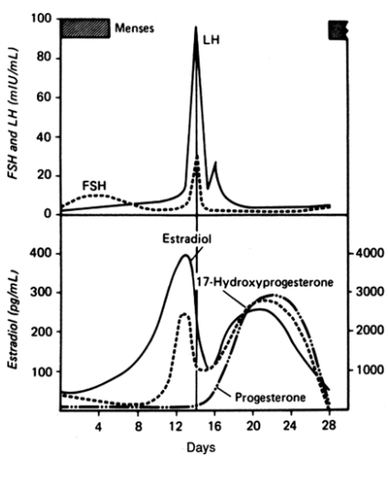

FIGURE 16.5. The cyclic secretion of gonadotropins and sex steroids during the normal 28-day menstrual cycle. Note that the estradiol and 17-hydroxyprogesterone peak precedes the mid-cycle surge of the gonadotropins luteinizing hormone and follicle-stimulating hormone. After the mid-cycle gonadotropin peak, there is a second peak of 17-hydroxyprogesterone and progesterone, which decreases to baseline levels when the cycle begins again. (From Ode WD, Moyer DL. *Physiology of reproduction*. St. Louis: Mosby, 1971, with permission.)

female patients, the most critical piece of information, with the exception of the actual level, is the menstrual status of the woman. As Fig. 16.5 demonstrates, the LH and FSH concentrations vary considerably throughout the menstrual cycle. It is imperative that the physician have access to accurate menstrual information when interpreting gonadotropin results.

POSTERIOR PITUITARY

Part of "16 - Endocrine Function and Carbohydrates"

Physiology

Antidiuretic hormone [(ADH), vasopressin] is secreted from hypothalamic neurons of the supraoptic nuclei and transported to the posterior pituitary by axoplasmic flow. From these storage sites, it is released into the systemic circulation in response to osmotic and volume stimuli and circulates to the kidney. At the renal tubule level, the effect of ADH is to increase water permeability of the distal tubule collecting duct, permitting water resorption resulting in concentration of the final urine. The osmoreceptors responsible for ADH release are located in the anterior hypothalamus near the supraoptic nuclei and are responsive to small changes in extracellular tonicity.

A physiologic set point for ADH secretion exists at an approximate plasma osmolality of 280 mOsm/kg. Below this set point ADH secretion is suppressed. ADH secretion rises rapidly above this set point, with maximal ADH levels achieved at extracellular tonicities of approximately 300 mOsm/kg, at which point thirst and water seeking are also stimulated in an integrated fashion. The threshold and sensitivity for ADH secretion vary among individuals and are increased by hypovolemia and hypercalcemia, as well as by many drugs, including lithium and carbamazepine. The threshold is lowered by hypervolemia, glucocorticoids, alcohol, and opiates.

ADH secretion is also altered by isosmotic changes in extracellular volume. Decreases in volume amplify the ADH release to any given osmotic stimulus, and increased volume suppresses ADH secretion in a similar manner. Nausea, pain, and many drugs such as narcotics are also potent nonosmotic stimulators of ADH secretion.

Clinical Disorders

Diabetes Insipidus

Defects in ADH secretion (central) or renal tubular action (nephrogenic) result in chronic polyuria, polydipsia, and thirst. In addition, functional suppression of ADH occurs with chronic psychogenic water drinking, producing a similar clinical picture (16). Central diabetes insipidus can result from a variety of hypothalamic etiologies, including trauma, various neoplasms, and granulomatous and infectious disorders. A heritable familial autosomal dominant central disorder is also described. In a significant percentage of patients with central diabetes insipidus, no specific etiology can be determined and the patients are labeled idiopathic.

Nephrogenic diabetes insipidus can occur as a result of renal parenchymal disorders such as amyloidosis, polycystic renal disease, and sickle cell disease, as well as after relief of urinary tract obstruction. Drugs such as lithium, demeclocycline, and methoxyflurane can also produce nephrogenic diabetes insipidus. A familial X-linked recessive disorder is also recognized (17).

The diagnosis of diabetes insipidus and the differentiation between central and nephrogenic etiologies is achieved by a structured dehydration test. In short, the procedure requires the determination of baseline values for body weight, serum and urine osmolality, and serum electrolytes. Fluid is withheld, and body weight and urine osmolality are monitored to assess the adequacy of the dehydration stimulus. The end point is achieved when there has been a 3% to 5% decrease in body weight. In patients with central diabetes insipidus despite an adequate dehydration stimulus, there is a failure to achieve urine osmolalities greater than the serum osmolality in the presence of low plasma ADH levels. Confirmation of the diagnosis is achieved by the administration of an ADH analog, such as desamino-D-arginine vasopressin (DDAVP), which produces a urine concentration increase of 50% over the preadministration value. This demonstration of the renal tubule to respond to ADH confirms the failure to secret ADH as the etiology of the diabetes insipidus. In patients with nephrogenic diabetes insipidus, there is an inability to concentrate urine to an osmolality greater than serum osmolality and there is an insufficient response after administration of an ADH analog. Patients with excessive water drinking (primary polydipsia) have an acquired defect in urinary concentration attributable to a physiologic resistance to ADH owing to the high volume of water intake and the reduced medullary tonicity. Consequently, urine concentration during dehydration may be submaximal but will exceed 300 mOsm/kg with no further increase in urine osmolality after exogenous ADH or DDAVP administration. More prolonged fluid restriction or therapeutic ADH administration restores full urine-concentrating ability.

Primary Hypodipsia

In some patients with or without coexistent central diabetes insipidus, defects in thirst perception owing to destruction of hypothalamic osmoreceptors are also present. These defects lead to an inappropriate thirst response to dehydration and at times striking asymptomatic hypernatremia and hyperosmolality. Other causes of hypernatremia, including inadequate fluid intake secondary to coma or physical restraints preventing access to fluids, should be excluded. Plasma ADH levels are usually appropriate for the degree of osmolality unless diabetes insipidus is also present. Table 16.5 lists some common plasma and urine laboratory results for polyuria.

TABLE 16.5. URINE OSMOLALITY FOR DIABETES INSIPIDUS OF DIFFERENT ORIGINS AND POLYDIPSIA

	Neurogenic Diabetes Insipidus	Nephrogenic Diabetes Insipidus	Psychogenic Polydipsia
Random plasma osmolality	↑	↑	↓
Random urine osmolality	↓	↓	↓
Urine osmolality during mild water deprivation	No change	No change	↑
Urine osmolality during nicotine or hypertonic saline	No change	No change	↑
Urine osmolality after vasopressin intravenously	↑	No change	↑
Plasma vasopressin	Low	Normal or high	Low

From Greenspan PS. *Basic endocrinology*, 3rd ed. Norwalk, CT: Appleton & Lange, 1991, with permission.

Syndrome of Inappropriate Secretion of ADH

The continued secretion of ADH despite appropriate serum osmolality and continued unrestricted water intake, results in dilutional hypoosmolality and hyponatremia, inappropriately increased urinary osmolality, and increased urinary sodium excretion (18). Many etiologies may be responsible. Ectopic production of ADH by nonendocrine carcinoma, several acute and chronic pulmonary conditions, and a variety of intracranial disorders

are the most common etiologies. The diagnosis is established clinically by documenting hyponatremia and hypoosmolality in the setting of normal extracellular volume. Spurious hyponatremia secondary to hyperglycemia, dysproteinemia, and hyperlipemia should be excluded, as well as hypothyroidism and hypoadrenalism, which can impair renal free water excretion. (18).

THYROID

Part of "16 - Endocrine Function and Carbohydrates"

Thyroid Physiology

Iodide is concentrated by the thyroid gland, organified into tyrosine units on thyroglobulin, and stored in colloid-containing thyroid follicles until secretion. The metabolism of iodine is shown in Fig. 16.6. Synthesis and secretion of T_4 and T_3 is controlled by pituitary TSH secretion through classic negative feedback regulation in combination with the stimulatory effects of hypothalamic TRH. Serum T_3 arises both from direct thyroid gland secretion (15%) and from peripheral monodeiodination of the outer tyrosine ring of T_4 (85%). The synthesis and control of thyroid hormones is diagrammed in Fig. 16.7. A biologically inactive reverse T_3 (RT_3) also arises from peripheral monodeiodination of the inner tyrosine ring of T_4.

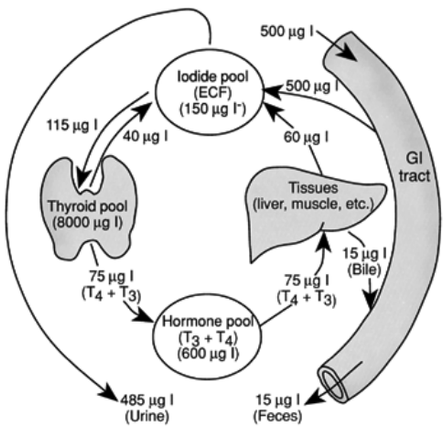

FIGURE 16.6. Daily iodine adsorption, synthesis and excretion in a healthy subject. (From Greenspan FS, Rapoport B. Thyroid gland. In: Greenspan FS, ed. *Basic and clinical endocrinology*, 3rd ed. Norwalk, CT: Appleton & Lange, 1991:188–246, with permission.)

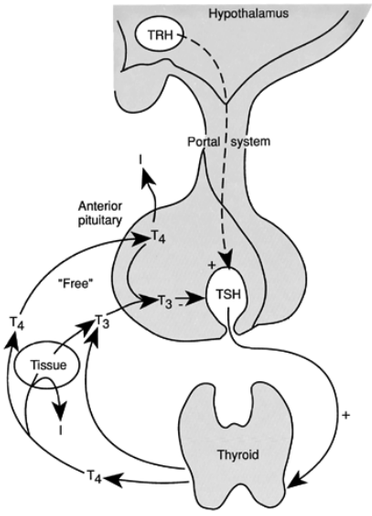

FIGURE 16.7. The hypothalamic-hypophyseal-thyroid axis in the production of thyroid hormones. Pathways marked with a | indicate inhibition, whereas those with a + indicate stimulation. I indicates deiodination of the parent thyroxine molecule to produce triiodothyronine. (From Greenspan FS, Rapoport B. Thyroid gland. In: Greenspan FS, ed. *Basic and clinical endocrinology*, 3rd ed. Norwalk, CT: Appleton & Lange, 1991:188–246, with permission.)

Thyroid Transport

Circulating T_3 and T_4 are bound to a variety of thyroid transport proteins, including thyroid-binding globulin (TBG), thyroid binding prealbumin, and albumin. Only approximately 0.03% of T_4 and 0.3% of T_3 are “free” and hence biologically active. It is the excess or deficiency of the free T_4 fractions that determines hyperthyroidism and hypothyroidism. Because many drugs and disease states affect the concentrations of the thyroid transport proteins, it is important that thyroid function studies distinguish between elevations or depressions of the bound or total concentration, and changes in the free fraction of T_4 and T_3 (19).

The most common abnormalities in thyroid hormone studies are related to the widespread use of oral estrogens for contraception and postmenopausal estrogen replacement therapy. The estrogen-related increase in the hepatic production of TBG produces an elevation of serum total T_4, with preservation of normal free T_4 levels. A less common cause for abnormal total T_4 levels is a hereditary X-linked familial trait that occurs in approximately one in 5,000 newborns. This genetic defect causes an increase in TBG levels with the resultant elevation of total T_4 levels.

Clinical Disorders

Hyperthyroidism

Independent of the etiology, hyperthyroidism is characterized by the presence of elevated levels of thyroid hormone. The diagnosis of hyperthyroidism is established by thyroid function studies including biochemical, radioactive iodine uptake, and thyroid scans. In the extreme, the condition is easily diagnosed, but there is a spectrum of presentations that may be more problematic. The most common etiology of hyperthyroidism is Graves' disease,

or diffuse toxic goiter. Graves' disease is considered to have a major autoimmune component. Graves' disease patients have circulating antibodies that were originally called long-acting thyroid stimulators but are now referred to as either thyroid-stimulating antibodies or thyroid-stimulating immunoglobulins. The mode of action of these antibodies is to bind to the TSH receptor and stimulate the thyroid, causing the secretion of thyroid hormones. This stimulation of the thyroid is not sensitive to feedback mechanisms and therefore does not respond to therapeutic measures directed at TSH or TRH control. Other etiologies of hyperthyroidism include toxic solitary or multinodular thyroid disorders, inflammatory disorders of the thyroid gland such as subacute thyroiditis, hyperthyroidism secondary to placenta chorionic thyroid stimulators, excess exogenous thyroid administration, and, rarely, TSH production from a pituitary adenoma. With the exception of the latter, circulating free T_4 and free T_3 levels, as determined directly or calculated by indexing techniques, are elevated and serum TSH levels, as measured by sensitive immunoassay methods, are suppressed. When reviewing the laboratory results, an occasional patient will have only an elevated T_3 (T_3 toxicosis), in support of the diagnosis (19).

To prove TSH suppression in patients with hyperthyroidism, provocative testing with TRH can be undertaken (TRH, 250 to 500 mg i.v., serum TSH at 0 and 30 minutes). Normal patients will respond with a two- to fivefold rise in serum TSH concentration, whereas patients with hyperthyroidism will not exhibit an increase in TSH levels. This suppression is the result of a competent feedback loop responding to the elevated T_4 and T_3. With the introduction of new, sensitive TSH assays capable of measuring serum TSH levels in the range of 0.01 μU/mL, TRH testing has become less frequent. Hyperthyroidism has the potential of manifesting itself in one or more organ systems without obvious thyroid dysfunction. Therefore, evaluation of thyroid status is a prudent action when evaluating patients with such common and diverse complaints as weight loss, sexual dysfunction, cardiac disease, or complaints of generalized weakness.

Hypothyroidism

The diagnosis of primary hypothyroidism is simplified by documentation of an elevated serum TSH. If the negative feedback loop were intact, the thyroid gland would be secreting thyroid hormones in response to the elevated levels of TSH. In patients with central or secondary hypothyroidism (5%), serum TSH levels are inappropriately normal, indicating failure at the pituitary-hypothalamic level to increase TSH concentration in response to decreased circulating thyroid hormone levels. Some hypothyroid patients (a small percentage) will have serum total and free T_4 levels within normal reference intervals and will be recognized as having primary hypothyroidism on the basis of an isolated serum TSH elevation or an exaggerated serum TSH response after TRH administration. Occasional spurious serum TSH elevations can arise from interference in immunoassays by circulating autoantibodies to TSH antimurine antibodies used in the TSH assays. TRH administration results in an excess increase in serum TSH in patients with indeterminate or borderline elevations of basal serum TSH levels.

Neonatal screening for congenital hypothyroidism has become nearly universal. Initial screening is performed using serum T_4 determinations by methods adapted to specimens collected and transported on filter paper. These specimens are then analyzed for TSH and an elevated result is strong evidence for primary hypothyroidism The incidence of neonatal primary hypothyroidism is approximately 1:5,000. The disorder is sporadic and usually nonfamilial, requiring universal screening of newborns to permit early diagnosis and prompt institution of thyroid replacement therapy. False-positive results (low T_4 result) may occur with heritable TBG deficiency or decreased serum TBG concentrations related to prematurity.

The Euthyroid Sick State

A unique problem arises in the thyroid evaluation of critically ill hospitalized patients. A complex series of events, including decreased serum thyroid binding protein concentration, circulating inhibitors of thyroid binding, decreased peripheral T_4 deiodination to T_3, qualitative abnormalities in serum TSH glycosylation,

and quantitative abnormalities in TSH secretion, combine to produce distortions of conventional thyroid function tests in these patients. These effects are further complicated by the common use of drugs such as glucocorticoids, beta-blockers, and DOPA (which directly suppress pituitary TSH secretion) in these critically ill patients. To resolve the true thyroid status often requires direct measurement of free T_4 rather than indirect estimates of free thyroid hormone levels. An elevation of serum TSH of more than 15 μU/mL is satisfactory evidence of coexistent primary hypothyroidism in these critically ill patients. Current evidence suggests that at least some of these changes are the result of a metabolic adaptation to catabolic systemic illness and that thyroid replacement therapy is unwarranted and unhelpful.

Nodular Thyroid Disease

Laboratory thyroid function studies play a limited role in the diagnosis and management of patients with nodular and multi-nodular thyroid disease. Multinodular thyroid glands may produce hyperthyroidism if sufficient non-TSH-regulated thyroid function arises from autonomous nodules. Conversely, multi-nodular thyroid disease can be a secondary result of chronic TSH hypersecretion in patients with underlying hypothyroidism. In either case, the functional diagnosis must be separated from any anatomical etiology.

Patients with carcinoma of the thyroid present with isolated thyroid nodules and are usually euthyroid. The initial diagnosis and subsequent monitoring of therapy for papillary and follicular thyroid carcinoma may be supplemented by measurement of TSH, serum thyroglobulin and serum calcitonin levels. The latter may be enhanced by stimulatory tests employing pentagastrin and intravenous calcium administration.

Thyroid Therapy

Thyroid function studies are employed in the initial diagnosis of thyroid dysfunction and in the subsequent monitoring of the patient's response to therapy. It is essential to understand the effect of therapy on thyroid function and laboratory thyroid function testing. Increasingly, third-generation serum TSH assays are becoming the monitor of antithyroid therapy of hyperthyroidism, thyroid replacement therapy in primary hypothyroidism, and thyroid suppression in patients with benign and malignant thyroid neoplastic disorders (20).

Laboratory Diagnosis

Until recently the basis for all laboratory methods used in a thyroid evaluation was immunochemical. Modern automated chemistry analyzers are now capable of performing adequate total T_4 and T_3 resin uptake assays. The exquisite sensitivity and specificity of current antibodies have made the other thyroid testing a routine event in most clinical laboratories. Total T_3, free T_4, free T_3, TSH, TBG, and even some of the byproducts such as RT_3 can be measured accurately and precisely with only a fraction of the effort required several years ago. Because of current technology, laboratories are able to choose procedures for thyroid function testing that will fit in with the existing work flow and other techniques employed in the clinical laboratory.

Special patient preparation is not required for biochemical thyroid studies. If possible, a serum specimen obtained after an overnight fast is preferred. However, if time or circumstance does not permit the collection of a fasting specimen, a random specimen may be used. Serum should be separated from the cells and refrigerated until the time of assay or frozen for analyses that will be performed longer than 8 hours after the specimen collection. There is an extensive list of drugs that interfere with thyroid physiology and/or specimen analysis, and therefore the laboratory should periodically refer to one of the publications that deals with drug interference in common laboratory tests. Some of the more commonly occurring drugs that are known to affect testing are prostaglandin, estrogen, oral contraceptives, androgens, aspirin, corticosteroids, lithium, some antibiotics, phenothiazines, dexamethasone, propranolol, and certainly many others (21).

As is the case with all laboratory procedures, each laboratory should establish their own reference intervals for the population they serve. As a guide, serum T_4 is between 4.5 and 12 mg/dL, T_3 resin uptake between 20% and 35%, serum total T_3 between 100 and 220 ng/dL, and serum TSH between 0.5 and 5.0 IU/L. Because of the diversity of these reference intervals, Table 16.6 lists thyroid function studies in terms of increase, decrease, or normal. This is a common technique used to show the relationship among the thyroid studies without having to be concerned about the specific reference intervals of a method or geographic location.

The measurement of free T_4 or the estimation of free T_4 by indexing procedures is now widely practiced and has complemented total T_4 measurements. In the past, free T_4 measurements were done by equilibrium dialysis, which was most commonly done in research laboratories or large clinical reference laboratories. Early attempts to approximate the free T_4 concentration by using calculated indices, although cost-effective, proved to be limited in some clinical applications. Proprietary analog procedures to estimate free T_4 were an improvement over the calculated indices but were still problematic when measuring free T_4 in samples from sick euthyroid patients. If the laboratory is thoroughly familiar with the limitations of the analog procedures, they can prove useful in free T_4 assessment.

There is growing enthusiasm for measuring serum TSH (by a third-generation ultrasensitive TSH assay) as an initial step in thyroid evaluation followed by a free T_4 in those cases that require further investigation. This approach will replace the total T_4 and T_3 resin uptake that is currently done by a large number of laboratories, as the costs of the former become more competitive. The serum ultrasensitive TSH is also employed to monitor thyroid hormone replacement and suppression therapy in patients receiving thyroid therapy. Serum TSH should be maintained within or slightly below the normal reference interval for thyroid replacement therapy or in the case of thyroid suppression, in a range that, although below the reference interval, remains easily measurable.

Triiodothyronine

Total T_3 measurements are influenced by many factors, including protein concentration. Free T_3 measurement fulfills a similar function

to free T_4 because it is a direct measurement of the physiologically active hormone and is not affected by protein concentration.

T_3 Uptake

This is the historical way of measuring thyroid hormone binding to serum proteins. Although there are many approaches to this assay, all T_3 uptake assays attempt to estimate the relative saturation of all the serum proteins capable of binding T_4. This result, when multiplied by the total T_4 result, produces a value referred to as free T_4 index (FTI). Before there were direct measurements for free T_4, this approach gave a reasonable estimate of free T_4. Today there are several methods available for the quantitation of free T_4, so the FTI is less important.

Thyroid-Stimulating Hormone (Thyrotropin)

Many commercial immunoassays are available that are in the ultrasensitive or supersensitive category, meaning that circulating TSH at levels of 0.01 to 0.03 U/L can be accurately measured (22). It is this generation of TSH assay that is being considered as one of the first assays for thyroid screening.

Thyroid-Binding Globulin

Assays for TBG are available that are sufficiently reliable and simple so that most laboratories can perform them on a routine basis. It should be remembered that the specificity of immunoassays results in a quantitation of the TBG protein and not an assessment of the available thyroid-hormone binding sites. Therefore, the serum TBG assay is not a functional replacement for T_3 uptake or for measurement of the serum free T_4 concentration.

Evocative Testing

Stimulation by the intravenous administration of TRH amplifies the information available from measurement of steady-state thyroid and TSH levels. TRH (250 to 500 μg) is administered intravenously over approximately 1 minute. Serum TSH levels are obtained at time zero and at 30 or 60 minutes. In normal subjects, an increase of from 5 to 20 mIU/mL over baseline is obtained. In patients with hyperthyroidism, the low serum TSH does not increase after TRH administration. In patients with primary hypothyroidism, an excessive rise in serum TSH occurs at 30 and 60 minutes. In hypothyroidism secondary to pituitary or hypothalamic disease, serum TSH increase is either absent, suboptimal, or delayed. The wide availability of the new ultrasensitive serum TSH measurement has diminished the need for dynamic TRH testing.

Serum Thyroglobulin

Serum thyroglobulin determinations are an important aspect of monitoring for residual or recurrent differentiated papillary and

follicular thyroid carcinoma, either at the time of original diagnosis or after surgical or radioisotope therapy. Elevated serum thyroglobulin indicates residual carcinoma even in the absence of clinical or thyroid scan evidence of residual disease. Maximum sensitivity of serum thyroglobulin measurements is achieved after either withdrawal of thyroid suppression or administration of exogenous recombinant TSH administration to elevate serum thyroglobulin levels. Elevated serum thyroglobulin levels are also seen in inflammatory thyroid disorders such as subacute thyroiditis.

Serum Calcitonin

Serum calcitonin determinations are employed to screen for medullary thyroid carcinoma. Medullary thyroid carcinoma may be sporadic or associated with multiple endocrine neoplasia syndrome type 2 (MEN 2). MEN 2A is a multiple endocrine disorder including medullary thyroid carcinoma, hyperparathyroidism, and pheochromocytoma. MEN 2B is a similar MEN disorder but with the addition of clinical mucosal neuromas. MEN1 is an independent disorder of pituitary adenoma, hyperparathyroidism, and pancreatic or foregut neuroendocrine tumors including gastrinomas, insulinomas, and other neuroendocrine neoplasms. MEN 2 and MEN 2A are caused by mutations in the *ret* oncogene located on chromosome 10. Molecular techniques for DNA screening of the *ret* oncogene have been useful in diagnosis and screening of the *ret* oncogene in families suspected of having this autosomal dominant disorder.

ADRENAL CORTEX

Part of "16 - Endocrine Function and Carbohydrates"

Physiology of Adrenal Biosynthesis and Regulation

The adrenal cortex is composed of three distinct anatomical layers, each associated with specific steroid hormone synthesis and secretion. The glomerulosa is the most superficial and is responsible for mineralocorticoid biosynthesis and resultant renal sodium:potassium homeostasis. The glomerulosa is controlled principally by the renin–angiotensin system.

The fasciculata is the second layer of the adrenal cortex, is the thickest and most prominent on examination, and is responsible for glucocorticoid production, including cortisol. The fasciculata is under the regulation of pituitary ACTH in a long-loop negative feedback from peripheral cortisol. Stimulation is accomplished through the release of ACTH-releasing hormone from the central hypothalamus. ACTH is the product of the anterior pituitary processing a large precursor peptide, pro-opiomelanocorticotropin, which also contains melanocyte stimulating hormone (MSH) and endorphin sequences. Cortisol circulates in both the bound and free form. The bound portion (90%) is associated with a specific transport protein, cortisol-binding globulin (CBG), and serum albumin. The 10% of cortisol that circulates as free cortisol is the biologically active fraction.

The reticularis is the innermost zone of the adrenal cortex and is responsible for androgen and estrogen production. Regulation is achieved through pituitary ACTH levels but only in response to cortisol feedback from the fasciculata, an important interrelationship in congenital adrenal hyperplasia syndromes related to adrenal enzyme defects.

Another important regulator of adrenal steroid synthesis and secretion is the renin–angiotensin system that selectively regulates adrenal mineralocorticoid production. This system is strongly influenced by adrenergic factors and by sodium and potassium concentrations.

Clinical Disorders

Cushing Syndrome

Cushing's syndrome is the clinical disorder that results from sustained glucocorticoid excess. Clinical features include central weight gain, weakness, and facial plethora as well as hirsutism and menstrual irregularity in female patients. When Cushing's syndrome is suspected, screening laboratory studies are indicated to establish glucocorticoid excess followed by additional studies to define the etiology of the disorder and to plan specific therapy.

The most common etiology of Cushing's syndrome is pituitary ACTH–dependent, bilateral adrenal hyperplasia (Cushing's disease). Other etiologies include primary tumors of either adrenal gland, bilateral macronodular adrenal hyperplasia, or pigmented micronodular hyperplasia. Finally, some nonendocrine neoplasms of the lung and pancreas in addition to carcinoid tumors of the bronchi and thymus can produce ectopic nonpituitary ACTH syndromes (23).

Elevated urinary excretion of cortisol and cortisol metabolites is reflected in 17-hydroxysteroid, and 17-ketosteroid determinations. Urinary creatinine should always be included to ensure adequate collections. Elevated serum cortisol and loss of normal physiologic diurnal variation of serum cortisol are complementary or alternative methods of establishing quantitative glucocorticoid excess. Obesity alone may increase urinary cortisol metabolite excretion and estrogens, either endogenous secondary to pregnancy or exogenous secondary to anovulatory or estrogen replacement therapy, may increase CBG and result in false-positive serum cortisol elevations. In ACTH-dependent Cushing's syndrome secondary to either pituitary ACTH–dependent Cushing's syndrome or ectopic ACTH production from a paraendocrine neoplasm, plasma ACTH concentrations will be either frankly elevated or inappropriately normal, i.e., nonsuppressed.

Dexamethasone, a potent glucocorticoid derivative, may be used to document qualitative glucocorticoid abnormality by demonstrating lack of physiologic adrenal suppressibility. Normal patients or those with uncomplicated obesity will demonstrate a decrease of 50%, and often 90% or more, in urinary cortisol excretion when treated with dexamethasone (0.5 mg orally every 6 hours for 48 hours). A single dose of dexamethasone, 1 mg orally at 11 p.m., will suppress serum cortisol at 8 a.m. the following morning. Patients with any of the Cushing's syndrome etiologies will not demonstrate physiologic serum or urinary suppression. False positives may arise from estrogen administration, which increases serum cortisol binding (CBG), or the administration of drugs such as phenobarbital and analeptics, which accelerate metabolic clearance of dexamethasone.

Patients with bilateral adrenal hyperplasia suppress urinary cortisol excretion with larger doses of dexamethasone (2 mg orally every 6 hours, for a subsequent 48 hours) (24). Those with autonomous primary adrenal disorders such as adrenal adenoma or carcinoma or those with autonomous ACTH secretion arising from paraendocrine neoplasms will also fail to suppress with the larger dose of dexamethasone (25).

Alternatively, exogenous ACTH or endogenous ACTH stimulated through inhibition of cortisol synthesis by pharmacologic agents such as metyrapone may also provide useful supplementary information (Table 16.7).

TABLE 16.7. CUSHING'S SYNDROME

	Normal	Cushing's Syndrome			
Screening Studies					
Urinary free cortisol	<80 µg/24 h	>100 µg/24 h			
Overnight dexamethasone suppression study	<5µg/dl	>5 µg/dl			
	Normal	**Pituitary Dependent**	**Adrenal Adenoma**	**Adrenal Carcinoma**	**Ectopid ACTH**
Definitive Studies					
Baseline					
Urinary					
17-OHCS (mg/24 h)	2-8	>100%	>100%	>100%	>>100%
17-Ketosteroid	5-15			>>100%	
Cortisol (µg/24 h)	20-80	>100%	>100%	>100%	>100%
Serum					
Cortisol 8 AM (µg/dl)	6-26				
Cortisol 4-8 PM	4-14				
Dehydroepiandrosterone sulfate (µg/dl)	40-360			>>100%	
Plasma corticotropin pg/mL	20-80	>50	<20	<20	>>50
Suppression					
Dexamethasone (0.5 mg every 6 h × 48 h)	>50%	>50%	>50%	>50%	>50%
Dexamethasone (2.0 mg every 6 h × 48 h)	>90%	>90%	>50%	>50%	>50%
Stimulation					
ACTH stimulation (0.5 mg i.v./8 h)	>50%	>100%	Often >50%	10%	Variable
Metapyrone stimulation: 750 mg every 6 h × 24 h	>50%	>50%	<50%	<50%	<50%
Corticotropin-releasing hormone (100 µg i.v.)					
Serum cortisol		>20%	<20%	<20%	<20%
Plasma corticotropin		>50%	<20%	<20%	<20%

Pituitary localization as well as lateralization can be accomplished by measurement of plasma ACTH obtained by bilateral petrosal sinus catheterization (26). This information is particularly helpful when transsphenoidal pituitary surgery for correction of ACTH-dependent Cushing's disease is anticipated.

Adrenal Insufficiency

Adrenal insufficiency (Addison's disease) can arise from either primary adrenal cortical failure or because of secondary pituitary ACTH deficiency. The disorder can present as both a chronic and an acute syndrome.

The most common etiology of chronic adrenal insufficiency is autoimmune adrenalitis. Other etiologies include granulomatous disorders such as tuberculosis, sarcoidosis, adrenal leukodystrophy, and metastatic adrenal involvement. Autoimmune adrenalitis may occur as an isolated phenomenon or as a component of polyglandular autoimmune syndromes. Polyglandular autoimmune syndrome type I includes patients with adrenal insufficiency, hypoparathyroidism, and mucocutaneous moniliasis. Polyglandular autoimmune syndrome type II includes patients with adrenal insufficiency, diabetes mellitus, and thyroid dysfunction. Fatigue, weight loss, nausea, and hyperpigmentation are clinical presentations in patients with chronic adrenal insufficiency. The latter is related to the overproduction of pituitary ACTH and MSH sequences, which are derived from pituitary processing of pro-opiomelanocortin. Acute adrenal insufficiency is most often seen in the intensive care setting in stressed and anticoagulated patients. Hypotension and shock dominate the clinical picture of acute adrenal insufficiency.

Secondary adrenal insufficiency arises as a result of infiltrative or destructive disorders of the hypothalamic-pituitary axis or from functional suppression by exogenous glucocorticoid administration.

Congenital adrenal hyperplasia syndromes are the result of heritable defects in the enzymes required for cortisol biosynthesis. The resultant disorders are characterized both by cortisol deficiency and often by androgen excess resulting from ACTH stimulation secondary to cortisol deficiency. The most common disorders involve deficiencies of the 21-hydroxylase enzyme involved in cortisol and mineralocorticoid synthesis. In the newborn, syndromes of glucocorticoid and mineralocorticoid deficiency as well as ambiguous external genitalia in female patients are common. In later childhood and adolescent stages, disorders of hirsutism, virilization, and menstrual irregularity are seen.

Isolated Mineralocorticoid Deficiency

A syndrome of isolated mineralocorticoid deficiency is seen in older patients who present with recurrent hyperkalemia but normal cortisol and ACTH secretion. This disorder is particularly

common in patients with diabetes mellitus and underlying kidney diseases such as interstitial nephritis. Evaluation requires exclusion of primary adrenocortical insufficiency by serum cortisol and ACTH testing followed by documentation of defective plasma renin and serum aldosterone response to sodium restriction and upright posture.

Adrenal Virilization and Congenital Adrenal Hyperplasia

Virilization secondary to adrenal disorders occurs in patients with congenital adrenal hyperplasia syndromes and as a component of Cushing's syndrome secondary to adrenocortical androgen excess. Rarely, adrenal cortical adenoma may secrete androgens alone, producing isolated adrenal androgen excess. Elevated serum dehydroepiandrosterone (DHEA) sulfate, an excellent marker of adrenal androgen excess, is the most consistent finding, as are selective elevations of urinary 17-ketosteroids.

The syndromes of congenital adrenal hyperplasia are a group of inborn disorders of adrenal cortisol biosynthesis that have defects in cortisol biosynthesis and often androgen excess as a consequence of increased ACTH secretion. The most common enzyme defect is at the 21-hydroxylase step (27). Affected female newborns present with ambiguous genitalia as a result of intrauterine exposure to excessive adrenal androgens. Affected male newborns have normal external genitalia and share with their female counterparts variable renal sodium loss as a result of mineralocorticoid deficiency. Affected individuals not properly diagnosed at birth may present in later childhood with sexual precocity in males and virilization in females as a result of ongoing adrenal androgen production. The diagnosis of congenital adrenal hyperplasia is established by measurement of serum 17-hydroxyprogesterone, which is the precursor for the 21-hydroxylase enzyme. Recently, a more subtle defect in 21-hydroxylase has been recognized in girls at puberty with resultant hirsutism and menstrual irregularity. Diagnosis requires measurement of 17-hydroxyprogesterone before and 60 minutes after ACTH (Cortrosyn) administration. Other relatively common adrenal enzymatic disorders occur at the 11-hydroxylase and 3ß-dehydrogenase steps. The former is associated with increased desoxycorticosterone synthesis, resulting in hypertension rather than sodium loss, and the latter by profound cortisol, mineralocorticoid, and androgen deficiency. The laboratory diagnosis is established by documentation of increased 11-desoxycortisol in the 11-hydroxylase disorder and by the ratio of pregnenolone:progesterone, 17-hydroxypregnenolone:17-hydroxyprogesterone, or DHEA:androstenedione in the 3ß-dehydrogenase deficiency. Finally, it should be noted that all steroid hormones exert their biological actions through cellular receptors and that clinical disorders that mimic adrenal biosynthetic abnormalities may arise as a result of defects in glucocorticoid, mineralocorticoid, or androgen receptors.

Adrenal Hypertension

Hypertension resulting from primary adrenal mineralocorticoid excess can be caused either from mineralocorticoid-secreting solitary adrenal adenomas (aldosterone-secreting adenomas) or from bilateral adrenal adenomatous hyperplasia. Hypokalemia and elevated urinary potassium excretion are related to increased mineralocorticoid biosynthesis, and plasma renin is suppressed by the resultant extracellular volume expansion. Failure of serum aldosterone to suppress after intravenous saline infusion and of plasma renin to increase after sodium restriction, upright posture, and diuretic administration are additional characteristics (28). The specific etiology can then be distinguished by the use of adrenal computed tomography (CT) scanning, ^{131}I-iodo-cholesterol adrenal scanning, or differential adrenal vein catheterization studies. Rarely, other mineralocorticoid-secreting adrenal adenomas may produce a similar clinical picture.

Secondary aldosterone hypersecretion as a result of increased renin secretion is associated with renal artery stenosis, accelerated hypertension of any etiology, and, in some patients, oral estrogen administration, particularly anovulatory agents, as a result of estrogen-mediated hepatic angiotensinogen secretion.

Adrenal Incidentaloma

With the widespread use of CT and magnetic resonance imaging for abdominal imaging, a substantial number of adrenal incidentalomas have been recognized. It is suggested that as many as 5% of the population may have such incidental adrenal nodules. These represent adenomas and other focal adrenal gland enlargements in patients without previously recognized adrenal abnormality. Laboratory evaluation should include a serum cortisol, before and after overnight dexamethasone administration, serum electrolytes, serum DHEA sulfate, and urinary vanilmandelic acid (VMA) and metanephrines to exclude an occult functional adrenal lesion. If the nodules are less than 5 cm and nonfunctional, no intervention is necessary and imaging should be repeated in 6 months. Nodules greater than 5 cm should be removed surgically to exclude possible occult adrenal carcinoma.

THE ENDOCRINE PANCREAS AND GASTROINTESTINAL PEPTIDES

Part of "16 - Endocrine Function and Carbohydrates"

The islet cells of the pancreas and the endocrine cells of the foregut constitute an integrated endocrine system functionally related to alimentation and metabolic fuel integration. The islets of Langerhans of the pancreas contain alpha, beta, and delta cells respectively secreting glucagon, insulin, and somatostatin. The close proximity of these cells permits both paracrine, (i.e., local interactions at a cell-to-cell level) and more traditional endocrine actions. The common embryologic origin of these endocrine cells from histochemically distinct amine uptake and decarboxylation (APUD) cells of the embryologic neuroectoderm results in the presence of cells in the adult foregut that secrete gastrin, motilin, vasoactive intestinal peptide (VIP), and somatostatin and in peptide-secreting cells that are distributed from the hypothalamic-pituitary axis, through the thyroid and bronchial epithelium, to the distal small bowel. These foregut peptides are involved in the integration of intestinal secretion and motility. All these sites may become clinically involved in endocrine neoplastic syndromes.

Diabetes Mellitus

The most common endocrine disorder of the endocrine pancreas is type I insulin-dependent diabetes mellitus (IDDM). In this disorder, there is progressive loss of pancreatic beta-cell function and without treatment the ultimate development of hyperglycemia and ketoacidosis. Antibodies to islet cells are present in a high percentage of cases at the time of clinical onset, and there is a relationship between IDDM and the HLA histocompatibility loci DR3 and DR4 on the sixth chromosome.

IDDM accounts for approximately 10% of patients with diabetes. Ninety percent of patients with diabetes have type II diabetes, noninsulin-dependent diabetes, which is often associated with obesity and is present particularly in patients older than 40 years of age. In this disorder, insulin resistance complicates a quantitatively less severe defect in insulin secretion. Islet cell antibodies are negative and there is no relationship to HLA abnormalities.

A final group of younger patients with hyperglycemia may have maturity onset diabetes of youth. This disorder in some kindreds is related to a glucokinase deficiency and is often associated with an autosomal dominant family history, acanthosis nigricans, and central obesity.

An additional category of impaired glucose tolerance (IGT) is reserved for patients with abnormalities of glucose tolerance testing but without fasting hyperglycemia or other overt evidence of diabetes mellitus. Diabetes can also occur secondary to other endocrine disorders such as acromegaly or Cushing's disease, in which elevations of counterregulatory hormones develop. IGT may initially present during pregnancy in patients with subclinical insulin deficiency as a result of the secretion of placental hormones that antagonize insulin action.

Diagnosis of Diabetes Mellitus

The diagnosis of diabetes mellitus is usually straightforward when fasting hyperglycemia is present. A fasting blood sugar greater than 125 mg/dL (5.0 mmol/L) on two occasions is diagnostic of diabetes mellitus.

There has been substantial revision of the diagnostic criteria for diabetes mellitus prompted by the presence of significant macrovascular and microvascular complications at the time of initial diagnosis using previous criteria. Normal fasting blood sugar is now less than 110 mg/dL, diabetes is more than 126 mg/dL, and a new category, impaired fasting glucose, analogous with IGT with fasting blood sugar of 110 to 126 mg/dL.

Greater sensitivity but decreased specificity is achieved by the use of oral glucose tolerance testing, which is unnecessary if fasting hypoglycemia is documented (29). The patient should have eaten at least 150 g of carbohydrate for 3 days preceding the test. Glucose (75 g) is administered to nonpregnant adults at time zero (1.75 g/kg in children) and serum samples are obtained at zero, 1, and 2 hours. For screening during pregnancy, 50 g of glucose is administered without respect to fasting between weeks 24 and 28 of pregnancy. If blood sugar exceeds 140 mg/dL 60 minutes after the administration of glucose, a formal glucose tolerance test is performed with 100 g of glucose and with serum samples obtained at zero, 1, 2, and 3 hours. For the evaluation of patients with suspected reactive hypoglycemia, 75 to 100 g of glucose is administered and blood sugars obtained at zero, 1, 2, 3, 4, and 5 hours and additionally with spontaneous symptoms. In nonpregnant adults blood sugars greater than 200 mg/dL at either 1 or 2 hours is diagnostic of diabetes. In pregnant women, gestational diabetes is diagnosed if two of the following are achieved: fasting blood sugar is greater than 105 mg/dL, 1-hour blood sugar is 160 mg/dL, 2-hour blood sugar is 165 mg/dL, or 3-hour blood sugar is 145 mg/dL. A summary of the criteria for making the diagnosis of diabetes mellitus is given in Table 16.8.

TABLE 16.8. CRITERIA FOR THE DIAGNOSIS OF DIABETES MELLITUS

	FBS (mg/dl)	1 h (mg/dl)	2 h (mg/dl)	3 h (mg/dl)
Adult				
Diabetes mellitus				
Fasting	>126			
Glucose tolerance test (75 g glucose or 1.75 g glucose/kg body weight)	>126	>200	>200	—
Impaired glucose tolerance (75 g glucose)	>110	140–200		
Gestational diabetes mellitus				
Screening (50 g glucose)		>140		
Definitive (100 g glucose)	>105	>190	>165	>145
Pediatric				
Diabetes mellitus				
Fasting	>140			
Glucose tolerance test (1.75 g glucose/kg body weight)	>140	>200	>200	

Management of Diabetes Mellitus

The contemporary management of diabetes mellitus relies heavily on the use of frequent capillary blood sugars. This process has become extremely convenient for patient and physician with the widespread use of portable glucometers. Several times a day, a patient can obtain his or her own blood specimen obtained with disposable lancets, place the drop of blood on a reagent strip, and read the glucose level on the glucose meters. A log is kept and reviewed with the physician at the next visit. This process will enable the patient to monitor his or her glucose as often as necessary with the

objective of maintaining much tighter glucose control. Although these devices make a significant contribution to diabetic management, it is important to understand the limitations of the individual devices. Some are sensitive to hematocrit and others are limited in the lower or upper range of glucose concentrations.

Urinary glucose monitoring is not sufficiently precise for optimal diabetic control, although the measurement of urinary ketones may be helpful during episodes of acute illness and potential ketoacidosis. These blood sugar results are supplemented by the measurement of one of several glycolated proteins, including glycosylated hemoglobins, hemoglobin A_1c, glycosylated albumin, and fucosamine. These proteins undergo nonenzymatic glycation as a function of integrated blood sugar levels (30). The concentrations of these glycated proteins are a function of the degree of hyperglycemia and the half-life of the involved cells or proteins. Glycosylated hemoglobin, as an example, gives an integrated estimate of blood sugar over the approximately 3-month life span of the erythrocyte. Glycosylated proteins such as hemoglobin A_1c should be monitored every 3 to 6 months in stable patients and every 6 to 12 weeks at the onset of therapy. For unstable diabetics requiring changes in therapy and in pregnancy complicated by diabetes, the monitoring period should be 6 to 12 weeks until the patient is stabilized. A target range of hemoglobin A_1c less than 7.0% is sought to minimize the development and progression of microvascular and possibly macrovascular complications.

Hypoglycemia

Hypoglycemia, either documented or clinically suspected, can be divided into disorders in which symptoms occur when fasting and are often associated with decreased levels of consciousness or mentation (i.e., fasting hypoglycemia) and disorders that typically occur within several hours after eating and are typically associated with sympathomimetic symptoms such as anxiety, palpitations, and anxiety (31).

Fasting hypoglycemia can arise from disorders of insulin secretion, from autoimmune mechanisms involving either the insulin molecule or the insulin receptor, from defects in counterregulatory hormone secretion such as cortisol and growth hormone, and from exogenous means such as insulin or sulfonylurea administration. Measurement of blood sugar and serum insulin levels after an overnight fast and during spontaneous symptoms is essential. With blood sugars below 50 mg/dL, serum insulin should be undetectable and the ratio of serum insulin (uU/ml) to blood glucose (mg/dL) less than 0.3. In addition, measurement of the serum insulin C-peptide or serum proinsulin may be useful in identifying endogenous versus exogenous insulin, because C-peptide and proinsulin are not present in exogenous insulin preparations. Finally, antibodies to insulin may be helpful in identifying both exogenous insulin administration and spontaneous insulin antibodies with partial agonist actions.

Patients with postprandial symptoms may have reactive hypoglycemia. The symptoms are dominated by shakiness, anxiety, fatigue, and hunger rather than loss of consciousness. Postgastrectomy patients and patients with early type II diabetes mellitus with delayed but ultimately normal or even elevated serum insulin levels may present in this manner.

The criteria for the diagnosis of reactive hypoglycemia are problematic, and blood sugars obtained at the time of spontaneous symptoms are more appropriate and preferred when this diagnosis is being considered. The diagnosis of reactive hypoglycemia is frequently made uncritically by patients and physicians alike. Many subjective symptoms that may or may not be related to eating or are associated with food relief are attributed to low blood sugar. This tendency is compounded by the excessive and uncritical use of the glucose tolerance test to establish this diagnosis.

The mean blood glucose nadir in normal subjects after glucose administration is 64 mg/dL, and 10% of normal subjects have blood sugars below 47 mg/dL. Failure to recognize these variances has led to the overdiagnosis of hypoglycemia by glucose tolerance testing and has led many authorities to recommend that glucose tolerance tests not be employed in the evaluation of patients with suspected hypoglycemia.

Islet Cell–Foregut Peptides

Neoplasms of the cells of the pancreatic islet and the neuroectodermal cells of the foregut arise infrequently but may produce distinctive and characteristic endocrine syndromes (32). Benign and malignant tumors of the beta cells of the pancreas produce the insulinoma syndrome, characterized by fasting hypoglycemia and inappropriately elevated serum insulin levels, which is reviewed under fasting hypoglycemia.

Gastrin

Tumors of the delta cells of the islets or of gastrin-secreting cells of the foregut produce the gastrinoma syndrome (Zollinger-Ellison syndrome), characterized by recurrent duodenal and distal small bowel peptic ulcer disease and diarrhea secondary to increased gastric acid secretion and resultant small bowel pH disruption. These tumors are often malignant and may be multifocal. The diagnosis is based on the documentation of elevated fasting serum gastrin levels by immunochemical methods (more than 100 pg/mL) in the setting of increased gastric acid secretion or by the paroxysmal increase (more than 200 pg/mL) in serum gastrin after intravenous secretin administration (2 U/kg i.v.) when basal serum gastrin levels are not clearly elevated.

Vasoactive Peptide

A second syndrome associated with watery diarrhea and resultant hypokalemia as a result of increased diarrheal potassium loss is the watery diarrhea–achlorhydria–hypokalemia syndrome or Verner-Morrison syndrome. Gastric acid secretion is not elevated in this disorder, which results from the excessive secretion of vasoactive intestinal peptide (VIP) from pancreatic islet cell tumors. Serum VIP levels by immunoassay are elevated (more than 50 pg/mL) in the majority of patients with this disorder.

Glucagon

A syndrome characterized by hyperglycemia, anemia, weight loss, and a migratory necrotizing dermatitis skin rash is related to

glucagon-secreting neoplasms of the islet cells of the pancreas. These tumors are often malignant and extensive before diagnosis is established. Serum glucagon levels are elevated (more than 100 pg/mL). The etiology of the rash, which is seen in approximately two thirds of the patients, is unknown.

Somatostatin

Several patients with diabetes, diarrhea, and gallstones secondary to decreased gallbladder contractility have been described secondary to somatostatin-secreting islet cell pancreatic tumors. These symptoms are consistent with the known actions of somatostatin on insulin secretion and gastrointestinal and biliary tract motility. Serum somatostatin levels by immunoassay are elevated.

Carcinoid Syndrome

The syndrome characterized by flushing, diarrhea, asthma, and right-sided endocardial valvular thickening and dysfunction is produced by carcinoid tumors of the chromaffin cells of the distal intestine and bronchial epithelium. These symptoms are related to episodic serotonin and bradykinin secretion. Diagnosis is usually confirmed by documentation of elevated urinary excretion of 5-hydroxyindoleacetic acid (a metabolite of serotonin) or by increased serum serotonin levels.

Other Gastrointestinal Peptide Syndromes

Many other gastrointestinal peptides are known, including pancreatic polypeptide (PP), gastric inhibitory peptide (GIP, bombesin), secretin, and cholecystokinin. No recognized endocrine syndromes are associated with these peptides. Elevation of serum levels by radioimmunoassay may serve as markers in other APUD endocrine syndromes. Serum ß-hCG, α-fetoprotein, and chromogranin-A may also be useful as serum markers of pancreatic-gastrointestinal pancreatic syndromes.

HYPERCALCEMIA/HYPOCALCEMIA METABOLIC BONE DISEASE

Part of "16 - Endocrine Function and Carbohydrates"

Physiology

Serum Calcium Regulation

Maintenance of serum ionized calcium is essential to a variety of critical biological functions, including nerve transmission, muscle contractility, and exocrine secretion. Serum calcium regulation is achieved by the interactions of parathormone, vitamin D and its activated metabolites, and calcitonin. These hormones act at the skeletal, gastrointestinal, and renal levels to maintain a stable ionized serum calcium concentration in the setting of highly variable dietary calcium intake. The major hormones responsible for calcium homeostasis and their modes of action are listed in Table 16.9.

TABLE 16.9. CALCIUM REGULATION BY HORMONE AND SITE OF ACTION

	Bone	Kidney	Intestine
Parathyroid hormone	Increases resorption of calcium and phosphate	Increases reabsorption of calcium, decreases reabsorption of phosphate; increases conversion of 25-OHD_3 to $1,25(OH)_2D_3$; decreases reabsorption of bicarbonate	No direct effects
Calcitonin	Decreases resorption of calcium and phosphate questionable effect on vitamin D metabolism	Decreases reabsorption of calcium and phosphate:	No direct effects
Vitamin D	Maintains Ca^{2+} transport system	Decreases reabsorption of calcium	Increases absorption of calcium and phosphate

From Greenspan FS. *Basic endocrinology*, 3rd ed. Norwalk, CT: Appleton & Lange, 1991, with permission.

Dietary calcium intake is approximately 1,000 mg daily. Eighty percent of dietary calcium is initially absorbed, although 60% is subsequently secreted into the gastrointestinal tract as calcium-containing exocrine pancreatic secretion and sulcus entericus, with a resultant net absorption of dietary calcium of approximately 20%. Calcium is also available from the skeletal system, which serves as a reservoir of calcium through the integrated processes of new bone formation and resorption of existing bone, as part of continuous bone remodeling. Approximately 10,000 mg of ionized calcium is filtered at the glomerulus of the kidney, although efficient proximal and distal tubule resorption limits urinary calcium excretion to only 100 to 300 mg daily.

A fall in serum ionized calcium results in a rise in serum parathormone as a result of the direct negative feedback regulation of parathormone by serum ionized calcium. The rise in serum parathormone simultaneously increases bone resorption of calcium, increases renal calcium tubular resorption, and activates the 1-hydroxylation of 25-hydroxyvitamin D to its active metabolite 1,25-dihydroxyvitamin D, which in turn increases gastrointestinal calcium absorption and amplifies parathormone-mediated bone resorption. These actions serve to return the serum calcium to a normal range. Spontaneous increases in serum calcium have the opposite effects with resultant decrease in serum calcium. Calcitonin appears to have little influence on steady-state serum calcium regulation but moderates the rise in serum calcium during unsteady-state serum calcium changes. Through these hormonal, dietary, and physical activity relationships, both serum calcium and bone mineral remodeling are maintained.

Clinical Disorders

Hypercalcemia

Clinical hypercalcemia results from the pathologic disruption of serum calcium regulation by several clinical disorders (33).

Primary hyperparathyroidism is the most common etiology of hypercalcemia and is characterized by a rise in serum ionized

calcium as a result of increased parathormone secretion, most commonly from a parathyroid adenoma (90%) involving one of the four parathyroid glands, although occasionally as a result of multiple adenomas or hyperplasia involving all four parathyroid glands. The resultant hypercalcemia can produce symptoms of lassitude and increased fatigue. Increased bone resorption can produce demineralization and fractures, and increased urinary calcium secretion can lead to renal calculi. With newer and widespread monitoring of serum calcium by biochemical profile determinations, many older patients are found to have relatively asymptomatic hypercalcemia and hyperparathyroidism. In all these instances, serum parathormone is elevated when determined by appropriate immunoassay techniques (34). This is in contradistinction to other causes of hypercalcemia in which serum parathormone levels are suppressed by nonparathyroid-dependent hypercalcemia. Hyperparathyroidism may occur alone or as a component of MEN 1 and 2, in which case parathyroid hyperplasia involving all four parathyroid glands is seen. In MEN 1 hyperparathyroidism is associated with pancreatic islet cell neoplasms and pituitary adenomas. In MEN 2, hyperparathyroidism is associated with medullary thyroid carcinoma and pheochromocytoma, often bilateral. Both disorders are inherited as autosomal dominant disorders.

Hypercalcemia is one of the most common metabolic complications of malignancy, and several unique mechanisms are recognized. Hematologic malignancies such as multiple myeloma are associated with the production of osteolytic cytokines such as interleukin-1 and tumor necrosis factor. In addition, some lymphomas are associated with increased 1,25-dihydroxyvitamin D levels as a result of tumor-related extrarenal 1-hydroxylase enzyme systems. Some epithelial tumors produce a parathyroid hormone related peptide, or humoral hypercalcemia of malignancy peptide, which is similar in amino acid composition to parathormone in the amino acid terminus of the molecule, although highly distinct in its complete structure (35). Hypercalcemia in these patients is generally severe and associated with decreased serum parathormone levels and with both hypercalcuria and hypochloremia as a result of suppression of parathormone tubular actions on calcium and hydrogen ion resorption.

Sarcoidosis and other granulomatous disorders such as tuberculosis, coccidiomycosis, and berylliosis may be associated with extrarenal 1-hydroxylase enzyme activity, which results in hypercalcemia from increased dietary calcium absorption.

Some drugs may elevate serum calcium, including vitamins A and D, thiazide diuretics, and lithium. The mechanisms are quite distinct. Vitamin D excess leads to increased circulating vitamin D levels, thiazides decrease urinary calcium excretion, and lithium appears to alter transmembrane calcium transport.

The syndrome of familial hypocalcuric hypercalcemia is associated with mild hypercalcemia, normal to slightly elevated serum parathormone concentrations, and low urinary calcium excretion (urinary calcium clearance:urinary creatinine clearance less than 0.01). The disorder is an autosomal dominant abnormality in which an inactivating mutation of a transmembrane calcium transporter is present that is similar to that in patients with lithium-associated hypercalcemia. Care should be exercised to avoid unnecessary parathyroid surgical exploration in these patients.

Hypocalcemia

Hypocalcemia results from failure of the parathormone–vitamin D system to maintain stable ionized calcium levels. It is important to recall that approximately 50% of serum calcium is bound to serum albumin. As a result, a decrease in serum total calcium can arise from decreased serum albumin concentration without any change in biologically active ionized serum calcium. Ionized serum calcium needs to be either measured directly or estimated by adding 0.8 mg/dL of serum calcium to the observed serum total calcium for every 1.0 g/dL decrease in serum albumin concentration.

Hypoparathyroidism results from failure of appropriate parathormone secretion or action. Hypoparathyroidism may follow thyroid or parathyroid surgery in which parathyroid glands are compromised or may arise as idiopathic hypoparathyroidism as a result of immunologic parathyroid dysfunction. The latter may arise as a component of one of two multiple endocrine immunodeficiency syndromes: type I with idiopathic hypoparathyroidism, adrenal insufficiency, and mucocutaneous moniliasis or type II with idiopathic hypoparathyroidism, immunologic thyroid dysfunction (such as Hashimoto's thyroiditis or Graves' disease), and IDDM.

Pseudohypoparathyroidism is an uncommon disorder in which parathormone secretion is normal, but parathormone action is deficient as a result of blunted parathormone receptor activity. Serum parathormone levels are elevated, and the patients do not respond to exogenous parathormone administration by either a rise in serum calcium or urinary cyclic AMP excretion. In some patients, this defect is associated with a defective guanidine-nucleotide coupling protein, which serves to integrate the external parathormone binding receptor with the internally located adenyl cyclase catalytic subunit.

Because magnesium is necessary for both parathormone secretion and action, magnesium depletion is associated with hypocalcemia and decreased serum parathormone levels. Replacement of magnesium corrects both the hypocalcemia and the impaired parathormone secretion, which is not responsive to calcium replacement alone.

Demineralization

The participation of the skeletal system in the maintenance of serum calcium homeostasis gives rise to several significant clinical syndromes in which loss of skeletal mineral content may progress to the point of demineralization and fracture.

Osteoporosis

The most common demineralization disorder is osteoporosis. Osteoporosis is responsible for more than 1.5 million fractures annually in the United States, with annual costs estimated to be more than 15 billion dollars and with a substantial increase in mortality, particularly in relation to hip fractures (36). Most patients have primary osteoporosis related to age, gender, race and menopausal status in which a gradual loss of bone mineral occurs as a result of decreased bone formation relative to bone resorption. The residual bone is qualitatively normal although quantitatively reduced in mass. Additional contributory factors include

limited dietary calcium intake, excessive alcohol or tobacco use, and family history. Osteoporosis can arise secondary to hyperthyroidism, hyperparathyroidism, Cushing's disease (particularly related to steroid use), myeloproliferative disorders, and malabsorptive disorders. As a result of the relatively low levels of negative calcium balance, laboratory parameters are usually quite unremarkable. Contributory secondary factors can be excluded by laboratory means. Bone mineral density studies including dual x-ray absorptiometry (DEXA) and quantitative CT scanning can define bone mineral loss before fracture. Markers of bone formation such as bone-specific alkaline phosphatase and osteocalcin, as well as markers of bone resorption such as urinary N-telopeptide and deoxypyridinoline, are helpful in defining high bone turnover states. These markers may be additionally helpful in monitoring early treatment response and may complement serial DEXA evaluation of bone mineral mass.

Osteomalacia

Defective bone mineralization despite adequate bone matrix formation is seen in osteomalacia. The resultant bone is qualitatively abnormal, with wide osteoid seams of unmineralized bone collagen owing to inadequate bone mineralization. Malabsorption and chronic acidotic disorders are common contributing abnormalities. Drugs such as phenytoin and barbiturates may be factors as a result of hepatic enzyme induction and increased clearance of vitamin D. Inborn errors of vitamin D metabolism and action, such as vitamin D–dependent rickets and vitamin D–resistance rickets, also occur. Although serum calcium levels are well maintained despite the lack of adequate calcium for mineralization, decreased serum phosphorus levels as a result of secondary hyperparathyroidism, increased alkaline phosphatase activity, and low urinary calcium excretion are commonly seen. Definitive diagnosis may require bone biopsy.

Paget's Disease

Paget's disease, a common disorder of older patients is characterized by increased osteoclastic bone resorption, chaotic new bone formation, and elevated serum alkaline phosphatase levels. The latter may lead to the initial diagnosis of Paget's disease in asymptomatic patients without fracture or other skeletal abnormality.

Azotemic osteodystrophy is the complex metabolic bone disease that is commonly seen in patients with chronic renal insufficiency. As dialysis extends life in these patients, the combination of chronic acidosis, secondary hyperparathyroidism as a result of phosphate retention, vitamin D abnormalities as a result of decreased renal 1-hydroxylation of vitamin D, and skeletal aluminum accumulation all lead to a progressively disabling metabolic bone disease.

Metabolic Stone Disease

Renal calculi can arise from increased solute excretion (calcium, uric acid, cysteine), from decreased urinary volume or pH (uric acid, calcium oxalate, calcium phosphate), as a result of loss of biological inhibitors of urinary crystallization (e.g., citrate, pyrophosphate, magnesium), or secondary to underlying obstruction and infection. Evaluation requires exclusion of hypercalcemic disorders; quantitation of urinary calcium, oxalate, and uric acid excretion; and exclusion of underlying obstruction or infection (37).

REPRODUCTIVE ENDOCRINOLOGY

Part of "16 - Endocrine Function and Carbohydrates"

Physiology

Pituitary gonadotropin secretion in both men and women is initiated by the secretion of hypothalamic GnRH into the hypothalamic-hypophyseal portal vasculature in pulsatile fashion at 60- to 90-minute intervals (38). The resulting stimulation of pituitary FSH and LH secretion is further modulated by both positive and negative feedback by gonadal steroids and nonsteroidal peptides such as the inhibins.

In men, LH binds to receptors on the interstitial Leydig cell of the testis where it stimulates the production of testosterone and estradiol. FSH binds to receptors on the Sertoli cell of the seminiferous tubule, leading to the production of inhibin and an androgen-binding protein produces the high local concentrations of testosterone needed for spermatogenesis. Inhibin feeds back through the systemic circulation to downregulate pituitary FSH secretion, whereas estradiol and testosterone feed back to downregulate pituitary LH secretion.

In women, similar but much more dynamic hypothalamic-pituitary-ovarian relationships are present. FSH binds to the granulosa cells of the developing follicle where it stimulates oocyte maturation, estradiol secretion, and inhibin production. Estradiol and inhibin downregulate FSH secretion by feedback inhibition. LH stimulates estrogen and androgen secretion from the interstitial cells of the ovary. These steroid hormones feed back initially to negatively inhibit LH secretion. At a critical threshold of estradiol, however, positive feedback—probably from a different set of hypothalamic neurons—results, with a resultant estrogen-stimulated peak in LH and FSH secretion, which is necessary for ovulation. Thereafter, the site of ovulation undergoes luteinization and becomes morphologically the corpus luteum, the site of progesterone secretion during the second half or luteal phase of the cycle. Under the influence of estrogen, the endometrial lining of the uterus undergoes proliferative changes. These proliferative changes are further modified by progesterone-dependent glycogen deposition during the luteal phase of the cycle to prepare the endometrium for implantation should fertilization occur. If fertilization does not occur, these levels decline and withdrawal of estradiol and progesterone brings about loss of the endometrium as a menstrual cycle preliminary to initiation of the subsequent menstrual cycle.

Fetal testicular androgen secretion is necessary for intrauterine male external genital differentiation. Female external genital differentiation occurs passively in the absence of directive testosterone secretion. Pituitary gonadotropin secretion is low during pediatric development in both sexes. At puberty, an increase in serum FSH and LH secretion occurs as a result of increased hypothalamic GnRH secretion, initially leading to secondary sexual maturation in both sexes and ultimately to reproductive function.

Clinical Disorders

Male

Hypogonadism

Delayed or absent sexual maturation in males can occur as a result of lack of hypothalamic-pituitary gonadotropin secretion, failure of gonadal response to pituitary gonadotropins, or failure of androgen action at the target cell receptor or postreceptor level.

When the defect is at the pituitary-hypothalamic level, low serum FSH and LH levels as well as low testosterone levels will be present. With organic lesions such as pituitary adenomas, craniopharyngiomas, or infiltrative or granulomatous disorders, other pituitary functions such as GH, TSH, and ACTH function may be impaired. The association of isolated hypogonadotropic hypogonadism with anosmia is known as Kallman's syndrome.

Not all abnormalities are organic. A common clinical problem is functional delay, in which ultimately normal physiologic sexual maturation may be delayed into late adolescence or early adulthood.

When the defect is at the testicular level, testosterone levels are low and pituitary gonadotropin levels are elevated as a result of lack of physiologic feedback regulation of both testosterone and inhibin. In addition to traumatic testicular injury, Klinefelter's syndrome, a relatively common chromosomal disorder associated with an additional X chromosome (i.e., 47,XXY or 47,XXY/46,XY versus 46,XY in normal males), may be present.

Sexual Dysfunction

Sexual dysfunction, including decreased libido and failure of erection and ejaculation, often prompts pituitary-testicular endocrine evaluation. Although endocrine factors, including low testosterone states, may be present, other nonendocrine etiologies, including vascular and neurogenic disorders, must be considered. Disorders resulting in serum hPrL elevation may also be present.

Gynecomastia

Gynecomastia is the presence of clinically significant subareolar breast tissue in male subjects. The disorder can arise from testosterone deficiency, inhibition of testosterone action by drugs such as spironolactone or cimetidine, and neoplastic disorders with either ectopic chorionic gonadotropin or estrogen secretion. Pubertal gynecomastia is a common disorder in male adolescents associated with the initiation of physiologic pubertal gonadotropin secretion, which is usually self-limited and not associated with sustained androgen abnormality.

Female

Amenorrhea

Primary amenorrhea, the absence of menses by age 16, may result from endocrine, chromosomal, anatomical, or functional disorders. With endocrine abnormalities, there is usually an associated lack of appropriate physiologic sexual maturation. Turner's syndrome, with a 45/XO karyotype including mosaic variations in which only a portion of cells express a loss of the X chromosome, is usually associated with short stature. Elevated serum FSH levels implicate primary ovarian failure. Decreased serum gonadotropins indicate either organic or functional hypothalamic-pituitary dysfunction, the latter often related to low body weight and vigorous physical activity. Normal gonadotropin levels generally indicate loss of the physiologic cycle necessary for ovulation and menses. In patients with amenorrhea, pregnancy should always be excluded by appropriate hCG determinations.

Secondary amenorrhea is the cessation of periods in a previously menstruating patient. Pregnancy must again be excluded by beta hCG determination. The history of having had periods documents an intact uterus and functional endometrium in the absence of gynecologic intervention. hPrL excess, as a result of either psychotropic medications such as phenothiazines or pituitary microprolactinomas and macroprolactinomas, requires exclusion by serum hPrL measurement. Premature ovarian failure is associated with elevated serum gonadotropin levels. In patients with polycystic ovary syndrome, variable clinical and laboratory evidence of androgen excess is present.

Hirsutism and Virilization

Excessive hair growth in androgen-responsive areas is a common clinical problem (39). Many drugs such as danazol, minoxidil, phenytoin, glucocorticoids, and cyclosporine may produce hirsutism. If other signs of androgen expression in addition to hirsutism are present, such as acne, amenorrhea, temporal hair recession, and masculinization, systemic androgen excess or virilization is present. Laboratory evaluation of hirsutism should include measurement of serum testosterone to document biochemical androgen excess and serum DHEA sulfate, an adrenal androgen, to distinguish adrenal from ovarian etiology. Additional laboratory studies may include measurement of serum free testosterone to distinguish free biologically active versus bound testosterone, androstenedione, cortisol, and pituitary serum FSH and LH levels. In patients with adrenal and ovarian neoplasms, the elevated serum androgen levels also qualitatively fail to suppress after dexamethasone administration.

Patients with latent-onset 21-hydroxylase congenital adrenal hyperplasia may have elevated serum 17-hydroxyprogesterone levels, although often only after Cortrosyn stimulation testing (0.25 mg i.v., serum 17-hydroxyprogesterone at 0 and 60 minutes). Such tests should not be performed during the luteal phase of the menstrual cycle, when 17-hydroxyprogesterone secretion by both the ovarian corpus luteum and the adrenal gland may be present. Androgen suppression with dexamethasone may also be demonstrated.

Menopause

Physiologic cessation of menses occurs in the mid to late 40s in a majority of patients secondary to ovarian senescence. This change is monitored most appropriately by elevation of serum FSH levels as a result of decreased estrogen and inhibin negative feedback suppression. Premature ovarian failure may occur at any age. The disorder may occur either as an isolated defect or as a component of a polyglandular autoimmune syndrome and the diagnosis documented by premature serum FSH elevation.

Laboratory Diagnosis

Figure 16.8 illustrates a diagnostic workup to determine the various causes of amenorrhea.

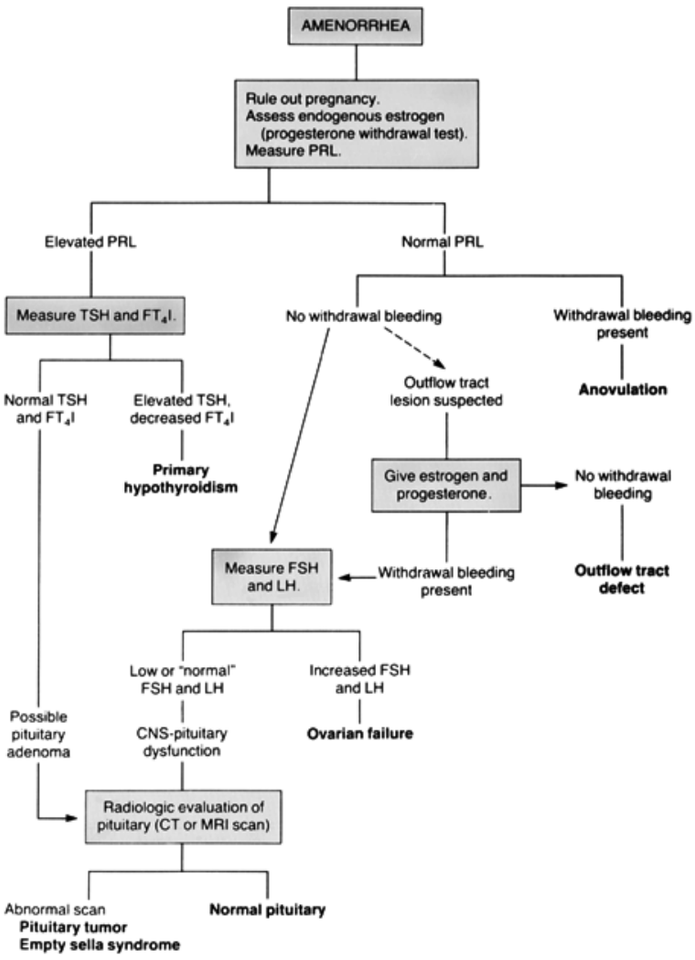

FIGURE 16.8. Potential decision tree for evaluation of amenorrhea. (From Goldfien A, Monroe SE. Ovaries. In: Greenspan FS, ed. *Basic and clinical endocrinology*. Norwalk CT: Appleton & Lange, 1991:442–490, with permission.)

ADRENAL MEDULLA

Part of "16 - Endocrine Function and Carbohydrates"

The adrenal medulla is composed of chromaffin cells, which produce and secrete the vasoactive catecholamines epinephrine and norepinephrine. These cells share a common embryologic origin with the cells of the sympathetic nervous system and with chromaffin cells of extrasympathetic distribution ranging from the carotid bodies to the organ of Zuckerkandl at the bifurcation of the aorta. The symptoms attributable to catecholamine excess are usually related predominantly to their cardiovascular effects.

Clinical Disorders

Pheochromocytomas are tumors arising from the adrenal medulla or sympathetic ganglia that produce hypertension that may be either labile or sustained and is often associated with episodic symptoms of anxiety, headache, tremor, and weight loss. Such tumors may present sporadically or as a component of MEN types IIa and IIb in association with medullary carcinoma of the thyroid and hyperparathyroidism. The diagnosis is often first considered as a result of labile hypertension noted at the time of general anesthesia and surgery.

A high index of suspicion is warranted in the presence of labile hypertension, particularly in younger patients with episodic symptoms including anxiety, tremulousness, and weight loss.

Laboratory Diagnosis

The diagnosis of pheochromocytoma is based on the demonstration of increased concentrations of the catecholamines and their metabolites supplemented by anatomical localization employing CT scanning (40). Because of the labile and variable nature of plasma catecholamines, more integrated urinary collections for measurement of urinary catecholamines and their metabolites, metanephrines and vanillylmandelic acid, are preferred. All collections should include urinary creatinine to ensure adequacy of collection and to permit expression of catecholamines and metabolites per 1,000 mg of creatinine excretion. Such collections may encompass brief periods of spontaneous symptomatology or 24-hour periods with or without spontaneous symptoms. Attention must be given to the exclusion of multiple potential interfering medications. Initial anatomical localization is attempted with abdominal CT imaging. Arteriography or nuclear medicine localization by adrenal imaging with metaiodobenzylguanidine is reserved for those patients who fail to localize with CT scanning or in whom extraadrenal pheochromocytoma is suspected.

Electrolytes and Acid-Base Balance

Elizabeth Lee-Lewandrowski

Robert W. Burnett

Kent Lewandrowski

The essential concepts necessary to understand the mechanisms underlying acid-base, fluid, and electrolyte disorders are described here. For more details, an excellent discussion of this topic by Rose (1) is recommended.

SODIUM, POTASSIUM, AND CHLORIDE

Part of "17 - Electrolytes and Acid-Base Balance"

Normal Physiology and Homeostasis

Measurements of electrolyte concentrations are among the most commonly performed tests in the clinical laboratory, both because there is a wide variety of disorders that may cause electrolyte abnormalities and because the administration of intravenous and parenteral fluids necessitates periodic reassessment of serum electrolytes and osmolality.

In a healthy person, homeostatic mechanisms maintain the water and electrolyte composition of the body within relatively narrow limits. The total body water constitutes 60% of the lean body mass and is distributed as intracellular fluid (ICF) and extracellular fluid (ECF). The distribution of water in a lean 70-kg man is shown in Table 17.1. Note that by convention extracellular fluid includes both blood plasma and the fluid inside blood cells.

TABLE 17.1. Water Distribution in a 70-kg Person

Component	Volume (*liters*)
Total body water (60% of lean body mass)	42
Intracellular fluid (66% of total body water)	28
Extracellular fluid (34% of total body water)	14
Interstitial fluid	10.5
Vascular compartment (including blood cells)	3.5

TABLE 17.2. Electrolyte Composition of Plasma

Cations	
Sodium	135–145 mmol/L
Potassium	3.2–5.0 mmol/L
Calcium (total)	2.3–2.6 mmol/L
Magnesium	0.7–1.1 mmol/L
Trace elements	˜ 1 mmol/L
Anions	
Chloride	95–105 mmol/L
Bicarbonate	24–32 mmol/L
Phosphate	0.8–1.5 mmol/L
Other (proteins, anions of organic acids, sulfate)	˜ 21 mmol/L

It is important to understand the difference between the ECF and the effective circulating volume (ECV). The ECV is the portion of the ECF that is actively perfusing tissues. Normally the ECF and the ECV are similar, but in some pathologic states (such as patients with heart failure, ascites, or edema), the effective circulating volume may be decreased despite an increase in the total ECF. These patients behave as if they are volume depleted despite an increase in the ECV. From a physiologic perspective, the ECV, not the ECF, is regulated by the volume receptors. A fall in the ECV results in sodium and water retention.

The ECF and ICF are in osmotic equilibrium, but the electrolyte composition of the two compartments differs. Table 17.2 shows the composition of the major electrolytes in plasma. Sodium is the major cation in the ECF, whereas potassium ion predominates in the cells. Sodium salts are thus the major component of the plasma osmolality.

The regulation of the plasma sodium, osmolality, and the effective circulating volume are complex and closely interrelated. The plasma sodium and osmolality are regulated by water balance, whereas volume is maintained by regulating sodium (2).

The plasma sodium and osmolality are regulated by water intake and renal water excretion. Renal water excretion is regulated by pituitary antidiuretic hormone (ADH), which acts on the renal collecting tubules. A change in the plasma osmolality is detected by hypothalamic osmoreceptors. An increase in the plasma osmolality stimulates thirst and ADH secretion. ADH enhances renal water conservation, resulting in a concentrated urine. Collectively these adaptations restore the plasma osmolality to normal. ADH secretion may also be stimulated by a decrease in the effective circulating volume, which is detected by baroreceptors in the aorta and carotid artery (3). Conversely, a fall in osmolality produces water excretion and a dilute urine.

Sodium and water balance is regulated by the kidney. Several variables influence renal sodium excretion, including the plasma sodium concentration, aldosterone, atrial natriuretic peptide (ANP), as well as other minor factors (2).

Volume regulation is monitored by receptors in the carotid sinuses, the aortic arch, and the juxtaglomerular arterioles. The juxtaglomerular sensors regulate the renin–angiotensin–aldosterone system. Aldosterone acts on the renal collecting tubules to increase sodium resorption and potassium secretion. Sodium resorption leads to an expansion of the ECF volume. The extrarenal sensors regulate ANP, which promotes sodium excretion by the kidney. In addition to aldosterone and ANP, other factors may also influence volume regulation. For example, a fall in the ECV results in stimulation of the sympathetic nervous system with vasoconstriction and an increase in cardiac output and an increase in aldosterone. An expansion of the ECV produces the opposite effect.

Potassium salts are the major intracellular ions, whereas only 2% of the total body potassium is extracellular. The normal plasma potassium is 3.2 to 5.0 mmol/L, whereas the normal intracellular concentration is approximately 150 mmol/L. Redistribution of potassium between cells and the ECF occurs in several

situations. For example, if potassium is lost through the kidney for some reason, the plasma level does not drop as much as might be expected because of the cellular potassium that is available for redistribution. Potassium balance is dependent on intake and renal excretion. A small amount of potassium is also excreted by the gastrointestinal tract, but this fraction may increase markedly in some hyperkalemic states.

Potassium is filtered by the kidney and resorbed in the proximal tubule. However, the distal renal tubule is the major site for regulation of renal potassium excretion. Aldosterone regulates potassium excretion in the distal tubule (aldosterone promotes potassium excretion).

Laboratory Measurement

Flame Photometry

In this method for sodium and potassium, a sample is diluted and introduced into a high-temperature, air-propane flame. In the flame, electrons in sodium and potassium ions are excited and emit light as they return to their ground state. The wavelength of emitted light is characteristic of the particular ionic species, resulting in a high specificity for this method.

Flame photometry is a robust method in that the result is not generally affected by the matrix of the specimen. Thus, aqueous calibration materials may be used, and flame photometry is suitable for analysis of sodium and potassium in serum, plasma, urine, or other body fluids. Most flame photometers use an internal standard such as a cesium or lithium salt, which is added to the diluent to compensate for dilution imprecision and for signal fluctuations owing to changes in the aspiration rate of the sample. Instruments for clinical use are generally dual channel, so that sodium and potassium may be measured simultaneously. Because of the excellent accuracy and precision of flame photometry, this technique is the basis for the reference method for sodium and potassium in serum.

Ion-Selective Electrodes

An ion-selective electrode (ISE) is a device that develops a small voltage when in contact with a solution containing a particular ion. The critical element in the electrode is a thin membrane of a material chosen for its ability to bind one ion species preferentially over other ions in the sample.

Sometimes these membranes are made of glass, for example, the well-known pH electrode and some sodium electrodes. More often, the membrane contains a large organic molecule, called an ionophore, which has different affinities for different ions.

To measure the voltage at the ISE, a second (reference) electrode must be used to complete a circuit. The voltage at the reference electrode must be held constant. Consequently, the reference electrode is isolated from the sample (or calibrator) solution by a “salt bridge” or “liquid junction.” A small voltage also exists at the interface between the salt bridge and the sample solution that is dependent on the composition of both the sample and the bridge solution. This voltage is called the liquid junction potential, *Ej*, and is one of the largest sources of error in ISE methods.

The difference between *Ej* with the unknown solution and *Ej* with the calibration solution is called the residual liquid junction potential. This quantity must be zero for the total cell voltage to reflect accurately the activity of the ion of interest. In other words, the voltage at the ISE itself should be the only voltage that varies when the test solution is changed. Although this is never completely true, the contributions of the bridge solution and the test solution to the liquid junction potential are not equal, and consequently the composition of the bridge solution can be chosen to minimize the variation in *Ej* with different test solutions.

A saturated, or nearly saturated, solution of potassium chloride is one popular choice of bridge solution for general-purpose ISE methods. However, electrode systems designed specifically for measurements on blood or plasma may use a different bridge solution to minimize the residual liquid junction potential in the particular test solution matrix.

Another common source of error in ISE methods is imperfect selectivity of the electrode for the ion of interest. For example, some ISEs intended for chloride measurements also respond, to a lesser but measurable extent, to bicarbonate ions in the sample. The matrix of the samples to be measured determines how selective the ISE must be. For example, for measurements in plasma, which has a sodium concentration approximately 30 times higher than the potassium concentration, a sodium electrode that responds slightly to potassium might be acceptable, whereas a potassium electrode with a significant sodium response could not be tolerated. ISEs are available for determination of sodium, potassium, and chloride as well as several other ions in body fluids.

Coulometry

One of the most accurate methods for serum chloride uses the principle of coulometry. This method measures the number of coulombs (which is proportional to the number of electrons) transferred in an electrochemical reaction. An apparatus called a chloride titrator has been designed for the determination of chloride in serum. A sample is added to an acid diluent in a cell containing a silver anode and a reference electrode, and a constant

current is imposed that generates silver ions at a constant rate. Insoluble silver chloride is formed until all the chloride ion in the sample has been used. Excess silver ions are then generated and detected, either potentiometrically or amperometrically, using a third electrode, and the titration is stopped. Because a constant current is used for the duration of the titration, the number of silver ions generated (which equals the number of chloride ions in the sample) is directly proportional to the duration of the titration, which is usually on the order of 1 or 2 minutes.

This method is both accurate (in the absence of other halides) and precise and is the accepted reference method for serum chloride. Possible interferences include iodide, bromide, and any other anion that will react with the silver ion. Coulometry is also a robust method with respect to the sample matrix and is thus suitable for chloride analysis in serum, plasma, urine, and other body fluids.

Spectrophotometry

Sodium and Potassium

A spectrophotometric method for sodium and potassium measurement has been developed based on the affinity of these ions for particular large synthetic, cyclic organic molecules. These molecules, called macrocyclic ionophores, include crown ethers, cryptanols, spherands, and related structures (4). Like the ionophores used in ISEs, these molecules are designed to selectively complex ions such as sodium and potassium. The difference is that in this case the formation of the complex results in a change in color, which is measured spectrophotometrically. The color change can be accomplished either by extracting the cation of interest along with an anionic dye into a nonaqueous phase containing the ionophore or by using an ionophore that includes a chromophore and is water soluble. In the latter case, binding of the cation by the ionophore results in a spectral shift in the chromophore. The change in absorbance is proportional to the sodium or potassium concentration in the sample.

These methods are suitable for use with very small sample volumes, and because the methods are based on spectrophotometry, they can be readily integrated into multitest analyzers without requiring an additional instrument module for ISEs or flame photometry.

Chloride

Chloride in serum and other body fluids can be measured spectrophotometrically using a reagent containing mercuric thiocyanate and ferric ion. Chloride displaces thiocyanate to form mercuric chloride, and free thiocyanate then combines with ferric ion to form a reddish complex with an absorbance maximum of approximately 500 nm. The sensitivity of the method can be increased by adding mercuric nitrate to the reagent. The free mercuric ions combine with the first available chloride ions so that only excess chloride is responsible for the formation of the colored ferric thiocyanate, as shown below.

$Hg(NO_3)_2 + Cl^- \rightarrow HgCl_2 + 2NO_3^-$

$Hg(SCN)_2 + Cl^-$ (excess) $\rightarrow HgCl_2 + 2SCN^-$

$3SCN^- + Fe^{3+} \rightarrow Fe(SCN)_3$ (reddish color)

This method was once the most widely used method for measuring chloride levels, but it is being replaced by the adaptation of ISE technology in clinical laboratory instruments.

Ion Activity and Ion Concentration

When a sodium ISE is brought into contact with a sample, the electrode signal reflects the activity, not the concentration, of sodium ions in the sample. The activity of an ion may be thought of as an effective concentration that takes into account the influence of all other ionic species present in the solution. The activity is always less than the concentration, and the two quantities are related by the equation

$a = \gamma c$

where a is activity, c is concentration, and γ is called the activity coefficient. The activity coefficient of an ion depends primarily on the total ionic strength of the solution, which for normal plasma is approximately 160 mmol/L.

Activity measurements are important because biochemical reactions involving ions proceed at rates that are dependent on activity and are only indirectly related to concentration. However, because the ionic composition of plasma is closely regulated, the activity coefficients of ions in solution stay within narrow limits, and there is nearly a constant relationship between the activity and the concentration of the ion. Thus, the distinction between activity and concentration is of more theoretical than practical importance in the clinical laboratory.

Plasma Volume Versus Water Volume

The distinction between the total volume of a plasma (or serum) sample and the volume of water contained in the sample is of much more importance than that between activity and concentration because the water fraction of plasma can vary greatly in different patient samples. Normally, plasma contains 93% water by volume. Most of the remaining volume results from dissolved proteins. If the protein concentration is markedly abnormal, the water fraction of plasma will change correspondingly. Triglycerides, either in solution or as chylomicrons, can also significantly reduce the water space when present at high concentrations.

Homeostatic mechanisms for electrolytes respond to the activity of ions in the *water space* of plasma. Hyperproteinemia or hyperlipidemia may result in a marked decrease in the water fraction, but the activity of sodium ions in the water space will not change, and thus the osmoreceptors controlling sodium balance will not be affected. The sodium concentration as measured by an ISE in an undiluted sample will likewise be unaffected. In contrast, a flame photometer or an ISE measurement on a diluted sample will reflect the amount of sodium in a fixed volume of sample. The measured result will be lower because of the volume occupied by the increased protein or lipid resulting in a misleading sodium value referred to as pseudohyponatremia.

ISE methods that use undiluted samples are sometimes called direct methods, whereas those that require dilution of a sample are called indirect. It has been recommended that

methods using undiluted samples be calibrated to agree with methods using diluted samples for specimens of normal protein and lipid composition. This avoids having two different (and overlapping) sets of reference intervals for sodium, potassium, and chloride. Unfortunately, a single method of calibration has not been widely adopted, resulting in some variability of results from different instruments even on samples of normal composition.

Specimen Selection and Specimen Handling

Although sodium, potassium, and chloride ions are inherently stable, there is a large difference between the concentrations of these ions in plasma and in blood cells, especially for potassium. When using plasma samples, care must be taken to avoid hemolysis and to promptly separate blood cells after the specimen is obtained. If visible hemolysis is present in a plasma sample for potassium analysis, either another specimen should be obtained or a note of the presence of hemolysis should be included with the laboratory report.

Serum concentrations of potassium are normally approximately 0.3 mmol/L higher than in plasma because of potassium released from platelets and leukocytes during the clotting process. This difference can be much greater if the platelet or leukocyte count is very high. Many instruments that use ISEs in undiluted samples are capable of using whole blood as the sample. This is advantageous in situations in which short turnaround time is important but has the disadvantage that hemolysis cannot be detected.

Osmolality

The major contributors to the plasma osmolality are sodium salts, glucose, and urea. Plasma osmolality can be measured directly by osmometry (normally 275 to 290 mOsm/kg) or estimated by summing the concentrations of the major solutes (sodium, chloride, bicarbonate, urea, glucose) as shown in the following formula. Because sodium is the major cation, the sum of the anions and cations can be approximated by multiplying the sodium concentration by 2. Thus, only sodium, urea, and glucose need to be measured.

$$\text{Calculated osmolality (mOsm/kg)} \cong 2C_{\text{sodium}}\,(\text{mmol/L}) + \frac{C_{\text{glucose}}\,(\text{mg/dL})}{18} + \frac{C_{\text{urea N}}\,(\text{mg/dL})}{2.8}$$

A more complete discussion of formulas for calculated osmolality may be found in reference 5. The factors 18 and 2.8 are used to convert milligrams per deciliter to millimoles per liter and would not be required for glucose and urea concentrations reported in Sl units.

Unlike sodium and glucose, urea freely crosses cell membranes and does not influence the distribution of water in the body (3). Therefore, the effective plasma osmolality can be calculated by dropping the term for urea and may be more useful than the measured osmolality for evaluating disorders of fluid and electrolyte balance in patients with renal failure and an elevated plasma urea.

INTERPRETATION OF ELECTROLYTE DISORDERS

Part of "17 - Electrolytes and Acid-Base Balance"

Hyponatremia

Hyponatremia is defined as a plasma sodium less than 135 mmol/L. Usually hyponatremia is associated with hypoosmolality. Hyponatremia results in water movement into cells, producing cellular swelling with cerebral edema and metabolic encephalopathy. The severity of the these symptoms depends on the degree of hyponatremia and the rate of change of the plasma sodium. Acute hyponatremia less than 125 mmol/L may produce severe symptoms, whereas an equivalent level of chronic hyponatremia may be asymptomatic.

An approach to the differential diagnosis of hyponatremia is shown in Fig. 17.1. In principle, hyponatremia may result from loss of sodium or an increase in body water. The kidney will normally excrete excess water to prevent hyponatremia. Consequently, most patients with hyponatremia exhibit abnormal water excretion as occurs in patients with effective volume depletion, renal failure, inappropriate ADH secretion, and other causes as shown in Fig. 17.1 (6). Three categories of hyponatremia may be distinguished based on the plasma osmolality.

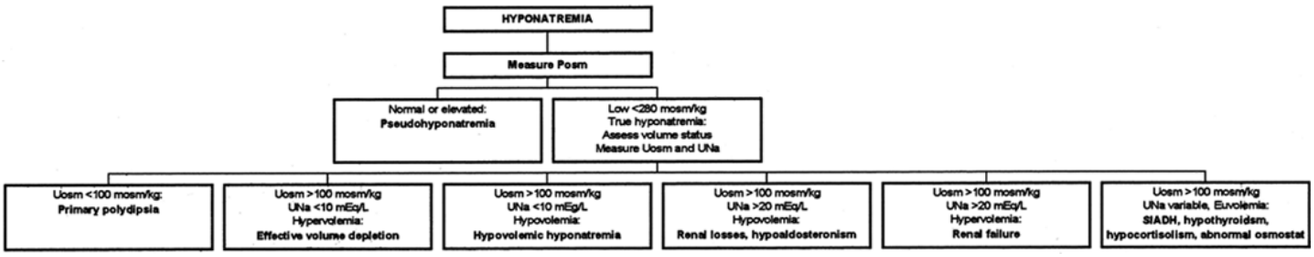

FIGURE 17.1. Selective differential diagnosis and laboratory approach to hyponatremia. Posm: Plasma osmolality; Uosm: Urine osmolality; UNa: Urine sodium; SIADH: Syndrome of inappropriate antidiuretic hormone release.

Hyponatremia with a Low Plasma Osmolality

Effective circulating volume depletion stimulates thirst and secretion of ADH. The result is hypoosmolality and hyponatremia. As described previously, some of these patients have hypervolemia (heart failure, ascites, edema) despite a low effective circulating volume. Other cases exhibit hypovolemia (vomiting, diarrhea, skin losses).

Severe renal failure may result in water retention. Sodium losses may produce hyponatremia as occurs in hypoaldosteronism and salt-losing syndromes (polycystic kidney disease, tubulointerstitial diseases). Hypothyroidism and hypocortisolism produce effective volume depletion, resulting in water retention by the kidney.

The syndrome of inappropriate secretion of ADH (SIADH) is a common cause of hyponatremia especially in hospitalized patients. SIADH occurs in a variety of conditions, including ectopic ADH production by tumors (e.g., bronchogenic carcinoma especially of the small cell type), various pulmonary disorders (e.g., tuberculosis, pneumonia), central nervous system (CNS) diseases (e.g., brain tumors, CNS infections, trauma, hemorrhage, or infarction), a variety of drugs, and miscellaneous conditions (3). The diagnosis of SIADH is based on clinical criteria including hyponatremia, hypoosmolality with normovolemia, a urine osmolality greater than 100 mOsm/kg with an inappropriate urine sodium concentration, normal renal, adrenal, and thyroid function in a patient not taking diuretics.

Rarely, hyponatremia is observed in a condition called primary polydipsia or in patients with abnormal osmoregulator function. Hyponatremia owing to deficient oral salt intake is also quite rare.

Hyponatremia with an Elevated Plasma Osmolality

Hyponatremia with an elevated plasma osmolality may be observed in patients with hyperglycemia or after administration of

mannitol, both of which draw water out of cells, resulting in hyponatremia. Hyperosmolality owing to an elevated plasma urea is not associated with hyponatremia because urea does not alter the distribution of water in the body

Pseudohyponatremia

A condition called pseudohyponatremia may occur with serum or plasma samples containing large amounts of lipids (hyperlipidemia) or proteins (e.g., paraproteinemia). This condition is a laboratory artifact, which was discussed previously, and has no clinical significance other than calling attention to the underlying cause of the hyperlipidemia or hyperproteinemia. The osmolality is unaffected because osmometers measure only the solutes in the plasma water.

Laboratory Differential Diagnosis

A selective differential diagnosis and approach to the evaluation of hyponatremia is shown in Fig. 17.1. The plasma osmolality may be used to exclude pseudohyponatremia. In patients with true hyponatremia, the next step is to assess the patient's volume status based on clinical criteria and to measure the urinary sodium and osmolality (or specific gravity). In patients with renal failure, the plasma osmolality may be misleading because of the presence of urea. In these patients, the plasma osmolality is best estimated by the formula: plasma osmolality = 2 × plasma sodium. The urine osmolality is useful to assess renal water excretion. A low urine osmolality (or a specific gravity less than 1.004) is consistent with primary polydipsia, whereas an osmolality greater than 100 mOsm/kg is indicative of abnormal water excretion (6). Measurement of the urine sodium is useful to assess patients with an abnormal renal water excretion as shown in Fig. 17.1. A low urinary sodium concentration (less than 10 mmol/L) is consistent with extrarenal disorders or effective circulating volume depletion. In contrast, renal diseases that produce hyponatremia exhibit a high urinary sodium concentration (more than 20 mmol/L).

Hypernatremia

Hypernatremia is defined as a serum sodium greater than 150 mmol/L. Patients with hypernatremia characteristically exhibit an increased osmolality. The symptoms of hypernatremia are mainly neurologic (metabolic encephalopathy) and depend on the severity of the associated hyperosmolality and the time interval over which the hypernatremia has developed. Acute hypernatremia may be symptomatic at a plasma sodium of 160 mmol/L, whereas in chronic hypernatremia, symptoms may not be evident at sodium concentrations significantly higher than this level.

In theory, hypernatremia can result from water losses or from a gain in sodium. Ordinarily the body responds to hyperosmolality by conserving water (ADH secretion) and by increasing water intake. Consequently, hypernatremia generally will not occur unless the thirst response is abnormal or the patient cannot increase water intake (e.g., a patient in coma or in infants). A selective differential diagnosis of hypernatremia is shown in Fig. 17.2.

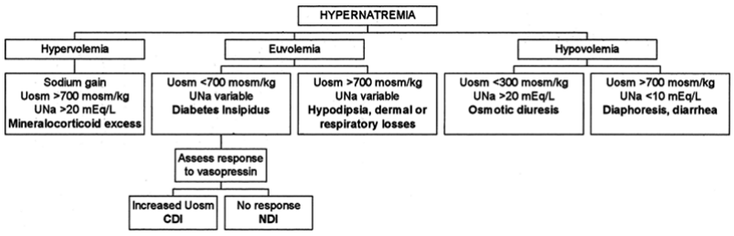

FIGURE 17.2. Selective differential diagnosis and laboratory approach to hypernatremia. Uosm: Urine osmolality; UNa: Urine sodium; NDI: Nephrogenic diabetes insipidus; CDI: Central diabetes insipidus.

Hypothalamic disorders may impair the thirst mechanism or produce abnormal osmoreceptor function (hyperaldosteronism, Cushing's disease), resulting in hypernatremia. Hypodipsia may be observed in patients with various CNS disorders. Rarely, excessive sodium intake may produce hypernatremia as may occur after infusion of hypertonic solutions or in infants fed hypertonic formulas.

Diabetes insipidus (DI) is an important cause of hypernatremia that results either from a defect in ADH secretion (central DI) or from an impaired renal response to ADH (nephrogenic DI). In either case, the result is an abnormal renal concentrating ability. Usually patients do not develop hypernatremia unless the thirst mechanism is abnormal the patient cannot increase oral water intake (6). DI usually presents with polyuria or polydipsia. The differential diagnosis of central DI includes a large number of CNS disorders, such as CNS ischemia or trauma, or may occur as an idiopathic form. Other causes include brain tumors, infections, and neurosurgery. Nephrogenic DI may occur in association with renal failure, hypokalemia, hypercalcemia, various drugs (diuretics, lithium), as a congenital form, or from other causes.

Laboratory Differential Diagnosis

Most adults with hypernatremia exhibit altered mental status or less commonly an abnormal thirst response. Hyponatremia may also be observed in infants. In patients with hypernatremia, the urine should be concentrated (more than 700 mOsm/kg) with a high specific gravity (more than 1.023). If this is not found, DI should be considered. The evaluation begins by assessing the patient's volume status followed by measurement of the urine osmolality and urine sodium. Central DI can be differentiated from nephrogenic DI by observing the response of the urine osmolality to ADH administration. A patient with central DI will exhibit an increase in the urine osmolality.

Hypokalemia

Signs and symptoms of hypokalemia generally do not occur until the plasma potassium has fallen below 3.0 mmol/L (7) and include neuromuscular disturbances (muscle weakness, paralysis), impaired urinary concentrating ability, cardiac arrhythmia, and increased digitalis sensitivity. The electrocardiogram may show flat or inverted T waves, prominent U waves, or S-T segment depression (8). Hypokalemia may result from decreased potassium intake; redistribution of potassium into cells; gastrointestinal, renal, or sweat losses; and hemodialysis. An approach to the evaluation of hypokalemia and a selected differential diagnosis is shown in Fig. 17.3.

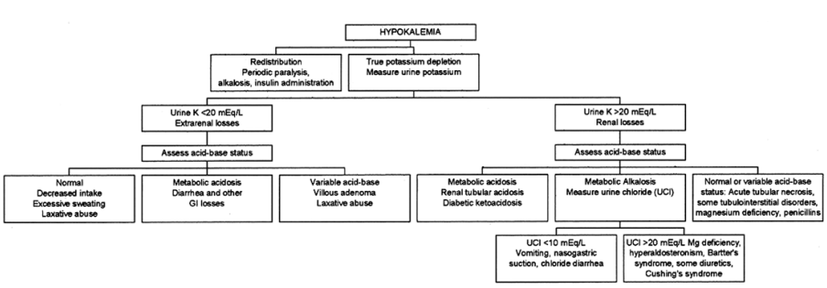

FIGURE 17.3. Selective differential diagnosis and laboratory approach to hypokalemia. UCl: Urine chloride; Mg: Magnesium.

A transient hypokalemia may occur by shifting potassium into cells as may occur in alkalosis, insulin, catecholamines, and increased ß-adrenergic activity (severe stress). Treatment of severe anemia may result in hypokalemia owing to uptake of potassium by newly formed cells. Periodic paralysis is a rare disorder that can be familial or acquired and can produce intermittent hypokalemia with muscle weakness or paralysis presumably owing to cellular uptake of potassium ions.

Hypokalemia may occur in patients on intravenous fluids without potassium supplementation or, rarely, owing to severe dietary deficiency (7).

Extrarenal potassium losses produce hypokalemia owing to potassium lost in gastrointestinal secretions (diarrhea, vomiting, nasogastric suction, Zollinger-Ellison syndrome) or through the skin (e.g., sweating, burns). Hypokalemia resulting from urinary losses may occur in hyperaldosteronism, Bartter's syndrome, acute tubular necrosis, tubulointerstitial disorders, renal tubular acidosis (RTA), and hypomagnesemia or in association with some drugs such as amphotericin or diuretics.

The initial evaluation of hypokalemia should consider the patient's potassium intake, potassium losses, and underlying conditions that may predispose to hypokalemia. Serum electrolytes, arterial blood gases, and urinary electrolytes may be useful in arriving at a correct diagnosis as shown in Fig. 17.3. Further tests (e.g., aldosterone, plasma renin activity, serum magnesium) can be requested when appropriate. The urinary potassium concentration is helpful because it will differentiate renal potassium losses from other causes of hypokalemia.

Hyperkalemia

The signs and symptoms of hyperkalemia include muscle weakness and abnormal cardiac conduction. Muscle weakness generally does not occur until the serum potassium is more than 7 mmol/L. Electrocardiographic changes can be seen with plasma levels greater than 6 mmol/L. More severe hyperkalemia (in excess of 8.0 mmol/L) is associated with a sine wave pattern on the electrocardiogram with imminent ventricular fibrillation and cardiac arrest (7).

An approach to the evaluation of hyperkalemia and a selected differential diagnosis is shown in Fig. 17.4. Hyperkalemia can result from increased intake, redistribution, and decreased renal potassium excretion. Normally the kidney excretes excess potassium and consequently chronic hyperkalemia implies impaired urinary excretion.

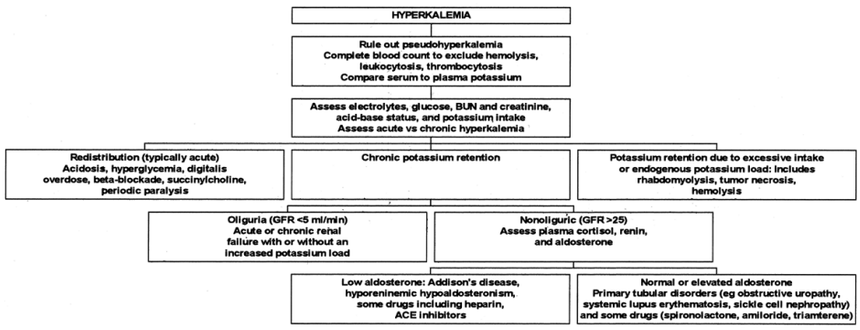

FIGURE 17.4. Selective differential diagnosis and laboratory approach to hyperkalemia. GFR: Glomerular filtration rate; ACE: Angiotensin converting enzyme.

Acidemia promotes the exchange of plasma hydrogen ions for cellular potassium and thus is a cause of hyperkalemia. The resulting hyperkalemia is greatest with hyperchloremic metabolic acidosis (8).

Hyperkalemia may occur despite a deficit of total body potassium stores. For example, in patients with diabetes mellitus, insulin deficiency enhances uptake of both glucose and potassium by cells. Rhabdomyolysis, or any state of tissue breakdown (e.g., trauma, hemolysis, or tumor lysis after chemotherapy) can release cellular potassium and cause hyperkalemia. Several drugs promote potassium loss from cells such as succinylcholine, whereas digitalis overdose interferes with the cellular sodium/potassium ATPase pump. Hyperkalemic periodic paralysis is a rare autosomal dominant condition characterized by episodes of paralysis with acute hyperkalemia.

Several conditions produce hyperkalemia by impairing renal potassium excretion including renal failure and hypoaldosteronism. The differential diagnosis of hypoaldosteronism is extensive and includes hyporeninemic hypoaldosteronism, several drugs (nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme inhibitors, cyclosporine), adrenal insufficiency, congenital adrenal hyperplasia, and aldosterone resistance (potassium-sparing diuretics, pseudohypoaldosteronism, cyclosporine) (9).

Pseudohyperkalemia may occur in samples with hemolysis or in specimens with leukocytosis or thrombocytosis that have been allowed to stand for an excessive period before processing

Hyperchloremia and Hypochloremia

Chloride is quantitatively the most important extracellular anion. As such, abnormalities in the serum chloride may occur in a variety of settings as a component of acid-base, fluid, or electrolyte disorders. From a clinical perspective, the abnormality in the serum chloride itself is of little concern. Rather, attention is focused on the underlying disorder causing the hyperchloremia or hypochloremia. A selected differential diagnosis is shown in Table 17.3.

Of the various conditions listed in Table 17.3, only one, bromism, merits specific discussion here. Elevations of serum bromide once occurred in patients ingesting bromide ion in the

TABLE 17.3. Differential Diagnosis of Hyperchloremia and Hypochloremia

Hyperchloremia
Metabolic acidosis associated with gastrointestinal bicarbonate loss
Renal tubular acidosis
Hypoaldosteronism
Respiratory alkalosis
Hyponatremia with sodium losses in excess of chloride
Bromism
Administration of NH_4Cl, amino acids (hyperalimentation), saline, carbonic anhydrase inhibitors
Some cases of hyperparathyroidism
Hypochloremia
Gastrointestinal chloride losses (vomiting, nasogastric suction)
Anion-gap metabolic acidosis
Tubulointerstitial disorders
Hyperaldosteronism
Compensated respiratory acidosis
Metabolic alkalosis
Hyponatremia
Adrenocortical insufficiency

form of over-the-counter drug formulations or as an anticonvulsant. These drugs are not often used today, and, as a result, the incidence of bromism has declined. The one case we did observe was a foreign patient visiting the United States. Aside from its toxic properties, bromide ion causes falsely elevated chloride levels with ISE, coulometric, and, to a lesser degree, mercurimetric methods. Other conditions listed in Table 17.3 are discussed elsewhere in this chapter.

pH, PCO_2, AND BICARBONATE

Part of "17 - Electrolytes and Acid-Base Balance"

Physiology of Acid-Base Balance

An optimal pH is important for the functioning of cellular enzymes. The pH of the blood is normally maintained (Table 17.4) by a combination of the body's buffering systems and by renal and respiratory regulatory mechanisms. As a general rule, acidemia below pH 6.8 or alkalemia above pH 7.8 is not compatible with life. Less dramatic alterations in acid-base balance may cause significant morbidity and mortality, especially when superimposed on other serious illnesses.

TABLE 17.4. Reference Intervals for Arterial Blood pH and Gases

pH	7.36–7.44
Po_2	80–100 mm Hg
Pco_2	35–45 mm Hg
Oxygen saturation	>95%
Bicarbonate	22–26 mmol/L
Total CO_2	23–27 mmol/L
Base excess	-2 to +2 mmol/L

It is useful in discussing acid-base balance to distinguish between abnormalities in blood pH (acidemia and alkalemia) and conditions that tend to produce acidemia and alkalemia (acidosis and alkalosis). As are discussed, different types of acidosis and alkalosis can be present simultaneously, and the resultant blood pH may be either high, low, or normal.

Acidemia is defined as an arterial pH below 7.36 and alkalemia as a pH above 7.44. Acid-base disorders affect a variety of metabolic processes, ultimately leading to impairment of essential functions, but the clinical signs and symptoms of acidosis and alkalosis are relatively nonspecific. Therefore, the diagnosis requires laboratory confirmation by measurement of blood pH and gases.

Carbon dioxide is produced by cellular respiration and is the most important substance to challenge the acid-base balance of the body. Acid is produced by the association of CO_2 with water, forming carbonic acid, which dissociates to hydrogen ion and bicarbonate.

$CO_2 + H_2O$ [left harpoon over right harpoon] H_2CO_3 [left harpoon over right harpoon] $H^+ + HCO_3^-$

Almost all the CO_2 produced (volatile acid) is eliminated in the lungs. An additional acid load is created by the metabolism of proteins and the hydrolysis of phosphoester bonds, resulting in the production of nonvolatile acids, predominantly sulfuric and phosphoric acids. Other metabolic processes produce alkali in the form of bicarbonate, mainly by the oxidation of organic anions. Consequently, the body requires a finely regulated but flexible mechanism to cope with acid or base challenges.

Body Buffering Systems

The Henderson-Hasselbalch equation describes the relationship between pH and the acidic and basic forms of a buffer. The general relationship is

$$\mathrm{pH} = \mathrm{pK'} + \log\left(\frac{C_{\text{basic form of buffer}}}{C_{\text{acidic form of buffer}}}\right)$$

where C represents concentration and pK' represents the negative logarithm of the equilibrium constant for the buffer pair.

The principal buffering system of plasma is the bicarbonate/carbonic acid system. Carbonic acid in plasma is in equilibrium with dissolved CO_2. This in turn is directly measurable as PCO_2, and the two quantities are related by the solubility coefficient of CO_2 in plasma, which is 0.03 mmol + L^{-1} + mm Hg^{-1}.

CCO_2 (dissolved) = 0.03 PCO_2

For the bicarbonate/carbonic acid system, the Henderson-Hasselbalch equation can thus be written as

$$\mathrm{pH} = 6.1 + \log\left(\frac{C_{HCO_3^-}}{0.03\ P_{CO_2}}\right)$$

where $CHCO_3^-$ is expressed in millimoles per liter and PCO_2 is expressed in millimeters of mercury.

Normally the ratio of bicarbonate to dissolved CO_2 is 20/1. Changes in either the bicarbonate concentration or the PCO_2 will affect the ratio and thus change the pH of the blood. Blood gas analyzers measure pH, PCO_2, and PO_2, and the Henderson-Hasselbalch equation is used by the microprocessor built into the analyzer to calculate other quantities such as bicarbonate and total CO_2 concentrations.

The Henderson-Hasselbalch equation could also be written for any of the other buffer pairs in the body. Because all buffers must be in equilibrium, acid-base status can be expressed in terms of only the carbonic acid–bicarbonate system.

Respiration and Acid-Base Regulation

The rate of alveolar ventilation affects acid-base status through changes in the PCO_2.The rate of respiration is influenced by the arterial PO_2 and pH. Arterial pH is detected by chemoreceptors in the aortic arch and carotid bodies (peripheral) and in the brainstem (central). Acidemia stimulates respiration, resulting in a fall in the PCO_2 and an increase in arterial pH. Conversely, alkalemia induces hypoventilation with CO_2 retention and a decrease in pH toward normal. This forms the basis of the respiratory compensatory mechanism. Conversely, a pathologic alteration in alveolar ventilation may itself be the cause of an acid-base disorder by inducing CO_2 retention (respiratory acidosis) or excessive CO_2 elimination (respiratory alkalosis).

Renal Acid-Base Regulation

The kidney plays an important role in acid-base balance. The kidney regulates bicarbonate resorption and acid excretion, primarily in the form of ammonium ion. Plasma bicarbonate is filtered by the glomerulus and is resorbed to maintain acid-base balance. In alkalotic states, the kidney can also excrete bicarbonate to compensate for an elevated pH.

Normally the body produces a net excess of acid (50 to 100 mmol/day) (10). However, the minimum urinary pH is approximately 4.5 (9), and at this pH, only a small number of free hydrogen ions can be excreted. Consequently, the kidney requires an alternate mechanism to excrete the normal daily acid load. The two most important species in this regard are phosphate (HPO_4^{2-}) and ammonia, both of which can combine with hydrogen ions secreted by renal tubular cells and are excreted in urine as $H_2PO_4^2$ and NH_4^+. The amount of phosphate available for combination with H^+ cannot be increased significantly from its normal level; however, the production of ammonia can be greatly increased. Ammonia produced by the renal tubular epithelium diffuses into the tubular lumen where it combines with hydrogen ions to form ammonium ion, which is charged and cannot diffuse back into the cell. The hydrogen ions are thus trapped and are excreted in the urine. Therefore, ammonia formation is the most important mechanism of the kidney to increase acid excretion.

Measurement of pH, PCO_2, and Bicarbonate

Analytical Methods

Blood gas analyzers measure three quantities, pH, PCO_2, PO_2. All other quantities including bicarbonate, total CO_2, dissolved CO_2, and base excess are calculated by the microprocessor in the instrument.

pH Measurement

The method for measuring the pH of blood is essentially the same as that in any other liquid. The pH is determined by measurement of the voltage in an electrochemical cell containing a glass electrode that is selective for hydrogen ions. The principles of ISE measurements were discussed previously, so only those factors unique to blood pH measurement are included here.

The reference electrode is usually a saturated calomel electrode and the bridge solution is usually saturated, or nearly saturated, potassium chloride, although other solutions are sometimes used.

Calibration of the system is performed with two phosphate buffers that are traceable to the primary pH standards certified by the National Institute of Standards and Technology. The buffers most often used have a pH between 6.84 and 7.39 at 37°C. This narrow range is appropriate because the physiologic range of the blood pH is also quite narrow.

Blood pH, PCO_2, and PO_2 are all temperature dependent. By convention, measurements are made at 37.0°C, and the temperature is controlled (to within ±0.05°C) to ensure accurate results. This is important because the temperature coefficient of blood pH is approximately 10 times larger than that of the phosphate buffers used as calibrators. Therefore, if the instrument temperature drifts, it will not be detected (or compensated) by a shift in the pH of the calibrators and will result in a measurement error.

The other source of significant systematic bias in blood pH measurements is residual liquid junction potential. As explained earlier, this error arises in potentiometric measurements when the potential at the liquid junction between the salt bridge and the solution is not the same for the calibrators and the test solutions. In the case of blood pH, two different sources of bias arise at the liquid junction.

The first is known as a *suspension effect* and is a result of the presence of red cells at the interface with a concentrated KCl bridge solution. A bridge of 4 mol/L KCl causes the pH of whole blood to appear approximately 0.01 lower than the pH of the corresponding plasma. This effect can be eliminated by changing the bridge solution to sodium formate, but it is often simply ignored.

The second source of bias is a classic example of a residual liquid junction potential. The matrix of the phosphate calibration buffers is much different from whole blood. In particular, the ionic strength of plasma is much greater and the mix of ionic species is different. The liquid junction potential between these two kinds of solutions and a concentrated KCl salt bridge is not the same, and the difference makes the apparent pH of whole blood samples approximately 0.03 lower than would be the case in the absence of this bias.

Both of the systematic errors described above exist in commonly used instruments for blood pH measurement. Eliminating these errors is technically feasible, but the bias is nearly constant and has been included in the reference interval used for clinical interpretation of blood pH. The current consensus is that the costs of such a change outweigh the benefits (11).

PCO_2 Measurement

The partial pressure of CO_2 in whole blood (PCO_2) is measured using an electrode system first described by Stow et al. (12) and modified by Severinghaus and Bradley (13). The system consists of a pH-sensitive glass electrode in contact with a weak bicarbonate solution. This solution is separated from the sample by a membrane permeable to CO_2. When CO_2 from the sample diffuses across the membrane into the bicarbonate solution, the pH

change is sensed by the glass electrode and the change in pH is related to the P_{CO2} in the sample, which can be either a gas or a liquid. There is no bias owing to sample matrix or residual liquid junction potential because the sample is isolated from the cell by the gas-permeable membrane.

Blood gas partial pressures are quite dependent on the sample temperature. The solubility of gases in aqueous solutions increases as the temperature of the solution is lowered. Therefore, as temperature is increased, gases come out of the solution and the partial pressures of the gases increase. For CO_2, this increase is approximately 5% per degree Celsius. Therefore, the temperature of blood gas electrode systems is always held constant, conventionally at 37.0°C.

Calibration of Blood Gas Electrode Systems

The measurement of PCO_2 and PO_2 is performed simultaneously in most blood gas instruments. PO_2 measurement is discussed in Chapter 18. Calibration of both electrodes is done at two points, usually with gas mixtures containing known percentages of O_2 and CO_2. The two points chosen for CO_2 are usually 5% and 10%. The nature of the oxygen electrode permits a zero adjustment with an oxygen-free gas, and the second calibration point is usually either 12% or 20% O_2. These are merely conventions; other gas compositions can be used, but the composition must be accurately known, typically to within ±0.03%.

Although the composition of a gas mixture is stated as a percentage of each component, the partial pressures of O_2 and CO_2 in blood are expressed in units of millimeters of mercury (mm Hg) or kilopascals (kPa) (1 mm Hg equals 0.1333 kPa). To calculate the partial pressure of CO_2 and O_2 in a calibration gas, the vapor pressure of water (PH_2O) and the total (barometric) pressure (Ptotal) must also be known. The vapor pressure of water is needed because the (dry) gas mixture is saturated with water at 37°C before it reaches the electrodes. The partial pressure of gas G (PG) is calculated as

$$P_G = \frac{X_G}{100}(P_{total} - P_{H_2O})$$

where XG is the percentage of gas G in the dry gas mixture. The vapor pressure of water at 37°C is 47 mm Hg. Many blood gas analyzers have an automatic calibration feature with a built-in barometer, and the above calculation is performed internally.

Total CO_2

Total CO_2 is defined as the sum of the concentrations of the various CO_2-containing species in plasma (dissolved CO_2 gas, carbonic acid, bicarbonate ion, carbonate ion, and CO_2 associated with proteins as carbamates). Normally, bicarbonate ion and dissolved CO_2 account for approximately 94% and 5%, respectively, of the total CO_2. The total CO_2 is measured by adding acid or base to the sample to convert essentially all the CO_2 forms to either dissolved CO_2, bicarbonate, or carbonate ions and then measuring the concentration of that particular species.

The classic, and still the most accurate, methods begin with acidification of the sample to convert all forms of CO_2 to dissolved CO_2. Several techniques have been used to quantitate the CO_2 gas produced.

1. Manometry. This is an accurate method but requires special apparatus and is time-consuming.
2. Colorimetry, with the CO_2 gas being dissolved in a weak buffer containing an indicator such as phenolphthalein. This was very widely used in continuous-flow methods but is less common today.
3. A CO_2 electrode, whereby the increase in PCO_2 is measured directly using the same type of electrode used in blood gas analyzers.
4. Thermal conductivity, whereby a gas stream containing the CO_2 is passed over a "hot-wire" detector of the type used in gas chromatography.
5. Titrimetry, whereby the CO_2 released is recaptured in a basic solution, and the solution is titrated back to its original pH with standardized sodium hydroxide.

Another popular methodological principle begins by buffering the sample so that virtually all the CO_2 is in the form of bicarbonate, which is then measured enzymatically by the following reactions.

$$\text{Bicarbonate} + \text{Phosphoenol pyruvate} \xrightarrow{\text{PEPC}} \text{Oxaloacetate} + \text{Phosphate}$$

$$\text{Oxaloacetate} + \text{NADH} \xrightarrow{\text{MDH}} \text{Malate} + \text{NAD}$$

where PEPC is phosphoenolpyruvate carboxylase and MDH is malate dehydrogenase. The disappearance of NADH (nicotinamide adenine dinucleotide, reduced form) can be monitored spectrophotometrically at 340 nm, or this reaction can be coupled to another redox indicator, which can be monitored in the visible region of the spectrum.

A third method that has been used is based on raising the pH of the sample to shift the equilibria toward carbonate ion, which is then measured directly using a carbonate ISE.

Although most of the methods described above are capable of good precision, there is a need for a practical reference method. The manometric method has both high accuracy and precision but requires a specialized apparatus and careful technique. A titrimetric method based on capturing CO_2 in a $BaCl_2$ solution after liberation from an acidified sample has been proposed as a candidate reference method (14).

Calculations and Derived Quantities

Total CO_2 and Bicarbonate

Although the total CO_2 can be measured in serum, it is also common to calculate it in conjunction with direct measurement of pH and PCO_2 in whole blood. The relationship needed to calculate bicarbonate concentration is the Henderson-Hasselbalch equation, which may be written in the form

$$\log CHCO_3^- = pH - pK' + \log PCO_2 + \log \alpha$$

where pK′ for the equilibrium between the dissolved CO_2 and bicarbonate is 6.105 and α, the solubility coefficient of CO_2 in plasma, is $0.0307 \cdot mmol \cdot L^{-1} \cdot mm\ Hg^{-1}$. A close approximation of the total CO_2 can be made by adding the bicarbonate concentration and the concentration of dissolved CO_2 (i.e., ignoring the small amounts of carbonate ion and protein carbamates). This approximation is

Ctotal CO_2 = $CHCO_3^-$ + α PCO_2.

The preceding two equations are incorporated into most blood gas analyzers. There has been some controversy in the literature about the applicability of the Henderson-Hasselbalch equation in acutely ill patients. This has been carefully reviewed (15), with the conclusion that, although minor variations in pK′ certainly occur, they are not large enough to affect the clinical usefulness of a calculated total CO_2 (or bicarbonate). This calculation is usually a part of routine blood pH and gas analysis and facilitates the interpretation of blood gas data.

Base Excess

When blood pH and PCO_2 are abnormal, it is often not immediately obvious whether the abnormality is purely respiratory in nature or whether a metabolic component is present. Additional insight may be gained by using one of the many nomograms that have been constructed for this purpose. In addition, attempts have been made to define a quantity that can be readily calculated and that would reflect only the metabolic component of an acid-base imbalance.

Several quantities have been proposed, but base excess of ECF, CBE, is generally believed to be the most useful of these. Although in principle base excess can be measured, it is much more common to calculate it from the relationship (16)

CBE = $CHCO_3^-$ - 24.8 + 16.2 (pH - 7.40)

Base excess has also been defined for whole blood, which is calculated differently. Although there is agreement that this quantity is not as accurate in reflecting metabolic acid-base disturbances, its use preceded that of ECF base excess and became well established. Unfortunately, manufacturers of blood gas analyzers persist in making both types of base excess calculations available, so care must be taken not to use the base excess of whole blood. Many laboratories avoid the potential confusion by simply not reporting base excess. The rationale is that base excess, like any other calculated quantity, adds no essential information and is useful only to the extent that it facilitates interpretation of the measured quantities. The particular type of interpretive aid favored (if any) usually reflects how a person was trained to interpret acidbase data. There is no inherent reason to prefer calculation of ECF base excess to use of a nomogram or to some other approach.

Temperature Corrections

pH, PCO_2, and PO_2 are all temperature-dependent quantities, and by convention measurements are always made at 37.0°C. However, if the body temperature of the patient differs from 37°C, then the question arises whether to adjust the measured values to the temperature of the patient. There has always been some controversy about the desirability of making this adjustment. On the one hand, it is reasonable to do so because the adjusted values would correspond to the actual conditions *in vivo*. On the other hand, the reference intervals used to interpret the pH, PCO_2, and PO_2 were determined at 37°C, and the question of what values should be considered normal at other temperatures is unresolved. To minimize confusion, it is wise to report only the values measured at 37°C or to report both and the values adjusted to body temperature. Most blood gas analyzers include software to automatically calculate adjusted values if the body temperature of the patient is known, and algorithms suggested for these adjustments have been published (16).

Specimens and Specimen Handling

The collection and handling of specimens for blood pH and gas analysis have requirements unlike those for other clinical laboratory tests. These apply to the site and technique of collection, the specimen container, the anticoagulant, and the transport and storage of the specimen. All these topics and several others were recently reviewed by a subcommittee of the National Committee for Clinical Laboratory Standards (NCCLS), and a guideline document was published covering specimen collection as well as calibration and quality control issues (17). The essence of the NCCLS recommendations on specimen collection and handling are covered in this section.

Site and Technique

In the majority of requests for blood gas testing, there is a need to evaluate the degree of oxygenation of the blood in addition to the acid-base status. A specimen of arterial blood is therefore required. The technique of obtaining an arterial blood specimen is more difficult and more hazardous to the patient than venous sampling. Another NCCLS publication (18) contains detailed procedures and precautions to be observed in arterial blood sampling and is recommended.

If it is not practical to obtain arterial blood, capillary blood may be used, but with some constraints (19). The capillaries, usually of the foot or the fingertip, must be dilated by warming the skin so that the PO_2 will be close to the arterial level. Despite this, the correlation of capillary PO_2 to arterial PO_2 is not very good, in part owing to the difficulty in obtaining a capillary sample without exposing the blood to room air. The correlation is good, however, for PCO_2 and pH.

If arterial PO_2 is not a concern, the acid-base status of the blood can be evaluated by analysis of venous blood for pH and PCO_2 to avoid the discomfort and hazard of arterial puncture.

Container and Storage

Capillary specimens are collected in preheparinized glass capillary tubes. Recommended specifications for the tubes have been published (20). The blood must be well mixed in the tube to ensure homogeneity and dissolution of the anticoagulant.

Venous specimens (for pH and PCO_2 only) may be collected in either syringes or evacuated tubes, but the latter must be completely filled. Arterial specimens should be collected in a syringe. Both glass and plastic syringes are used for blood gas specimens, and two factors influence the choice: (a) the expense of maintaining a system to clean, sterilize, and reuse glass syringes and (b) the length of time that may elapse before the specimens are analyzed. Glass is superior because plastic syringes can alter the PO_2 (and, to a lesser extent, the PCO_2) of a blood specimen, presumably owing to room air dissolved in the plastic syringe barrel and plunger tip (21,22). The size of the error depends on the PO_2

and the temperature of the blood but is complicated because the buffering of PO_2 by hemoglobin changes with PO_2, as reflected by the oxygen-hemoglobin association curve. The error is increased when the specimen is cooled in ice water because oxygen solubility increases at lower temperatures.

Beginning at a PO_2 of 100 mm Hg, the oxygen level of a specimen in a plastic syringe stored in ice water may increase as much as 8 mm Hg in 30 minutes. This error is much smaller at lower PO_2 because hemoglobin is unsaturated and is also much smaller if the specimen is kept at room temperature instead of being iced. A complication of not chilling the specimen is that metabolic processes utilizing oxygen proceed at a faster rate in the blood specimen, which constitutes yet another source of error. This error is particularly significant in blood with an elevated leukocyte or platelet count.

It is recommended that if plastic syringes are used, the blood not be chilled but that the analysis be completed within 20 minutes to reduce the probability of error owing to metabolic changes. Conversely, if glass syringes are used, the specimens should be cooled in ice water so that metabolic changes will be insignificant even with moderate elevations in leukocytes or platelets, and most specimens can then be held at least an hour before analysis, if necessary.

Room air has a PO_2 of approximately 150 mm Hg and a PCO_2 of less than 1 mm Hg. Obviously, contact between the blood and room air must be prevented. No air bubbles may be present in the specimen, and the needle should be replaced with an airtight cap as soon as the specimen is drawn.

Anticoagulant

Sodium or lithium heparin is the anticoagulant to be used for blood pH and gas analysis. Both are available in dry and liquid forms.

If the liquid preparation is used, care must be taken not to use more volume than necessary because the errors caused by sample dilution can be significant. If a heparin strength of 1,000 IU/mL is used, the volume in just the syringe dead space (needle and hub) is sufficient to anticoagulate a specimen in a 3-mL syringe. More concentrated heparin solutions are not recommended.

Heparin in solid form is used in some capillaries and prepacked syringes, either as a pellet or as a coating on the container wall. Dilution errors are obviously avoided, but extra care must be taken to dissolve the heparin in the blood by vigorous mixing.

Quality Control and Proficiency Testing for Blood pH and Gas Analysis

The basic principles and issues of quality control and proficiency testing (QC/PT) that apply to all analytes in clinical chemistry apply also to blood pH and gases, but there are some additional aspects that are unique to blood gas QC/PT.

Materials and Matrix Effects

A universally accepted principle in QC/PT is that the sample used must have the same characteristics as fresh patient samples. However, this is often impractical. As a result, QC/PT materials may give results that are different from those expected on patient samples. Such differences are known as matrix effects and are of particular concern in blood gas QC/PT (23).

Commercially available controls for blood pH and gases usually are sold in the form of sealed glass ampules containing a solution in equilibrium with a gas phase above it. The solution matrix is one of three types: (a) aqueous; (b) blood based, either stabilized whole blood or a hemolysate; or (c) perfluorocarbon emulsion. In all cases, the solution is buffered to stabilize the pH. The most important differences are related to the PO_2 stability in the QC material when exposed to room air. This is an important issue because it is impossible to completely avoid contact between a QC sample for blood gas analysis and room air.

Blood gas analyzers have been carefully designed to give accurate results when whole blood is used as the sample. Matrix effects with other materials are primarily owing to differences in the solubility of oxygen and carbon dioxide in these materials, and the effect is especially noticeable for PO_2. The solubility of oxygen in whole blood is much greater than in aqueous solutions because of the presence of hemoglobin. Exposure of a whole blood sample to a small amount of room air will change the PO_2, but hemoglobin will tend to buffer this change as long as it is not fully saturated with oxygen. Aqueous solutions, having no hemoglobin, will show relatively large changes in PO_2 when exposed to room air. Perfluorocarbon emulsions are used because the solubility of oxygen in perfluorocarbons is much higher than in water, and this will minimize the error caused by contamination of the sample with room air.

In PT programs in which both perfluorocarbon emulsions and aqueous materials are used, data from perfluorocarbons show significantly better precision for PO_2 than do aqueous materials (23). Conversely, perfluorocarbons do not resemble a whole blood matrix, and this material may not be usable in analyzers containing a potassium ISE because of interaction between perfluorocarbons and the potassium ionophore.

Blood-based controls do not necessarily behave like fresh patient samples either. Often the hemoglobin present in such controls is fully saturated with oxygen at a very low PO_2, and the sensitivity to room air contamination approaches that of aqueous solutions. However, some blood-based materials, or fresh whole blood, can be used for blood gas QC using a procedure called tonometry. Tonometry is the process of equilibrating a liquid with a gas of known composition. The apparatus used to accomplish this is called a tonometer. Tonometry makes it possible to prepare QC materials with an accurately known PO_2 and PCO_2, one of the rare instances in clinical chemistry when a QC material can be used as a test of accuracy as well as precision. Tonometers are readily available and the procedure and sources of error have been well described (17,24), but the technique is underutilized because of the perception that it is too time-consuming to be performed routinely. Nevertheless, tonometry is the basis for the reference method for blood PO_2 and PCO_2.

Further details and recommendations for quality control programs in a blood gas laboratory have been published by the NCCLS (17).

Temperature and Altitude Effects

Control materials that are packaged in sealed ampules containing a gas bubble are subject to a source of preanalytical error not seen

with patient samples. As the temperature of the sealed ampule rises and falls, the solubility of oxygen and carbon dioxide in the liquid changes, and the amount of gas dissolved in the liquid phase changes. Thus, the measured PO_2 and PCO_2 will depend on the temperature of the ampule when it is opened, and the instructions for handling QC/PT materials must specify what this temperature should be. This effect does not occur in patient samples because care is taken to exclude bubbles from the specimen.

Another source of error in blood gas analysis that can be important in PT is the effect of ambient pressure. It has been observed that the PO_2 and, to a lesser extent, the PCO_2 measured in PT samples tend to be lower if the laboratory is at high altitude. The effect is too small to be important clinically. However, the bias can be a significant fraction of the allowable error in PT programs, and laboratories at high altitude should use a correction factor if available (25).

INTERPRETATION OF ACID-BASE DISORDERS

Part of "17 - Electrolytes and Acid-Base Balance"

Acid-base disorders are classified into one of four categories: respiratory acidosis, respiratory alkalosis, metabolic acidosis, and metabolic alkalosis. Each of these categories includes a number of possible causes. The evaluation of an acid-base abnormality requires the correct classification of the disorder, followed by a consideration of the differential diagnostic possibilities to obtain the specific etiology. The interpretation may be complicated by differences in acute versus chronic acid-base disorders, by the effects of renal and respiratory compensatory mechanisms, and by the presence of mixed acid-base abnormalities.

In response to an abnormal pH, the body initiates compensatory mechanisms to restore the pH. The renal compensatory mechanisms include the ability of the kidney to alter bicarbonate resorption and to increase acid excretion. The respiratory compensatory mechanism operates by changing the alveolar ventilation and thus retaining CO_2 (hypoventilation) or releasing additional CO_2 (hyperventilation). The effect of compensatory mechanisms is to create a mixed acid-base disorder in which the compensatory response is superimposed on the primary acid-base abnormality. Mixed disorders may also occur in a patient with two simultaneous but unrelated primary acid-base abnormalities.

The ability of the body to normalize the arterial pH is limited, because correction of the pH would shut off the physiologic mechanisms driving the compensatory response. For this reason, the arterial pH usually remains somewhat abnormal even in the compensated state.

Table 17.5 shows the various types of primary acid-base disorders, the principal mechanism causing the disorder, the expected laboratory abnormalities, and the effects of compensatory responses.

TABLE 17.5. Characteristics of Primary Acid-Base Disorders

Disorder	Primary Change	Compensatory Response
Metabolic acidosis	Decreased HCO_3	Hyperventilation
	Decreased pH	Decreased Pco_2
Metabolic alkalosis	Increased HCO_3	Hypoventilation
	Increased pH	Increased Pco_2
Respiratory acidosis	Increased Pco_2	Increased acid excretion and HCO_3 resorption
	Decreased pH	
Respiratory alkalosis	Decreased Pco_2	Decreased acid excretion and HCO_3 resorption
	Increased pH	

There are several general approaches to the evaluation of acid-base disturbances. One system utilizes an acid-base nomogram such as the one shown in Fig. 17.5. If the pH and the PCO_2 are measured, then a presumptive diagnosis may be made by locating the point corresponding to the two values on the nomogram to determine which of the seven diagnostic zones it falls into. For example, a patient with an arterial pH of 7.3 and a PCO_2 of 30 would be classified as having a metabolic acidosis. The advantages of this method are that it is simple, requires no calculations, and provides a reliable classification of the disorder, even with mixed acid-base abnormalities. The disadvantage of using a nomogram is that these charts are not always readily available, especially at the bedside in emergency situations. For this reason, it is essential to have a simplified system for interpreting acid-base disorders that does not rely on a nomogram or the use of complex calculations.

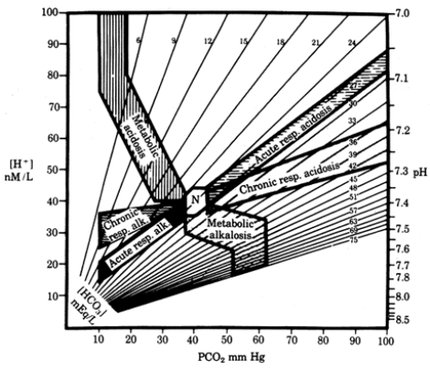

FIGURE 17.5. Diagram for interpretation of acid-base data. (From *JAMA*1973;223:269.)

Various textbooks describe sets of rules of thumb that permit a rapid interpretation of acid-base abnormalities (26,27 and 28). The major drawback to the use of these rules is that complex acid-base disorders are difficult to interpret. The clinical history must be considered whenever possible, rather than attempting a diagnosis based on laboratory data alone. Recognizing the need for a practical approach to the interpretation of acid-base data, the American Heart Association has recommended the use of a set of simplified rules that permit rapid interpretation of acid-base data (26,27). Two of these rules are shown in Table 17.6 and should be memorized and practiced. Most acid-base disorders can be interpreted by using only the first rule.

TABLE 17.6. Simplified Rules for the Interpretation of Acid-Base Disorders

Rule 1:	A change in Pco_2 of 10 mm Hg will change the pH by 0.08.
Rule 2:	A change in bicarbonate of 10 mmol/L will change the pH by 0.15.

Adapted from Comella L, Braen R, Olding M. Blood gases and acid-base disorders. In: *Clinician's pocket reference*, 4th ed. Laguna Niguel, CA: Capistrano Press, 1983:157–168.

The usefulness of rule 1 is best illustrated by example. Suppose a patient has a pH of 7.32 and a PCO_2 of 50 mm Hg. In this case, the PCO_2 is elevated by 10 mm Hg. Using rule 1, this should produce a decrease in pH of 0.08, and therefore the predicted pH is 7.32 (7.40 to 0.08). Because the measured pH and the calculated pH are the same (or close), all the change can be explained by respiratory dysfunction. The most likely diagnosis is therefore acute respiratory acidosis. Now consider a second patient with a pH of 7.35 and a PCO_2 of 52 mm Hg. The elevated PCO_2 again indicates a component of respiratory acidosis. However, rule 1 predicts a pH of approximately 7.30. The measured pH is greater (closer to normal) than predicted by 0.05, indicating that compensation has occurred. The correct diagnosis is respiratory acidosis with partial renal compensation (chronic respiratory acidosis).

Either the acid-base nomogram or these rules permit a classification of acid-base disorders into one of the categories shown in Table 17.5. The next step is to consider the differential diagnostic possibilities that comprise each category.

Respiratory Acidosis

Respiratory acidosis results from any condition that impairs CO_2 elimination by the lungs and is characterized by an increased

PCO_2 and a decreased pH. A large number of disorders may produce respiratory acidosis, as seen in Table 17.7. These disorders may be classified as neuromuscular diseases, airway obstruction, and cardiopulmonary-thoracic disorders. Neuromuscular diseases may affect the respiratory apparatus at any level, including the CNS respiratory center in the brainstem, the peripheral nerves innervating the diaphragm and chest wall muscles, or the respiratory muscles themselves. The result is hypoventilation and retention of CO_2. Several drugs produce respiratory acidosis by depressing the central respiratory center. Narcotic overdose is a classic example of this effect. Airway obstruction can occur at any level of the respiratory tract. Cardiopulmonary-thoracic disorders also include a variety of other conditions that impair gas exchange.

TABLE 17.7. Selected Differential Diagnosis of Acid-Base Disorders

Respiratory acidosis
Neuromuscular
Brainstem/spinal cord injury
Narcotic overdose
Guillain-Barré syndrome
Myasthenia gravis
Poliomyelitis
Botulism
Diaphragmatic paralysis
Myopathy of respiratory muscles
Cardiopulmonary
Airway obstruction (foreign body, tumor bronchospasm, COPD)
Cardiac arrest
Severe pneumonia or pulmonary edema
Pulmonary embolus
Mechanical underventilation
Plural effusion
Restrictive disease of thorax
Metabolic
Myxedema
Metabolic acidosis
High anion gap
Lactic acidosis
Ketoacidosis (diabetic or alcoholic)
Aspirin overdose (late)
Methanol/ethylene glycol intoxication
Paraldehyde
Renal failure
Rhabdomyolysis
Normal anion gap
GI loss of bicarbonate (diarrhea, pancreatic or biliary drainage)
Renal loss of bicarbonate (RTA, tubulointestitial diseases, hypoaldosteronism)
Acid gain (ammonium chloride, amino acid administration)
Respiratory alkalosis
Central nervous system
Anxiety
Aspirin overdose (early)
Fever
CNS infection, tumor, stroke
Hypoxia
Pulmonary
Pulmonary emboli
Pneumonia
Interstitial lung disease
ARDS
Pulmonary edema (mild)
High altitude
Mechanical overventilation
Metabolic/other
Hepatic failure
Pregnancy
Sepsis
Metabolic alkalosis
Chloride responsive
Vomiting, nasogastric suction
Diuretics
Villous adenoma
Cystic fibrosis
Posthypercapnia
Congenital chloridorrhea
Chloride resistant
Hyperaldosteronism
Cushing's syndrome
Bartter's syndrome
Excessive licorice ingestion
Severe potassium depletion
Miscellaneous
Alkalinizing agents
Milk alkali syndrome
Hypoparathyroidism
Drugs: carbenicillin, penicillin (large doses)

Adapted from Alder S, Lam M, Connors A. Acid-base and electrolyte disorders. In: A pocket manual of differential diagnosis. Boston, 1982: Little, Brown, 1–7.
CNS, central nervous system; ARDS, adult respiratory distress syndrome; COPD, chronic obstructive pulmonary disease; GI, gastrointestinal; RTA, renal tubular acidosis.

In acute respiratory acidosis, the bicarbonate level and total CO_2 are normal. The increase in PCO_2 will stimulate the central respiratory center to increase respiration. Renal compensatory mechanisms require more time to show an effective response. The effect of renal compensation is to convert CO_2 and water to hydrogen ion, which is excreted, and bicarbonate, which is reabsorbed into the plasma. When this occurs, the acid-base disorder is classified as chronic respiratory acidosis, characterized by an increased PCO_2, a decreased pH, and an increase in the plasma bicarbonate and total CO_2.

There are also effects on other electrolytes, notably the plasma potassium and chloride. Acidemia is associated with mild hyperkalemia followed by increased renal potassium excretion, and ultimately potassium depletion. The increase in renal bicarbonate resorption is balanced by increased excretion of chloride to maintain electroneutrality. Thus, hypochloremia may accompany respiratory acidosis.

Respiratory Alkalosis

Respiratory alkalosis results from hyperventilation and is characterized by a decreased PCO_2 and an increased pH. The differential diagnosis includes primary disorders of the central respiratory center, pulmonary diseases associated with hypoxemia, and a variety of miscellaneous causes of hyperventilation (Table 17.7). Symptoms of respiratory alkalosis include lightheadedness, paresthesias, tetany, and, in severe cases, syncope. The two most common causes are acute anxiety and hyperventilation in response to hypoxemia. A less obvious cause of respiratory alkalosis is the rapid correction of a metabolic acidosis, for example, by bicarbonate infusion. Although the blood pH may return to normal, the CNS system requires some time to equilibrate with the periphery. The temporary persistence of CNS acidosis continues to stimulate the respiratory control center with the resultant hyperventilation and peripheral respiratory alkalosis.

Acute respiratory alkalosis is characterized by a low PCO_2, a high pH, and a normal bicarbonate and total CO_2. Alkalemia depresses the respiratory control center, which tends to limit the

hyperventilation in some cases, but the primary compensation is renal. The kidneys respond by decreasing acid excretion and bicarbonate resorption, which causes the plasma bicarbonate to fall. In chronic respiratory alkalosis, therefore, the PCO_2 is low, the pH is high (but not as high as in the acute condition), and the plasma bicarbonate and total CO_2 are decreased.

Other electrolytes may show abnormalities as well. Alkalemia is associated with a mild hypokalemia. Increased renal bicarbonate excretion is accompanied by chloride retention, resulting in hyperchloremia.

Metabolic Alkalosis

Metabolic alkalosis is characterized by increased pH, bicarbonate, and total CO_2. The causes are often divided into two categories, designated chloride-responsive and chloride-resistant types (Table 17.7). The laboratory distinction is made by measuring the urine chloride; a level below 20 mmol/L is classified chloride responsive and above 20 mmol/L is chloride resistant.

One of the more common subcategories of chloride-responsive metabolic alkalosis is called contraction alkalosis. This condition results from a depletion of salt (NaCl) and water without a proportionate loss of bicarbonate (7). Contraction of the ECF volume results in an increase in the plasma bicarbonate concentration and thus metabolic alkalosis. Ordinarily the kidney would excrete the excess bicarbonate, but in the setting of salt and water depletion, the kidney conserves sodium to maintain the circulating volume and thus cannot excrete the bicarbonate (28).

Several causes of chloride-responsive metabolic alkalosis are associated with the loss of hydrogen ions from the gastrointestinal tract. Gastric secretions contain hydrochloride. Consequently, prolonged vomiting or nasogastric suctioning can produce metabolic alkalosis. Volume and salt depletion also contribute to the metabolic alkalosis as described above.

Villous adenomas of the intestine may secrete large amounts of sodium, chloride, and water (contraction alkalosis). In cystic

fibrosis, large amounts of sodium chloride may be lost in the sweat.

The major causes of chloride-resistant metabolic alkalosis are hyperaldosteronism, Cushing's syndrome, Bartter's syndrome, and severe potassium depletion. Hyperaldosteronism promotes renal hydrogen ion and potassium excretion. Cushing's syndrome may cause metabolic alkalosis because cortisol has weak mineralocorticoid activity. Bartter's syndrome, a rare disorder characterized by juxtaglomerular cell hyperplasia, produces a hypokalemic metabolic alkalosis as a result of increased renin production and resultant hyperaldosteronism. Licorice contains a steroid with weak mineralocorticoid activity (28).

Metabolic Acidosis

Metabolic acidosis is caused by an increased production of organic acids, decreased renal hydrogen ion excretion, or loss of bicarbonate. Any of these mechanisms causes a decrease in the pH, the bicarbonate concentration, and the total CO_2. The respiratory compensatory mechanism will partially correct the acidosis by increasing the rate of respiration, thereby lowering the PCO_2. The renal compensatory mechanism will increase hydrogen ion excretion and bicarbonate resorption. Metabolic acidosis is the most complicated of the various acid-base abnormalities; an excellent discussion is presented by Black (10).

Metabolic acidosis is usually classified based on whether the anion gap is increased. The anion gap (AG) is a calculated quantity that reflects the difference between the measured cations and the measured anions, as discussed earlier in this chapter. The AG is usually defined as

$AG = (C_{Na^+}) - (C_{Cl^-}) - (C_{HCO_3^-})$

The reference interval for the AG is 8 to 14 mmol/L. Although many conditions can alter the AG (5), its only clinical use is in the differential diagnosis of metabolic acidosis (Table 17.7).

There are five conditions that may cause a high-AG metabolic acidosis: renal failure, lactic acidosis, ketoacidosis, rhabdomyolysis, and some drugs and toxins.

Renal Failure

Renal failure can cause either a normal AG or a high-AG metabolic acidosis. Renal disease impairs hydrogen ion excretion due to a decrease in ammonia synthesis. Impaired hydrogen ion excretion necessitates a decrease in renal HCO_3^- resorption and thus the plasma HCO_3^- falls. Chloride replaces bicarbonate in the blood, resulting in a normal AG (hyperchloremic) acidosis. Conversely, severe renal failure is associated with renal retention of phosphate and sulfates (both unmeasured anions) and thus a high-AG acidosis.

Lactic Acidosis

Lactic acidosis is a common cause of high-AG acidosis. Lactic acid is a product of anaerobic metabolism. Major causes of lactic acidosis include tissue hypoxia (e.g., severe exercise, seizures, cardiac failure, hypoxemia); drugs and toxins (e.g., phenformin, catecholamines, salicylate, isoniazid, cyanide), congenital forms of lactic acidosis (such as defects in gluconeogenic enzymes), and a variety of severe illnesses, including sepsis, liver failure, and neoplasms (10). Lactate levels in excess of 5 mmol/L (reference interval 0.5 to 2.2 mmol/L) are diagnostic of lactic acidosis. The increase in the AG results from the unmeasured lactate anion.

Ketoacidosis

Ketoacidosis may occur in uncontrolled diabetes mellitus, starvation, or alcohol ingestion. Ketoacids (acetoacetic acid and β-hydroxybutyric acid) are overproduced by the liver, resulting in an increase in unmeasured anions and a high-AG acidosis.

Rhabdomyolysis

Massive destruction of muscle tissue releases organic acids from damaged myocytes, leading to a high-AG metabolic acidosis.

Drugs and Toxins

The four most common substances in this group are aspirin, methanol, ethylene glycol, and paraldehyde.

1. Salicylate overdose initially causes a respiratory alkalosis because the drug has a stimulatory effect on the central respiratory center. Eventually a high-AG acidosis occurs owing to the salicylate itself and to the effects of salicylate on peripheral metabolism, resulting in the production of a variety of organic acids, including lactate and ketoacids.
2. Methanol is metabolized to formaldehyde and formic acid. Accumulation of formate causes a high-AG acidosis. Methanol intoxication may also cause blindness.
3. Ethylene glycol, a component of antifreeze, is metabolized to glycolic, oxalic, and other organic acids. The toxic effects may include respiratory failure and acute renal failure, the latter owing to precipitation of calcium oxalate and hippurate crystals in the kidney. Urinalysis may therefore reveal oxalate and hippuric acid crystals.
4. Paraldehyde was once used to treat seizures. The drug is metabolized to acetic acid, although the metabolic acidosis may actually be caused by the presence of ketoacids in patients treated with this drug. The only case we recently encountered was observed in a foreign visitor to the United States.

The differential diagnosis of a high-AG acidosis may be simplified by calculation of the osmolal gap. The osmolal gap is the difference between the measured serum or plasma osmolality and the calculated osmolality as defined earlier in this chapter.

The osmolal gap is normally less than 10 mOsm/kg. If the measured osmolality exceeds the calculated osmolality by more than 10, the presence of a hidden osmotically active substance should be suspected (10). A high osmolal gap with a high-AG metabolic acidosis is suggestive of methanol or ethylene glycol poisoning.

Normal-AG Metabolic Acidosis (Hyperchloremic Acidosis)

A normal-AG acidosis can occur in several situations, including bicarbonate losses in the gastrointestinal tract, infusion of acids, and after recovery from ketoacidosis.

Pancreatic and biliary secretions contain bicarbonate that may be lost in patients with diarrhea, pancreatic or biliary drainage, or ureterosigmoidostomies.

A normal-AG acidosis can also result from a net gain in acid. This is usually owing to the use of acidifying agents such as ammonium chloride or to the administration of hyperalimentation fluids containing amino acids (10).

RTA may occur in a number of conditions associated with either decreased renal hydrogen ion excretion or renal bicarbonate wasting. Type 1 RTA (distal or classic RTA) results from an inability to secrete hydrogen ions in the distal tubule. The urine pH is high (above 5.3) despite acidemia. The causes include a primary idiopathic form(s), various autoimmune disorders, nephrocalcinosis, some drugs, several congenital conditions, pyelonephritis and urinary obstruction, and cirrhosis (10). Type 2 RTA (proximal RTA) results from renal bicarbonate wasting as evidenced by a rapid excretion of a bicarbonate load and fractional excretion of bicarbonate greater than 15%. Like type 1, RTA the differential diagnosis includes a long list of conditions (10). Type 4 RTA (there is no type 3 RTA) results from a deficiency of aldosterone or from aldosterone resistance. The causes include adrenal insufficiency, congenital adrenal hyperplasia, hyporeninemic hypoaldosteronism, and administration of angiotensin-converting enzyme inhibitors.

- PATHOPHYSIOLOGY AND INTERPRETATION

NORMAL PHYSIOLOGY

Part of "18 - Respiration and Measurement of Oxygen and Hemoglobin"

Respiration is the exchange of oxygen and carbon dioxide between the environment and cells. In the lungs, gas exchange is accomplished by diffusion of oxygen from alveoli into the blood and of carbon dioxide from the blood into the alveoli. At the cellular level, respiration requires the transport of oxygen into the cells and the removal of carbon dioxide. A brief review of normal physiology is helpful to understand pathophysiology.

Components of Respiration

Respiration depends on the proper functioning of the following components:

1. Ventilation,
2. Gas exchange between the lungs and the blood,
3. Oxygen binding to hemoglobin,
4. Adequate cardiac output.

The exchange of oxygen and carbon dioxide in the lungs requires alveolar ventilation and the matching of ventilation to pulmonary blood flow. Gas exchange, therefore, depends on the rate and the depth of ventilation.

The airways are divided into two zones: a conducting and a respiratory zone. The conducting zone consists of the trachea, right and left mainstream bronchi, lobar bronchi, segmental bronchi, and terminal bronchioles. The respiratory zone comprises the structures in which gas exchange occurs. This includes the respiratory bronchioles, alveolar ducts, and alveoli. Passive diffusion of gases takes place primarily at the level of the alveolar-pulmonary capillary membrane. The pulmonary capillary membrane must be thin (0.3 μm) to permit efficient diffusion of gases. This membrane consists of the alveolar epithelium, the underlying basement membrane, and the pulmonary capillary endothelium.

A constant flow of blood is essential to allow proper gas exchange. Systemic (venous), deoxygenated blood carrying CO_2 is transported to the right side of the heart and from there to the pulmonary arteries. Gas exchange then occurs in the pulmonary capillary bed, and the oxygenated blood is transported via the pulmonary veins to the left side of the heart and then to the systemic arterial circulation. Ventilation can increase 20- to 30-fold with increased oxygen demand such as occurs with strenuous exercise.

The exchange of gases across the pulmonary capillary membrane is governed by gradients in the partial pressures of individual gases. Dry room air is composed of 78% nitrogen, 21% oxygen, 0.03% carbon dioxide, and 0.1% inert gases. Inspired air is rapidly warmed to 37°C in the upper respiratory passages and becomes saturated with water (PH_2O = 47 mm Hg at 37°C). Normal values for the partial pressures of gases in inspired air and in arterial and venous blood are shown in Table 18.1.

TABLE 18.1. Partial Pressures of Gases in the Respiratory Tract and Blood[a]

Compartment	Po_2	Pco_2	Ph_2o
	mm Hg	*mm Hg*	*mm Hg*
Inspired air	160	0.25	Variable
Arterial blood	100	40	—
Venous blood	40	46	—
Expired air	115	30	47

[a]For atmospheric pressure = 760 mm Hg.

The respiratory system is designed such that (a) forces exerted by the respiratory muscles counteract the elastic recoil and airway resistance of the lungs, (b) a minimal pulmonary capillary membrane thickness is maintained, (c) right and left heart output are balanced, and (d) ventilation ([V with dot above]) and perfusion ([Q with dot above]) within the lung are matched. Compliance is a measure of the stretchability of the lung and is inversely proportional to elasticity. Most of the energy required for expiration is derived from the elastic recoil properties of the lung. Conversely, inspiration requires energy expenditure from the respiratory muscles that is proportional to the pulmonary compliance. Low compliance results in difficulty with inspiration (restrictive disease), whereas a high compliance decreases the work of inspiration but impairs expiration. A similar concept applies at the level of the alveoli. Laplace's law describes the relationship between the alveolar volume (radius, *R*), surface tension of the alveolar fluid (*T*), and the pressure (*P*) required to maintain an inflated alveolus ($P = 2T/R$). In theory, the smaller the alveolar radius, the greater the pressure required to maintain the alveolar volume, assuming that the surface tension is the same. Pressure differences between alveoli might result in collapse of smaller alveoli were it not for the type II pneumocytes that secrete pulmonary surfactant. Surfactant is a mixture of phospholipids (chiefly lecithin) that lowers alveolar surface tension and thus prevents the collapse of small airspaces. A deficiency of surfactant results in stiff, noncompliant lungs. This condition underlies the pathogenesis of respiratory distress syndrome (RDS) in premature infants. The level of surfactant produced by the fetal lung increases during fetal development,

with a large increase after 35 weeks of gestation. Infants born between 32 and 36 weeks exhibit a 15% to 20% risk of developing RDS, compared with 5% born after 37 weeks.

Ventilation, Perfusion, and the Ventilation-Perfusion Ratio

Ventilation

Ventilation ([V with dot above]) is the exchange of gases between ambient air and the lungs. At the end of expiration, a certain amount of gas remains in the conducting airways and alveoli. Thus, with inspiration, fresh air mixes with retained gases in the lung. The inspired volume, termed the tidal volume, is normally 0.5 L. Therefore, an average respiratory rate of 12 to 15 breaths per minute accounts for a minute ventilation of 6 to 7.5 L/min. Ventilation to nonperfused areas is termed dead-space ventilation and includes anatomic dead space (conducting system) and alveolar dead space (nonperfused alveoli). Essentially no alveolar dead space exists in the normal physiologic state. The distribution of ventilation in the lungs depends on two variables: airway resistance and the ability of alveoli to accommodate pressure differentials (Laplace's law). Resistance to airflow is equal throughout the pulmonary tree in the normal lung, but variances in small airway resistance are a common cause of uneven ventilation in disease states. However, the ventilation distribution is not uniform even in healthy persons because of a gradient in pleural pressure between the uppermost and lowermost regions of the lung. As a consequence, alveoli are larger at the apex than at the base of the lungs.

Perfusion

Perfusion ([Q with dot above]) refers to the flow of blood through the lungs and specifically to the flow through the pulmonary capillaries that are in close proximity to alveoli. The distribution of perfusion depends on several variables: gravity, cardiac output, and pulmonary vascular autoregulation. The pulmonary vasculature normally operates under low pressure. Therefore, gravity has a significant impact on the distribution of perfusion. Perfusion is greater at the base of the lung (dependent area) than at the apex. As cardiac output increases, pulmonary vascular pressure increases, and nondependent areas are better perfused.

Ventilation-Perfusion Matching ([V with dot above]/[Q with dot above] Ratio)

Although both ventilation and perfusion are unevenly distributed in the normal lung, the critical feature is that ventilated areas are perfused and that perfused areas are ventilated. Most of the total ventilation, and an even greater proportion of the pulmonary blood flow, is directed to dependent areas of the lungs. The result is a slightly higher [V with dot above]/[Q with dot above] ratio in nondependent areas (the lung apices in a standing person) than in dependent areas (the lung bases). Because alveolar ventilation is approximately 4 L/min and cardiac output averages 5 L/min, the overall [V with dot above]/[Q with dot above] ratio is normally approximately 0.8. Pathologic mismatches of [V with dot above] and [Q with dot above] ([V with dot above]/[Q with dot above] mismatch) are the most common cause of hypoxemia in disease states.

Alveolar-Arterial PO_2 Difference (A-a O_2 Gradient)

The A-a O_2 gradient is the difference between the partial pressure of oxygen in alveolar air (PAO_2) and the partial pressure of oxygen in the arterial blood (PaO_2). The A-a O_2 gradient reflects the efficiency of gas exchange between the alveoli and pulmonary vasculature and is useful in evaluating patients with hypoxemia. The PaO_2 is measured, whereas the P_AO_2 is calculated from the alveolar gas equation:

$$PAO_2 = (Ptotal - PH_2O)\ FIO_2 - PaCO_2/RQ$$

where Ptotal is the barometric pressure (760 mm Hg at sea level), PH_2O is the water vapor pressure (47 mm Hg at 37°C), FIO_2 is the mole fraction of inspired oxygen (0.21 in room air), $PaCO_2$ is the arterial PCO_2 (normally 40 mm Hg), and RQ is the respiratory quotient (usually 0.8). Normally the A-a O_2 gradient is less than 15 mm Hg, rising slightly with age.

To determine the A-a O_2 gradient, the patient is normally placed on room air. Under these conditions, the inspired O_2 is 150 mm Hg, R = 0.08, and the $PaCO_2$ is measured (normally 40 mm Hg). The PAO_2 is then calculated as follows:

$$PAO_2 = 150 - (40/0.8) = 100 \text{ mm Hg}$$

If the PAO_2 is normally 100 mm Hg and the PaO_2 is, for example, 70 mm Hg, then the A-a gradient would be 30 mm Hg. A simplified equation for calculating the PAO_2 for use in determining the A-a gradient is: $PAO_2 = 7 \times \%$ inspired $O_2 - 1.25 \times PaCO_2$. For a patient breathing room air, the equation becomes $PAO_2 = 150 - 1.25 \times PaCO_2$.

The A-a gradient is useful to distinguish hypoventilation (normal A-a gradient) from other causes of hypoxemia in which the A-a gradient is increased.

Regulation of Respiration

Respiration is regulated by the interaction of the medullary respiratory center in the brain, peripheral chemoreceptors, and mechanoreceptors and by the effects of local mediators. Involuntary changes in the rate or depth of respiration are directed by the medullary respiratory center, which is influenced by peripheral and central chemoreceptors. Central chemoreceptors, located beneath the ventral surface of the medulla oblongata, respond to changes in the pH of the cerebrospinal fluid. Peripheral chemoreceptors, which include the carotid and aortic bodies, respond to both pH and PO_2. A decrease in pH stimulates both the central and peripheral chemoreceptors, whereas a decrease in PO_2 stimulates only the peripheral chemoreceptors. Stimulation

of these receptors results in an increase in ventilation with a subsequent increased gas exchange. To the extent that the PCO_2 affects the arterial pH, changes in the PCO_2 will also affect the rate and depth of respiration.

Local decreases in oxygen tension cause constriction of the pulmonary vasculature. The result is shunting of blood away from unventilated areas of the lung to ventilated areas. This phenomenon occurs in the normal physiologic state (such as in dependent areas of the lung where the [V with dot above]/[Q with dot above] ratio is relatively low) as well as in a number of disease states. The opposite effect (vasodilation) occurs in the systemic circulation, thus facilitating delivery of oxygen to peripheral tissues.

Mechanoreceptors (J receptors) in the lung respond to the stretching forces exerted on the lung during inspiration and reflexively excite expiration.

An additional sensor of hypoxia deserves brief mention. Juxtaproximal tubular cells in the kidney sense hypoxia and respond by stimulating erythropoiesis via erythropoietin. The result is an increased red blood cell mass and an increased O_2 carrying capacity of the blood.

Hemoglobin and the Oxygen Dissociation Curve

In addition to adequate ventilation and gas exchange with blood, respiration requires transportation of oxygen to cells. The solubility of oxygen in plasma, and therefore the oxygen content of plasma, is relatively low. Hemoglobin in erythrocytes provides the means, through binding of oxygen molecules, of transporting oxygen to cells. Hemoglobin is a protein made up of four subunits. One molecule of hemoglobin can therefore bind four oxygen molecules.

The binding of oxygen to hemoglobin alters the quaternary structure of the tetramer such that subsequent binding of additional O_2 molecules is facilitated. This effect results in the sigmoidal shape of the oxygen–hemoglobin equilibrium curve (also called the oxygen dissociation curve), which relates the PO_2 to the oxygen saturation of hemoglobin (SO_2), as shown in Fig. 18.1.

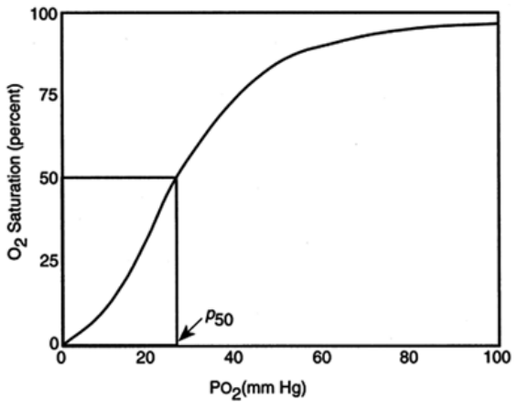

FIGURE 18.1. Oxygen–hemoglobin equilibrium curve.

At the PO_2 normally present in arterial blood, hemoglobin is more than 95% saturated with oxygen. At a PO_2 greater than 100 to 120 mm Hg, hemoglobin is virtually saturated. At this point, increases in inspired oxygen will increase only the dissolved oxygen content of blood and not the amount bound to hemoglobin. Thus, once hemoglobin is saturated, a higher FIO_2 will not appreciably increase the oxygen content of the blood (although the PO_2 may be markedly elevated).

The position of the oxygen dissociation curve reflects the affinity of hemoglobin for oxygen. Hemoglobin–oxygen affinity is influenced by a number of factors. Affinity is reduced by increases in temperature, decreases in pH, increases in PCO_2 (at constant pH), and increases in the erythrocyte 2,3-diphosphoglycerate (DPG) concentration.

An increase in hemoglobin–oxygen affinity shifts the oxygen dissociation curve to the left, whereas a decrease in affinity shifts the curve to the right. Thus, a right shift in the curve is observed with elevated DPG concentration, acidemia, and hypercapnia. The effect of these variables in normal physiology is important to the delivery of oxygen to the tissues. In the lung, where the PO_2 is high, hemoglobin takes up O_2 and releases CO_2, whereas in the tissues, PO_2 is low and the reverse occurs. The comparatively high pH and PCO_2 found in the tissues further enhances oxygen release from hemoglobin. Conversely, pathologic changes in pH, PCO_2, or temperature may impair oxygen delivery. DPG is an intermediate in normal glycolysis in red blood cells. The effect of DPG is to lower the hemoglobin–oxygen affinity and thus promote O_2 delivery to tissues. DPG concentrations increase in red blood cells in response to states of anemia or alkalosis, which tends to compensate for the primary disorder. DPG concentrations tend to decrease with length of storage of blood.

MEASUREMENT OF OXYGEN AND HEMOGLOBIN SPECIES

Part of "18 - Respiration and Measurement of Oxygen and Hemoglobin"

The Oxygen Electrode

The routine measurement of PO_2 in blood became practical with the development of the oxygen electrode by Clark in 1956. In contrast to ion-selective electrode methods used for hydrogen ion, sodium, potassium, and other ions, which are based on potentiometry, the oxygen electrode method is amperometric; that is, the PO_2 is related to the amount of current flowing in an electrochemical cell. In this cell, oxygen is reduced at a platinum wire cathode. The other half-cell is usually a silver–silver chloride electrode. When a voltage of approximately 0.6 V is applied to the cathode, oxygen is reduced according to the following reaction:

$O_2 + 2H^+ + 4e^- \rightarrow 2OH^-$

The current depends on the number of oxygen molecules reaching the cathode per unit time, which in turn depends on the concentration of dissolved oxygen in the sample, which is proportional to the PO_2. The area of the cathode is kept very small so that only a tiny fraction of the total dissolved oxygen is reduced, and the current then assumes a constant value proportional to the PO_2.

A diagram of the oxygen electrode is shown in Fig. 18.2. The platinum cathode is in contact with a very thin layer of buffer, which is separated from the blood sample by a gas-permeable membrane. The membrane serves to keep other reducible substances in blood from reaching the cathode, which would add to the cell current and could foul the electrode surface. The membrane itself adsorbs small amounts of protein from the blood samples and needs to be replaced periodically in most electrode designs.

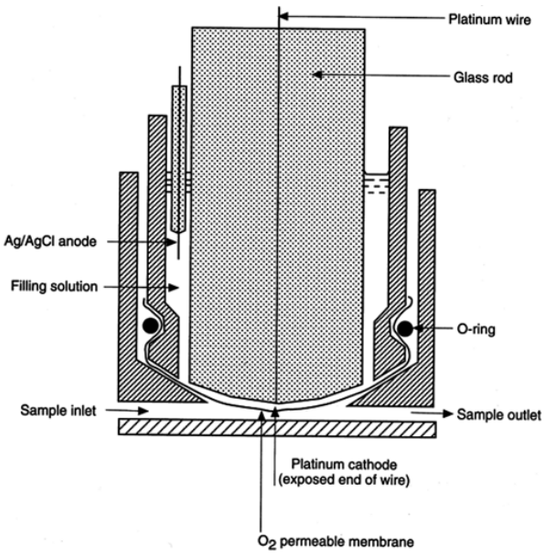

FIGURE 18.2. Schematic illustration of a PO_2 electrode. (Adapted from Siggaard-Andersen O. *The acid-base status of the blood*, 4th ed. Baltimore: Williams & Wilkins, 1974.)

Calibration of the oxygen electrode is usually done with two gas mixtures whose composition is known with very high accuracy. One contains no oxygen, which allows a zero point to be established, and the other contains a known oxygen percentage, usually either 12% or 20% (±0.03%) by volume. Further details about the calibration of blood gas analyzers and the preanalytical variables that affect PO_2 measurements are discussed in Chapter 17.

Spectrophotometry of Hemoglobin Species

The measurement of total hemoglobin is a routine part of a hematology profile. The measurement of oxyhemoglobin (O_2Hb), deoxyhemoglobin (Hb), carboxyhemoglobin (COHb), and methemoglobin (metHb) by spectrophotometry may be performed as an adjunct to blood gas measurements and is therefore discussed here.

Each of the hemoglobin species has a unique absorbance spectrum in the visible region, as illustrated in Fig. 18.3. After the spectrum of each species is established with solutions of known concentration, the analysis of a mixture is carried out by simply measuring the absorbance of a hemolysate at multiple wavelengths, one wavelength for each of the species to be determined. Beer's law applies to the absorbance at each wavelength.

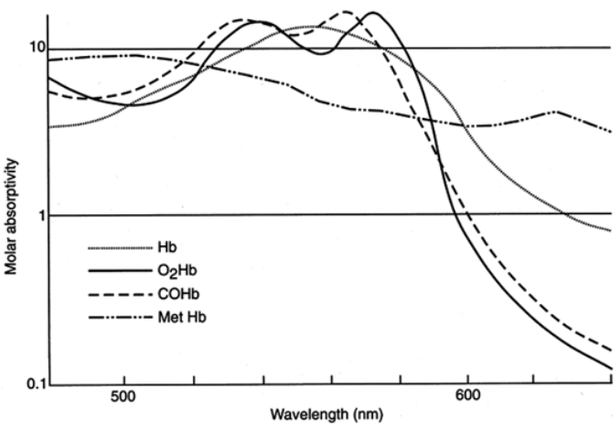

FIGURE 18.3. Absorbance spectrum of hemoglobin species.

$$A_{\lambda 1} = E_{\lambda}(1)\,C(1) + E_{\lambda 1}(2)\,C(2) + \ldots + E_{\lambda 1}(n)\;C(n)$$

$$A_{\lambda 2} = E_{\lambda 2}(1)\;C(1) + E_{\lambda 2}(2)\;C(2) + \ldots + E_{\lambda 2}(n)\;C(n)$$

$$A_{\lambda n} = E_{\lambda n}(1)\;C(1) + E_{\lambda n}(2)\;C(2) + \ldots + E_{\lambda n}(n)\;C(n)$$

where $E_{\lambda 1}$ (1) is the absorptivity at wavelength λ1 and C(1) is the concentration of the first component, and so forth.

To determine the concentrations of O_2Hb, Hb, COHb, and metHb in blood, the absorbance is measured at four wavelengths, giving four equations of the form above, which can be solved simultaneously to yield the concentrations. The absorptivities are constants that are permanently stored in the instrument. The absorbance scale may be calibrated with a total hemoglobin standard, and a microprocessor in the instrument then performs the calculations necessary to give concentrations of each hemoglobin species as well as calculations for the several derived quantities commonly reported. It should be recognized that if all four of the hemoglobin species mentioned are to be measured, a minimum of four different wavelengths must be used. Some older laboratory oximeters and oximeters used in point-of-care testing use two or three wavelengths and are intended

to measure only O_2Hb. With such devices, it is important to understand what errors will be seen if significant amounts of COHb or metHb are present (1,2).

Specimens and Specimen Handling

The measurement of O_2Hb and other hemoglobin species may be requested in conjunction with arterial blood gas measurements. In this case, the same specimen is used for both, namely, heparinized arterial blood.

If one is only interested in the measurement of COHb or metHb, then venous blood is preferred to avoid the discomfort and difficulty of an arterial puncture. In addition, the issues of the type of container and whether to store the specimen on ice are not relevant. Both COHb and metHb are relatively stable, so a specimen anticoagulated with heparin or ethylenediaminetetraacetic acid and transported at ambient temperature is satisfactory.

The most important aspect of specimen handling is to ensure that the blood is thoroughly mixed. Incomplete mixing of whole blood cannot be detected by eye but can produce significant errors in either direction in the total hemoglobin measurement.

Derived Quantities

There has long been confusion about definitions and conventions used in blood gas analysis. This has been addressed by two different organizations, the National Committee for Clinical Laboratory Standards and the International Federation of Clinical Chemists, and their documents are recommended for a more complete description of the various derived quantities that are in use (3,4).

O_2Hb Fraction and Oxygen Saturation

Results are usually expressed as a fraction (or percentage) of the total hemoglobin concentration, which is obtained by simply adding the concentrations of each of the components. For example, the O_2Hb fraction (in a percentage) would be calculated as

$$F_{O_2Hb}\,(\%) = \frac{100\,C_{O_2Hb}}{C_{O_2Hb} + C_{Hb} + C_{COHb} + C_{metHb}}$$

Fractions of COHb and metHb are calculated similarly.

Care must be taken not to confuse O_2Hb fraction with a related quantity, oxygen saturation (SO_2). The latter quantity, also called oxygen saturation of available hemoglobin, is defined as the concentration of O_2Hb expressed as a percentage of only the hemoglobin available for oxygen binding.

$$SO_2\,(\%) = \frac{100\,C_{O_2Hb}}{C_{O_2Hb} + C_{Hb}}$$

Thus, SO_2 can also be calculated from the measured concentrations of O_2Hb and Hb, and many oximeters perform this calculation automatically.

Comparison of these two equations shows that the two quantities are equal if no COHb or metHb is present. This is partly why the two are often confused, and the term *oxygen saturation* is unfortunately still loosely used to refer to either oxygen saturation or O_2Hb fraction. However, it is quite important for the laboratory to clearly identify which quantity is being reported so that clinicians are not confused when treating a patient with carbon monoxide poisoning or methemoglobinemia.

Oxygen Content

The concentration of total oxygen (CtO_2) in blood, also called oxygen content, is the sum of hemoglobin-bound oxygen and oxygen dissolved in blood. Oxygen content can therefore be calculated as

$CtO_2 = CO_2Hb + \alpha o_2\ PO_2$

where αO_2 is the solubility coefficient of oxygen in blood plasma.

Because 98% to 99% of the total oxygen is normally bound to hemoglobin, the term for dissolved oxygen is often ignored, in which case O_2 content can be closely estimated from oximeter data alone. Oxygen content is often expressed in milliliters of oxygen (at standard temperature and pressure) per deciliter of whole blood, and the measured quantities available are O_2Hb fraction and total hemoglobin. Oxygen content is then estimated as

CtO_2 (mL O_2/dL) = 1.39 FO_2Hb CtHb

where CtHb is total hemoglobin in grams per deciliter and 1.39 is the oxygen binding capacity of hemoglobin expressed as milliliters of O_2 per gram of hemoglobin.

P_{50}

The partial pressure of oxygen corresponding to an oxygen saturation of 50% is called P_{50} and is a measure of hemoglobin–oxygen affinity. In principle, if one assumes a normal shape of the oxygen dissociation curve and measures both the PO_2 and oxygen saturation, then this point on the curve can be used to calculate the PO_2 that would give 50% saturation. In practice, this can be done accurately as long as the oxygen saturation is less than approximately 90%. To interpret the calculated P_{50}, one must also measure the quantities mentioned above that affect the position of the oxygen dissociation curve. The determination of P_{50} is not commonly performed but can be useful, for example, in determining *in vivo* oxygen affinity or in testing for hemoglobin variants with abnormal oxygen affinity. Further details and the calculation procedure are given in reference 5.

Quality Control and Proficiency Testing

Quality control (QC) of PO_2 measurements is discussed with pH and PCO_2 in Chapter 17. This brief discussion relates to QC of oximetry measurements. One of the primary difficulties with QC and proficiency testing (PT) in blood gas analysis applies also to oximetry measurements, namely, the lack of a control material that closely resembles whole blood. Materials used for QC fall into three categories: (a) a dye mixture, (b) stabilized hemolysates, and (c) stabilized whole blood.

Dye mixtures are, in principle, adequate for QC of the spectrophotometer module of an oximeter. The principal drawbacks are that readings may not correspond to values encountered in patient samples and that different readings are usually obtained on various makes and models of oximeters. These problems are avoided by using a stabilized hemolysate. The main limitation of both these matrices is that they cannot check the functioning of the hemolyzer portion of the oximeter. This is important because incomplete hemolysis of samples can result in inaccurate readings that may not be noticed; for example, the errors may appear as moderate elevations of COHb or metHb. Although stabilized whole blood would seem to be a logical matrix, the products commercially available may not work satisfactorily in all oximeters. For example, stabilized erythrocytes may be more resistant to lysis than normal red cells, leading to erratic results on QC materials even when the instrument is functioning well with patient samples.

A useful adjunct to any QC program is to run occasional patient samples in duplicate on two different instruments. This is one way of using fresh whole blood for QC, and this should be done whenever two or more instruments are used. In addition, the accuracy of the total hemoglobin measured by an oximeter can be checked by using fresh whole blood together with the cyanmethemoglobin reference method for total hemoglobin.

Point-of-Care Testing

Some tests, including blood gas analysis and oximetry, can now be performed at the patient's bedside. This has several advantages but also raises some concerns (6,7 and 8). Advantages include minimizing turnaround time, limiting iatrogenic blood loss and patient discomfort, and eliminating problems relating to specimen transport (9,10). Areas of concern include cost, adequate quality control, adequate training of nonlaboratory personnel, and differences in reference ranges that may affect the interpretation of results. Several problems are particular to the acute-care setting. Precision, for example, may be more important than accuracy in situations in which an acute change in an analyte is more important than absolute values (11,12).

Important parameters in the critical care setting include the PO_2, the O_2 saturation, the PCO_2, pH, electrolytes (Na^+, K^+, Ca^+), and glucose. Table 18.2 summarizes the methodologies employed by a number of bedside instruments.

TABLE 18.2. Methodologies Used in Point-of-Care Instrument

Analytes	Electrochemical	Optical
Po_2	Amperometric Clark-type electrode	Optode based on: •Fluorescence quenching, or •Absorbance change of O_2 binding molecules
Pco_2	Potentiometric Severinghaus-type electrode	Optode based on pH sensor and gas permeable membrane
pH	Glass or polymer membrane electrodes	Optode based on fluorescence or absorbance measurement of immobilized pH indicator
Electrolytes	Ion selective electrodes (potentiometric)	Solution phase complexing reagents or colorimetric strip test
Hematocrit	Conductivity cell or ISEs (measure change in electrolytes after RBC lysis)	Microcentrifuge or cell counter
Total hemoglobin	—	Direct absorbance measurement or colorimetric measurement of pseudoperoxidase activity
Glucose	Amperometric enzyme electrodes based	Colorimetric measurement of glucose on immobilized glucose oxidase metabolite

Adapted from Misiano DR, Meyerhoff ME, Collison ME. Current and future directions in the technology relating to bedside testing of critically ill patients. *Chest* 1990 (Suppl);204S–214S.

Bedside testing instrumentation can be divided into four major groups:

1. Continuous noninvasive methods,
2. Discrete sample analyzers,
3. Extracorporeal sensing systems,
4. Continuous invasive methods.

Continuous Noninvasive Methods

Continuous noninvasive analyte testing is conceptually the ideal. Real-time continuous values are provided without the need to withdraw blood or use indwelling catheters. Currently, this technology is limited to the transcutaneous measurement of oxygen and carbon dioxide, and O_2 saturation by pulse oximetry. Future innovations may allow for noninvasive measurement of other analytes, including electrolytes and glucose.

Transcutaneous sensors use methods similar to conventional blood gas instruments (13,14). Clark-style amperometric oxygen and Stow-Severinghaus–style potentiometric carbon dioxide sensors have modified electrode designs to allow attachment of the monitor to the skin. Correlation studies comparing conventional PO_2 and PCO_2 measurements to transcutaneous values demonstrate significant biases, particularly in adults. Establishing appropriate reference ranges is therefore essential. Transcutaneous measurements are most commonly used for monitoring infants and neonates, in whom the discrepancies from established methods are less pronounced. Differences between the transcutaneous PO_2 and the PaO_2 are particularly pronounced in

shock and low-flow states. In some cases, this discrepancy is helpful to identify patients with these disorders (15).

Pulse oximetry measures the percentage of O_2 saturation of hemoglobin by the transmission of light at 660 nm (O_2Hb peak) and 940 nm (Hb peak) through a finger. The relative absorbance at each wavelength is measured and a ratio of O_2Hb to total hemoglobin is calculated. The measurement is conducted to coincide with the arterial pulse, thereby reflecting arterial blood (16). Advantages of pulse oximetry include simplicity, the performance of real-time measurements, and blood conservation. However, potential technical or mechanical problems may arise in patients with hypothermia, peripheral vascular disease, hyperbilirubinemia, or altered heme species or from stray ambient lighting (1,2,17,18 and 19). Nevertheless, pulse oximetry is one of the most widely used continuous noninvasive methodologies, particularly in settings in which early warning of sudden change is essential.

Discrete Sample Analyzers

Discrete sample analyzers include single-use, disposable analyzers (e.g., glucose meters) and multitest (e.g., PO_2, PCO_2, pH, Na, K, Ca, hematocrit, hemoglobin, glucose) analyzers. All these instruments require withdrawing blood from the patient, and therefore the test results are not true real-time values. The multitest analyzers may be placed in a central location in the critical care unit and function in a manner similar to that of a “stat lab.” Smaller, more portable analyzers may be moved closer to the patient for easier access and more rapid results. As instruments move from the central laboratory to the bedside, issues of QC and operator training and proficiency become more problematic (8). Establishing protocols for the use of bedside devices is mandated by the Clinical Laboratory Improvement Act (CLIA), and is often the responsibility of the clinical laboratory.

Extracorporeal Sensing Systems

Extracorporeal sensors are instruments that sample arterial blood, measure analytes, and return the blood to a vein (in-line) or pass the blood to a waste receptacle (on-line). The advantage of these systems is that they can provide real-time measurements of analytes by conventional methods. The disadvantages include the risk of infection, thrombotic complications, and mechanical damage to erythrocytes, all of which mandate short-term use of these devices. The use of extracorporeal monitoring systems is currently limited to dialysis and cardiac surgery settings.

Continuous Invasive (*In Vivo*) Methods

Continuous invasive monitoring is achieved by attaching the sensor directly to an indwelling catheter. Analytes are measured continuously and in real time at sites such as the pulmonary artery. Catheter tips with miniaturized O_2, CO_2, and pH sensors have been devised, and implantable sensors for glucose are being developed (20). Disadvantages include the complications usually associated with indwelling catheters, such as thrombosis and infection. The present technological obstacle is the development of miniaturized, durable, and biocompatible sensors that can function reliably at the end of an indwelling catheter.

Mechanical and technical variables remain the major obstacles to refining and implementing cost-effective point-of-care testing. Newer technologies, such as near-infrared spectroscopy (for the transcutaneous measurement of blood glucose) (21,22 and 23), magnetic resonance spectroscopy (24,25), and diffuse-sink sampling (26), as well as advances in instrumentation (27) have the potential to significantly advance point-of-care testing and improve patient care.

PATHOPHYSIOLOGY AND INTERPRETATION

Part of "18 - Respiration and Measurement of Oxygen and Hemoglobin"

Respiratory failure is a clinical condition that is best defined by abnormalities in arterial blood gas values. Although in some cases the diagnosis is obvious based on the patient's signs and symptoms (e.g., dyspnea, respiratory rate, cyanosis), the diagnosis usually requires analysis of arterial blood gases (PO_2, PCO_2, and pH). The clinical signs and symptoms of hypoxemia and hypercapnia are unreliable in predicting blood gas values. Reference intervals are shown in Table 17.4 of Chapter 17. As a general guideline, respiratory failure may be defined as a PaO_2 less than 50 to 60 mm Hg or a $PaCO_2$ greater than 50 mm Hg. In acute respiratory failure, the arterial pH may be decreased owing to retention of CO_2 (acute respiratory acidosis), whereas in chronic respiratory failure, the pH is less affected because of renal compensation. The evaluation of blood gas results is closely related to the topic of acid-base balance (see Chapter 17). This section is limited to a discussion of respiratory failure, and the differential diagnosis of hypoxemia (decreased PO_2) and hypercapnia (elevated PCO_2).

It is important to distinguish between the terms hypoxemia and hypoxia. Hypoxemia refers to a decreased blood PO_2, whereas hypoxia is a condition in which inadequate amounts of oxygen are available to the tissues. Hypoxemia is one cause of hypoxia, but hypoxia can exist with normal PO_2 (e.g., arterial thrombosis). Delivery of oxygen to the tissues depends on cardiac output, intact vasculature, and the oxygen content of the blood. Clinical assessment of these variables is an important adjunct to arterial blood gas measurements.

Respiratory failure may be viewed in terms of pathophysiologic mechanisms (hyperventilation, [V with dot above]/[Q with dot above] mismatch, shunts) or from an anatomic (pulmonary versus extrapulmonary) or etiologic perspective (e.g., pneumonia). Each approach has its advantages and is discussed below. An excellent discussion of this topic may also be found in reference 28.

Anatomic Analysis

One approach to respiratory failure is to consider whether the underlying problem is the lungs or outside the lungs. For example, extrapulmonary causes of respiratory failure include disorders of the respiratory center, neuromuscular system, chest wall, pleura, or upper airway. All these are associated with hypoventilation, hypoxemia, and hypercapnia. Respiratory failure may result from diseases of the lower airways, the pulmonary circulation or the pulmonary interstitium resulting in hypoxemia with or without hypercapnia. In a patient with hypercapnia, the main problem is inadequate ventilation, whereas in respiratory failure without CO_2 retention the main problem is with oxygenation.

Pathophysiologic Approach

This approach divides hypoxemia or hypercapnia according to the pathophysiologic mechanism. After the mechanism has been identified, the specific etiology can be determined.

Hypoxemia may result from one of five pathophysiologic mechanisms, as shown in Table 18.3. Breathing air with a low oxygen content may be seen in subjects at high altitudes or other unusual situations but does not occur in a typical patient population. A similar statement can be made regarding diffusion impairment as a cause of hypoxemia. In principle, diffusion impairment can occur whenever the alveolar-capillary membrane is thickened or infiltrated by fluid, fibrosis, or other substances. In practice, diffusion impairment contributes little to hypoxemia in most pulmonary diseases. This is because gas exchange occurs after only one third of the time that blood spends in transit in the alveolar capillary. Severe pulmonary interstitial fibrosis or edema, pulmonary amyloidosis, and some types of pneumoconioses may produce hypoxemia as a consequence of diffusion impairment, but this situation is uncommon. Arterial blood gas values in patients with significant diffusion impairment typically show hypoxemia often with hypocapnia and a greatly increased A-a gradient. There is often a coexisting ventilation–perfusion mismatch.

TABLE 18.3. Pathophysiologic Classification of Respiratory Failure

Mechanism	Blood Gas Values	A-a O_2 Gradient	Response to O_2
Low inspired oxygen	Low Po_2 and low/normal Pco_2	Normal	Increased Po_2
Hypoventilation	Low Po_2, elevated Pco_2	Normal	Increased Po_2
Ventilation/perfusion ([V with dot above]/[Q with dot above]) mismatch	Low Po_2, elevated Pco_2 when severe	Increased	Increased Po_2
Right to left shunt	Low Po_2 and normal Pco_2	Increased	Minimal improvement
Diffusion impairment	Low Po_2 and elevated Pco_2	Increased	Minimal improvement

The majority of patients with hypoxemia can be classified into one of three pathophysiologic mechanisms: hypoventilation, ventilation–perfusion mismatch, or shunting as shown in Figure 18.4. In some patients, more than one of these mechanisms may be operating simultaneously.

Hypoventilation

Hypoventilation produces an increase in arterial PCO_2 (CO_2 retention, or hypercapnia) and a decrease in arterial PO_2 (hypoxemia). Hypoventilation may result from a number of extrapulmonary disorders including diseases that affect the central respiratory center (heroin overdose, stroke), neuromuscular disorders (Guillain-Barré syndrome, myasthenia gravis, poliomyelitis), abnormalities of the chest wall or diaphragm (trauma, diaphragmatic paralysis, kyphoscoliosis), upper airway obstruction (foreign bodies, epiglottitis, tumors), or restrictive pleural disease. It is important to recognize that hypoventilation is not caused by diseases of the lung itself (excluding the pleura). Consequently, gas exchange is normal and the A-a O_2 gradient is also normal.

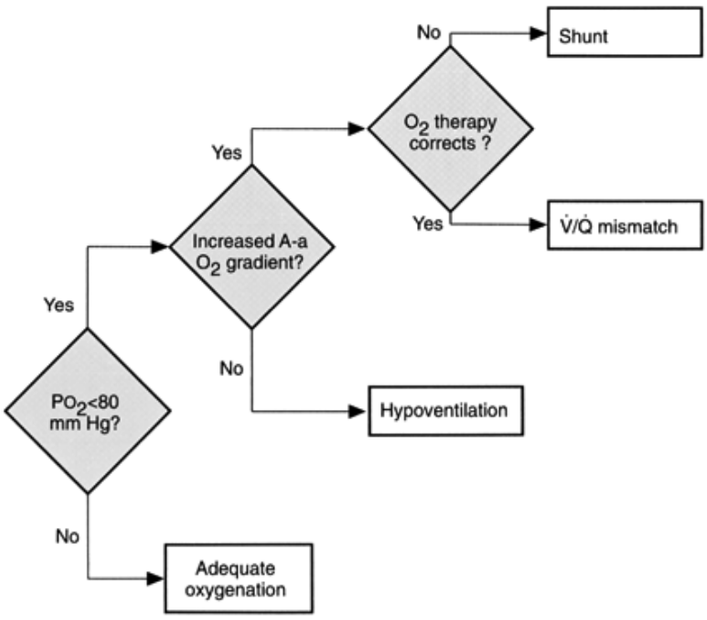

FIGURE 18.4. Algorithm for the evaluation of hypoxemia.

The treatment of hypoventilation includes maneuvers to improve ventilation to correct the hypoxemia and associated respiratory acidosis owing to hypercapnia (Fig. 18.4).

Ventilation–Perfusion Mismatch

Ventilation–perfusion mismatch is the most common cause of hypoxemia. Physiologic ventilation–perfusion mismatching occurs in normal subjects as described previously. There are two types of ventilation–perfusion mismatch: The first type is called low [V with dot above]/[Q with dot above] and refers to inadequate ventilation relative to perfusion. Conversely, high [V with dot above]/[Q with dot above] refers to inadequate perfusion relative to ventilation.

Areas of low [V with dot above]/[Q with dot above] result in a decrease in the PO_2 and the oxygen content of the affected pulmonary blood. This can be partially offset by a slight increase in oxygen content in areas of high [V with dot above]/[Q with dot above]. However, the compensatory effect is inadequate because of the fact that hemoglobin in the pulmonary capillaries is saturated with oxygen. Low [V with dot above]/[Q with dot above] decreases the oxygen content more than the areas of high [V with dot above]/[Q with dot above] can increase it. Mixing of the pulmonary capillary blood in the pulmonary venous system and left heart results in a low PO_2, a low oxygen content, and an increased A-a gradient. The PCO_2 may or may not be elevated. Retention of CO_2 in a patient with a V:Q mismatch is generally observed only with severe ventilation–perfusion mismatching. Part of the explanation for this is that diffusion of CO_2 across the alveolar-capillary membrane is more efficient than diffusion of oxygen. Consequently, the lung can usually eliminate excess CO_2 unless the ventilation–perfusion mismatch is severe.

The differential diagnosis of ventilation–perfusion mismatch is extensive and includes some of the most common pulmonary disorders encountered in clinical practice (e.g., asthma, emphysema, atelectasis, pneumonia, pulmonary embolus, adult RDS (ARDS), pneumothorax, lower airway obstruction, pulmonary edema). As with hypoventilation, hypoxemia owing to ventilation–perfusion mismatching may respond favorably to oxygen administration.

Shunting

Arteriovenous (right-to-left) shunts are defined as any process that permits unoxygenated venous blood to mix with oxygenated arterial blood. The term for mixing of blood from nonventilated (or markedly underventilated) airspaces with blood from ventilated areas is called venous admixture and can be expressed as a percentage of the cardiac output. Shunting of venous blood into the arterial circulation (including pulmonary arterial blood into the pulmonary venous system) reduces the arterial O_2 content and PO_2 and results in an increased A-a O_2 gradient. Shunts may be normal (anatomic) or pathologic.

Normal anatomic (physiologic) shunts contribute a small amount to venous admixture. The thebesian veins, which drain the myocardium, partially empty into the pulmonary veins, and intrapulmonary anatomic arteriovenous shunts bypass ventilated areas. Collectively, these normal shunts account for approximately 5% of right heart output.

Pathologic shunts may be intrapulmonary or extrapulmonary. Right-to-left cardiac shunts are examples of extrapulmonary shunts, as are shunts occurring in the great vessels. Most intrapulmonary shunts represent an extreme case of ventilation–perfusion mismatch and occur when blood perfuses areas of lung in which the alveoli are not ventilated (atelectasis, obstruction) or are filled with fluid or blood (e.g., pulmonary edema, pneumonia, hemorrhage). Thus, the differential diagnosis of

right-to-left shunts overlaps to some degree with conditions causing ventilation–perfusion mismatch, and many patients exhibit features of both. In contrast to patients with hypoventilation or ventilation–perfusion mismatching, patients with shunts exhibit a poor response to oxygen therapy.

Hypoxemia may occur in the presence or absence of arterial hypercapnia. Hypercapnia may result from one of three mechanisms.

1. Breathing air with a high PCO_2. This mechanism is not relevant in the usual clinical setting but may occur in some states of suffocation or in subjects rebreathing expired air (e.g., in the treatment of respiratory alkalosis).
2. Hypoventilation.
3. Severe ventilation–perfusion mismatch.

The pathophysiologic approach to respiratory failure can be extended to include three major subtypes (Table 18.4). The first is called type 1 oxygenation failure, characterized by a low PO_2, a normal or elevated PCO_2, and an elevated A-a gradient. Type 1 respiratory failure is caused by V:Q mismatch or shunts. In contrast, type 2 respiratory failure (or ventilation failure) is characterized by a low PO_2, an elevated PCO_2, and a normal A-a gradient. Finally, type 3 respiratory failure (or combined failure) is characterized by a low PO_2, an elevated PCO_2, and an increased A-a gradient. Type 3 failure occurs when ventilation cannot be increased sufficiently to maintain a normal PCO_2, in a patient with a marked V:Q mismatch. The result is hypoxemia, hypercapnia, and an increased A-a gradient. Type 3 respiratory failure most often occurs in patients with diffuse alveolar damage, severe asthma, or chronic obstructive pulmonary disease (COPD).

TABLE 18.4. Respiratory Failure: Pathophysiologic Approach

Failure Type	Po_2	Pco_2	A-a Gradient	Etiology
Oxygenation failure	Low	Normal/elevated	Elevated	V:Q mismatch/shunt
Ventilation failure	Low	Elevated	Normal	Hypoventilation
Combined failure	Low	Elevated	Elevated	Combined oxygenation/ventilation failure

Specific Diseases

The differential diagnosis of hypoxemia and hypercapnia encompasses a large number of disease entities. A detailed discussion of this topic is beyond the scope of this chapter, but some additional comments concerning the more common disease entities are given.

Patterns of Breathing

Various patterns of breathing may suggest specific disease states or result from compensatory mechanisms for ineffective respiration. Hyperventilation may be a pathologic primary event (resulting in respiratory alkalosis) or may result from stimulation by the chemoreceptors as an appropriate compensatory response to correct acidosis and hypoxia. Likewise, hypoventilation may be pathologic, resulting in respiratory acidosis, or may occur as a compensatory response in the setting of metabolic alkalosis.

Two examples of clinically significant abnormal patterns of breathing are Cheyne-Stokes and Kussmaul respirations. Cheyne-Stokes breathing is alternating hyperventilation and hypoventilation with periods of apnea. It may result from asynchronous sensory output from peripheral and central chemoreceptors and can occur in patients with congestive heart failure or cerebral vascular accidents. Kussmaul breathing is a regular, deep, and rapid breathing pattern seen in severe metabolic acidosis (such as diabetic ketoacidosis).

Restrictive Versus Obstructive Lung Disease

Spirometry is a frequently used method to assess the ventilatory function of the lungs, although it is usually performed in a location outside the clinical laboratory. Spirometry can be used to classify certain lung diseases into two categories termed restrictive and obstructive (see below). Spirometry is useful in monitoring patients with chronic pulmonary diseases to assess the progress of disease activity.

Chronic Obstructive Pulmonary Disease

COPD refers to a group of related disorders characterized by chronic, progressive airway obstruction resulting either from narrowing of the bronchial lumina as a consequence of inflammation and mucous hypersecretion (chronic bronchitis) or constriction (bronchial asthma), or loss of lung parenchyma and elastic recoil (emphysema). Proximal bronchial narrowing and mucous plugging leads to inadequate alveolar ventilation (ventilation–perfusion mismatch), hypoxemia, and, when severe, CO_2 retention. A component of pulmonary parenchymal shunting is also typically present. The major physiologic defect in COPD is an increase in resistance to airflow with limitation of expiratory airflow rates during expiration. COPD can be divided into two clinical types.

Type A patients have been called “pink puffers” or “fighters” because they increase ventilation to prevent hypercapnia. Type B patients are termed “blue bloaters” or “nonfighters” because their ventilatory response is blunted. The former generally have a mildly decreased or normal PO_2 and a normal PCO_2, whereas the latter exhibit a low PO_2 and an elevated PCO_2. Although type A is typically associated with emphysema and type B with chronic bronchitis, most patients with COPD have features of both. Hypoxia may be the primary mechanism driving ventilation in advanced COPD. Overzealous oxygen therapy may therefore aggravate hypercapnia and respiratory acidosis by decreasing the patient's respiratory drive. For this reason, oxygen is usually given judiciously to maintain a moderately low PO_2.

Diffuse Interstitial Diseases

In contrast to COPD, which results from airway obstruction, diffuse interstitial diseases are characterized by a restrictive process producing a reduced expansion of the lung and a decreased total lung capacity. Although patients with COPD cannot expire normally, patients with restrictive diseases typically exhibit a normal rate of airflow. Thus, the respiratory cycle as seen on spirometry is normal but with reduced volumes. The differential diagnosis of diffuse interstitial disease is extensive and includes disorders induced by occupational and environmental inhalants, drugs, and toxins. All are characterized by alveolitis and variable degrees of interstitial fibrosis. The primary underlying pathophysiology is inadequate ventilation, and hence interstitial diseases are characterized by ventilation–perfusion mismatch. Interstitial fibrosis results in decreased lung compliance, increased work of ventilation, and a rapid and shallow breathing pattern. A minor contributor to hypoxemia is impaired diffusion across a thickened alveolar-capillary membrane, but this occurs only in severe cases. Blood gas measurements may be normal in mild disease but may demonstrate a fall in the PO_2 with exercise. The A-a O_2 gradient is typically increased. Severe disease produces increasing hypoxemia and hypercapnia.

Atelectasis

Atelectasis is characterized by incomplete expansion of the lung (or part of the lungs) or collapse of previously inflated tissue. Atelectasis may result from many causes including airway obstruction with resorption of residual air, inadequate respiratory effort, extrinsic compression of the lung (e.g., pneumothorax), contraction of pleural or pulmonary scars, or loss of pulmonary surfactant (e.g., adult RDS).

Pulmonary Edema

Theoretically, pulmonary edema can result from alteration of any of the components of Starling's law. Increased hydrostatic pressure occurs in left ventricular failure, mitral stenosis, and pulmonary vein occlusion. Decreased plasma oncotic pressure can be seen in hypoproteinemic states such as nephrotic syndrome, cirrhosis, and massive crystalloid infusion. The capillary membrane permeability may be altered in septic shock, pneumonia, lung trauma, oxygen toxicity, disseminated intravascular coagulation, systemic lupus erythematosus, and many other conditions. Finally, compromise of lymphatic drainage may occur in lymphangitic carcinomatosis or radiation pneumonitis. The most common cause of pulmonary edema is left ventricular failure.

Generally, the interstitial compartment is the initial site of fluid accumulation. Eventually fluid accumulates in the pulmonary alveolar spaces as well. Compromised ventilation and subsequent hypoxemia usually are not present until alveolar filling occurs. In early (interstitial) pulmonary edema, the PO_2, PCO_2, and respiratory rate may be normal but exertion (e.g., climbing a flight of stairs) can cause dyspnea as the oxygen requirement is increased. Alveolar filling generally results in hypoxemia, an increased A-a O_2 gradient, a normal or decreased PCO_2, and dyspnea. The PCO_2 is increased only in very severe cases.

Adult Respiratory Distress Syndrome

ARDS (also called diffuse alveolar damage or shock lung) is a condition caused by alveolar capillary damage with rapid onset of severe respiratory failure. The differential diagnosis includes sepsis, shock, head injury, aspiration, smoke inhalation, drug overdose, pancreatitis, burns, oxygen toxicity, and diffuse pneumonia (especially viral) and a long list of other conditions. The pathophysiology of ARDS involves derangement of alveolar-capillary permeability, resulting in extravasation of fluid into the lung. The initial injury is to the capillary endothelium, but ultimately the epithelium is also affected (29). The mechanism of alveolar capillary damage depends on the etiology and may include aggregation of leukocytes in the pulmonary vessels, oxygen-derived free radicals, toxins, and other factors (29). The morphologic features of ARDS include congestion, edema, epithelial cell necrosis, and the formation of hyaline membranes. Clinically, patients exhibit hypoxemia, decreased pulmonary compliance, and diffuse pulmonary infiltrates. The hypoxemia is only minimally responsive to oxygen therapy because of pulmonary vascular shunting but may respond to positive end-expiratory pressure induced by mechanical ventilation.

Pulmonary Embolism

Pulmonary embolism is the principal cause of death in approximately 10% of hospitalized patients. Nonfatal emboli are even more common. Ordinarily pulmonary emboli do not cause infarction of the lung because the bronchial circulation is usually sufficient to prevent ischemic necrosis of the lung parenchyma. However, infarcts may occur in patients with preexisting cardiac or lung disease. Most emboli arise from thrombi that form in the deep veins of the legs, but some may originate from thrombi in the pelvic veins or other sites. Large pulmonary emboli are one cause of sudden death, whereas smaller emboli can produce a spectrum of symptoms from none at all to severe respiratory distress. Arterial blood gases show a low PO_2, often a low PCO_2 (owing to hyperventilation) and an increased A-a O_2 gradient (owing to severe ventilation–perfusion mismatch).

Pulmonary Infections

Many organisms may infect the lungs, and the degree of respiratory compromise is also quite variable. Inflammation, edema, congestion, and hemorrhage may produce hypoxemia, an increased A-a O_2 gradient, and a normal, elevated, or decreased PCO_2, depending on the degree of intrapulmonary shunting and ventilation–perfusion mismatch. Initially, a fall in the arterial PO_2 induces hyperventilation, which may lower the PCO_2, but as with other causes of respiratory failure, with severe disease, there may be CO_2 retention.

Methemoglobinemia

In normal hemoglobin, the iron atoms are in the reduced (ferrous) state. Oxidation of the iron to the trivalent ferric state produces a brown hemoglobin (metHb). metHb cannot combine with oxygen, and if the concentration of metHb is significantly elevated,

cyanosis and hypoxia (not hypoxemia) occur. MetHb is normally produced in small quantities and is reduced back to the ferrous state by various red blood cell enzymes (metHb reductases) or by reducing agents (e.g., glutathione, ascorbic acid). The normal concentration of metHb is less than 1.5% of the total hemoglobin, whereas levels above 10% produce cyanosis, levels above 35% produce symptoms, and concentrations above 60% may be fatal.

Increased levels of metHb may be hereditary (owing to enzyme deficiencies, most commonly an autosomal recessive metHb reductase deficiency) or may be acquired (owing to oxidant drugs or toxins, e.g., nitrites, nitrates, sulfones, aniline dyes, sulfonamides, phenacetin). Homozygous metHb reductase deficiency produces elevated metHb levels with cyanosis. Heterozygotes exhibit normal metHb concentrations unless subjected to an oxidant stress. Rarely, methemoglobinemia is caused by abnormal hemoglobins called (hemoglobin Ms), in which the iron atom cannot be reduced from the ferric state.

Acquired methemoglobinemia (and that occurring in reductase-deficient heterozygotes) results from ingestion of a variety of chemicals and drugs that oxidize hemoglobin.

Methemoglobinemia may be treated by the administration of methylene blue, which accelerates the activity of the reductase system, or reducing agents such as ascorbic acid, glutathione, cysteine, and British anti-Lewisite (dimercaprol).

Carboxyhemoglobinemia

COHb normally constitutes a small fraction (0.5%) of the total hemoglobin. It is formed by the reversible interaction of carbon monoxide with hemoglobin. Carbon monoxide binds hemoglobin with high affinity (210 times that of O_2), resulting in a left shift of the oxygen dissociation curve and a characteristic cherry red color of the blood. Because of the high affinity of CO for hemoglobin, COHb accumulates in acute or chronic CO exposure. Inhalation of CO may occur in subjects exposed to the products of incomplete combustion such as occurs in fires, charcoal grills, heating appliances, internal combustion engines, and tobacco products. Smokers may exhibit COHb levels of 4% to 8% of total hemoglobin.

In some patients, symptomatic CO toxicity (exertional dyspnea) can occur at levels as low as 10%, but overt symptoms usually do not occur until the blood level exceeds 30% (headache, syncope, confusion). Levels above 60% produce loss of consciousness or death. Oxygen therapy is effective treatment for CO poisoning because the CO–hemoglobin bond is reversible. The half-life of COHb in a patient breathing room air is approximately 4 to 5 hours, and this can be shortened to approximately 1 hour by breathing 100% oxygen.

RENAL PHYSIOLOGY

Part of "19 - Nitrogen Metabolites and Renal Function"

The kidneys are regulatory organs responsible for the maintenance of extracellular fluid volume and electrolyte and acid base balance, along with the excretion of toxic metabolites, drugs, and metabolic waste products. The kidney accomplishes this homeostasis by the formation of urine through ultrafiltration in the glomerulus, selective tubular reabsorption of water and solutes, and selective tubular secretion of solutes. The kidney also has an endocrine role; it produces erythropoietin, which regulates red cell mass, and renin, which affects sodium balance and regulates blood pressure, and metabolizes vitamin D, which influences calcium balance.

The two bean-shaped kidneys, which lie in the retroperitoneal space on either side of the aorta, are each approximately 10 to 12 cm in length and weigh approximately 150 g. Each kidney has an outer cortex that averages 40 mm in thickness surrounding the inner medulla. The medulla consists of a number of conical renal pyramids that terminate in a papilla. The papillae protrude into the renal pelvis, which collects urine. The renal pelvis drains into the ureter connecting the kidney to the urinary bladder. Within the cortex and medulla are the functional units of the kidney, called the nephrons. Each kidney contains approximately 1.25×10^6 nephrons, which operate in parallel with each other. A nephron is composed of a glomerulus, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct.

The glomerulus is composed of a cluster of capillaries formed from an afferent arteriole and is surrounded by an epithelial saccular expansion of the proximal tubule, forming Bowman's space. The proximal convoluted tubule coils extensively in the cortex and penetrates the deeper layers of the cortex to the outer medulla. The thin descending and thin and then thick ascending loops of Henle are located in the medulla in a hairpin configuration. This hairpin configuration allows a countercurrent multiplication concentrating process to occur. The distal convoluted tubule arises from the ascending thick loop of Henle and traverses through the cortex, terminating in a collecting duct near the original glomerulus. The collecting duct is formed in the outer cortex by the junction of two or more distal convoluted tubules and traverses through the cortex into the medulla, where several collecting ducts fuse to form the papillary ducts that terminate in the renal pyramid of the medulla. The total length of the nephron is 40 to 60 mm. The afferent arteriole leaves the glomerulus as the efferent arteriole and penetrates deep into the medulla, forming a network around the loop of Henle called the vasa recta. Tubular function depends on the anatomy of the loop of Henle and the surrounding vasa recta. The close proximity of the vasa recta to the loop of Henle is responsible for maintaining the medullary osmotic gradient, by a countercurrent exchange between the renal tubule and the corresponding arteriole (Fig. 19.1).

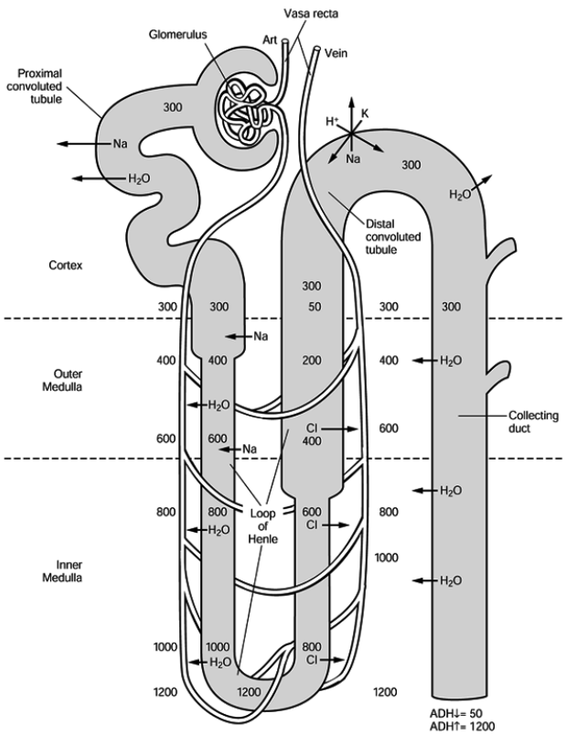

FIGURE 19.1. Diagram of the renal nephron. The numerals indicate the changes in osmolality (mOsm/kg H_2O) in the interstitium and the tubular fluid. The tubular exchanges of water and ions during the course of the production of urine are indicated.

Glomerular filtration is the initial event in the formation of urine. As blood flows through the glomerulus, ultrafiltration occurs owing to hydrostatic pressure within the glomerular capillaries, forcing plasma water and smaller solutes (<50,000 d) across the capillary membrane, opposed by the oncotic pressure of plasma proteins remaining in the glomerular capillaries and the hydrostatic pressure in Bowman's space. The glomerular filtration rate (GFR) depends on the balance of these Starling forces: the permeability of the capillary wall to water and solutes, the total surface area of the capillaries, and the rate of plasma flow through the capillaries. The GFR is the total glomerular filtrate formed by all the glomeruli per unit time. In the average-sized person, the GFR is 125 mL/minute or 180 L/day. The GFR can be determined with clearance studies using solutes that are filtered and subsequently neither reabsorbed nor secreted. The determination of the GFR provides an estimation of the functional renal mass and can be of considerable importance in the initial evaluation and follow-up of patients with renal disease. Certain extrarenal conditions will also cause the GFR to rise or fall significantly. Most important is the volume of the extracellular fluid. Expansion of the extracellular fluid volume is accompanied by an increase in the GFR rate, and an actual or perceived depletion of the extracellular fluid volume causes a marked reduction in the GFR rate. Postrenal obstruction of the outflow tract (urethra, bilateral ureters) will cause a decrease in the GFR proportional to the obstruction.

A large amount of ultrafiltrate (180 L/day) devoid of blood cells and protein containing 300 mOsm/kg H_2O of solute enters the tubules, and only 1% of that filtrate with a markedly altered solute content reaches the renal pelvis as urine. In the renal tubules, there is both selective reabsorption and secretion. Tubular reabsorption facilitates the conservation of substances essential for homeostasis. Examples are water, bicarbonate, glucose,

amino acids, and electrolytes. The reabsorption may be passive (e.g., urea and water) or active, defined as a net movement of the substance against an electrochemical potential gradient with the loss of metabolic energy (e.g., sodium or chloride). Tubular secretion involves the movement of substances from the tubular cell into the tubular fluid. Tubular secretion may also be passive or active. Many of the secreted substances are weak acids or bases, such as drugs, or metabolic end products that are eliminated from the body in the urine.

In the proximal convoluted tubule, 70% to 80% of the filtered solute and water are reabsorbed into the renal circulation. All the solutes are reabsorbed actively, except chloride, which is reabsorbed passively with sodium. Water is reabsorbed passively owing to the osmotic gradient from the active transport of sodium. At the end of the proximal convoluted tubule, the tubular fluid is sharply reduced in volume to approximately 20% of the original filtrate, whereas the osmolar concentration remains isotonic. As the tubular fluid flows through the loop of Henle, concentration of the filtrate first occurs owing to a countercurrent multiplication. In the thin descending loop of Henle, water diffuses out of the tubule into the hypertonic interstitium of the medulla, and a small amount of sodium diffuses into the tubule. At the hairpin curve deep in the medulla, the tubular fluid is maximally concentrated to nearly 1,200 mOsm/kg H_2O. In the thick ascending loop of Henle, the tubule is impermeable to water, whereas chloride is actively reabsorbed with sodium into the interstitium. The osmolar concentration decreases in the ascending loop of Henle until the tubular fluid is hypotonic (50 to 100

mOsm/kg H_2O) entering the distal convoluted tubule. The marked osmotic gradient established in the medullary interstitium is established by the active reabsorption of chloride followed by sodium in the ascending loop of Henle and the passive reabsorption of urea in the collecting duct. The rich capillary network (vasa recta) enveloping the tubule allows a countercurrent exchange to occur between the interstitial fluid and the renal blood flow. This exchange allows the reabsorption of water and electrolytes from the medullary interstitium into the renal circulation and is responsible for maintaining the hyperosmolality of the interstitium. In the distal convoluted tubule under the influence of aldosterone, 5% to 10% of the original filtered sodium is reabsorbed against a steep concentration gradient in exchange for hydrogen and potassium. In the collecting ducts, water reabsorption is regulated by antidiuretic hormone (ADH). Under the influence of ADH, the collecting ducts become permeable to water. Water is reabsorbed along with urea into the hyperosmolar medullary interstitium and tubular fluid becomes hypertonic. In the absence of ADH, the collecting duct is relatively impermeable to water and the tubular fluid remains hypotonic.

The renal nephron is also responsible for the maintenance of acid-base balance through the elimination of hydrogen ions and the regulation of plasma bicarbonate by conserving, regenerating, or eliminating bicarbonate. The renal tubular cells are capable of hydrogen ion secretion along much of the length of the nephron (Fig. 19.2). In the tubular cell, carbon dioxide is used as a source of hydrogen ion and bicarbonate. The hydrogen ion is secreted into the tubular lumen in exchange for a cation, usually sodium. In the proximal convoluted tubule, the hydrogen ion that is secreted into the tubular fluid is used up almost entirely in reabsorbing filtered bicarbonate, and the pH of the tubular fluid changes very little. In the distal convoluted tubule, under the influence of aldosterone, hydrogen ion and potassium ion are secreted into the tubular lumen in exchange for sodium. In addition to combining with bicarbonate in the distal tubular fluid, hydrogen ion can combine with other buffer ions such as hydrogen phosphate or can combine with ammonia to form ammonium ion. The secretion of hydrogen ion in the distal tubules changes the pH of the urine dramatically (less than pH 5.5) owing to the relatively small amount of bicarbonate remaining in the tubular fluid after proximal reabsorption of bicarbonate.

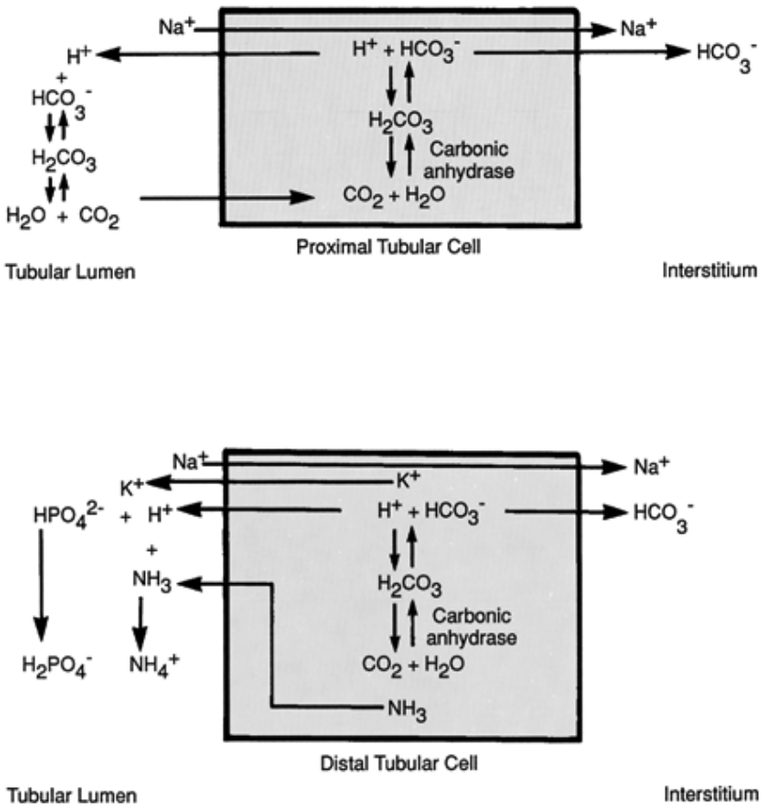

FIGURE 19.2. Hydrogen ion secretion in the proximal and distal renal tubular cells.

WATER BALANCE, SPECIFIC GRAVITY, AND OSMOLALITY

Part of "19 - Nitrogen Metabolites and Renal Function"

Water accounts for 50% to 60% of total body weight. Two thirds of total body water is intracellular, and one third is located in the extracellular fluid space. Water is freely diffusible across cell membranes. The distribution of water between the intracellular and extracellular spaces is determined by the concentration of osmotically active particles (osmolality) in each fluid. The osmolality of a fluid is roughly equal to the sum of the concentrations of individual solutes in the fluid. Total body water is regulated by thirst, which controls fluid intake, ADH, and renal function, which in turn controls renal conservation of water. With fluid deprivation,

there is a decrease in extracellular fluid volume and a corresponding increase in plasma osmolality. When the osmole receptors in the hypothalamus detect an increase in osmolality as little as 1% to 2%, both thirst and ADH pituitary release are stimulated. There is a linear increase in plasma ADH with an increase in plasma osmolality, with a maximum ADH response when the plasma osmolality reaches 290 mOsm/kg H_2O. Thirst increases water consumption and ADH increases water reabsorption in the collecting ducts of the kidney, resulting in water conservation and excretion of a concentrated urine. Urine volume is reduced, and urine osmolality is typically greater than 800 mOsm/kg. Conversely, when there is extracellular fluid volume expansion, receptors in the hypothalamus sense the fall in plasma osmolality and cause inhibition of both thirst and the pituitary release of ADH. The absence of ADH renders the collecting duct relatively impermeable to water, and hypotonic urine is produced with relatively high urine volume and osmolality typically less than 100 mOsm/kg. Both thirst and ADH release are also regulated directly by extracellular fluid volume in addition to osmolality. A decrease in extracellular fluid volume is sensed by carotid baroreceptors and stretch receptors in the left atrium of the heart, and signals are sent to the hypothalamus via the vagus nerve to stimulate thirst and ADH release. Extracellular fluid volume can override the regulation from plasma osmolality if there is a disparity between the two. For example, decreased extracellular fluid volume with low osmolality can actually cause stimulation of thirst and ADH release.

The concentrating and diluting function of the kidney is reflected in the solute concentration of the urine, which can be measured by specific gravity or osmolality. Specific gravity is defined as the ratio of the weight of a volume of urine to the weight of an equal volume of water. The specific gravity, like osmolality, is related to the concentration of dissolved solutes.

The specific gravity of a 24-hour urine specimen normally varies between 1.015 and 1.025, while the specific gravity of random urine samples can vary between 1.003 and 1.030, depending on fluid intake and state of hydration. After an overnight fast, a random urine specific gravity over 1.020 is considered to reflect normal renal concentrating ability.

There will be disparity between urine specific gravity and osmolality when significant amounts of compounds are present that contribute more to specific gravity than osmolality. These can include protein, glucose, and radiopaque dyes. The contribution to specific gravity is about 0.003 for each 1 g/dL of protein, and 0.004 for each 1 g/dL of glucose.

Specific gravity can be determined with a “urinometer,” a hydrometer specifically designed for urine samples, but this requires a large sample size and is seldom used.

Specific gravity is often estimated using a urine test strip or “dipstick.” The reagent includes a polymer with repeating carboxylic acid groups. When the polymer-impregnated strip is immersed into urine, the ionic species of the urine interact with the carboxylic acid groups and the pH change on the test strip is detected using an indicator such as bromthymol blue. The color on the test strip correlates with the specific gravity of the urine except in the presence of high concentrations of glucose or other nonionic species. The method also underestimates specific gravity in alkaline urine (pH greater than 6.5).

The specific gravity of urine can also be determined by refractometry. The principle of refractometry is based on the fact that light bends as it passes through a liquid. This angle of refraction is known as the refractive index and is related to the specific gravity of the solution being measured. A refractometer specially calibrated for use with urine is available.

The urine osmolality is a better measure of renal concentrating ability than the urine specific gravity. The sum of the active concentrations of all species dissolved in a solution determines the osmolality.

The colligative properties of a solution are directly related to the number of particles dissolved per unit mass of solvent, and the measurement of osmolality is based on one of these colligative properties. A 1-molal “ideal” solution will lower the freezing point by 1.86°C, lower the vapor pressure by 0.3 mm Hg, raise the osmotic pressure by 22.4 atm, and raise the boiling point by 0.52°C. The colligative properties most commonly used in the laboratory to measure osmolality are depression of the freezing point and depression of the vapor pressure. Real solutions usually have somewhat lesser effects on the freezing point and vapor pressure of the solvent than an ideal solution. The osmolality of a real solution is expressed as

Osmolality (mosm/kg H_2O) = φnC

where φ is the osmotic coefficient, which is 1.0 for an ideal solution and somewhat less than 1 for electrolytes that are incompletely dissociated or for solutes that tend to associate because of electrostatic or other forces, n is the number of particles formed by complete dissociation of the molecular species (mOsm/mmol), and C is the molality of the solute in mmol/kg H_2O.

Clinical Use of Urine Osmolality

The osmolality of urine can vary from 50 to 1,200 mOsm/kg H_2O, depending on the state of hydration. A random urine sample is usually in the range of 300 to 800 mOsm/kg H_2O. With a water load and corresponding decreased plasma osmolality, there is an inhibition of thirst and ADH release, which leads to diuresis with low urine osmolality. With water deprivation and a corresponding high plasma osmolality, thirst and ADH release are stimulated, and renal water conservation occurs, with a resultant low urine volume with high osmolality. Although the measurement of urine osmolality alone is of limited use in the diagnosis of water and electrolyte imbalance, a ratio of the urine osmolality to plasma osmolality can be extremely helpful in the differentiation of water imbalance states. In normal individuals, the urine osmolality to serum osmolality ratio is usually between 1.0 and 2.5. In chronic renal failure, the concentrating ability of the renal tubules is progressively lost. The urine-to-plasma osmolality ratio is less than 1.2 if there is predominantly tubular damage, but is more than 1.2 if there is predominantly a decrease in GFR rate. In acute tubular necrosis, the urine osmolality can be less than or equal to the plasma osmolality. Normal renal concentrating ability should result in a urine osmolality of more than 800 mOsm/kg H_2O after an overnight fast.

The urine-to-plasma osmolality ratio is also helpful in the diagnosis of polyuria. Polyuria can be caused by water diuresis induced

by insufficient ADH, suppression of ADH by excessive water consumption seen in such entities as psychogenic polydipsia, organic brain disease, and iatrogenic water ingestion, or failure of the kidney to respond to ADH, as seen in congenital nephrogenic diabetes insipidus, chronic renal disease, and acquired tubular defects from drugs such as lithium, phenytoin, ethanol, and amphotericin B.

Diabetes insipidus is a partial or total lack of the ability to produce ADH. Diabetes insipidus can be an inherited condition or can result from an insult to the hypothalamus or posterior pituitary gland. Nephrogenic diabetes insipidus is a different condition in which the distal nephron remains relatively impermeable to water reabsorption despite large amounts of ADH. The condition may also be inherited but is more commonly related to nephrotoxic drugs such as lithium, phenytoin, ethanol, and amphotericin B.

Either a lack of ADH, suppression of ADH, or a failure of the kidney to respond to ADH will result in copious volumes of dilute urine owing to the collecting duct being impermeable to water. There may be as much as 10 to 15 L of urine a day, with osmolalities of less than 100 mOsm/kg H_2O. Serious dehydration will occur unless water intake matches the urine output. Water diuresis states can be studied by concentration tests. The principle of a concentration test is that polyuria should be corrected by either fluid deprivation or ADH administration. With the patient fasting, plasma osmolality is determined every 2 hours. All urine excreted is also collected. The patient is adequately prepared when the plasma osmolality reaches 300 mOsm/kg or when the urine has a level plateau of osmolality. Baseline plasma and urine osmolality and plasma ADH levels are then determined. The patient is then given 5 mU of ADH subcutaneously, and the urine osmolality is measured 1 hour later. With diabetes insipidus, the result will be a high baseline plasma osmolality, low urine osmolality, absent plasma ADH level, and rise in urine osmolality after ADH injection. With suppression of ADH caused by psychogenic polydipsia, the results will usually be normal to low plasma osmolality with low urine osmolality, low plasma ADH level, and a rise in urine osmolality after administration of ADH. With nephrogenic diabetes insipidus, the results will be high plasma osmolality, low urine osmolality, high plasma ADH level, and absent rise in urine osmolality after ADH injection (Table 19.1).

TABLE 19.1. Laboratory Differentiation of Polyuria

Laboratory Parameter	Psychogenic Polydipsia	Diabetes Insipidus	Nephrogenic Diabetes Insipidus	Osmotic Diuresis
Posm	N, ↓	↑	↑	N, ↑
Uosm	↓	↓	↓	↑
Plasma ADH	↓	↓	↑	↑
Uosm after ADH	Increase	Increase	Nil	Slight increase

Posm, plasma osmolality; Uosm, urine osmolality.

Other concentration tests such as the Hickey-Hare test utilizing hypertonic saline can be used in the differential diagnosis of polyuria. In the Hickey-Hare test, samples for plasma osmolality and ADH levels are obtained at 20-minute intervals after hypertonic saline is started intravenously. In diabetes insipidus, there are undetectable ADH levels even when the plasma osmolality reaches 300 mOsm/kg H_2O.

The ratio of urine to plasma osmolality (U/P osm) is also helpful in the diagnosis of the syndrome of inappropriate ADH. In this syndrome, there is a pathologic amount of ADH, producing the opposite biochemical effects of diabetes insipidus. The excess ADH causes increased permeability of the collecting ducts to water, leading to water retention and hyponatremia. The urine osmolality will be elevated compared with the plasma osmolality (Uosm/Posm >2). The increased extracellular fluid volume leads to an increased GFR, increased tubular fluid flow, and a resultant sodium washout into the urine. There can be a substantial urinary loss of sodium in this condition, with urine sodium concentrations exceeding 20 mmol/L. The syndrome of inappropriate ADH can be seen in a variety of conditions, most commonly in pathologic lesions of the central nervous system or pulmonary system and in malignant tumors producing ADH, such as small cell carcinoma of the lung.

UREA

Part of "19 - Nitrogen Metabolites and Renal Function"

Urea is the major nitrogen-containing metabolite from the degradation of protein arising from the ammonia produced from the deamination of amino acids. The formation of urea occurs primarily in the liver, with minor amounts of urea formation occurring in the kidney and brain. The concentration of urea in the bloodstream depends on several factors. These are the rate of urea production, the volume of body water in which the urea is distributed, and the rate of urea elimination. The rate of urea production depends on the amount of protein in the diet, protein and blood in the gastrointestinal tract, catabolic states, and liver function. Urea is freely diffusible across cell membranes and is equally distributed in the total body water. Urea excretion depends on the GFR and the subsequent tubular reabsorption of urea. Urea is freely filtered across the glomerular membrane, with approximately 40% of the urea reabsorbed into the extracellular fluid from the tubule. The reabsorptive process is passive and depends on the fraction of filtered water that is reabsorbed.

Plasma urea will rise as the GFR decreases in patients with renal disease. The urea level is insensitive to a minimal fall in GFR and rises sharply only after 40% to 60% of the nephrons have ceased to function. Plasma urea increases progressively with a hyperbolic relationship to the GFR as renal disease progresses,

such that a 50% drop in the GFR results in an approximate doubling of plasma urea (Fig. 19.3).

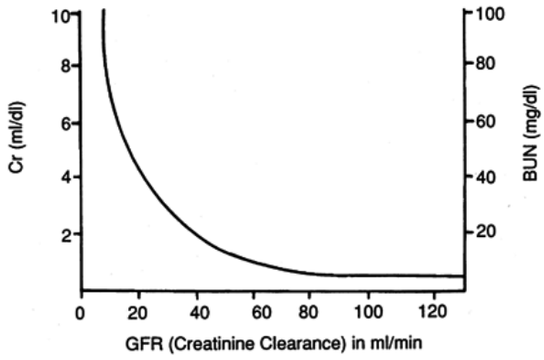

FIGURE 19.3. Relationship of serum creatinine or blood urea nitrogen to the glomerular filtration rate as measured by the creatinine clearance.

Etiologies of elevated urea level can be categorized as prerenal, renal, and postrenal (Table 19.2). Prerenal causes are related to increased production of urea or decreased renal perfusion. Renal causes are related to a loss of functioning nephrons with a corresponding decrease in GFR. Postrenal causes are related to obstruction of the urinary tract with a decreased urine flow.

TABLE 19.2. Etiologies of Elevated Serum Urea

Prerenal
Increased synthesis of urea
Catabolic states: fever, stress, burns
High-protein diet
Gastro intestinal bleeding
Hyperthyroidism
Cushing's syndrome
Hemolysis
Antianabolic drugs/tetracycline
Steroid therapy
Low calorie diet
Malignancy
Sepsis
Decreased perfusion of kidney
Congestive heart failure
Hypotension, shock
Renal vein thrombosis
Dehydration
Cirrhosis, ascites
Intrinsic renal disease
Glomerular disease
Tubular disease—acute tubular necrosis
Interstitial disease
Postrenal
Urinary tract obstruction
Benign prostatic hyperplasia
Prostatic carcinoma
Carcinoma of bladder of bilateral ureters
Retroperitoneal tumor
Calculi
Extravasation of urine into tissues

Urea may be abnormally low in several conditions in which there is a low rate or urea production, hemodilution, or increased rate of urea excretion. Decreased urea synthesis can occur with a low protein intake, administration of androgens or growth hormone, and severe liver dysfunction. Hemodilution can occur with overhydration, psychogenic polydipsia, and diabetes insipidus. Increased rates of elimination can be seen in hemodilution, pregnancy, and postdialysis states.

Analysis of Urea

1. *Urease (EC 3.5.1.5) with glutamate dehydrogenase (EC 1.4.1.3) coupled reaction*. This is the most common method for analysis of urea on automated systems. The highly specific urease enzyme converts urea into ammonia. A coupled reaction utilizing glutamate dehydrogenase with nicotinamide adenine dinucleotide (reduced form) (NADH) and α-ketoglutarate is monitored by measuring the decrease in absorbance at 340 nm as NADH is converted to NAD^+. Interferences may be seen in the assay if other enzymes that can also oxidize NADH are elevated in the specimen.

2. *Conductimetric urease*. There is an increase in conductivity of the specimen after the addition of urease (EC 3.5.1.5). The liberated bicarbonate and ammonium increase the conductivity of the solution. The rate of change of conductivity of the mixture as nonionized urea is transformed to the ionic species and can be monitored with a conductivity cell.

3. *Urease with quinolinium dye*. The urease (EC.3.5.1.5) enzyme liberates ammonia from urea. The ammonia reacts with merocyanine dye, which can be measured at 670 nm. This method is used in multilayer dry film assays and dry reagent strips where the reagents are incorporated into a matrix of hydrophilic polymers coated on top of a transparent base. The ammonia liberated transfuses through the base onto another layer containing the quinolinium indicator dye, which changes color with a change in pH.

4. *O-Phthalaldehyde*. Urea binds to O-phthalaldehyde to form a colored chromogen that can be monitored at 510 nm. The disadvantage of this method is interference by other primary amines.

5. *Diacetyl*. Diacetyl monoxime is hydrolyzed to form diacetyl and hydroxylamine. The diacetyl complexes with urea in an acid solution containing an oxidizing agent to form a yellow diazine compound (Fearon reaction), which can be measured at 550 nm, or fluorometrically at 415 nm. This method is easily automated. The disadvantage of this method is that nonspecific substances may produce chromogens and there is a low specificity compared with the enzymatic assays. The end color fades and usually a stabilizer such as thiosemicarbazide is added to enhance and stabilize the end product. An oxidizing agent may also be added to remove hydroxylamine and ensure a complete reaction.

6. *Berthelot reaction*. Urea is hydrolyzed with urease to carbonic acid and ammonia. Sodium phenate and hypochlorite react with ammonia in the presence of sodium nitroprusside to produce a blue indophenol complex with maximum absorbance at 630 nm. The disadvantages of this reaction are nonspecificity and long reaction times. The advantages are that protein precipitation is not required and turbidity is not a problem.

7. *Definitive Method*. Isotope dilution-mass spectrometry method is available as a definitive method.

The earliest methods for urea in the clinical laboratory used whole blood as the sample, and an analytical method that measured nitrogen in urea. This led to the convention of reporting concentrations in terms of milligrams of nitrogen per deciliter of sample, which is still used except in areas where SI units have been adopted. The misnomer BUN (for blood urea nitrogen) is also still commonly used today, even though plasma or serum urea nitrogen is meant.

The reference interval for plasma (or serum) urea nitrogen is 7 to 22 mg/dL.

CREATININE

Part of "19 - Nitrogen Metabolites and Renal Function"

Creatine is synthesized in the liver from arginine and glycine and is transported to muscle, which contains 98% of the total body stores of creatine. The creatine pool is related primarily to muscle mass, which is affected primarily by gender and age and to a lesser extent by dietary intake of creatine. Approximately 1.5% of the total body creatine is degraded to creatinine each day by nonenzymatic dehydration. Creatinine is not bound to protein but is freely distributed through the total body water and is excreted from the body by glomerular filtration, with an additional 10% to 20% of creatinine secreted through the tubule. Creatinine is not reabsorbed in the tubule.

The serum creatinine level is determined by creatinine production, state of hydration, and creatinine excretion. Increased creatinine production is seen in acute muscle disease such as dermatomyositis, and decreased creatinine production is seen in muscle-wasting diseases. Decreased renal perfusion, as in shock, hypotension, congestive heart failure, or cirrhosis, will decrease the GFR and raise the serum creatinine. Creatinine will also be elevated whenever the GFR is low because of renal disease or postrenal obstruction. Like urea, the etiologies of elevated creatinine level can be categorized as prerenal, renal, or postrenal and are summarized in Table 19.3.

TABLE 19.3. Etiologies of Elevated Serum Creatinine Level

Prerenal
Increased synthesis of creatinine
Muscle hypertrophy
Muscle necrosis
Anabolic steroid use
High-meat diet
Drug—phenacemide
Severe exercise
Decreased renal perfusion
Hypotension, shock
Congestive heart failure
Cirrhosis, ascites
Renal
Glomerular
Tubulointerstitial
Decreased tubular secretion
Drugs—cimetidine, trimethroprim, probeneoid
Postrenal
Urinary tract obstruction
Benign prostatic hyperplasia
Carcinoma of prostate, bladder, or ureters
Calculi
Retroperitoneal tumor

Also like urea, creatinine has a nonlinear relationship to the GFR and does not become significantly elevated until the GFR decreases by 40% to 60% (Fig. 19.3).

Simultaneous determination of the serum creatinine and urea levels and calculating the serum urea nitrogen:creatinine ratio may be of benefit in separating prerenal and postrenal conditions from renal diseases as the cause of an elevated serum creatinine or urea level. The normal serum urea nitrogen:creatinine ratio is in the range of 10:1 to 20:1. An elevated serum urea nitrogen:creatinine ratio is seen in prerenal and postrenal conditions, whereas a normal serum urea nitrogen:creatinine ratio is seen in renal disease. The ratio is elevated in prerenal or postrenal conditions due to either increased tubular reabsorption of urea or increased production of urea. In renal disease, the serum urea nitrogen:creatinine ratio remains in the normal range owing to both being similarly affected by the loss of functioning nephrons.

The amount of creatinine excreted in a 24-hour urine depends primarily on the muscle mass of the individual. A man excretes 14 to 26 mg of creatinine per kilogram per day, and a woman excretes 11 to 20 mg/kg per day in the urine, but the amount is fairly consistent for a given individual. The urine creatinine therefore provides a rough estimate of the completeness of a timed urine collection.

Creatinine Methods

The most common methods for the analysis of creatinine are based either on the Jaffé reaction or on one of several enzymatic reactions.

The Jaffé reaction, first described in 1886, is the reaction between creatinine and picrate in an alkaline medium, forming a red-orange complex that absorbs in the range of 480 to 520 nm. Optimal performance of the reaction depends on the concentrations of the various reagent components, especially the concentration of the alkali, which determines the rate of the reaction and the wavelength of maximal absorbance. Most manual methods are end-point assays with 10 to 15 minutes allowed for the reaction. The Jaffé reaction is not specific for creatinine, as a variety of other substances can also react with the picrate. These are called noncreatinine chromogens, and the most common are protein, acetoacetone, glucose, ascorbic acid, guanidine, acetone, α-ketoacids, urea, and cephalosporin antibiotics. Many modifications have been introduced to minimize these interferences. These include pretreatment with Lloyd's reagent (aluminum silicate) to remove most of the noncreatinine chromogens, dialysis or precipitation to remove protein, the addition of buffers to complex glucose and ascorbic acid, and the introduction of a kinetic approach rather than an end-point determination. The kinetic analysis is useful because there is a time interval (usually 25 to 60 seconds) during which the reaction rate is predominantly caused by the formation of a creatinine picrate complex. There is still some positive interference owing to acetoacetone, and bilirubin causes a negative interference. The kinetic rate method allows the Jaffé reaction to be more specific, faster, and easily automated.

Enzymatic methods. There are several enzymatic methods for the analysis of creatinine, which are usually based on one of two

enzymes. Creatinine deaminase (creatinine iminohydrolase) (EC 3.5.4.21) catalyzes creatinine degradation to n-methylhydantoin and ammonium ion. This is then followed by detection of the ammonium ion. Detection of the ammonium ion by reaction with bromphenol blue has been used in dry multilayer film methods with the ammonia diffusing through a semipermeable layer to react with the bromphenol blue. Creatininase (creatinine amidohydrolase) (EC 3.5.2.10) catalyzes hydrolysis of creatinine to creatine. The creatine can be coupled to other enzymatic reactions that, for example, usually culminate in measuring a change in NADH absorbance at 340 nm. The enzymatic methods are more specific than the Jaffé methods and give 10% to 20% lower serum creatinine values than a corresponding Jaffe method.

3,5-Dinitrobenzoic acid. This method involves creatinine reacting with the 3,5-dinitrobenzoic acid at an alkaline pH to give a purple color. The method correlates with the alkaline picrate methods.

High-pressure liquid chromatography. Several high-pressure liquid chromatography methods have been described involving the separation of creatinine from interfering substances using an isocratic reverse-phase method. Although this method is not practical for routine clinical use, it is useful for validating other methods because of its high specificity. A description of a definitive method using isotope dilution gas chromatography/mass spectrometry has also been published. This method is also extremely specific, and the creatinine values of the definitive method are approximately 20% lower than values from the alkaline picrate method when serum samples are used.

Analysis of creatinine in urine requires a dilution of 1:100 because the urine creatinine concentration is 100-fold that of serum.

CLEARANCE TESTS

Part of "19 - Nitrogen Metabolites and Renal Function"

The renal clearance of a substance can be thought of as the volume of plasma that can be completely cleared of that substance each minute by the kidney. The renal clearance of any substance can be calculated with the following relationship:

$$\text{Clearance (mL/min)} = \frac{\text{Urine concentration}}{\text{Plasma concentration}} \times \text{Timed urine volume (mL/min)}$$

The clearance is proportional to the renal parenchymal mass, which in turn is roughly proportional to the total body surface area. To compare clearance studies of individuals with varying body sizes, the clearance can be expressed in terms of a standard body surface area of 1.73 m^2. This is done by dividing 1.73 by the patient's body surface area and multiplying the observed clearance by this corrected surface area. Nomograms can be used to calculate body surface area from the patient's body weight and height.

The clearance of a substance that is freely filtered through the glomerulus and is not subsequently reabsorbed or secreted by the tubule is a measure of GFR. Inulin is such a substance. Inulin is an inert polysaccharide with a molecular weight of approximately 5,000 that is not bound to plasma proteins. The measurement of inulin clearance necessitates a continuous intravenous infusion of inulin to maintain a plasma inulin steady state. Intravenous administration of radiolabeled substances such as ^{51}Cr (creatinine)-EDTA (ethylenediaminetetraacetic acid), ^{125}I (iodine-125)-iothalamate, and ^{99m}Tc (technetium-99m)-DTPA (diethylenetriamine pentaacetic acid) can also be used to obtain clearances that directly measure the GFR.

Because determination of the clearance of these compounds is time-consuming and impractical to perform routinely, the endogenous creatinine clearance is commonly used for the estimation of GFR. Creatinine is produced in muscle at a relatively constant rate, is not bound to plasma protein, and is freely filtered through the glomerulus. Because a small amount (less than 10%) of creatinine is also secreted by the tubules, the creatinine clearance is slightly higher than a simultaneously measured inulin clearance, and thus slightly overestimates the GFR. If the creatinine analyses are performed with the Jaffé reaction, the presence of noncreatinine chromogens in the plasma but not in the urine will minimize this overestimation by partially cancelling out the secreted creatinine in the urine. More specific enzymatic creatinine methods will produce a creatinine clearance with a more pronounced overestimation of the GFR. With increasing renal failure, the creatinine clearance overestimates the GFR even more owing to increased tubular creatinine secretion.

The creatinine clearance averages 125 mL/min in adult males and 115 mL/min in adult females. The GFR is relatively stable from the first year of life through the fourth decade. After the fourth decade, the GFR decreases approximately 1 mL/min per year, and thus the normal range for creatinine clearance in elderly adults is lower than in younger individuals.

There are several other important factors to consider in interpreting the creatinine clearance. The coefficient of variation of creatinine clearance varies from 10% to 20% because of the imprecision of the creatinine measurement, biological variation of creatinine synthesis, variations in the urinary excretion of creatinine, and variations in the timing and collection of urine specimens. The creatinine clearance can also be estimated from the serum creatinine, taking into account the patient's age, weight, gender, and body size and using the Cockcroff and Gault formulas.

$$\text{Ccr} = \frac{(140 - \text{age}) \times \text{wt}}{\text{Pcr} \times 72} \text{ (males)} \quad \text{or} \quad \text{Ccr} = \frac{(140 - \text{age}) \times \text{wt}\ (0.85)}{\text{Pcr} \times 72} \text{ (females)}$$

where age is in years, weight in kilograms, and plasma creatinine in milligrams per deciliter. These formulas may not be accurate in estimating the GFR in patients with edema, obesity, cachexia, or muscle-wasting conditions. This estimation nonetheless may be helpful in the calculation of the dosage of many potentially toxic drugs.

The relationship between plasma creatinine and urea and the GFR is nonlinear (Fig. 19.3). It is evident that with normal to moderately low values of GFR, a large change in the GFR results in only a small rise in the plasma creatinine or urea level, whereas with lower values of GFR, the increase in urea or plasma creatinine level becomes increasingly greater as the GFR falls. Thus,

urea and creatinine are relatively insensitive tests of early renal disease; the GFR must fall by approximately 50% before these tests become significantly abnormal.

An abnormal creatinine clearance is not a specific indication of renal disease because of other factors that influence the GFR. With decreased renal perfusion (e.g., congestive heart failure, cirrhosis, dehydration, hemorrhage) or decreased tubular fluid flow seen in postrenal obstruction (e.g., benign prostatic hyperplasia, urinary bladder or prostatic carcinoma, calculi), the GFR will fall, with a corresponding decrease in the creatinine clearance. The GFR also increases in high renal perfusion states such as pregnancy and inappropriate ADH, leading to a corresponding increase in the creatinine clearance.

Other types of renal clearances can be used to determine parameters other than the GFR. For example, renal plasma flow can be estimated by *p*-aminohippurate clearance, tubular function by sodium clearance, and osmolar excretion by osmotic clearance.

CREATINE

Part of "19 - Nitrogen Metabolites and Renal Function"

Creatine can be measured directly by (a) the condensation of creatine with diacetyl-1-naphthol to form a pink product, (b) the use of creatine kinase enzyme with a fluorometric assay, and (c) the use of guanidine with ninhydrin in an alkaline solution to produce a fluorescent product. Creatine is commonly measured indirectly by converting creatine to creatinine through heating the sample with acid in the presence of a heavy metal. Creatinine is measured before and after the addition of the reagent, and creatine is calculated from the difference in the concentrations. Plasma creatine is increased with muscle necrosis and most muscle diseases, but the utilization of plasma creatine measurements has declined sharply in favor of the analysis of muscle enzymes such as creatine phosphokinase.

URIC ACID

Part of "19 - Nitrogen Metabolites and Renal Function"

Uric acid is the major end product of purine metabolism, specifically the catabolism of the purine nucleosides adenosine and guanosine. The metabolism of these nucleosides is as follows:

$$\begin{array}{r} \text{Adenosine} \rightarrow \text{Inosine} \rightarrow \text{Hypoxanthine} \\ \downarrow \text{Xanthine oxidase} \\ \text{Guanosine} \rightarrow \text{Guanine} \rightarrow \text{Xanthine} \\ \downarrow \text{Xanthine oxidase} \\ \text{Uric Acid} \end{array}$$

Uric acid production occurs primarily in the liver and intestinal mucosa because of the high xanthine oxidase enzyme activity in these two tissues. Daily synthesis of uric acid is approximately 700 mg, with dietary nucleoprotein contributing 300 mg to the daily total uric acid production. The body pool of uric acid is approximately 1.2 g, and approximately 60% of this pool turns over every day. Since the pKa of uric acid is 5.75, the majority of uric acid in the body exists as the urate ion.

The only effective route for excretion of uric acid from the body is through the kidney. Uric acid excretion is complex. Of filtered uric acid, 98% to 100% is actively reabsorbed in the proximal portion of the proximal convoluted tubule, is secreted in the distal portion of the proximal convoluted tubule, and finally is actively reabsorbed in the distal convoluted tubule. Only 6% to 12% of the original filtered uric acid is excreted in the urine, which amounts to 400 to 800 mg excreted in the urine daily.

Plasma uric acid levels show day-to-day and seasonal variations in the same patient. The uric acid level is higher in the summer than in the winter in most individuals. Plasma levels are lower during childhood, reaching adult levels by age 18. The reference range depends on the method that is used to analyze uric acid and is in the range of 4.0 to 7.5 mg/dL for adult males and 2.7 to 6.0 mg/dL for adult females when a uricase method is used. Uric acid levels tend to increase gradually with age, with an average 10% increase from age 20 to 60 years. There is a significant rise in uric acid in women after menopause. Several factors influence the uric acid level, most of which are poorly understood. Increases in exercise, stress, and weight, along with hypertension, diabetes mellitus, and type A personalities are associated with higher values of uric acid. Drugs can affect uric acid levels by altering the rate of synthesis and/or excretion. Drugs that have been reported to elevate uric acid are ethanol, acetaminophen, androgens, low-dose aspirin, furosemide, and mercurial diuretics; the following drugs have been reported to lower uric acid: high-dose aspirin, allopurinol, chlorpromazine, cortical steroids, warfarin (Coumadin), estrogens, and phenothiazines.

Hyperuricemia is seen in several pathologic conditions. These conditions can be owing to either an increased production of uric acid or decreased renal excretion of uric acid. Increased production of uric acid is seen with increased nucleic acid turnover, which leads to increased catabolism of purines. This condition can be seen if there is a rapid proliferation of cells, such as in lymphoproliferative disorders or malignancy, in hemolytic anemia, with a rich purine diet, or with increased *de novo* synthesis, such as in primary gout. A decreased urinary excretion of uric acid can be seen in acute or chronic renal disease of any type (Table 19.4).

TABLE 19.4. Etiology of Hyperuricemia

Increased uric acid synthesis
Gout
Purine-rich diet (organ meats)
Tissue catabolism (necrosis, radiation)
Myeloproliferative disorders
Lymphoproliferative disorders
Chemotherapy of malignancy
Lesch–Nyhan syndrome
Decreased renal excretion of uric acid
Renal failure
Drugs
Diuretics
Small-dose aspirin (< 2 g/day)
Metabolic acidosis
Toxemia or pregnancy
Miscellaneous etiologies
Intoxications (ethanol, methanol)
Endocrine (acromegaly, hyperparathyroidism)
Psychosocial, hypertension, type A personality
Psoriasis

Gout is a disorder of purine metabolism or renal excretion characterized by an increase in the total body uric acid and the precipitation of monosodium urate as deposits (tophi) in and around joints, bursae, periarticular cartilage, bone, and subcutaneous tissue. There can be recurrent attacks of arthritis and nephropathy with nephrolithiasis. The deposits of urate crystals are responsible for the clinical signs and symptoms of the disease. There is thought to be a genetic disposition, although fewer than one third of patients have a positive family history. Men make up 90% of all cases, and gout is uncommon in women before menopause. The peak age of onset of gout is in the fifth decade. The plasma level of uric acid correlates roughly with the clinical severity of gout; however, there is extreme variability from individual to individual with the same level of uric acid producing different degrees of clinical symptoms.

Hypouricemia, defined as a uric acid level below 2.0 mg/dL, can be seen in severe liver disease with a decreased synthesis of purines, a hereditary deficiency of xanthine oxidase, administration of allopurinol (a xanthine oxidase inhibitor) or uricosuric drugs, and a defect in renal tubular reabsorption of uric acid seen in Fanconi's syndrome.

Analytical methods for uric acid fall into two categories: phosphotungstic acid and uricase methods.

Phosphotungstic acid oxidizes uric acid to allantoin. The reduction product of phosphotungstate in an alkaline medium is blue and can be quantitated by measuring absorbance at approximately 700 nm. Phosphotungstic acid methods differ in the reagents used to intensify the blue color. The reaction is nonspecific, and positive interferences can be seen for glucose, ascorbic acid, glutathione, cystine, and drugs such as aspirin, acetaminophen, caffeine, and theophylline. Protein must be removed to avoid turbidity and quenching of the color development. Phosphotungstic acid methods give plasma uric acid values 0.2 to 0.4 mg/dL higher than uricase methods.

Uricase methods are based on the oxidation of uric acid to allantoin and hydrogen peroxide by the enzyme uricase (urate oxidase, EC 1.7.3.3) and have the advantage of greater specificity and accuracy. There are many adaptations of this method. Uric acid is maximally absorbed between 290 and 295 nm at an alkaline pH. This absorbance disappears as uric acid is oxidized with uricase. The concentration of uric acid can therefore be calculated from the difference in absorbance before and after the action of uricase. In another approach, coupled uricase methods utilize the hydrogen peroxide produced as a substrate for a chemical indicator reaction catalyzed by peroxidase or catalase. A coupled uricase method is utilized in the dry multilayer film technology methods. The reference method for uric acid analysis is based on the uricase reaction, and there is also a definitive method using isotope dilution/mass spectrometry.

AMMONIA

Part of "19 - Nitrogen Metabolites and Renal Function"

Ammonia is a product of amino acid metabolism, primarily in the liver, where oxidative deamination of L-glutamate occurs to form α-ketoglutarate and ammonia. The major source of ammonia, however, is absorption from the gastrointestinal tract where bacteria proteases, ureases, and amine oxidases act on protein contents in the colon, and simultaneous hydrolysis of glutamine occurs in the small and large intestines to form a large amount of ammonia. Ammonia is absorbed into the portal blood system and is ultimately metabolized to urea in the liver through the urea cycle. A small amount of ammonia is converted into glutamine and stored in the liver, brain, and skeletal muscle. The ammonia concentration in the systemic circulation is low, in the range of 10 to 60 μgN/dL. Elevated ammonia levels can be seen in congenital deficiencies of any of the enzymes of the urea cycle, in Reye's syndrome, and in severe liver disease. In severe hepatic failure, hepatic encephalopathy and coma are associated with high blood ammonia and glutamine, but the severity of the clinical signs does not correlate well with the blood ammonia level.

The most common method for the analysis of ammonia uses the enzyme glutamate dehydrogenase (GLDH) (EC 1.4.1.3) in the following reaction:

$$NH_4^+ + \alpha\text{-ketoglutarate} + NADPH \xrightarrow{GLDH}$$

$$\text{L-glutamate} + NADP^+ + H_2O$$

The ammonia level is determined by measuring the decrease in absorbance at 340 nm as NADPH is converted to $NADP^+$.

Two-stage assays are also available. In the first stage, the plasma is mixed with a cation exchange resin that binds ammonium ion. The ammonium is eluted off the resin and quantitated with Nessler's reagent or the Berthelot reaction (phenolhypochlorite).

Ammonia analysis in the clinical laboratory is particularly subject to preanalytical sources of error because of the very low concentration of ammonia that is normally present. The ammonia content of blood rises rapidly after collection because of the *in vitro* metabolism of nitrogenous compounds and the degradation of glutamine. Hemolysis can lead to an increased ammonia level because of a higher concentration of ammonia in red cells than the plasma. These can be minimized by keeping the sample on ice and beginning the analysis within 30 minutes. Ammonia is stable for at least 2 days if plasma is frozen at -20°C. Cigarette smoking can cause a marked contamination of ammonia in the sample.

RENAL DISORDERS

Part of "19 - Nitrogen Metabolites and Renal Function"

Acute Renal Failure

An abrupt decline in renal function is a common clinical problem. This is manifested clinically by the onset of oliguria (less than 500 mL of urine per day) and an acute rise in serum creatinine and urea. Approximately 70% to 75% of cases have a prerenal etiology associated with decreased renal perfusion, and 25% of cases are owing to intrinsic renal disease from ischemia or toxins. Decreased renal perfusion can be the result of volume depletion from hemorrhage or gastrointestinal tract fluid loss, hypotension associated with septic shock, congestive heart failure, and cirrhosis. The most common renal disease associated with acute renal failure is acute tubular necrosis (ATN). ATN is manifested by sloughing of renal tubular cells and occlusion of the tubules by cellular debris. ATN is associated with hypoxic injury of the tubule by renal ischemia or tubular injury caused by toxins

or drugs, such as aminoglycosides, radiologic contrast media, heme pigments, amphotericin B, and cisplatin. The oliguric phase of ATN lasts 7 to 21 days and is followed by a diuretic phase. Azotemia decreases 1 to 3 weeks after the onset of diuresis.

The mortality rate is 40% to 60%. It is important to differentiate between decreased renal perfusion and ATN as the cause of acute renal failure because the treatment for the two conditions is quite different. In general, the treatment for decreased renal perfusion is fluid administration to expand blood volume, whereas ATN requires careful management of fluid to control water and electrolyte imbalance.

In acute renal failure caused by decreased renal perfusion, serum urea tends to be elevated proportionately more than creatinine because of increased reabsorption of urea in the renal tubule. The urea-to-creatinine ratio is generally greater than 20. The decreased plasma volume stimulates ADH and aldosterone, resulting in production of smaller urine volume. The urine is relatively concentrated with a high osmolality but with a low sodium concentration.

Renal tubular damage seen in ATN results in marked tubular dysfunction with a loss of concentrating ability and inability to conserve sodium. The urine osmolality is similar to plasma osmolality, and the urine sodium is more than 40 mEq/L (refer to Table 19.5 for differentiation between ATN and decreased renal perfusion).

TABLE 19.5. Laboratory Differentiation of Acute Tubular Necrosis and Renal Hypoperfusion

Value	Hypoperfusion	ATN
UN/cr	> 20	< 15
Uosm	> 500	< 350
U/Posm	> 1.5:1	1:1
U/Pcr	> 40	< 15
UNa	< 20	> 30–40
SG	> 1.015	< 1.010
FE_{Na}	< 1	> 2
CH_2O	-20 to -100	-20 to +#

ATN, acute tubular necrosis; UN/cr, urea nitrogen:creatinine ratio; FE_{Na}, fractional excretion of sodium; SG, specific gravity; UNa, urinary sodium (mEq/liter); Uosm, urinary osmolality; U/Pc, ratio of urinary to plasma creatinine; U/Posm, ratio of urinary to plasma osmolality; CH_2O, free water clearance.

The fractional excretion of sodium (FE_{Na}) may also be of help in differentiating between ATN and decreased renal perfusion. The FE_{Na} is an index of the ability of the kidney to conserve sodium and represents the percentage of filtered sodium that is excreted in the urine. The FE_{Na} can be calculated by simultaneously measuring urinary and plasma sodium (U_{Na}, P_{Na}) and creatinine (U_{cr}, P_{cr}) and using the following formula:

$$FE_{Na}\,(\%) = \frac{U_{Na} \times P_{cr}}{U_{cr} \times P_{Na}} \times 100$$

In decreased renal perfusion, the FE_{Na} will be less than 1%, whereas in ATN, it will generally be greater than 2%.

Free water clearance (CH_2O) determination also is a valuable test to differentiate between prerenal azotemia and ATN. Water excretion by the kidney can be divided into that needed to excrete the solutes, which is called the osmolar clearance (Cosm). Free water clearance is the volume of solute free water that has been added to the solute water (hypotonic urine) or that subtracted from the solute water (hypertonic urine). Free water clearance can be calculated by the following formula:

$$\text{Cosm} = \frac{\text{Uosm} \times \text{Uvol}}{\text{Posm}}$$

$$\text{Uvol} = \text{Cosm} + CH_2O$$

$$\text{thus } CH_2O = \text{Uvol} - \text{Cosm}$$

In prerenal azotemia with a concentrated urine, the free water clearance will be markedly negative (-20 to -100), whereas with ATN, the free water clearance will usually be a positive number because of a lack of tubular concentration.

Chronic Renal Disease

Patients with early renal disease are usually asymptomatic. However, there may be complaints relating to the urinary tract, such as urinary frequency, hematuria, and pain, or there may be systemic complaints, such as edema, hypertension, lassitude, and weakness. The urinalysis is one of the most important tests to detect early renal disease. The kinds of abnormalities seen in the urinalysis are related to the type of renal disease present.

Renal disease can be divided into glomerular, tubular, and interstitial diseases. Glomerular diseases are usually caused by immunologic factors and are defined by specific pathologic changes seen on microscopy. Usually the first manifestation of glomerular disease is altered permeability of the glomerulus, causing proteinuria or hematuria. Additional glomerular damage leads to a decreased GFR, seen as a progressive decrease in the creatinine clearance, and finally an elevation in plasma urea and creatinine. Because of the hyperbolic relationship between plasma urea or creatinine and the GFR, as mentioned earlier, these measurements are poor indicators of early renal disease.

Tubular and interstitial damage can be secondary to multiple myeloma, ATN, nephrotoxic drugs, and pyelonephritis. Tubular dysfunction can be detected by abnormal tests of urinary concentration such as changes in specific gravity, urine and plasma osmolality ratios, inability to conserve sodium, defects in acidification of the urine, increased fractional excretion of sodium, and positive free water clearance.

Progressive and irreversible deterioration of renal function will lead to the kidney's progressive inability to perform its excretory, secretory, and regulatory functions. When more than 90% of the nephrons are nonfunctioning, signs and symptoms known as the uremic syndrome can develop. The uremic syndrome consists of anorexia, nausea and vomiting, lassitude, anemia, bleeding tendency, altered endocrine function, neuromuscular symptoms, and hypertension. Characteristic laboratory findings include anemia, abnormal urinalysis, elevated urea and creatinine, low creatinine clearance, elevated phosphorus, hyperkalemia, hypocalcemia, hyperuricemia, hypermagnesemia, elevated alkaline phosphatase, metabolic acidosis, and a loss of concentrating ability. Diabetes mellitus and essential hypertension are contributing factors in a sizable portion of all chronic renal disease patients. When the GFR decreases to less than 25 mL/min, most patients require dialysis or renal transplantation to prevent the onset of the uremic syndrome.

Renal Tubular Acidosis

Renal tubular acidosis is a term applied to a group of diverse disorders in which the kidneys are unable to acidify urine normally. The common feature is a mild hyperchloremic metabolic acidosis caused by abnormal renal acid-base handling. These disorders show little alteration in the GFR rate. There are two major types of renal tubular acidosis involving either the proximal or the distal convoluted tubules and a third subtype of distal disorder.

Type I renal tubular acidosis was the first renal tubular acidosis described. It occurs more often in female children than in adults. Type I renal tubular acidosis usually presents with growth retardation, muscle weakness, and renal abnormalities. It is caused by a reduced ability of the distal convoluted tubule to acidify urine. Patients with type I distal renal tubular acidosis cannot produce urine with a pH less than 6.0. The exact mechanism is uncertain.

The presence of a urine pH less than 5.2 excludes the diagnosis of distal renal tubular acidosis. There may be an associated abnormal loss of potassium, phosphorus, and calcium in the urine, with the formation of renal calculi. Type I renal tubular acidosis may be familial, autosomal-dominant, or secondary to toxic or metabolic etiologies such as hyperparathyroidism, hypergammaglobulinemia, autoimmune disorders, vitamin D intoxication, use of amphotericin B, and hydronephrosis (Table 19.6). Diagnosis can be made with an ammonium chloride (100 mg/kg) challenge test, in which the urine pH (greater than 5.5) remains inappropriately high in relation to the degree of induced systemic acidosis. A bicarbonate loading test will usually be normal (less than 10%) in this disorder.

TABLE 19.6. Causes of Distal Renal Tubular Acidosis (Type I)

Hereditary
Diseases associated with gammopathy
Amyloidosis
Systemic lupus erythematosus
Sarcoidosis
Macroglobulinemia
Tubulointerstitial disease
Analgesic nephropathy
Sickle cell disease
Chronic pyelonephritis
Obstruction of the urinary tract
Nephrocalcinosis
Hyperparathyroidism
Vitamin D intoxication
Drugs
Amphotericin B
Lithium
Analgesics

TABLE 19.7. Causes of Proximal Renal Tubular Acidosis (Type II)

Idiopathic or hereditary
Vitamin D deficiency
Hyperparathyroidism
Fanconi's syndrome
Chronic renal disease
Amyloidosis
Systemic lupus erythematosus
Drugs
Tetracycline
Carbonic anhydrase inhibitors
Streptozotocin
Gentamicin
Heavy metal intoxication
Wilson's disease
Multiple myeloma
Cystinosis
Galactosemia

Type II renal tubular acidosis is a proximal renal tubular acidosis that usually presents in male children with symptoms of growth retardation. Type II renal tubular acidosis is caused by an inability of proximal renal tubular cells to conserve bicarbonate. In the renal tubule, the majority of renal hydrogen ion secretion occurs in the proximal convoluted tubule, which is responsible for reabsorbing 85% of the filtered bicarbonate. In this disorder, the proximal reabsorption of bicarbonate is impaired, and thus bicarbonate is lost in the urine. Distal hydrogen ion secretion is normal in these patients. In some patients with type II renal tubular acidosis, the net acid secretion may be normal if the serum bicarbonate is low. When the serum bicarbonate falls, a level is reached at which the proximal tubular cells are able to recover all of the filtered bicarbonate. The distal tubule then can acidify the urine in a normal manner. A bicarbonate loading test will reveal the fractional bicarbonate excretion will be more than 15%. Other significant laboratory findings include hypokalemia and increased urinary excretion of calcium, sodium, and potassium. Type II proximal renal tubular acidosis may be an isolated hereditary defect but is more commonly associated with other proximal defects, such as aminoaciduria, glycosuria, and phosphaturia (Fanconi's syndrome). Type II renal tubular acidosis can be secondary to multiple myeloma, cystinosis, galactosemia, heavy-metal intoxication, carbonic anhydrase inhibitors, tetracycline use, hyperparathyroidism, and amyloid infiltration (Table 19.7). The treatment is large dosages of bicarbonate.

Type IV renal tubular acidosis is a type of distal renal tubular acidosis associated with a hyporenin–hypoaldosterone state. Because of a decreased response or absence of aldosterone, there are a failure of potassium and hydrogen ion secretion in the distal tubule and a failure of the distal convoluted tubular cells to produce ammonia will result in metabolic acidosis with hyperkalemia. This type of renal tubular acidosis may also be seen in generalized renal disease.

Laboratory differentiation of the different types of renal tubular acidosis is tabulated in Table 19.8.

TABLE 19.8. Differentiation of Type I, II, and IV Renal Tubular Acidosis

Clinical or Laboratory Features	Type I	Type II	Type IV
Urinary pH with			
HCO_3> 20	> 5.5	> 5.5	> 5.5
HCO_3 < 15	> 5.5	< 5.5	> 5.5
Potassium	↓	↓	↑
Calculi	Yes	No	No
NH_4Cl loading	> 5.5	< 5.5	> 5.5
Fanconi's	No	Yes	No
% HCO_3 excretion	< 10	> 15	< 10
Bone disease	Yes	No	No

Calcium, Magnesium, and Phosphate

John G. Toffaletti

The electrolytes calcium, magnesium, and phosphate are the principal inorganic constituents of bone and are vital in the function of membranes, hundreds of enzymes, genetic regulation, muscle contraction, and energy utilization. Their distribution between bone, soft tissues, and extracellular fluids is regulated by parathyroid hormone and vitamin D. As with most electrolytes, the kidneys are a most important regulator of the concentration of these ions in blood.

With the exception of parathyroid dysfunction and occult causes of hypercalcemia, the usefulness of these electrolytes in diagnostic tests was of only moderate interest through the 1970s. During the past 15 to 20 years, the discovery and awareness of the importance of calcium and magnesium in cellular regulation, energy metabolism, ion regulation, ischemia, and contraction, especially of myocardial and smooth muscle cells, has led to a much more prominent role for these tests in monitoring during and after surgery, in critical care, and in the neonate. The role of intracellular calcium ions and protection by magnesium ion in reperfusion injury following ischemia, the potentially fatal complications from hypomagnesemia in cardiovascular disease, and the importance of adequate phosphate for regulation of oxygen delivery and energy utilization are some examples of the vital importance of these electrolytes in critically ill patients.

Although the importance of these electrolytes in health and cellular survival is well established, the measurement of their physiologically active forms remains challenging. Measurements of ionized calcium are reliable and readily available on several analyzers. While measurements of ionized magnesium have achieved acceptable reliability, they are less reliable than measurements of ionized calcium and are in lower clinical demand. An even greater challenge arises in measuring and interpreting intracellular concentrations of magnesium and phosphate. Techniques that measure intracellular concentrations of any of these electrolytes remain relatively crude and too slow to be of value for clinical decision making in an acute care setting, but they are the subject of continuing research and development.

CALCIUM

Part of "20 - Calcium, Magnesium, and Phosphate"

Biochemistry and Physiology

In 1883, Ringer showed that calcium was essential for myocardial contraction (1). In the 1930s, McLean and Hastings studied the actions of bound and free forms of calcium on frog heart contraction. They showed that the ionized (free) calcium concentration was proportional to the amplitude of frog heart contraction, while protein-bound and citrate-bound calcium had no effect (2). From this observation, they concluded that the free ionized calcium was the physiologically active form of calcium in blood and used isolated frog hearts to develop the first assay for ionized calcium. While the method had poor precision by today's standards, they were able to show that blood-ionized calcium was both closely regulated and had a mean concentration in humans of about 1.18 mmol/L.

Of all the calcium in the body, 99% is in the bone. The remaining 1% is mostly in the blood and other extracellular fluids. The amount of calcium inside of cells is relatively low, with an extremely low concentration of free ionized calcium (5,000 to 10,000 lower than blood) maintained in the cytosol of many cells, such as cardiac or smooth muscle cells. Calcium circulates in the blood is several forms:

45% to 50% free ionized

40% to 45% bound to protein, mostly albumin

10% to 15% bound to anions such as bicarbonate, citrate, phosphate, and lactate

As shown in Figure 20.1, the bound forms of calcium ions are in equilibrium with the free calcium ions. pH has a significant effect on calcium ion binding to protein, with each 0.1 unit decrease or increase in pH causing ionized calcium to change inversely by about 0.05 mmol/L. The distribution of these forms of calcium can change, especially during surgery or critical care situations, where concentrations of citrate, bicarbonate, and lactate can change rapidly.

Because decreased ionized calcium may impair myocardial function, maintaining ionized calcium at a clinically acceptable concentration is an important goal both during surgery and in critically ill patients (3). The flow of calcium ions into cells in the myocardium helps control cardiac contraction and rhythm. Calcium binds to contractile proteins, which initiates the contractile process. The rate at which calcium ions flow into smooth muscle cells influences the tension of arterioles, which regulate blood pressure. A diagram showing these basic intracellular movements of calcium ions is shown in Figure 20.2.

Because the intracellular concentration of calcium ions is an important factor in muscle contraction, the regulation of calcium

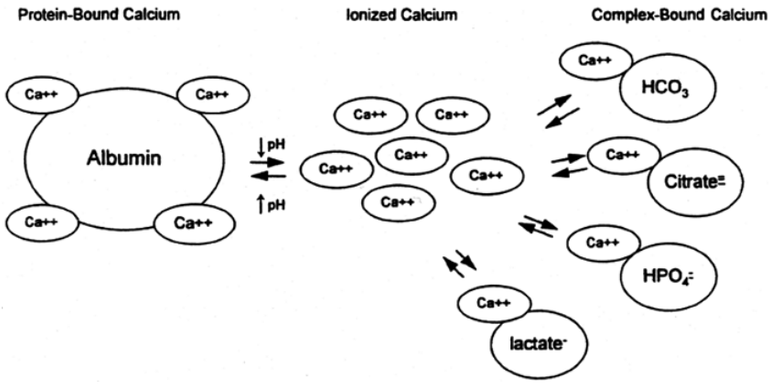

FIGURE 20.1. Equilibria between protein-bound, complex-bound, and ionized calcium in blood. (From AACC Self-Study Course: Understanding the Critical User of Blood Gases and Electrolytes. Washington DC: AACC Education Programs, 1998:41. Used with permission.)

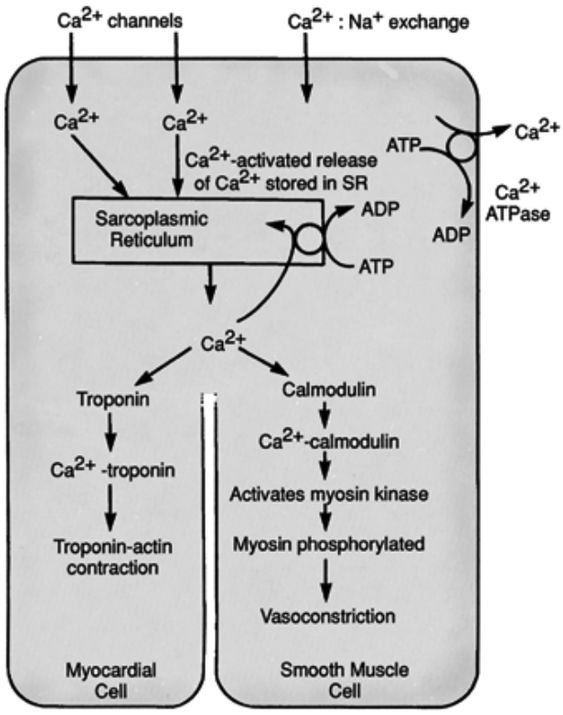

FIGURE 20.2. Basic intracellular movements of calcium ions that result in the contraction of myocardial or smooth muscle cells. The reactions characteristic of a myocardial cell are shown in the bottom left, while the reactions in a smooth muscle cell are shown in the bottom right of the figure.

ion flow into and out of cells is extremely important. Two types of calcium channels on the cell membrane are known to regulate this flow: a voltage-dependent and a phosphorylation-dependent channel. These gates function as follows: the voltage-dependent gate opens when the membrane is depolarized, while the phosphorylation-dependent gate requires a cAMP-activated protein kinase. The cardiotropic drugs epinephrine and isoproterenol facilitate transport of calcium ions through these channels, while acetyl choline hinders the transport of calcium ions (4). In addition, magnesium ion helps to stabilize these channels.

Note that this inward flux of calcium ions does not directly trigger contraction of the myocardial cell. Rather, these ions amplify intracellular calcium by releasing calcium ions from both the sarcoplasmic reticulum and the inner cell membrane.

To remove the excess calcium ions that have accumulated inside the cell, ATPases are necessary: a membrane-bound ATPase extrudes calcium ions from the cell, while a magnesium ATPase transports calcium ions back into the sarcoplasmic reticulum for future release.

Calcium ions also are important as “second messengers” in controlling the secretion of many hormones such as insulin, aldosterone, vasopressin, and renin. Following stimulation at the cell surface by a specific molecule (first messenger), the inward flux of calcium ions (second messenger) initiates intracellular events, such as production of a hormone.

Decreased ionized calcium concentrations in blood can cause both cardiovascular disorders, such as cardiac insufficiency and arrhythmias, and neuromuscular irritability, which may become clinically apparent as irregular muscle spasms, called tetany. Studies have shown that the rate of fall of ionized calcium in blood initiates tetany as much as the absolute decrease in concentration of ionized calcium (5).

Regulation of Calcium in the Blood

Three hormones are known to participate in serum calcium regulation, and have rates of secretion that depend on ionized calcium

concentration. These hormones are parathyroid hormone (PTH), 1,25 dihydroxyvitamin D, and calcitonin. Their actions are depicted in Figure 20.3. Parathyroid hormone-related protein (PTHRP) has hypercalcemic actions similar to PTH, however, the role of PTHRP in normal calcium homeostasis has yet to be clearly defined.

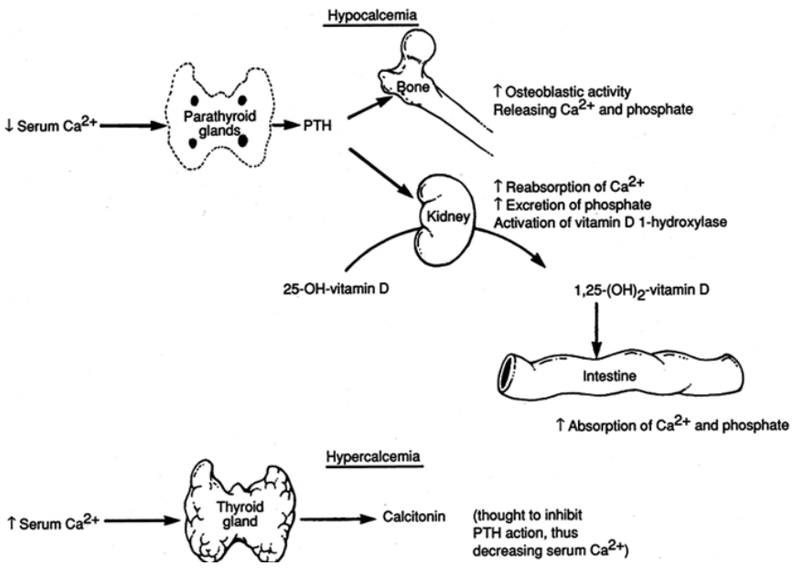

FIGURE 20.3. Hormonal responses to hypocalcemia and hypercalcemia.

The parathyroid gland responds rapidly to a decrease in ionized calcium, with a fourfold increase in PTH secretion stimulated by a 5% decrease in ionized calcium (6, 7). An increase in ionized calcium will reduce circulating PTH concentrations: a recent study found that when oral calcium increased serum ionized calcium by 0.07 mmol/L, serum intact PTH decreased (8).

PTH circulates as intact hormone and several fragments of varying biological activity. Both intact PTH and amino-terminal PTH have biological activity by an ability to bind to a PTH receptor on cell membranes (9).

PTH acts on both bone and kidney to increase calcium in blood. In the bone, PTH activates osteoclasts that break down bone and subsequently release calcium and phosphate into the extracellular fluid. In the kidneys, PTH conserves calcium by increasing tubular reabsorption of calcium ions and lowers phosphate by inhibiting tubular reabsorption of phosphate. PTH also activates a specific hydroxylase enzyme in the kidney that increases renal production of active vitamin D.

Vitamin D_3, a cholecalciferol, is most often obtained either in the diet or from exposure of the skin to sunlight. Vitamin D_3 from either source is converted in the liver to 25-hydroxycholecalciferol(25-OH-D_3), an inactive form of vitamin D. In the kidney, 25-OH-D_3 is specifically hydroxylated by a 1[α]-hydroxylase to form 1,25-dihydroxycholecalciferol($1,25-(OH)_2-D_3$), the most active form. This form of vitamin D increases calcium and phosphate absorption in the intestine and enhances the effect of PTH on bone resorption and calcium retention by the kidneys (9).

Calcitonin is synthesized and secreted by the parafollicular cells of the thyroid gland in response to an increased concentration of calcium in blood (9). While an acute infusion of calcium stimulates calcitonin secretion, calcitonin may not contribute to normal calcium homeostasis, because calcitonin does not change in response to a 1% to 2% increase in ionized calcium. Chronic hypercalcemia has little effect on calcitonin secretion. A study on hemodialysis patients showed that ionized calcium had to increase by about 10% to elicit a marked calcitonin response (10). Calcitonin inhibits osteoclast activity and apparently exerts its calcium-lowering effect by inhibiting the actions of both parathyroid hormone and vitamin D.

Distribution Of Calcium in Blood and Cells

Over 99% of the calcium in the body is part of bone. The remaining 1% is mostly in the blood and other extracellular fluid, with very little in intracellular stores. In fact, the concentration of ionized calcium in blood plasma is 5,000 to 10,000 times higher than in the cytosol of cardiac or smooth muscle cells. Maintenance of this large gradient is vital to allowing the rapid inward flux of calcium ions that is essential for the initiation of muscle contraction.

Calcium in blood is distributed among several forms. About 45% circulates as ionized calcium (i.e., free calcium ions), 40% is bound to anionic sites on protein (mostly albumin), and 15% is bound to anions such as bicarbonate, citrate, phosphate, and lactate (11). This distribution can change in disease because concentrations of citrate, bicarbonate, lactate, phosphate, and albumin can change dramatically, especially during surgery or in critically ill patients. This is the principal reason why ionized calcium cannot be accurately calculated from total calcium measurements. In addition, calcium binding to protein is dependent on pH. As pH increases, hydrogen ions dissociate from anionic sites on protein and more calcium ions bind to protein, which lowers the ionized calcium concentration. As a rough guide, an increase of pH by 0.1 pH unit will decrease ionized calcium by about 0.06 mmol/L (12).

Clinical Interpretation of Calcium Measurements

Most cases of abnormal serum calcium concentration are related to one of the following:

A defect in parathyroid function

A defect in vitamin D metabolism

Malignancy

Renal disease

An iatrogenic cause (e.g., administration of citrate, calcium, or saline)

In addition, calcium measurements are useful in the monitoring of neonates, critically ill patients, and patients undergoing surgery.

Both total calcium and ionized calcium measurements are available in many laboratories. The relative merits of each test are briefly mentioned in this section. As emphasized many years ago by Ladenson et al. (13), ionized calcium cannot be accurately calculated from a total calcium concentration, although a recent editorial mentions that ionized calcium can be calculated from total calcium, total protein, albumin, and anion gap, a total of six to seven measurements (14). Given the simplicity, speed, and accuracy of current ionized calcium analyzers, it would seem more efficient to measure ionized calcium directly.

Ionized calcium measurements also may be reported as a pH-adjusted ionized calcium parameter ($[Ca^{2+}]_{7.4}$). This was introduced as a convenience to allow the measurement of ionized calcium in serum collected for the performance of routine chemistry tests. These samples usually are exposed to room air, and the pH-adjusted parameter attempts to correct for loss of carbon dioxide, which increases pH. The increased pH increases calcium-ion binding by proteins, which lowers the ionized calcium concentration. Because the pH correction may be less accurate in patients undergoing surgery, patients who are critically ill, patients with renal disease, or neonates, ionized calcium measured on anaerobically collected blood should be used.

Hypocalcemic Disorders

Hypocalcemia occurs most commonly in patients receiving citrated blood products during major surgery, in patients with renal disease, in patients with parathyroid gland insufficiency following surgery, in neonates, in patients with a magnesium deficiency, and in patients with pancreatitis. A flow diagram for the evaluation of hypocalcemic disorders is shown in Figure 20.4.

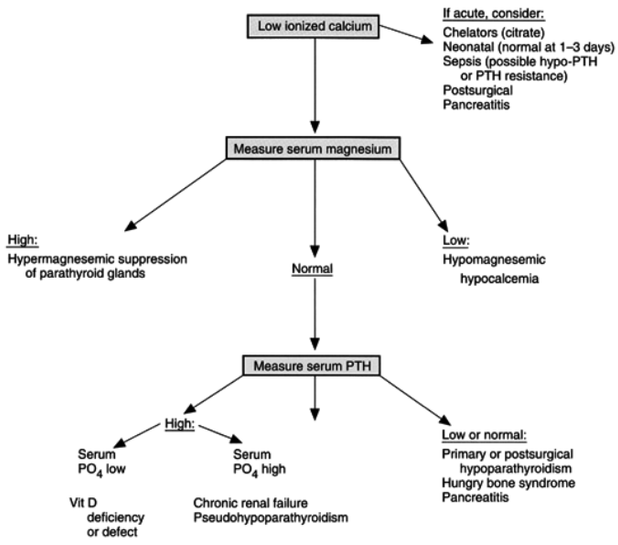

FIGURE 20.4. Evaluation of hypocalcemia.

HYPOPARATHYROIDISM

Part of "20 - Calcium, Magnesium, and Phosphate"

While hypoparathyroidism may be acquired by autoimmune or other chronic processes, most cases of hypocalcemia from hypoparathyroidism result from surgical removal of tissue during parathyroid or thyroid surgery. Hypocalcemia usually is transient (lasting less than 5 days) unless surgery has removed too much parathyroid tissue or has interfered with the parathyroid blood supply. Zaloga and Chernow recommend that serum ionized calcium should be monitored every 12 hours after neck surgery until a rise in the ionized calcium concentration indicates recovery of the parathyroid gland (4).

Pseudohypoparathyroidism is a condition in which renal cells do not respond to PTH. The combined effects of PTH resistance and hyperphosphatemia may suppress renal 1[α]hydroxylase activity, leading to vitamin D deficiency and hypocalcemia.

RENAL DISEASES

Part of "20 - Calcium, Magnesium, and Phosphate"

Patients with renal glomerular disease often have altered concentrations of calcium, phosphate, albumin, magnesium, and hydrogen ion (pH). Because these conditions tend to change ionized calcium independently of total calcium, ionized calcium is usually better for accurately monitoring calcium status in renal disease (15). In chronic renal disease, a marked increase in serum PTH levels (secondary hyperparathyroidism) compensates for hypocalcemia caused either by hyperphosphatemia, in which phosphate binds calcium, or by altered vitamin D metabolism. Interestingly, among end-stage renal disease patients beginning dialysis, initial PTH levels above 200 pg/mL were associated with half the mortality of similar patients with PTH levels below 65 pg/mL. Controlling ionized calcium by monitoring its concentration can avoid problems from hypocalcemia, such as osteodystrophy, unstable cardiac output, unstable blood pressure, and problems arising from hypercalcemia such as renal stones or other soft-tissue calcifications (7, 16).

NEONATAL MONITORING

Part of "20 - Calcium, Magnesium, and Phosphate"

The ionized calcium concentration in the blood of neonates typically is high at birth, then declines by 10% to 20% after 1 to 3 days. After about a week, ionized calcium concentrations in the neonate stabilize at concentrations slightly higher than in adults (16), and no treatment usually is needed.

Neonatal hypocalcemia may be either of two types. The first type, which normally develops within 1 to 3 days after birth, is associated with parathyroid immaturity and usually resolves by the first week of life. This type of neonatal hypocalcemia in healthy infants may be a normal stimulus to activate parathyroid

gland function. The second type of neonatal hypocalcemia usually is seen about 1 week after birth and is associated with both hyperphosphatemia from a high phosphate intake from milk and hypomagnesemia caused by decreased intestinal absorption of magnesium (4). Other factors that increase the incidence and severity of hypocalcemia during this period are prematurity, maternal diabetes mellitus, complications during delivery, and birth asphyxia (4). Hypocalcemia even may become life-threatening if it is severe, prolonged, or accompanied by seizures, hypotension, hypoglycemia, or sepsis. Neonatal seizures occur especially in infants of diabetic mothers, with hypocalcemia and hypomagnesemia being possible causes (18).

Ionized calcium measurements are preferred over total calcium in monitoring calcium status in the neonate (17). Rather large changes in the concentration of ionized calcium may occur in the early neonatal period, because calcium may be lost rapidly and not readily reabsorbed. Several possible etiologies have been suggested, including abnormal PTH and vitamin D metabolism, hypercalcitoninemia, hyperphosphatemia, and hypomagnesemia (17).

MONITORING IN SURGERY AND ACUTE CARE

Part of "20 - Calcium, Magnesium, and Phosphate"

Largely because of the importance of both transcellular and intracellular movement of calcium ions in myocardial and vascular smooth muscle cells, the maintenance of a normal ionized calcium concentration in blood is important to the patient in either surgery or intensive care. Adequate calcium concentrations promote good cardiac output and maintain adequate blood pressure. Monitoring and adjusting calcium concentrations may be most critical in open-heart surgery when the heart is restarted. Normalizing ionized calcium by administering calcium as a cardiotropic agent is preferred before giving drugs such as epinephrine or isoproterenol (3). Monitoring of ionized calcium is important during liver transplantation, because large volumes of citrated blood are given at a time when the function of the liver (the major organ for metabolizing citrate) is compromised or absent.
